In the first 1–3 days, creatinine concentrations are often in the range 141–194 $\mu\text{mol/L}$. This gradually falls to 88–106 $\mu\text{mol/L}$ over the first 2–3 wk as renal function matures. The likely cause is an inability of creatinine to equilibrate across placental membranes. A mildly elevated creatinine concentration in an otherwise healthy foal (that has urinated normally) is therefore probably of little concern. However, if the concentration does not decline over 3–4 days or remains $>200 \mu\text{mol/L}$ on day 3, then **peritoneal or retroperitoneal accumulation** of urine, **renal hypoplasia** or other causes of renal failure should be considered (*q.v.*).

Unlike creatinine, blood urea concentrations in foals are typically low ($<5 \mu\text{mol/L}$) after day 2 and remain low for the first several months of life. This finding can be attributed to the anabolic state of the growing foal.

The trend in creatinine and urea concentrations in azotemic foals should be closely monitored; a continued increase would suggest renal dysfunction and demands additional evaluation.

Urinalysis in foals

Urinalysis in normal neonatal foals is significantly different from adult horses:

1. Normal foals frequently show a marked proteinuria for 1–2 days after birth.
2. By nature of their milk diet, foals have a **high water intake** (approximately 250 mL/kg/day compared with the adult water intake of 50 mL/kg/day). After day 2, urine is hyposthenuric (specific gravity 1.002–1.006) and remains so for several months.
3. Urine pH is neutral to acidic.
4. Urinary enzyme activity and sodium and chloride clearances may be greater than adult values.

CONGENITAL ABNORMALITIES

Congenital defects in the foal are rare apart from **patent urachus** (*q.v.*) and failure of the **normal fusion** of the urinary bladder (*q.v.*). Reported defects include renal agenesis, polycystic kidneys, renal glomerular hypoplasia and ectopic ureters (*q.v.*). Various dysplastic conditions (where the renal structure has a chaotic or disorganized nature) also occur.

The age of onset of relevant clinical signs is dependent on the degree of renal pathology and the extent of loss of function. In some cases the conditions are fully compatible with life and are only detected incidentally at post mortem examination at a later age; in others clinical signs are delayed until 6–18 mo although some evidence can usually be found before that.

Renal agenesis or hypoplasia/dysplasia

Agenesis of both kidneys is not compatible with life. Foals with renal agenesis will develop renal failure shortly after birth.

Renal glomerular hypoplasia is more common and cases tend to be asymptomatic with stunted growth and chronic renal failure developing as yearlings (*q.v.*). Hypoplasia is diagnosed when one or both kidneys are smaller than 50% of normal or, in the case of unilateral hypoplasia, when the kidney is smaller than a normal kidney. The diagnosis can also be made when the renal mass is reduced by more than one half. However, these parameters may not be easily measured in the live horse and in any case **unilateral hypoplasia** may pass unnoticed. **Bilateral hypoplasia** usually leads to chronic renal failure at an early age.

Renal cysts

Cysts are more common in the cortex than medulla and vary in size from microscopic to large cysts that involve the whole kidney (either singly or in multiple forms). They are usually found incidentally at post mortem or ultrasound examination. They may have no material clinical consequence. It is important to differentiate congenital cysts from acquired cysts: congenital cysts have no scarring while acquired ones invariably have extensive scarring.

Polycystic kidneys

Numerous small, often loculated and variably sized cysts distributed through the cortex in particular are described. The kidneys can be massively enlarged and the expansion of the cysts causes pressure necrosis of the adjacent normal tissue. The condition is difficult to diagnose at an early age but ultrasonography of the kidneys is probably warranted in any young horse that fails to grow normally and particularly when there is evidence of micro- or macro-hematuria or renal failure (or both). The condition is untreatable. **Chronic renal failure** usually develops before 2–3 yr of age but a few cases have survived for longer.

Ureteral defects

Ureteral defects have been reported in both fillies and colts. This rare disorder can easily be confused with traumatic rupture of one or both ureters (*q.v.*). The clinical signs are dependent on the location of the ureteral defect and may range from **urinary incontinence** to **uroperitoneum** (*q.v.*). In some cases, leakage from the ureter fills the retroperitoneal space. In fillies this may cause bulging of the vagina and can then be mistaken for an **intact hymen**. If the retroperitoneal membrane ruptures, then the clinical signs and clinical pathologic changes are identical to those of a ruptured bladder.

Ectopic ureter

Ectopic ureter is the most commonly reported congenital anomaly of the equine urinary tract. Most of the reported cases occur in females but this may in part reflect that incontinence from birth is easier to recognize in females. The condition may develop when:

1. The ureteric bud (metanephric duct) fails to be incorporated into the urogenital sinus or fails to migrate into the bladder neck. In these cases the ureter opens into the vagina near the urethral papilla (or in males into the pelvic urethra near the seminal vesicles).
2. The mesonephric ducts fail to regress. The ureter opens anywhere along the vagina, cervix or uterus. This type does not occur in males.

Clinical signs

Cases are presented when **urine scalding** of the hindlegs is noticed; sometimes this occurs at a later age. The persistent dribbling is easily mistaken for a neurologic problem with the bladder (*q.v.*) but the two conditions affect different ages of horse. **Urine pooling in the vagina** can lead to infertility. Renal function is usually normal but the affected ureter may be grossly dilated and is often infected.

Diagnosis

The precise location of the opening can be visualized in some cases using vaginoscopy, but a contrast excretory urogram may be helpful. Cystoscopy will usually confirm the side of the missing ureter.

Treatment

Treatment usually involves **ipsilateral nephrectomy**. It goes without saying that it is imperative that the correct kidney is removed. Nephrectomy in the horse is a highly specialized procedure that is performed under lateral recumbency general anesthesia. The approach to the left and right kidneys is somewhat different but the surgeon will require to remove the 17th and possibly the 18th rib on the left side and the 16th or 17th on the right side before the kidney can be approached. Once the kidney is identified it can be freed retroperitoneally and the major vessels and ureter can be identified and ligated using an aneurysm hook. The procedure is well tolerated but complications during surgery from blood loss are often catastrophic. **Absolute asepsis** is essential.

Surgical **ureteral relocation** has been reported. This is technically even more difficult than nephrectomy and in any case the abnormal ureter may not function normally. In cases of ectopic ureter the sensible approach is to perform the relatively simpler nephrectomy.

Patent urachus

The urachus is the structure through which fetal urine passes into the allantoic cavity. Normally the urachus closes at birth but **incomplete closure** is a common abnormality of the equine urinary tract. It occurs more commonly in foals with **longer umbilical cords** or with partial torsion of the cord.

Clinical signs

A patent urachus may be present immediately following birth when **persistent dribbling of urine** from the umbilicus may be noticed. More usually, however, the navel is wet and inflamed as a result of the leakage of urine onto the umbilical remnants and surrounding skin. The umbilicus may appear normal during the first days of life but may subsequently become patent.

Urine leakage through the umbilicus may or may not be accompanied by leakage into the **abdominal cavity** or subcutaneous tissues of the abdominal wall. Sometimes the umbilicus remains normal and all urine leakage occurs into the abdominal cavity, presenting signs indistinguishable from **patent bladder syndrome** (*q.v.*).

Sometimes the urachus ruptures more distally than usual, allowing urine to pass into the abdominal musculature or the peritoneal cavity (or both). This is a possible complication of **dystocia** (*q.v.*) or cord tension at delivery (such as might occur during a standing delivery). The swelling may be differentiated clinically from a **hematoma** or **umbilical infection** because it may enlarge quickly and often becomes cold. Subcutaneous accumulation of urine, ventral abdominal swelling, stranguria, signs of colic, and distress are seen and then surgical intervention is essential. Where the condition is suspected, early surgery may be justified because urine is intensely toxic to the local tissues and extensive necrosis can make treatment impossible (or at least extremely difficult).

Patent urachus is also a common feature in older sick and debilitated foals and it is important to differentiate a congenitally patent urachus from an **acquired infected umbilicus** (*q.v.*). A simple patent urachus is not life threatening but a **septic umbilicus** may develop into or be part of a serious **neonatal sepsis syndrome** that can easily result in death.

Affected foals are often septicemic or hospitalized for treatment of prematurity, hypoxic-ischemic encephalopathy, or botulism (*q.v.*) and uroperitoneum is recognized later (e.g. after 5–10 days of treatment). Prolonged recumbency and bladder distension are likely risk factors. Again, urine may be seen to drip continuously from the navel and there may be some more obvious “squirting” during micturition. The inflamed and infected site represents a potential site for bacterial entry to the urinary tract and subsequent development of a local **omphalophlebitis** (*q.v.*) or ascending urinary tract infection, both of which may result in septicemia. Inappropriate weight gain (e.g. >2 kg in 24 h) is another common finding in hospitalized neonates that develop **uroperitoneum**.

Diagnosis

Detailed ultrasonographic examination of the umbilical structures should always be performed because it is sometimes very difficult to differentiate the various conditions on clinical appearance and palpable characteristics alone. Local aspiration of fluid and measurement of its creatinine concentration (two-fold or greater than in serum) may help to confirm the diagnosis.

Treatment

The care of a foal with a patent urachus is dependent on clinical preferences. When it is associated with septicemia and or umbilical stump infection or urachal rupture, a much higher clinician input is required. Underlying primary septicemia should be managed first.

For acquired patency (associated with sepsis) antibiotics are compulsory; if this alone fails to control the leakage within 5–7 days, surgery is probably indicated. A combination of Gram-negative and Gram-positive bacteria are usually implicated in sepsis, and a combination of **gentamicin** (6.0 mg/kg q 24 h) and **crystalline penicillin** (15 000–20 000 IU/kg q 6 h) is usually used by the IV route. Other effective antibiotics include **ticarcillin** (50 mg/kg q 12 h) and **amikacin** (6 mg/kg q 8 h). Third generation cephalosporins including **ceftiofur** (5 mg/kg q 12 h IV) or potentiated sulfonamides (35 mg/kg total substance q 12–24 h) can also be used but selection must depend on specific culture and sensitivity results. A few cases respond to local and systemic antibiotics alone and others respond to **local cautery** using swabs soaked in phenol, 7% iodine solution or silver nitrate styptic pencils (using silver nitrate or phenol swabs) and nursing of the umbilicus.

Provided the foal is not septicemic, **surgical removal** of the entire umbilical remnant is the best approach. Delays simply provide opportunity for deterioration and complication. Surgery removes all infected structures and frees the apex of the bladder from the urachal remnant. The surgical procedure is simple and is described in standard surgical texts.

Ruptured/patent bladder syndrome

Patent bladder affects approximately 1% of Thoroughbred foals; the prevalence in other breeds is not known but all may be affected. The perception that colt foals are more often affected has been challenged. Two distinct types of patency are recognized:

1. **Congenitally patent bladder** where the margins of the bladder defect are smooth and show no evidence of an inflammatory/traumatic origin. Such cases may result from failure of embryologic bladder fusion in the dorsal fold during development. There may be one or more small defects but they can also be extensive.
2. **Traumatic rupture:** Here the defect is hemorrhagic and gives every impression of being a traumatic tear; however it occurs also in the dorsal wall of the bladder, implying that this area may be weaker than other regions.

Because the signs are identical, the clinical syndrome should also include **ureteral rupture**. This syndrome usually occurs as a result of **rib fracture**, often assumed to be a result of abdominal pressure on a distended bladder during parturition or, more likely, trauma in the immediate post birth period. In some of these cases the accumulation of urine can be retroperitoneal and so there may be few easily detectable early indications of the problem.

It is generally assumed that most traumatic ruptures occur during parturition and clinical signs then develop progressively over 36–96 h, but older foals may also have spontaneous ruptures of the bladder or umbilical vessels as a result of local necrosis of these structures, occurring secondary to ascending umbilical infection or cystitis (*q.v.*).

Uroperitoneum may also develop in foals with urachal infection or ischemia (*q.v.*). Disruption of the urachus at the level of the abdominal wall will lead to subcutaneous fluid accumulation and gross local swelling, usually without the severe metabolic/systemic signs associated with a patent bladder.

For practical purposes the etiology is irrelevant as the clinical and pathophysiologic problems are identical. The treatment may, however, vary somewhat.

Clinical signs

Affected foals are usually normal at birth and have a normal post partum adaptive period. They usually feed well and show no problems until 36–96 h of age. The **absence of urine** is highly significant but, remarkably, is easily missed except on higher quality breeding farms. The passage of a normal stream of urine does not necessarily eliminate the possibility of a ruptured bladder because the defect may be small.

The first signs are non-specific and are easily overlooked. The foal shows progressive reluctance to feed properly (**decreased nursing time**), lethargy, depression and increased time spent in recumbency. The foal may exhibit dysuria or pollakiuria with repeated straining and posturing as if to urinate (hindlegs stretched out and the back concave). The other major cause of abdominal straining is **meconium retention/impaction** (*q.v.*) but this usually affects foals within 24 h of birth and they strain with back arched. They also show more overt colic signs.

Abdominal distension may be obvious but if the defect is small this may not be a major feature. **Respiratory distress** secondary to diaphragmatic compression may also be noted. Fluid within the abdomen can usually be identified by ballottement, paracentesis, ultrasonography and standing lateral radiographs.

In the later stages the foal will be reluctant to stand and then unable to stand. Seizures and cardiac arrhythmia may develop secondary to the azotemia and electrolyte imbalances. Cardiac dysrhythmia is usually detectable when plasma K^+ concentration >6.5 mmol/L.

Diagnosis

Ultrasonography can confirm the volume of fluid and even the site and extent of the defect. This technique is totally safe and is recommended in all suspected cases. It may be possible to identify retroperitoneal fluid accumulation. Hyponatremia, hypochloremia and hyperkalemia are highly suggestive of a ruptured bladder. Foals are also azotemic and acidotic but both erythrocyte and leukocyte profiles are usually normal in early, uncomplicated cases. Guided **paracentesis** and standing lateral radiographs are helpful. Comparing the creatinine concentration of abdominal fluid with that in plasma can confirm ruptured bladder. If the peritoneal fluid to plasma creatinine ratio is $>2:1$ then uroperitoneum is present. Additional diagnostic procedures such as injection of dyes into the bladder and retrieval via abdominocentesis and single/double contrast cystography are generally not required.

Treatment

All foals with a ruptured bladder require **surgical correction**. It is neither safe nor wise to rely upon indwelling urinary catheters. Affected foals should, however, be stabilized prior to anesthesia by removal of accumulated urine and restoration of **normal electrolyte status** by infusion of normal saline and possibly bicarbonate solutions IV to normalize the acid-base status. Infusions should be adjusted carefully to address identified deficits by regular electrolyte

and blood gas analysis. Slow draining of abdominal fluid by placement of a **peritoneal cannula** during the preliminary stabilization stage also removes nitrogenous products that can lead to a chemical peritonitis and decreases diaphragmatic compression.

IV fluid therapy with normal saline (0.9%) is essential. Saline replaces Na^+ and Cl^- deficits while supporting and expanding the circulating volume. Sodium bicarbonate may be administered if the foal is acidotic*; dextrose (5%) will help to stabilize the potassium distribution. **There is no possible indication for fluids containing potassium.** If cardiac arrhythmia (*q.v.*) secondary to the hyperkalemia (flattened P waves, widened QRS complexes and spiky T waves on electrocardiography) is present, calcium may be helpful. Diazepam (5–20 mg to effect) can be used IV to control seizures.

Once the patient is stabilized, surgical repair of the bladder defect can be performed. The surgical procedure is performed through a paramedian incision in dorsal recumbency. The procedure is described in standard texts. When the leakage site involves the abdominal umbilical vessels, routine removal of the umbilical remnants (see below) will resolve this problem. Foals that fail to respond adequately to bladder surgery may need further tests to evaluate the ureters for tears (*q.v.*) or for failure of the bladder closure and so careful postoperative monitoring for 7 days is essential.

RENAL DISORDERS

INTRODUCTION

The perceived incidence of renal disease in the horse is low compared with other domesticated species. For practical purposes renal disease is divided into **acute or chronic renal failure**. The clinical circumstances that predispose to renal failure are common, although failure usually remains undetected until some 75% of the functional reserve is lost. At this stage both **uremia** and **azotemia** are detectable.

Over 95% of the filtered water is reabsorbed by the renal tubules and so even small decreases in the absorptive capacity of the tubules will have a disproportionately large effect on urine volume; often even a slight reduction in water absorption by the tubules will result in doubling of the urine output. Renal failure is the term used to describe the state in which renal function cannot maintain normal homeostasis.

The ability of the kidney to concentrate urine declines when 75% of the functioning nephrons have been destroyed. The main clinical feature will be water loss (and consequent **polydipsia**). Renal failure is characterized by a fall in the GFR, which leads to an increase in the circulating concentration of nitrogenous waste products (azotemia).

Two major types of renal failure are recognized clinically:

1. **Acute renal failure:** Acute renal failure means abrupt failure of renal excretory function owing to depression of the glomerular filtration.

* The volume (mL) of molar (8.4%) bicarbonate required can be calculated from the equation:
 $\text{Base excess} \times 0.3 \times \text{body weight (kg)}$.

2. **Chronic renal failure:** The distinction between acute and chronic renal failure is not always clear from either the clinical or biochemical investigations. It is entirely possible that an acute episode can be superimposed on the chronic state, and progression to chronic renal failure is a common sequel to profound or long-standing acute renal failure or where treatment for acute renal failure is inappropriate or inadequate.

A raised serum urea concentration (azotemia) may arise from:

1. Pre-renal problems
2. Renal disease
3. Post-renal problems (obstruction).

More than one of these may be present at the same time in an individual patient. Azotemia is often the **first indicator** of renal dysfunction in the horse since earlier clinical signs may be non-specific.

The diagnosis of renal disease centers on detection of **failure of function**. Failure to clear waste products is identified by a fall in the GFR and/or the presence of azotemia (*q.v.*). Loss of water and electrolyte homeostasis is identified by abnormal changes in the urinary specific gravity, tubular function tests and plasma electrolyte concentrations. In addition, evidence of kidney damage may be revealed by abnormal inclusions in the urine (proteinuria, glycosuria, cells and casts), while anatomic changes may be appreciated by palpation, ultrasonography and, if appropriate, biopsy (*q.v.*).

Collectively, this information provides an objective measure of the extent of dysfunction and even possibly the etiology. However, the specificity and sensitivity of many of the tests currently used is questionable.

ACUTE RENAL FAILURE

Acute renal failure (ARF) in adults and foals is a clinical syndrome associated with **abrupt reduction of glomerular filtration** and is usually a consequence of:

1. Pre-renal factors, which reduce vascular perfusion.
2. Renal (intrinsic) factors, e.g. hypoperfusion or ischemia. Ischemic (vasomotor nephropathy) or toxic damage to tubules, tubular obstruction, acute glomerular nephritis leading to primary reduction in filtration capacity of the glomeruli and interstitial inflammation and edema are primary causes of intrinsic renal failure.
3. Post-renal urinary obstruction.

Examples of the factors responsible for its development are listed in Box 12.5.

Etiology

Renal tubular epithelial cell degeneration or (tubular) necrosis may follow prolonged renal ischemia from any of the pre-renal vascular disturbances but **nephrotoxic chemicals** and drugs, particularly the **aminoglycoside antibiotics**, are most commonly implicated.

The etiology in foals is often subtly different from adult horses but the principles of diagnosis and management are similar. In foals there is perhaps an

Box 12.5 Examples of factors associated with the development of acute renal failure in the horse**Pre-renal factors**

- Dehydration
- Endotoxemia
- Hemorrhage
- Cardiovascular insufficiency

Intrinsic factors

- Prolonged pre-renal disturbance
- Nephrotoxins
 - Drugs
 - Toxic plants
 - Mycotoxins
 - Heavy metals
 - Hemoglobinuria
 - Myoglobinuria
- Intrinsic diseases
- Glomerulonephritis
 - Pyelonephritis
 - Renal lithiasis
 - Hydronephrosis
 - Neoplasia

Post-renal factors

- Urolithiasis (ureter/bladder/urethra)
- Bladder rupture
- Urethral trauma
- Obstructive neoplasia

even more pressing need to recognize and counter the condition because of the fragility of the neonatal physiology and lack of renal maturity. Foals that experience dystocia, premature placental separation or placentitis (*q.v.*) may become hypoxic during birth and also develop acute renal failure.

Acute tubular necrosis is the most common pathologic lesion causing ARF in **neonatal foals** arising from hemodynamic or nephrotoxic causes but it is also an important cause in **adult horses**.

Hemodynamic causes of acute tubular necrosis occur most commonly in septicemic foals or in foals with acute diarrhea where severe volume depletion and renal ischemia predispose to renal damage. Many cases are identified during or after episodes of diarrhea and are probably a direct consequence of poor renal perfusion. Surprisingly, diarrhea-related ARF does not always seem to be associated with the severe forms of diarrhea.

In both foals and adult horses, **hydration and electrolyte status** are critical factors in the safe use of potentially nephrotoxic drugs; a well-hydrated patient with normal electrolytes will tolerate the drugs much better than a dehydrated patient with concurrent diarrhea, septicemia or endotoxemia.

Nephrotoxicity from endogenous toxins (e.g. hemoglobin, myoglobin) or exogenous toxins (e.g. aminoglycosides, tetracyclines, non-steroidal anti-inflammatory agents) is another significant cause of ARF. **Aminoglycoside toxicity** is probably the most significant cause of toxigenic acute renal failure in foals and to a lesser extent in adult horses. These antibiotics have a direct toxicity to tubular cells in which they selectively accumulate. Healthy kidney tolerates a single overdose without detectable detriment, and toxicity is much more likely with prolonged high doses in excess of 10 days.

Gentamicin (6 mg/kg q 24h) or **amikacin** (6.0 mg/kg q 12h) may be safely administered for >10 days if the patient is adequately hydrated, appropriate trough concentrations in the plasma are measured and normal creatinine concentrations are maintained. Single daily doses of gentamicin are microbiologically effective but significantly reduce nephrotoxicity. Sick neonates are often critically ill and/or dehydrated and are at much greater risk. Regardless of which aminoglycoside antibiotic is selected, monitoring **trough concentrations** (<2 µg/mL for gentamicin and <4 µg/mL for amikacin) will limit the risks.

Premature foals appear to be at even greater risk of nephrotoxicity. Carefully planned fluid therapy to correct dehydration and maintain blood pressure will reduce the risks considerably.

Multifocal renal abscesses and/or septic embolism as a complication of neonatal septicemia can lead directly to ARF. Infection is caused by a mixed population of both Gram-positive and Gram-negative bacteria. *Actinobacillus equuli* (*q.v.*) is the most common pathogen causing renal abscesses. It has a predilection for renal tissue and may infect foals in utero or within the first 48 h of life, producing septicemia. Affected foals usually die acutely from septic shock before clinical signs of ARF develop or, if they survive long enough, may develop purulent glomerulonephritis.

Inflammatory parenchymal diseases are rarely reported in adult horses. Some inflammatory conditions are unilateral; because of compensatory activity by the healthy kidney there will be no overt or biochemical evidence of renal failure.

Pre-renal factors are probably the most common cause of ARF. Sustained, marked hypotension and hemodynamic disturbances that impair renal perfusion such as acute diarrhea, endotoxemia or toxic forms of colic (*q.v.*) have the potential to cause ARF because they are associated with **hypovolemia** and **circulatory insufficiency**. Hemorrhagic shock, severe intravascular volume deficit (as with **enterocolitis**), septic shock and coagulopathy (*q.v.*) are important risk factors for vasomotor acute renal failure. In these cases the primary condition may be the major concern but the renal effects are important.

Vasomotor nephropathy results from renal vascular constriction as a result of endogenous pressor agents. The predominant lesion in vasomotor nephropathy is acute tubular necrosis, although diffuse renal cortical or renal medullary necrosis may occur in some cases.

Non-steroidal anti-inflammatory drugs (NSAIDs) can cause **medullary crest necrosis**, detectable as gross or micro-hematuria but, unless this is severe, clinical signs and creatinine elevations are unlikely; indeed, creatine concentrations may actually fall. Most horses show no obvious adverse effects to NSAIDs (*q.v.*) so long as the dose, frequency and courses are correct and they are **not dehydrated**. Excessive doses, over-frequent administration, dehydration, gastrointestinal disease (ulceration) and protein-losing enteropathy and other concurrent

nephrotoxic drugs may precipitate an **acute renal failure crisis**. A single overdose or prolonged low-dose course of NSAIDs in normally hydrated healthy horses is unlikely to cause significant damage. The use of NSAIDs in dehydrated or hypovolemic patients increases the risk of acute renal failure. **Chronic interstitial nephritis** and **nephrolithiasis** (*q.v.*) have been reported in some horses receiving high doses of NSAIDs over long courses (months to years).

Organic or inorganic mercury, cadmium, zinc, arsenic and lead salts (*q.v.*) are nephrotoxic and accidental ingestion may result in acute tubular necrosis and ARF. The clinical effects are widespread and renal failure (either acute or chronic) is unlikely to be the main or only clinical sign. If ingestion is suspected then a **full forensic analysis** is warranted.

Pigment nephropathy (*q.v.*) may arise from either hemoglobinuria or myoglobinuria. Although many texts describe the development of acute tubular necrosis and ARF secondary to rhabdomyolysis (*q.v.*), this is in fact uncommon unless the condition is severe and prolonged. Hemolysis is an even less common cause of pigment nephropathy than myopathy. However, cases with severe hemolysis or those with hemolysis accompanied by disseminated intravascular coagulopathy are at significantly greater risk.

Subclinical glomerular damage also accompanies a number of other diseases, especially immune-mediated disorders such as purpura hemorrhagica (*q.v.*), but ARF is rarely significant unless any of the factors listed in Box 12.5 are present.

ARF can also be caused by infection with *Leptospira interrogans* serovar *pomona* but this is poorly documented in horses. **Leptospirosis** (*q.v.*) should be included in the list of possible causes of ARF when an underlying primary disease leading to vasomotor nephropathy is not apparent and there has been no exposure to nephrotoxins.

Clinical signs

Acute renal failure may be transient (subclinical) if hypotension or vasomotor constriction to the kidneys is corrected quickly and there are no other complicating factors. Also, it is **usually reversible** over a period of days or weeks depending upon the severity of the causative insult and the effects of treatment and elimination of causative factors. If a state of ARF is sustained for any significant time **azotemia** (*q.v.*) will develop.

Depression and subcutaneous and pulmonary **edema** are early signs in foals. **Oliguria** or even **anuria** can develop 12–24 h before significant depression or azotemia is recognized. Urine output should be carefully monitored in all sick foals. **Fluid retention** during incipient ARF can be detected from inappropriate weight gain (e.g. >2 kg in 24 h).

Because of the range of clinical disorders that can provoke pre-renal failure, the presenting signs may simply reflect the primary disease. For example, acute diarrhea, colic, laminitis or hemolytic anemia (*q.v.*) may predispose to renal failure yet mask its clinical expression. In other cases, azotemia may be associated with moderate to profound **depression**.

The volume of urine passed may vary from low (oliguria) to excessive (polyuria). **Oliguria** is typical in early stages as the GFR falls and the resulting urine is usually concentrated (high SG). As tubular damage progresses the urine becomes progressively more dilute. **Urine color** may therefore vary

between normal (concentrated), pale (dilute), or discolored (e.g. hematuria). There are concurrent disturbances of fluid, electrolyte and acid-base balance and these can be life threatening.

Although the clinical signs of the primary condition vary and may mask evidence of ARF, a **disproportionate depression** and anorexia with or without signs of mild colic are suggestive of ARF. Nephrotoxic ARF should be considered when horses being treated with aminoglycosides become inexplicably depressed and inappetent within 2–3 days of the start of treatment.

Polyuria may be detected before the onset of depression and anorexia or, if the patient becomes oliguric, mild **stranguria** and repeated posturing to urinate may be observed. Ataxic or manifest neurologic signs similar to **hepatoencephalopathy** (*q.v.*) may be seen in severe ARF.

Although grossly discolored **pigmenturia** is not a prerequisite for the development of renal failure in cases of azoturia or intravascular hemolysis, ARF should be suspected in horses that become anorectic and depressed within 7 days of an episode of tying-up (*q.v.*) or a hemolytic crisis.

Infectious acute renal failure is characterized by fever, partial anorexia, depression and gross hematuria. Rapid development of azotemia and low urine specific gravity (<1.020) without bacteriuria may be encountered.

Post-renal obstructions leading to renal failure present with overt discomfort, anuria and/or dysuria.

Rectal palpation may reveal enlarged, painful kidneys in some cases of ARF and any enlargement can be confirmed by renal ultrasonography. **Renal ultrasonography** may also reveal perirenal edema, loss of corticomedullary distinction and/or renal pelvis dilatation. Obstructions of the lower urinary tract are easily recognized per rectum unless the bladder has ruptured.

Diagnosis

A diagnosis is confirmed from history, potential exposure to nephrotoxins, clinical signs and laboratory findings. ARF should be suspected in patients showing **more marked depression** and anorexia than would be expected with the primary disease process and in patients that fail to produce urine within 6–12 h of initiating fluid therapy. A tentative diagnosis of nephrotoxicity can be based on a history of **aminoglycoside use** (*q.v.*) and azotemia plus enzymuria with the presence of casts in the urine. The increase in **creatinine** (*q.v.*) is much greater than increases in blood urea, often resulting in a urea–creatinine ratio $<10:1$. Hyponatremia, hypochloremia and hypocalcemia are usually present and, in more severe cases, hyperkalemia, hyperphosphatemia and metabolic acidosis may also be detected.

Seroconversion or high serum titers and positive fluorescent antibody test results for *Leptospira* spp. (*q.v.*) confirm exposure to the bacteria.

Urinalysis should be performed on all horses in which ARF is suspected:

1. A **low urine specific gravity** (1.020 or less) in the face of dehydration and gross or microscopic hematuria are common findings with ARF.
2. Proximal tubular damage results in **increased urinary gamma glutamyl-transferase** (GGT) activity and/or glycosuria.
3. Significant **proteinuria** (urine protein to creatinine ratio $>2:1$) supports a diagnosis of glomerular disease.

4. Urine **sediment** may reveal casts and increased numbers of erythrocytes and leukocytes while subjectively the amount of urine calcium carbonate crystals may be decreased.
5. Increased **fractional clearances** of sodium and phosphorus are also common. However, administration of IV fluids to healthy horses will also result in increased fractional clearances of sodium, chloride and phosphorus and so electrolyte clearances should be determined using the initial urine sample voided after admission or a sample collected via catheterization before urine could be altered by fluid therapy.

The most accurate assessment of renal function involves measurement of **glomerular filtration rate (GFR)** but this is seldom pursued in practice. Changes in GFR can be more practically assessed by **daily creatinine estimation**.

Glomerular injury can be confirmed by renal biopsy (*q.v.*) but this is rarely indicated in cases of ARF because the diagnosis is usually obvious and there are significant dangers of life-threatening hemorrhage with the procedure. Renal biopsy is mostly indicated in the evaluation of horses with ARF for which no clinical or historical cause can be established.

Response to fluid therapy is an important consideration, especially in oliguric acute renal failure. Oliguria that fails to resolve in spite of fluid therapy is an early indicator of vasomotor acute renal failure. Production of dilute urine (specific gravity <1.020) that may be discolored through hematuria and/or hemoglobinuria may be observed once urination is re-established. Even if urine is “clear”, micro-hematuria is usually present; this will be detectable with a **urine dipstick**. Proximal tubular damage may also impair tubular resorption of glucose and so **glycosuria** (*q.v.*) will be present (also detectable on dipstick).

Serum creatine kinase and aspartate aminotransferase are invariably elevated during any (even a mild) episode of rhabdomyolysis (*q.v.*). Since there is little preformed creatinine in muscle, rhabdomyolysis alone does not produce an increase in creatinine and so any elevations are likely the result of ARF.

Management

Treatment of ARF in all ages of horse centers on correction of the primary problem. Restoration and maintenance of the hydration status through twice daily measurement of body weight and repeated blood analysis are important.

Infection control

Control of infection with appropriate antimicrobial therapy is essential, especially in foals, but unless this is carefully planned it may simply shift the problem to toxic nephropathy. Ideally, all **nephrotoxic agents** should be discontinued; this is usually impossible in septic foals because the **aminoglycosides** are by far the best approach to many neonatal infections. If septic embolism/septicemia is suspected, IV therapy with combination of **penicillin and gentamicin** (*q.v.*) for a prolonged period is recommended. Careful planning, determination of plasma aminoglycoside concentrations and adjustment of the dosage will limit renal tubular damage.

Urine output measurement

Urine output must be monitored in all septic and diarrheic foals; if oliguria or anuria develop IV fluid therapy is essential:

1. Physiologic (0.9%) saline or a 5% dextrose solution is the ideal fluid. Hydration is maintained so as to restore deficits and ensure a suitable maintenance flow. A 50 kg foal that is 5% dehydrated will need a volume of 1 liter of fluid and then maintenance at 5–10 mL/kg/h.
2. Fluids with potassium must be avoided since hyperkalemia is a complication with potentially fatal consequences.
3. Fluids must be carefully monitored in conjunction with urine output; excess fluid can cause volume overload and pulmonary edema, which will cause a progressive increase in the foal's respiration rate.

If the foal fails to urinate in response to fluids, then low-dose **dopamine** (2–5 µg/kg/min IV) should be administered. Higher concentrations should not be administered as renal artery vasoconstriction will occur and complicate the problem. The diuretic **furosemide** (0.5–1 mg/kg IM or IV) can also be administered, as it is **synergistic** with dopamine in inducing urine production. If the foal still fails to urinate, IV **mannitol** or **dialysis** may be considered.

Dialysis

Dialysis is usually restricted to transperitoneal separation in foals only. Arterial dialysis has been described but it is an almost impossible technique in practice. Peritoneal dialysis is a mechanism for temporary reduction of nitrogenous and other waste materials that will diffuse across the peritoneal lining into an electrolyte introduced into the peritoneal cavity. Usually a volume of **Hartman's solution (Ringer lactate)** or **saline** (up to 3–5 L) is introduced into the peritoneal cavity and this is left in situ for up to 230 min before draining via a dependent egress port. In the foal a continuous flow mechanism can be used whereby fluid is run into the peritoneal cavity and simultaneously drained from a dependent point through a one-way valve system. Progress is monitored by repeated estimations of urea and creatinine. Complications include peritonitis (*q.v.*) and repeated blocking of the egress drain. If sedation or analgesia (or both) is necessary, **xylazine** (1 mg/kg IV) or **detomidine** (0.03 mg/kg IV) can be administered provided intravascular volume and blood pressure are not overly compromised. Peripheral vasodilators and hypotensive agents (e.g. acepromazine) should not be used.

General principles of fluid therapy

Because ARF is usually (but not always) treatable, the essential principles in treating uncomplicated cases are to identify and remove the underlying cause while correcting fluid, electrolyte and acid-base imbalances. The extent of azotemia and serum concentrations of sodium, chloride, potassium and bicarbonate must be closely monitored, at least once daily.

The causes of ARF may be more obvious to the clinician than the state of renal insufficiency they produce. Hemodynamic disturbances such as acute diarrhea, hemorrhage, congestive heart failure and bacterial toxemia should

be treated appropriately. Potential **iatrogenic causes** of tubular necrosis (nephrotoxic drugs) should be withdrawn.

After correction of volume deficits and electrolyte and acid-base abnormalities, an attempt should be made to determine whether the animal is oliguric or non-oliguric (polyuric); the prognosis for recovery is more favorable with **non-oliguric acute renal failure**.

In all cases, initial treatment is centered on **rational fluid therapy**. Sodium and chloride replacement can be accomplished by using 0.9% NaCl IV and/or oral replacement therapy until hydration and electrolyte status are normalized. Serum potassium concentrations should not be required unless there is a post-renal obstruction or rupture of the urinary tract. Correction of the mild hypocalcemia should not be needed.

Large volumes of fluid may be given by **nasogastric tube** providing there is no concurrent gastric reflux. Up to 8 L warm water or isotonic electrolyte solution may be given to a 500 kg horse and repeated every hour providing reflux is checked before administration. In critical cases, sterile fluids can be given rapidly IV at 10 L/h if two veins are catheterized simultaneously.

In **non-oliguric cases**, once volume deficits have been replaced IV saline is maintained by infusion until a marked fall in serum creatinine concentration is achieved. Fluid volume replacement is then reduced until a steady state is obtained. During infusion the **conjunctivae** should be examined periodically for evidence of edema (chemosis) indicative of **over-hydration**. Diuretics are usually unnecessary in non-oliguric cases. Non-oliguric horses pass moderate volumes of dilute urine during the initial 6–12 h of treatment.

With **pre-renal azotemia**, creatinine should decrease by at least 30–50% within the initial 24 h of fluid therapy. In intrinsic ARF creatinine remains unchanged or may even increase during the fluid therapy. Some horses may remain hypotensive (systolic pressure <80 mmHg) despite administration of large volumes of IV fluids because fluid accumulates extravascularly as edema or is sequestered into the abdomen, chest or lungs. If systemic blood pressure remains low, hypertonic saline, dobutamine and/or other pressor agents may be needed to restore blood pressure and glomerular filtration.

The position is significantly different in **oliguric ARF**. Oliguric horses fail to produce expected amounts of urine in the initial 12–24 h of IV fluid therapy and the bedding remains dry. Edema (fluid overload) can develop rapidly in horses with oliguric acute renal failure. Fluid and electrolyte replacement should be followed by diuretic treatment. Parenteral furosemide stimulates urination within 30–60 min and so requires repeated dosage (1 mg/kg q 2 h). Continued fluid administration should be restricted to maintenance requirements (20–50 mL/kg/day) and overhydration (indicated by chemosis) avoided. Fluid and sodium replacement and normal systemic blood pressure must be monitored closely because excessive fluid will result in **generalized edema**, which may initially be seen as chemosis (conjunctival edema).

If oliguria persists after 12–24 h of appropriate fluid and electrolyte replacement and restoration of systemic blood pressure, **furosemide** (1 mg/kg IV q 2 h) should be administered. However, this is often ineffective in increasing renal blood flow, GFR and tubular flow in horses with acute renal failure. If urine is not voided after the second dose, administration of **mannitol**

(1 mg/kg as a 10–20% solution) and/or a **dopamine** infusion (3–7 µg/kg/min IV) can be instituted.

If over 24–72 h this approach converts oliguria to polyuria, treatment can be discontinued; however, continued close monitoring is required over the next few days.

Fortunately, the majority of horses with ARF resulting from **acute tubular necrosis** (ATN) are non-oliguric rather than oliguric, and administration of furosemide, mannitol or dopamine is not needed in most of cases of non-oliguric acute renal failure. As long as the horse is eating and drinking well, IV fluids can be discontinued.

Monitoring therapy

Repeated **monitoring of vital signs** (body temperature, heart and respiratory rate, capillary refill time and body weight), hematocrit and total plasma protein concentration must be undertaken. Twice daily body weight measurement may be the only indicator of fluid retention (patients should not gain weight after rehydration); this is particularly obvious in foals (see above). Careful recording of fluid intake (oral consumption plus fluid therapy volume) and urinary output is helpful.

If treatment for oliguria is unsuccessful for >72 h, the prognosis becomes grave and **dialysis** (*q.v.*) is indicated. However, peritoneal dialysis (or hemodialysis) is a specialized procedure (*q.v.*) and the complications are probably a strong deterrent.

After volume deficits have been restored and polyuria has been achieved, fluid therapy (0.9% NaCl or another balanced electrolyte solution, 40–80 mL/kg/day) is maintained to promote a continued decrease in creatinine. **Fluid therapy** may need to be continued (20–40 mL/kg/day) for several days until creatinine returns to reference values and the horse is eating and drinking adequate amounts. **Oral salt** (25–50 g twice daily) will encourage drinking and diuresis. **Potassium chloride supplementation** (25 g twice daily) helps to balance urinary losses. If the patient remains anorexic, 50–100 g of dextrose per liter of fluids is helpful but if anorexia persists for several days caloric intake may need to be provided by nasogastric tube feeding or total parenteral nutrition.

Creatinine should be measured within 3–5 days of cessation of therapy to ensure that it has not increased. Occasionally, creatinine may not decrease to below 2–3 mg/dL despite continued fluid therapy. In some horses a normal creatinine will only be achieved after some months but continued measurements should establish a “beneficial” trend. Some cases have a persistently elevated creatinine indicative of a permanent loss of renal function and a shift to chronic renal failure (*q.v.*).

Obstructive causes of renal failure usually require **surgical treatment** together with correction of fluid, electrolyte and acid-base balance.

If an **infectious cause** is suspected antibiotics are indicated but care should be taken in the selection to ensure maximal tubular distribution without toxicity. Successful treatment has been accomplished with IV fluids and penicillin (15 000–25 000 IU/kg q 12 h) using either IM **procaine benzylpenicillin** or IV **sodium benzylpenicillin**. The treatment course often needs to be at least 5 days.

Prognosis

The prognosis for ARF depends on the duration and severity of the problem as well as the ability to eliminate the primary problem. It would seem reasonable to assume that foals that have suffered from ARF will have an increased risk of developing chronic renal failure in later life but this is not yet established.

Non-oliguric to polyuric acute renal failure generally has a favorable outcome as long as the duration of ARF is limited, the underlying disease processes can be corrected, and there are no complications that cannot be removed or treated, such as concurrent treatment with other **nephrotoxic drugs** such as non-steroidal anti-inflammatory drugs (phenylbutazone in particular).

The prognosis for oliguric cases is much poorer and there is a higher tendency to progression to **chronic renal failure**. However, prompt diagnosis and rational treatment improves the outlook. The well-being of the patient is often a good index of the effects of treatment. Progressive dullness and inappetence indicates that the problem is not being controlled effectively. If this state persists, **acute tubular necrosis** (*q.v.*) will develop and the prognosis is correspondingly worse.

CHRONIC RENAL FAILURE

Chronic renal failure (CRF) is an **irreversible state**, caused by a progressive intrinsic disease of both kidneys and characterized by a progressive decline in GFR, in which there is an **absolute loss** of functional nephrons. CRF may be divided by clinical and pathologic findings into two broad primary categories:

1. Glomerular disease
2. Tubulointerstitial disease.

Pathology in one portion of the nephron usually leads to altered function and eventual pathology in the entire nephron. Primary lesions are rare but include **progressive tubular necrosis** (unresolved acute tubular necrosis), **pyelonephritis** (possibly in association with urolithiasis), **glomerulonephritis** (usually immune mediated), **amyloidosis** and **neoplasia**.

Etiopathogenesis

Primary glomerular diseases that can lead to CRF in horses include:

1. Glomerulonephritis
2. Non-specific glomerulopathy
3. Renal glomerular hypoplasia
4. Amyloidosis.

Glomerulonephritis is the most common glomerular disease causing CRF. Most cases are **immune mediated**, resulting from immune complexes being deposited along the glomerular capillaries or in situ formation on the glomerular basement membrane (suggesting a type III hypersensitivity). **Streptococcal antigens** (*q.v.*) have been suggested as an important trigger for development of proliferative glomerulonephritis. However, immune complex deposition is far more frequent than CRF so a more complex pathogenesis is likely.

Tubulointerstitial diseases causing CRF (also called chronic interstitial nephritis) include:

1. Incomplete recovery from acute tubular necrosis
2. Pyelonephritis
3. Nephrolithiasis
4. Hydronephrosis
5. Renal dysplasia.

Chronic interstitial nephritis (CIN) and fibrosis may be the most common cause of CRF in horses. Interstitial nephritis (tubulointerstitial disease) usually develops as a sequel to acute tubular necrosis (*q.v.*) consequent to exposure to **nephrotoxins** or **vasomotor nephropathy** (*q.v.*). Other causes include drug-induced interstitial nephritis, urinary obstruction, pyelonephritis, renal hypoplasia/dysplasia, and papillary necrosis (a feature of non-steroidal drug use).

Although the majority of horses that develop ARF attributable to these causes recover with apparently normal renal function (they remain non-azotemic), a few may survive with significant loss of renal functional mass and subsequently (**often years later**) develop signs of CRF attributable to chronic interstitial nephritis.

In horses <5 yr of age that develop CRF that cannot be attributed to other causes, anomalies of development including renal hypoplasia, dysplasia, or polycystic kidney disease (*q.v.*) should be strongly suspected.

Bilateral septic pyelonephritis is a result of an ascending infection, but is a very rare cause of CRF. It is often accompanied by nephrolithiasis and/or ureterolithiasis (*q.v.*). Possible instigating or predisposing conditions include dystocia, bladder paralysis and bladder neoplasia (*q.v.*). Gram-negative organisms appear to be the most common causative agents, although *Staphylococcus* spp., *Streptococcus* spp. or *Corynebacterium* spp. may be isolated, and mixed bacterial infections are not uncommon.

Rarer causes of CRF in horses include renal (or generalized) amyloidosis, neoplasia, focal glomerulosclerosis-like disease, and chronic oxalate nephrosis; the latter is most probably a consequence, rather than a cause, of CRF.

Unfortunately, because renal disease is invariably advanced on first presentation, the inciting cause is difficult to establish, and **end-stage kidney disease (ESKD)** may be the only realistic pathologic diagnosis. Possible causes may be deduced from the history rather than clinical findings at presentation, especially for primary tubulointerstitial diseases. Supportive laboratory assessment, renal ultrasonography and renal biopsy seldom confirm the primary condition.

Clinical signs

Chronic (progressive) weight loss is the most common clinical sign of CRF. A small **plaque of edema** between the forelimbs occurs commonly but large plaques of ventral edema and filling of the limbs are less common. Patients are frequently oliguric; moderate polyuria and polydipsia (PU/PD) (*q.v.*) are usually present but may not be noticed by the owner. Lethargy and weakness and anemia (hematocrit 20–30%) from decreased renal erythropoietin production are fairly constant but non-specific findings. Dysuria is not reported unless there is underlying pyelonephritis, bladder paralysis, lithiasis (in ureter or bladder),

lower urinary tract infection or neoplasia (*q.v.*). Significant alterations in urine composition may help to support the diagnosis in some of these cases. Hematuria (gross or microscopic) or pyuria may be present with pyelonephritis, urinary calculi or neoplasia. Although abdominal pain would be expected, colic signs are seldom reported in horses with obstructive nephroliths or ureteroliths.

The loss of calcium excretory function and renal mucus production, and the consequent polyuria result in a **characteristic water-clear high volume urine output**. Accumulation of **dental tartar**, especially on the incisors and canine teeth, **melena** and **oral ulcers** are other occasional findings.

Growth and performance may be reduced in horses with renal hypoplasia, dysplasia or polycystic kidney disease (*q.v.*).

Diagnosis

A diagnosis of CRF is most commonly made in horses presented with weight loss and/or decreased performance with azotemia and isosthenuria¹. A horse may be azotemic for a considerable period without showing obvious clinical signs. It can therefore be difficult to differentiate between acute and chronic failure since acute onset of signs may occur in both situations. A definitive diagnosis of renal failure relies on **combinations of biochemical tests**.

Moderate to severe azotemia (creatinine concentration $>200 \mu\text{mol/L}$) is usual. The urea to creatinine ratio may vary according to protein intake, muscle mass, hydration and degree of azotemia but is usually 10:1 or greater. Mild hyperkalemia, hyponatremia and hypochloremia are commonly found. Hypercalcemia, with serum concentrations sometimes exceeding $9\text{--}12 \text{ mol/L}$, is sometimes **but not always** found; actual concentrations vary according to diet and extent of azotemia. Serum inorganic phosphate concentration is usually normal to decreased. Metabolic acidosis is a common finding with ESKD.

Hypoproteinemia (mainly hypoalbuminemia) is associated with protein losing nephropathy and intestinal ulceration. Hyperglobulinemia may be detected in horses with immune-mediated diseases or chronic pyelonephritis (*q.v.*).

Urine is transparent and typically **isosthenuric** (SG 1.008–1.014), although heavy proteinuria may increase this to 1.020. Quantification of proteinuria requires biochemical tests rather than a dipstick test. The urine protein-creatinine ratio is usually $>2:1$. In the earlier stages of glomerulonephritis excessive urine protein is primarily albumin, but with progression of glomerular pathology an increasing amount of globulin is also lost in the urine. Horses with CIN usually do not have significant proteinuria.

Pyuria (>5 leukocytes/high-power field) and significant bacteriuria on sediment examination may be detected in cases with pyelonephritis or lower tract infections. Usually, $>10\,000$ colony-forming units/mL suggest infection but lower numbers can reflect significant pathology.

Rectal examination and ultrasonography may be helpful if the kidneys are small or distorted. Palpably enlarged ureters or ureteric calculi are always significant. Horses with significant renal parenchymal damage and fibrosis may show ultrasonographic evidence of calculi and a loss of corticomedullary distinction. The echogenicity of renal tissue may be similar to or even greater than

¹ Isothenuria – a condition in which the kidneys produce urine with a specific gravity of protein-free blood plasma.

that of the spleen. IV pyelography provides little information in adult horses and its use is generally limited to foals <50 kg. When hematuria or dysuria accompanies CRF, cystoscopic examination can be helpful in determining the side (e.g. right vs. left) from which renal hematuria is originating and allows assessment of urine flow from each kidney.

Measurement of GFR provides the most accurate assessment of renal function and repeated measurements at monthly or longer intervals can be a useful index of progression of CRF. It is also a useful measure of renal function in horses that are thought to be suffering from early CRF before significant azotemia has developed.

Renal biopsy (*q.v.*) is rarely justifiable since treatment of CRF (and in particular ESKD) is supportive and long-term prognosis poor.

Treatment

Treatment in horses presented with end-stage kidney disease (ESKD) is only supportive/palliative. The condition is usually so advanced that any treatment is unlikely to be successful. In CRF the causative condition is seldom identifiable and may no longer be present. The primary objective is to provide sufficient fluids and electrolytes to stabilize patients with polyuria and so prolong their lifespan and improve their well-being. In most cases there is a need for sodium and chloride replacement: at its simplest this can be provided by ad libitum **water** and free choice **salt**. However, **if edema develops, as in glomerular disease, sodium should not be supplied.**

Plasma transfusions to replace albumin are of limited benefit, but **diuretics** such as IV **furosemide** (1–3 mg/kg q 12 h) may help if hydration is satisfactory. The survival time with glomerular disease is shorter than in the case of tubulointerstitial disease and no useful rationale has emerged for treating the underlying disorder. Nutrition in cases of CRF should aim at supplying readily digestible carbohydrate. Reduction in dietary protein is usually suggested but protein deprivation does not in fact reduce the “work” of the kidney.

Some improvement may be expected where there is an acute, reversible component such as exposure to nephrotoxins or vasomotor nephropathy secondary to diseases producing hypovolemia (e.g. diarrhea or sepsis causing volume depletion) exacerbating the condition. Ascending urinary tract infection and/or obstruction can also exacerbate CRF. If an acute component is detected, it should be corrected rapidly. Treatment of CRF consequent to glomerular nephritis is even less rewarding than that caused by **tubulointerstitial disease** (CIN) (*q.v.*).

Management changes in cases with relatively stable CRF should be kept to a minimum and made gradually. Treatment consists of **supportive care**, providing sufficient fluids, electrolytes and nutritional support. Water should be available at all times, and salt (60–120 g added to the feed) can be provided as long as edema or hypertension is absent. If edema develops, salt should be restricted, even if hyponatremia is present. If **metabolic acidosis** is detected (e.g. blood pH is <7.35 or serum bicarbonate concentration is <20 mEq/L) and the patient is not edematous, sodium bicarbonate powder (100–200 g/day) or a mix of sodium bicarbonate and salt should be added to the diet to maintain serum electrolyte concentrations and acid-base balance within reference ranges.

Progression of disease should be monitored with the full range of tests at regular intervals (usually 2–3 mo maximum). The effect of electrolyte

supplementation on progression of CRF is unclear as high salt diets may actually hasten the decline in GFR and exacerbate proteinuria in human patients with CRF. Decreasing calcium intake (e.g. replacing alfalfa or other legume hays with grass hay) may result in a restoration of normal serum calcium concentration. Regular administration of vitamin B complex and **anabolic steroids** may be helpful to stimulate appetite. If appetite remains good, anabolic steroids may further limit muscle wasting and may increase packed cell volume.

NSAIDs and corticosteroids are best avoided or, if considered essential for other reasons, should be used very carefully.

Diuretics may temporarily reduce edema, and plasma transfusions may be of temporary benefit to horses with edema and hypoalbuminemia. IV **furosemide** may be given at 1–3 mg/kg q 12 h).

Nutritional management (*q.v.*) is probably the most important aspect of supportive care. Cases of CRF are often inappetent and so a **highly palatable diet** is essential. Frequent small appetizing meals, feeding smaller meals more frequently, and varying the diet (e.g. offering various types of concentrate feeds as appetite may vary from day to day) are helpful methods to increase food intake. Increasing carbohydrate (grain) intake and up to 0.5 L of corn oil per day are recommended. Omega-3 fatty acids (available in linseed oil or flaxseed oil) may retard progression of the disease. Restriction of dietary protein intake is not helpful; a greater benefit is gained from provision of adequate amounts of dietary protein and energy to meet, or slightly exceed, predicted requirements while maintaining a neutral nitrogen balance. Adequacy of dietary protein intake can be assessed by the **urea to creatinine ratio** (*q.v.*): values >15:1 suggest excessive protein intake while <10:1 may indicate protein–calorie deficit.

Currently, dialysis systems (*q.v.*) involving either peritoneal dialysis or full arterial dialysis are probably both impractical and unhelpful.

Prognosis

The rate of decline in GFR varies between affected horses: the short-term (i.e. months to a couple of years) prognosis is guarded to favorable while the long-term prognosis remains poor.

Although progressive loss of nephron function makes long-term treatment impossible, many horses with early CRF may remain active and useful for some months to a few years. Provided that creatinine remains <200 $\mu\text{mol/L}$, and the urea to creatinine ratio <15:1, affected horses seem to maintain a reasonably good attitude, appetite and body condition. Once creatinine exceeds 200 $\mu\text{mol/L}$, the rate of progression of CRF appears to accelerate and signs of **uremia** (e.g. anorexia, poor haircoat and loss of body condition) become much more apparent. Deterioration is usually rapid. Although threshold values for creatinine are prognostically useful at first, progression of CRF is highly variable. Ultimately all cases will require humane euthanasia.

PIGMENTURIA

Until the true nature and source of any grossly red to brown discoloration of urine is established, the condition is best termed *pigmenturia*. There are many causes of pigmenturia in horses although the prevalence of each of these is low. From a urinary tract perspective by far the most common cause is **hematuria**.

The specificity of the ortho-toluidine dipstick test is low and a positive result can be shown with:

1. Hematuria (blood) (Box 12.6)
2. Hemoglobinuria (free hemoglobin), which can arise from a number of causes of hemolytic disease (*q.v.*) (Box 12.7)

Box 12.6 Causes of hematuria

- Urinary tract infection
 - Pyelonephritis
 - Renal abscess
 - Cystitis
 - Urethritis
- Urolithiasis
 - Renal calculi
 - Cystic calculi
- Urinary tract neoplasia
 - Renal carcinoma
 - Bladder neoplasia
- Renal infarction
 - Strongyle damage to renal vessels
 - Endocarditis
- Coagulopathy
 - Warfarin toxicity
 - Disseminated intravascular coagulation
 - Thrombocytopenia
 - Late hepatic failure
 - Hemophilia
- Urinary tract trauma
- Endometrial and vaginal diseases
- Preputial and penile diseases

Box 12.7 Causes of hemoglobinuria

- Infectious causes
 - Equine infectious anemia
 - Equine babesiosis (piroplasmosis)
 - Equine ehrlichiosis
- Toxic agents
 - Wilted red maple leaves
 - Onions
 - Phenothiazine
- Immune-mediated hemolysis
 - Isoimmune hemolytic anemia
 - Autoimmune hemolytic anemia
 - Incompatible blood transfusion

3. Myoglobinuria (muscle pigment myoglobin), the main causes of which are exertional rhabdomyolysis (azoturia) (*q.v.*) and post-anesthetic and nutritional myopathy (*q.v.*).

The nature of the condition responsible has a significant bearing on the management of the problem from a renal perspective.

Hematuria of any description always has **urinary tract implications**. By contrast, free hemoglobin and myoglobin usually have a pre-renal origin without any underlying renal disease. However, it is important to recognize that they may have **long-term effects** on renal function and may under some conditions cause both acute and chronic renal failure (*q.v.*).

Rhabdomyolysis and hemolysis are generally accompanied by other clinical signs while hematuria throughout urination may be the presenting complaint for urinary tract infection (cystitis or pyelonephritis), urolithiasis, urinary tract neoplasia, idiopathic renal hematuria or drug toxicity (NSAIDs, particularly phenylbutazone) (*q.v.*).

Gross pigmenturia throughout urination is consistent with rhabdomyolysis, hemolysis or hemorrhage from the kidneys, ureters or bladder (*q.v.*) while **pigmenturia (usually hematuria) at the beginning or end of urination** may be associated with lesions in the distal or proximal urethra, respectively. **Pigmenturia that is variable through urination** usually indicates a hemorrhagic focus in the bladder or urethra.

Differentiation between hemoglobinuria and myoglobinuria can be made using an **ammonium sulfate precipitation test (Blondheim test)**, see Box 12.4, *q.v.*

Diagnosing the cause of hematuria depends on a thorough clinical examination of the horse, followed, where applicable, by more detailed examination of the urinary tract. There are several possible causes of persistent or recurrent hematuria (see Box 12.6) including:

1. **Cystic or ureteral calculi** (*q.v.*).
2. **Chronic cystitis**. This is rare in horses as a primary event, although their short urethra renders mares more susceptible.
3. **Coagulopathy**. Urinary tract bleeding can be a feature of hemorrhagic disorders (*q.v.*) but usually there are concurrent signs such as epistaxis and oral/mucosal bleeding.
4. **Idiopathic renal hemorrhage**, which results from spontaneous (unexplained) often massive (life-threatening) intermittent hemorrhage from one or both kidneys in the absence of any other identifiable cause of hemorrhage. All diagnostic procedures are very unrewarding; in spite of the large clots of blood and profuse hemorrhage, a primary disease process cannot often be found even at post mortem examination. Endoscopically, blood clots may be seen exiting one or both ureteral orifices. The condition is seen in both males and females of all breeds although Arabians are over-represented. Usually renal function is normal.

Treatment of idiopathic renal hemorrhage consists of support for acute blood loss, including blood transfusions (*q.v.*). Systemic coagulant therapy with vitamin K, α -amino-caproic acid or IV formalin is of no value. If a unilateral hemorrhage is consistently identified, ipsilateral nephrectomy is

indicated but there remains a risk of occurrence in the remaining kidney, especially in the Arabian breed.

5. **Urethral hemorrhage.** A defect or tear in the proximal urethra at the level of the ischial arch that results in obvious (often quite profuse) bleeding at the end of urination is a condition that occurs predominantly in **Standardbred geldings**. The etiology is likely a “blow-out” of the corpus spongiosum penis during strong urethral contractions at the end of urination (or during ejaculation in stallions). Cases void normal urine without any discomfort, and urethral contractions at the end of urination result in squirts of bright red (sometimes clotted) blood. Endoscopically, a lesion is typically seen along the dorsocaudal aspect of the urethra at the level of the ischial arch but even with a videoendoscope it may be difficult to identify. There is no related renal or other urinary tract disease.

Urinalysis is normal although a sample collected at the end of urination may be positive for blood. The diagnosis is made via **endoscopic examination** of the urethra. External palpation of the urethra in this area is usually unremarkable but can assist in localizing the lesion because external digital palpation can be seen via the endoscope. With hematuria of several weeks’ duration, there is little evidence of inflammation; rather, the lesion appears as a fistula communicating with the vasculature of the corpus spongiosum penis.

A few cases resolve spontaneously but many are persistent. A temporary sub-ischial “incomplete” urethrotomy may be successful in treatment. The surgery is performed after sedation and epidural or local anesthesia. A catheter is placed in the urethra and a vertical incision made into the corpus spongiosum penis but not into the urethral lumen. The surgical wound is left to close by second intention and hematuria should resolve within a week following this procedure. In effect, the surgery is simply preventing continued pressure disruption of the defect until it has healed fully.

6. **Renal or bladder neoplasia** (see below).

POLYURIA–POLYDIPSIA

INTRODUCTION

Urine production and water consumption vary with age, diet, workload, environmental temperature and gastrointestinal water absorption. A “pathologic” state of **polyuria–polydipsia (PU/PD)** (*q.v.*) is taken to be when urine production >50 mL/kg/day and/or water consumption >100 mL/kg/day. For a 500 kg horse this equates to 25 L of urine and a water intake of 50 L per day.

The major causes of PU/PD in horses include (Table 12.4):

1. Chronic renal failure (*q.v.*)
2. Equine Cushing’s disease (hypothalamic degenerative disorder/pituitary adenoma) (*q.v.*)
3. Primary or “psychogenic” polydipsia (*q.v.*)
4. Diabetes insipidus (*q.v.*).

Table 12.4 Causes and laboratory features of polyuria

Disease	Causes	Possible hematology and serum biochemistry changes	Possible urinalysis changes
Chronic renal failure	Glomerulonephritis Interstitial nephritis Pyelonephritis Amyloidosis Oxalate nephropathy	Elevated serum urea Elevated creatinine Hypercalcemia Hypophosphatemia Hypochloremia Hyponatremia Hyperkalemia Hypoalbuminemia Anemia Leukocytosis	Reduced SG Acidic pH Proteinuria Glucosuria Granular casts
Cushing's syndrome	Pituitary adenoma of the pars intermedia	Neutrophilia Lymphopenia Hyperglycemia Hyperlipemia	Glucosuria
Diabetes mellitus	Chronic pancreatitis Pancreatic neoplasia	Hyperglycemia Hyperlipemia	Glucosuria Ketonuria
Addison's disease	Adrenal insufficiency	Hyponatremia Mild hypokalemia	Reduced SG
Diabetes insipidus	Central diabetes insipidus (e.g. with pituitary tumor) Nephrogenic diabetes insipidus	Nil	Reduced SG
Psychogenic water drinking		Nil	Reduced SG

Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus, diabetes mellitus, sepsis and/or endotoxemia and iatrogenic causes (e.g. sedation with α_2 -agonists, corticosteroid therapy or diuretic use).

EQUINE CUSHING'S DISEASE

Equine Cushing's disease (ECD) (*q.v.*) is a common disorder of the **geriatric horse** resulting in hyperadrenocorticalism and hypercortisolemia. PU/PD is a prominent sign of the condition, occurring in >70% of cases. It is likely that owners do not always recognize PU/PD in these cases because the water intake is only around twice normal and therefore less than would be seen with psychogenic polydipsia (*q.v.*) or diabetes insipidus (around five times normal). Furthermore, old horses are often left to their own devices and abnormally high water intake and urine production may not be reported at all.

ECD causes PU/PD through several mechanisms; it is likely that the PU/PD is a result of variable combinations of several physiologic mechanisms that are not related to abnormal renal function. The suggested mechanisms include:

1. **Osmotic diuresis** as a result of hyperglycemia and glycosuria. The renal threshold for glucose in horses is 7.5–8.0 mmol/L; when plasma glucose

concentration exceeds this, glycosuria occurs. This is a **primary polyuria that results in polydipsia**.

2. An antagonistic effect by cortisol on the action of antidiuretic hormone (ADH) on the collecting ducts. The major effect is on urine production and so the polydipsia is secondary.
3. Decreased ADH production and release as a result of direct pressure on the neurohypophysis would result in central diabetes insipidus. Again, polydipsia in this case is secondary to polyuria.
4. Central stimulation of thirst by **hypercortisolemia**, i.e. this is a primary polydipsia that results in polyuria.

PSYCHOGENIC POLYDIPSIA

Primary or “psychogenic” polydipsia is probably the most common cause of complaint for PU/PD in adult horses. This is not a renal disease—renal function simply has to cope with a vast increase in water intake. Horses with this problem are generally in **good body condition** and are not azotemic. Further, the magnitude of polyuria is typically dramatic with owners reporting that horses drink two to three times more water than their stable mates and stalls can be flooded with urine. It may become a **stable vice**.

The diagnosis of primary polydipsia is supported when there is no alternative diagnosis such as excessive salt intake, hyperadrenocorticalism/ECD syndrome or renal failure. Diabetes insipidus (*q.v.*) is excluded by demonstrating urinary concentrating ability after water deprivation. Following water deprivation sufficient to cause a 5% body weight loss (usually 12–24 h), urine specific gravity should be >1.025 .

Where medullary washout has occurred as a result of prolonged polyuria, the osmotic gradient between the lumen of the collecting tubule and the medullary interstitium may be diminished so that ADH has limited concentrating effects. In this case water deprivation may lead to an increase in urine specific gravity to values >1.020 .

In horses with primary polydipsia of several weeks' duration that fail to concentrate their urine after 24 h of water deprivation, a modified water deprivation test (*q.v.*) may be indicated. Water intake is restricted to approximately 40 mL/kg/day for 3–4 days. Urine specific gravity should >1.025 if medullary washout is present. If urine specific gravity remains in the isosthenuric range (1.008–1.014), the polyuric horse should be further evaluated for early chronic renal failure (*q.v.*).

DIABETES INSIPIDUS

Diabetes insipidus (DI) results from failure of production of antidiuretic hormone (ADH), (**neurogenic DI**) or decreased sensitivity to circulating ADH of collecting duct epithelium (**nephrogenic DI**). With both forms of DI, dramatic PU/PD may be reported and affected animals fail to concentrate urine in the face of water deprivation.

Either of these conditions is rare in horses but the diagnoses remain a possibility. After determining that an equine patient with PU/PD is not azotemic,

the initial diagnostic test to differentiate DI from primary polydipsia is a **water deprivation test** (*q.v.*). Particular care should be taken if DI is suspected because the animal has no ability to concentrate urine in the face of deprivation and may become substantially **dehydrated** (10–15%) within 12 h of water deprivation. Because equine ADH cannot be measured, the concentrating ability of the kidney can be tested by measuring **urine SG** before and after administration of synthetic ADH (60 IU, IM or SC, q 6 h).

IATROGENIC POLYURIA

The most common iatrogenic cause of polyuria is excessive fluid therapy. PU/PD is not a common feature of **glucocorticoid therapy** in horses although it has been reported. A **transient diuresis** accompanies sedation with the α_2 -agonists **xylazine** and **detomidine**. This is likely to be a result of activation of α_2 -adrenoreceptors on collecting duct epithelial cells.

DYSURIA

INTRODUCTION

Dysuria means **difficult and/or painful micturition**, and the sign is invariably related to the bladder or urethra. There are four major causes of dysuria:

1. **Neurogenic dysuria** (incontinence) (dyssynergia and paralysis) (*q.v.*).
2. **Obstructive dysuria**.
3. **Neoplastic dysuria** (*q.v.*).
4. **Inflammatory dysuria** (urinary tract infections). These can be anatomically divided into those affecting the **upper urinary tract** (kidneys and ureters) and those affecting the **lower urinary tract** (bladder and urethra). The former are less common but potentially life-threatening while the latter are usually less serious. Infections involving the whole tract are likely, especially if the primary problem is in the kidney.

URINARY TRACT INFECTIONS

Etiology

The urinary tract is usually almost sterile (although in mares there may be a low level of residual infection in the urethra). Because the sterility of the urinary tract relies heavily upon a **flushing mechanism** (rather than any secretory function), alterations in the normal flow patterns as result of neurologic or physical obstructions commonly result in infection. There is a close relationship between urinary tract infection (UTI) and alterations in function and lithiasis and partial obstructions. The most common risk factors for development of UTI in horses are:

1. **Bladder paralysis**. Horses with bladder paralysis (**detrusor dysfunction**) or decreased urethral sphincter tone (from trauma or neurologic disease)

are clearly at greater risk of UTI than horses with normal detrusor and urethral sphincter function (*q.v.*).

2. **Concurrent urolithiasis.** There is controversy about the primary event in horses with lithiasis (*q.v.*) and infection. In any case both problems have to be dealt with if UTI is to be controlled.
3. **Urethral damage,** e.g. foaling trauma in mares, neoplasia or habronemiasis in males (*q.v.*).

Iatrogenic infection following **bladder catheterization** is an accepted risk because it is virtually impossible to perform this in a sterile fashion. If the bladder is healthy and functioning normally there should be no residual infection. However, when urethral or bladder mucosa has been damaged or when urine stasis (**bladder paralysis**) is present, catheterization has a far greater risk of producing more persistent infection. Significant infection can also develop if an indwelling catheter is in place and the end is not protected by a one-way valve that prevents aspiration of air.

Escherichia coli, *Staphylococcus* spp., *Corynebacterium* spp., *Pseudomonas aeruginosa*, *Proteus mirabilis*, *Klebsiella* spp. and *Enterobacter* spp. are the most common pathogens (*q.v.*).

Clinical signs

Upper tract inflammation produces less specific, more subtle clinical signs and so may be easily overlooked. Horses with upper tract infection often have concurrent signs of **systemic infection** such as fever and weight loss.

Lower tract infection typically shows disturbances in urine flow but seldom any evidence of systemic infection. Dysuria, stranguria, pollakiuria and incontinence may be present. **Chronic infection** may cause perineal urine scalding in mares and sheath and hindleg dermatitis in males. Gross **pyuria** may also be observed as passage of mucopurulent debris in otherwise clear urine.

Diagnosis

The presence of urinary tract infection is based on clinical signs and laboratory analysis of blood and urine samples.

Lower tract inflammation seldom results in any hematologic or biochemical changes while chronic upper tract infection may induce total protein and globulin increases. Azotemia only develops when both kidneys are severely infected. **Bacteriologic culture** of urine obtained from the bladder or specifically from either ureter or kidney may identify specific infections and their antibiotic sensitivity.

Rectal examination may help confirm the diagnosis and the extent of urinary tract involvement or a predisposing cause, e.g. enlarged and atonic bladder, cystic calculi, accumulation of sabulous urine sediment or a bladder mass. **Chronic cystitis** (*q.v.*) also usually leads to bladder wall thickening. **Ultrasonography** may help to focus on abnormal renal size, shape or consistency in horses with upper tract infections in particular.

Endoscopic examination is potentially very useful but before embarking on ureteroscopy the operator must be aware that there is a risk of carrying infection to the renal pelvis from the urethra or bladder. With long-standing cystitis, especially when bladder paralysis is the underlying cause, ureteral orifices may become dilated (and appear wide open) allowing for vesicoureteral reflux and development of ascending pyelonephritis. Collection of a urine sample from each ureter can be helpful.

Treatment

Treatment is focused on the primary cause and the secondary effects of the infection, especially if they are long standing. Antibiotic selection is critical to success but the major mechanism for maintaining urinary tract sterility is **flushing**, and so where there are problems with bladder or urethral function the control of infection may be much more problematic. Important aspects of antibiotic therapy include:

1. Antibiotic sensitivity profiles of the bacteria involved
2. Delivery of the antibiotic to renal tissue and urine
3. Activity of the antibiotic within the urinary tract
4. Compatibility with other drugs
5. Ease of administration (practicality)
6. Toxicity (potential or actual)
7. Expense.

In vitro resistance to a particular antibiotic may not preclude successful treatment with the drug as long as **high concentrations** are achieved in urine. Similarly, in vitro susceptibility does not always guarantee a successful response to treatment.

Potentiated sulfonamides are a mainstay of therapy; trimethoprim–sulfa combinations at 35 mg/kg (total substance) can be administered PO (q 12 h) or IV (q 12 h) and maintained for up to 21 days or more without significant harmful effects in most cases. This combination is useful because both components are excreted into urine in high concentrations in a non-metabolized state. They are also very safe even in very ill or dehydrated horses.

Penicillin administered parenterally (e.g. procaine benzylpenicillin 20 000 IU/kg q 12 h for 5–7 days) is effective for treating upper or lower UTIs caused by susceptible *Corynebacterium* spp., *Streptococcus* spp., and some *Staphylococcus* spp. and *Leptospira* spp.

Gentamicin (6.0 mg/kg q 24 h IV) (*q.v.*) and other aminoglycosides should be reserved for resistant lower tract or acute life-threatening infections caused by Gram-negative organisms. The drugs are however **nephrotoxic** and should certainly not be used when there is renal failure.

Cephalosporins, tetracyclines and chloramphenicol are concentrated in urine and can be useful in treatment.

Enrofloxacin (2.5 mg/kg PO or IV) can be used for resistant infections but it has severe side effects on growth plates in young growing horses.

Prolonged courses of antibiotics are required in all urinary tract infections; courses of 1–6 wk may be indicated. Ideally, a **midstream voided urine** sample should be submitted for bacterial culture 2–4 days after initiation of therapy and again 1–2 wk after treatment has been discontinued. Urine submitted for culture must be cooled as quickly as possible to 4°C and cultured as soon as possible after collection. Prolonged room temperature storage results in significant overgrowth and bacterial contamination.

Urinary acidification can be helpful in controlling bacterial growth and enhancing antibiotic function, but it is not easy to achieve. The horse is singularly resistant to acidification of the urine using ammonium chloride (15 g q 6 h PO) or sodium dihydrogen (acid) phosphate (25 g q 12 h PO). It may be possible to acidify urine using a diet with a **high dietary cation–anion balance (DCAB)**. This is a little researched and poorly understood aspect of equine nutrition but it can be useful to establish a mildly acidic urine. The DCAB is a measure of the acid-base balance of the horse as affected by the diet (*q.v.*).

Low DCAB diets (i.e. those that are anionic or acidic) induce metabolic acidosis and this results in acidification of the urine.*

Low DCAB diets have a significant effect on mineral metabolic status. They induce an increased calcium loss in the urine due to the role of the kidney in maintaining acid-base balance. Mineral deficiencies may be masked under these conditions.

Recurrent infections with the same pathogen should alert the clinician to the possibility of a primary focus in the upper tract, e.g. **nephroliths** (*q.v.*) or other parenchymal disease. Cystoscopy and ureteral catheterization can also be pursued. Recurrence with a different pathogen suggests an anatomic or functional cause of abnormal urine flow.

URINARY TRACT CALCULI

Urinary tract obstruction (obstructive dysuria) is a relatively common event in horses and is a considerable therapeutic challenge. Mares seldom have bladder or urethral obstructions.

Calculi may develop within the kidney, the ureters or the bladder. Obstructive urinary disease may occur in these organs depending on the exact location and the extent of the obstruction the calculi cause. The urethra may also be obstructed in male horses.

Urinary tract calculi are most commonly composed of calcium carbonate and/or calcium phosphate. In any site they probably require a **nidus** of some sort, although this is usually not recognized clinically; interstitial inflammation, infection or fibrosis or an area of medullary crest necrosis adjacent to the renal pelvis are examples of nidus formation. **NSAID use** is also a possible risk factor. Anomalies of development (e.g. renal hypoplasia, dysplasia or polycystic disease) or prior exposure to **nephrotoxins** could also provide a nidus for stone formation. Renal pelvic calculi can be identified

* Baker, L.A., Toliff, D.R., Freeman, D.W., Teeter, R.G., Breazile, J.W. (1992) Effects of dietary cation-anion balance on acid base status in horses, *Journal of Equine Veterinary Science* 12: 160–163.

ultrasonographically and sometimes take on the “staghorn” shape of the renal pelvis.

Renal and ureteral calculi can produce partial or complete obstruction of one or both sides of the upper urinary tract and can lead to acute renal failure. **Nephroliths** (*q.v.*) usually develop within or adjacent to the renal pelvis and obstruction can lead to hydronephrosis; the more distal the obstruction the more extensive will be the pressure-induced changes. **Ureteral obstructions** therefore cause the most extensive problems. Nevertheless, involvement of a single kidney or limited areas of one or both kidneys may show little or no clinical evidence. When both sides of the upper tract are affected, the condition typically progresses to **chronic renal failure** (*q.v.*).

Most ureteroliths originate as nephroliths (either from the renal pelvis or the renal parenchyma) that pass into the ureter where they become lodged and enlarge over time. Ureteral stones mainly lodge in the distal ureter; they may be palpable per rectum or visible endoscopically at the vesicoureteral opening. They rarely cause colic.

Many cases with renal or ureteral calculi have no clinical symptoms but **weight loss**, unexplained loss of performance and chronic renal failure may be reported. In addition to intermittent signs of mild colic, unilateral nephroliths may occasionally cause intermittent or persistent obvious hematuria. However, gross hematuria is uncommon unless stones have been passed into the bladder or urethra; urinalysis usually reveals pigmenturia and microscopic hematuria.

Cystic calculus is the most common form of urolithiasis in horses. Males are at greater risk than females; this may simply be because small calculi are easier to pass in mares. Bladder calculi are usually single, large spiculated, roughly spherical (but sometimes ovoid and lodging in the neck of the bladder) stones composed of calcium carbonate crystals. Less commonly, multiple stones can be found.

Hematuria after exercise is a common sign of bladder calculus. Pollakiuria, stranguria or incontinence and, in some cases, abdominal pain may also be observed. Less commonly, dysuria may be caused by accumulation of urine sediment in the ventral aspect of the bladder. This condition is termed **sabulous urolithiasis** (*q.v.*). Bladder calculi result in recurrent cystitis and urinary infections (often with different organisms).

Total urethral obstruction causes progressive colic and signs of distress. An enlarged, turgid bladder is detected per rectum. The exact location of the obstruction may be identified by rectal examination and palpation of the ischial urethra. **Bladder rupture** is likely to develop before any evidence of renal failure develops; this may be confirmed by careful clinical investigations supported by elevations of potassium and creatinine/urea. Abdominal ultrasound and paracentesis will confirm the presence of urine in the abdomen. Partial urethral obstruction is usually accompanied by dysuria, incontinence and urine scalding of the hindlimbs.

Prolonged acute obstruction may result in a permanently paralyzed, non-functional bladder. Fortunately the effects are reversible if treated early enough and so prompt relief of obstruction is crucial. Calculi, neoplasms, congenital anomalies and preputial edema and inflammation can produce partial or complete urethral obstruction.

Diagnosis

Diagnosis of nephrolithiasis or ureteral calculus is very difficult because clinical signs are mild (**recurrent colic**) or non-existent and azotemia is usually absent. Often the calculi are found incidentally during routine examination or at necropsy. Small calculi passing into the bladder may obstruct the urethra and so the **entire urinary tract** should be evaluated carefully in cases that have recurrent urethral obstruction. This is the more important because multiple small calculi are rarely associated with the bladder. Furthermore, upper tract calculus should be suspected in horses with **recurrent urinary tract infections** with the **same organism**. Concurrent azotemia (*q.v.*) may be a direct result of bilateral calculus formation but can simply be a component of a more extensive renal pathology.

Transabdominal ultrasonography is a valuable tool for detection of nephroliths, dilatation of the renal pelvis (or complete hydronephrosis) and renal fibrosis (increased echogenicity). Small nephroliths (<1 cm in diameter) can be missed despite a complete ultrasonographic examination. Transrectal ultrasonography is also useful for detection of ureteral dilatation and lithiasis.

Bladder calculi are usually identifiable by **rectal palpation**; most can be felt with only the hand and wrist in the rectum. The bladder is usually small and cystic calculi can be missed if the examiner passes quickly beyond the calculus during the rectal examination. Ultrasonographic diagnosis is not useful unless there are several stones present. Endoscopic examination is the method of choice; the number, size and location of the stones can be identified.

Diagnosis of urethral obstruction is based on clinical signs, rectal examination findings, external examination of the penis and prepuce, and passage of a catheter or endoscope.

Treatment

If upper urinary tract obstruction is diagnosed before development of more severe azotemia, nephrotomy and/or ureterotomy may be required. **Electrohydraulic lithotripsy**¹ is possible in specialist hospitals and is the preferred technique for removal of ureteral stones. However, both procedures are very difficult and nephrectomy may be a slightly simpler solution to a unilateral problem.

Bladder calculi are best removed via **laparotomy**. The rarer condition in mares is amenable to manual removal via gentle manual **urethral dilatation** (with a small hand), with or without **urethral sphincterotomy**. A calculus removed from the bladder should be examined carefully for smooth facets that might indicate the presence of other stones.

Urethral calculi can either be removed via a **sub-ischial urethrotomy** over the site of obstruction or by hydropulsion through the urethrotomy incision; excessive tissue trauma may increase the risk of urethral stricture and recurrent urolithiasis.

In theory, urinary acidification with **ammonium chloride** (50–200 mg/kg/day PO) or **ammonium sulfate** (200–300 mg/kg/day PO) should help but this is not easily achieved. Similarly, **reducing dietary calcium** (e.g. by removing alfalfa from the diet) is theoretically of help. A more practical

¹ A procedure to break up stones in the urinary tract using shock waves.

recommendation may be to administer **25–50 g of salt** in the feed daily to increase water consumption and urine flow.

Prognosis

The prognosis for renal or ureteral calculus is very guarded simply because the cause is unknown and therefore prevention is not usually feasible. Furthermore, it is impossible to remove every calculus.

Following removal of bladder calculi the chances of recurrence are low.

URINARY INCONTINENCE

INTRODUCTION

Urinary incontinence is a relatively common problem in horses and is a considerable **diagnostic challenge**. Urinary incontinence develops when intravesicular pressure generated by the detrusor exceeds outflow resistance generated by the urethral sphincter and results in involuntary passage of urine. This may occur with both neurologic and non-neurologic disorders.

The main problems with the clinical investigation relate to the late presentation of cases and the extent of secondary changes including **perineal scalding** in mares and **hindlimb dermatitis** and **penile paralysis** in males (*q.v.*). As is typical of any neurologic disorder, the opportunities for treatment are limited and even the retardation of progression is sometimes impossible.

Horses with detrusor dysfunction typically develop **sabulous urolithiasis** (*q.v.*), an accumulation of a large amount of urine sediment in the ventral aspect of the bladder that exacerbates bladder distension and contributes to further loss of detrusor function and eventual complete bladder paralysis (*q.v.*).

Urinary incontinence in the horse can result from:

1. **Congenital defects** of the urinary tract, e.g. ectopic ureter (*q.v.*).
2. **Urolithiasis** (*q.v.*).
3. Secondary incontinence from long-standing **lumbosacral or lower back** problems that make it difficult for horses to posture to urinate, resulting in incomplete bladder emptying. Calcium carbonate crystals accumulate in the ventral aspect of the bladder and as this becomes heavy and, in some cases, quite firm it further prevents complete bladder emptying. This condition, which has been termed **sabulous urolithiasis** (*q.v.*), can accompany bladder paralysis of any cause but may also be able to produce secondary bladder dysfunction without underlying neurologic problems.
4. **Neurologic diseases** (*q.v.*) accompanied by bladder dysfunction.
5. **Trauma**. Trauma-induced incontinence may develop after physical disruption of the urethral sphincter in mares as a breeding or dystocia injury (*q.v.*) or in both sexes following sacral or spinal injury.
6. **Neoplasia** (*q.v.*). Horses with neoplasia of the lower urinary tract can also present with incontinence but other complaints (e.g. stranguria or hematuria) are usually reported as well.

NEUROGENIC INCONTINENCE

Neurologic disorders (*q.v.*) that commonly result in bladder paralysis and incontinence include:

1. Spinal or pelvic trauma
2. Equine herpesvirus myelitis
3. Cauda equina neuritis (polyneuritis equi)
4. Sorghum ("Milo grass") toxicosis
5. Equine protozoal myelitis
6. Rabies.

Categories

For the most part, **neurogenic dysuria** can be divided into three categories, each of which has a distinctive general clinical character (Box 12.8).

Although the classical separation of lower from upper motor neuron bladder dysfunction may be useful for neuroanatomic localization of spinal cord disease, it is important to recognize that the separation is not absolute.

Involuntary urine passage that is limited to exercise may indicate decreased sphincter tone, rather than detrusor dysfunction, as the cause of incontinence. Similarly, horses that posture to urinate are assumed to have intact sensation of

Box 12.8 Categories of neurogenic dysuria

1. Upper motor neuron dysfunction/interruption

Upper motor neurons in the lumbar or higher portions of the spinal cord are damaged; this causes increased urethral resistance, leading to increased intravesicular pressure before voiding can occur. A tense, moderately enlarged bladder is identified by rectal examination.

2. Lower motor neuron dysfunction

The pathology originates in the gray matter of the sacral spinal segments or in the peripheral pathways of the sacral nerves. Lower motor neuron damage leads to loss of detrusor function and overflow incontinence. A large, easily expressed bladder is found on rectal palpation.

3. Dyssynergia (loss of detrusor–urethral sphincter coordination)

Dyssynergia (detrusor areflexia) arises from injury to the spinal cord above the sacral segments. It results in detrusor hyperreflexia and detrusor–external sphincter dyssynergia, a lack of coordination between detrusor and urethral sphincter activity. This causes an imbalance between the detrusor and urethral muscles (dyssynergia) resulting in short bursts of urine under high pressure but with painful and abrupt cessation. Rectal examination may reveal a turgid bladder that is small, normal or large in size. Incomplete bladder emptying may occur and so sabulous urolithiasis can develop and culminate in detrusor paralysis.

bladder fullness while those that never posture have likely lost bladder sensation as well as motor function.

Despite a large number of possible causes, the prognosis for recovery from incontinence due to **bladder paralysis** is generally poor because **sabulous concretions** and **urinary tract infection (UTI)** quickly complicate the problem.

Upper motor neuron signs of bladder dysfunction may be missed in horses until **overflow incontinence** develops as a result of accumulation of urine sediment (sabulous urolithiasis) and progressive loss of detrusor function. For these reasons bladder paralysis and overflow incontinence, consistent with lower motor neuron disease, may occasionally be found in horses with neurologic diseases that typically do not affect the gray matter of the sacral segments (e.g. **cervical stenotic myelopathy** or **equine degenerative myelopathy**) (*q.v.*).

Diagnosis

Diagnosis of neurogenic incontinence is directed to defining a cause if possible or at least establishing the extent, location and possible nature of the problem as well as any secondary conditions, e.g. infection, calculus or sabulous urolithiasis, that will affect the prognosis. Nevertheless in many cases a definitive etiology cannot be reached and then an anatomic description is used.

The history is essential because the initiating cause may have occurred months to years before incontinence actually became a problem and there may be historical facts that help considerably with a diagnosis, e.g. **ingestion of sorghum**, contact with **rabies** (*q.v.*) and previous contact with **respiratory tract infections** or a **traumatic episode**.

Direct observation of any attempts made by the animal to urinate is important. Inevitably a full neurologic examination (*q.v.*) is essential to establish if the dysuria has a neurologic basis and to identify the likely location for this. Although upper motor neuron signs are initially different from those of lower motor neuron disease, incontinence is usually not recognized until **overflow incontinence** develops as a result of sabulous urolithiasis (*q.v.*) and progressive loss of detrusor function. This explains why bladder paralysis and incontinence may occasionally be found in horses with other neurologic diseases including vertebral stenosis/instability (wobbler) (*q.v.*) cases, equine degenerative myelopathy (*q.v.*), and even viral encephalomyelitis, including equine herpesvirus (*q.v.*), rabies (*q.v.*) and the viral encephalitides (*q.v.*). Concurrent signs of lower motor neuron dysfunction such as loss of anal or tail tone or upper motor neuron dysfunction (e.g. ataxia) may help to differentiate the conditions and focus on a possible site for the pathology.

Rectal palpation will usually discriminate between accumulation of urine sediment (which can be indented with firm digital pressure) and a bladder calculus. Further, the latter problem does not present with overflow incontinence during palpation of the bladder.

Endoscopy and ultrasonography are used to establish the presence of complicating factors such as lithiasis, tumors and inflammation (*q.v.*). With longstanding incontinence and detrusor dysfunction, the ureteral openings may become dilated due to chronic distension and a loss of bladder compliance. Endoscopic visualization of open ureteral orifices would imply occurrence of vesicoureteral reflux and increased risk of upper tract infection.

Laboratory analyses of blood and urine, including a **quantitative urine culture**, should be performed in all horses with incontinence because infection is an almost invariable consequence of incontinence.

Treatment

Treatment is always directed toward correction of underlying causes but treatment of **neurogenic dysuria** is frequently unrewarding. Excessive amounts of calcium carbonate sludge can be washed out of the bladder using a urinary catheter. This gives temporary relief in a few cases but overt signs soon recur and secondary infections often develop to complicate the condition. Neurogenic dysuria/incontinence caused by equine herpesvirus myelitis (*q.v.*) and equine protozoal myelitis (*q.v.*) offers some hope of resolution.

Removal of sabulous crystalloid material and placement of a **temporary indwelling bladder catheter** in recent onset bladder paresis may be helpful because the intravesicular pressure is eliminated and so permanent detrusor atony is minimized. Antimicrobial treatment, ideally based on urine culture results, is also indicated in all cases of bladder paralysis.

The parasympathomimetic drug **bethanechol** has been recommended (0.25–0.75 mg/kg SC or PO) for improving detrusor tone and strength of contraction in horses with bladder paralysis. Bethanechol also increases ureteral peristalsis and relaxes the bladder neck and external urethral sphincter. The drug should never be given IV or IM. The response can be disappointing in long-standing cases. **Phenoxybenzamine** (0.7 mg/kg PO, q 6 h), an α -adrenergic blocker, decreases urethral sphincter tone and can be used with bethanechol in cases with upper motor neuron bladder dysfunction. In horses with evidence of urethral sphincter hypotonia, the sympathomimetic agent **phenylpropanolamine** (1 mg/kg PO, q 8–12 h) can be attempted but results are again likely to be disappointing.

It is not uncommon for geldings with incontinence and sabulous urolithiasis to be presented for suspected **cystolithiasis**. These patients should be carefully evaluated before an unnecessary cystotomy is performed because thick urine sediment can generally be removed by **bladder lavage** (via a urethral catheter) and rectal manipulation of the bladder.

Horses recovering from anesthesia or those that have not been comfortable with the circumstances of urination (such as transport or long distance riding) may develop a **spontaneous urethral spasm**. This condition is easily relieved by **catheterization** and is a major indicator for **prophylactic catheterization during anesthesia**. It seems that the overdistended bladder is less able to empty normally, and excessive straining may be seen with a fine dribble of urine or no urine at all. **Decompression of the bladder** with an indwelling urinary catheter is also the treatment of choice for horses with acute onset of bladder paresis and incontinence attributable to neurologic disease such as herpes myeloencephalitis or equine protozoal myelitis (*q.v.*).

Post partum mares may develop **urine retention** associated with bladder and/or urethral trauma. Early recognition of this complication and temporary placement of an indwelling balloon catheter to decompress the bladder is the treatment of choice. Despite aggressive post partum management, some affected mares may never fully recover bladder or urethral sphincter function.

If the condition is not immediately recognized, complete bladder paresis and incontinence may develop months to years later.

Indwelling urinary catheters should always be fitted with a **one-way valve** (made from a cut-off condom or surgical glove finger) to prevent aspiration of air and development of infection.

Ascending urinary tract infection is a major complication of incontinence and so full urinalysis is essential. **Prophylactic antibiotics** should probably always be used.

Prognosis

Horses with subtle neurologic deficits accompanied by incontinence or with idiopathic incontinence are often not presented until months or years after the onset. **Irreversible detrusor dysfunction** regardless of the initiating cause is usually untreatable and the best that can be expected is to manage the condition and its secondary effects. The long-term prognosis for recovery is usually very poor. Most causes of **neurogenic dysuria** are untreatable even if a definitive cause can be established. Almost invariably, the long-term prognosis is hopeless; in almost every case, the progression of the disease results in euthanasia.

Equine herpesvirus myelitis and equine protozoal myelitis (*q.v.*) are probably the only conditions that carry any chance of resolution, but even this may be difficult and incomplete.

NEOPLASIA

ETIOPATHOGENESIS

Urinary tract neoplasia is rare and the large majority of tumors are secondary. Primary tumors occur in the kidney (nephroblastoma and renal carcinoma) and the bladder (squamous cell carcinoma and more rarely transitional cell carcinoma).

Renal cell carcinoma (or adenocarcinoma) occurs more frequently in older horses but nephroblastomas may be detected in young horses. Nephroblastoma usually remains limited to the kidney but renal cell carcinomas (*q.v.*) commonly metastasize to the liver and lungs.

Fibromatous polyps may also occur in younger horses while **bladder tumors** usually develop in middle-aged to older horses.

The most common secondary tumors tend to affect the kidney and include lymphosarcoma, hemangiosarcoma and melanoma (*q.v.*).

CLINICAL SIGNS

Clinical signs of all tumor types include various combinations of hematuria, pollakiuria and stranguria, weight loss and recurrent colic. Sudden death may occur if the neoplasm hemorrhages into the abdomen or thorax.

Bladder tumors may be palpable per rectum but should not be confused with a **cystolith** or **sabulous accumulation**. Azotemia is not commonly present

but mild anemia may be detected when gross hematuria is observed. Neoplastic cells may be found in urine but this is unusual and they may be masked by inflammatory cells and hemorrhage.

Renal tumors may result in marked enlargement of the kidneys such that both the left and right kidneys may be found on rectal palpation. In other cases tumors may be small, circumscribed lesions within a kidney that cannot be felt during rectal palpation. Small tumors may also be difficult to visualize on ultrasonographic examination. Thoracic radiographs are helpful in detecting pulmonary metastases.

DIAGNOSIS

The diagnosis of bladder neoplasia may be confirmed by cystoscopic examination and biopsy. Renal biopsy may be performed under ultrasonographic guidance and a pinch biopsy can be obtained endoscopically from the bladder or the urethra.

TREATMENT

In theory, unilateral renal neoplasia can be treated by nephrectomy but most renal cell carcinomas have **metastases** by the time the diagnosis is made. Surgical intervention is of little benefit to horses with disseminated disease.

Treatment of bladder tumors includes surgical excision and/or topical chemotherapy (via endoscopic delivery) (*q.v.*) using either **5-fluorouracil** or **piroxicam**. Doses and courses of treatment have not yet been established for any of these compounds and there are currently too few reports to make conclusive recommendations.

Chapter 13

The stallion and mare reproductive system

INTRODUCTION

It has often been suggested that the equine species inherently achieves comparatively low fertility figures and that domestication makes matters worse. With good management, this is not the case. Analysis of the annual *Returns for Mares*, published by Weatherbys, keepers of the UK and Irish Thoroughbred Stud Book, shows that some well-managed Thoroughbred stallions, with mares indirectly selected for good fertility by fees, regularly achieve conception rates of 90–100% and live foal rates of approximately 80–90%. Even for the total Thoroughbred population of UK and Ireland, there is evidence that conception and live foal rates have increased and that barren mare rates have decreased over the last 20 years, suggesting improvements in management. Data from the same source demonstrate a linear decline in the fertility potential of mares with age. The live foal rate of 4-year-old mares is approximately 75%, whereas that of 20-year-old mares is approximately 50%. Although directly comparable data do not appear to be available from other countries, there is no reason to believe that the results of similarly managed equine populations are significantly different.

An infertile mare is incapable of conceiving when mated by a fertile stallion and is thus, by true definition, a sterile mare. The latter is uncommon, in contrast to the temporary breeding failures that are relatively common, and these mares are more correctly termed **subfertile**. A **barren mare** is one that is not pregnant at end of the breeding season, for whatever reason.

Reproductive success is measured in terms of the birth of a healthy foal and failure may thus involve problems that may occur at any stage of the events which lead to that end, i.e. the stallion (libido, ejaculatory or seminal abnormalities), the non-pregnant mare (failure of conception), the pregnant mare (early fetal death, abortion or periparturient fetal death) and/or the management of all these events. The veterinarian must consider all “links” of the reproductive “chain” when aiding management or investigating problems.

THE STALLION

CONGENITAL ABNORMALITIES

Gonadal dysgenesis

Chromosomal abnormalities, definable by karyotype, have been reported in infertile and subfertile stallions.

Hermaphroditism

This rare condition can be differentiated into true hermaphroditism, male pseudohermaphroditism (testes plus female external genitalia) and female pseudohermaphroditism (ovaries plus rudimentary tubular reproductive tract plus external genitalia resembling those of the male). These horses are sterile and unsuitable for breeding purposes. **Reconstructive surgery** can make them resemble one or the other sex.

Testicular aplasia/hypoplasia

Aplasia is the rare failure of development of one or both testes. In **hypoplasia**, which is not uncommon in some native pony breeds and other horses, one or both testicles are smaller than expected for age and breed of stallion and may vary in consistency from hard to soft. Diagnosis is made subjectively by **palpation** or more objectively by measuring the length, width and height of the fully descended testicle through the scrotum with calipers or ultrasonographic imaging. The condition has been associated with cryptorchidism, hermaphroditism and chromosomal abnormalities, e.g. XXY (**Klinefelter's syndrome**). Normal fertility (cryptorchidism), reduced fertility or infertility is observed. Collected ejaculates can range from totally aspermic to within normal in vitro parameters. The condition must be differentiated from testicular atrophy.

Monorchidism

Complete absence, through failure of development, of one testicle is rare in the stallion but such cases may be normally fertile.

Cryptorchidism

Stallions with cryptorchidism are colloquially called **rigs**. Cryptorchidism is the failure of one (unilateral cryptorchidism) or both (bilateral cryptorchidism) testes to descend, with their tunics, through the inguinal canal into the scrotum. **Inguinal cryptorchidism** (the retained testis is in the inguinal canal) may be temporary or permanent. **Abdominal cryptorchidism** (the retained testis is in the abdomen) is permanent. In unilateral cryptorchidism, which is most common, sperm production is not necessarily affected and such stallions are often normally fertile. Bilateral, especially abdominal, cryptorchids are infertile. A **genetic predisposition** is suspected for the condition and therefore many breed societies do not register cryptorchids to be used for breeding.

Diagnosis is made clinically by careful visual inspection and palpation of the scrotum, if necessary after tranquilization. Both the visual and palpable absence of one or both testicles and the absence of castration scars on the scrotum are indicative of the condition. Serum estrone sulfate levels (>0.2 ng/mL) in horses over 3 years old suggest cryptorchidism. The **hCG (6000 IU) stimulation test** provokes a rise in serum testosterone level (>100 pg/mL) as measured prior to and 30–120 min after IV injection in cryptorchids and this test should be used in horses younger than 3 yr old, in donkeys and in others where estrone sulfate levels are equivocal. Clinicians are advised to consult the laboratories to which

they refer samples for endocrinologic analyses for their reference ranges and interpretations as assays may differ significantly between laboratories. Ultrasonographic examinations may be used to identify a testicle located in the inguinal canal. Laparoscopic examination may be useful to confirm the presence or absence of abdominal testicles in those horses where a reliable history of a previously attempted castration is not known.

Treatment of choice is the localization of the ectopic testis or testes followed by **bilateral castration**. Abdominally and sometimes inguinally retained testes are now often removed by laparoscopic surgical techniques.

Congenital testicular rotation

A 180° rotation of one or both testes can be diagnosed by palpation, where the tail of the epididymis is found to be directed cranially. This condition is caused by malpositioning during testicular descent and is rarely associated with complications. Transient testicular rotation can occur.

Acute testicular torsion

Testicular rotation must be differentiated from acquired **testicular torsion**, which is characterized by rotation of the testicle and spermatic cord by greater than 180° and which is accompanied by signs of acute colic and swelling of the testicle and scrotum. Acute testicular torsion requires urgent surgical correction.

Inguinal/scrotal hernia

The colt foal presents with a unilateral or bilateral swelling, associated with intestines, alongside the testes, in the scrotum. This may be confirmed by **ultrasound imaging**. If intestinal **strangulation** occurs, there are signs of acute colic. To prevent this possibility it is usually prudent to castrate the foal and close the enlarged inguinal ring or rings. As the condition is believed to be heritable, it is considered wise to seek permission from the owner to perform bilateral castration.

INJURIES TO THE GENITAL ORGANS

Penis and prepuce

Traumatic injuries may result from kicks at mating, the use of stallion rings and brushes, injury by vulvar sutures at mating, incorrectly prepared or used artificial vaginas, and accidents involving gates, fences or sticks. There may be open skin wounds in addition to hemorrhage and edema.

First aid treatment with local applications of **cold water and/or crushed ice** is recommended. Systemic non-steroidal anti-inflammatory drugs (NSAIDs) and antibiotic therapy are indicated to reduce swelling and to control secondary infection. Dependent edema and swelling may be controlled by the provision of mechanical support with a custom-made sling using women's tights or similar materials. The stallion should be kept quiet and sexual stimulation avoided; tranquilizers, which cause penile relaxation, are contraindicated.

Complications include **lateral or ventral deviation** of the penis associated with fibrosis and adhesion formation, damage to the closed vascular system of the corpus cavernosum penis and reduced libido or abnormal mating behavior associated with pain or apprehension.

Urethra

Urethral injury may follow penile trauma, the passage of urethral calculi (*q.v.*), repeated catheterization, endoscopic examinations, or the use of tight stallion rings or irritant chemicals. **Hemospermia** and secondary infection with *Pseudomonas aeruginosa* (*q.v.*) are recognized sequelae that can result in subfertility. Diagnosis is by urethral endoscopic, contrast radiographic and bacteriologic examinations. Treatment with repeated **urethral flushing** with 1% silver nitrate solution has been helpful in some cases.

Testes

Testicular injuries may be caused by kicks received at mating or by accidental injuries involving fences, gates, poles and harness lines. Scrotal edema, hemorrhage, hematomas, lacerations and orchitis may occur and result in transient or permanent disturbance of spermatogenesis, depending on severity. More rarely, anti-sperm antibody production and epididymal obstruction may follow.

Immediate first aid treatment with local applications of cold water and/or crushed ice is recommended. Systemic NSAID and antibiotic therapy is indicated to reduce swelling and to control secondary infection. Ultrasound imaging may monitor the extent of damage, during the acute and healing phases. Where damage to one testis is severe, unilateral castration may be indicated in order to avoid anti-sperm antibody production.

Epididymis

Epididymal injury may result in obstruction, which is characterized by a **sperm-free ejaculate** and distended ampullae. Diagnosis is made by external palpation and ultrasound scan. Rectal palpation and ultrasound imaging of the ampullae reveal distension. Treatment consists of massaging the ampullae **per rectum** and inducing extreme sexual excitement, followed by ejaculation until sperm-rich ejaculates are obtained. It has been reported that the administration of 10–20 IU oxytocin per 450 kg body weight, IV, after ejaculation in conjunction with massage of the ampullae and repeated ejaculation until normal sperm is obtained has been successful in some cases. **Oxytocin** may help by increasing the contractility of epididymal smooth muscle.

Ampullae

Ampullary blockage can occur apparently spontaneously in breeding stallions for reasons that are not understood. Diagnosis is made, following a period of infertility and azoospermia, by palpation and ultrasound imaging of the ampullae per rectum, revealing distension. Treatment consists of massaging the

ampullae per rectum and inducing extreme sexual excitement, followed by ejaculation until sperm-rich ejaculates are obtained. Oxytocin therapy, as described above, may help by increasing the contractility of ampullary smooth muscle.

BEHAVIORAL ABNORMALITIES AND EJACULATORY DYSFUNCTION

The events leading to normal mating are regulated by a complex pattern of reflexes that are under hormonal and autonomic nervous control (*q.v.*). The phenomenon of sexual excitement and enthusiasm before and at mating is called **libido**. Sexual arousal results in penile erection, teasing, mounting, intromission, thrusting, ejaculation, resting, withdrawal and dismount.

Ejaculation can be divided into emission and ejection. **Emission** consists of those events leading to the emptying of the contents of the caudae epididymis, ductus deferentia, ampullae, prostate gland and seminal vesicles into the penile urethra. This is accompanied by closure of the neck of the urinary bladder. These events are controlled by the sympathetic nervous system (α -adrenergic mediation). The preganglionic sympathetic nerve fibers that leave the lumbosacral segment of the spinal cord, with their principal connections in the caudal mesenteric plexus, constitute the efferent arch of the emission reflex. Sympathetic stimuli mediated by the pudendal nerve and sacral segment of the spinal cord lead to **ejection**, i.e. the voiding of formed semen through the penile urethra. Ejection is principally the result of rhythmic contractions of the ischiocavernosus, bulbospongiosus and urethralis smooth muscles. Rhythmic dorsoventral movements of the tail ("flagging") and contractions of the anal sphincter accompany ejaculation. Five to ten jets of semen, in decreasing volume, sperm concentration and pressure, are produced.

Low libido

This most frequent of behavioral disorders is characterized by diminished or a lack of sexual interest and arousal when the stallion is presented with estrous mares. In sexually active stallions, over-use, change of location and management, abusive handling, accidents in the covering yard, unsuitably constructed phantoms and the incorrect use of artificial vaginas can lead to this disorder. It is often seen in **young or inexperienced stallions** that have been actively discouraged from exhibiting normal sexual behavior during competition careers. The abuse of **anabolic steroids** during a competition career can lead to breeding shyness and is associated with small testicular size and low levels of circulating androgens (*q.v.*).

A detailed examination must be performed in order to detect abnormalities such as the presence of stallion rings, painful lesions of the penis and physical lameness, which must be eliminated before presenting the stallion to an overtly estrous mare. Retraining stallions with reduced libido to assume normal mating behavior requires time and patience from experienced handling staff. Once the novice stallion has experienced his **first ejaculation** he will usually exhibit normal libido and mating behavior. Retraining involves the enhancement of sexual arousal by presenting a variety of estrous mares to the stallion to attain maximum stimulation. Allowing the stallion to run freely

with receptive estrous mares will often achieve success. Digital stimulation of the base of the penis, with or without the application of hot compresses may help stimulate ejaculation. Non-steroidal analgesic agents, such as **phenylbutazone**, can help overcome musculoskeletal sources of pain.

When these methods are not successful, the additional use of pharmacologic agents may be considered. **Human chorionic gonadotropin (hCG)**, 5000 IU administered IV 2 h prior to mating, is often tried first. Shy stallions with low levels of circulating androgens can be treated with gonadotropin-releasing hormone (GnRH). The injection of 50 µg GnRH SC 2 h and again 1 h before mating has been suggested.

Anxiety in breeding stallions can be treated using 0.05 mg/kg (not exceeding 20 mg) **diazepam**, administered slowly IV 5–7 min before mating. Mild transient ataxia may be observed for 3–4 min following injection.

Excessive libido

Stallions that exhibit excessive libido can pose a serious threat to handlers and mares in terms of physical injury. Most cases result from **poor stallion management** and handling, and in these cases treatment consists of retraining both the stallion and his handlers. The truly savage stallion often shows periods of normal behavior followed by episodes of unpredictable aggression and cannot be reliably retrained. Circumstantial evidence suggests that family traits exist.

Ejaculatory failure

Ejaculatory failure is seen in stallions that exhibit normal mounting, intromission and thrusting, yet fail to emit and eject semen. Frustration leads to **aggressive behavior** toward mares and handlers. Ultimately, libido declines and at that stage it may be difficult to differentiate from primary libido failure. Ejaculatory failure may be caused by a variety of conditions including musculoskeletal pain, aorto-iliac thrombosis, pleuritis, orchitis, urethritis and penile injuries (*q.v.*). Poor semen collection technique may produce a negative experience that may lead to partial ejaculation. Retrograde ejaculation into the bladder has been postulated but has yet to be conclusively confirmed in the stallion.

For the treatment of primary ejaculatory failure (including “retrograde ejaculation”) the administration of 0.01 mg/kg **norepinephrine** (noradrenaline) IM 15 min prior to mating and 0.015 mg/kg **carazolol** (a β-adrenergic antagonist) IM 10 min prior to mating has been recommended. Reports suggest that 100–600 mg **imipramine** PO b.i.d. for a minimum of 2 wk may improve ejaculatory competence. When given in tranquil surroundings, 0.66 mg/kg xylazine IV can induce ejaculation at rest, i.e. without erection or mating, in approximately 25% of stallions. In cooperative stallions this technique can be used to collect semen into a plastic bag, which is tied over the prepuce with a girth strap.

Urospermia

Urospermia, which appears to happen more frequently in older stallions, can occur intermittently. It leads to the contamination of an ejaculate with urine,

rendering the semen **non-viable**. The postulated cause is incompetence of the neck of the bladder. The ejaculate is discolored, the smell of urine can be detected and indicator strips confirm **high urea** concentrations. No specific pharmacologic therapy, including the use of diuretics, has yet been described and management should be directed toward encouraging the stallion to empty his bladder shortly before mating. Physical exercise often stimulates urination.

Azoospermia and oligospermia

Azoospermia is a rare condition in which the ejaculate is devoid of spermatozoa. It is usually associated with a **bilateral blockage** of the ampullae or ductus deferens. Treatment consists of transrectal manual massage of the ampullae, extreme sexual stimulation and repeated encouragement to ejaculate. If the blockages can be relieved by this method, subsequent ejaculates and fertility return to normal.

Oligospermia, where ejaculates contain smaller than normal numbers of spermatozoa, is most commonly seen in **aging stallions** in association with testicular atrophy. The spermatozoa that are present in the ejaculate are usually morphologically normal and exhibit normal progressive motility. Affected stallions must be managed carefully by limiting the number of matings per day to a minimum, by careful mare management.

VENEREAL AND OTHER INFECTIONS OF THE GENITAL ORGANS

Venereal infections can be caused by bacteria (*Taylorella equigenitalis*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*) or viruses (equine herpesvirus 3, equine viral arteritis) (*q.v.*) and may be transmitted at natural mating, through artificial insemination or by iatrogenic mechanical transfer. Generalized infectious processes, while they may primarily involve other organ systems, can affect the male reproductive tract. Pyrexia leads to disturbances in spermatogenesis. This results in a **reduction in seminal sperm** concentration and fertility approximately 4–6 wk after the pyrexia. Infections of the internal genitalia (orchitis, epididymitis, seminal vesiculitis, prostatitis), unless secondary to injury, are unusual in stallions but may result in pain, visible swelling and leukocytes in the ejaculate, which may lead to reduced or absent libido, poor sperm motility/viability and depressed fertility.

Bacterial infections

T. equigenitalis, *K. pneumoniae* (capsule types 1, 2 and 5) and *P. aeruginosa* are distinguished from other equine bacterial pathogens (e.g. *Streptococcus* spp., *Staphylococcus* spp., *Escherichia coli*) by their potential to spread venereally and to cause outbreaks of **endometritis** within groups of previously healthy mares. The stallion's external genital skin is normally colonized by a diverse microflora of these non-venereal microorganisms. When *T. equigenitalis*, *K. pneumoniae* or *P. aeruginosa* (*q.v.*) are introduced to and proliferate on the genital skin, the stallion seldom shows clinical signs of illness or abnormal semen quality but may become a mechanical transmitter of infection to mares,

which develop endometritis. Treatment therefore aims to eliminate the organism and to re-establish the normal genital skin microflora.

The Horserace Betting Levy Board (HBLB) of UK has produced a highly successful framework for the control of venereal diseases for the Thoroughbred industry by issuing the *Common Code of Practice for the Control of Equine Bacterial Venereal Diseases (including Contagious Equine Metritis) and Equine Viral Arteritis in France, Germany, Ireland, Italy and the United Kingdom*. This Code is updated on a yearly basis and other breed societies are recommended to follow similar guidelines. Clinicians in other countries are recommended to seek the guidance of their own appropriate industry and veterinary organizations. Semen intended for export must be collected from stallions that fulfill the health requirements of the importing country.

The HBLB *Code of Practice* requires that swabs are taken from the urethra, urethral fossa, prepuce and pre-ejaculatory fluid of all Thoroughbred stallions in France, Germany, Ireland, Italy and UK, on two occasions not less than 7 days apart, after January 1 and before the start of the mating season. Similar sets of swabs are also taken from the stallion during the breeding season if there is clinical evidence to suggest that venereally transmitted endometritis is affecting his mares (successively mated mares returning to estrus, often early, with vulvar discharges or cytologic and bacteriologic evidence of endometritis). The swabs are submitted for bacteriologic examination by quality assured **designated laboratories** that examine specifically for *T. equigenitalis*, *K. pneumoniae* (capsule types 1, 2 or 5) and *P. aeruginosa*, in addition to other potential non-venereal pathogens, and provide official certification. Contagious equine metritis (CEM) (*q.v.*) is a **notifiable disease** in the UK, France and Ireland.

If one of these three bacterial pathogens is isolated from a stallion, the start of mating is delayed or mating is stopped until the significance of the organism, in terms of its potential to produce outbreaks of true venereal disease, is determined.

Two strains of *T. equigenitalis* (streptomycin sensitive and resistant) have been identified but both have clinically demonstrated their potential to produce outbreaks of true venereal disease in mares. The stallion is treated daily for 5 days by teasing him to penile erection and then thoroughly washing the penis and prepuce with chlorhexidine surgical scrub (4% weight/volume), rinsing and drying, and then applying 0.2% nitrofurazone soluble ointment (if available), particularly packing the urethral fossa and diverticulum. Following treatment, it is recommended that a **normal genital skin microflora** should be established as soon as possible, and an individually prepared bacterial broth culture of specifically selected common equine genital commensals may be applied.

Many strains of *K. pneumoniae*, identified by capsule type, have been isolated and only capsule types 1, 2 and 5 have clinically demonstrated their potential to produce outbreaks of true venereal disease in mares. Capsule types 7 and 68 and many others have been isolated from the genitalia of individual stallions and mares but have not clinically demonstrated their potential to cause true venereal disease. They have sometimes been isolated from equine feces, urine and other non-genital sites. Therefore, **further specialized laboratory examination** of the isolate is required before the decision is made to treat the stallion.

If capsule types 1, 2 or 5 are isolated (or another capsule type if it is demonstrated to be causing true venereal disease), the stallion is treated daily for

7 days by teasing him to penile erection and then thoroughly washing the penis and prepuce with non-antiseptic soap and water to remove all the accumulated smegma. Following this, his penis and prepuce are washed with an aqueous solution of 1% hypochlorite solution, rinsing and drying, and then applying soluble gentamicin ointment, particularly packing the urethral fossa and diverticulum. Some stallions may show signs of local sensitivity to this treatment with inflammation and discomfort. In such cases, care must be taken to keep the penile skin supple to prevent cracking. Following treatment, it is recommended that a **normal genital skin microflora** should be established as soon as possible, and an individually prepared bacterial broth culture of specifically selected common equine genital commensals may be applied. *K. pneumoniae* is frequently difficult to treat and **repeated attempts** may be required before success is proven.

Many strains of *P. aeruginosa* (*q.v.*), identified by serotype, have been isolated, but no association has been proven with their potential to produce outbreaks of true venereal disease in mares. *P. aeruginosa* has been isolated from individual mares with endometritis and from equine feces, urine and other non-genital sites, but the organism has also been isolated in outbreaks of true venereal disease. The clinician therefore has no alternative but to treat all isolates as potential venereal disease risks, unless a **test-mating program** can be arranged. Even if this shows that the isolate is not being transmitted to the test mares, it is probable that the organism will cause endometritis in mares who are “susceptible” to infection and these may be very difficult to treat.

The stallion is treated daily for 10 days by teasing him to penile erection and then thoroughly washing his penis and prepuce with **non-antiseptic soap** and water to remove all the accumulated smegma. Following thorough drying, his penis and prepuce are thoroughly sprayed with **1% silver nitrate** solution. Following treatment, it is recommended that a normal genital skin microflora should be established as soon as possible, and an individually prepared bacterial broth culture of specifically selected common equine genital commensals may be applied. *P. aeruginosa* is frequently difficult to treat and **repeated attempts** may be required before success is proven. Recently, success has been achieved following local treatment of enrofloxacin-sensitive strains of *P. aeruginosa* with 50 mg/mL enrofloxacin. The 10% (100 mg/mL) injection preparation is diluted 50% with water and massaged liberally and thoroughly into the erect penile and preputial skin, daily for at least 7 days.

After the stallion has been treated for any of these three organisms, **three sets** of urethral, urethral fossa, prepuce and pre-ejaculatory fluid swabs are taken at intervals of not less than 7 days to confirm removal of the organism. The first swab should not be taken until at least 7 days after treatment has been completed. The stallion should then be test mated to **at least three mares** before the normal mating program is started or resumed.

Viral infections

Equine herpesvirus 3 (EHV-3, coital exanthema)

EHV-3 infection (*q.v.*) causes the development of **small vesicles** on the penis and the prepuce up to 10 days after mating a carrier mare. Stallions may exhibit generalized symptoms of lethargy, anorexia and pyrexia, libido is

depressed and they may be unwilling to mate mares. The vesicles form pustules before eroding and then ulcerating and becoming secondarily infected with bacteria resulting in purulent crust formation and discharge from the surface of the penis. This may be confused with excessive **smegma formation**.

Immunity is short-lived but the condition often recurs with less severe clinical signs. The stallion can become a symptomless carrier with periods of **typical herpesvirus recrudescence**.

Diagnosis is made on the basis of typical clinical signs, often following the occurrence of symptoms in mares covered by the stallion. The definitive diagnosis may be confirmed during the acute stage by isolating the virus from swabs and scrapings taken from the edge of erosions. Histologically, typical herpesvirus inclusion bodies can be demonstrated from fresh lesions and herpesvirus particles can be seen with an electron microscope. **Serologic examinations** can be used to confirm exposure to the virus. Complement fixing and neutralizing antibodies reportedly peak 14–21 days after infection. The former decline by 60 days while the latter can be demonstrated for (at least) up to 1 yr.

Mating should be suspended for 10 days, during which time treatment is aimed at controlling secondary bacterial infection. **Topical disinfection** with povidone-iodine surgical scrub, followed by the application of sodium fusidate ointment, is indicated in severe cases. In all but severely affected stallions, lesions have healed by 10 days to 2 wk after infection, and mating may resume. The infection has **no direct effect on the fertility** of either stallions or mares.

Equine viral arteritis (EVA)

EVA (*q.v.*), which is spread via respiratory and venereal infection, is caused by a member of the Togaviridae family. While clinical outbreaks of a disease similar to EVA are described in the veterinary literature of the last century, the virus was first isolated from an outbreak in the USA in 1953. Until 1993, the clinical disease had not been reported in the UK or Ireland and the level of seropositivity seen in these horse populations was <1%.

Epidemiologic evidence obtained from serologic studies performed internationally suggests that the virus is being **spread globally** through increased transport of some populations of horses and semen. Standardbreds, Thoroughbreds and other breeds have been affected by outbreaks in North America and elsewhere. Serologic studies of Warmblood breeds in various European countries have shown significant levels of exposure. The virus is spread **by aerosol** via the respiratory route and **in semen** at mating or insemination.

Typical cases show marked pyrexia, conjunctivitis, serous nasal discharge, head and limb edema, periorbital swelling and skin rashes. Stallions can develop edema of the scrotum and prepuce. Hematologic examinations, performed during the acute phase, reveal leukopenia. The virus may be isolated from peripheral leukocytes, nasopharyngeal swabs and urine during the acute phase. Serologic confirmation can be obtained using serum neutralizing (titers >1:4) or complement fixation tests from serum samples taken during the acute and convalescent stages of the disease. Approximately one third of infected stallions become permanent **seminal “shedders”** and therefore persistent carriers of the disease. Infected and symptomless seropositive stallions should be screened by **seminal virus isolation**.

Treatment is symptomatic and supportive and **most horses recover**, with the exception of some pneumonic foals. Prevention is based on identification of acute cases and symptomless carriers, followed by isolation and segregation.

In Kentucky, stallions are examined serologically prior to the start of the breeding season and seropositive stallions are test mated to determine if they are seminal “shedders” of the virus. Shedding stallions can only be mated to seropositive or vaccinated mares. A **safe and effective but live vaccine** is available in North America but is not licensed for use in many other countries, including the UK. It has been shown to be helpful in limiting the spread of the disease in outbreaks. A **formalin-fixed vaccine** is licensed for use in Germany and is available in the UK for use under the terms of a Government Animal Test Certificate (ATC), and under similar arrangements in Ireland and France, and is widely used for breeding stallions. A similarly prepared formalin-fixed vaccine has been shown to protect stallions in Japan from becoming semen shedders.

Artificial insemination using transported EVA-contaminated semen can result in the infection of the recipient mare and transmission to other in-contact horses via respiratory spread. Mare owners importing semen to UK and Ireland should establish the **antibody status of the donor stallion** before importation so that they do not import EVA to these highly susceptible horse populations. (See also the *Common Code of Practice for the Control of Equine Bacterial Venereal Diseases (including Contagious Equine Metritis) and Equine Viral Arteritis in France, Germany, Ireland, Italy and the United Kingdom* and the British Equine Veterinary Association's *Code of Practice for Artificial Insemination*.)

EVA is a **notifiable disease** in the UK and Ireland.

Protozoal infection

Trypanosoma equiperdum

Dourine (*q.v.*) is a venereal disease that was prevalent in western Europe during the earlier part of the 20th century but has not been reported to occur there for many years. It is a **notifiable disease** in many countries. The disease is still seen in horses in Asia, Africa, South America, southern and eastern Europe and Mexico. It is transmitted in semen at natural mating or insemination.

Clinical signs appear from 5 to 6 days to several weeks after infection and include pyrexia, anorexia, edema of the genitalia, discharge from the urethra and characteristic raised urticarial skin plaques (2–10 cm in diameter) that appear on the lower parts of the body and then disappear within hours. If these plaques persist they leave depigmented areas. **Small pustules** develop in waves on the penis and prepuce. They ulcerate and heal slowly leaving slightly elevated unpigmented scars reminiscent of those seen following EHV-3 infection (*q.v.*). Penile and generalized muscular paralysis can develop, leading eventually to emaciation, lameness and death. Differential diagnosis includes EHV-3 and the paralytic form of EHV-1. Diagnosis is confirmed **serologically** with complement fixation test or demonstration of the organism in smears of exudative fluid. Treatment is attempted with **quinapyramine sulfate** (3 mg/kg SC) but it is not known whether recovered stallions are safe for breeding purposes; eradication is therefore the best policy.

NEOPLASTIC DISEASES OF THE GENITAL ORGANS

Tumors situated on the penis, prepuce and scrotum can cause pain, hemospemia and loss of libido. **Squamous cell carcinoma** (*q.v.*) is the most commonly seen penile tumor of horses, often arising from the areas of the urethral process at the tip of the glans, with a predilection for unpigmented skin. The tumor ulcerates and then proliferates and can spread to regional lymph nodes. If removed early in its course the condition may be cured, and surgical debulking followed by laser or cryosurgery has been found to be particularly useful. Where local recurrence occurs, **penile amputation** is indicated. The diagnosis can be confirmed by histologic examination.

Melanomas, fibromas, sarcoids, hemangiomas and fibropapillomas can be encountered on the skin of the penis, prepuce and scrotum, as they can elsewhere on the body (*q.v.*).

Tumors of the testis and epididymis are usually unilateral and benign or of low malignancy. They include seminomas (mainly encountered in older stallions), lipomas, Sertoli and interstitial cell tumors. Dermoid cysts, teratomas and adenocarcinomas have also been reported. Diagnosis is facilitated with the aid of **ultrasound imaging**. Tumors must be differentiated from abscesses or hematomas. Testicular biopsies, not performed without risk, may be indicated to reach a definitive diagnosis. Treatment for **seminoma**, the most commonly seen equine testicular neoplasm, is unilateral castration, i.e. removal of the affected testicle.

SEMINAL CHARACTERISTICS AND MORPHOLOGY

The evaluation of semen samples is required for so-called “breeding soundness” examinations, infertility investigations and evaluation for suitability for preservation using chilling or freezing. Complete ejaculates can be obtained, from most but not all stallions, with artificial vaginas or condoms. Incomplete samples can be obtained from a stallion’s penis or a mare’s vagina or uterus immediately after dismount. These incomplete samples are of limited value only, but can confirm the presence of live sperm. Ideally, in order to obtain **optimal information**, a stallion should be allowed to ejaculate several times during the fortnight preceding collection. A 2–3 day rest should then be allowed before collecting two ejaculates spaced 1 h apart. When fertility problems occur with popular stallions during the breeding season it is seldom possible to organize 2 days of rest.

Normal ejaculates are gray to opalescent in appearance, odorless and do not contain clots, blood or urine. Total volume varies according to age, time from the preceding ejaculate and degree of sexual excitement. The proportion of gel to gel-free fractions varies between stallions and especially with degree of sexual excitement. The gel is removed and the gel-free volume of semen is measured. Gel-free semen volumes >40 mL can be considered normal in 500–600 kg stallions.

Sperm **concentration** can be measured with a hemocytometer chamber or a spectrophotometer calibrated for stallion semen. Depending on the ejaculation frequency and timing of ejaculations prior to collection, sperm concentrations

can vary between 50 and 700×10^6 spermatozoa per mL. The total number of sperm per ejaculate is then obtained by multiplying the sperm concentration with the gel-free volume.

Initial **motility** of spermatozoa is usually estimated subjectively, within 5 min of collection, on a microscope slide at 37°C. Overall motility should range from 60% to 80% with 40–70% progressive motility. Dilution in semen extender will increase these figures due to decreased viscosity. These estimations are subjective and vary from one observer to another. More objective computerized motility analyzers are available for equine use.

As an estimate of sperm **longevity**, raw sperm kept at 37°C should not show significant decreases in motility over the first 30 min. Motility can be comparatively estimated periodically until <10% sperm are alive, when the semen is maintained in dark and airtight conditions at room temperature (22°C), but precise reference data have not been published. Semen extended in equal volumes of a standard skim milk and glucose extender and kept at 4°C should maintain sperm motility of greater than 40% when warmed to 37°C after 24 h. Correlation between the fertility of fresh raw semen and motility of extended chilled semen at 24 h has not been satisfactorily established. The pH of semen immediately after collection should be 7.2–7.6.

Sperm **morphology** may be examined by viewing unstained fixed slides under phase contrast or differential interference microscopy. Alternatively, spermatozoa can be stained following fixation and examined by conventional light microscopy. The classical nigrosin/eosin and some other stains allow differential staining of those sperm which were considered live and those that were dead at the time of collection. There are special acrosome stains. Hematoxylin and eosin stain permits the examination for leukocytes and primitive spermatogenic cells. **Primary sperm abnormalities** are those acquired during spermatogenesis, **secondary abnormalities** occur during maturation, storage in the epididymis and ejaculation, and **tertiary abnormalities** occur after collection. Sperm are classified, according to morphologic features, as normal sperm, abnormal heads, detached heads, proximal mid-piece droplets, distal mid-piece droplets, abnormal mid-pieces, and abnormal tails. Further morphologic features can be ascertained using electron microscopic examinations. A normal equine ejaculate should contain a minimum of 50–55% morphologically normal sperm. **Sperm chromatin assays** are available at specialized laboratories.

No precise correlation between individual seminal characteristics and fertility exists as mare and managerial factors are at least as important, if not more important, for results obtained in a commercial breeding program. The evaluation of repeated semen samples combined with history, physical examination and behavioral observations must be considered prior to making conclusions and recommendations concerning an individual stallion's fertility. The **total number of normal motile spermatozoa** that a stallion can repeatedly produce is probably the most useful parameter that can be determined by semen analysis, in terms of the prediction of fertility potential. The numbers and fertility potential of the mares that he is expected to mate or inseminate are very important as are the managerial and veterinary supervision of the stallion and his mares.

THE NON-PREGNANT MARE

CONGENITAL ABNORMALITIES

Gonadal dysgenesis

The most common chromosome abnormalities seen in phenotypic females are the 63XO or 64XY genotype, or a variety of combinations of **mosaicism**. The most common clinical presentations are persistent anestrus, non-cyclic estrus or conception failure. Gynecologic examinations reveal persistently small (<1 cm) and echographically non-functional ovaries and a small uterus. Endometrial biopsy reveals marked endometrial hypoplasia. The diagnosis is confirmed by **karyotyping** and affected mares are permanently sterile.

Developmental abnormalities

Vaginal agenesis has been seen in the occasional mare. Gynecologic examinations reveal what appears to be a thick, **imperforate hymen**. Palpation and echographic examinations reveal discontinuity between the uterus and the vagina. Affected mares are unsuitable for breeding purposes.

ESTROUS CYCLE ABNORMALITIES

The **normal mare** is seasonally polyestrous, with transitional periods of varying length before and after winter anestrus. Normal cyclic ovulatory estrous periods occur, varying with individuals, between February/March/April and September/October/December in the northern hemisphere. The normal estrous period is 3–5 days of estrus (sexually receptive, follicular phase), with ovulation occurring at or near its end, followed by 14–16 days of diestrus (sexually non-receptive, luteal or progestational phase).

Prolonged diestrus

Inadequate endogenous endometrial gland prostaglandin ($\text{PGF}_{2\alpha}$) secretion causes failure of normal luteolysis, resulting in persistence of the corpus luteum and therefore **prolonged diestrus** (≥ 21 days) (*q.v.*). Gynecologic examinations reveal a pale, dry, tightly closed cervix and a peripheral progesterone level of ≥ 2 ng/mL. After careful **echographic confirmation** of non-pregnancy, the administration of exogenous $\text{PGF}_{2\alpha}$ usually results in luteolysis followed by normal ovulatory estrus within 3–7 days.

Shortened diestrus

Endometritis (*q.v.*) causes premature endogenous endometrial $\text{PGF}_{2\alpha}$ secretion, resulting in premature luteolysis, shortened diestrus (≤ 12 days) and premature return to estrus. **Gynecologic examinations** reveal an inflamed, moist, relaxed cervix, sometimes but not always with purulent discharge, and a peripheral progesterone level of ≤ 1 ng/mL. After confirmation of uterine infection with cytologic and bacteriologic examinations, uterine antibiotic

treatment and correction of predisposing factors, e.g. **pneumovagina** (*q.v.*), will usually be followed by normal diestrus length.

Silent estrus

For perhaps psychological reasons, apparently normal cyclic ovarian activity is not associated with sexual receptivity in some mares. Gynecologic examinations reveal a pink, moist, relaxed cervix; palpation and echographic examinations reveal mature ovarian follicular activity and a peripheral progesterone level of ≤ 1 ng/mL. Treatment is **tranquilization**, the administration of exogenous estradiol benzoate or artificial insemination (if appropriate).

Ovulation and luteinization failure

Little is known of the incidence or pathogenesis of **ovulatory abnormalities**. When echographic examinations are routinely used to monitor ovulation, it is recognized that in some mares typical echographic signs of ovulation, indicating follicular evacuation and collapse, do not always occur although the mare ceases to be sexually receptive and peripheral progesterone levels rise to ≥ 2 ng/mL. This is assumed to indicate **ovulation failure**. Conversely, typical echographic signs of ovulation (follicular evacuation and collapse) may occur although the mare remains sexually receptive and peripheral progesterone levels remain at ≤ 1 ng/mL. This is assumed to indicate **failure of luteinization**. In some mares a large, apparently mature follicle fails to ovulate, persists and develops particulate or flocculent fluid, sometimes with fibrinous strands. These are referred to as **anovulatory follicles**. On the basis of gross and histopathologic examinations of one such case only, these may be analogous to the follicular cysts that are well recognized in women.

Ovulation delay

If an otherwise apparently normal ovarian follicle appears to suffer a delay in ovulating, the administration of **human chorionic gonadotropin (hCG)** or synthetic **gonadotropin-releasing hormone (GnRH)** is usually followed by apparently normal ovulation.

PERINEAL CONFORMATION ABNORMALITIES AND INJURIES

The “normal” mare has three functional **genital seals** that form barriers between the external environment and the uterine lumen: the vulva, the vestibule and the cervix. During estrus, the vulva and the cervix relax, leaving the vestibule as the sole remaining seal. When the upper commissure of the vulva is high in relation to the pelvic brim, the vestibular seal is compromised and pneumovagina (*q.v.*) (“**wind-sucking**”) occurs. When the vulva slopes cranially toward a “sunken” anus (increased angle of declination), **pneumovagina** is complicated by fecal material falling into the vestibule. When the vestibule and urethral opening are displaced cranially, **urovagina** (*q.v.*) may occur. Pneumovagina, urovagina and/or vestibular fecal soiling lead to cervicitis and endometritis, which, if left untreated, usually result in conception or early pregnancy failure.

Pneumovagina

Pneumovagina is corrected by Caslick's vulvoplasty and/or Pouret's perineal reconstruction operations.

Caslick's vulvoplasty operation is performed if the pneumovagina is caused by a simple elevation of the upper commissure of the vulva above the pelvic brim, as judged by digital examination. With the mare bridled and restrained as for a routine gynecologic examination, the tail is bandaged and the perineum is washed and prepared. Under **local infiltration anesthesia**, a thin strip of the mucocutaneous junction is removed from either side of the vulva, from the upper commissure to the level of the pelvic brim. The adjacent exposed submucosal tissues are then sutured together to relocate the upper commissure ventrally. Once a mare has been "stitched", an episiotomy operation **must be performed before each subsequent foaling** and repaired again afterwards.

Pouret's perineal resection operation is performed if the angle of declination of the vulva is such that simple Caslick's vulvoplasty is insufficient to correct the pneumovagina. This procedure is best performed under hospital/clinic conditions with the mare sedated and restrained in stocks. **Epidural anesthesia** (*q.v.*) is induced, the tail is bandaged, the rectum is evacuated of feces and the perineum is clipped and prepared for surgery. Local anesthetic solution is infiltrated into the rectovaginal shelf. A horizontal skin incision is made halfway between the anus and the upper commissure of the vulva. The submucosal tissues are dissected and the rectovaginal shelf is split horizontally by sectioning the muscular and ligamentous connections between the anus, vulva, caudal rectum and vagina until the peritoneal reflection is reached. The subcutaneous tissues and then skin are apposed using a T-shaped closure to make maximal use of the horizontal perineal shelf that has been produced. No attempt is made to close the perineal "dead space" and the end result is to allow the upper commissure of the vulva to return to its "normal" caudal position, independent of the cranially displaced anus. Careful aftercare is required to prevent post-surgical abscess development and to deal with any local seromas that may occur.

Urovagina

Some cases of urovagina occur temporarily in association with an **enlarged uterus** (e.g. during the post-parturient period) and these respond to medical treatment for acute endometritis and delayed uterine involution. Others may respond to Pouret's perineal resection operation, which allows the urethral opening in the vestibule to return to a more "normal" caudal position. Intractable cases may require caudal relocation of the urethral opening, for which a number of vestibuloplasty operations have been described.

Vulvar and vaginal injuries

Injuries to the vulva may occur following direct trauma, e.g. a kick. They should always be repaired with care to restore a functional vulvar seal, in order to preserve the mare's future fertility. Rectovaginal injuries rarely occur during mating and more commonly occur at parturition.

CERVICAL INJURIES

Injuries to the cervix may occur at mating or at parturition or abortion.

Cervical lacerations

Full-thickness lacerations always carry a poor prognosis for future fertility because it is frequently difficult to restore adequate function and many suffer late-gestational failures with posterior pole placentitis. Surgical repair is performed under hospital conditions, with the mare sedated and restrained in stocks. **Epidural anesthesia** (*q.v.*) is induced, the tail is bandaged, the rectum is evacuated of feces and the perineum is clipped and prepared for surgery. Stay sutures are placed to open the vulvar lips to the buttocks to provide maximal exposure. Stay sutures are placed in the distal edges of the cervical laceration, which are then retracted as far distal as possible to aid exposure. With long instruments, the edges of the laceration are debrided and are apposed with a three-layer closure, i.e. external mucosa, connective tissue and internal mucosa. **Careful postoperative care**, with repeated digital manipulation with an **antibiotic/hydrocortisone ointment**, is necessary to prevent adhesion formation and to restore a functional cervical canal.

Some mucosal tears and focal adhesions may be repaired by repeated digital manipulation with an antibiotic/hydrocortisone ointment, to restore a functional cervical canal.

Cervical incompetence

Cervical incompetence may follow injury to the cervical musculature at mating or, more commonly, at parturition or abortion. The cervical seal may be disrupted and late-gestational failures may occur with posterior pole placentitis. The defect can be palpated digitally and attempts at repair, where indicated, are best made by converting the defect into a full-thickness cervical laceration and repairing it surgically as described above.

VENEREAL INFECTIONS

Infectious conditions may be acquired by the mare at mating. In France, Germany, Ireland, Italy and the UK, the HBLB's voluntary Code of Practice (*q.v.*) provides a framework for the control of equine venereal diseases in the Thoroughbred horse and some other equine populations. Many other breed societies have adopted similar codes and it is in the interests of the total horse population that these guidelines (or other appropriate codes in other countries) are followed by all. Clinicians in other countries are recommended to seek the guidance of their own appropriate industry and veterinary organizations.

Equine herpesvirus 3 (EHV-3)

Equine coital exanthema (*q.v.*) results in small vesicles forming at the vulvar mucocutaneous junction and sometimes over the adjacent perineal skin,

appearing approximately 7 days after mating. The vesicles may cause irritation but are rarely associated with pyrexia. They soon burst, leaving ulcers that become secondarily infected with external genital bacteria unless treated with local applications of antibiotic or antiseptic ointments. The condition is not associated with subfertility or infertility and mares may become pregnant following the mating at which they were infected. Diagnosis is by clinical appearance and the history of recent mating, but can be confirmed by histologic examination of lesion biopsy or viral serologic tests, if necessary. Healed lesions on the vulva or penis may remain depigmented.

Equine viral arteritis (EVA)

This togavirus causes pyrexia, depression, conjunctivitis, increased respiratory rate, skin lesions, and edema of the limbs, head and trunk. Mares may be infected at natural mating or during artificial insemination with semen from virus-shedding stallions. Mares who are infected during pregnancy, via the respiratory route, may abort.

The incubation period ranges from 3 to 14 days with an average of 7 days. Diagnosis is confirmed by virus isolation from respiratory secretions or urine, or by a greater than four-fold increase in serum neutralizing EAV antibody titer (seroconversion). Immunity following infection or live virus vaccination is life-long and therefore **viral serologic tests may indicate past challenge rather than active infection**. The carrier state has not been identified in mares and so a seropositive mare with no signs of active infection and a static or falling serum neutralizing EAV titer is considered immune and of **no risk for transmission** of infection to other horses.

Equine arteritis (*q.v.*) appears to be endemic in some populations of horses, notably Standardbreds and Warmbloods, throughout the world, as judged by levels of seropositivity. In the UK the incidence of seropositivity in indigenous horses is extremely low and it must be assumed that the UK mare population is very susceptible to the clinical disease. The first small and limited outbreak of EVA occurred in the UK in 1993. Cases were isolated and the outbreak was successfully controlled. Outbreaks of EVA involving stallions have since occurred in France and in Ireland. Measures designed to prevent the recurrence of EVA in France, Germany, Ireland, Italy and the UK are recommended in the HBLB's voluntary Code of Practice (*q.v.*).

Taylorella equigenitalis

Taylorella equigenitalis is a small, slow-growing (3–7 days on specialized hemolyzed blood agar), Gram-negative, microaerophilic, catalase-positive, oxidase-positive but otherwise biochemically unreactive coccobacillus. It is the cause of **contagious equine metritis** (CEM), which was first defined in Newmarket in 1977. It causes **epidemic acute endometritis**, with clinical signs varying from a copious mucoid/gray vaginal discharge, which may be first seen as early as 2 days after mating, to no gross signs of abnormality. The acute endometritis usually causes conception failure, but some mares resolve the acute infection soon enough to allow conception and normal pregnancy to proceed. Mares may become symptomless carriers, the **clitoral fossa and sinuses** being the important sites of persistence. The diagnosis is confirmed

by the growth of the organism from **endometrial (acute infection) and/or clitoral (carrier state) swab samples**.

Acute endometritis can be successfully treated by repeated intrauterine irrigation with penicillin. At the same time the clitoral fossa and sinuses must be thoroughly and repeatedly treated by washing with **chlorhexidine solution** and packing with **nitrofurazone ointment**. Following this external genital “sterilization” it is prudent to treat the clitoral fossa and sinuses with an actively growing bacterial broth purpose-made from **normal equine external genital commensals**, to discourage the overgrowth of *Pseudomonas* spp. or *Klebsiella* spp.

In intractable cases, **clitoral sinusectomy**, performed under local infiltration anesthesia with the mare sedated and restrained in the standing position, may be required.

Contagious equine metritis (CEM) (*q.v.*) is a notifiable disease in several countries including the UK, France and Ireland. In the UK, the isolation of *T. equigenitalis* must be reported by the isolating laboratory.

T. equigenitalis has been successfully eradicated from the Thoroughbred horse population of the UK by the vigorous application of the HBLB’s Code of Practice (*q.v.*). It remains endemic in many non-Thoroughbred horse populations in mainland Europe and therefore the potential for reintroduction remains, as demonstrated by transmission of CEM by a Warmblood stallion imported into the UK in 2002 and the isolation of the organism from an imported Warmblood stallion in 2005.

Klebsiella pneumoniae

Some strains (capsule types) of this Gram-negative, lactose-fermenting, aerobic bacillus, which produces luxuriant mucoid pink colonies on MacConkey’s agar overnight, can cause venereal disease. Capsule types 1, 2 and 5 have been known to cause epidemics of **acute endometritis**, with a variable cream-colored vaginal discharge that may be first seen as early as 3–4 days after mating. Capsule types 7, 30, 68 and those isolates that do not type with capsule-typing antisera 1, 2, 5, 7, 30 and 68 have not yet been reliably associated with true epidemic venereal disease but may, as any other bacteria may, cause acute endometritis in so-called “susceptible” mares. The acute endometritis usually causes **conception failure**, but some mares resolve the acute infection soon enough to allow conception and pregnancy to proceed, sometimes followed by placentitis, gestational failure or the eventual birth of a septicemic foal, suggesting that the organism can persist. Mares may become **symptomless carriers**, the clitoral fossa and urethra being the most importantly recognized sites of persistence. Diagnosis is confirmed by the growth of the organism from endometrial (acute infection) and/or clitoral/urethral (carrier state) swab samples.

Acute endometritis can be successfully treated by **repeated intrauterine irrigation** with gentamicin, or sometimes neomycin. At the same time the clitoral fossa, sinuses and urethral opening must be thoroughly and repeatedly treated with **gentamicin ointment**. Following this external genital “sterilization”, it is prudent to treat the clitoral fossa and sinuses with an actively growing bacterial broth purpose-made from normal equine external genital commensals, to encourage the establishment of a normal external genital microflora. In intractable cases, **clitorectomy**, performed under local infiltration anesthesia

with the mare sedated and restrained in the standing position, may be required to resolve the problem.

The incidence of isolation of *K. pneumoniae* (capsule types 1, 2 and 5) from Thoroughbred mares in the UK has been significantly reduced by the application of the HBLB's Code of Practice (*q.v.*).

Pseudomonas aeruginosa

Some strains of this Gram-negative, lactose-fermenting, aerobic bacillus, which produces luxuriant greenish, foul-smelling colonies on MacConkey's agar overnight, can cause venereal disease, with a variable cream-colored vaginal discharge which may be first seen as early as 3–4 days after mating. Strain typing may be performed but, unfortunately, no reliable association between strain type and the potential to produce true epidemic venereal disease has been found. "Non-venereal" strains, as with any other bacteria, may cause **acute endometritis** in so-called "susceptible" mares. The acute endometritis usually causes conception failure, but some mares resolve the acute infection soon enough to allow conception and pregnancy to proceed, sometimes followed by placentitis, gestational failure or the eventual birth of a septicemic foal, suggesting persistence. Mares may become symptomless carriers, the **clitoral fossa** being the importantly recognized site of persistence. Diagnosis is confirmed by the growth of the organism from endometrial (acute infection) and/or clitoral (carrier state) swab samples.

Acute endometritis can be successfully treated by **repeated intrauterine irrigation** with gentamicin, or ticarcillin and clavulanic acid. At the same time the clitoral fossa and sinuses must be thoroughly and repeatedly treated with gentamicin ointment or repeatedly treated with **1% silver nitrate solution** (for its desiccant effect). Following this external genital "sterilization", it is prudent to treat the clitoral fossa and sinuses with an actively growing bacterial broth purpose-made from normal equine external genital commensals, to encourage the establishment of a normal external genital microflora. In intractable cases, clitorectomy, performed under local infiltration anesthesia with the mare sedated and restrained in the standing position, may be required to resolve the problem.

The incidence of isolation of *P. aeruginosa* from Thoroughbred mares in the UK has been significantly reduced by the application of the HBLB's Code of Practice (*q.v.*).

NON-VENEREAL AEROBIC AND ANAEROBIC BACTERIAL ENDOMETRITIS

During estrus, the mare's cervix relaxes to allow intrauterine ejaculation by the stallion. All mares' endometria are therefore challenged at natural mating with the variety of microorganisms that normally inhabit the external genitalia of both mare and stallion. "Normal", genitally healthy mares are able to resolve this **acute endometritis** within 72 h, returning the endometrium to a healthy state by the time the fertilized ovum enters the uterus from the Fallopian tube at approximately Day 5 after ovulation.

Mares with perineal, vaginal, cervical or uterine structural or functional abnormalities, particularly those who are unable to clear uterine fluid from

their uteri, are unable to resolve this acute endometritis, which persists, resulting in **conception or gestational failure**. Such mares may also succumb to persistent acute endometritis spontaneously or following foaling or veterinary examination. Recurrent and/or persistent acute endometritis and **uterine fluid pooling** are thought to be important contributing causes of chronic endometrial disease, which leads to the almost linear decline in fertility potential that is well recognized in Thoroughbred broodmares.

Clinical signs may or may not include uterine fluid pooling (ultrasound scan), vaginal/vulvar discharge and shortened diestrus. Of the normal equine external genital microflora, the aerobes *Streptococcus zooepidemicus*, *Escherichia coli* and *Staphylococcus aureus*, and the anaerobe *Bacteroides fragilis* are most frequently isolated from endometrial swab samples in the presence of acute endometritis. Treatment with **intrauterine antibiotic irrigations** is indicated where there is concurrent cytologic evidence of acute endometritis (polymorphonuclear leukocytes in an endometrial smear, washing or biopsy sample). The choice of antibiotic preparation may be based upon **in vitro sensitivity tests**, but mixed infections with multiple species of aerobes and anaerobes are common and thus a broad-spectrum approach is usually appropriate. Particular care should be taken to avoid insoluble or irritant preparations/vehicles, which are likely to induce chronic endometritis, sometimes encouraging *Pseudomonas aeruginosa* or **fungal superinfection**.

Ceftiofur sodium, 1 g dissolved in 20 mL sterile water for injection administered IU daily for 3–5 days, has been found to be particularly useful as a non-irritant, no-residue, “first choice” approach. Mixed aerobic and anaerobic uterine infections are common and *B. fragilis* is the predominant equine uterine anaerobe, an organism that is frequently resistant to penicillin and aminoglycoside antibiotics. Culturing anaerobic bacteria is time consuming and so the use of an antibiotic with anti *B. fragilis* activity (e.g. ceftiofur sodium) is logical, helping to prevent persistent aerobe-negative endometritis. Following IU antibiotic treatments, 25 IU oxytocin may be administered IV to aid uterine clearance of fluids and the mare should be exercised, if possible.

These external genital microflora organisms are **opportunistic pathogens** and thus predisposing factors such as pneumovagina, urovagina, cervical injury/incompetence or delayed post partum uterine involution must also be treated. Where there are additional signs of uterine fluid accumulation or pyometra, large-volume (3 L, repeated) **sterile saline irrigation**, with hydrogen peroxide added (2%), may be used prior to starting antibiotic treatment. Irrigation may be performed via a large-bore equine uterine flushing catheter. Following IU sterile saline uterine flushing and antibiotic treatments, 2.5 IU oxytocin may be administered IV to aid uterine clearance of fluids and the mare should be exercised, if possible.

MYCOTIC ENDOMETRITIS

The fungal organisms (*q.v.*) most commonly isolated from cases of equine acute endometritis are *Candida* spp., *Aspergillus* spp., *Mucor* spp. and *Allescheria boydii*. They are opportunistic pathogens and interpretation of the significance of their isolation depends upon clinical and/or cytologic criteria. Fungal hyphae and/or spores should be demonstrable in endometrial smear, washing or

biopsy samples, with polymorphonuclear leukocytes. Fungal cultures are performed on Sabouraud's agar. Isolates are sometimes made on simple blood agar plates during aerobic bacterial screening.

Treatment is by **intrauterine irrigation** with large volumes of saline solution and 2% organic (povidone) iodine. Specific antifungal antibiotics such as nystatin, amphotericin, clotrimazole and econazole are available, but they are usually in tablet or pessary form designed for human use and are therefore not ideally suited for the treatment of mares. The administration of 3 g **ketoconazole** (15 × 200 mg tablets) orally daily for 10 days has been found to be a useful adjunct to IU treatment in some mares suffering from mycotic endometritis.

UTERINE IMMUNE AND/OR FLUID CLEARANCE INCOMPETENCE

Where demonstrable physical predisposing factors, e.g. pneumovagina (*q.v.*), have been corrected and there remains a history of recurrent acute endometritis with or without uterine fluid pooling, mares are specifically managed to try to prevent the development of persistent post-mating endometritis. Prior treatment with large-volume saline flush and/or antibiotic irrigation is essential to resolve active endometritis.

"**Minimal contamination breeding techniques**" (Box 13.1) have been found to be useful prophylactic techniques for mares with apparent **uterine immune incompetence**, aiding the resolution of normal transient post-mating endometritis and preventing persistent endometritis.

DEVELOPMENTAL, FUNCTIONAL, DEGENERATIVE AND NEOPLASTIC DISEASES OF THE OVARIES, UTERUS AND FALLOPIAN TUBES

Endometrial hypoplasia

Diffuse glandular under-development has been seen in endometrial biopsy specimens collected from barren maiden mares, sometimes in association

Box 13.1 Minimal contamination breeding techniques

1. The mare should have been successfully treated, if appropriate, and should be free of acute endometritis, prior to the use of these techniques.
2. She should be mated once only per estrous period, just prior to the anticipated ovulation of an apparently normally developing mature ovarian follicle, with the administration of hCG or GnRH to ensure that a second mating is not required.
3. A standard skimmed milk and glucose semen extender, with antibiotics added at concentration designed for this purpose, may be instilled into the mare's uterus just prior to mating, in mares with particular problems.
4. The uterus is flushed with 3 L sterile saline solution 12–24 h after mating then treated with 1 g ceftiofur sodium in 20 mL water for injection and 25 IU oxytocin IV.
5. The uterus is irrigated with 1 g ceftiofur sodium in 20 mL water for injection and 25 IU oxytocin is administered IV daily for the next 2 days.

with ovarian cyclic irregularities. Hypoplasia appears to be a feature of **relative genital immaturity** and usually resolves, without treatment, in time. Where the degree of hypoplasia is marked and ovarian size is minimal, or where the condition persists, the possibility of gonadal dysgenesis should be considered (*q.v.*).

Endometrial hyperplasia

Diffuse glandular hyperplasia with hypersecretion is a normal feature of endometrial biopsy specimens collected from mares during the post partum or post pregnancy failure period. Normal glandular architecture and secretory activity is usually achieved by 10–12 days, suggesting successful involution, but occasionally hyperplasia may persist for weeks if not months, when it is considered pathologic. Concurrent acute endometritis (*q.v.*) is frequently seen. Treatment with 50 IU oxytocin in 500 mL saline by slow IV drip has been used with good results.

In some cases, recurrent acute endometritis/pyometritis appears to produce **diffuse glandular hyperplasia**, possibly associated with recurrent premature luteolysis and hyperestrogenism. Successful treatment of the acute endometritis will reduce the signs of diffuse glandular hyperplasia.

Chronic infiltrative endometritis

Mononuclear cells, i.e. histiocytes/lymphocytes and plasma cells, are commonly seen diffusely and/or in focal stromal aggregations in endometrial biopsy specimens. The presence of these cells indicates a local immune response and therefore previous or ongoing antigenic challenge. No specific treatment is indicated.

A severe **granulomatous endometritis**, with large numbers of plasma and epithelioid-type cells, is occasionally seen in long-term, end-stage pyometra and is considered an indication for retirement.

Chronic degenerative endometrial disease

Glandular degenerative changes are seen in the form of functional or non-functional “nests”, surrounded by lamellae of fibrous tissue or, less commonly, gland “cysts”, lined by glandular epithelial cells and containing packed glandular secretion, in endometrial biopsy specimens. Periglandular, perivascular or, less commonly, **diffuse stromal fibrosis** is seen. Vascular degenerative changes may be identified. Pools of tissue fluid may be seen scattered in the stroma. Large and multiple lymphatic “lacunae”, lined by lymphatic endothelial cells, may be seen in the stroma. It is unusual to sample an endometrial lymphatic cyst, using these biopsy techniques, but these are thought to have a similar pathogenesis.

These changes indicate **chronic degenerative endometrial disease** (sometimes called **endometriosis**). This is a normal progressive condition associated with aging and is thought to reflect long-term endocrinologic effects of repeated ovarian cyclic activity. Mares who are pregnant and have atraumatic parturitions and successful uterine involutions year after year develop these

chronic degenerative changes at a slower rate than do mares who have pregnancy “gaps” for whatever reasons. The performance mare that retires late to stud is notoriously difficult to start breeding and examination of biopsy samples often shows chronic endometrial degenerative changes that are considered to be well in advance of what would be expected for age-matched multiparous mares. In addition, the repeated stimulatory challenges of semen, microorganisms, external genital and environmental debris and fetoplacental antigens, and the repeated physical challenges of pregnancy, parturition and involution may accelerate the development, distribution and severity of these degenerative changes. The changes may significantly contribute to the **linear decline in fertility** seen in the Thoroughbred mare population and are frequently seen in mares that suffer repeated pregnancy failure or prolonged gestation with fetal dysmaturity.

Endometrial degenerative changes develop to a degree that is quite predictable and thus each biopsy specimen examined must be assessed in terms of the mare's **age and parity**. Where the degree of degenerative change is considered excessive, treatment with endometrial mechanical curettage may be attempted. The aim of this technique is to stimulate an increase in endometrial blood supply. Improvements in histopathologic appearance and fertility can be expected in 50% of mares <17 years and this technique is safer and more humane than chemical curettage.

In some cases, **recurrent acute endometritis/pyometritis** produces diffuse stromal fibrosis, possibly associated with recurrent premature luteolysis and hyperestrogenism. Successful treatment of the acute endometritis, followed by pregnancy, can sometimes reduce the signs of diffuse stromal fibrosis. Where there is concurrent acute endometritis, dimethyl sulfoxide may be added to the antibiotic mixture in an attempt to aid stromal penetration.

Cystic endometrial disease

Large **lymphatic cysts**, which project into the uterine lumen, and large lymphatic lacunae in the endometrial stroma may be found in many multiparous mares >14 years. Unless they are very large or are so extensive that they significantly reduce the functional endometrial surface area, resulting in gestational failure, they have little demonstrable effect on fertility. Large individual cysts that may interfere with normal early conceptual mobility or may confuse early pregnancy diagnosis may be **ruptured** by videoendoscope-directed laser surgery or snared and removed by videoendoscope-directed “hot-wire” thermocautery.

Myometrial degenerative disease

Myometrial incompetence and uterine postural considerations in aging mares are believed to play an important role in the failure of some multiparous mares to clear uterine fluids post mating and therefore predispose to the persistence of **post-mating endometritis**. Such mares are treated with 25IU oxytocin IV after uterine sterile saline flushes, uterine irrigations with antibiotics and after mating (see Box 13.1).

Ventral uterine dilatations (areas of fold atrophy and myometrial stretching) are sometimes palpated in older multiparous mares. They may contain hypo-echoic luminal fluid accumulations or large endometrial cysts or lymphatic lacunae. It is possible that they may embarrass normal uterine clearance of luminal fluid and may have a role to play in some cases of recurrent acute endometritis. Treatment with 50°C hypertonic saline solution by intrauterine infusion, and/or 60 IU oxytocin in 500 mL saline solution by slow IV drip may improve myometrial tone and aid the clearance of pooled uterine fluid in such severe cases.

Endometrial atrophy

Diffuse glandular atrophy is seen in endometrial biopsy specimens of mares following prolonged ovarian inactivity and is therefore a normal temporary feature during winter anestrus. **True persistent endometrial atrophy**, with luminal epithelial and glandular atrophy, may be seen in aged mares, usually in association with senile ovarian malfunction. Rarely, it has been seen in younger mares following severe recurrent acute endometritis with *Pseudomonas aeruginosa* infection. No treatment is successful for persistent “senile” endometrial atrophy and retirement should be recommended.

Endometrial neoplasia

In contrast to some other species, endometrial neoplasia is relatively rare in the mare.

Leiomyoma/fibroleiomyoma tumors are usually small and benign, and have no primary effect on fertility. Treatment, by surgical removal, is only indicated where the tumor is large, when it may be pedunculated and cause persistent endometrial hemorrhage and secondary endometritis.

Rare cases of **adenocarcinoma** have been recorded in the literature. One mare had respiratory signs and post mortem examination confirmed pulmonary metastases.

Fallopian tube abnormality

Palpable or echographic abnormalities of the fallopian tubes are uncommon and bilateral blockage is very rare in mares. **Para-ovarian cysts** or other local developmental abnormalities may be incidental findings at rectal palpation or ultrasound imaging. They seldom have a specific effect on fertility.

Salpingitis

Mononuclear cell infiltrations of the submucosal layers of the fallopian tubes are as common as they are in the endometrium and again are presumed to be indicators of local genital tract immune responses to antigenic challenge. **Acute salpingitis** (polymorphonuclear cell infiltrations) is thought to be rare but may perhaps account for some failures of blastocyst transport in older mares with histories of recurrent acute endometritis.

Occlusive disease

Occlusive disease is thought to be very rare and then usually unilateral, not significantly depressing fertility.

Ovarian hypoplasia

Markedly small or absent ovaries in barren maiden mares suggest gonadal dysgenesis, definable by karyotyping. These mares are sterile. For reasons that can only be speculated upon, some mares appear to suffer delayed sexual maturity, showing poor ovarian follicular development, cyclic activity and ovulatory function until they are 6–7 yr old.

Ovarian cystic disease

True cystic ovarian disease, as seen in some other species, is uncommon in mares. Normal ovarian follicular size is very variable and many large “cysts” appear to ovulate normally, suggesting that they were normal follicles. Occasionally, mares develop large hyperechoic follicles that contain fibrin-like strands and are often referred to as anovulatory follicles. These may be **follicular cysts** and are often refractory to hormone treatments although they may not prevent the production and ovulation of other follicles on the same or the contralateral ovary. **Luteal cysts** may occur rarely in mares but it is difficult to make a precise diagnosis without histopathologic confirmation. **Ovulation fossa inclusion cysts** occur sometimes, usually in older mares, where multiple small follicles that have not matured and ovulated block the progress of other maturing follicles into and though the ovulation fossa. Treatment with repeated large doses of hCG or GnRH and then PGF_{2α} may resolve the problem in some cases.

Ovarian hematoma

Ovarian hematomas are difficult to define by palpation alone, but can be accurately diagnosed by their diffuse hyperechogenicity. Most cases resolve by **natural resorption**, require no treatment and have no lasting effect. In rare cases they can become very large, persist and cause abdominal pain necessitating ovariectomy. In even rarer cases, rupture of the hematoma may occur, resulting in fatal hemoperitoneum. Therefore, laparoscopic removal of persistent non-resolving ovarian hematomas is recommended.

Ovarian neoplasia

Granulosa/thecal cell tumor (*q.v.*) is the most commonly found equine ovarian neoplasm. The affected ovary is enlarged and palpably hard and is echographically polycystic, the cyst walls being relatively thick. The ovulation fossa is not palpable. The contralateral ovary is small and inactive. The mare may show **nymphomania**, **virilism** or **maternal behavior** depending upon neoplastic steroidogenesis.

Approximately 60% of affected mares have demonstrably **high circulating testosterone and estrone sulfate** levels. Many have **high circulating inhibin** levels but commercially available assays are not yet readily available for use in

most countries. Clinicians with access to assays are recommended to seek reference ranges from the laboratory concerned as assays vary between laboratories. Therefore, in most instances, equine granulosa cell tumors cannot yet be reliably diagnosed by blood hormone tests except where plasma testosterone and estrone sulfate or inhibin results are markedly elevated. **Gynecologic examinations**, with comparison of the size and ultrasonographic appearance of both ovaries, are required. Equine granulosa cell tumors are usually benign and, following unilateral ovariectomy, which now is usually performed by laparoscopic surgery, the contralateral ovary eventually regains normal function and the mare returns to fertile cyclic estrus.

Teratomas are unusual benign tumors and may contain teeth or hair. They are treated by unilateral ovariectomy.

Ovarian **adenocarcinomas** are aggressively malignant and cases invariably require euthanasia. Most exfoliate carcinoma cells and therefore peritoneal fluid analysis may aid diagnosis.

THE PREGNANT MARE

EARLY PREGNANCY FAILURE/EARLY FETAL DEATH

Early pregnancy failure (EPF) may arise from early fetal death (EFD) or fetal membrane abnormality. EFD is defined as loss of the conceptus before 150 days' gestation. Organogenesis is completed by 40 days, and pregnancy loss before this may be called **embryonic death**. No category of mares—lactating, barren or maiden—has been proven to be particularly susceptible. Lactating mares mated at “foal heat” are reported to have a relatively higher incidence, but not at subsequent estrous periods. Advanced age, >12 years, is reported to be related to a higher rate of EPF. Mares prone to uterine infection or those with advanced **chronic degenerative endometrial disease** are also reported to be more susceptible to EPF. In populations of Thoroughbred mares where the incidence of acute endometritis and advanced chronic endometrial degenerative disease is low, there is no obvious age or reproductive status bias and the majority of cases are suspected to be associated with genetic, developmental or functional abnormalities.

Incidence

Incidence rates from 5% to 45% have been reported for EPF. This wide range reflects the types of mares surveyed, the accuracy of pregnancy diagnosis and management conditions. Under modern stud management conditions, the incidence of EPF is reported to be 10–15%.

Etiology and pathogenesis

Malnutrition

Experimentally, maternal malnutrition has been shown to cause EPF between 25 and 31 days' gestation. Temporary starvation has been used in an attempt to encourage the reduction of adjacent twin conceptuses to a singleton, with a

success rate of approximately 60% reported by some authors and no significant effect reported by others.

Bacterial endometritis

Persistent acute endometritis (*q.v.*), established before mating, is often a cause of conception failure. However, **low-grade persistent endometritis** is an important cause of EPF. Low-grade endometritis may exist prior to mating or may result from inadequacy of uterine defenses to resolve the acute endometritis stimulated by natural service (*q.v.*). EPF may occur as a result of **direct fetal infection** or following **infection of the fetal membranes**.

Chronic degenerative endometrial disease

Recurrent endometritis/pyometritis appears to accelerate the development of chronic degenerative endometrial disease and produce diffuse stromal fibrosis. Repeated year-on-year pregnancy and atraumatic parturition, coupled with careful mare management with the application of minimal contamination techniques at mating, or artificial insemination where appropriate, may slow the progression of the condition (*q.v.*).

Genetic factors

Genetic factors are known to be causes of EFD in other species, and are thus suspected in the horse. These factors are not necessarily inherited directly from the parents, and may arise in the definitive gamete. **Chromosomal abnormalities** arising before organogenesis may cause EFD.

Maternal stress

Undue stress at any stage during pregnancy should be avoided. Increasingly horses, including pregnant mares, are **transported for long distances**. The period of pregnancy most susceptible to stress has not been identified, but it is generally recommended that transport stress should be avoided during the 20–45 day stage, when critical events such as transition from yolk sac to chorioallantoic placentation are occurring.

Endotoxemia

A pyrexemic or septicemic process involving the release of endotoxins or inflammatory mediators into the mare's circulation may cause EFD. This is associated with a fall in circulating progesterone but it is not clear whether this is a primary or secondary phenomenon. The period most sensitive to the luteolytic actions of endotoxins is up to Day 45. After this time, additional progesterone is provided from secondary corpora lutea.

Mare reproductive loss syndrome (MRLS)

This extraordinary syndrome was seen in Kentucky and some other states of North America in 2001, 2002 and to a lesser extent in 2003. MRLS (*q.v.*) caused **dramatic losses** in the form of early fetal deaths and late fetal losses (*q.v.*) and appeared also to manifest in cases of **pericarditis** and **unilateral ophthalmitis**.

The early fetal deaths manifested as pregnancy failures during May, June and July, with ultrasonographic signs of fetal death and fetal fluid hyper-echogenicity in those cases where the mare was examined during the period before expulsion of the dead fetus and its membranes. It is now believed that the unavoidable ingestion of **Eastern Tent caterpillars** that occurred following the massive increase in their population in 2001, contaminating feed and water containers, led to the mechanical transmucosal transmission of bacterial infection (most frequently α -hemolytic streptococci) and/or as yet undefined toxins. Control of the caterpillar population by removal of their habitats in the black cherry trees appears to have controlled the problem.

Diagnosis

Return to estrus

A relatively high rate of EPF is suspected to occur before 14 days but, as ultrasonographic pregnancy diagnosis is seldom used before 14 days, losses will not be detected and luteolysis and return to estrus occurs at the same time as in non-pregnant mares. If EPF occurs after 15 days, the primary corpus luteum may persist for 30–90 days, resulting in persistent diestrus. If EPF occurs after the production of endometrial cups (after 36 days), the mare may not return to fertile estrus until 90–150 days after conception.

Rectal palpation

Rectal palpation as a means of pregnancy diagnosis depends on the assessment of **uterine tone** and the presence of a **conceptual bulge**. Palpation findings in EPF depend on the interval between fetal or embryonic loss and collapse of the conceptual sac.

Ultrasonography

The use of **ultrasound imaging** has greatly improved the accuracy of pregnancy diagnosis and the detection of EPF. Pregnancy diagnosis is now possible as early as 9–12 days' gestation. EPF should be suspected in the following situations:

1. The **conceptual sac** is small for age. A high percentage (62–78%) of under-sized vesicles (more than 1 or 2 standard deviations below the mean diameter for age) are lost before 25 days; others continue to grow but may be lost later. A 16–20 day conceptus should be at least 20 mm, and circular with an obvious echoic "specular" reflection at the sac boundary. A small endometrial cyst may be confused with a conceptus, but cysts are usually less regular in outline on scan image, and they may contain hyperechoic divisions. The conceptual sac becomes less circular in outline between 18 and 25 days due to increasing uterine tone and probably reduced tenseness in the yolk sac wall. Where cysts present a diagnostic problem, cyst mapping of the uterus may be used prior to mating. Alternatively, serial scanning and assessment of progressive size helps to differentiate a cyst from a conceptus.

2. The **fluid image** is irregular in outline and has a grainy/flocculent (hyper-echoic) appearance. There may be signs of fetal disintegration and fetal membrane separation.
3. There is **edema** of the endometrial folds and uterine fluid is sometimes visible in the same or contralateral uterine horn.
4. An embryo with a **visible heartbeat** is not detectable after 22–25 days' gestation. After about 50 days the increased fetal size may hamper visualization of the heart, but fetal limb and body movements will help to confirm fetal viability.

Laboratory tests

Progesterone

Measurement of plasma or milk progesterone is a test of luteal function, and a level >2 ng/mL indicates the presence of a functional corpus luteum. **There is no reliable correlation** between peripheral progesterone concentrations and the viability of the conceptus. Although in most, if not all mares, peripheral progesterone levels fall in response to abnormality elsewhere in the fetoplacental unit, there is no convincing evidence to support the theory that primary progesterone deficiency is a cause of fetal loss in mares. Therefore, plasma progesterone levels **cannot be used** as a reliable means of assessment of fetal health.

Equine chorionic gonadotropin (eCG, PMSG)

A positive eCG result indicates endometrial cup activity, associated with the presence of a fetus at 35–40 days' gestation. However, eCG continues to be produced even after fetal death and circulating eCG will remain high until the endometrial cups are destroyed at 90–95 days. This scenario produces a false positive blood pregnancy test result in cases of EPF that occur after 30–35 days. The “window” for practical use of this test is therefore **45–95 days of gestation**.

Estrogens

A marked rise in circulating estrogens is detectable in the mare circulation after 90–100 days' gestation. These hormones are produced by the fetal gonads, and high levels of estrone sulfate (>160 ng/mL) are maintained from 120 days to term when a normal live fetus is present. Total urinary estrogen assay (**urine Cuboni test**) can similarly be used to confirm the presence of a live fetus after about 150 days' gestation.

Treatment

The most commonly applied “treatment” for EPF is exogenous progesterone or progestogen supplementation. As there is no convincing evidence that primary progesterone deficiency is a cause of fetal loss, **there is no rationale for the use of progesterone supplementation**. Nevertheless, large quantities of progestogens are administered to pregnant mares internationally, mostly for managerial reasons, sometimes with anecdotal claims of efficacy in individual cases.

However, once EPF has been reliably diagnosed, treatment is aimed at returning the mare to estrus and making sure that the uterus is in a condition for

optimal fertility at the earliest opportunity. Before 36 days, **PGF_{2α} treatment** will be effective in producing luteolysis and returning the mare to estrus, with relaxation of the cervix and expulsion of the fetus and membranes. **Uterine irrigation** with sterile saline solution and broad-spectrum antibiotics are recommended to assist in removal of uterine luminal debris. If the mare is to be mated again during the same breeding season, the use of minimal contamination breeding techniques (see Box 13.1, *q.v.*) is recommended, as the mare is considered somewhat more susceptible to persistent acute endometritis.

Once endometrial cups have formed, circulating eCG can prevent the effects of PGF_{2α} and repeated daily or twice daily injections may be needed to produce estrus. Estrous periods induced at this stage appear to have lowered fertility and most mares in this condition then demonstrate significantly greater susceptibility to persistent acute endometritis. In most cases it is better **not to attempt to mate the mare again** that breeding season.

Prophylaxis

As acute endometritis is an important cause of preventable EPF, attempts should be made to **avoid mating mares in this condition**. Cervicouterine cytologic and bacteriologic examinations and ultrasound scan examination to check for uterine fluid accumulation, performed in early estrus, will enable detection and characterization of uterine inflammation so that appropriate action can be taken. In cases with severe inflammation and bacterial infection, treatment and time for recovery is indicated. Where there are signs of low-grade inflammation, minimal contamination techniques, or uterine irrigation with sterile saline solution and broad-spectrum antibiotics following mating are indicated. Uterine irrigation with 3 L isotonic saline (at 37°C) daily for up to 3 days after mating has been used with some success. The **first flush** may be as early as 4 h following mating. Similarly, **antibiotic irrigations** can be used for up to 3 days after mating, starting on the following day. These techniques are aimed at assisting the uterine defense mechanisms by reducing the inevitable microbial contamination of the uterus that results from natural mating.

In mares with a history of repeated EPF, **endometrial biopsy** is indicated. An assessment of the histopathologic features can help to formulate a rational treatment regimen. It has been shown that paired biopsy techniques, the second following appropriate treatment and time for recuperation, provide a more accurate prognosis of fertility. Uterine biopsy is particularly useful for the assessment and quantification of chronic glandular degenerative change and stromal fibrosis. In cases where the degree of chronic endometrial degenerative disease is in advance of the mare's age, **endometrial curettage** may improve the condition of the endometrium in some cases. There is no doubt that repeated pregnancy throughout a mare's breeding career helps to slow her development of chronic endometrial degenerative disease and so successful gynecologic management helps to prevent EPF.

Aging gametes are known to be important causes of EFD in other species, and thus it is wise to time mating as close as possible to ovulation.

As early diagnosis of EPF or EFD is most useful, **serial pregnancy diagnoses** using rectal palpation and ultrasonographic examinations will enable

early detection of EPF, and examinations are recommended at the following stages:

1. 14 to 17 days after ovulation, when detection of twins facilitates the manual crushing of one. Further examinations at 20–25 days are then indicated to monitor progress of the remaining conceptus. In the case of adjacent twin conceptuses, the success rate for crushing one conceptus is lower, depending on the expertise of the operator. Monitoring the pregnancy for natural reduction of one twin is a risky option because, if not successful, the “window of opportunity” for successful manual reduction by crushing has been lost. Further examinations must then be made between 30 and 35 days; if twins are still present at this stage they can be eliminated by PGF_{2α}-induced luteolysis before endometrial cup formation.
2. 25 to 30 days, when the presence of a single live fetus may be confirmed.
3. 40 to 45 days.
4. 60 to 90 days.

ABORTION

Abortion is defined as **expulsion of the fetus** before 300 days of gestation when, due to immaturity, it has little chance of survival, even with intensive care. Abortion is an important cause of wastage and reproductive failure in breeding horses.

Incidence

Incidence rates for abortion of 4–19% are quoted in the literature. This wide range is a result of variations in mare populations and their management, of accuracy and timing of pregnancy diagnosis, and because many abortions are not observed. UK surveys from the *General Stud Book*, which include only abortions that are observed later in pregnancy, result in a rate of approximately 2% of mares mated. Excluding abortion due to equine herpesvirus (EHV) and equine arteritis virus (EAV) infection (*q.v.*), where abortion storms may occur, abortions are generally sporadic.

Etiology

Infectious causes

Bacterial infections

A 5-year survey of post mortem examinations in Newmarket revealed that 1.4% of cases were associated with fetal bacterial septicemia, 2.4% with acute placentitis, 5.7% with chronic placentitis and 2.4% with posterior (cervical) pole placentitis.

Infective agents include *Streptococcus zooepidemicus*, *Escherichia coli* and *Staphylococcus aureus* (*q.v.*), usually causing placentitis, fetal septicemia and premature placental separation. *Salmonella* spp. infection (*q.v.*), once an important cause of abortion in mares, has disappeared from most parts of the world.

Leptospirosis (*q.v.*) causes placentitis and fetal septicemia in North America and Ireland but has not been reported in the UK. A focal placentitis associated with a nocardioform infection has been reported in Kentucky. It was a common cause of abortion for a few years but the incidence of this infection seems to have decreased, for reasons that have not been clearly explained.

Fungal infections

In the Newmarket survey, 0.5% of cases were associated with fetal fungal pneumonia and 0.5% with fungal placentitis. The majority of fungal abortions have been associated with *Mucor* or *Aspergillus* spp. Thick, mucopurulent placentitis is often a feature, sometimes leading to premature mammary development and purulent vaginal discharge. One case due to *Allescheria* spp. has been reported.

Viral infections

Some 6.7% of the Newmarket survey cases were associated with equine herpesvirus infections (*q.v.*).

Equine herpesvirus (EHV, rhinopneumonitis) and equine arteritis virus (EAV) may cause **abortion** in mares. EHV (types 1 and 4) commonly causes innocuous equine **respiratory infections**, but if the virus crosses the placenta it can cause fetal viremia and **fatal focal necrotic hepatitis** and/or pneumonia. A less common variant is now becoming recognized where EHV infection causes abortion following **endometrial and/or placental vasculitis**, following maternal viremia. In these cases there appears to be no fetal infection. EAV (*q.v.*) causes equine arteritis (EVA), which can cause individual or epidemic abortions associated with placental vasculitis, following maternal viremia.

Non-infectious causes

Twins

The Newmarket post mortem survey, involving both local and referred cases, revealed that 2.9% of cases were associated with twin pregnancy.

Before the widespread use of ultrasonographic imaging in equine pregnancy diagnosis, **twinning** was the most important cause of abortion in Thoroughbred mares, accounting for up to 29% of all abortions. Now that early detection of twins is possible, appropriate action can be taken to eliminate one conceptus and leave a singleton, or terminate the pregnancy and mate the mare again, as appropriate. Nevertheless, the occasional twin pregnancy evades detection.

Umbilical cord abnormalities

The Newmarket post mortem survey revealed that 46.2% of cases were associated with **umbilical cord vascular compromise**, clearly now one of the most important causes of abortion in Thoroughbred mares.

Developmental abnormalities or **excessive cord length** may constrict blood vessels and cause circulatory disturbances. It has been shown that excessive cord length (>90cm) is associated with an increased incidence of vascular embarrassment leading to fetal death. Presumably a longer cord allows the fetus greater mobility, predisposing to cord accidents including strangulation

of the cord around the fetal neck, body or limbs, pinching of the cord between the fetus and the maternal pelvis, and excessive twisting of the cord.

Placentopathy

The Newmarket post mortem survey revealed that 8.1% of cases were associated with premature placental separation, 1.4% with posterior (cervical) pole placentopathy and 4.8% with other placental abnormalities.

An apparently non-septic posterior (cervical) pole ischemic placentopathy can cause abortion in mares, sometimes associated with excessive umbilical cord length and placental vascular inadequacy. **Premature placental separation** may occasionally be caused by endometrial and placental vasculitis associated with “atypical” EHV infections.

Nutritional deficiencies

Vitamin A and energy deficiencies have been suspected as causes of abortion.

Mare reproductive loss syndrome (MRLS)

Late fetal losses in MRLS (*q.v.*) manifest as **late term premature placental separations** (“red bag” deliveries) resulting in the birth of weak and often non-viable foals.

Other causes

The Newmarket post mortem survey revealed that 1.9% of cases were associated with maternal illness and that for 5.2% the cause of the abortion was not established.

Other probable but as yet incompletely defined causes include **endocrinologic dysfunction, chromosome or gross developmental abnormalities, maternal and/or fetal circulatory disturbances** caused by changes in maternal posture, fright or trauma. Certain surgical procedures (e.g. colic surgery) necessitate placing a pregnant mare in dorsal recumbency. In this position, the weight of the gravid uterus leads to aortocaval compression. There is a reduction in venous return to the heart, a reduction in cardiac output, and a significant drop in peripheral blood pressure resulting in reduced blood flow and oxygen delivery to the uterus. Maternal pulmonary gas exchange may also be impaired, compounding the fetal hypoxia. Precautions should be taken to **minimize anesthetic and surgical time**, especially time in dorsal recumbency, and maintain adequate maternal blood pressure (mean arterial pressure >80 mmHg). Intermittent positive pressure ventilation is recommended to improve pulmonary gas exchange. In general, the **unnecessary administration of drugs** during pregnancy should be avoided.

Pathogenesis

There are two principal pathways leading to expulsion of the fetus: **fetal death in utero preceding expulsion**, which occurs in cases of infectious abortion and non-infectious disturbances causing cardiac and circulatory failure; and **the abortion of a live premature fetus**, where the fetus may be expelled with its heart beating and may establish a respiratory rhythm for minutes or

even hours. In these cases the causal factors probably arise from the maternal side of the placenta, or from **fetal endocrinologic malfunction**.

Placental insufficiency, related to infective or non-infective causes, is an important cause of abortion. Twins are an example where reduced placental function leads to death of one fetus and eventually to abortion of both fetuses.

Clinical signs

Frequently there are **no premonitory signs** of impending abortion, and the foal is expelled with minimal effort, dystocia (*q.v.*) being unusual. The fetal membranes may be expelled with the foal or may be seen hanging from the vulva. Occasionally there is a prolonged third stage requiring therapeutic removal of the fetal membranes. A mucopurulent vulvar discharge is usually an indication of **chronic placentitis**, bacterial or fungal, or **premature placental separation**. In protracted cases, premature mammary development and lactation are frequently seen. A vulvar discharge may also be seen where fetal death has occurred in utero, although this usually results in rapid expulsion, and fetal mummification is rare in mares. Premature mammary secretion without vulvar discharge was often a sign of impending twin abortion but now that twin pregnancy is so uncommon it is more commonly seen with cases of placentopathy.

Diagnosis

Diagnosis of the cause of abortion depends on **detailed pathologic examination** of the fetus and its membranes. It is particularly important that a full examination is performed in every case so that EHV infection (*q.v.*) is not overlooked.

Bacterial infections

Bacterial abortions account for up to 13% of all equine abortions. Abortion due to bacterial placentitis can occur at any stage of gestation, but typically occurs after 5 months' gestation. There are three possible routes of access of the bacteria to the fetal tissues: **ascending infection** via the cervix resulting in caudal chorionitis—cervical incompetence will predispose to this situation, although the cervix often appears normal on examination; **hematogenous spread** via systemic infection of the mare—in this case the chorion is affected in a diffuse fashion; and **local spread** from deep-seated foci of endometritis.

The affected placenta is thickened and the maternal surface necrotic with areas covered in grayish exudate. Focal placental separation occurs. Pregnancy continues until the remaining area of functional placenta is insufficient to nourish the foal, and fetal distress or death precipitates expulsion. The infection generally involves 5–25% of the chorion, but in some cases gross placental lesions are minimal and microscopic examination of representative areas, including the cervical star, should be performed.

Infection may spread to the amnion via the allantois causing fetal lung pathology. In this case the causal organism can be cultured from the fetal stomach contents. Alternatively, the organism enters the fetus via the umbilical vein and lesions are seen in its liver. Typical signs of fetal septicemia are congested

mucous membranes and serosal surfaces, serous exudates and dark red/purple coloration of the muscles. Histopathologic changes will depend on the ability of the fetus to mount a cellular response to infection, and may be obscured by autolysis occurring between fetal death and expulsion.

Fungal infections

Fungi are responsible for up to 10% of all abortions in mares. The typical clinical presentation includes **premature lactation** and a **purulent vulvar discharge**. The pathology is usually confined to the placenta but may spread to the amnion, and occasionally to the fetus itself. The fetus is small and emaciated due to chronic placental insufficiency, and may be born alive but usually succumbs soon after birth.

Examination of the placenta reveals gross thickening, particularly at the cervical pole, and a brown/white sticky exudate. Histopathologic changes include **widespread necrosis of the chorionic villi**, an intense polymorphonuclear cell inflammatory response in the subepithelial chorionic tissue, multinucleate giant cells, and demonstrable fungal hyphae within the tissue. Amniotic lesions consist of irregular necrotic plaques. When fetal infection is present, small grayish-white nodules are seen scattered throughout the lung. Microscopically, fungal elements can be demonstrated by the use of special stains (e.g. periodic acid–Schiff and Grocott).

Equine herpesvirus (EHV, rhinopneumonitis)

EHV-1 and to a lesser extent EHV-4 (*q.v.*) are the only currently recognized forms of **contagious abortion** in the mare in the UK. In countries where EVA is endemic, this virus may cause multiple abortions following infection in a group of pregnant mares. The potential threat of an EHV-1 epidemic or “abortion storm” (not recognized with EHV-4) is such that precautions should be taken in every case of abortion until EHV-1 has been ruled out, as recommended by the HBLB Code of Practice (*q.v.*). The aborting mare should be isolated, a movement ban imposed and measures taken by personnel to limit spread. The fetus and fetal membranes should be submitted for post mortem examination and a diagnosis established as rapidly as possible.

Epidemiology

EHV infection during pregnancy, often linked to **foal-at-foot respiratory infection** at around 3 months' gestation, may result in abortion at 7 months onwards or the birth of a weak viremic foal at term. It is reported that susceptible **pregnant mares may abort** 3 wk to 4 mo after infection. The virus survives for about 14 days outside the body, and this may be extended to 40 days if it becomes dried onto organic matter. Late pregnant mares become **infected by contact** with aborted fetuses, fetal membranes and fluids, or aerosol shedding of virulent strains of the virus via the respiratory route from other individuals and may abort soon afterwards. The virus has been isolated from the respiratory tract of an apparently healthy foal during an outbreak. After abortion, the virus does not appear to persist in the reproductive tract but the **mare may shed virus via the respiratory route**.

Diagnosis

Abortion from EHV has its greatest incidence in gestational months 8 and 9, but has been recorded as early as 4 months. The infection is also responsible for stillbirth or neonatal illness/death. Typical gross changes seen in the fetal tissues at post mortem examination form an important means of early presumptive diagnosis, but these gross changes are highly variable in terms of severity and organ pathology, particularly in vaccinated mares. Definitive confirmation must be provided by microscopic examination of the fetal tissues, fetal and placental tissue EHV PCR tests, fetal and placental tissue EHV immunostaining and/or viral culture.

Some, but rarely all, of the typical gross lesions described below will be seen in the affected fetus or foal. Over half of EHV-1 abortions are born within intact fetal membranes. In other cases, rapid expulsion may occur and the membranes are delivered **villous side outermost**. Premature placental separation is not specific for EHV-1 infection, but it serves as a cautionary sign. The fetus usually appears to be in **good bodily condition** and good state of preservation. Jaundice of the mucous membranes, abdominal organs, footpads and joint surfaces is usually seen. Excessive amber-colored peritoneal, pleural and pericardial fluids are often seen.

White/yellow **pinhead-sized spots** under the liver capsule are an important diagnostic feature but their absence does not rule out infection. On gross section these lesions are found scattered throughout the liver parenchyma. The signs of jaundice, excessive amber-colored peritoneal and pleural fluids, gelatinous perirenal fat and the liver lesions have been found to be the most dependable gross findings, where they occur. The lungs may show subpleural edema, congestion, petechial hemorrhages and pneumonia. The spleen may be congested with petechial hemorrhages beneath the capsule and the lymphoid follicles may "stand out" in a granular manner.

Same day or overnight microscopic sections from formalin-fixed tissues are now obtained using modern microwave embedding processes. The diagnosis of viral abortion on microscopic examination depends upon the demonstration of typical eosinophilic **Cowdry type A intranuclear inclusion bodies**. The pathologic findings may differ between early (before 6 months) and later abortions. Before 6 months the fetus has either a limited or no ability to produce inflammatory and immune responses, and the lesions are characterized by widespread necrosis, whereas more mature fetuses can mount an inflammatory response.

The typical lesions are **hyperemia** and in some cases hemorrhage in the **liver**, with focal areas of cell necrosis with karyolysis and pyknosis. Inclusion bodies are seen in hepatocyte nuclei bordering the necrotic area. Inclusion bodies may also be seen in bile duct epithelia, blood vessel endothelia, fibroblasts and smooth muscle cells within the liver. There are varying degrees of congestion and pneumonia in the **lungs**, with necrotic inflammatory debris plugging the airways. Virus inclusion bodies are most frequently demonstrated in the lining epithelial cells of bronchi, bronchioles and alveoli. Necrosis of primary follicles with inclusion bodies is seen in the **thymus**, and in the **spleen** necrosis of splenic cores with inclusion bodies can be found. Similar foci of necrosis and inclusion bodies are often found in the adrenal cortex.

Definitive confirmation of EHV infection is made on the basis of specific PCR tests performed on fetal and placental tissues, backed up, if necessary, by immunostaining. **Virus culture** may be made from fetal viscera (fresh fetal lung, liver, spleen and thymus tissues in viral transport medium dispatched to a suitable virology laboratory without delay) but results may require 8–10 days in tissue culture.

Serologic studies may assist in investigating the epidemiology of an outbreak, but used alone are not a suitable means of diagnosis. Complement fixation tests (CFT) may be useful in differentiating infected from uninfected animals, so that they can be segregated from each other during an outbreak. CF antibody is normally detected 10 days after initial infection, and a four-fold increase in titer is seen. Virus neutralizing antibody persists for longer than CF antibody and may be used to demonstrate previous exposure. No association between susceptibility to infection and virus neutralizing antibody provided by previous infections has been found, and mares can become infected each year. This is, however, rare.

So-called “atypical” cases have been seen in Newmarket where the aborted fetus shows no histopathologic or viral evidence of EHV-1 infection but the placenta shows signs of infection (PCR and immunostain positive). Focal placentopathy and early placental separation is involved. Cases have been solitary, so far, usually in vaccinated mares. Their epidemiologic significance currently remains unclear.

Equine viral arteritis (EVA)

EVA is an acute contagious viral disease, characterized by fever, edema and abortion. The virus is transmitted between horses as a respiratory aerosol and via semen from seropositive stallions. The incubation period is 7–10 days. The existence of symptomless carriers serves as a reservoir of infection.

In contrast to EHV abortion (*q.v.*) where the mare shows no clinical signs of disease, EVA abortion (*q.v.*) occurs during the **acute phase of maternal infection** and the mare may show clinical signs of depression, fever ($\geq 40^{\circ}\text{C}$), leukopenia, keratitis, palpebral edema, photophobia and dependent edema. In pregnant mares, fetal death is followed by abortion 7–10 days after the first signs of clinical disease. In some mares the clinical signs of maternal illness are so slight that they remain undetected.

Pathogenesis

It is believed that decreased blood supply to the placenta and fetus results in myometrial edema, tissue distension and loss of myometrial tonicity. There is mechanical compression of the blood vessels, placental detachment and delivery of a dead, moribund fetus.

Diagnosis

Diagnosis is based upon a detailed post mortem examination of the fetus and its membranes, revealing only signs of congestion and placental separation. Definitive diagnosis is obtained by specific PCR tests, viral culture of fetal tissues, and serologic tests on the blood of the infected mares. The serum neutralization test currently remains the international standard blood test but there is a clear need for a reliable ELISA test.

Treatment of abortion

The most commonly applied “treatment” is exogenous progesterone supplementation, but there is no scientific rationale to commend it. It is doubtful whether non-infectious abortion can be prevented or whether attempts to do so are indicated. Where fetal death is confirmed and/or when it is clear that abortion is inevitable, it is more appropriate to aid **speedy, atraumatic delivery** and to direct treatment toward returning the mare to optimal breeding condition as quickly as possible.

For **infectious abortion**, where a vulvar discharge is present, bacterial and fungal culture of the vulvar discharge may help characterize the infectious agent, so that systemic and/or local antibacterial or antimycotic agents can be employed. If there is pneumovagina (*q.v.*), appropriate vulvar surgery should be performed. If early treatment is applied, the pregnancy may be maintained closer to term, but in many cases where the foal is born alive it is weak and non-viable. Following expulsion of placental membranes affected by bacterial or fungal infection, the infection rarely persists in the mare’s uterus. However, involution should be monitored, using cervicouterine bacteriologic and cytologic examinations at first post partum estrus to detect residual infection/inflammation. Uterine antibiotic/saline irrigations can then be employed as necessary.

Prevention of abortion

An inactivated EHV-1 and 4 vaccine (Duvaxyn EHV1,4) is available and licensed for use in pregnant mares against EHV abortion in the UK and some other European states, and its widespread use has reduced the incidence of abortions from EHV-1 and 4. The manufacturers recommend vaccination at 5, 7 and 9 mo of pregnancy each succeeding year. Ideally, in-contact horses on the stud farm should also be vaccinated using a priming course and a yearly booster. The vaccine does not prevent sporadic abortion but may help to prevent the occurrence of abortion storms. The use of another inactivated EHV-1 vaccine (Pneumabort-K) in Kentucky between 1950 and 1980 coincided with a reduction in diagnosed EHV-1 abortions from 25% to 10%.

An attenuated live virus (Bucyrus strain) EVA vaccine has been used in North America and has been found to produce a high degree of immunity. It is not recommended for use in mares in late gestation and it should be remembered that vaccination will complicate the diagnosis of EVA by serologic methods. Currently, a formalin-fixed EVA vaccine is licensed for use in Germany and is available in the UK under an Animal Test Certificate (ATC) and is similarly used in France and Ireland (usually for stallions rather than mares).

PARTURITION AND THE POST PARTUM MARE

PRE PARTUM CONDITIONS

The colic complex

Colic in a mare during her last trimester of pregnancy presents the clinician with a diagnostic challenge. **Gastrointestinal tract abnormalities** (*q.v.*) must

be eliminated by careful clinical examination, but the size and position of the fetus often makes optimal examination difficult. Some conditions of the genital tract can cause colic during this period.

Abortion/premature parturition may present as mild to moderate colic, with minimal premonitory signs such as mammary development. Vaginal examination reveals a moist, pink vagina, usually with loss of the cervical plug and relaxation of the cervix. In the early stages of abortion, rectal examination reveals the fetus to be engaged in the birth canal and there may be a **palpable pain response**. Veterinary intervention should be to facilitate an atraumatic delivery and then to provide post partum care of the mare, if required. All aborted fetuses should undergo a post mortem examination in order to eliminate EHV infection and the mare should be isolated until results are available.

Uterine dorsoretroflexion is seen in the last trimester of gestation. It usually presents as an acute moderate to severe colic, with inappetence, difficulty passing feces and in some cases abdominal straining. There is frequently vulvar and perineal swelling. On **rectal examination** a live fetus is characteristically palpable in a tight sac-like distension of the uterus, immediately under the hand, just cranial to the anus. Palpation of the fetus produces a marked pain response. Smooth muscle relaxant drugs (**butylscopolamine bromide** 0.2 mg/kg IV, or **clenbuterol** 0.8 µg/kg IV) should be administered in order to relax the myometrium and allow the fetus to return to a more cranial position in the abdomen, relieving the mare's discomfort. Food intake is reduced, and the mare given gentle exercise. Repeated administration of smooth muscle relaxants may be necessary in some cases. The pregnancy then usually proceeds uneventfully.

Uterine torsion is uncommon in mares. It usually occurs in **late gestation**, however it can occur at parturition. It presents as colic of varying severity, which may continue over several days. There is usually some **difficulty passing feces**. The condition is confirmed by rectal examination. It is often difficult to advance the arm in the rectum and the fetus is not palpable. Palpation of the broad ligaments will identify the torsion and indicate its direction. In cases of **anticlockwise torsion** the left uterine ligament is tight, runs ventrally and is caudal, the right ligament is slacker, runs from right to left and is cranial to the left ligament. It is possible to confuse the uterine ligaments with mesenteric bands associated with a large intestinal displacement, but in these cases the fetus is palpable. In mares, the vagina is very rarely involved, unlike cases of uterine torsion in the cow. Once a diagnosis has been made, **surgical correction** is indicated without delay in order to maintain fetal viability. This is performed either by standing flank laparotomy, sometimes requiring a two-surgeon, two-sided approach, or midline laparotomy in dorsal recumbency under general anesthesia in order to reposition the uterus. Where the fetus is already dead, confirmed if necessary by ultrasound imaging, Cesarean section is indicated.

Fetal hypermotility presents as **mild colic in late pregnancy**. It is associated with excessive violent movements of the fetus of unknown cause. Attempts by the fetus to correct an uncomfortable in utero position have been postulated. The condition appears to be more common in **first foaling mares** and older mares. Treatment with smooth muscle spasmolytics (e.g. **butylscopolamine bromide** 0.2 mg/kg IV) is usually effective. The possibility of fetal distress must be considered. If signs persist or if there are signs of premature parturition, a full assessment of the fetus with external transabdominal ultrasonographic

imaging should be performed and calcium and electrolyte levels of mammary secretion assessed.

Hydrops allantois is an uncommon condition seen in **multiparous mares**. Until the allantoic fluid reaches volumes in excess of 100 L there may be no clinical signs. The condition is seen in the last trimester of pregnancy, presenting as sudden marked abdominal distension, often with low-grade signs of colic, inappetence, dyspnea (particularly when recumbent) and difficulty in passing feces. On **rectal examination** the fetus is characteristically not palpable, and the uterus appears excessively distended and clearly fluid filled. Transabdominal ultrasound scan examination may be used to measure the allantoic fluid (>20 cm is abnormal). In cases of severe distension **prepubic tendon rupture** may occur, with associated pain and ventral abdominal swelling. The condition is progressive and parturition should be induced when the mare's clinical condition starts to deteriorate. Oxytocin may not be effective because the myometrium is over-stretched. **Prostaglandin E₂ pessaries** should be used to dilate the cervix to allow manual rupture of the allantochorion. Half the allantoic fluid should then be siphoned off. An **oxytocin drip** (20 IU) should then be administered to prevent cardiovascular shock associated with pooling in the splanchnic vasculature. In some cases supportive fluid therapy may be indicated.

Vaginal discharges

Vulvar and/or vaginal discharges are not uncommon in late pregnancy. Confusion can occur with urine staining or liquefaction of the cervical plug.

If vaginoscopic examinations reveal a vaginitis and cervicitis, **swab samples** should be collected for cytologic, bacteriologic and fungal examinations. Pus may be seen discharging though the cervix in cases of cervical pole placentitis. Topical treatment with appropriate antibiotics or specific antifungal preparations may be helpful, though in cases of placentitis the results are frequently disappointing. In cases where the fetus is viable and the pregnancy continues, the foal should be considered "high risk" and appropriate precautions taken at parturition.

Hemorrhage from **varicose vaginal vessels** is sometimes observed, but the quantities of blood lost are usually small and treatment is seldom necessary. These vessels are usually found dorsally at the level of the redundant hymen. If the problem persists, individual vessels can be identified via a "duck-billed" speculum held sideways and cauterized or coagulated with the application of swabs moistened with 5–10% formol saline.

Prolonged gestation

It is reported that 1% of pregnancies continue over 370 days, often resulting in a small foal. The condition is not uncommonly seen in aging mares with **advanced chronic degenerative endometrial disease**, where eventual parturition produces a dysmature foal. In other mares it has been postulated that a period of embryonic diapause may be involved.

If clinical examination of the mare reveals no abnormality, prolonged gestation is not an indication to induce parturition, as this may produce an at-risk

dysmature foal. External transabdominal ultrasonographic imaging can be used to evaluate the health of the fetus and its placental membranes.

Estrous behavior during pregnancy

Some mares repeatedly exhibit signs of estrus during pregnancy, which should be confirmed and the viability of the fetus assessed.

Rupture of the prepubic tendon

Tearing or complete rupture of the **prepubic tendon** may occur at its insertion to the pelvis, usually after the ninth month of pregnancy. The rupture usually occurs a little to one side of the midline and there is **gross ventral edema** associated with obstruction to venous drainage. Early induction of parturition and assistance at foaling due to reduced expulsive forces may be necessary in acute cases. In stabilized, non-painful cases, normal parturition usually occurs, the mare compensating for the lack of ventral abdominal tone by lying down and using the floor as abdominal support. Attempts at surgical repair using a synthetic mesh have been reported, but in rare cases of complete painful rupture the prognosis is hopeless.

Premature lactation

Premature lactation is not an uncommon condition and may be an indication of abnormality of the fetoplacental unit, most commonly placental separation and placentitis, or twin pregnancy with the death of one fetus. In some cases no obvious cause is proven.

The measurement of mammary secretion electrolyte levels may help to determine fetoplacental “readiness for birth”. During the last 3 weeks prior to parturition there are marked changes, which are more diagnostically reliable in multiparous than in primiparous mares: **sodium** falls from 118 mmol/L to ≤ 30 mmol/L; **potassium** rises from 13 mmol/L to ≥ 30 mmol/L; **chloride** falls from 91 mmol/L to 33 mmol/L; **magnesium** rises from 3 mmol/L to ≥ 10 mmol/L; and **calcium** rises to ≥ 10 mmol/L.

External transabdominal ultrasonographic imaging should be performed to evaluate the health of the fetus. A 3.0 or 3.5 MHz linear array scanner is preferred. Normal fetal heart rate in the last 30 days of gestation is 76 ± 8 bpm, with marked variations during periods of fetal activity.

If mammary development progresses and premature lactation occurs, the colostrum should be collected and IgG levels measured. If ≥ 70 g/L, the colostrum should be frozen for future administration to the newborn foal. If IgG levels are inadequate, the newborn foal should be given **good-quality donor colostrum** by bottle or stomach tube.

Orthopedic problems

Problems can develop in late gestation, particularly in overweight mares. Previous limb injuries may recur. **Strain injuries** to the hindlimbs are common due to increased weight on the suspensory apparatus and joints. These

require careful management with restricted exercise, support bandages and management of weight gain. **Laminitis** (*q.v.*) can occur in late pregnancy and may prove difficult to manage at that stage. Induction of parturition may be indicated on humane grounds. **Peripheral edema** of the hindlimbs is sometimes seen, apparently associated with poor lymphatic drainage and decreased exercise during late gestation. Gentle exercise and judicious use of phenylbutazone may be necessary to help the mare through to parturition.

INTRA PARTUM CONDITIONS

Dystocia

Dystocia is relatively uncommon in the mare. Most commonly, cases are associated with fetal deformity (e.g. hyperflexed forelegs), fetal death (active fetal movements are required to produce the correct birth posture) or twin presentation.

Foaling is a rapid and forceful event. **Early intervention** is necessary if the foal is to be saved. If delay is inevitable, appropriate advice to the attendants may affect the outcome. For example, in cases of **malpresentation** the mare should be kept up and walking to reduce further abdominal straining and prevent impaction of the foal in the birth canal; in cases of **premature placental separation** causing "red bag delivery", the allantochorion should be immediately ruptured manually and delivery assisted; **posteriorly presented foals** should be delivered as rapidly as possible, without undue force, in order to prevent umbilical cord compression; if the foal's foot or muzzle has caused a **rupture of the rectovaginal shelf**, but the foal is alive, delivery should be assisted without immediate concern for third degree perineal tearing, if unavoidable. If possible, the foal's limb or head should be replaced in the vagina before delivery to limit damage to a rectovaginal fistula; if the foal has **failed to rotate** into dorsal position the mare should be allowed to get up and down and roll in an attempt to correct the situation.

Careful examination of the mare and foal is essential to allow accurate diagnosis and treatment. The mare should be **restrained in the standing position** with one attendant holding her head and one holding her tail in order to maintain her in standing position. She will be distressed and uncomfortable and will attempt to get down, and examinations and manipulations may sometimes need to be made while walking slowly around the stable. The attendant at the head can help by holding the mare's tongue out of the side of her mouth to reduce the force of abdominal straining. **Copious lubrication is essential**. A thorough assessment should be made to determine the answers to the following questions: Is the foal alive? Are fore or hindlimbs presented? Is the foal deformed? Are twins presented? Is the birth canal adequately relaxed to allow vaginal delivery? Is the foal relatively oversized? Will an epidural anesthetic, by reducing abdominal straining, assist delivery?

Following careful assessment it is important to make an early decision whether Cesarean section or fetotomy (*q.v.*) is necessary.

For **assisted vaginal delivery**, the mare should be restrained standing to facilitate repositioning of the foal. Once this is achieved, the mare should be encouraged to lie down. The birth canal must be **fully relaxed before traction**

is **applied**, and plenty of lubrication is essential. Once repositioning has been completed, traction should be applied in unison with abdominal straining, and the foal pulled in a downward curving arc, one leg at a time to reduce width at the shoulders. Careful positioning of color-coded ropes may be helpful. In some circumstances, repositioning and vaginal delivery may be carried out under general anesthesia. Epidural anesthesia (*q.v.*) may be useful to abolish abdominal straining, and raising the hindquarters may also help.

Cesarean section, when performed by an experienced surgical team at an early stage, now generally carries a good prognosis for both mare and foal and is the preferred option when the foal is alive and where prolonged and difficult manipulation and traction would clearly endanger the health of both.

Fetotomy is a potentially **hazardous procedure** for the mare. It should only be used by experienced clinicians, in situations when it can be performed easily and safely, preferably external to the vulva. When economic considerations preclude Cesarean section and the foal is dead, this technique may be used to save the mare in spite of the risk of cervical damage. The mare should be sedated, an **epidural** anesthetic administered and smooth muscle relaxants, e.g. **isoxsuprine**, may be administered.

After an assisted foaling the mare should be examined for vaginal or cervical **lacerations**. Antibiotic therapy (including oral **metronidazole** to help prevent anaerobic infections) is advisable to reduce the risk of metritis (*q.v.*) and the mare should be exercised to assist uterine involution and to avoid pooling of uterine fluid.

Premature separation of the allantochorion

Sometimes the chorion separates prior to rupture at the cervical pole. The chorioallantois is presented as an intact velvety red sac at the vulvar lips ("**red bag delivery**"). Rapid manual rupture and assisted delivery are essential to save the foal.

Failure to lie down

Mares may sometimes foal in the standing position, particularly if attendants disturb them. Mares with musculoskeletal problems may be too uncomfortable to lie down. Once the situation is clear the mare should be restrained and the foal supported to prevent injury and premature rupture of the umbilical cord. Traction is usually necessary as contractions are less forceful in the standing position.

Uterine inertia

This is an unusual condition which may be more common in primiparous than multiparous mares. The mare remains relatively comfortable in persistent first stage labor, with a relaxed cervix, but does not initiate second stage. Parturition should be induced with 0.5IU oxytocin administered in 1 L saline by IV drip, usually without complications.

Failure to strain

This may be due to heart, chest or orthopedic problems. The mare is uncomfortable in second stage labor but does not complete delivery because of diminished or failed abdominal straining. In some cases there may be no obvious cause. Assisted delivery by traction is necessary.

Relative fetal oversize

This may sometimes be seen in primiparous mares and may be due to inadequate pelvic relaxation. Any traction must be applied with great care not to damage either the foal, particularly at the chest, or the mare.

POST PARTUM CONDITIONS

A variety of maternal injuries and complications occur in association with the rapid and forceful equine birth process. These may be life threatening or may adversely affect future fertility.

Retained placenta

Normally, the equine placenta is fully and atraumatically released from the uterus within 1–2 h of the end of second stage labor. Retention may be diagnosed if release has not occurred by **the morning after parturition**. It is a relatively common complication that is most commonly associated with dystocia, abortion or Cesarean section, but may occur spontaneously. The non-pregnant placental horn is most commonly involved, especially at its tip. The recommended approach to removal is described in Box 13.2.

Vaginal hematomas

A hematoma may protrude through the vulvar lips, and can alarm attendants. When sizable, hematomas can produce abdominal straining. They can be drained or left to resolve according to individual circumstances. It is wise to provide systemic antibiotic medication to prevent secondary infection.

Uterine hemorrhage

Hemorrhage from the **uterine artery** is most commonly seen in older multiparous mares, but has been seen in primiparous mares. Dystocia (*q.v.*) does not appear to increase its incidence. Hemorrhage is not always fatal if it is contained within the broad ligament and associated tissues, but the mare will exsanguinate if the hematoma ruptures into the peritoneal cavity or the uterus.

Initial signs, seen within minutes or hours of parturition, are **acute moderate to severe colic** and sweating, with rapid pulse, which progresses to **cardiovascular shock**. The mare should be kept quiet with mild sedatives and analgesics. **Hypotensive tranquilizers** such as acepromazine or detomidine may help to encourage clotting to occur in some cases but may risk accelerating cardiovascular collapse (*q.v.*) in others. Fluid therapy with blood or

Box 13.2 Removal of retained placenta

- **Manual removal** should only be attempted with great care and should be abandoned if not immediately and easily successful. There is a considerable risk of causing chorionic microvillous retention, which can lead to **septic metritis**. Also there is risk of uterine wall damage and hemorrhage. Tearing the fragile placenta delays further natural release and increases the risk of leaving areas of placenta in the uterus. Sometimes the placenta appears to become impeded in the vagina; by gently collecting it together, lifting and rotating, release is easily completed.
- If gentle manual removal is not immediately successful, an **IV drip containing 50 IU oxytocin in 500 mL of sterile saline** should be administered over approximately 15 min. An IM bolus of 30–50 IU oxytocin may be effective when administered in the first 24 h after parturition. Repeated doses may be necessary beyond this period. These classically recommended doses of oxytocin are probably excessive, and 15–20 IU are probably as effective and more humane.
- If repeated IV drips of oxytocin are not successful then **large volumes (10–12 L) of warm water with dilute povidone-iodine** may be pumped into the allantochorionic space via a stomach tube. This distends the uterus and placenta, releases chorionic microvilli and stimulates uterine contractions and is usually effective within 30 min.
- **Systemic antibiotics** (including oral metronidazole to help prevent anaerobic infections) and flunixin (1.1 mg/kg IV to help minimize the effects of endotoxin release) therapy is indicated in most cases. If the placenta is retained for more than 8 h, bacterial multiplication is rapid and there is a risk of septic metritis and laminitis. Intrauterine antibiotic irrigations may also be useful in some cases.

plasma expander or hypertonic saline does not seem to alter the course of the condition and may be contraindicated as it often stresses the mare and increases blood pressure and further hemorrhage, delaying clotting. Treatment with hypertonic saline solutions has been reported to be useful in some cases. In mares that survive, the hematoma will be palpable for some considerable time.

Uterine rupture

Uterine rupture may follow dystocia or normal parturition. If the rupture is large, the mare will show signs of **peritonitis and cardiovascular shock** (*q.v.*), usually with a rapidly fatal outcome. If the uterine serosa remains intact the mare will show signs of colic but may survive with careful supportive treatment. Smaller tears may not become apparent until signs of peritonitis develop. Broad-spectrum systemic antibiotics (including **oral metronidazole** to help prevent anaerobic infections) and **flunixin** (1.1 mg/kg IV, to help minimize the effects of endotoxin release) therapy should be instituted, and early surgical repair considered. Small perforations sometimes only become apparent when localized peritonitis develops into a localized abscess and these may

respond to medical treatment with prolonged courses of antibiotics. Cautious IV sodium iodide therapy (0.4 mL/kg 16% aqueous **sodium iodide**, twice weekly for 4 wk) may be helpful.

Uterine prolapse

The cranial and lateral attachments of the equine broad ligament make uterine prolapse uncommon. It may occur at parturition but is more often associated with dystocia or placental retention (*q.v.*).

The mare should be sedated, an epidural anesthetic (*q.v.*) administered and broad-spectrum systemic antibiotics (including **oral metronidazole** to help prevent anaerobic infections) and **flunixin** (1.1 mg/kg IV to help minimize the effects of endotoxin release) therapy should be instituted. It is usually easier to replace the uterus with the mare's hindquarters raised. The uterus should be cleaned with a **dilute povidone-iodine solution** and examined carefully for lacerations, which should be repaired, before it is carefully replaced. The vulva should be temporarily sutured with heavy-duty suture material, allowing just enough opening for urination. IV oxytocin drips and large-volume intrauterine antibiotic irrigations are recommended to aid uterine involution and to prevent septic metritis (*q.v.*).

Thoroughbred mares may suffer from **hypovolemic shock**, and intensive care with IV fluid therapy may be required.

Cervical lacerations

Cervical lacerations may occur at foaling, most commonly associated with dystocia. **Mucosal splits** may heal completely with the aid of applications of local antibiotic ointment to prevent infection and adhesion formation. Lacerations involving the **muscular layer** interfere with closure of the cervical os and **profoundly reduce fertility**. Surgical repair is attempted after initial healing, with the mare sedated and restrained standing in stocks, under epidural anesthesia. After debridement, a three-layer closure is made (internal and external mucosae and muscularis) but this is never technically simple and reconstruction is seldom functionally ideal. Fertility, in most cases, remains depressed. Abortion and premature parturition, associated with posterior pole placentitis, are common sequelae.

Cervical lacerations can be prevented during fetal repositioning and assisted delivery if maximal cervical dilatation is encouraged, **copious lubrication** used and Cesarean section (*q.v.*) is considered as an alternative to fetotomy.

Vaginal rupture

Perforation of the dorsal vaginal wall by the **foal's foot** or muzzle during delivery occurs more commonly in primiparous than multiparous mares. It can also occur during obstetric manipulation. Cranial ruptures communicate directly with the peritoneal cavity, and the abdominal viscera may be damaged or may **prolapse** through the tear. Surgical repair is most readily attempted with the mare sedated and under epidural anesthesia (*q.v.*), restrained standing in stocks.

Broad-spectrum systemic antibiotics (including **oral metronidazole** to help prevent anaerobic infections) and **flunixin** therapy should be instituted to minimize the effects of endotoxin, and antibiotics should be administered into the abdominal cavity prior to closure. Traction of cervical stay sutures may improve exposure but the heavy post partum uterus makes full retraction difficult. The edges of the tear should be apposed using absorbable sutures, and a **Caslick's vulvoplasty** (*q.v.*) operation performed to prevent aspiration of air.

Retroperitoneal abscesses can develop secondary to vaginal lacerations that may have been overlooked. These often become chronic and require prolonged courses of appropriate antibiotic therapy. IV sodium iodide treatment (0.4 mL/kg 16% aqueous sodium iodide, twice weekly for 4 wk) has been very helpful in resolving some cases.

Endometrial hemorrhage

A persistent **hemorrhagic discharge** is observed for 3–4 days after parturition. **Oxytocin**, 50 IU in 500 mL of sterile saline, should be administered by IV drip over approximately 15 min or 15–20 IU IM, and may be repeated 2–3 times daily. If there is severe hemorrhage, exercise should be restricted and supportive treatment administered. Focal peri-uterine or endometrial hemorrhages are sometimes seen during ultrasound examinations at the first post partum estrus (“foal heat”).

Delayed uterine involution

Delayed involution may be associated with grossly retained placenta, retained chorionic microvilli, uterine infection or lack of exercise. The mare may be dull with a poor appetite and signs of mild abdominal discomfort. There may be more serious signs of septicemia, toxemia and/or laminitis. There is usually a persistent hemorrhagic discharge that may be foul smelling. Vaginal examination will reveal a **downward tilt of the vagina**, often urine pooling and associated marked vaginitis. Rectal examination reveals the uterus to be voluminous. Ultrasound imaging reveals turbid fluid in the uterus.

When there is systemic involvement, parenteral antibiotics (including **oral metronidazole** to help prevent anaerobic infections) and **flunixin** therapy should be given. Large-volume **uterine lavage** should be used to remove accumulated exudates, and 20–50 IU oxytocin in 500 mL sterile saline should be administered over approximately 15 min to stimulate uterine contraction or 15–20 IU IM may be repeated 2–3 times daily. Exercise is also beneficial.

Pelvic fracture

Fractures (*q.v.*) most frequently occur in the iliac shaft or pubic symphysis following prolonged dystocia or a fall, during or after delivery. Confinement and supportive therapy allows repair in some cases but euthanasia may be indicated on humane grounds for others.

Metritis/laminitis/toxemia

This is an uncommon but **serious post partum complication**. Acute metritis may develop secondary to dystocia (*q.v.*), retained placenta or uterine contamination at or after delivery. The mare shows signs of depression, anorexia, pyrexia, congested mucous membranes and reluctance to move. The uterus is voluminous and filled with fetid brownish fluid, which may contain a small piece or pieces of placenta.

Treatment should include **systemic broad-spectrum antibiotic** (including **oral metronidazole** to help prevent anaerobic infections) and **flunixin** medication. The uterus should be irrigated using a **warm dilute povidone-iodine solution** and two stomach tubes. The lavage should be continued until the egress fluid is clear and may need to be repeated daily or twice daily until the uterus starts to involute, placental fragments and/or retained microvilli slough and are removed. Oxytocin, 15–20 IU administered IM, will help evacuate fluid from the uterus and hasten involution. A course of intrauterine antibiotics should be given. Early treatment for laminitis (*q.v.*), including sole supports or heart bar shoes, is important.

Gastrointestinal complications

Cecal rupture (*q.v.*) often involves an area of **avascular necrosis** at the cecal tip. The incidence is low (approximately 0.1%) and the cause is unknown, although chronic compression of the cecal tip between the fetus and maternal pelvis has been postulated. Parturition is often normal until second stage labor, when assisted delivery is required. Signs of colic, cardiovascular shock and acute peritonitis develop rapidly and euthanasia is required on humane grounds.

Constipation associated with bruising: Mares with severe bruising of the vagina and perineum may fail to pass feces for 24–48 h because of **perineal pain** and perhaps local neurologic impairment. Treatment with a **laxative** diet (preferably grass), exercise, 4 L liquid paraffin by stomach tube and analgesics are helpful. Periodic careful manual removal of the impacted feces may be required.

Colon torsion (*q.v.*) may be seen in the immediate post partum period. The degree of severity of signs is dependent on the degree of torsion and its duration. **Colic signs are usually severe** with abdominal distension, and signs of cardiovascular shock develop rapidly. Early surgical correction by emergency laparotomy is essential if irreparable colonic vascular damage is to be avoided.

Perineal injuries

Perineal injuries are classified according to their severity. **First-degree** lacerations consist of a tear of the dorsal commissure of the vulva and mucous membrane of the vestibule. Repair using Caslick's vulvoplasty operation (*q.v.*) is usually all that is required. **Second-degree** lacerations involve the vestibular mucosa, submucosa and perineal body. Caslick's vulvoplasty operation plus internal repair, as indicated, is used but if there is severe bruising and extensive tissue damage it may be appropriate to allow second intention healing to occur before final repair is completed. **Third-degree** lacerations involve

the ceiling of the vestibule, floor of the rectum, perineal septum, musculature and anal sphincter.

A minimum of 4–6 wk should be allowed for second intention healing, reduction in inflammation and wound contracture. During this period the wound should be kept clean, and broad-spectrum systemic antibiotic (including **oral metronidazole** to help prevent anaerobic infections) and non-steroidal anti-inflammatory treatment administered as necessary. As most cases are unsuitable for mating during the same breeding season, it is often preferable to delay repair until the foal is weaned. **Surgical repair** is usually performed in two phases, 4–6 wk apart. The mare is restrained standing in stocks, sedated and under epidural anesthesia. Systemic antibiotic and non-steroidal anti-inflammatory therapy is provided. The first stage involves reconstruction of the rectovaginal shelf and the second involves repair of the perineal body and vulva. The anal sphincter remains functionally incompetent.

Rectovaginal fistula involves an internal laceration though the rectovaginal shelf, the perineal body remaining intact. This can either be repaired by first converting to a third-degree laceration and then repaired as described above, or by splitting the intact caudal rectovaginal shelf cranially to and through the fistula, and then repairing the defect in the rectum transversely and the defect in the vagina longitudinally. The latter method has the advantage of maintaining the integrity and function of the anal sphincter. Some caudal rectovaginal fistulas will heal completely without surgical interference, given time, and others will become small enough to be repaired surgically via the vagina.

INTRODUCTION

This chapter highlights the contributions of theriogenology, intensive care medicine and neonatology to the emerging clinical specialty of perinatology. Historically, research focused on infertility and early pregnancy loss in mares. The endocrinology of estrus and early pregnancy was investigated and strategies developed to manipulate estrus and ovulation. The introduction of **trans-rectal ultrasonography** allowed pregnancy detection as early as 15 days post ovulation with positive pregnancy diagnosis awaiting sonographic detection of a fetal heartbeat by Day 23. Ultrasonography improved the ability to detect **twin conceptions** early enough to allow crushing of one embryo as a means of ensuring a viable pregnancy with the remaining conceptus.

Endocrinologic confirmation of pregnancy has also been explored using maternal serum (and occasionally urine) concentrations of various hormones including pregnant mare serum gonadotropin, estrone sulfate, relaxin and progesterone. Unfortunately, most of these hormones are not sensitive enough markers of pregnancy loss, since elevated hormone concentrations frequently persist for variable intervals following embryonic or fetal death.

Impending **embryonic/fetal demise** is difficult to predict. Careful sonographic examination of the "embryo at risk" may reveal a small-for-date conceptus. An abnormally slow fetal heart rate during the **first trimester** suggests an unhealthy outcome. The value of attempts to intervene and maintain such pregnancies is controversial. If an **abnormal uterine environment** or **fetal chromosomal anomaly** is responsible for early fetal wastage, then intervention to try and maintain the pregnancy is probably unwise. An unhealthy in utero environment so early in gestation is likely to predispose to abnormal fetal growth and development. Conversely, intervention can be justified in pregnancies at risk due to extrauterine stresses such as **endotoxemia**. Progesterone supplementation and flunixin meglumine administration have been shown to exert a protective effect when given to mares before or soon after the onset of endotoxemia during early gestation (<90–120 days).

Mid-gestation appears to be the safest period for fetal development. The same maternal illnesses that may have terminated the pregnancy in early gestation as a result of luteolysis and progesterone deficiency are unlikely to have the same deleterious effect during the **second trimester** when the primary source of progestogens has become the fetoplacental unit. Drugs administered to the mare are more likely to have a teratogenic effect on the fetus during early pregnancy than during the second trimester when **organogenesis** has

already been completed. Causes of fetal death during mid-gestation are still poorly understood. Often pregnancy loss is not detected until weeks after it has occurred.

Late pregnancy remains the focus of most fetal monitoring techniques, with the goal being to recognize fetal compromise early enough to prevent irreversible damage. In women, the two most popular tests of fetal well-being during the **third trimester** are the **non-stress test (NST)** and **biophysical profile (BPP)**. The NST requires simultaneous, continuous monitoring of fetal heart rate and movement, and is based on the premise that fetal heart rate should accelerate in response to fetal movement. During a 20 min observation window, the healthy human fetus should experience two heart rate accelerations exceeding 15 bpm in amplitude above the baseline heart rate and lasting for at least 15 s. An NST meeting these criteria is termed **reactive** and is a reassuring sign of fetal well-being. The BPP involves a 30 min sonographic survey of fetal heart reactivity, muscle tone, body movements and breathing movements and an evaluation of **amniotic fluid volume (AFV)**.

Developmentally, **fetal muscle tone** is the first of these parameters to emerge. Fetal movement can be characterized by flexion and extension of the extremities and rolling movements of the torso. Three episodes of **fetal activity** during a 30 min period are considered normal. If fetal movement is observed, then muscle tone is considered to be present. Breathing movements in the human fetus develop during the end of the first trimester. At least 30 s of **fetal breathing** should be observed during the diagnostic window in late gestation. **AFV** is a measure of **fetal renal function** and general placental nutritive function. Amniotic fluid in women corresponds to allantoic fluid in mares, in that both contain fetal urine. Oligohydramnios (decreased AFV) in women has been associated with premature membrane rupture and hypoxia.

Each of the parameters is assigned a score of 2 (present) or 0 (absent). A significant decrease in AFV is considered an ominous sign even if the other parameters are still normal. As the BPP score decreases to $<6/10$ the incidence of perinatal complications and uteroplacental insufficiency increases.

During a transabdominal sonogram, the **placenta** is also evaluated for thickness, textural changes and premature separation. Fetal presentation and size are determined. Normal indices for the BPP in the equine fetus are being established.

While **transabdominal ultrasonography** may not become a routine screen for all pregnant mares, its use should be considered for those individuals with a history of previous perinatal loss, premature placental detachment, twinning or premature delivery (*q.v.*). Sonographic evaluation of fetal well-being can also be justified in those mares with unexplained or excessive abdominal enlargement, vaginal discharge, premature udder development or other severe systemic illness. If sonographic evaluation suggests fetal well-being, then therapy can be directed at maintaining pregnancy as long as possible to permit continued fetal maturation. If **fetal distress** is detected, then timely termination of the pregnancy can be coordinated with preparations to stabilize and treat a compromised neonate.

Management strategies for the abnormal pregnancy vary with the problem. A purulent vaginal discharge (*q.v.*) in a late pregnant mare may or may not result in placental insufficiency and the birth of a compromised and possibly

infected foal. Observation of a generalized increase in placental thickness and fetal fluid echogenicity raises the index of suspicion that **fetoplacental function** has been affected. Marked elevations in maternal concentrations of equine fetal protein provide biochemical confirmation of this condition. Such pregnancies need not be lost. Affected mares may be treated with antibiotics, and low (anti-endotoxic) doses of flunixin meglumine, progesterone and β -sympathomimetic drugs such as isoxsuprine hydrochloride to help maintain pregnancy. If signs of **fetal compromise** develop, induction is performed in a suitable intensive care environment (*q.v.*).

Sonographic determination of **anterior fetal presentation** (*q.v.*) in late pregnant mares provides reassurance that dystocia will not be a problem due to posterior presentation. Several studies have shown that after the ninth month it is extremely unlikely that the equine fetus will change its presentation between anterior and posterior.

Transabdominal ultrasonography may also provide insight into another common periparturient problem, **premature placental separation**. In most cases, it is unknown when the placenta begins to detach. Foals that are the product of premature placental separation are at increased risk for hypoxic organ damage. Although neonatal intensive care units have become quite adept at saving such foals, preventing or limiting fetal exposure to hypoxia is preferred. If significant areas of premature placental detachment are detected in a late pregnant mare, induction of parturition should be considered, rather than waiting for increasing hypoxia and fetal compromise to occur.

In utero determinants of **fetal size** are still being evaluated. If intrauterine growth retardation could be identified early in gestation, perhaps therapy could be directed at trying to improve uteroplacental blood flow. Intrauterine growth retardation is still being investigated in human medicine and perhaps the equine fetus might serve as a model for future research.

A successful **perinatal program** requires the collaborative efforts of those trained in reproduction and neonatology. A working knowledge of equine obstetric procedures and therapies for the more common periparturient emergencies is essential. **Enhanced neonatal survival** depends on a thorough understanding of foal physiology, an ability to recognize early signs of neonatal compromise, and the expertise, facility and equipment required to provide neonatal resuscitation and intensive nursing care. Successful management of the critically ill neonate requires rapid diagnosis and treatment of specific disease processes while addressing the unique metabolic demands and physiologic instability of the newborn.

The most serious threats to perinatal survival include septicemia, hypoxia and dysmaturity (*q.v.*). Treatment of these conditions post partum has become increasingly successful, but is still limited by how quickly the problem is recognized, how rapidly patient stabilization can begin, the economic restraints of the owner, and the limitations of the veterinary facility. Farm managers and foal owners must be fully informed of a sick foal's condition, the intensity of treatment required, and the possible sequelae. The decision to treat requires the **complete commitment** of both owner and veterinarian; otherwise, foal mortality will remain disappointingly high and many of the survivors will have their future performance limited by lingering disabilities associated with neonatal disease.

Frequently, disruptions in fetal maturation/adaptation begin prior to or during parturition. Recognition of the perinatal risk factors associated with **disturbed fetal development** allows the most important management change to occur: **increased surveillance** of a mare with a potentially abnormal pregnancy. Once the mare is identified as a high-risk candidate, more sophisticated periparturient monitoring techniques can be employed. Arrangements can be made to allow her to foal in a facility equipped to provide emergency care ranging from controlled parturition or Cesarean section (*q.v.*) to neonatal resuscitation and intensive care. Learning more about the perinatal events of an abnormal pregnancy will in turn improve reproductive management of the mare and care of the newborn foal. Successful integration of prenatal and neonatal care should reduce periparturient foal mortality in an economically sound manner.

ENDOCRINOLOGY OF THE PERIPARTURIENT PERIOD

GESTATION

To understand the endocrinology of the periparturient period, it is necessary to review the endocrinologic events of gestation (*q.v.*).

Progestogens

Progesterone (*q.v.*) plays a role in maintaining cervical and uterine tone, embryo motility, fixation and orientation, and uterine secretion of nutrients to the embryo. It is the only ovarian hormone necessary to maintain the first 70 days of pregnancy.

The primary corpus luteum starts to produce progesterone at ovulation and plasma concentrations rise $>4\text{ ng/mL}$ within 6–8 days. The presence of the mobile embryo prevents the release of **endometrial prostaglandin $F_{2\alpha}$** (**PGF $_{2\alpha}$**) into the maternal circulation, thus preventing luteolysis. Progesterone concentrations decrease between Days 14 and 30. A second increase in plasma progesterone concentrations occurs again between Days 35 and 40 due to the resurgence of the primary corpus luteum (due to stimulation by equine chorionic gonadotropin). Additional follicles develop and ovulate between Days 40 and 70. The luteinization of these secondary follicles between Days 40 and 150 forms the secondary corpora lutea. Progesterone concentrations plateau near Day 60 of gestation at approximately 15 ng/mL .

There is great variation in plasma progesterone concentrations among normal mares during early gestation. Pregnancy should be maintained as long as plasma concentrations of progesterone are $>4\text{ ng/mL}$ prior to 120 days of gestation. The luteal structures function until Day 150 and then progesterone gradually decreases to low plasma concentrations ($1\text{--}2\text{ ng/mL}$) at approximately 180 days. The ovaries have little activity throughout the remainder of gestation.

Between Days 30 and 60 of gestation, the conceptus begins to secrete progestogens, primarily pregnanes and $20\text{-}\alpha$ -dihydroprogesterone. Concentrations gradually increase until Day 300 and then rise more sharply during the last month before parturition. The $5\text{-}\alpha$ -pregnanes reach high concentrations

(some up to 2000 ng/mL) during late gestation. Progestogens decrease from as early as 2–3 days to as late as 4–12 h before parturition.

Both the stage of gestation and the assay specificity must be known to **interpret progesterone assay results** correctly for pregnant mares. Assays that have cross-reactivity between pregnanes and progesterones will have progestogen concentrations normally high in late gestation. Assays specific for progesterone will indicate low progesterone concentrations for normal mares in late gestation.

Equine chorionic gonadotropin

Trophoblastic cells from the chorionic girdle invade the endometrium to form endometrial cups. Endometrial cups secrete a glycoprotein called **equine chorionic gonadotropin (eCG)** (*q.v.*), formerly known as pregnant mare serum gonadotropin (PMSG).

Equine chorionic gonadotropin is present in the mare's blood between Days 35 and 120, with peak concentrations around Day 60. There is great variation among mares in the amounts of eCG produced and the timing of its production. Relatively small amounts of eCG are present in the urine and milk of pregnant mares. Demise of the endometrial cups is due to a lymphocytic immune reaction by the mare that destroys the endometrial cups.

Because use of exogenous eCG in cattle and sheep has both follicle-stimulating hormone (FSH) and luteinizing hormone (LH) activity that stimulates superovulation and ovulation, it was previously thought that eCG caused the development and ovulation of additional follicles in the mare to form secondary corpora lutea. However, many follicles are present on mare ovaries prior to the appearance of eCG and, therefore, it is not thought to have FSH-like activity in mares. Also, exogenous eCG does not increase follicular activity in mares. Equine chorionic gonadotropin does, however, have LH-like activity in mares and is luteotropic to the primary corpus luteum on Day 35, causing a resurgence of progesterone secretion prior to causing ovulation and/or luteinization of the secondary follicles of pregnancy. The primary and secondary corpora lutea also produce estrogens and, possibly, androgens.

Bioassays based on ovarian and uterine weight changes in immature rats were the first quantitative measurements of eCG. An LH radioimmunoassay can be used to estimate eCG because there is high cross-reactivity with LH. Immunoassays using anti-eCG serum-absorbed inhibition assay and hemagglutination inhibition assays are also available. Enzyme-linked immunosorbent assays (ELISA) are once again commercially available as a **pregnancy test** (*q.v.*) in the mare, although false positive results may occur because the endometrial cups are maintained until 120 days even if the fetus has died. False negative results may occur if the mare is tested before Day 35 or after Day 120 of gestation.

Estrogens

The equine conceptus is capable of estrogen production as early as Day 14 but increases in maternal circulation of estrogen (*q.v.*) are not seen until after Day 35. At 35–40 days, total plasma estrogens increase and a plateau of 3 ng/mL is reached on Days 40–60. Estrone sulfate is secreted by the fetoplacental unit

after Day 80 and steadily increases during the fourth month. High concentrations are maintained until the eighth or ninth month.

Conjugated equilin also increases during the fourth month and does not decrease until the last month of gestation. It is thought that the fetal gonads contain large amounts of estrogen precursors that the placenta subsequently converts to estrogens. Interestingly, estrogen concentrations decrease during the last month of gestation.

Interpretation of **estrogen assays** must be made carefully because estrogens of pregnancy exist in many forms and may be conjugated (bound to sulfates) or unconjugated (free in blood). The pregnant mare excretes huge amounts of estrogen in urine, principally **estrone** and **equilin**, which are used to produce commercial preparations of estrogen.

Assay of **estrone sulfate** can be used as a pregnancy test (*q.v.*) after the third month of gestation. Estrone sulfate assays can also be used to indicate fetal well-being because the fetus must be alive for concentrations to be elevated.

Estrogens are believed to have a positive effect on uterine, placental and fetal growth, perhaps through regulation of blood flow through the uterine and placental blood vessels and in the synthesis and storage of prostaglandin precursors in the endometrium and myometrium. During late gestation estrogens stimulate prostaglandin production, gap junction formation and oxytocin receptor synthesis. Gonadectomizing horse fetuses in mid to late gestation results in decreased maternal estrogen levels, weak ineffective labor associated with low prostaglandin levels, and the birth of dysmature foals.

Relaxin

The **placenta** is thought to be the sole source of relaxin in the mare. Placental secretion of relaxin (*q.v.*) begins on about Day 80 of pregnancy and peaks initially at approximately Day 175. A 50% decline occurs by Day 225, but concentrations then increase again gradually until parturition. Relaxin decreases the collagen content in the extracellular matrices of the pubic symphysis and uterine cervix, inhibits uterine contractility, and may play a role in mammary gland development.

Relaxin has been demonstrated to be an **indicator of fetoplacental health** in the late gestational mare. Low relaxin concentrations have been associated with varying types of placentitis and placental insufficiency.

Mares exposed to **endophyte-infected tall fescue** (*q.v.*) experience a decrease in circulating relaxin levels that coincides with placental dysfunction and fetal distress. When affected mares are treated successfully with **domperidone**, a D₂ dopamine agonist capable of reversing the signs of fescue toxicosis, the mares' clinical signs resolve and relaxin levels return to normal. This hormone represents a promising marker of fetoplacental function. No commercial assay for relaxin is currently available.

Prolactin

Prolactin (*q.v.*) concentrations rise markedly during the last week of gestation and remain high for 1–2 mo after parturition. Research in other species suggests that prolactin is involved with mammary development and lactation.

PARTURITION

The hormonal events controlling parturition (*q.v.*) affect **maturation of the fetus** and cause physical changes in the dam necessary to allow delivery, including relaxation of the pelvic ligaments and cervix, and uterine contractions. **Lactation and maternal behavior** are also influenced by hormones. In domestic farm animals, parturition is initiated by the fetus, but the mare can delay delivery temporarily if she is disturbed. Progestogen concentrations appear to decrease from 2–3 days before foaling.

Mare plasma $\text{PGF}_{2\alpha}$ concentrations are higher in late gestation (≥ 270 days) than in early gestation. $\text{PGF}_{2\alpha}$ and 13,14-dihydro-15-keto-prostaglandin- $\text{F}_{2\alpha}$ (PGFM) dramatically increase during parturition, but concentrations are minimal within 1–2 days after parturition. Prostaglandin E_2 (PGE_2) concentrations gradually increase near term and are thought to play a role in cervical softening.

In sheep, the hypothalamus stimulates the anterior pituitary to produce ACTH that causes the fetal adrenal to increase secretion of cortisol during the last 48–72 h of gestation. Cortisol is thought to activate placental enzyme systems that convert progesterone to estrogen, which is needed for $\text{PGF}_{2\alpha}$ production and increase of oxytocin receptors. $\text{PGF}_{2\alpha}$ causes release of oxytocin from the posterior pituitary and softens the cervix. The oxytocin in turn stimulates myometrium contraction that results in delivery of the fetus.

The exact mechanism regulating parturition in the mare is not known, but it is thought to be similar to that in sheep. There is evidence that the fetus plays an important role. Equine fetal adrenals undergo **rapid hypertrophy** immediately before parturition and **fetal plasma cortisol** increases slightly near term. Concentrations of cortisol in the amniotic fluid also increase near term. In the mare, there is no change in plasma concentrations of glucocorticoids before parturition. Ovarian hormones are not necessary for parturition and pregnant, ovariectomized mares have normal parturitions. Exogenous progesterone will not prolong gestation.

In the mare, **$\text{PGF}_{2\alpha}$ and oxytocin** are involved with parturition but are not necessary for luteolysis. Oxytocin receptor formation seems to be controlled by estrogen–progesterone ratios and increased $\text{PGF}_{2\alpha}$ production. Oxytocin (*q.v.*) is only increased during **second stage labor** and until the placenta is passed. As oxytocin is a neurohormone under the control of the mare's central nervous system, this may be the mechanism by which she can “select” timing of delivery.

As the fetus and placenta are passed, steroid production by the conceptus is lost. Within 30 min of parturition, progestogen and estrogen concentrations in the mare decline precipitously. A **surge of FSH** occurs at the time of parturition, beginning a few days before and reaching a peak on or just before the day of parturition. Follicular development, therefore, soon resumes and estrogen concentrations increase during the first estrus (**foal heat**), which occurs approximately 7–11 days after foaling.

FSH (*q.v.*) concentrations then gradually decrease due to the inhibitory effect of the developing follicles associated with foal heat. However, LH (*q.v.*) concentrations are low prior to parturition due to the suppressing effect of progestogens. LH increases after the progestogens decrease following parturition. Further increases in LH concentrations occur due to estrogens produced by

follicles during foal heat. After foal heat ovulation, progesterone increases due to its production by the corpus luteum, and a normal estrous cycle ensues.

HORMONE ASSAYS

Before the 1960s, investigations on hormone regulations were performed with bioassays that measured changes in organ size or weights due to stimulation by a particular substance. In the late 1960s, competitive protein binding assays and later radioimmunoassays confirmed information learned from the bioassays. Very sensitive radioimmunoassays allowed for much more accurate determination of hormone concentrations.

Much work has been done to develop assays that do not require long, tedious laboratory techniques and radioactive isotopes. ELISA tests use highly specific monoclonal antibodies and involve enzyme-induced color changes that do not require radioactive agents. Assays can be performed quickly and outside laboratories that have to meet the regulated requirements for handling and disposing of radioactive materials. Some assays are in a simple dipstick form and give qualitative results indicating the presence or absence of the hormone. Quantitative results can be obtained using plate readers that give an accurate determination of hormone concentrations. **ELISA tests** are available for progesterone, equine LH and eCG. Interpretation of results must be made carefully, after following assay directions, using appropriate control standards, and with comparison to concentration ranges in normal mares for the particular reproductive stage.

PERIPARTURIENT COMPLICATIONS

VARICOSE VESSELS IN THE VAGINA

A distended blood vessel with possible hemorrhage may be seen in the vulva/vagina of the pregnant mare near term. Varicose veins are more common in **older mares**.

Etiology

During late gestation, the blood vessels supplying the genital tract enlarge; blood flow to the genitalia increases under the influence of estrogens, and retrograde pressure exerted by the weight of the fetus and uterus may compromise venous return in some areas, resulting in a varicose vein. Common sites for such varicosities are the hymen (transverse fold) and floor of the vagina. Occasionally, a varicose vein may rupture and cause frank bleeding that appears as a bloody **vulval discharge**. This clinical sign may cause great alarm to the novice mare breeder.

Clinical signs

A frank bloody vulval discharge may be present. The source of the bleeding is determined by **vaginal speculum** examination. If rupture of the vessel has not occurred, there may be no obvious clinical signs.

Treatment

Usually, no treatment is indicated. If severe hemorrhage occurs, the vessel may be ligated or cauterized. Light exercise may help improve circulation and lessen the occurrence of this problem. The condition will resolve after parturition.

UTERINE TORSION

Torsion of the uterus (*q.v.*) occurs during late gestation but is not usually associated with parturition as in the cow. The uterus rotates about its **long axis** and typically does not directly involve the cervix. The degree of rotation is quite variable and can range from 90 to $>360^\circ$. The severity of clinical signs is related to the degree of torsion, and any gastrointestinal organ involvement or vascular compromise.

Etiology

Uterine torsion may be caused by the mare falling down or rolling or by increased activity of the fetus, but often there may not be any history of these events.

Clinical signs

The mare may appear as if she is in first stage labor. There may be restlessness, sweating, anorexia, frequent attempts to urinate, and signs of intermittent colic that is unresponsive to treatment. Severity of pain is related to degree of torsion and/or concurrent involvement of gastrointestinal viscera. Dystocia (*q.v.*) may be the presenting sign if uterine torsion occurs near term.

Diagnosis

On **palpation per rectum**, the broad ligament will feel very tense on one side as it is pulled under the pregnant uterus and the opposite side will seem to bulge up over the uterus. The uterine wall should be palpated carefully to assess the degree of congestion, necrosis or possible rupture.

Treatment

Uterine torsion can be corrected surgically, manually or by rolling. **Surgical correction** by rotation of the uterus can be made through a flank incision in a standing, sedated mare. If there is a suspicion that the uterus has been severely compromised and/or rupture has occurred, a ventral midline incision with the mare under general anesthesia (*q.v.*) is recommended.

If the mare is near term and the torsion not severe, **manual correction** per vaginam is possible provided the torsion is $<270^\circ$. The mare should be prepared as for dystocia evaluation. The **cervix must be adequately dilated** and a portion of the fetus palpable. If the fetal membranes are intact they should be ruptured to release fluids and reduce the size and weight of the uterus. The fetus may be rocked to flip the uterus into normal position. The foal may then be delivered immediately. Parturition may be hastened by induction with **oxytocin** after the torsion has been corrected.

The mare can be **rolled** to correct uterine torsion. This procedure should not be used near term because of the increased risk of uterine rupture (*q.v.*). Anesthesia is induced using a short-acting injectable anesthetic and maintained with inhalation anesthesia (*q.v.*). The mare is placed in **lateral recumbency** with the side in the direction of the torsion down. The legs should be hobbled and ropes applied to the limbs. Place a **plank** (3.5 m long \times 0.3 m wide \times 5 cm thick) perpendicularly against the mare's back and flank. While one person kneels on the plank to hold the uterus in place, roll the mare such that her legs swing over her back in the direction of the torsion. Care should be taken to protect the mare's head from injury. Success of correction can be evaluated by **palpation per rectum** for the proper positioning of the broad ligament. If the torsion has not been corrected, the procedure can be repeated. Pregnancy should be monitored closely for several days.

Complications associated with correction of uterine torsion include premature placental separation with fetal compromise and/or death and abortion, uterine wall necrosis and rupture, peritonitis and recurrence of the torsion during the same pregnancy.

HYDROPS AMNII AND HYDROPS ALLANTOIS

Hydrops amnii (excessive accumulation of amniotic fluid) in the mare has been associated with foals with **hydrocephalus** (*q.v.*) and with **umbilical cord anomalies**. **Hydrops allantois** is an excessive accumulation of allantoic fluid that occurs during the last trimester of gestation. Although both conditions are rare in the mare, hydrops allantois is the more common of the two.

Etiology

Amniotic fluid is comprised of saliva and upper respiratory tract secretions and is cleared in part by fetal swallowing. Therefore any condition that impedes or results in **impaired fetal swallowing** may contribute to development of hydrops amnii. The exact cause of hydrops allantois is unknown but it is thought to be related to a **dysfunction of the chorioallantois** resulting in abnormal allantoic fluid maintenance. Some cases have been associated with fetal anomalies, heavy edematous placentas and umbilical cord disorders.

Clinical signs

Hydrops allantois is associated with dramatic and rapid enlargement of the abdomen over several weeks. Mares with hydrops amnii develop mild abdominal distension over a more prolonged time period of weeks to months. The increased volume of fetal fluids exerts pressure on the gastrointestinal tract and thoracic cavity and results in maternal anorexia, tachycardia, tachypnea, dyspnea, depression, colic, decreased manure production, difficulty walking and marked ventral edema (*q.v.*).

Advanced cases may develop ventral abdominal hernia or prepubic tendon rupture (*q.v.*). Other complications include uterine rupture and uterine inertia (*q.v.*). **Palpation per rectum** reveals a large, fluid-distended uterus. It is often difficult or impossible to feel the fetus. In the early stages of hydrops, an absolute diagnosis may be difficult to make. The condition is confirmed via **transabdominal ultrasonography**. Large volumes of clear fetal fluids are observed.

Treatment

Hydrops allantois tends to be more **life threatening** for the mare due to its **rapid onset** and the excessive volume of fluids that accumulate. Prognosis for both mare and fetus is grave unless the mare is at term. The fetus may be normal in these pregnancies, but survival depends on how late in the pregnancy the condition develops and how successfully the mare is supported during labor. Often the best chance for saving the mare is by **termination** of the pregnancy.

Hydrops amnii is often associated with fetal birth defects and/or umbilical cord anomalies. In cases of hydrops amnii the prognosis for the pregnancy is poor because **abortion and premature delivery** are common. Future fertility is often not impaired if there is no accompanying prepubic tendon rupture or ventral abdominal herniation.

If the mare is comfortable and close to term, fluid accumulation is mild to moderate and fetal viability is reasonable, then the mare can be supported with IV fluids supplemented with B vitamins and dextrose, a laxative diet, oral vitamin E and **altrenogest** (0.044–0.088 mg/kg PO q 24 h).

In advanced cases of hydrops, **parturition should be induced** to relieve pressure on the mare's internal organs and avoid prepubic tendon rupture, abdominal hernia formation or uterine rupture which can end a mare's reproductive career and increase the risk of colic post foaling. The mare's muscle enzymes should be monitored. Sudden increases in maternal **serum creatine phosphokinase (CPK)** concentrations herald increasing muscle damage and impending prepubic tendon rupture or hernia formation.

During delivery the sudden expulsion of large volumes of fetal fluids results in **hypotensive shock** (*q.v.*) in the mare. Manual rupture of the chorioallantois is often too blunt and results in rapid fluid expulsion. A sharp 20 to 32 French trocar catheter can be used to make a **puncture** through the chorioallantois to drain off allantoic fluid as **slowly as possible**. To prevent maternal shock, the mare should be **pre-treated** with at least 20 L of IV fluids. One to two liters of hypertonic saline or hetastarch (10 mL/kg) can be administered to improve oncotic pressure and combat hypotension.

Corticosteroids can also be given to treat shock (*q.v.*). **Oxytocin** is administered to stimulate uterine contractions, but uterine inertia should be anticipated and chains should be available to help extract the fetus as rapidly as possible to minimize peri partum asphyxia. Post partum, **flunixin** administration can improve maternal comfort.

Retained fetal membranes (*q.v.*) are common and are treated with repeated doses of oxytocin (10–20 IU IV/IM) q 3–4 h. The mare should be started on antibiotics and NSAIDs to reduce the risk of metritis, endotoxemia and laminitis (*q.v.*). Uterine involution may be delayed and additional oxytocin, IV calcium supplementation and uterine lavages may be indicated.

RUPTURED PREPUBIC TENDON AND VENTRAL ABDOMINAL HERNIA

Prepubic desmorrhesis (ligament rupture) and **abdominal hernia formation** are more common in older draft mares and other heavier breeds, but have been reported in other breeds including Arabs and ponies. Conditions that cause

severe distension of the body wall such as hydrops, twins, severe ventral edema, or trauma may result in rupture of the prepubic tendon or abdominal hernia. It may be difficult to distinguish between prepubic desmorrhaxis and abdominal hernia (*q.v.*), and clinical progression of the two conditions is similar.

Etiology

The rupture tends to occur during the last 2 mo of gestation due to the excessive weight of the gravid uterus.

Clinical signs

Prior to rupture, the mare may be noted to be lying down frequently. A marked, thick, painful edema extending from the udder to the xiphoid region often precedes rupture of the prepubic tendon. Serum concentrations of **CPK** are usually elevated. After rupture has occurred, the mare will have a stiff, cautious gait and refuse to lie down. The mare will often assume a “**sawhorse**” stance with an elevation of the tail head and the ischial tuberosities. The udder and teats will be flattened and stretched cranially.

If rupture occurs suddenly, **intense pain and colic** may be accompanied by sweating, increased respiration, rapid weak pulse, internal hemorrhage and shock (*q.v.*) that often progress to death of the mare and fetus.

Management

Repair of the acute condition is not possible. Confine the mare to a stall, limit exercise, and avoid giving bulky feeds. The mare should be fitted with a **wide abdominal support** heavily padded over the back. Because abdominal contractions during parturition will not be effective, parturition should be induced when the mare is near term so that delivery can be assisted. Affected mares should not be expected to carry a pregnancy again.

Complications include death of the mare due to internal hemorrhage and/or bowel damage, ventral evisceration following rupture of the body wall, and colic after delivery associated with bowel trauma and intra-abdominal adhesions.

Minor rents in the body wall can be surgically repaired. Larger tears are not amenable to successful repair. Foals delivered from mares with hydrops or prepubic tendon rupture are at increased risk for problems associated with **chronic placental insufficiency** such as compromised growth and development and **hypoxic ischemic encephalopathy**.

Deliveries associated with these conditions are often difficult and protracted, thereby adding the additional insult of acute hypoxia to already stressed neonates. Many of these foals are weak, slow to stand and nurse, and unable to absorb adequate amounts of colostral antibodies, thereby rendering them more susceptible to early sepsis.

INDUCTION OF PARTURITION

The main advantage of induction is that it ensures the presence of assistance for mares that have a history of complications or that have experienced problems during gestation. It is very important to evaluate carefully the mare and her

reproductive status and to be sure that several criteria are met before making a decision to induce parturition. Poor timing of and preparation for induction of parturition can result in a premature foal and/or dystocia. Once owners have become accustomed to inducing parturitions, it may become difficult to convince them to wait when a mare is not yet ready.

Indications

1. Mares that have previously produced dead or severely hypoxic foals due to premature placental separation associated with delayed parturition.
2. Mares that have suffered problems during a previous foaling(s) such as dystocia, lacerations or other injuries, and that require professional assistance with delivery and immediate foal care.
3. Mares in which gestation is greatly prolonged beyond 12 mo and is associated with a very large fetus. NB Usually, mares with a prolonged gestation (>365 days) have small or normal size foals.
4. Mares in which there is the presence or possibility of rupture of the prepubic tendon.
5. Mares with hydrops.
6. Mares that have produced foals affected by neonatal isoerythrolysis, so the newborn foal may be prevented from ingesting colostrum before its red blood cells can be checked against the mare's serum.
7. Mares that have sustained pelvic fractures or other injury to the birth canal such that the canal is reduced and manual assistance during delivery is anticipated.
8. Preparation of nurse mares.

Criteria for induction

1. **Length of gestation.** Induction should only be performed when the fetus is mature enough to adapt to the environment outside the uterus. A minimum of 330 days usually ensures adequate fetal maturity at the time of induction if all other criteria are fulfilled.
2. **Adequate mammary development.** The udder should be enlarged and the teats distended with colostrum. In uncomplicated pregnancies, concentrations of calcium, sodium and potassium undergo distinct changes in pre partum mammary secretions associated with fetal maturity and readiness for birth. Calcium concentrations >40 mg/dL are associated with a mature fetus and values <12 mg/dL are associated with reduced fetal viability. As delivery approaches, sodium concentrations decrease to <30 mg/dL and potassium levels increase >35 mg/dL. **Water hardness test strips** can be used to monitor calcium concentration.
3. **Relaxation of the vulva and sacrosciatic ligaments.** Maximum relaxation occurs very close to foaling and can dramatically increase during the first stage of labor. The degree of these changes is quite variable among mares.

4. **Relaxation of the cervix.** The cervix should be soft and easily compressed, with some degree of dilatation. Cervical relaxation may normally occur as early as 1 mo before term or as late as first stage labor.

Methods of induction

Oxytocin (*q.v.*) is the most commonly used agent for inducing parturition. Parturition will occur rapidly and safely with small doses of oxytocin. Oxytocin, 20 IU administered IM, will cause a slow, quiet foaling. An IV bolus of 5–10 IU is also effective. Smaller IV doses such as 2.5–5 IU given every 20–40 min produce a more gradual onset of labor in late term mares and may reduce the risk of dystocia and premature placental separation that is observed with the use of larger doses of oxytocin.

Infusion of 60 IU oxytocin in 1 L of physiologic saline IV at a rate of 0.5–1 IU oxytocin/min produces parturition that **appears physiologically normal**. Second stage labor usually occurs 20–35 min after the start of infusion. Often, the mare will deliver while standing, which may be an advantage if one suspects that manual intervention will be necessary. Oxytocin may be continued until the placenta is passed.

Natural $\text{PGF}_{2\alpha}$ is not recommended for induction of parturition in the mare. Because of the strong uterine contractions it induces there is a high incidence of premature placental separation and fetal morbidity and mortality associated with its use. Some synthetic prostaglandins have however been used on a limited basis in mares. One synthetic $\text{PGF}_{2\alpha}$ that can be used is **fluprostenol sodium** (2.2 $\mu\text{g}/\text{kg}$). Doses of 1000 μg for mares and 250 μg for ponies administered IM are effective and signs of first stage labor will commence within 30 min of injection. Birth usually occurs within 2 h. There is some controversy over the safety and efficacy of fluprostenol for induction. Other synthetic prostaglandins that have been used in the mare are **prostaglandin** and **fenprostalene**. These drugs are dosed at 4 mg SC and 0.5 mg SC respectively. Studies using these drugs indicate that a viable fetus can be obtained approximately 4 h after administration.

Large doses of **corticoids** are necessary to induce parturition in the mare. Daily administration of 100 mg of dexamethasone for 4 days starting after Day 321 will induce parturition between 6.5 and 7 days after initiation of treatment. This delay between administration and delivery of the foal decreases the usefulness of this drug for induction. There is some thought that it may be beneficial to a potentially dysmature foal to administer corticosteroids for 2–3 days pre partum and then induce parturition with oxytocin.

PLACENTITIS

Placentitis (*q.v.*) describes inflammation of the fetal membranes and is a common **cause of reproductive losses** in mares. Most cases of placentitis are infectious in origin; the infection ascends by direct extension from the mare's lower reproductive tract or spreads hematogenously from the mare's systemic circulation. Acute placentitis may cause abortion or premature birth with or without infection of the newborn. Chronic placentitis can result in growth retardation of the newborn or death of the fetus.

Etiology

The most common cause of placentitis is **bacterial infection** that ascends from the dam's urogenital tract through a relaxing cervix. Early placental lesions are first detected around the cervical pole of the fetal membranes.

The bacteria most commonly isolated include *Streptococcus equi* var. *zooepidemicus*, *Escherichia coli*, *Enterobacter agglomerans*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* (q.v.).

In Kentucky, a slightly different form of placentitis has been recognized. It is characterized by **focally extensive inflammation** located predominantly at the junction of the uterine horns and the body of the placenta. The affected area is covered with thick, tenacious brown mucoid exudate and the underlying chorionic villi are necrotic, absent or reduced in size. This form is associated with infection by a group of Gram-positive, branching, filamentous nocardioform-like organisms.

A far less common route of infection is hematogenous as part of systemic disease in the dam. This form of placentitis is often diffuse in nature as seen with leptospirosis and *Corynebacterium pseudotuberculosis* (q.v.).

Clinical signs

Clinical signs of placentitis include **premature udder development**, **preco-cious lactation** and purulent or hemorrhagic **vaginal discharge** that may be evident on the mare's vulva, tail or inner thighs.

Despite even **voluminous vaginal discharge**, most mares with placentitis do not become febrile and do maintain a normal appetite. The dam's white blood cell count usually remains within normal limits. Transrectal ultrasonography can be used to detect early areas of placental separation and increased uteroplacental thickness in the pericervical area. Transabdominal ultrasonography can be used to evaluate other areas of the placenta to detect separation and thickening. If placentitis is severe enough to alter placental function and disrupt oxygen delivery then the fetus may demonstrate reduced fetal movement, loss of heart rate variability and persistent bradycardia.

Treatment

Samples of vaginal discharge should be cultured and Gram stains performed to identify the bacterial pathogens involved. The goal of maternal therapy is to treat the placental infection and maintain the pregnancy provided there is no evidence of severe fetal distress or demise and the mare remains healthy. Therapy includes **broad-spectrum antibiotics**, low dosages of **flunixin meglumine** (0.25 mg/kg IV q 8h) to decrease inflammation and prevent prostaglandin-mediated induction of delivery, and **altrenogest** (0.044–0.088 mg/kg PO q 24h) to quiet the myometrium and maintain cervical competency.

Clenbuterol has been administered as a **tocolytic agent** to suppress uterine contractions (0.8–1.2 µg/kg PO q 12h) and reduce the risk of premature labor. Pentoxifylline (8.4 mg/kg PO q 8–12h) has been used to support microcirculation. Oral vitamin E (5000–7000 U/day) can be fed for its antioxidant effect. If there is sonographic evidence of placental edema and thickening, IV dimethyl sulfoxide (DMSO) (0.5–1.0 g/kg administered as a 10% solution) can be administered for its anti-inflammatory and antioxidant properties.

The well-being of the dam and fetus should be monitored while treating placentitis. Tocolytic agents should be discontinued if fetal demise is suspected. **Termination** of the pregnancy should be pursued if the dam shows systemic signs of endotoxemia (*q.v.*). Delivery should be attended since there is an increased risk of premature placental separation, dystocia, retained placenta and the birth of a weak, hypoxic foal.

PREMATURE SEPARATION OF THE CHORIOALLANTOIS ("RED BAG")

Normally, at the end of the first stage of parturition, the chorioallantois bulges into the cervix and then ruptures in the area over the cervix (cervical star), releasing the allantoic fluid ("**first water**"). This lubricates the birth canal and allows passage of the foal. Normally, because the placenta is still attached to the endometrium and functioning, oxygen exchange continues. However, if the chorioallantois does not rupture, and the foal is delivered within this membrane, contact between placenta and endometrium is disrupted and fetal hypoxia occurs.

Clinical signs

If the chorioallantois fails to rupture at the cervical star and the second stage of labor commences, a "**red bag**" (prematurely separated chorioallantois) (*q.v.*) may appear at the vulvar lips as a velvety red membrane. It is not possible to predict to what degree placental oxygen exchange is compromised, but the foal may become anoxic and die or be born severely hypoxic.

Treatment

Premature separation of the chorioallantois is a medical emergency. The chorioallantois should be immediately ruptured by hand or with a blunt instrument and the foal manually delivered. Once the foal is out, rub it briskly with towels to stimulate deep breaths. The severity of asphyxiation depends on the degree and duration of placental separation and whether there is pre-existing placental disease.

Foals that are products of **premature placental separation** should be evaluated for asphyxia. Therapy includes oxygen administration and brisk rubbing to stimulate breathing. Foals that are not breathing require aggressive cardiopulmonary resuscitation (CPR) (*q.v.*).

Delivery also may be complicated by **meconium staining** of the fetus and fluids. Fetal hypoxia stimulates premature passage of meconium in utero. If this occurs, clear the foal's nose and mouth of meconium to reduce the risk of aspiration. Affected foals may benefit from oxygen via a mask or nasal cannula. **Meconium stained foals** should be monitored closely for signs of hypoxic ischemic encephalopathy (i.e. neonatal maladjustment syndrome) (*q.v.*).

DYSTOCIA

During normal parturition, the foal is delivered in an anterior longitudinal presentation, dorsal-sacral position with the forelimbs in an extended posture.

Deviations from this are the most common cause of a delayed or difficult birth. Other causes of dystocia are discussed elsewhere (*q.v.*).

Normal parturition is divided into three stages. During the **first stage**, uterine contractions occur, the fetus rotates from the dorsal-ventral or dorsal-lateral position it was in during gestation to a dorsal-sacral position, and the cervix dilates. The mare will be restless, sweat behind her elbow and flanks, urinate small amounts frequently, lie down and get up repeatedly, and appear to have colic. First stage labor lasts from 30 min to 4 h and early in this stage the mare can voluntarily delay parturition if disturbed.

Eventually, the cervical star of the chorioallantois ruptures and the allantoic fluid ("first water") is released. This marks the end of first stage labor. During the **second stage**, the fetus is expelled through the pelvic canal by continued uterine contractions and strong abdominal contractions. The second stage normally takes less than 30 min.

During the **third stage**, the uterus continues to contract and the fetal membranes are expelled within 15–90 min. If the placenta has not been passed after 3 h, treatment should be instituted.

If the second stage is not progressing normally, i.e. if after 15–20 min two forelegs and a nose are not seen at the vulvar lips, an examination should be performed to determine whether there is **malpresentation**. The mare's tail will already have been wrapped and the perineum should now be cleansed thoroughly. It is critical to maintain hygiene and use **plenty of lubrication**. The operator should thoroughly scrub arms and hands. Water-soluble methylcellulose lubricant is preferred because large volumes can be pumped into the uterine lumen using a sterile stomach tube and pump, if necessary. Petrolatum jelly may offer better protection to the vagina if a fetotomy is to be performed, but should be avoided if a Cesarean section (*q.v.*) is anticipated because it can be quite irritating to the peritoneal cavity.

It is preferable for the mare to remain standing during the initial examination. Care should be taken to prevent injury to the mare and operator. In many cases, restraint by a twitch or lip chain may permit initial examination.

Sedation should be avoided because it may depress the fetus. **Acepromazine maleate** (0.07 mg/kg IV) can be used to quiet the mare. If more sedation and analgesia are needed, 0.44 mg/kg **xylazine** IV followed in 5 min by 0.044 mg/kg **butorphanol tartrate** IV can be effective. **Caudal epidural anesthesia** (lidocaine 0.5–1.0 mL 2% per 100 kg body weight [BW]) may help stop straining by the mare. A possible 30 min delay to effect may be too long for it to be of assistance. It is important to evaluate the fetus and birth canal carefully in making the diagnosis.

Treatment

There are many causes of dystocia, including malpresentation, fetal–maternal disproportion, uterine abnormalities (such as torsion, inertia, ruptured prepubic tendon, pelvic and perineal abnormalities) and fetal abnormalities (such as skeletal malformation or fetal emphysema) (*q.v.*). The most common cause of dystocia in the mare is **fetal malpresentation**, particularly flexion of the anterior limbs or head and neck. This discussion of treatment will be confined to these common problems.

After a diagnosis of malpresentation has been made, a plan to correct the problem must be instituted. The birth canal and uterus should be **well lubricated** with a water-soluble lubricant. Great care should be taken to maintain **good hygiene** and avoid unnecessary contamination of the uterus.

Many malpresentations can be corrected with **mutation and traction**. Deviation of a fetus' forelimb is relatively common in the mare. The limb may be flexed at the carpus or extended back alongside the fetus' body. In such cases, the fetus should be repelled. The limb position can then be corrected by repelling the foot while rotating the carpus laterally. This manipulation reduces the longitudinal arc that the foot must traverse through the birth canal. Traction can be applied to the extremity by applying an **obstetric chain** dorsally above the fetlock with a second half loop over the pastern to extend the limb.

If the **head and neck** are deviated, first determine the position of the head. If the mare is in lateral recumbency and the head in a lateral posture, reposition the mare so that the head is above the fetal body. **Repulse the fetal body** to make room to manipulate the head and neck. Loop a chain around the neck and grasp the muzzle or eye orbits with finger, hook or snare to extend the head and neck. Sometimes it is helpful to flex and repel the limb on the side of the head deviation to provide more space for manipulation. Once posture is corrected, traction should be applied to both front legs and head by pulling out and down toward the mare's hocks as opposed to straight out behind the mare.

If the position cannot be corrected, it may become necessary to perform a **fetotomy** or **Cesarean section** (*q.v.*). To proceed with a fetotomy, amputation of the head and neck at the base of the neck may allow vaginal delivery of the fetus. Extensive fetotomy procedures often result in irreparable damage to the reproductive tract. Accordingly, it is generally felt that if difficult dystocias cannot be relieved using no more than two fetotomy cuts, a Cesarean section is warranted.

Because retained placenta and uterine contamination frequently occur in association with dystocias, broad-spectrum antibiotics and non-steroidal anti-inflammatory drugs (NSAIDs) should be administered.

UTERINE RUPTURE

Perforation of the uterus may occur with or without evidence of dystocia. Tears tend to occur either at the tip of a uterine horn or just cranial to the cervix. Death due to hemorrhagic shock may occur if the rupture is extensive. Contamination and hemorrhage into the abdomen may cause peritonitis (*q.v.*).

Clinical signs

The mare may be febrile, anorexic, endotoxic, have an elevated heart rate and be in shock (*q.v.*). The severity of illness depends on the degree of abdominal inflammation and hemorrhage. The tear is usually not palpable per rectum, but an atypically small and tonic uterus for the stage post partum may be felt. Palpation of the uterus per vagina frequently is sufficient to locate the laceration. **Transmural palpation** of the uterus (one hand per rectum and one hand per vagina) may help in evaluation of some tears, especially those that are partial thickness. The tips of the horns, which may be difficult to reach immediately after delivery of a foal, should be carefully evaluated. **Abdominocentesis** (*q.v.*) assists in the detection of peritonitis and hemorrhage.

Treatment

Uterine lavage is to be avoided if there is any suspicion of a **laceration**. Administration of broad-spectrum antibiotics and NSAIDs is necessary if **peritonitis** (*q.v.*) is present. Poor exposure of the uterine defect at laparotomy may make surgical repair difficult. However, if uterine contents continue to cause abdominal contamination, the laceration will need to be sutured. Some lacerations will heal on their own, but **adhesions** may occur, depending on the degree of peritonitis (*q.v.*).

UTERINE ARTERY RUPTURE

Older (≥ 11 years) multiparous mares are prone to rupture of the **uterine artery** during late gestation or at parturition, but the exact cause is unknown.

Clinical findings

Hemorrhage may be free flowing in the abdomen or uterine lumen or can form a hematoma as blood is trapped within the broad ligament. If it occurs at **parturition**, the mare will continue to **sweat** and **appear anxious** after the foal has been delivered. Respiration and heart rates will be elevated and the mare may be weak and stagger. If hemorrhage dissects between planes of uterine tissue, the mare will tend to be more uncomfortable and show a more severe degree of **colic**. The mucous membranes will be pale and packed cell volume may decrease dramatically. Many mares may curl their upper lips frequently. If hemorrhage is severe enough, the mare will go into shock and die. Death is often sudden and can occur within half an hour of delivery or days later.

If hemorrhage is confined within the **broad ligament**, it may be possible to palpate and visualize the hematoma by ultrasonography per rectum. In acute conditions, these procedures may be contraindicated because they may exacerbate the mare's condition. Peritoneocentesis and uterine examination per vagina will help determine the location of the hemorrhage.

Treatment

It is recommended that the mare be kept as quiet as possible, in her own stall with the lights turned out, and exposed to minimum disturbance. Some sources recommend administration of **acepromazine** (0.01–0.02 mg/kg IV) to decrease anxiety and to lower blood pressure and help stop the bleeding. However, if blood pressure is already critical, the acepromazine may cause shock and death.

Transfusion of large quantities of blood may help, but it is difficult to administer sufficient amounts rapidly enough to be effective. **Oxytocin** (20 IU IM q 60 min) helps decrease myometrial hemorrhage and/or intrauterine bleeding only. Oxytocin should not be administered if there is a hematoma within the broad ligament. **Flunixin meglumine** (1.0 mg/kg IV q 12–24 h) should be given to decrease pain. Clinical reports indicate that **naloxone** (4 mg) may help a mare that is in shock and may prevent death. IV fluids can be administered if the mare shows signs of hypotensive shock.

Aminocaproic acid (10–20 mg/kg diluted in 1–3 L saline) administered slowly IV in the fluids may help reduce ongoing hemorrhage but should not

be administered during acute stages. IV formaldehyde has also been given to control hemorrhaging with anecdotal success. However, controlled studies using IV formaldehyde failed to demonstrate any significant effect on parameters of hemostasis. The recommended dose is 10 mL of 37% formaldehyde in 1 L of lactated Ringer's solution administered IV over 15 min. Higher doses may produce undesirable side effects including tachycardia, lacrimation, salivation and muscle fasciculations. **Antibiotic administration** is recommended for surviving mares to reduce the risk of secondary infection associated with bleeding into the uterus or peritoneal cavity.

Some cases have been saved by **surgical ligation** of the ruptured vessel. This is possible only if the affected vessel can be identified. Frequently, adequate exposure of the vessel is not possible and the mare may die under anesthesia during surgery.

Mares that recover from a uterine artery rupture are thought to be at a higher risk to experience more severe hemorrhage in subsequent pregnancies. Likewise, there are some mares that foal uneventfully during later pregnancies.

PERINEAL LACERATION

Perineal lacerations occur at the time of parturition.

Etiology/clinical signs

First-degree laceration involves tearing of the mucosa of the vestibule or vulvar lips. It often involves the dorsal commissure of the vulvar lips due to rapid stretching during expulsion of the foal or failure to adequately open a Caslick vulvoplasty (*q.v.*). **Second-degree** laceration involves mucosa and submucosa of the vestibule or vulva and perineal body musculature. **Third-degree** laceration involves vaginal mucosa, perineal body and anal sphincter. A **recto-vestibular fistula** is an opening between the vagina and/or vestibule and rectum that does not involve the anal sphincter or pudendal body. These conditions result when the foal's feet fail to pass the vestibular fold and are pushed dorsally through the vaginal wall into the rectum.

Treatment

A first- or second-degree laceration may be surgically repaired soon after foaling. If extensive tissue damage with subsequent necrosis has occurred, surgical repair should be delayed. Repair of third-degree lacerations or fistula is generally delayed until at least 1 mo after foaling or after weaning to give devitalized tissue time to repair. These repairs may require two to three procedures. Success requires proper preparation of the mare's fecal consistency by diet manipulation.

UTERINE PROLAPSE

Uterine prolapse (*q.v.*) rarely occurs in the mare because of the cranial attachment of the broad ligaments, and is more likely to occur following retained placenta or dystocia. Presence of the uterus, cervix or vagina at the vulvar lips is indicative of prolapse.

Treatment

The prolapsed uterus should be **carefully inspected** for lacerations and cleansed with **sterile saline**. Harsh antiseptics should be avoided. If the placenta is loosely attached, it should be possible to remove it. The uterus is then replaced into the abdomen, care being taken to position the uterine horns properly. The vulva is closed with heavy suture material to prevent re-prolapse. If the placenta is not easily removed, sufficient space must be allowed for the expelled portion to hang from the vulva.

NSAIDs such as **flunixin meglumine** (0.25–0.35 mg/kg IV q 8 h) or phenylbutazone (2.2–4.4 mg/kg q 12 h) are indicated together with broad-spectrum antibiotics such as penicillin (**benzylpenicillin potassium**, 22 000 IU/kg q 6 h) and gentamicin (**gentamicin sulfate**, 6.6 mg/kg q 24 h or 2.2 mg/kg q 6 h) until uterine involution has occurred. A low dose of **oxytocin** (10–20 IU) may help tone and decrease the size of the uterus.

RETAINED PLACENTA

The interval from delivery of the fetus to passage of the placenta (third stage labor) is short in the mare (usually ≤ 3 h). The exact time when the presence of placenta becomes pathological (i.e. is a “retained” placenta) is variable (*q.v.*). Feral mares have been observed with placenta retained for up to 48 h without evidence of illness and have subsequently shown continued fertility by producing a foal within the ensuing 12 mo. In contrast, severe complications, even death, can be sequelae of placenta retained < 8 h. Degree of difficulty of parturition, degree of contamination of and trauma to the reproductive tract, frequency of foal nursing, and physical activity may all influence the outcome.

Clinical signs

Diagnosis of **retained placenta** (*q.v.*) is by: (1) observation of the presence of fetal membranes hanging from the vulvar lips > 3 h after parturition; or (2) examination of the passed membranes revealing that portions are missing that cannot be accounted for by trauma in the stall (mare stepping on them). The mare may become febrile and show signs of endotoxemia and laminitis (*q.v.*).

Treatment

If placental membranes are retained, the treatment schedule to be followed should be as in Table 14.1. If dystocia and uterine contamination have occurred, treatment with antibiotics and NSAIDs should be initiated soon after birth.

In some instances, the placenta is detached but remains within the uterus. In such cases, it is acceptable to lift and apply **gentle traction**. Otherwise, manual removal, and especially any kind of forced detachment, is contraindicated because hemorrhage may occur and small portions of chorion may be torn and remain in the uterus. Studies in cattle report that manual removal lowers subsequent fertility.

Infusion of the allantoic cavity with 10–12 L sterile saline will re-distend the uterus and cause release of endogenous oxytocin. Although this technique may be successful by physiologic mimicking mechanisms, extreme hygiene and care are necessary to avoid uterine contamination.

Table 14.1 Treatment schedule for retention of placental membranes

<3 h	No treatment
3–8 h	Bolus oxytocin 20 IU IM or IV; repeat q 2–3 h until passage is complete May give oxytocin saline with 500 mL calcium borogluconate added as IV drip administering 0.5–1.0 IU/min
<8 h	Continue oxytocin Administer broad-spectrum antibiotics such as penicillin (20 000 IU/kg IV q 6 h) and gentamicin (6.6 mg/kg IV q 24 h) Administer NSAID such as flunixin meglumine (0.25–0.35 mg/kg IV q 8 h) or phenylbutazone (2.2 mg/kg q 12 h)

POST PARTUM ENDOMETRITIS/METRITIS

Uterine involution is rapid in the normal mare and is histologically complete within 7–11 days, which coincides with the first post partum estrus (“foal heat”) (*q.v.*).

Following parturition, most normal mares experience a **transient endometritis frequently associated with a β -hemolytic streptococcal infection** (*q.v.*). Such endometritis usually resolves spontaneously and only rarely requires therapy.

Etiology

If dystocia, significant uterine contamination, or retained placenta occurs, the fetus does not suckle, or the environmental situation prevents proper exercise for the mare, **metritis** may occur.

Clinical signs

Metritis differs from endometritis in that the myometrium is also inflamed.

The mare may exhibit systemic signs of fever, anorexia, elevated heart rate, congested mucous membranes, endotoxemia and laminitis (*q.v.*). Physical examination of the uterus by palpation per rectum reveals an open cervix and enlarged flaccid uterus that may expel fetid, muddy brown fluid with manual pressure. The uterus does not respond to manual manipulation by contracting and increasing its tone as occurs in a uterus undergoing normal involution.

Treatment

The uterus should be **lavaged daily** with several liters of warm (45°C) sterile saline until the character of the effluent is similar to that of the sterile saline. Harsh antiseptics are to be avoided because they can exacerbate tissue inflammation.

Oxytocin (20 IU IV and 20 IU IM) may help to empty the uterus completely of its fluid. Exercise after administration of oxytocin will enhance the mechanical emptying of the uterus. Infusion of the uterus with antibiotics will do little in the presence of large amounts of uterine fluid.

Systemic broad-spectrum antibiotics (penicillin 22 000 IU/kg q 6 h, gentamicin 6.6 mg/kg q 24 h or 2.2 mg/kg q 6 h) and **NSAIDs** (flunixin meglumine 0.25–0.35 mg/kg IV q 8 h or phenylbutazone 2.2 mg/kg q 12 h) should be administered if the mare exhibits any systemic signs of illness.

CERVICAL LACERATION

Etiology

Cervical laceration can occur during an otherwise normal spontaneous delivery or during manipulation of the fetus during correction of a dystocia (particularly if a fetotomy was performed). There may be no clinical signs other than failure to maintain pregnancy.

Diagnosis

Thorough evaluation of the cervix requires **manual palpation per vagina** of the entire cervix during diestrus or while the mare is under the influence of exogenous progesterone. A laceration is likely to have occurred if a portion of the cervix is absent. Sufficient mucosa and muscular portions of the cervix must be present to form a competent cervical canal. Frequently, **cervical adhesions** may occlude the lumen or prevent adequate closure of the cervix.

Treatment

The treatment of choice is surgical repair; however, the endometrium should be evaluated for soundness prior to surgery. Surgery may be performed with the mare under epidural anesthesia or xylazine–morphine tranquilization (*q.v.*).

Lacerations can be repaired surgically by separating the luminal mucosa, muscularis and vaginal mucosa and suturing each respectively to re-establish a competent canal. Lacerations tend to recur at each subsequent foaling.

MANAGEMENT OF THE HIGH-RISK PREGNANCY

INTRODUCTION

Considerable attention has been focused on how to improve conception rates in the mare and how to save the **critically ill foal**. Once the mare is confirmed pregnant and there is no evidence of twinning, veterinary attention frequently wanes until parturition. Following delivery, sophisticated and aggressive intensive care strategies have been developed to improve survival rates of compromised foals. Many foals still die, not because their primary problem is untreatable, but because veterinary intervention was delayed, delivery was unattended, or neonatal compromise was not recognized in a timely fashion. **Close supervision** of a mare at risk for an abnormal pregnancy or difficult parturition allows earlier detection, treatment and/or possible prevention of neonatal disease.

The three periparturient events that have the most devastating effect on neonatal survival are **hypoxia**, **infection** and **derangement of in utero development**. Periparturient monitoring should focus on early recognition of these events to permit rapid post partum treatment of the affected neonate and investigation of therapy designed to ameliorate these conditions pre partum. Recognition of periparturient events associated with high-risk foals (Box 14.1) helps to identify mares that warrant close pre partum monitoring.

When considering problem pregnancies there are three populations of mares: (1) mares with histories of abnormal deliveries; (2) mares at risk for a problem

Box 14.1 Periparturient conditions associated with high-risk pregnancy**Maternal factors**

- Severe systemic disease: colitis, hepatic disease, pneumonia/pleuritis
- Severe neurologic disease: equine protozoal myelitis, cervical cord compression, herpes myelitis
- Endocrinopathy: Cushing's syndrome, fescue toxicosis/ergopeptine toxicity
- Endotoxemia
- Abdominal surgery/general anesthesia
- Fever
- Anemia
- Severe hypoproteinemia
- Severe malnutrition
- Premature udder development/vaginal discharge/precocious lactation
- Hydrops allantois/amnii
- Prepubic tendon rupture
- Pelvic injuries
- Severe endometrial fibrosis
- Premature labor
- Production of poor quality colostrum

Placental factors

- Small placenta
- Placentitis: bacterial, fungal, nocardioform
- Premature placental separation
- Umbilical cord complications: umbilical cord torsion, excessively short cord
- Vasculitis, edema
- Thrombosis, infarction
- Placental insufficiency

Periparturient factors

- Induction of labor
- Dystocia
- Cesarean section
- Postmaturity syndrome
- Early umbilical cord rupture
- Premature placental separation (acute)
- Prolonged labor, uterine inertia

Fetal/neonatal factors

- Congenital anomalies
- Chromosomal anomalies
- Cardiopulmonary disease
- Inherited immunodeficiency disease
- Infection
- Prematurity/dysmaturity
- Twinning
- Failure of passive transfer

with the current pregnancy; (3) mares with no apparent risk factors that experience an abnormal periparturient event. Premature placental separation, dystocia, placentitis and premature delivery (*q.v.*) are examples of recurrent problems some mares experience during successive pregnancies. Regardless of the mare's past reproductive history, the following conditions during late gestation increase the risk of an abnormal pregnancy outcome: severe maternal illness and debilitation, general anesthesia, acute abdominal crisis, vaginal discharge, premature udder development or excessive abdominal enlargement. Mares in the first two groups are candidates for more **intensive periparturient monitoring** to evaluate maternal and fetal well-being. These high-risk mares should be assured of an attended delivery in a facility capable of providing assistance during parturition, post partum resuscitation and stabilization of the newborn foal.

Management strategies for the high-risk mare involve the use of physical and biochemical parameters to assess the health of the fetoplacental unit.

PERIPARTURIENT ENDOCRINOLOGY

The exact mechanism regulating parturition in the mare is unknown. Current concepts of hormonal regulation of gestation are discussed in detail elsewhere (*q.v.*).

During early pregnancy, **progesterone** (*q.v.*) is produced by the primary and secondary corpora lutea. The placenta begins to produce progesterone during the first trimester and eventually becomes the sole source of this hormone after the corpora lutea have ceased to function between Days 150 and 200. The developing fetus and placenta produce other progestogens, primarily α -pregnanes and pregnenolone, which contribute to support of the pregnancy beginning around Day 60.

Understanding the role of progesterone and maintenance of pregnancy during late gestation is confounded by the fact that there is cross-reaction between the α -pregnanes and progesterone. Most progesterone assays measure only progesterone and not fetoplacental progestogens. Yet both groups of metabolites contribute to maintenance of pregnancy.

During the first trimester, several clinical conditions have been associated with **inadequate maternal progesterone** concentrations and pregnancy loss. Mares with **endometritis** may experience premature luteolysis and low progesterone concentrations. **Severe stress**, such as fatigue or food deprivation, may cause decreased progesterone levels and jeopardize pregnancy. Endotoxemia and surgical manipulation of the uterus result in abortion via $\text{PGF}_{2\alpha}$ secretion, compromised luteal activity and inadequate progesterone production. **Progesterone supplementation** (0.044–0.088 mg/kg PO q 24 h) in these instances can certainly be justified. Administration of flunixin meglumine (0.25 mg/kg IV q 8 h) is beneficial due to its ability to inhibit prostaglandin production.

Elevated **estrogen concentrations** are present in maternal blood and urine during the second half of gestation with peak values obtained during the 7th and 8th month followed by a gradual decline thereafter. There are two main groups of estrogens in the mare: common phenolic estrogens (estrone and estradiol 17β) and ring β -unsaturated estrogens (equilin and equilenin). Fetal gonads also provide estrogen precursors such as dihydroepiandrosterone

(DHA) that are converted by the placenta to the final estrogen products. Since normal estrone sulfate concentrations (≥ 2 ng/mL) after Day 40 require a viable fetus, **estrone sulfate measurement** may be helpful in monitoring fetal viability. An accurate reference range for estrone sulfate concentrations throughout pregnancy remains to be developed.

Gonadectomized foals from estrogen-deficient mares are dysmature at birth. Labor in these mares is weak and inefficient and associated with low prostaglandin levels. Estrogens appear to play a role in normal fetal development, an effect that may be mediated by alteration of uteroplacental blood. A correlation between fetal distress, growth retardation and death and changes in maternal and urinary estrogen concentrations has been suggested. Further investigations remain to be performed before these relationships are fully understood.

FETAL ELECTROCARDIOGRAPHY

Fetal electrocardiography (ECG) can be used to confirm pregnancy and monitor fetal viability after Day 150. Twinning produces two separate heart rate patterns. **Fetal cardiac arrhythmias** occur with a variety of abnormal pregnancies. Severe bradycardia often indicates hypoxemia and impending fetal demise.

The limb lead electrode (LA) is placed on the dorsal midline of the mare in the mid-lumbar region. The other limb lead electrode (LL) is placed approximately 15–20 cm cranial to the mare's udder on the ventral midline. Alcohol or ECG gel should be used to improve skin contact with the electrodes. The hair should be clipped prior to lead placement. Maternal ECG deflections are larger and slower and usually have a different polarity than those of the fetus. Fetal ECG polarity is variable and depends on fetal position. A poor fetal signal may result from fetal movement, improper electrode placement or electronic noise. See also Chapter 8, page 455.

TRANSABDOMINAL ULTRASONOGRAPHY

Transabdominal ultrasonography allows non-invasive monitoring of fetal development and assessment of fetal well-being during mid and late gestation. Due to the deeper tissue penetration required to image the fetus in late gestation, transducers with lower frequencies of 2–4 MHz are used. In preparation for scanning, the mare's ventral abdomen is cleaned and clipped. A viscosity coupling gel is applied to the abdomen and transducer. This abdominal approach can be used after the gravid uterus contacts the ventral abdominal wall after Day 150 of gestation but is used most frequently during the second and third trimesters.

Twins can be detected at any stage of pregnancy but are more difficult to locate during late gestation. The heart rate, presentation and position of each twin should be noted. During late pregnancy the entire gravid uterus must be explored systematically. Twins located **one on top of the other** may be mistaken for one fetus. In addition to visualizing only one fetus, it is helpful to identify the empty non-fetal horn to eliminate the possibility of twins.

Ultrasonographic assessment of fetal well-being incorporates a variety of fetal parameters into a biophysical profile. In humans this profile includes measurements of fetal heart rate, reactivity, movement, tone and breathing

patterns, and measurement of amniotic fluid volume. The placenta is examined for changes in thickness and texture and the clarity of fetal fluids is evaluated. Measurements of various fetal body parts including head circumference and femur length have resulted in elaborate in utero growth charts for various stages of gestation.

The size of the equine fetus makes some of these measurements impossible. Parameters that can be assessed in the horse include fetal heart rate (at rest and after spontaneous activity), frequency and vigor of fetal movements, aortic diameter, fetal breathing movements, measurements of placental thickness, and gross evaluation of allantoic and amniotic fluid volumes and clarity. Reliable indices of fetal size have yet to be established. Limited studies have been performed relating fetal size to measurements of fetal aortic diameter, fetal orbit diameter, biparietal diameter and thoracic girth.

Placental separation can be detected with careful methodical scanning. It is important to remember that not all of the placenta can be visualized during transabdominal examination. Transrectal ultrasonography should be used to evaluate the allantochorion in the pericervical area.

During late gestation, all fetuses exhibit some movements ranging from limb flexion to rotation about the long axis of the body. Brief periods of fetal inactivity may be associated with normal sleep patterns. Prolonged periods of inactivity (≥ 40 min) are rare and suggest fetal distress.

Fetal **heart rates** average between 60 and 100 bpm during late gestation with transient bouts of tachycardia (25–40 bpm above baseline) observed during or immediately after fetal activity. **Persistent bradycardia** is associated with fetal distress and is mediated by a vagal response to hypoxemia (*q.v.*). **Severe tachycardia** and arrhythmias have been associated with fetal stress and sepsis (*q.v.*). **Maternal sedation** will affect fetal heart rate.

Placental thickness can be estimated by measuring the uteroplacental unit and averages between 0.8–1.3 cm. Abnormally thickened placentas have been associated with placentitis and edema. Transrectal ultrasound using a 5 MHz linear transducer provides an excellent image of the allantochorion in the area of the cervical star. An increased measurement during mid to late gestation (>7 mm prior to 270 days of gestation, >8 mm between Days 271 and 300, >10 mm between Days 301 and 330, and >12 mm after Day 330) suggests **placental failure** and **impending abortion**. Pockets of fluid accumulation between the placenta and uterine wall are compatible with premature placental detachment.

Fetal **aortic diameter** measurements have been used to predict fetal weight and size. The aortic diameter for near-term thoroughbred foals is approximately 2.0–2.2 cm. An abnormally small fetus detected in late gestation is compatible with an inaccurate breeding date or some form of **intrauterine growth retardation (IUGR)**. Possible causes of IUGR include perinatal infection, congenital anomalies, uteroplacental insufficiency and inadequate maternal nutrition.

The maximum ventral fetal fluid pocket depths average 8 cm for amniotic fluid and 13 cm for allantoic fluid. Excessive fetal fluid accumulation is observed in cases of hydrops. The amniotic and allantoic fluids normally become more echogenic during the last months of gestation. Free floating, swirling particles in the fluid are usually composed of mineral deposits and mucoproteins. Abnormal **particulate matter** in either fluid compartment may include blood,

meconium or inflammatory debris such as white blood cells and protein. Hemorrhage suggests loss of placental integrity. Meconium signifies fetal distress, often due to hypoxia. Inflammatory debris suggests in utero infection.

Pre partum **fetal asphyxia** may result in **renal compromise** and decreased urine production leading to a reduction in allantoic fluid volume. Dramatic decreases in fluid volume may predispose to abnormal umbilical cord compression pre partum and during birth resulting in fetal compromise. Decreased allantoic fluid volume has been associated with poor neonatal outcome and chronic hypoxia.

PRE PARTUM MAMMARY SECRETIONS

Electrolyte concentrations in pre partum mammary secretions begin to change prior to parturition. A rise in the **calcium** concentration in the precolostral milk is the most reliable indicator of impending delivery. Calcium levels >40 mg/dL have been associated with fetal maturity. A scoring system using colostral calcium, sodium and potassium concentrations helps predict “readiness to give birth” and can help determine an appropriate time for elective induction or Cesarean section. Table 14.2 lists the parameters for the scoring system.

Variations of water **hardness test strips** are used to measure the calcium concentrations in pre partum mammary secretions to predict the likelihood of foaling. These strip tests are marketed under a variety of names: Predict-A-Foal Test (Animal Health Care Products, Vernon, CA 90054, USA) and Sofcheck (Environmental Test Systems Inc., Elkhart, IN 46514-0659, USA). Causes of false negative results using the calcium milk strip test include severe maternal malnutrition and premature delivery. Causes of false positive results include placental infection and premature lactation. Occasionally, normal mares with normal deliveries have abnormal test results. The milk strip test is not foolproof and should be used only as an aid in predicting “readiness for birth”.

FETAL FLUID ANALYSIS

Amniotic fluid (AF) can be aspirated directly from the amniotic sac immediately prior to rupture during parturition. Pre partum, amniocentesis can be performed during late pregnancy using a 20G needle with a trocar and an ultrasound-guided, transabdominal approach. The ideal location is the **AF pocket** located between the front legs and thorax of the fetus. This area is usually visualized best just cranial and lateral to one side of the dam’s mammary gland. Mares may require **light sedation** and can be pre-treated with flunixin

Table 14.2 Scoring system for electrolyte concentrations in mammary secretions

Calcium (mg/dL)	Sodium (mEq/L)	Potassium (mEq/L)	Points for each electrolyte
≥ 40	≤ 30	≥ 35	15
≥ 28	≤ 50	≥ 30	10
≥ 20	≤ 80	≥ 20	5

Total score ≥ 35 suggests probably safe induction.

Adapted from Ousey, J.C., Dudan, F., Rossdale, P.C. Equine Veterinary Journal 16: 259.

meglumine. A sharp needle is essential to allow clean penetration of the free-floating, echogenic amniotic membrane separating allantoic and amniotic fluid compartments.

Allantocentesis can be performed using a similar procedure. Fetal fluid collection remains a research tool and is not used routinely in clinical cases.

Cortisol and creatinine concentrations have been examined in amniotic fluid in relation to fetal maturation and gestational age. Preliminary results in the horse are inconclusive.

Phospholipid components of surfactant, lecithin (L), sphingomyelin (S) and phosphatidylglycerol (PG), are measured in amniotic fluid to predict fetal lung maturation and the risk for neonatal respiratory distress syndrome. In women, $L:S \geq 2.0$ and the presence of PG in amniotic fluid are associated with fetal lung maturity and a low incidence of respiratory distress syndrome. Once again, preliminary results in the horse are inconclusive.

Fetal fluid samples can also be cultured for bacteria and viruses. Samples stored frozen for several weeks have yielded positive cultures for herpes and equine viral arteritis viruses. Fetal fluid cytology can be used to detect infection. Fetal karyotyping can be performed, but is rarely used in clinical practice.

Neonatal serum creatinine concentration

Markedly **elevated serum creatinine concentrations** in foals less than a few hours of age have been associated with clinical signs of **birth hypoxia**. Since the placenta essentially functions as an in utero kidney for the fetus, it is not surprising that certain forms of placental dysfunction might result in **fetal azotemia**. Peri partum hypoxia can also cause primary renal tubular damage resulting in persistent neonatal azotemia post partum.

Neonatal serum glucose concentration

Presuckle hypoglycemia (glucose <35 mg/dL) immediately following birth is suggestive of placental dysfunction and hypoxia. Persistent hypoglycemia during the first 48 h post partum suggests immature insulin response and marginal glucose reserves. Hyperglycemia (glucose >180 – 200 mg/dL) is associated with hypoxia-induced pancreatic endocrine dysfunction, sepsis-induced release of glucagon, catecholamines and cortisol resulting in peripheral insulin resistance (*q.v.*).

Equine fetal protein

Alpha-fetoprotein (AFP) is a glycoprotein produced primarily by the fetal liver. Other sites of synthesis include the yolk sac, placenta and fetal gastrointestinal tissues. AFP is closely related to albumin. Its function is unclear, but may include the role of a transport protein. This fetal specific protein has been identified in numerous mammalian species including sheep, cattle, pigs and horses. The highest concentrations are in fetal serum, fetal urine and fetal CSF. Decreasing amounts are present in fetal fluids and the sera of pregnant females.

AFP is secreted via fetal urine into amniotic fluid in women and into allantoic fluid in horses. Trace amounts of AFP enter the maternal circulation

transplacentally or by direct diffusion. In pregnant women, elevated AFP concentrations are associated with open neural tube defects, multiple births, fetal demise, fetal distress, congenital defects, low birth weight, placentitis and spontaneous abortion. Abnormally low levels have been associated with poor fetal outcome and chromosomal defects. Today AFP testing in women is used primarily to screen for open neural tube defects during the second trimester.

In pregnant mares, elevated equine fetal protein (EFP) concentrations have been associated with **premature placental separation**, the birth of **maladjusted foals, twinning, placentitis** and **uterine trauma**. The highest values are observed in mares with placentitis and recent or impending fetal demise. The test is a microtiter plate ELISA. In normal pregnant mares, serum EFP concentrations range between 4 and 10 units/mL. Normal values are currently being established for amniotic and allantoic fluids. Foal EFP concentrations are dramatically higher than those of their dams and decrease to adult levels within 100 days post partum.

APGAR SCORE

The APGAR score is used to evaluate the degree of **birth asphyxia** immediately post partum. APGAR stands for Appearance, Pulse, Grimace, Activity and Respiration (see Table 14.9, page 819). These parameters should be assessed continuously during the first 5–15 min of life to help determine the degree of birth asphyxia and need for neonatal resuscitation.

OTHER SURVEILLANCE METHODS

Mares under observation for signs of foaling should be checked frequently by trained attendants. Closed-circuit, stall-mounted television cameras facilitate periparturient monitoring. Other currently available delivery detecting devices include Foalert, Breeder Alert and Birth Alarm. The alarm system on all of these devices can also be connected to the phone lines and set to dial automatically specified numbers such as those of the veterinarian, farm manager, etc. The Foalert involves suturing a transmitter attached to an actuating magnet to the lips of the vulva. When the foal enters the birth canal, the vulva lips are parted, the magnet is activated and the alarm is transmitted to a pocket pager and the phone system. The Breeder Alert utilizes a monitor attached to the halter that activates the paging system whenever the mare lays down in lateral recumbency for >30 s. The Birth Alarm uses a transmitter attached to an anti-roll surcingle device that activates an alarm or paging system when the mare lays down in lateral recumbency.

EVALUATION AND MONITORING OF THE HIGH-RISK MARE

Any mare considered at increased risk of a problem pregnancy should receive a **complete physical examination**. Treatment of concurrent medical or surgical problems should proceed with maternal and fetal well-being in mind. Any maternal event that reduces uteroplacental circulation and/or oxygenation poses an immediate threat to fetal well-being.

The diffuse epitheliochorial equine placenta is a more permeable barrier than the cotyledonary ruminant placenta. Oxygen, pH and glucose gradients between fetus and dam are far less in the mare than in the sheep or cow. In the ruminant, wide swings in maternal oxygen concentrations produce comparatively little change in fetal oxygenation. However, due to the more efficient oxygen exchange in the mare's placenta, maternal hyperoxia and hypoxia are accompanied by even greater changes in fetal oxygen levels.

While **maternal hypoxia** represents a relatively greater threat to the equine fetus, oxygen supplementation in the mare has the potential to improve dramatically certain forms of fetal hypoxia. Because of the more efficient transplacental glucose exchange in the mare, prolonged periods of maternal hypoglycemia must also be avoided. Force feeding or glucose supplementation should be considered for pregnant mares that are completely anorexic.

The **reproductive tract** can be evaluated initially by palpation and ultrasonography per rectum to appreciate fetal movement, gross body position and cervical tone. Sonographic visualization and measurement of the fetal orbit confirms anterior presentation and provides a rough estimate of fetal size. Transabdominal ultrasonography provides a more rewarding assessment of fetal well-being, fetal position and gross changes in placental integrity. When no fetal movement can be detected on rectal palpation, transabdominal ultrasonography can evaluate fetal viability by observing the absence or presence of fetal heart rate.

Although maternal **hypertension** is a serious complication in women, it has not been documented to occur in the mare. It is plausible that hypertension may develop in mares suffering from severe laminitis or other painful conditions. Blood pressure is easily monitored using a pneumatic cuff, the Doppler technique and the middle coccygeal artery. Severe untreated hypertension may impair uteroplacental perfusion.

Pre partum mammary secretions should be evaluated for rising calcium concentrations as a sign of impending parturition as soon as secretions are easily obtained from the gland. Monitoring frequency should increase to every 24 or 48 h when calcium concentrations begin to rise.

Near-term mares should be evaluated daily for signs of vulva elongation, sacroiliac ligament relaxation and degree of mammary development.

PERI PARTUM INTERVENTION

Pharmacologic intervention pre partum remains conservative in the mare. Seriously ill or stressed mares during the first trimester are candidates for pregnancy loss due to **progesterone deficiency** and benefit from exogenous progesterone administration to maintain progesterone concentrations >4 ng/mL. Only two forms of progestogen are readily available for use in the mare. Progesterone in oil requires IM injections of 150 mg daily. **Altrenogest**, a synthetic progestin, can be given orally at a dose of 0.044 mg/kg. Once begun, progesterone supplementation should continue through to Day 100. Progesterone administration after the first trimester remains controversial.

The abortifacient effect of **endotoxemia** (*q.v.*) in mares early in pregnancy is mediated indirectly through PGF_{2α} secretion, compromised luteal activity and inadequate progesterone secretion resulting in fetal death. **Flunixin meglumine**

(1.1 mg/kg IV) administered prior to or immediately after the onset of endotoxemia is believed to prevent early pregnancy loss by inhibiting synthesis and release of $\text{PGF}_{2\alpha}$. Successful treatment depends on early recognition or a high index of suspicion of endotoxemia.

A second mechanism that may be involved in endotoxin-induced fetal death and abortion is **compromised uteroplacental perfusion** associated with the systemic inflammation, cardiovascular collapse, hypotension and coagulopathies associated with endotoxemia. Therefore, administration of **flunixin meglumine** is a reasonable therapy for any pregnant mare at risk for endotoxemia.

In women, β -adrenergic agonists such as ritodrine, terbutaline and isoxsuprine have been used to improve uteroplacental blood flow and to prevent premature contractions. The use of these agents for these purposes in the pregnant mare is still experimental.

Mares examined for a potential **high-risk pregnancy** should have a database completed as outlined in Box 14.2. A careful history helps identify what problems to anticipate.

Box 14.2 Database for high-risk pregnancies

Signalment

- Age
- Breed

Past reproductive history

- Number of previous pregnancies
- Outcome of past pregnancies: if abnormal, classify as pre partum, intra partum, or post partum complications
- Length of gestation(s), date of delivery(ies), sex of foal(s)
- Results of most recent uterine biopsy/culture

Current reproductive history

- Date last bred
- 340 day due date
- Description of current medical problems
- Recent drug administration
- Presence of vaginal discharge or premature udder development
- Vaccination

Initial work-up and pre partum monitoring

- Physical examination
- Body weight
- Rectal palpation
- Vaginal examination (only if indicated clinically)
- Transrectal ultrasonography
- Transabdominal ultrasonography
- Blood pressure
- Mammary secretion electrolyte concentrations (as soon as secretions easily obtained)

Box 14.2 continues on page 798

Box 14.2 Database for high-risk pregnancies [continued]

- Daily evaluation of pelvic ligament relaxation, udder development, vulva elongation
- Frequent visual observation for signs of parturition (with or without the aid of television monitors and labor detection devices)

Post partum evaluation: mare

- Evaluation of placenta: description, weight, histopathology
- Specific gravity of colostrum
- Palpation/ultrasonography per rectum to evaluate uterine involution

Foal

- Physical examination
- White blood cell count, differential
- Fibrinogen
- Glucose
- Creatinine
- Blood culture if foal, placenta or delivery is abnormal
- Arterial blood gas if foal is weak or shows signs of respiratory distress
- IgG concentration between 12 and 18 h of age

Special **management guidelines** for various periparturient conditions are presented in Table 14.3. Frequent surveillance of a late pregnant mare is essential to ensure that delivery is attended. All the supplies required for a rectal examination, vaginal examination, epidural, correction of a dystocia and neonatal resuscitation should be readily available (Box 14.3).

Vaginal delivery is the preferred route of parturition. However, **induction of parturition** should be considered when abnormal conditions such as a non-reassuring biophysical profile or ultrasonic evidence of premature placental separation (*q.v.*) exist. A history of severe dystocia, or an obstructed pelvic canal secondary to previous trauma, urge consideration of an elective Cesarean section (*q.v.*). Other indications for induction or Cesarean section are presented in Box 14.4.

Whenever delivery is being artificially controlled, the mare should be as close to her physiologic due date as possible without jeopardizing fetal or maternal health. Gestation length beyond 320 days, pelvic ligament relaxation, udder development with colostrum-like secretions in the gland, and cervical dilatation are all encouraging signs that termination of the pregnancy will result in a close-to-term foal.

If a premature foal is anticipated, the most life-threatening neonatal condition is **respiratory distress** due to **primary surfactant deficiency**. Post partum intratracheal instillation of artificial or bovine origin surfactant is being evaluated for such foals.

During late pregnancy, satisfactory induction has been achieved using a slow, **continuous infusion of oxytocin** at a rate of 1 IU/min. Delivery frequently ensues within 30–40 min after beginning the oxytocin drip. The infusion is slowed to 0.5 IU/min after birth until the placenta is passed. Small IV/IM boluses of 2.5–5.0 IU oxytocin given every 20–30 min have also produced a gradual onset of labor and delivery.

Table 14.3 Management guidelines for selected causes of high-risk pregnancies

Maternal condition	Effect on pregnancy	Monitoring/treatment
Endotoxemia	Compromised uteroplacental perfusion; PG mediated abortion	Anti-endotoxin plasma; fluid therapy; flunixin meglumine; \pm progesterone; transabdominal US
Abdominal surgery/ general anesthesia	Compromised uteroplacental perfusion; anesthetic depression of fetus	Minimize duration of surgery; flunixin meglumine; progesterone; maintain adequate maternal PaO ₂ , BP; transabdominal US
Severe neurologic disease	Difficult delivery; possible trauma to mare or foal	Attended delivery; safe footing for mare; sling support if necessary
Severe hypoproteinemia	Compromised uteroplacental circulation	Fluid support; plasma; transabdominal US; high nutritional plane
Placentitis/purulent vaginal discharge/ premature lactation	In utero fetal infection; PG-induced premature delivery	Systemic broad-spectrum antibiotics; flunixin meglumine; progesterone; transabdominal US; immediate post partum neonatal evaluation; bloodwork, cultures
Pelvic injuries	Dystocia due to abnormal pelvic inlet	Assisted delivery; elective Cesarean section
Hydrops allantois	Fetal/uteroplacental compromise; maternal hypotension, cardiopulmonary collapse post partum; prepubic tendon rupture	Transabdominal US; induced, controlled delivery; maternal fluid and O ₂ support; abdominal belly wrap
Poor colostrum production	Neonatal FPT; increased risk of neonatal sepsis	Evaluate colostrum quality; provide alternate source of colostrum or plasma transfusion
Postmaturity syndrome	In utero fetal growth retardation and chronic hypoxia	Transabdominal US; induced delivery; evaluation of maternal endocrine function; uterine biopsy
History of premature placental separation	Fetal hypoxia	Transabdominal US; maternal O ₂ therapy; induced delivery; neonatal resuscitation

FPT, failure of passive transfer; PG, prostaglandin; US, ultrasonography.

Box 14.3 Supplies for foaling cart

Obstetric equipment

- Rectal sleeves and lubricant
- Clean, stainless steel bucket
- Cotton and bactericidal scrub for cleaning purposes
- Tail wrap
- Sterile nasogastric tube, pump, obstetric lubricant for use during dystocia
- Sterile lubricant and gloves for vaginal exam
- Light source for vaginal exam
- Obstetric straps or chains and handles
- Lidocaine, 18 G needles, 10 mL syringe for epidural

Box 14.3 continues on page 800

Box 14.3 *Supplies for foaling cart [continued]*

- IV catheters, fluid administration sets
- Xylazine, butorphanol for mare restraint if needed

Minimal resuscitation equipment

- Oxygen source: O₂ tank, wall source, oxygen concentrator
- Intranasal oxygen cannulas and oxygen tubing
- Ambu bag or oxygen demand valve
- Cuffed nasotracheal tubes (7–11 mm diameter, 55 cm long)
- Sterile lubricant and gloves
- Suction pump and tubing
- Towels
- Heat source
- IV catheters, fluid administration sets with coiled extension sets
- Liter bags of balanced electrolyte and dextrose-containing fluids
- Emergency drugs: adrenaline/epinephrine, calcium, bretylium, lidocaine, bicarbonate

Box 14.4 **Management of parturition****Indications for induction**

- History of premature placental separation and the birth of dead or hypoxic foals
- Sonographic evidence of fetal death or severe distress, large areas of placental separation
- Prolonged, unproductive first stage labor that fails to progress, uterine inertia
- Severe maternal illness that threatens fetal well-being
- Post-date pregnancy with evidence of severe fetal distress or growth retardation
- Prepubic tendon rupture
- Hydrops amnii or allantois

Indications for Cesarean section

- Severe dystocia
- Recurrent history of severe dystocia
- Pelvic injury resulting in obstruction of the birth canal
- Life-threatening gastrointestinal compromise in the dam necessitating exploratory celiotomy

If **Cesarean section** (*q.v.*) is indicated, it is important to keep the duration of fetal anesthesia to a minimum and to avoid intraoperative episodes of severe maternal hypotension or hypoxemia. Newborn foals experiencing **respiratory distress** from narcotics administered to the mare should receive an appropriate dose of a reversing agent such as **naloxone** (0.01–0.02 mg/kg IV). Ventilatory support and careful monitoring of body temperature are required by many anesthetized newborns.

The **placenta** should be evaluated grossly and microscopically for evidence of infection, premature detachment and other anomalies.

PHYSICAL EXAMINATION OF THE NEONATAL FOAL

HISTORY

Evaluation of the **health of a foal** should begin with a thorough reproductive history and physical examination of the mare. The breeding dates should be used to calculate an accurate gestational age. The normal length of gestation in the mare ranges from 320 to 365 days with a mean of 340 days. A gestational age of <320 days indicates prematurity.

Signs of **immaturity** include soft, silky haircoat, domed forehead, flexor tendon laxity, floppy ears, general weakness, low body weight and incomplete ossification of carpal and tarsal bones.

Foals that exhibit signs of immaturity but are of correct gestational age are **dysmature**. Dysmaturity is associated with placentitis, congenital abnormalities, drug exposure and other diseases. IUGR can result in dysmaturity or a foal that is small for its gestational age.

A history of abnormal events surrounding this pregnancy or others in the past may identify a foal at increased risk for the development of disease. Factors associated with compromise of the neonate include placentitis, premature separation of the placenta, twinning, Cesarean section, dystocia and vulvar discharge (*q.v.*).

PHYSICAL EXAMINATION OF THE MARE AND PLACENTA

One of the first signs of **poor nursing behavior** in the foal is a turgid and sometimes painful udder in the mare. These mammary gland changes are also compatible with **mastitis** (*q.v.*) so the milk should be examined. If the udder appears small and flaccid and little milk can be expressed, the mare may not be producing enough milk.

A foal may nurse as frequently as four to seven times an hour but should sleep in between feedings. Foals that are constantly at the udder are most likely not getting enough milk. A history of a mare dripping milk prior to parturition implies the mare has lost valuable colostrum. An equine Colostrometer (Lane Manufacturing Inc., Denver, CO, USA) or modified refractometer (Eclipse refractometer) can be used to measure the **quality of colostrum** based on specific gravity. Colostrum with a specific gravity ≥ 1.060 is considered good quality. If the mare's colostrum is of poor quality, then tested colostrum from another mare should be fed via a bottle or nasogastric tube prior to 12 h of age and preferably before 4 h of age.

In addition to examining the foal, the **placenta** should also be evaluated for signs of edema and infection. Examination of the fetal membranes can provide insight into the type and duration of in utero insult the fetus may have experienced. A normal placenta should weigh approximately 10% of the foal's BW. Heavier than normal membranes may be caused by **edema** or **placentitis** (*q.v.*) that may be acute or chronic in nature. A foal exposed to a brief bout of placental insufficiency/hypoxia has a better prognosis than a foal exposed to

chronic hypoxia. Full-term foals deal with chronic hypoxia more effectively than premature foals.

Since most intrauterine bacterial infections begin as an **ascending placentitis** of the chorioallantois, the area of discoloration and thickening originates at the cervical star and extends up the body of the placenta. Acute cases of placentitis may require histopathologic examination for a diagnosis. Cases of chronic placentitis are usually recognized by thickening and discoloration of the chorion. β -Hemolytic streptococci and *E. coli* are among the most common bacterial pathogens associated with placentitis. **Diffuse placentitis** is associated with hematogenous spread of infection such as is seen with **Leptospira** infection (*q.v.*).

It has been hypothesized that **nocardioform placentitis** may develop from a focal endometritis that was present prior to pregnancy. **Fungal placentitis** often presents with a sticky brown mucoid exudate covering parts of the chorion and is often associated with a small, emaciated foal. Sabouraud's agar should be used to isolate suspected fungal pathogens. A direct smear of the exudate can be examined with Gomori's methenamine silver stain. *Aspergillus* and *Mucor* species (*q.v.*) are the most fungal pathogens isolated. Systemic fungal infection of the foal is relatively rare.

When submitting samples of the placenta for microscopic examination, sections should be taken from the fetal and non-fetal horns, the body of the placenta, the region around the cervical star, any abnormal areas of the chorion, and the amnion.

The placenta should be examined for signs of hypoplastic chorionic villi, meconium staining or placentitis. **Hypoplastic chorionic villi** appear as pale, thin, shiny plaques in the chorion. Large areas can result in decreased placental exchange and have been associated with fetal growth retardation. In the case of twins, the opposing areas of placenta will have no villi.

Meconium staining imparts an orange-brown tinge to the amniotic membranes as well as the foal. Meconium staining is a sign of **fetal distress** prior to or during parturition. **Aspiration of meconium** by the foal can lead to severe respiratory compromise.

Placentitis (*q.v.*) is recognized by a thickening and discoloration of the placenta most often involving the area of the cervical star. Foals exposed to in utero infection may appear normal at birth and have a normal leukogram, but have an elevation in **plasma fibrinogen** levels indicative of chronic (≥ 2 days) inflammation (Table 14.4). It is important to remember that even though the placenta may appear normal, microscopic pathology can result in decreased placental exchange.

Adenomatous hyperplasia of the allantois may appear as hyperplasia and hypertrophy of the epithelial cells of the allantois with the formation of intraepithelial glands. More severely affected membranes may have raised firm tan nodules on the allantoic surface of the chorioallantois. These lesions consist of dilated, anastomosing glands surrounded by loose, collagenous stroma. Inflammatory changes are thought to be secondary to the adenomatous dysplasia. The cause of this lesion is not known, but it is seen with chronic placentitis, placental edema and fetal diarrhea.

Umbilical cord abnormalities may also affect the fetus. Granular debris and golden meconium particles on the amniotic portion of the cord suggest local inflammation. An excessively long umbilical cord (normal range 36–83 cm)

Table 14.4 Normal hematology values for neonatal full-term foals

	1 day of age	7 days of age
Red blood cells ($10^6/\mu\text{L}$)	8.2–11.0	7.4–10.6
Mean cell volume (fL)	36–46	35–44
Mean cell hemoglobin concentration (g/dL)	32–40	35–40
Hemoglobin (g/dL)	12–16.6	10.7–15.8
Packed cell volume (%)	32–46	28–43
Total leukocytes ($10^3/\mu\text{L}$)	4.9–11.7	6.3–13.6
Neutrophils ($10^3/\mu\text{L}$)	3.36–9.57	4.35–10.55
Lymphocytes ($10^3/\mu\text{L}$)	0.67–2.12	1.43–2.28
Monocytes ($10^3/\mu\text{L}$)	0.07–0.39	0.03–0.54
Eosinophils ($10^3/\mu\text{L}$)	0–0.02	0–0.09
Basophils ($10^3/\mu\text{L}$)	0–0.03	0–0.18
Platelets ($10^3/\mu\text{L}$)	129–409	111–387
Total plasma protein (g/dL)	5.2–8.0	5.2–7.5
Fibrinogen (mg/dL)	100–400	150–450

Reproduced with permission from Harvey, J.W. (1986) Normal haematologic values, in Korterba, A.M., Drummond, W.H., Kosch, P.C. (eds) *Equine Clinical Neonatology*. Lea & Febiger, Philadelphia, pp. 561–570.

may result in **strangulation** of the fetus with evidence of edema and vascular occlusion around the head and neck. If there is **excessive twisting** of the cord there may be compromised fetal circulation and/or obstruction of the urachus. **Urachal obstruction** may contribute to urachal patency or bladder rupture. An unusually **short cord** is prone to premature rupture and hemorrhage and may predispose the foal to hypoxic injury. Umbilical cord anomalies can also be associated with cases of **hydrops amnii** (*q.v.*).

RESPIRATORY SYSTEM

The foal's respiratory rate should be obtained prior to entering the stall. The **normal respiratory rate** of the foal just after birth is 60–80 breaths/min but decreases to 20–40 breaths/min within the first day of life. Although most foals have a normal respiratory pattern, some foals, when in a deep sleep, will exhibit periods of **apnea** followed by a series of rapid breaths. No nasal discharge should be present.

Auscultation of the lungs reveals air moving over the entire lung field without crackles or wheezes. Foals' lungs are louder and harsher than adult lungs as a result of a thinner chest wall. Areas of dullness or changes in pitch or character of lung sounds as auscultation continues ventrally indicate areas of **consolidation** or **atelectasis**.

Signs of respiratory distress due to **lung immaturity** (lack of surfactant, increased chest wall compliance, etc.) or **pneumonia** (*q.v.*) include nostril flare, increased respiratory effort, rib retraction and inspiratory or expiratory noises.

Foals on the brink of respiratory failure begin to grunt at the end of expiration as a form of physiologic "PEEP" (positive end expiratory pressure) in an attempt to keep alveoli inflated. Affected foals also demonstrate **paradoxical respiration** associated with collapse of the chest wall during inspiration due to respiratory muscle fatigue and increasing lung stiffness.

Thoracic auscultation in the foal can be misleading, as it may be normal despite severe pathology. If the clinician identifies signs of respiratory distress or has a suspicion of respiratory disease, **thoracic radiographs** should be taken and **arterial blood gas analysis** considered.

Periodic apnea and **abnormally slow respirations** are often the result of metabolic disturbances (e.g. hypoglycemia, hypocalcemia), hypothermia, advanced prematurity or hypoxia-induced suppression of the respiratory center. **Tachypnea** is often a response to pain or stress. If birth was difficult, check carefully for **fractured ribs**. In addition to palpating crepitus over the broken ribs, a faint clicking sound can be heard during inspiration on the side of the chest with the rib fracture(s). Affected foals often exhibit grunting during expirations and may prefer to lie on the unaffected side if rib fractures are unilateral.

Congenital defects of the respiratory system include various malformations of the nares, larynx, and trachea including stenotic nares, choanal atresia, subepiglottic cyst, collapsing trachea and guttural pouch tympany (*q.v.*).

CARDIOVASCULAR SYSTEM

The **rectal temperature** of a normal newborn foal is 37.2–38.9°C (99–102°F) and the **heart rate** ranges from 70 to 100 bpm. Heart rhythm should be regular; however, a **sinus arrhythmia** may be present for the first few hours after birth.

A healthy foal's distal extremities should be warm with easily palpable pulses. Normal blood pressure values are: systolic 144 ± 15 mmHg, diastolic 74 ± 9 mmHg, mean 95 ± 13 mmHg. **Thready pulses** herald cardiovascular collapse. **Hypotension** is associated with septic and hypovolemic shock, severe asphyxia and advanced prematurity.

During the first day following delivery the foal's heart rate should increase to >100 bpm and then stabilize between 90 and 100 bpm. A **jugular pulse** can be present in the distal one third of the jugular groove when the foal hangs his head or is in lateral recumbency.

A **systolic murmur** (*q.v.*) is frequently heard over the left heart base during the first 5–7 days of life and is usually associated with a closing **ductus arteriosus**. In these individuals the **patent ductus arteriosus (PDA)** (*q.v.*) is benign since birth-induced changes in intracardiac and pulmonary pressures result in a reversal of blood flow. A **PDA** presents with either a continuous machinery murmur or a holosystolic murmur loudest on the left side, which may persist for 1–4 days. Pathologic causes of a persistent murmur include PDA, VSD (ventral septal defect) and other valvular defects. A foal with a pathologic PDA suffers hypoxia since fetal circulatory pathways are maintained.

Mucous membranes should be pink and moist with a capillary refill time of 1–2 s. Signs of **septicemia** include injection or congestion of mucous membranes, a bright pink toxic ring around the teeth, jaundice or petechiation of mucous membranes and inside of the pinnae. **Jaundice** may also be a sign of **neonatal isoerythrolysis** or liver disease and EHV-1 infection (*q.v.*).

Tachycardia, unless associated with pain or excitement, is often an early sign of sepsis. Tachycardia has also been associated with hypocalcemia. **Bradycardia** may be associated with hypothermia, hyperkalemia and hypoglycemia.

GASTROINTESTINAL SYSTEM

The **suckle reflex** is present within 20 min of birth. In their first attempt to nurse, most foals explore the mare to find the udder but should nurse within 2 h. Healthy foals consume 15–25% of their body weight per day divided into many frequent feedings. Neonates nurse as frequently as every 10–20 min. **Loss of the suckle reflex** or inability to find the mare's udder can occur with **neonatal maladjustment syndrome**, sepsis or prematurity (*q.v.*).

A small percentage of foals will drip milk from the nose during the first few days of life with no associated pathology. Milk streaming from the nostrils following nursing is compatible with a **cleft palate** or dysphagia as a result of neonatal maladjustment syndrome, subepiglottic cyst, white muscle disease and occasionally prematurity (*q.v.*) and should be investigated. Inability to swallow milk adequately can lead to **aspiration pneumonia** and is evidenced by coughing or a rattling in the trachea after nursing.

Auscultation of the abdomen normally reveals borborygmi bilaterally. Abdominal distension indicates a mechanical or functional gastrointestinal obstruction. **Meconium**, the first feces a foal passes, should be passed in the first 24 h of life and appears as dark brown fecal balls compared with the softer light tan manure of a foal consuming mare's milk. Meconium is a combination of cellular debris, secretions and amniotic fluid swallowed by the foal during gestation and retained in the rectum and small colon. Ingestion of colostrum aids in the passage of meconium although many foals require an enema to prevent impaction. Passage of melena is associated with **clostridial enteritis** (*q.v.*) and **hypoxic-ischemic bowel injury**.

Distension of the small and/or large bowel results in generalized abdominal enlargement that is readily apparent due to the foal's thin body wall. Abdominal distension and colic may be associated with ileus, peritonitis, hypoxic gut damage, meconium impaction, or other intestinal obstruction such as intussusception and volvulus (*q.v.*).

Congenital defects affecting the gastrointestinal tract include atresia coli, atresia recti and atresia ani (*q.v.*). The all-white offspring of Overo spotted paint horses suffer from fatal **congenital ileocolonic aganglionosis**. This condition is termed Overo lethal white foal syndrome (OLWFS) (*q.v.*) and results in atrophy of the distal small intestine and colon. Affected foals retain meconium and demonstrate progressive colic beginning on Day 1 as a result of fatal functional intestinal obstruction. There is no cure for the disease, which is caused by a mutation in the endothelin B receptor. Genetic testing is available at the University of California Davis Veterinary Genetics Laboratory (<http://vgl.ucdavis.edu>). American Paint Horses with "frame Overo" coat pattern are heterozygous for the mutation.

UROGENITAL SYSTEM

Time to **first urination** is approximately 8 h. Colts generally urinate before filly. Some colts normally do not drop the penis to urinate for the first week post partum due to a **persistent frenulum**. Urination should be observed to rule out a **patent urachus**.

The **umbilicus** should be small and dry. Swelling around the umbilical stump may be associated with hemorrhage, urine accumulation, hernia formation or

infection. Umbilical cords that have been ligated or cut seem more prone to secondary infection. Excessive use of **concentrated iodine** solutions also results in an increased incidence of **omphalitis** and premature sloughing of the stump, which increases the risk of a patent urachus (*q.v.*). An inflamed or moist umbilical stump suggests infection and/or urachal patency. The internal umbilical remnants (e.g. two umbilical arteries, umbilical vein and urachus) can be palpated through the abdominal wall in some recumbent foals if they are relaxed.

The best way to evaluate internal umbilical remnants is with transabdominal ultrasound using a 5–7.5 MHz transducer. The umbilical vein is followed from umbilical stump cranially along the ventral midline to the liver. The diameter of the umbilical vein should be <1.0 cm. The umbilical stump is visualized and the two umbilical arteries and urachus are traced caudally to the bladder. The combined view of the two arteries and urachus just caudal to the stump should have a diameter $<1.5 \times 2.5$ cm. Both arteries should be examined at their attachment alongside the bladder. Each artery should have a diameter <1.0 cm. Omphalitis usually affects more than one structure within the umbilicus. At the first sign of umbilical infection the foal should be started on **broad-spectrum antibiotics** and the umbilicus should be disinfected using dilute iodine or chlorhexidine solution.

Observing the foal urinate cannot completely rule out ruptured bladder (*q.v.*). Signs of **uroperitoneum** include depression, dysuria and abdominal distension with a fluid wave. Transabdominal ultrasonography provides a rapid, non-invasive method of confirming the diagnosis. Uroperitoneum produces large volumes of non-echogenic fluid within the peritoneal cavity and surrounding the “floating” intestines and collapsed bladder.

Urine specific gravity in the foal is low due to a high-volume liquid diet and incomplete development of the kidney, resulting in decreased concentrating capacity compared with the adult.

Testes may not be descended at birth but the scrotum should be palpated for scrotal hernia. An **inguinal hernia** describes herniation of bowel or omentum through the deep inguinal ring into the inguinal canal. A **scrotal hernia** describes hernial contents that have passed through both deep and superficial inguinal rings into the scrotum. Most hernias are indirect, which means the vaginal process or tunica vaginalis forms the hernial sac. Rupture of the tunica vaginalis results in a direct hernia.

The best way to **evaluate inguinal and scrotal hernias** is with the foal in lateral recumbency. If the hernial contents can be reduced by gently milking the intestines and omentum back into the abdomen, the hernia may close spontaneously within 3–6 mo. To reduce scrotal hernias, gentle tension is placed on the testicle and the hernial contents are milked back up into the abdomen. The owner should be shown how to manually reduce the hernia several times daily. Hernias require surgical closure if the hernia continues to enlarge, fails to close spontaneously within 3–6 mo, or is no longer reducible.

The vulva should be evaluated in fillies to detect congenital defects.

NERVOUS SYSTEM

The nervous system of the foal is still continuing to develop after birth; therefore results of a neurologic examination of the foal differ from those of an adult horse (*q.v.*). The foal should stand within 30 min to 2 h of birth.

Foals spend much of their time sleeping and at times can be difficult to rouse, but once awake they should be bright, alert and responsive to stimuli.

The **suckle reflex** is present by 20 min after birth. Foals will make a nodding motion of the head when searching for the udder. When restrained, a foal will have periods of strong body tone interspersed with periods of sudden relaxation of all four limbs causing him to flop up and down. Head and neck carriage are upright and angular.

Healthy foals stand with an erect, angular head and neck carriage and a base-wide stance. Gait and limb movements are often exaggerated and limb reflexes are hyper-reflexive. When recumbent, foals have strong resting extensor tone and a crossed extensor reflex is present when a withdrawal reflex is elicited for up to 1 mo of age.

Hypotonia, seizures and hyperesthesia are often associated with **hypoxic-ischemic encephalopathy**. Jitteriness is a sign of mild hypoxia. More severe hypoxia results in progressive hypotonia. Such foals are more difficult to arouse from sleep. With more global CNS hypoxic-ischemic damage foals exhibit signs of grand mal seizures followed by periods of post ictal stupor. Septic meningitis is a less common cause of seizures. Affected foals display concurrent signs of sepsis including mucous membrane and scleral injection, depression and tachycardia.

Congenital defects of the brain and spinal cord include cerebellar abiotrophy, occipito-atlanto-axial malformation, hydrocephalus, hydrencephaly and hypomyelination (*q.v.*).

OPHTHALMIC SYSTEM

Although foals have adequate vision at birth, a consistent **menace response** may be absent during the first week of life. Pathologic causes of an absent menace response include cerebral edema associated with birth asphyxia, septic optic nerve neuritis and ocular defects such as detached retina and optic nerve hypoplasia (*q.v.*).

A **pupillary light response** is present unless the foal's pupils are dilated due to excitement or stress. Fixed, dilated pupils may also be associated with severe midbrain swelling and are observed in comatose foals suffering from head trauma or severe hypoxic-ischemic encephalopathy.

Ventromedial strabismus may be present during the first 2 weeks of life. The hyloid artery remnant can be seen coursing from the optic disk to spread on the posterior lens capsule, sometimes resembling a spider web. Suture lines can be seen in the center of the lens and should not be mistaken for cataracts. The normal neonatal lens may appear **cloudy** for the first few weeks of life. Persistent **pupillary membranes** may be visible (e.g. lens to iris, iris to cornea) and can result in small pigment nests on the anterior lens capsule. These persistent strands are reported more often in Thoroughbreds. No treatment is required. The persistent strands break down within 12 mo.

Examination of the eyes should rule out other congenital ocular anomalies including entropion, retinal detachment or hemorrhage, cataracts and microphthalmia (*q.v.*). Acquired or congenital **entropion** (*q.v.*) is the most common congenital ocular anomaly. Acquired entropion is associated with self-trauma, dehydration or prematurity and the lack of periorbital fat. Entropion should

be corrected promptly before serious corneal ulceration and keratitis develop. Manual eversion of the eyelids several times daily followed by topical application of topical antibiotic or ocular lubricant may resolve mild cases. Another short-term treatment consists of SC injections of **procaine benzylpenicillin** (1 mL) into the lower eyelid. Most foals with entropion will require placement of vertical or horizontal mattress sutures in the lower eyelid to correct the problem. The affected eye should be stained with **fluorescein** (*q.v.*) to detect concurrent corneal ulceration.

Uveitis, hypopyon, hyphema and scleral injection (*q.v.*) may also be associated with septicemia. Nystagmus and retinal hemorrhages may be observed in hypoxic foals. Scleral hemorrhage is usually the result of birth trauma and can take several weeks to resolve.

MUSCULOSKELETAL SYSTEM

The musculoskeletal system of the newborn foal should be examined for **fractures** of the long bones, ribs or mandible as a result of periparturient trauma.

Signs of **septic arthritis** (*q.v.*) include lameness, heat, swelling or pain on palpation of the joints. Joints in the neonate have an increased range of motion compared with the adult. The sole of the front foot can touch the caudal triceps in many foals.

The most common angular limb deformities are **contracted tendons** and **flexor tendon/periarticular laxity**. In cases of contracted tendons (*q.v.*), the tendons are not truly contracted, but rather the effective functional length of the musculotendinous unit is too short to allow normal leg extension. Fetlock and carpal contractures are the most common. Radiographs should be taken of limbs with severe deformities to be certain primary bone malformation is not the cause.

Mild **flexural deformities** respond to physical therapy and weight bearing. Judicious use of analgesics helps encourage conservative exercise. Heavy support bandages, splints and **oxytetracycline therapy** (1–3 g IV diluted in 100–500 mL of saline q 24 h for a maximum of three treatments) are more aggressive forms of therapy. High dosages of oxytetracycline have been shown to produce tendon relaxation in neonates, although the precise mechanism is uncertain. During oxytetracycline therapy the foal's renal function should be monitored. **Splints** should be reset frequently to prevent pressure sores.

All forms of therapy are more effective if there is concurrent weight bearing on the affected limbs. Severely affected foals are in pain and are often unable to stand unassisted. These cases require **analgesics** (e.g. ketoprofen 1.1–2.2 mg/kg IV q 24 h; phenylbutazone 2.2 mg/kg IV, PO q 12–24 h), **anti-ulcer medication** (e.g. omeprazole 4 mg/kg PO q 24 h; ranitidine 8 mg/kg PO q 8 h; cimetidine 6.6 mg/kg IV q 6 h or 20 mg/kg PO q 6 h, famotidine 2.8 mg/kg PO q 24 h) and assistance when nursing. Rupture of the lateral extensor tendons may complicate management of forelimb contractures.

Tendon laxity, if mild, can be treated conservatively with restricted exercise on good footing. Most foals have mild laxity that improves during the first 48–72 h following delivery. More severe cases benefit from shoes with heel

extensions. Affected foals should have restricted exercise until the soft tissue laxity improves. Excessive exercise and fatigue on weak tendons can result in soft tissue trauma and sesamoid bone fractures (*q.v.*).

Angular limb deformities (*q.v.*) may occur as a result of impaired cartilage nutrition due to abnormal cartilage thickening. If uneven bone growth occurs, deviation of the normal leg axis results. Anything that produces uneven pressure across growth plates can cause angular limb deformities. Such stresses include joint laxity, in utero malpositioning, excessive trauma due to large body size, excessive activity, impaired cuboidal bone ossification or opposite limb lameness. Deformities may be present at birth or acquired shortly thereafter. Most foals are born with mild carpal valgus conformation and subtle tendon laxity that self-correct within the first week of life.

CLINICAL PATHOLOGY

Good restraint is essential when obtaining a blood sample from the foal in order to prevent vessel trauma and decrease stress. The jugular veins are the largest accessible veins in the foal; however, the cephalic and saphenous veins are also common sites for venepuncture. The site should be prepared with alcohol prior to routine venepuncture. Sampling for blood cultures is a sterile procedure requiring aseptic preparation of the skin.

Sites for **arterial blood gas** sampling include the great metatarsal, brachial, femoral and facial arteries. Due to risk of severe hematoma formation, sampling from the carotid arteries should be reserved for those foals in which peripheral pulses are too weak to obtain a sample elsewhere. Once the artery has been identified by pulse palpation, the site should be prepared with an antiseptic solution. Blood should be drawn into a heparinized syringe and all air bubbles removed. The sample should be analyzed immediately or sealed and placed in an ice bath. The sample can be stored in this way for up to 5 h without significant changes in PaO₂. After the needle is withdrawn, pressure is applied to the artery for 3 min to prevent hematoma formation.

Reference ranges for hematology, biochemistry and blood gas values are presented in Tables 14.5–14.7.

If there is any suspicion about a newborn foal's well-being, the following database should be obtained: packed cell volume (PCV), total protein concentration, white blood cell count and differential, fibrinogen concentration and serum concentrations of IgG, creatinine and glucose. The use of **portable analyzers** has made stall-side determination of IgG, glucose, creatinine and fibrinogen concentrations easy, fast, accurate and affordable.

Newborn foals are born with an average PCV between 39% and 48%. The PCV decreases during the first 24 h as a result of colostrum ingestion, the osmotic effect of absorbed colostrum proteins and blood volume expansion. PCV is affected acutely by **hydration status** and blood loss or destruction. Poor nursing behavior quickly results in dehydration and an increase in PCV. A low PCV accompanied by icterus and hemoglobinuria is indicative of hemolysis (e.g. **neonatal isoerythrolysis**, *q.v.*) or **disseminated intravascular coagulation** (DIC) associated with sepsis. A low PCV is also observed following **umbilical cord hemorrhage**. Decreased red cell production causes slower,

Table 14.5 Normal clinical chemistry values for neonatal full-term foals

	1 day of age	7 days of age
Glucose (mg/dL)	121–233	121–192
Blood urea nitrogen (mg/dL)	9–40	4–20
Creatinine (mg/dL)	1.2–4.3	1.0–1.7
Total bilirubin (mg/dL)	1.3–4.5	0.8–3.0
Conjugated bilirubin (mg/dL)	0.3–0.7	0.3–0.7
Unconjugated bilirubin (mg/dL)	1.0–3.8	0.5–2.3
Cholesterol (mg/dL)	110–562	139–445
Triglycerides (mg/dL)	30–193	30–239
Albumin (g/dL)	2.5–3.6	2.7–3.4
Total globulin (g/dL)	1.5–4.6	1.6–3.9
Alkaline phosphatase (IU/L)	861–2671	137–1169
Glutamyl transferase (IU/L)	18–43	14–164
Sorbitol dehydrogenase (IU/L)	0.6–4.6	0.8–8.2
Aspartate aminotransferase (IU/L)	146–340	237–620

subtle changes in PCV. Premature foals tend to have a slightly lower PCV at birth. An elevated PCV >50% may be associated with chronic in utero hypoxia resulting in **neonatal polycythemia**.

Presuckle total protein (TP) concentration varies between individuals from 3.5 to >5.0 g/dL. Total protein concentration increases following colostrum ingestion due to immunoglobulin absorption and during dehydration. Without knowing the presuckle values, it is impossible to use TP to measure IgG absorption. Low TP values <3.5 g/dL are suggestive of a **failure of passive transfer** (FPT). Hypoproteinemia may also be associated with protein loss from the gastrointestinal and urinary systems.

Neutrophil numbers increase during late gestation to an average of 5000–6000/ μ L at birth. Immediately after birth a stress-induced cortisol release results in an increase in neutrophil numbers. Neutropenia (<2000/ μ L) is associated with septicemia and is accompanied by toxic changes within the neutrophils and increasing numbers of bands. At birth the neutrophil–lymphocyte ratio (N:L) should be >2–3. An inversion of the N:L ratio, without signs of sepsis, is compatible with prematurity and an underdeveloped hypothalamus–pituitary–adrenal axis. Lymphocyte counts may be <1000/ μ L in newborns, but should increase within the first few days of life. Persistent lymphopenia is a sign of **combined immune deficiency** (CID), severe stress, bacteremia or viremia.

Fibrinogen concentration increases slowly over 2–3 days following an inflammatory insult and reflects chronic rather than acute infection. Most healthy foals have values <200 mg/dL. Hyperfibrinogenemia at birth suggests in utero sepsis.

Healthy foals that have absorbed adequate colostrum have serum IgG concentrations well above 800 mg/dL within the first 18–24 h of life. IgG <200 mg/dL is termed failure of passive transfer (FPT). IgG between 200 and 400–800 mg/dL is considered partial FPT.

In the newborn foal **creatinine concentration** serves as a crude estimate of placental function pre partum. Neonatal azotemia has been associated with abnormal placentas and the birth of hypoxic or septic foals. Newborn foals should have a creatinine concentration <3.5–4.0 mg/dL.

Foals are born with relatively low blood **glucose** concentration (40–80 mg/dL). **Presuckle hypoglycemia** (glucose <35 mg/dL) immediately following birth is suggestive of **placental dysfunction** and hypoxia. Glucose concentration should increase in normal foals following birth as a result of colostrum ingestion and insulin release. Persistent hypoglycemia during the first 48 h post partum suggests immature insulin response and marginal glucose reserves. **Hyperglycemia** (glucose >180–200 mg/dL) is associated with hypoxia-induced pancreatic endocrine dysfunction, sepsis-induced release of glucagon, catecholamines and cortisol resulting in peripheral insulin resistance.

COMMON FOAL DISORDERS

MECONIUM IMPACTION

Meconium (*q.v.*) is composed of swallowed amniotic fluid, cellular debris and intestinal secretions and is dark brown to black in color. Due to the firm and

tenacious consistency of this material even normal foals must strain to pass the first manure. Meconium passage normally occurs within 24–36 h post partum and is followed by soft, tan-colored, **milk feces**.

Etiology

There is an increased incidence of **meconium impaction** in colts due to their narrow pelvic canal. Impaired gastrointestinal motility associated with asphyxia, sepsis or dysmaturity (*q.v.*) predisposes to meconium retention. Prolonged recumbency and dehydration are additional risk factors.

Clinical signs

Clinical signs associated with **meconium impaction** include tenesmus, frequent tail flagging, colic and loss of nursing vigor. If the impaction persists, abdominal distension develops contributing to the foal's discomfort. During episodes of **severe tenesmus**, the umbilicus may begin to bleed, the urachus may reopen and drip urine, and rectal prolapse (*q.v.*) may occur.

The diagnosis is frequently made based on a history of straining to defecate unsuccessfully, digital rectal evaluation and response to enema administration. Certain cases may require abdominal radiography, with or without a barium enema, to demonstrate the fecal impaction. Gas and/or fluid frequently accumulate proximal to the site of obstruction. **Transabdominal ultrasonography** has been used to identify firm fecal material within the distal colon. Other conditions that may be confused with meconium impaction include uroperitoneum, urachitis, cystitis, congenital defects such as atresia coli, and other causes of intestinal obstruction and colic such as large bowel volvulus, foreign body obstruction and intussusception (*q.v.*).

Treatment

Mild impactions respond to **gravity enema** administration using 0.5–1.0 L warm, soapy water or water mixed with rectal lubricant. Solutions containing docusate sodium should be used with extreme caution, due to its irritation of rectal and colonic mucosa. **Retention enemas** using 150 mL of a 4% solution of acetylcysteine (6 g acetylcysteine powder in 150 mL water) and administered through a cuffed urinary Foley catheter (left in place for 20–40 min) help dissolve refractory impactions. Retention enemas can be repeated several times without adverse affect.

If the impaction persists, oral laxatives can be administered in conjunction with oral fluids. Mineral oil (120–240 mL) administered via nasogastric tube is the safest and most commonly used laxative. Castor oil (15–30 mL) and docusate sodium (10–15 mL) should both be used cautiously due to their **extremely irritant** nature. Severe gastroenteritis has been induced in foals by misuse of both of these agents. **Increased exercise** is also beneficial. In chronic cases of meconium impaction, aggressive IV fluid therapy should be initiated. Only rare cases will require surgical intervention.

PATENT URACHUS

Normally the urachus closes spontaneously at birth or shortly thereafter and atrophies to become a scar on the apex of the bladder. The urachus may fail to

close following birth (**congenital patent urachus**) or may reopen post partum (**acquired patent urachus**). As long as urachal patency persists it represents a source of irritation and a potential route of infection.

Etiology

Congenital patency can result from urachal over-distension secondary to torsion of the umbilical cord in utero or during parturition. **Acquired patency**, the most common form, is usually associated with inflammation of the umbilicus and coincides with sloughing of the necrotic umbilical stump. Factors associated with acquired urachal patency include prolonged recumbency associated with urine scalding and umbilical irritation, ligation or cutting of the umbilical cord, and any neonatal condition producing increased intra-abdominal pressure such as tenesmus associated with constipation or dysuria due to cystitis, urachitis, urachal diverticulum, uroperitoneum or bladder catheterization.

Clinical signs

A patent urachus (*q.v.*) often results in a thicker than normal umbilicus that remains moist due to continuous or intermittent discharge of urine. The umbilicus may be warm and painful if inflammation is present. A 7.5 MHz ultrasonographic transducer (linear ray or sector scan) can be used to image a patent urachus as a fluid-filled structure located along the ventral midline next to the umbilical arteries. Communication between the urachus and bladder apex is best seen in the longitudinal view. Positive contrast radiography can also be used to demonstrate some urachal disorders.

Treatment

Local cautery of the urachus using silver nitrate applicators and 2% iodine aids closure in mild, uncomplicated cases. If tenesmus due to constipation or dysuria associated with cystitis (*q.v.*) is delaying urachal closure due to transient bouts of increased abdominal pressure, then these conditions must be treated concurrently. Constipation can be treated with enemas and laxatives.

Straining to urinate due to cystitis can be relieved using **phenazopyridine** (4 mg/kg PO q 8–12 h), a systemically administered diazo dye with local anesthetic effects on bladder mucosa.

If transabdominal ultrasonography reveals significant omphalitis complicated by focal areas of abscessation and/or marked urachal enlargement, then surgical resection of the umbilical remnants is indicated. Until the urachus closes or the umbilical remnants are resected the foal should be maintained on **broad-spectrum antibiotics**.

HYPOGAMMAGLOBULINEMIA

Overwhelming bacterial infection is one of the leading causes of neonatal foal mortality. One of the risk factors for septicemia is **hypogammaglobulinemia**. Although immunocompetent at birth, foals are immunologically naïve and rely on passive transfer of colostral immunoglobulins and non-specific host defense mechanisms for protection against infection during the first 2 mo of life. Complete failure of passive transfer (FPT) is generally defined as serum

IgG concentrations ≤ 200 mg/dL. Partial FPT is defined as serum IgG levels between 200 and 800 mg/dL.

Etiology

Foals are born virtually **agammaglobulinemic** due to the diffuse epithelio-chorial placenta of the mare that prevents maternofetal transfer of antibodies. The mare produces colostrum containing predominantly IgG during the last 2–4 wk of gestation. The foal absorbs colostral immunoglobulins via specialized epithelial cells within the small intestine. Absorption declines rapidly within 12 h of birth and **ceases completely** 24–36 h post partum. Most normal newborn foals attain serum IgG concentrations >800 mg/dL following colostrum ingestion.

The incidence of FPT is estimated to be between 3% and 25% and is affected by a variety of management practices. Causes of FPT include: (1) poor quality colostrum; (2) failure to produce adequate volumes of colostrum; (3) premature lactation; (4) failure of the newborn foal to ingest adequate colostrum within the first 12–24 h post partum; (5) ineffective intestinal absorption of IgG; (6) increased protein catabolism associated with sepsis.

Poor quality colostrum may be associated with advancing maternal age, maternal obesity, individual or breed variation, season and climate, poor prenatal maternal vaccination, premature delivery, premature lactation or agalactia. Failure to ingest adequate amounts of colostrum within the first 24 h of life may be due to neonatal weakness, musculoskeletal problems (e.g. tendon laxity, tendon contracture), abnormal behavior (e.g. hypoxic–ischemic encephalopathy), or foal rejection by the dam.

Peak colostrum absorption occurs within the first 10 h of life. Early feeding of colostrum not only ensures optimal IgG absorption, but may reduce the risk of infection from ingested pathogens by accelerating gut closure. Foals suffering from hypothermia, hypotension, severe hypoxia, prematurity or intestinal disease should not be expected to have normal gut function. Such foals require a **plasma transfusion** to ensure adequate IgG levels (*q.v.*).

Although most studies strongly suggest that FPT is a major predisposing factor for neonatal sepsis, there is evidence to suggest that on well-managed stud farms serum IgG levels in foals are not related to the incidence or severity of disease or to neonatal survival rates. The observation that many septic foals are hypogammaglobulinemic does not necessarily clarify the issue. Low serum IgG levels may predispose to infection or may be the result of increased protein catabolism associated with overwhelming sepsis.

The clinical significance of FPT must be determined on an individual basis and take into account environmental and management factors. Few would argue that foals at serious risk for sepsis or already showing signs of infection benefit from having serum IgG concentrations in the normal range (i.e. IgG >800 mg/dL). IgG supplementation is recommended for any foal with a serum IgG <200 mg/dL regardless of its health status or environment.

If the foal's IgG is between 200 and 800 mg/dL, **IgG supplementation** (*q.v.*) should be considered if one or more of the following conditions exist:

1. Gestation length <320 days or signs of prematurity/dysmaturity

2. Difficult delivery (e.g. dystocia, premature placental separation, meconium staining)
3. Grossly abnormal or heavy placenta ($>11\%$ foal's BW)
4. High environmental stresses including overcrowding and poor farm hygiene
5. Anticipated transportation off the farm within 7–10 days of foaling
6. Failure to stand and nurse within 3 h of delivery
7. Abnormal physical examination within 24 h of birth; significant abnormalities include generalized weakness, injected mucous membranes, poor suckle, severe angular limb deformities, enlarged umbilicus, patent urachus, colic, meconium retention, increased respiratory effort or other signs of localized infection.

Diagnosis

Serum IgG levels are routinely evaluated in foals between 12 and 24 h of age. Commonly used tests for **IgG assessment** include zinc sulfate turbidity, latex agglutination, glutaraldehyde precipitation and ELISA.

Treatment

If FPT is diagnosed within the first 18 h of life, **additional colostrum** can be administered. Ideally, a foal should receive at least 1 L of good quality colostrum. Oral administration of concentrated or lyophilized **equine IgG products** results in wide variations in serum immunoglobulin concentrations. **Bovine colostrum** provides some protection, but will not protect against exclusively equine pathogens. **Equine plasma** may be administered orally within the first 18–24 h of life or IV at any age. The recommended plasma dose depends on the foal's body weight, the severity of hypogammaglobulinemia, the IgG concentration in the plasma product, and whether or not the foal is already septic. The administration of 20 mL/kg of normal equine plasma (1 L for a 45 kg foal) routinely raises serum IgG concentration by 200 mg/dL in a healthy foal when given IV. Oral administration of plasma results in variable immunoglobulin absorption.

Clinically ill foals experience **increased IgG catabolism** and require additional plasma. In addition to providing antibody, plasma provides electrolytes, complement, opsonins, increased oncotic pressure and volume expansion, and it improves neonatal neutrophil function.

If equine plasma is not commercially available, the ideal donor is an adult horse, preferably a gelding, that has been **blood typed** (*q.v.*) and found to be negative for isoantibodies to the major equine RBC blood types (particularly A and Q alloantigens). Plasma should be administered at **room temperature** using a blood administration set and delivered at a rate of 1 L over 1–3 h. The foal should be monitored for a variety of transfusion reactions, examples of which are listed in Table 14.8.

The incidence of FPT can be reduced by observing periparturient mares closely for adequate mammary gland development and premature lactation. Good quality colostrum should be thick and sticky with a specific gravity >1.060 as measured on an equine Colostrometer.

Table 14.8 Types of immediate transfusion reactions

Type of reaction	Signs	Cause	Treatment
Acute hemolysis	Hemoglobinemia; hemoglobinuria	Incompatibility between donor plasma and recipient's RBCs	Discontinue transfusion
Non-hemolytic, febrile reaction	Fever, chills	Response to donor protein, antigens or WBC fragments	Antipyretics
Allergic reactions	Urticaria	Recipient's reaction to soluble antigens in donor's plasma	Slow transfusion; antihistamines
Anaphylactic reaction	Respiratory distress; hypotension; shock		Stop transfusion; epinephrine/adrenaline
Circulatory overload	Pulmonary edema; hypertension; cardiac failure	Volume overload	Slow or stop transfusion; diuretics

PERI PARTUM ASPHYXIA (NEONATAL MALADJUSTMENT SYNDROME)

Peri partum asphyxia affects multiple organ systems. Unfortunately, the popularized name, **neonatal maladjustment syndrome** (NMS), focuses attention on the more clinically obvious behavioral and neurologic signs associated with hypoxia-induced CNS damage (*q.v.*).

Asphyxia during late pregnancy and/or delivery causes a decrease in tissue perfusion and oxygenation in the newborn foal and results in a spectrum of clinical signs that include neurologic deficits ranging from hypotonia to grand mal seizures, gastrointestinal disturbances ranging from mild ileus and delayed gastric emptying to severe, bloody diarrhea and necrotizing enterocolitis (NEC) and renal compromise accompanied by varying degrees of oliguria.

Based on the neurologic deficits that include loss of affinity for the dam, seizures, abnormal vocalization and aimless wandering, affected foals have been called “dummies”, “convulsives”, “barkers”, and “wanderers”. NMS is a common term used to describe this condition. **Hypoxic–ischemic encephalopathy** (HIE) is a more precise medical term describing the CNS disturbances that include edema, necrosis and occasional hemorrhage.

Etiology

Asphyxia is caused by impaired oxygen delivery to cells and usually results from a combination of hypoxemia and ischemia. Other potential metabolic derangements include hypercarbia and metabolic acidemia. Fetal compensatory mechanisms to increasing asphyxia include bradycardia, decreased oxygen consumption, anaerobic glycolysis and circulatory redistribution resulting in increased blood flow to the heart, adrenals and brain and diminished flow to lungs, gut, spleen, kidneys, liver and muscle. The nature and extent of tissue

injury depend on the age of the neonate (full term or premature), and the duration and severity of asphyxia (acute or chronic, partial or complete).

An important mediator of ischemic tissue damage is the fast excitatory neurotransmitter, **glutamate**. At high extracellular concentrations, glutamate acts as a neurotoxin and mediates opening of ion channels that permit sodium to enter cells followed by an influx of chloride ions and water resulting in osmotic lysis and immediate neuronal death. Glutamate also mediates delayed cell death by provoking calcium influx through depolarization-induced opening of calcium channels and by direct stimulation of N-methyl-D-aspartate (NMDA) receptors that open additional calcium channels. High intracellular levels of free calcium result in activation of enzyme systems, generation of free radicals, and impaired mitochondrial function resulting in delayed neuronal death.

The wide variation in **CNS damage** associated with peri partum hypoxia illustrates how the type of asphyxia and age of fetus influence the final outcome. Mature fetuses dying of severe asphyxia demonstrate hemorrhagic softening involving primarily the cerebral cortex and hemispherical white matter. Immature fetuses dying of asphyxia show damage involving structures deep within the hemispheres. Partial prolonged asphyxia produces injury primarily in the hemispheres accompanied by significant brain edema. Acute, total asphyxia damages the brainstem and spinal cord and is less commonly associated with brain swelling.

Chronic hypoxia associated with placental insufficiency produces fetal growth retardation in a fashion reflecting redistributed blood flow. The brain is spared, but other organ systems are not, resulting in a small, runted fetus with a relatively large head. This disproportional growth is typical of IUGR. Chronic hypoxia stimulates fetal adrenals and enhances maturation of many fetal organs, including the lungs.

Perinatal asphyxia may be associated with a rapid, seemingly uncomplicated delivery of a term foal, dystocia, premature placental separation or Cesarean section. Peri partum asphyxia may not alter the delivery process itself, making it difficult for owners to understand how an outwardly normal birth could produce an abnormal foal. Specific peri partum causes of neonatal asphyxia are listed in Box 14.5.

Clinical signs

Pre partum, transabdominal ultrasonography can be used to evaluate fetal response to asphyxia by observing the following biophysical variables: fetal movement, breathing and heart rates, and fetal amniotic fluid volume. Chronic hypoxia can produce decreased renal blood flow, decreased fetal fluid production, depressed fetal limb and respiratory movements and bradycardia. Acute asphyxia may produce transient bouts of tachyarrhythmias. Post partum, a modified **APGAR score** (Table 14.9) can be used to evaluate severity of fetal stress and birth asphyxia.

Peri partum hypoxia produces a wide range of clinical signs, according to the organ system(s) involved. Mild hypoxia causes jitteriness and hyperexcitability and may go unrecognized. Moderate hypoxia results in stupor, somnolence, lethargy and hypotonia that may be accompanied by epileptiform

Box 14.5 Peri partum conditions associated with neonatal foal asphyxia**Maternal factors**

- Endotoxemia
- Severe hypotension, shock
- Severe anemia
- Hypoproteinemia
- Abdominal surgery/general anesthesia
- Hydrops
- Prepubic tendon rupture
- EHV-1 infection
- Fescue toxicosis

Placental factors

- Placentitis
- Placental insufficiency
- Small placenta
- Placental vasculitis, edema
- Placental thrombosis, infarction
- Umbilical cord complications

Periparturient factors

- Premature placental separation
- Dystocia, prolonged labor
- Induction of labor
- Cesarean section
- Early umbilical cord rupture

Fetal/neonatal factors

- Congenital cardiac anomalies
- Surfactant dysfunction
- Severe pulmonary disease
- Persistent fetal circulation
- Twinning

seizures and episodes of extensor rigidity and opisthotonus during recumbency. Moderate hypoxia is also associated with loss of suckle, dysphagia, decreased tongue tone, odontoprisia, central blindness, mydriasis, anisocoria, nystagmus and head tilt. Limb deficits and generalized spasticity are less common.

Premature foals exposed to moderate hypoxia are more likely to experience “subtle seizures” characterized by paroxysmal events including eye blinking, eye deviation, nystagmus, pedaling movements, a variety of oral–buccal–lingual movements such as intermittent tongue protrusion, sucking behavior, purposeless thrashing, and other vasomotor changes such as apnea, abnormal breathing patterns and changes in heart rate. Tonic posturing is another subtle seizure activity characterized by symmetric limb hyperextension or flexion and is often accompanied by abnormal eye movements and apnea. Severe

Table 14.9 Modified APGAR scoring system

Sign	0	1	2
1. Heart rate	Absent	<60 bpm, irregular	>60 bpm, regular
2. Respiratory effort	Absent	Slow, irregular	<30 breaths/min, regular; can whinny
3. Muscle tone	Limp, lateral recumbency	Some voluntary flexion of extremities	Active motion; sternal recumbency
4. Reflex irritability			
Nasal stimulation	No response	Grimace	Sneeze/cough
Ear tickle	No response	Weak ear flick	Ear flick/head shake
Thoracolumbar stimulation	No response	Head/neck motion	Head/neck/limb motion

Interpretation of score results

Score 7–8: minimal asphyxia; no intervention required.

Score 5–6: mild asphyxia; stimulate, rub, extend limbs; suction.

Score 3–4: moderate asphyxia; respiratory acidosis; positive pressure ventilation; intravenous fluids.

Score ≤2: severe asphyxia; respiratory and metabolic acidosis; positive pressure ventilation; aggressive circulatory support; bicarbonate administration.

hypoxia results in marked CNS depression, coma, and loss of central regulation of respiration, blood pressure and temperature, leading to death.

Renal dysfunction is common, but mild signs such as transient oliguria may be easily overlooked. Hypoxic **gut damage** produces colic, ileus, abdominal distension, gastric reflux, ulceration and diarrhea. **Cardiopulmonary complications**, including surfactant dysfunction, pulmonary hypertension, myocardial infarcts and persistent fetal circulatory patterns, can result in respiratory distress and cardiac failure. **Endocrine disorders** are difficult to identify but involve damage to the adrenal glands, pancreas and parathyroids. Hepatocellular necrosis and biliary stasis may also occur accompanied by **clinical jaundice**.

Few laboratory results are pathognomonic for birth asphyxia. Hematology reveals a normal or stress leukogram. Many foals suffer FPT due to **inadequate colostrum ingestion**. A mixed metabolic/respiratory acidosis develops in response to shock, poor perfusion, increased anaerobic metabolism and respiratory dysfunction. Elevated concentrations of **liver enzymes** reflect hepatocellular necrosis. Renal dysfunction produces hyponatremia, hypochloremia and azotemia. Marked elevations in **serum creatinine** concentrations immediately post partum have also been associated with placental dysfunction rather than primary neonatal renal disease. Elevated **serum creatinine kinase** concentrations are associated with ischemic muscle damage. Severe respiratory compromise produces hypoxemia and hypercapnia. Clinicopathologic conditions associated with peri partum asphyxia are summarized in Table 14.10.

Differential diagnoses for a weak, lethargic foal believed to be suffering from asphyxia should include septicemia, prematurity/dysmaturity, and other metabolic derangements such as hypoglycemia, hyper- or hyponatremia, and hypocalcemia (*q.v.*).

Treatment

Anticonvulsive therapy is crucial to control seizures in order to prevent recurrent episodes of CNS ischemia and hypoxia and to reduce the risk of neonatal

Table 14.10 Clinicopathologic conditions associated with peri partum hypoxia

Organ system	Sign	Lesion
CNS	Hypotonia/hyperesthesia, abnormal behavior, apnea, seizures, coma	Cerebral edema; ischemic necrosis; occasional CNS hemorrhage
Renal	Anuria, oliguria, generalized edema, azotemia, hyponatremia, hypochloremia	Tubular necrosis
Gastrointestinal	Colic, ileus, abdominal distension, diarrhea (\pm blood), gastric reflux	Ischemic necrosis, necrotizing enterocolitis, ulceration
Respiratory	Respiratory distress: tachypnea, dyspnea, rib retractions, decreased tidal volume; apnea, hypoxemia, hypercapnia, respiratory acidosis	Hyaline membrane formation, atelectasis, meconium aspiration, pulmonary hypertension
Cardiac	Arrhythmias, murmurs, hypotension, generalized edema, weak peripheral pulses, hypoxemia	Persistent fetal circulation, myocardial infarcts, valve insufficiency
Hepatic	Icterus, hyperbilirubinemia, elevated hepatocellular and biliary enzymes	Hepatocellular necrosis, biliary stasis
Endocrine		
Adrenals	Weakness; low serum cortisol	Necrosis, hemorrhage
Parathyroid	Hypocalcemia	Necrosis, hemorrhage

self-trauma. **Diazepam** (0.1–0.2 mg/kg IV) is used initially to stop seizures quickly because of its rapid onset of action but repetitive doses should be avoided to reduce the risk of respiratory depression. Due to its short duration, diazepam should be followed by **phenobarbital** (2–10 mg/kg slowly IV q 8–12 h) to control severe or recurrent seizures. Phenobarbital should be given slowly to minimize respiratory depression. Foals receiving phenobarbital should have their body temperature, blood pressure and respiratory rate monitored. If diazepam and phenobarbital are not available, **pentobarbital** (3–10 mg/kg IV to effect) can be used.

Naloxone (0.01–0.02 mg/kg IV) has been used as an opiate antagonist to diminish CNS depression. **Thiamine** (10–20 mg/kg q 12 h) can be added to the IV fluids to help preserve aerobic brain metabolism. Thiamine deficiency has been associated with intracellular and extracellular edema and neuronal cell death due to glutamate-induced and NMDA receptor mediated excitotoxicity. Xylazine should be avoided since it can cause transient hypertension with exacerbation of CNS hemorrhage. Acepromazine should be avoided also since it lowers the seizure threshold.

Cerebral edema occurs in some HIE foals. IV DMSO (0.5–1.0 g/kg) is administered as a 20% solution to help reduce brain swelling and intracranial pressure as well as to decrease inflammation and platelet aggregation. DMSO should be used cautiously in hypotensive neonates. The osmotic diuretic, **mannitol** (0.25–2.0 g/kg given as a 20% solution IV over 15–40 min), has been used to treat cerebral edema and to scavenge free radicals. To avoid exacerbation of cerebral edema, IV fluid administration should be conservative and **fluid balance monitored** in anuric or oliguric patients. Low doses of magnesium

sulfate administered as a continuous infusion have been used to reduce the hypoxia-induced increase in oxygen free radical generation. Other medications used for their antioxidant properties include ascorbic acid (vitamin C) and alpha-tocopherol (vitamin E).

Controversy surrounds the benefits of **glucose administration** to neonates during the early post-hypoxic period. Possible benefits include a reduced incidence of CNS infarction, attenuated brain damage, and some degree of neuroprotection by stimulating insulin release and reducing glycolysis, free radical formation and glutamate-mediated injury. However, hyperglycemia can augment hypoxic brain injury. Therefore, it is best to avoid extremes in glucose concentration.

Fluid therapy should be monitored closely to avoid over-hydration and hyper- and hypo-osmolar states. Low levels of **dopamine** (1.0–5.0 $\mu\text{g/kg/min}$) stimulate dopaminergic receptors and improve renal blood flow and urine production. Moderate doses stimulate β_1 receptors to increase heart rate and strength of contraction, which help improve renal perfusion by correcting mild cases of hypotension. High doses of dopamine compromise renal and gastrointestinal perfusion and should be avoided. **Furosemide** (0.25–0.5 mg/kg IV q 30–60 min administered during dopamine infusion or constant rate infusion [CRI] 0.25–2.0 mg/kg/h) works synergistically with dopamine to promote diuresis. Serum electrolytes should be monitored during diuretic therapy.

Ileus associated with hypoxic gut damage can result in bowel distension and colic (*q.v.*). To reduce the risk of **necrotizing enterocolitis (NEC)**, asphyxiated foals should have enteral feeding withheld until intestinal motility has returned. Reassuring signs include manure passage, normal borborygmi and stable vital signs (temperature, blood pressure). **Enteral feeding** should be started cautiously with fresh mare's milk or colostrum. Foals with severe gastrointestinal dysfunction should have enteral feeds withheld and should be started on **parenteral nutrition** using a hypertonic solution containing dextrose, amino acids and lipid emulsion. Since intestinal ischemia may predispose to **ulceration** (*q.v.*), H_2 blockers (cimetidine, ranitidine), proton pump inhibitors (omeprazole), or cytoprotective agents (sucralfate) are recommended.

Mild to moderate hypoxemia can be treated by increasing the amount of time the foal spends in **sternal recumbency** or **standing** and by administering modest flows of **humidified intranasal oxygen** (2–8 L per min). Foals suffering severe hypoxemia and hypercapnia ($\text{PaO}_2 < 40 \text{ mmHg}$, $\text{PaCO}_2 > 65 \text{ mmHg}$) require positive pressure ventilation.

Respiratory stimulants are used to treat periodic apnea and abnormally slow breathing patterns associated with central depression of the respiratory center. **Caffeine** (loading dose 10 mg/kg PO; maintenance dose 2.5–3.0 mg/kg PO q 24h) is used most frequently to stimulate the respiratory neuronal activity and increase receptor responsiveness to elevated carbon dioxide concentrations. Overdosing with respiratory stimulants leads to excessive CNS, myocardial and gastrointestinal stimulation resulting in agitation, seizures, tachycardia, hypertension, colic and diarrhea. Caffeine is the safest of the methylxanthines to use.

Maladjusted foals (*q.v.*) are at increased risk for FPT due to their abnormal nursing behavior. Serum IgG levels should be evaluated to ensure adequate

passive transfer of colostral antibodies. The foal's serum IgG should be >800 mg/dL by 18–24 h of age. If IgG <800 mg/dL, **colostrum** and/or **plasma** should be administered to treat hypogammaglobulinemia. Adequate nutrition must be provided until the foal is able to nurse normally from the mare.

It is reasonable to expect to see stabilization of CNS signs within the first 48–72 h following delivery followed by gradual improvement in neurologic signs within the first 3–5 days. Some foals may not regain the ability to nurse from the mare for 7–10 days or longer.

Treatment of the hypoxic foal must address all organ systems involved. A therapeutic plan designed to treat the variety of complications associated with hypoxic tissue damage is outlined in Box 14.6. Approximately 60–80% of foals affected with HIE recover.

Box 14.6 Therapeutic plan for hypoxia-induced disorders in foals

CNS dysfunction

- Seizure control: diazepam (0.11–0.44 mg/kg IV), phenobarbital (2–10 mg/kg IV q 12 h; monitor serum levels), pentobarbital (2–10 mg/kg IV)
- Avoid xylazine; causes transient hypertension and exacerbates CNS hemorrhage
- Avoid acepromazine; lowers seizure threshold
- IV DMSO (0.5–1.0 g/kg IV given as a 10–20% solution over 1–2 h; can repeat q 12 h); stabilizes membranes, prevents platelet aggregation, maintains vascular integrity, scavenges free radicals during reperfusion
- IV mannitol (0.25–1.0 g/kg IV over 15–20 min q 6–12 h); osmotic diuretic; contraindicated with cerebral hemorrhage
- Magnesium sulfate CRI: 50 mg/kg/h diluted to 1% and given slowly as a CRI over 1 h, then decreased to 25 mg/kg/h as a CRI for 24–48 h
- Ascorbic acid (vitamin C): 50–100 mg/kg/day; antioxidant
- Alpha-tocopherol (vitamin E): dose not established; 500 units PO/day has been recommended
- Thiamine: 10 mg/kg IV q 12 h; support cerebral metabolism

Renal dysfunction

- Monitor fluid in/urine out to avoid over-hydration and evaluate renal function
- Dopamine CRI (2–10 μ g/kg/min); improves renal blood flow and urine output
- Furosemide CRI (0.25–2.0 μ g/kg/h)
- Mannitol (0.25–1.0 g/kg IV q 6–12 h); osmotic diuretic
- Dobutamine CRI (2–10 μ g/kg/min); use if cardiac dysfunction and hypotension are contributing to poor renal perfusion

Gastrointestinal dysfunction

- Nasogastric decompression; percutaneous large bowel trocarization
- Prokinetic drugs for delayed gastric emptying: erythromycin (2 mg/kg PO/IV q 6 h); metoclopramide (0.25–0.4 mg/kg slow IV infusion q 6 h); bethanechol (0.03 mg/kg SC q 8 h, 0.16–0.2 mg/kg PO q 8 h); do not administer prokinetic drugs if there is evidence of severe ischemic bowel damage or obstruction

Box 14.6 continues on page 823

Box 14.6 Therapeutic plan for hypoxia-induced disorders in foals [continued]

- Anti-ulcer medication: ranitidine (8–10 mg/kg PO q 6–8 h; 1–2 mg/kg q 8 h), cimetidine (20 mg/kg PO q 6 h; 6.6 mg/kg IV q 6 h), omeprazole (4 mg/kg PO q 24 h), antacids
- In cases of severe asphyxia, hypotension and hypothermia, delay enteral feeding until gut motility is restored; begin parenteral nutrition
- Broad-spectrum bactericidal antibiotics

Cardiac dysfunction

- Dopamine, dobutamine to treat systemic hypotension and reduced cardiac output (dopamine: 1–15 μ g/kg/min CRI; dobutamine: 1–20 μ g/kg/min CRI)
- Avoid over-hydration
- Diuretics (furosemide) to treat edema associated with cardiac failure (0.5–1.0 mg/kg IV)
- Digoxin (0.02–0.35 mg/kg PO q 24 h) if cardiac failure is evident

Secondary infection

- Colostrum
- IV plasma
- Broad-spectrum bactericidal antibiotics

Dehydration and poor nursing behavior

- Cautious fluid therapy: maintenance rate: 4–5 mL/kg/h
- IV dextrose: avoid hyperglycemia
- Enteral feeding: 10–25% of foal's BW per day of mare's milk, artificial replacer, or goat's milk
- Parenteral nutrition to replace or supplement enteral feeds if gut function is compromised

Respiratory function

- Mild hypoxemia: increase time foal spends in sternal recumbency or standing; intranasal, humidified oxygen at 2–10 L/min
- Moderate to severe hypoxemia/hypercapnia ($\text{PaO}_2 < 65$ mmHg, $\text{PaCO}_2 > 65$ mmHg): provide positive pressure ventilation
- Intratracheal surfactant administration to treat surfactant dysfunction
- Respiratory stimulants: caffeine (loading dose: 10 mg/kg PO; maintenance dose: 2.5–3.0 mg/kg PO q 24 h) to treat periodic apnea and improve diaphragmatic contractility

Prognosis is determined by duration and severity of clinical signs and quality of nursing care. Foals with the poorest prognosis develop septicemia, fail to show any signs of improvement in neurologic function within the first 5 days of life and remain comatose and difficult to arouse. Poor prognostic signs include refractory hypotension and oliguria, signs of severe brainstem damage including loss of thermoregulatory control and profound apnea, and seizures that persist past 5 days of age despite anti-convulsant therapy.

Rare, long-term CNS sequelae include unusual docility as adults, vision impairment, residual gait spasticity and recurrent seizures. Recovered foals usually show no residual neurologic deficits.

PREMATURITY

Prematurity suggests **curtailed gestational length** (≤ 320 days) as the cause of fetal underdevelopment. Immaturity and dysmaturity imply an **abnormal intrauterine environment** (e.g. placentitis, hydrops, twinning, and placental insufficiency [*q.v.*]) that has resulted in retarded growth and/or development. Dysmature foals can have shortened, normal or prolonged gestation lengths. Some premature foals demonstrate comparable immaturity of all organ systems, while others show prematurity of some organs and selective, accelerated development of other systems. The difference depends on whether the foal was the product of simply a shortened gestation and otherwise normal intrauterine environment or was the result of chronic in utero disease contributing to abnormal fetal development.

Intrauterine growth retardation (IUGR) is pathologic and is due to genetic causes or epigenetic causes that affect placental function. IUGR results in a newborn that has a relatively large head and small body. In humans, most forms of IUGR are suspected to occur during the third trimester and are associated with placental vascular lesions, maternal starvation, twinning, intrauterine infections due to bacterial or fungal pathogens and chronic hypoxia. **Small for gestational age** (SGA) defines a foal that is smaller than normal for its gestational age. The relative weight of the term foal to its dam is approximately 10%.

Etiology

Causes of prematurity include any condition that adversely affects the intrauterine environment and fetal development or precipitates early delivery. **Placental abnormalities** associated with premature delivery include placentitis, premature membrane rupture, premature placental separation and hydrops (*q.v.*). **Fetal factors** include congenital anomalies and twinning (*q.v.*). Maternal conditions that predispose to early delivery include incompetent cervix, severe illness and chronic debilitation, general anesthesia and viral infection. Another unfortunate cause of prematurity is **untimely induction of labor**. The majority of premature deliveries remain undiagnosed.

Conditions associated with improved survival rates among premature foals include delivery associated with **chronic placentitis**, birth via spontaneous vaginal delivery, the absence of systemic disease in the mare and the presence of a suckle reflex in the foal. Laboratory findings in the foal associated with an optimistic prognosis include a white blood cell count ≥ 500 cells/ μL , a neutrophil-lymphocyte ratio $\geq 2:0$, the absence of severe metabolic acidosis, and appropriate insulin and cortisol responses. Frequently misleading is the **deceptively robust** appearance of many premature foals immediately post partum. However, within 48 h of birth the foal's inability to maintain homeostasis and signs of multiorgan dysfunction frequently become apparent.

Clinical signs

Physical characteristics of prematurity (Table 14.11) include low birth weight, generalized weakness, diminished suckle reflex, short, silky haircoat, domed forehead, floppy ears and deep red tongue. Periarticular and flexor tendon laxity results in sloped pasterns and increased passive range of limb motion. Premature and dysmature foals have difficulty adapting to the extra-uterine environment.

Table 14.11 Characteristics of prematurity in the foal

Parameter	Observation
Gestation length	<320 days
Electrolyte concentrations in pre partum mammary secretions	Calcium <40 mg/dL Sodium >30 mEq/L Potassium <35 mEq/L
Physical characteristics	Small size; fine, silky haircoat; generalized weakness; laxity of periarticular ligaments and flexor tendons; increased passive range of limb motion; floppy, pliant ears; incompletely ossified cuboidal bones
Behavior	Prolonged time to sit sternal, stand, and suckle
Thermoregulation	Increased incidence of hypothermia
Respiration	Increased work of breathing, tachypnea, nostril flare, expiratory grunting, paradoxical breathing, periodic apnea
Digestion	Poor tolerance of oral feeds; gut dysmotility, frequent colic
Hematology	Mean corpuscular volume >39 fL White blood cells = $6 \times 10^3/\mu\text{L}$ Neutrophil-lymphocyte <1.0
Blood gases/acid-base status	Arterial pH $\leq 7.208 \pm 0.034$ at birth PaCO ₂ = 66.2 ± 4.7 mmHg PaCO ₂ = 30.0 ± 4.1 mmHg HCO ₃ = 23.4 ± 1.7 mmol/L
Endocrine function (within 2 h post partum)	Cortisol <30 ng/mL Poor ACTH response with 28% increase in cortisol No change in neutrophil-lymphocyte ratio Glucose = 41.6 mg/dL Insulin = 8.6 $\mu\text{U/mL}$ Poor insulin response following IV glucose administration More rapid loss of sodium following furosemide administration

Hypothermia is a manifestation of **immature thermoregulation**. Oral feed intolerance accompanied by colic, flatulence, delayed gastric emptying and gastric reflux reflects **gut immaturity**. Incomplete innervation of the gut may contribute to dysmotility patterns and increased incidence of gastrointestinal disturbances observed among premature foals. Reduced collagen content associated with abnormal collagen synthesis and cross-linking contributes to weakened structural support of vessels and lungs, flexor tendon laxity and floppy ears.

Pulmonary insufficiency resulting in hypoventilation and respiratory distress is often multifactorial in origin. Causes include: (1) inefficient gas exchange due to recumbency and dependent lung atelectasis; (2) high compliance of the immature chest wall; (3) ineffectual reflex control of breathing; (4) abnormal paradoxical breathing; (5) pulmonary hypertension and an increase in right to left intrapulmonary shunting; (6) insufficient surfactant production. Many premature foals are born with incompletely ossified cuboidal bones and unrestricted exercise or excessive weight bearing can result in abnormal cuboidal bone calcification producing **severe angular limb deformities** (*q.v.*).

Laboratory findings associated with prematurity (Table 14.11) include leukopenia, neutropenia, hypoglycemia, hypocortisolemia, hypoxemia and hypercapnia. Premature foals delivered because of in utero infection often have a hyperfibrinogenemia.

Table 14.12 Symptomatic treatment of complications associated with prematurity

Condition	Sign or complications	Treatment
Altered behavior	Inability of stand or set sternally	Assist to stand and turn from side to side every 2 h; support in sternal position with pillow
	Inability to nurse from mare; ineffective suckle reflex or swallow reflex	Enteral alimentation via bucket, bottle or nasogastric tube; parenteral nutrition
Abnormal homeostasis	Hypothermia ($\leq 37.2^{\circ}\text{C}$)	Raise ambient temperature; hot water bottles, warmed IV fluids in insulated jackets, blankets, hot water pads, radiant heat lamps
	Metabolic acidemia ($\text{pH} < 7.35$)	Fluid replacement if hypovolemic; isotonic bicarbonate (1.3%) once adequate ventilation ensured
	Hemoconcentration; dehydration	IV fluids (maintenance rate = 80–120 mL/kg/day); higher sodium requirements
	Hypoglycemia (glucose ≤ 50 mg/dL)	IV dextrose (5%, 10%), enteral and/or parenteral alimentation
Pulmonary dysfunction	$\text{PaO}_2 < 65$ mmHg; PaO_2 normal	Humidified nasal insufflation of O_2 (3–10 L/min); increase time spent in sternal recumbency
	$\text{PaO}_2 \leq 65$ mmHg; $\text{PaO}_2 > 65$ mmHg	Mechanical ventilatory support via PaCO_2 normal nasotracheal intubation with positive end expiratory pressure; consider intratracheal surfactant administration
Hypogammaglobulinemia	$\text{IgG} < 400\text{--}800$ mg/dL	Oral colostrum (1 L minimum) if < 18 h old; IV plasma (20–40 mL/kg); broad-spectrum bactericidal antibiotics
Gastrointestinal dysmotility	Gastric reflux, ileus	Decrease frequency and volume of oral feeds; oral or IV metoclopramide
	Constipation, meconium	Gravity and/or retention enemas, retention oral fluids, oral mineral oil, IV fluids, add psyllium to enteral fluids
	Diarrhea	Oral protectants (bismuth subsalicylate), loperamide, <i>Lactobacillus</i> intestinal inoculants, active culture yogurt
	Ulceration	Ranitidine, sucralfate, antacids; avoid unnecessary use of NSAIDs
Flexor tendon laxity; periarticular laxity	Inability to stand or walk; increased slope to pasterns	Physical therapy; glue-on shoes with heel extensions; restricted exercise on soft surface
Incomplete cuboidal bone ossification	Angular limb deformities	Restricted exercise; if severe, rigid support with splint or casts

Treatment

Abnormal neuroendocrine and immune functions render the premature foal susceptible to **septicemia** and a variety of metabolic stresses. A certain percentage of premature foals fail to absorb sufficient immunoglobulins despite adequate colostrum ingestion and require **plasma transfusion** (*q.v.*) to correct hypogammaglobulinemia. Blunted insulin responses predispose to hypoglycemia, necessitating frequent enteral feeds and/or continuous glucose infusion. Symptomatic treatments for a variety of the complications associated with prematurity are presented in Table 14.12.

SEPTICEMIA AND SEPTIC SHOCK

Septicemia is the leading cause of neonatal foal morbidity and mortality and is most commonly associated with disseminated, Gram-negative and/or Gram-positive bacterial infection.

Etiology

Septicemia describes the constellation of clinical signs produced by the interaction of microbial toxins and the host immune system. **Over-activation** of the immune system provokes uncontrolled release of endogenous mediators and precipitates a **cascade** of metabolic and hemodynamic changes culminating in **multiple organ system failure**. **Septic shock** is characterized by circulatory failure, perfusion deficits and an inability of the body to use existing metabolic substrate effectively.

One of the most potent mediators of Gram-negative sepsis is **endotoxin** (*q.v.*), the lipopolysaccharide component in the outer cell membrane of Gram-negative bacteria. Endotoxins are released from Gram-negative bacteria whenever their cell membrane integrity is disrupted, as occurs during rapid growth and proliferation or cell death. Some of the local and systemic effects of endotoxin are presented in Table 14.13.

The interaction of endotoxin with neutrophils, mononuclear phagocytes, lymphocytes and vascular endothelial cells results in the release of a **second wave of endogenous mediators** that include tumor necrosis factor, interleukins, prostaglandins, interferons and eicosanoids.

Increased vascular permeability is accompanied by interstitial and pulmonary edema, hypovolemia and decreased cardiac output. Changes in vascular tone are characterized by pulmonary and systemic arterial hypotension and vasoconstriction contributing to a decrease in splanchnic perfusion. Coagulation pathways are activated and capillary microthrombi compromise tissue perfusion even further.

The hypermetabolism and increased catabolism associated with sepsis is mediated by the release of cortisol, catecholamines and glucagon resulting in **peripheral insulin resistance** and increased glycolysis and lipolysis. Sepsis hinders sequentially the utilization of glucose, fat and finally protein as an energy source.

Cardiovascular function is impaired indirectly by endotoxin-stimulated release of myocardial depressant factor. Endotoxin also exerts a direct inotropic depressant effect on the **heart muscle**. During early compensated sepsis,

Table 14.13 Local and systemic effects of endotoxin

Organ system	Response	Net results
Immune system		
Neutrophils	Release of eicosanoids Enhanced chemotaxis and degranulation Enhanced adherence to vascular endothelium Platelet activating factor released (PAF)	Increased inflammation Peripheral neutropenia; release of reactive O ₂ species and enzymes; auto-injury Vascular damage, increased vascular permeability Platelet activation, leukocyte chemotaxis, aggregation; macrophage activation; systemic vasodilatation, hypotension; pulmonary, coronary vasoconstriction, negative cardiac inotropy
Macrophages	Release of inflammatory cytokines: tumor necrosis factor (TNF), interleukin-1 (IL-1); neutral proteases; eicosanoids: leukotrienes, prostaglandins; PAF, reactive O ₂ species	Potent mediators of sepsis-induced inflammation, auto-injury, changes in systemic vascular tone and permeability, and hemostasis
Lymphocytes T cells B cells	Decreased suppressor cell activity Cytokines released; antibody production stimulated	Loss of immune system modulation Inflammation, systemic vascular changes
Vascular endothelial cells	Release of prostacyclins, interleukins, hematopoietic growth factor, PAF, endothelial relaxing factors	Collagen exposed; platelet aggregation, coagulation cascade stimulated; bradykinin released resulting in vasodilatation, hypotension
Platelets	Release of thromboxane, PAF, serotonin	Pulmonary hypertension, vasoconstriction, platelet aggregation, leukocyte chemotaxis
Cardiovascular system	Myocardial depressant factor Direct negative inotropy	Negative inotropy Initially, increased blood pressure; tachycardia, increased O ₂ consumption Terminally, decreased vascular tone, low vascular resistance, increased anaerobic metabolism; metabolic acidosis; myocardial failure; hypotension
Pulmonary system	Margination of leukocytes, lymphocytes Intrapulmonary leukocytes, platelets release PAF, eicosanoids	Endothelial damage, increased capillary permeability Initially, increased vascular resistance, pulmonary hypertension Terminally, pulmonary edema, atelectasis, intrapulmonary shunting
Endocrine system		
Pituitary gland	Release of endorphin Release of ACTH Release of antidiuretic hormone	Pain relief, change in mentation, altered vascular permeability Cortisol released Fluid retention
Adrenal gland	Release of cortisol and catecholamine Release of aldosterone	Glycolysis, lipolysis, peripheral insulin release Fluid and sodium retention
Gut	Release of glucagon	Lipolysis, peripheral insulin resistance

a sympathetic response results in an increased heart rate and cardiac index, improved myocardial contractility, and increased oxygen consumption.

As septicemia progresses there is a **decrease in vascular tone** and systemic vascular resistance disproportionate to the increase in cardiac output. Oxygen extraction by peripheral tissues is decreased, metabolic acidosis develops and anaerobic metabolism commences. Terminally, **myocardial failure** develops associated with decreased cardiac output, respiratory decompensation, severe hypotension and profound respiratory/metabolic acidosis.

During sepsis, pulmonary capillary permeability increases and polymorphonuclear leukocytes and lymphocytes marginate and accumulate in the pulmonary microvasculature. Neutrophil degranulation produces endothelial damage, increased capillary permeability and alveolar flooding. Intrapulmonary shunting develops followed by progressive atelectasis and pulmonary edema.

The origin of **neonatal infection** includes opportunistic organisms whose portal of entry includes the gastrointestinal, urogenital and respiratory tracts, the umbilicus and the placenta. Factors predisposing to neonatal septicemia include:

1. Environmental factors: overcrowding, poor ventilation and sanitation, inadequate umbilicus disinfection, iatrogenic stress, excessive use of antibiotics on the farm
2. Disorders of the neonatal immune system: failure of passive transfer, combined immunodeficiency
3. Perinatal stresses: peri partum hypoxia, prematurity, severe musculoskeletal deformities.

Organisms most commonly associated with foal septicemia include *Escherichia coli*, *Actinobacillus* spp., *Pasteurella* spp., *Klebsiella* spp., *Salmonella* spp., *Streptococcus* spp. and *Staphylococcus* spp. (*q.v.*).

Clinical signs

The wide spectrum of clinical signs associated with septicemia depends on the integrity of the **host immune system**, the duration of illness and the severity of the infection. Clinical conditions associated with neonatal sepsis are presented in Box 14.7.

During the early hyperdynamic phase of sepsis, foals display lethargy, loss of suckle, hyperemic mucous membranes due to peripheral vasodilatation, decreased capillary refill time, tachycardia, tachypnea, increased cardiac output, hyperkinetic pulses and variable body temperature. Extremities are still warm. Laboratory data typically reveal leukopenia and neutropenia with a degenerative left shift, and normal or low glucose concentration. Fibrinogen concentration is often normal. **Elevated fibrinogen** levels suggest the infection has been present for a minimum of 48–72 h.

Septic shock (*q.v.*) develops when infection overwhelms the host immune system. Affected foals are usually recumbent, dehydrated and almost moribund with hypotension and decreased cardiac output characterized by tachycardia, cold extremities, thready peripheral pulses, prolonged capillary refill time and oliguria. Hypothermia is common. Gut motility is often decreased and

may be accompanied by gastric reflux, constipation and variable degrees of abdominal distension. Signs of respiratory compromise associated with decreased pulmonary perfusion and increased vascular permeability include tachypnea, dyspnea and hypoxemia (*q.v.*).

Box 14.7 Clinical conditions associated with neonatal septicemia

History: Predisposing factors

- Severe maternal illness
- Premature lactation
- Maternal vaginal discharge, placentitis
- Neonatal hypogammaglobulinemia (FPT)
- Severe neonatal stress
- Prematurity

Physical examination findings

- Early sepsis
 - Loss of suckle reflex
 - Distended udder on dam
 - Lethargy, generalized weakness
 - Variable temperature
 - Injected sclera
 - Hyperemic mucous membranes and coronary bands
 - Variable capillary refill time
 - Tachycardia
 - Tachypnea
 - Hyperkinetic pulses
 - Petechiae on gums, sclera, vulva, pinnae, coronary bands
- Late sepsis
 - Profound weakness and depression
 - Complete anorexia
 - Tachycardia
 - Weak peripheral pulses, hypotension
 - Cold extremities
 - Prolonged capillary refill time
 - Oliguria/anuria
 - Respiratory distress
 - Hypothermia
- Localized sites of infection
 - Pneumonia/pleuritis
 - Meningitis
 - Hepatitis
 - Nephritis
 - Peritonitis, enteritis
 - Synovitis, osteomyelitis
 - Uveitis
 - Omphalitis

Box 14.7 continues on page 831

- Hematology and serum biochemistry
 - Leukopenia, neutropenia, degenerative left shift
 - Thrombocytopenia
 - Hyperfibrinogenemia (variable)
 - Metabolic acidosis
 - Respiratory acidosis
 - Hypoglycemia
 - Lipemia
 - Hypogammaglobulinemia
 - Hyperbilirubinemia
 - Azotemia
 - Disseminated intravascular coagulation

Terminally, **multiorgan system failure** occurs. If the foal does not die of acute septic shock, localized infections develop in one or more body systems (see Box 14.7). During the terminal stages of septicemia, foals frequently display a mixed respiratory/metabolic acidosis, marked hemoconcentration, lipemia, hyperbilirubinemia, azotemia, profound hypoglycemia, and leukopenia with a degenerative left shift. Endotoxin and tumor necrosis factor result in hemostatic dysfunction characterized by disseminated intravascular coagulation.

Hypogammaglobulinemia is common due to inadequate absorption of colostral antibodies and/or increased protein catabolism associated with sepsis. Serial blood cultures obtained prior to antimicrobial therapy increase the likelihood of isolating the offending pathogen(s).

Therapy

Guidelines for the treatment of neonatal septicemia are presented in Table 14.14. Therapy is focused on support of the cardiopulmonary and immune systems and provision of adequate nutrition and intensive nursing care. IV fluid therapy is the mainstay of cardiovascular support and should be administered at the maximal rate tolerated by the foal. Severe septic shock may require flow rates of 20–40 mL/kg/h. Volume expansion should be achieved using a **balanced electrolyte solution** or **plasma**.

The goal of fluid therapy is to reduce peripheral vasoconstriction, restore good peripheral pulse quality, improve renal perfusion and urine output, increase central venous pressure to ≥ 5 cm of water and restore arterial systolic blood pressure to ≥ 70 –80 mmHg. If fluid therapy alone fails to restore acceptable blood pressure and urinary output, β -adrenergic drugs may be indicated (e.g. dopamine, dobutamine). Since most septic foals are hypoglycemic, a **slower, continuous infusion of dextrose-containing solutions** should be included. Rapid administration of concentrated dextrose solutions must be avoided to prevent hyperglycemia and hyperosmolality.

Minimizing ventilation–perfusion mismatching is the focus of respiratory support. Fluid therapy should proceed cautiously to maintain a high enough left ventricular end diastolic pressure and left atrial pressure to create more

Table 14.14 Guidelines for treatment of neonatal septicemia

Abnormal condition	Cardiovascular support	Parameters to monitor
Dehydration hypotension associated with hypovolemia; oliguria/anuria	IV balanced electrolyte solution, plasma	HR, CVP, BP, pulse quality, urine production, PCV, TP
Anuria/oliguria despite rehydration	Dopamine: low dose (1–4 µg/kg/min): dopaminergic; improves RBF; intermediate dose (5–10 µg/kg/min): β ₁ -cardiotonic; β ₂ -systemic vasodilatation (at excessively high doses dopamine acts as an α ₁ -agonist causing systemic vasoconstriction, decreased RBF)	HR, BP, pulse quality, urine production
Impaired cardiac function; use echocardiography to assess cardiac contractility	Dopamine: intermediate dose for cardiotonic effects Dobutamine (2–15 µg/kg/min); selective β ₁ -agonist; minimal vasodilatation; increased contractility with little increase in HR	HR, BP, pulse quality, urine production HR, BP, pulse quality
Abnormal condition	Pulmonary support	Parameters to monitor
Hypoxemia associated with dependent lung atelectasis, pulmonary hypoperfusion	Intranasal oxygen (3–10 L/min) Increase time spent sternal Cautious fluid therapy	Arterial blood gas
Hypoxemia, hypercapnia, pulmonary edema due to capillary leak; atelectasis due to surfactant dysfunction, intrapulmonary shunting	PPV with PEEP Furosemide Correct acidosis Fluid and plasma therapy to maintain BP and CO	Arterial blood gas Capnography and pulse oximetry Thoracic radiographs
Abnormal condition	Immune system treatment	Parameters to monitor
Gram-negative bacteremia	Broad-spectrum bactericidal antibiotics	Cultures of blood and/or other body fluids (synovia, CSF, peritoneal fluid, urine, TTA); leukogram, fibrinogen concentration
Failure of passive transfer	Oral colostrum if <18 h old and gut is functional; plasma transfusion	IgG concentration
Endotoxemia	Low doses of flunixin meglumine; anti-endotoxin serum; hyperimmune plasma	Vital signs, BP, HR pulse quality, mucous membranes
Abnormal condition	Metabolic treatment	Parameters to monitor
Hypoglycemia	IV glucose Enteral feeds Parenteral alimentation	Glucose concentration (Dextrostix or glucometer)

Table 14.14 (Continued)

Abnormal condition	Metabolic treatment	Parameters to monitor
Metabolic acidosis	IV fluids to improve peripheral perfusion Cautious use of IV isotonic bicarbonate	Venous blood gas
Abnormal condition	Nutritional support	Parameters to monitor
Functional gut and inadequate intake	Enteral feeding via NGT or bottle using mare's milk, goat's milk, or foal milk replacer; goal is 20–25% BW/day divided into frequent feeds every 2–3 h	Body weight, gastrointestinal tolerance: gut motility, reflux, abdominal distension, fecal product
Compromised gut, inadequate intake	Parenteral alimentation using dextrose, amino acids, lipids, multivitamins and trace minerals	Plasma glucose, lipids, electrolytes, osmolarity; urine glucose, PCV/TP
Miscellaneous		
Abnormal condition	Treatment	Parameters to monitor
Hemostasis abnormalities; DIC; thrombocytopenia	Heparin, fresh plasma	Clotting parameters; platelet count
Increased capillary and membrane leakiness	Membrane stabilizing drugs: DMSO, steroids, PG inhibitors	Examine for pulmonary and/or generalized edema
Hypothermia	Warm, ambient temperature; warmed IV fluids, blankets, hot water bottles; fluid therapy to correct hypovolemia; radiant heat lamps	Body temperature
Recumbency	Frequent repositioning; chest coupage; bed on soft absorbent fleece mats; keep dry and clean	Examine daily for pressure sores

ABG, arterial blood gas; BP, blood pressure; BW, body weight; CO, cardiac output; CSF, cerebrospinal fluid; CVP, central venous pressure; DIC, disseminated intravascular coagulation; DMSO, dimethyl sulfoxide; HR, heart rate; NGT, nasogastric tube; PCV, packed cell volume; PEEP, positive end expiratory pressure; PG, prostaglandin; PPV, positive pressure ventilation; RBF, renal blood flow; TP, total protein; TTA, transtracheal aspirate.

uniform lung perfusion. Frequent repositioning of the patient's chest helps minimize the development of pulmonary edema. **Intranasal oxygen therapy** is used to treat mild hypoxemia. Mechanical positive pressure ventilation may be required to prevent further alveolar collapse associated with increased tissue pressure due to interstitial edema.

The hypermetabolism and protein catabolism associated with sepsis must be addressed. Parenteral alimentation is often necessary in foals unable or unwilling to consume enough calories orally. When peripheral insulin resistance and glucose intolerance develop, lipids become a valuable source of calories. In severely affected foals, caloric requirements often exceed 120 kcal/kg/day. Specific guidelines for nutritional support are presented elsewhere.

Antimicrobial therapy should be instituted without delay, as soon as sepsis is suspected and before culture results are available. Broad-spectrum, bactericidal antimicrobial agents should be used. If renal function is adequate, **penicillin** and an aminoglycoside (**amikacin** or **gentamicin**) are an effective

drug combination. If renal compromise is present then cephalosporins (**ceftiofur**) or extended spectrum penicillins should be considered.

Plasma from hyperimmunized donors is administered to treat not only failure of passive transfer, but to provide opsonins and to improve foal neutrophil function. Low doses (0.25 mg/kg IV q 8 h) of **flunixin meglumine** may help ameliorate some of the signs of endotoxemia.

Septic foals require **intensive nursing care**. Attention focuses on keeping the recumbent foal dry and clean to prevent decubital ulcers and urine/fecal scalding. Foals should be frequently repositioned to prevent decubital ulcers and dependent lung atelectasis. Vital signs are monitored on a frequent basis to detect subtle changes in the patient's condition. Survival depends on **aggressive supportive care** during the initial stages of acute sepsis to prevent death due to septic shock and to prevent the development of multiple sites of localized infection.

NEONATAL ISOERYTHROLYSIS

Neonatal isoerythrolysis (NI) (*q.v.*) is an important cause of **neonatal icterus** that develops in newborns foals following the ingestion of colostrum from a multiparous mare. The cardinal signs of NI are icterus, anemia and pigmenturia.

Etiology

NI is the result of RBC destruction by alloantibodies produced by the mare as a result of **alloimmunization** (*q.v.*) by foreign erythrocyte antigenic factors of the foal inherited from the stallion and not possessed by the mare. Although there are 32 blood group antigens (*q.v.*) known for horses, Aa and Qa are the antigens most commonly associated with the disease.

Clinical signs

Clinical signs of NI relate to the severity and rapidity of onset of **anemia**. Signs occur only after colostrum has been ingested and sufficient amounts of offending antibody absorbed to result in RBC destruction.

Antibody absorption is usually complete 4–5 h after a meal of colostrum is ingested. In severe cases **profound hemolysis** develops and results in a short, rapidly fatal clinical course that may be only hours in duration. These foals show pallor of mucous membranes, weakness, tachypnea, tachycardia, acute collapse and death. Seizures and other CNS signs may develop as a result of brain hypoxia.

Foals with milder forms of NI exhibit signs of anemia and icterus within hours to days following delivery. As hemolysis progresses, foals develop icterus, lethargy, weakness, loss of nursing vigor, tachypnea, tachycardia and pigmenturia. A low-grade fever may be associated with hemolysis.

Treatment

If clinical signs of NI are detected while the foal is still <24 h old, then further nursing from its dam should be prevented for a minimum of 24–36 h and the

mare stripped of all remaining colostrum. An **alternate source of colostrum** should be obtained. Tachypneic foals may benefit from intranasal oxygen to help fully saturate RBC hemoglobin. Rapidly developing hemolysis may predispose to brain hypoxia and the onset of seizures or other CNS signs (e.g. head tilt). Foals with seizures should receive anticonvulsants (diazepam 5–10 mg IV, or phenobarbital 3–9 mg/kg given slowly IV).

Foals with NI that experience severe, life-threatening hemolysis (PCV < 15%) are in need of an **immediate whole blood transfusion** (*q.v.*) to restore oxygen-carrying capacity. The donor red cells must be compatible with the mare's serum/colostral antibodies since those are the offending antibodies circulating in the foal. **The most unsatisfactory donor is the sire.** The ideal red cell donor is the dam since her red cells will not react with her own antibodies. However, only **washed red cells** from the mare are safe to administer.

Alternate blood sources include an Aa and Qa negative donor or an unmatched gelding or other horse not used for breeding. Oxyglobin (Oxyglobin, Biopure Corp, Cambridge, MA) represents an alternative solution for some valuable NI foals. Oxyglobin is a commercial product containing polymerized ultrapurified bovine hemoglobin. Oxyglobin is a potent colloid. Care must be taken when administering Oxyglobin to normovolemic patients due to its ability as a colloid to rapidly expand the plasma volume and cause circulatory overload and pulmonary edema. The recommended dose is 10–30 mL/kg BW administered at a rate not to exceed 10 mL/kg/h.

Prevention

Prevention of NI should be the focus of future matings. Blood typing can be used to identify mares “at risk” for having a NI foal and to select a “compatible” stallion. Most cases of NI occur when a mare that lacks either the blood group antigen Aa or Qa is bred to a stallion that possesses the corresponding factor, either Aa or Qa. Prevention of NI can be accomplished by identifying a mare at risk to produce an NI foal, identifying a compatible sire, and/or performing a **jaundiced foal agglutination (JFA)** test on the foal's presuckle blood and mare's colostrum. Once a mare has had a NI foal she is at increased risk to have another affected foal.

CLOSTRIDIAL ENTERITIS

Clostridial enteritis (*q.v.*) is increasing in frequency. *Clostridium perfringens* (most commonly type A, less commonly type C) and *Clostridium difficile* have both been identified as causative agents of colic and diarrhea in young foals as young as one day of age.

Etiology

Clostridial enteritis can be sporadic or can affect groups of foals on a farm. Clostridial spores may be ingested from the **environment**. Foals may be more susceptible to infection and overgrowth of the bacteria within the gut due to several factors including: (1) immaturity of the bile, (2) failure of passive transfer, (3) ingestion of diets high in carbohydrates and protein, (4) hypoxic gut damage, (5) concurrent infection with other pathogens such as rotavirus, and (6) concurrent administration of antibiotics.

Clostridial enteritis affects the small intestine more severely than the large intestine and results in **diffuse mucosal edema** with localized damage to the tips of villi or sloughing of the entire villous epithelium. Loss of mucosal integrity contributes to the development of endotoxemia and septicemia (*q.v.*) due to bacterial translocation from the gut lumen into the bloodstream.

Clinical signs

Clinical signs include colic, mild to moderate abdominal distension, and diarrhea. Fever is usually present. Diarrhea associated with *C. perfringens* is usually bloody. Diarrhea due to *C. difficile* may be bloody, but is often brown and fetid. *C. difficile* can also produce a fatal **hemorrhagic and necrotizing enterocolitis**. Blood work often demonstrates leukopenia and neutropenia and varying degrees of hypochloremia, hyponatremia and metabolic acidosis.

Sonographic examination of the abdomen often reveals increased small intestinal peristalsis with the bowel wall appearing more hypoechoic and thicker than normal. Occasionally gas echoes are visualized within the bowel, indicative of pneumatosis intestinalis. Feces should be submitted for **Clostridium cultures** using a Port-a-cul anaerobic tube (Becton Dickinson). Frozen feces should be submitted for toxin assays. A fresh fecal smear can be made to document the presence of Clostridium-like organisms.

Treatment

Therapy includes pain control using **dipyrone** (10–22 mg/kg IV; drug is only available through compounding pharmacies in US) and/or **butorphanol** (2–5 mg IV/IM). Low doses of **flunixin** (0.25 mg/kg IV q 8 h) are used sparingly to ameliorate the effects of endotoxemia. The drug of choice for clostridial enteritis is **metronidazole** (15 mg/kg PO q 8 h). Severe cases also should receive broad-spectrum, bactericidal antimicrobial therapy such as IV **potassium benzylpenicillin** (22 000–44 000 IU/kg IV q 6 h) and **amikacin** (20–30 mg/kg IV q 24 h).

Additional therapy includes **hyperimmune plasma** (containing high levels of Gram-negative core antigen antibodies) and aggressive **IV fluid support** using balanced electrolyte solutions containing added potassium and/or bicarbonate as indicated by serial venous blood gas analysis.

Ulcer prophylaxis should be administered IV in foals with severe colic and bowel distension and orally in foals that are nursing. Drugs and doses include **ranitidine** (1.5 mg/kg IV q 8 h, 8–10 mg/kg PO q 8 h), **cimetidine** (6.6 mg/kg IV q 6–8 h, 15 mg/kg PO q 6 h), and **omeprazole** (4 mg/kg PO q 24 h).

Oral administration of DTO smectite (BioSponge) may prevent binding of *C. difficile* toxins. **Smectite** is an alumino-magnesium silicate clay mixture with tremendous surface area capable of adhering to mucosa to increase barrier protection. Smectite is negatively charged and therefore can attract cations such as bacterial exotoxins and endotoxins. Foals should receive a loading dose of 113–120 g (4–6 oz) in a slurry, followed by 57–113 g (2–4 oz) q 6–8 h until the diarrhea resolves. **Bismuth subsalicylate** (60–120 mL PO q 4–6 h) may help absorb toxins and provide some gastroprotection.

A **Lactobacillus paste** containing *Saccharomyces* spp. should be administered to help re-establish normal gut flora. *Saccharomyces boulardii* has been shown to prevent binding of clostridial toxins.

Neonatal foals that are not nursing should have **blood glucose levels** monitored and should receive **dextrose-containing fluids**. Foals experiencing severe colic with marked abdominal distension and ileus should be prevented from nursing and supported with IV parenteral nutrition. Some foals recovering from clostridial enteritis display varying degrees of **lactose intolerance** (*q.v.*) and benefit from administration of commercially available lactase tablets.

NUTRITIONAL AND RESPIRATORY SUPPORT FOR THE NEONATAL FOAL

A rational feeding program for the sick foal must address the neonate's degree of maturity, high metabolic rate and requirements for rapid growth, and the special nutritional needs created by concurrent illness. Appropriate nutritional supplementation (*q.v.*) requires criteria for assessing nutritional status, guidelines for estimating an individual foal's nutrient requirements, and a thorough understanding of the nutritional formulas and routes of administration available.

EFFECTS OF MALNUTRITION

Malnourishment due to inadequate intake, abnormal absorption or increased utilization results in multiple organ dysfunction and increased morbidity and mortality.

Malnutrition has been associated with weight loss, depressed growth rates, generalized muscle weakness, impaired wound healing, retarded callus formation at fracture sites and decreased collagen production. Protein-calorie undernutrition results in gastrointestinal atrophy, dysmotility and impaired fat and carbohydrate digestion and absorption. Altered hepatic function reduces resistance to a variety of toxic agents including bacterial pathogens.

Nutritionally depleted patients experience **compromised pulmonary function** and reduced ventilatory capacity due to a loss of strength of diaphragmatic, intercostal and abdominal muscles. The most devastating consequence of undernutrition for the neonate is **impaired immune function** resulting in decreased resistance to infection. Malnutrition is associated with depressed bone marrow activity, atrophy of lymphoid tissues, abnormal neutrophil function, impaired antibody production, and depressed secretory, mucosal and cell-mediated immunity (*q.v.*).

NUTRITIONAL ASSESSMENT

Nutritional assessment begins with careful anamnesis and physical examination. Acute weight loss of 5% of BW or chronic weight loss of 10–15% BW is a clear indication for **nutritional supplementation**. However, a foal with a history of restricted oral intake, protracted nutritional losses or increased metabolic demands (Box 14.8) is a candidate for nutritional supplementation even before weight loss occurs or biochemical indices become abnormal.

Physical changes associated with malnourishment include weight loss, reduced growth, muscle atrophy, generalized weakness, lethargy, glossitis and scaly skin with reduced elasticity. Neonatal malnourishment may alter

Box 14.8 Indications for nutritional support in the foal**Restricted oral intake**

- Weak or absent suckle reflex due to:
 - Septicemia
 - Peri partum hypoxia
 - Prematurity/dysmaturity
- Dysphagia due to:
 - Botulism
 - Hypoxic brainstem damage
 - Prematurity
 - Congenital anomaly (e.g. cleft palate, subepiglottic cyst)
- Gastrointestinal dysfunction associated with:
 - Peritonitis, enterocolitis
 - Gastroduodenal ulceration
 - Ileus, gastric reflux, delayed gastric emptying
- Orphan foal
 - Loss of dam
 - Rejection by dam

Protracted nutritional losses

- Secretory diarrhea
 - Salmonellosis
- Malabsorption
 - Rotavirus diarrhea
 - Lactose intolerance

Increased metabolic needs

- Sepsis-induced catabolism and disruption of intermediary metabolism
- Increased growth requirements of prematurity
- Fever
- Localized infection (e.g. pneumonia, osteomyelitis)

the foal's long-term growth potential. In neonates, catch-up growth following malnutrition is complete only if the period of undernutrition is relatively brief.

Anthropometric measurements (e.g. triceps skin fold thickness, mid upper arm circumference) and body composition studies (e.g. measurements of body fat, plasma volume, total body water and lean body mass) are helpful in humans but have not been used in clinical veterinary medicine.

Biochemical indices of malnutrition include hypoalbuminemia and hypoproteinemia. Unfortunately, the long 20-day half-life of albumin in the horse renders this parameter unreliable during early stages of malnourishment. Total plasma protein concentrations may be misleading in newborn foals due to the wide range of presuckle protein values and the impact of colostrum ingestion on globulin concentration. Visceral protein markers of nutritional status such as fibronectin, prealbumin, retinal binding protein, transferrin and thyroxine-binding globulin have been helpful in humans, but have not been evaluated in the foal.

Sick, hypophagic adult horses mobilize fat reserves resulting in elevated levels of total lipids, triglycerides and cholesterol. The use of these parameters in foals is complicated by the fact that neonatal hyperlipemia also occurs due to sepsis-induced decreases in lipoprotein lipase activity and impaired lipid clearance.

The most reliable and practical immunologic indices of poor nutrition include **absolute** and **persistent lymphopenia** (≤ 2000 lymphocytes/ μL) and/or **anergy** (depression of delayed hypersensitivity response) following intradermal injection of antigen. Limited intradermal antigen testing has been performed in foals, but results are difficult to interpret since a variety of factors such as prematurity (alone) can result in an abnormal response.

DIGESTION AND ABSORPTION

The β -glycosidase, lactase, reaches maximal levels at birth followed by a steady decline after 4 mo of age. The α -glucosidases, maltase, sucrase and trehalase, are barely detectable in the equine fetus and increase slowly to reach adult levels by 10 mo of age. This pattern of disaccharidase development suggests that neonatal foals would not grow acceptably on a diet relying on sucrose, maltose or polysaccharides as its primary carbohydrate source.

NUTRITIONAL REQUIREMENTS

Since there are no specific nutritional requirements for neonatal foals, guidelines for nutrient intake have been estimated based on the average milk consumption of a healthy foal and the composition of mare's milk.

Healthy full-term foals nurse an average of seven times an hour, consume between 20% and 30% of their BW in mare's milk daily and gain approximately 0.5–1.4 kg/day. On this diet, a 50 kg foal would consume 10–12.5 L milk/day to provide 120–150 kcal/kg/day, 5–6 g protein/kg/day, and 4–5 g fat/kg/day.

Nutrient requirements for premature and growth-retarded foals are poorly defined and can only be extrapolated from guidelines established for infants with similar problems. Premature infants have higher energy and protein requirements and reduced fat absorption due to decreased bile salt synthesis and hepatic immaturity.

A healthy foal ingests approximately 250–290 mg/kg/day of **calcium**. Oral calcium requirements can only be estimated since the calcium retention rate in foals and the intestinal absorption coefficient of calcium in mare's milk are not known. Human milk alone cannot meet the calcium and phosphorus requirements of premature and low birth weight infants. It is likely that **dysmature and premature foals** with incomplete skeletal ossification have higher calcium and phosphorus requirements.

Serum calcium concentration is a poor indicator of the body's calcium needs. Parathyroid hormone (*q.v.*) stimulates calcium mobilization from bone and ensures normal serum calcium concentrations despite inadequate dietary intake. Abnormally elevated serum concentrations of alkaline phosphatase and radiographic decreases in bone density are suggestive of excessive calcium mobilization from bone associated with inadequate calcium intake.

SEPTICEMIA

Septicemia and endotoxin (*q.v.*) precipitate a neurohormonal cascade of events mediated by leukocyte endogenous mediator, catecholamines, glucocorticoids and glucagon resulting in disruption of intermediary metabolism and increased metabolic rate. Sepsis sequentially hinders utilization of carbohydrates, lipids and, finally, protein for energy.

Increased sympathetic activity associated with sepsis results in hepatic gluconeogenesis, glycolysis, lipolysis, proteolysis, water and sodium retention and increased urinary excretion of potassium and nitrogen. Mediators of sepsis inhibit insulin secretion and increase peripheral insulin resistance, thereby contributing to the hyperglycemia and glucose intolerance observed in septic neonates.

Fat utilization is impaired due to decreased lipoprotein lipase activity and a deficiency of the carrier peptide carnitine. Protein degradation, in particular branched chain amino acid catabolism, represents the final fuel source during sepsis. Eventually, excessive amino acid degradation overwhelms the liver's metabolic capacity resulting in uremia, production of false neurotransmitters, and clinical signs of hepatoencephalopathy.

ENTERAL FEEDING

If there is no medical contraindication for oral feeding and the gastrointestinal tract is functional, **enteral alimentation** is the preferred and most effective route of nutrient supplementation. Enteral feeding is more physiological, less expensive, facilitates normal gut maturation, stimulates hepatic and biliary secretions, promotes growth of intestinal villi and production of crypt cells, induces brush border disaccharidase activity and improves nitrogen retention. Oral feeding also stimulates release of enteroinsular hormones such as glucagon, gastrin, cholecystokinin and secretin, which exert a tropic effect on gut maturation.

Enteral feed intolerance is observed frequently among dysmature and growth-retarded foals. In utero malnutrition stunts growth and delays gastrointestinal development characterized by abnormal disaccharidase activity and depressed gut immunity. Foals suffering from hypoxia and septic shock experience **gastrointestinal ischemia** accompanied by varying degrees of mucosal damage, malabsorption and dysmotility. Enteral feeding in these foals must proceed cautiously.

Routes of feeding include nursing from the udder, bottle or bucket, and nasogastric tube intubation. If an effective suckle and swallow reflex is present, bottle feeding can be attempted using infant or lamb nipples.

Udder bumping and teat-seeking behavior can be stimulated by allowing the foal to approach the bottle from behind and under the handler's armpit. This technique also reduces the risk of aspiration by preventing overextension of the head and neck.

Bucket feeding allows the foal to drink with its head and neck in a flexed position and is helpful for foals with a weak swallow reflex or foals destined to be hand raised. Milk should be introduced in a shallow hand-held bowl

and the foal encouraged to drink by wetting the fingers in milk and allowing the foal to suckle from the finger as its head is lowered into the milk. “On demand” feeding is ideal but often impractical and too labor intensive. Foals <7 days of age should be fed a minimum of every 2 h.

Nasogastric intubation is required if ineffectual swallowing and suckling are present. A small-bore, flexible silicone tube (5–7 mm internal diameter) is preferred. Individual choice dictates whether or not the tube is left indwelling or passed with each feeding. Indwelling tubes may be sutured to the nares or taped to the halter with the end positioned in the distal esophagus or stomach. Tubes must be **sealed between feedings** to prevent aerophagia. Recumbent foals should be maintained in sternal recumbency immediately after tube feeding to reduce the risk of gastroesophageal reflux and aspiration.

Popular enteral formulas for foals include mare’s milk, goat’s milk and artificial milk replacers formulated for foals. **Mare’s milk** is preferred since it is the most physiological. **Goat’s milk** is an acceptable alternative, and is higher in fat, total solids and gross energy than mare’s milk. It is more digestible than cow’s milk due to its composition of simpler fatty acids, smaller fat globules, and better buffering capacity. Foals raised on goat’s milk occasionally exhibit mild constipation.

Cow’s milk can be substituted for mare’s milk if **additional sugar** is added and some of the fat is removed. This can be accomplished by using 2% skim milk and adding 20 g dextrose/L milk. A variety of commercially available **mare’s milk replacers** are available. The ideal replacer should contain 22% crude protein, 15% fat and less than 0.5% fiber on a dry matter basis. Many of the formulas when reconstituted are more concentrated than mare’s milk and may predispose to constipation and dehydration in foals raised solely on milk replacer. Free access to water can ameliorate these problems.

Complications associated with enteral feeding are listed in Box 14.9. Signs of diet intolerance include constipation, diarrhea, gastric reflux, flatulence, abdominal distension and colic. Although healthy foals consume between 20% and 25% BW in milk daily, the provision of 10% BW is a reasonable goal when initiating enteral alimentation in sick foals. At this rate a 50 kg foal requires a minimum of 417 mL of milk every 2 h. Milk should be fed as close to body temperature as possible. Any changes in volume or composition of the enteral diet should be made slowly.

Delayed gastric emptying and **gastroduodenal dysmotility** can be improved in some foals with **metoclopramide** given IV as a slow infusion (0.25 mg/kg/h) or orally (0.6 mg/kg q 4 h). Overdosage is associated with excitement. Metoclopramide is contraindicated if **gastrointestinal obstruction** is suspected.

Diarrhea is treated symptomatically with oral **bismuth subsalicylate** (1–2 mL/kg PO q 4–6 h) and/or **loperamide** (0.1–0.2 mg/kg PO q 6 h). Diarrhea may also respond to administration of a commercial intestinal **probiotic** or **active culture yogurt**.

Nasopharyngeal irritation from repetitive or chronic nasogastric intubation delays the return of a normal suckle reflex. Insufflation of a nasopharyngeal spray containing prednisolone, furacin, glycerin and DMSO helps reduce inflammation.

Box 14.9 Complications associated with nutritional support**Parenteral alimentation**

- Metabolic disturbances
 - Hyperglycemia/hypoglycemia
 - Glucosuria/osmotic diuresis
 - Hyperosmolar states
 - Hyperlipemia
 - Hyperchloremic acidosis
 - Uremia/azotemia
 - Electrolyte imbalances
 - Mineral/vitamin imbalances
- Catheter related
 - Thrombosis
 - Phlebitis
 - Sepsis

Enteral alimentation

- Metabolic disturbances
 - Hypoglycemia
 - Electrolyte imbalances
- Gastrointestinal intolerance
 - Colic, ileus
 - Abdominal distension
 - Gastric reflux
 - Diarrhea
 - Constipation
 - Flatulence
- Nasogastric tube-related problems
 - Misplacement of tube
 - Tube occlusion/dislodgement
 - Aerophagia, gastric distension
 - Gastric irritation
 - Rhinitis, pharyngitis, esophagitis
 - Aspiration pneumonia
- Formula problems
 - Poor palatability

PARENTERAL NUTRITION

Parenteral nutrition (PN) involves the IV administration of **hypertonic solutions** containing dextrose, amino acids, lipids, vitamins, electrolytes and trace minerals, and is indicated whenever feeding via the gastrointestinal tract is inadequate, contraindicated or impossible. These PN solutions must be administered **continuously IV** through a large diameter vein to minimize vessel irritation, prevent osmotic diuresis, avoid hyperosmolar states and maximize

Box 14.10 Sample calculations for a 45 kg foal receiving parenteral alimentation**Initial formula**

- Glucose $10 \text{ g/kg} \times 45 \text{ kg} = 450 \text{ g} = 900 \text{ mL } 50\% \text{ dextrose}$
- Amino acid $2 \text{ g/kg} \times 45 \text{ kg} = 90 \text{ g} = 900 \text{ mL } 10\% \text{ amino acid}$
- Lipid $1 \text{ g/kg} \times 45 \text{ kg} = 45 \text{ g} = 450 \text{ mL } 10\% \text{ lipid}$
- Total 24 h fluid volume = 2250 mL; flow rate = 94 mL/h

Calories provided

- Glucose $3.4 \text{ kcal/g} \times 450 \text{ g} = 1530 \text{ kcal}$
- Amino acid $4.0 \text{ kcal/g} \times 90 \text{ g} = 360 \text{ kcal}$
- Lipids $9.0 \text{ kcal/g} \times 45 \text{ g} = 405 \text{ kcal}$
- Total caloric intake = 2295; 51 kcal/kg/day

Caloric source

- Glucose = 66% Amino acid = 16% Lipids = 18%
- Non-protein calories = 1935
6.25 g protein = 1 g nitrogen
- Total nitrogen = $90 \text{ g}/6.25 = 14.4 \text{ g}$
- Non-protein calories: g nitrogen = $1935/14.4 = 134$

substrate utilization. Complications associated with parenteral alimentation are presented in Box 14.9.

Jugular catheterization is the most common access route for PN therapy. Catheters should be of low reactivity and approximately 12–20 cm in length. The Arrow catheter (Arrow International Inc., Reading, PA 19610, USA) is a 16 G, 20 cm polyurethane catheter that is easy to insert using a short introduction trocar and guide wire. These catheters have been used in sick neonates for PN, drug and fluid therapy for as long as 2–3 wk without complications. All catheters should be inserted using aseptic technique. The catheterized vessel should be examined **at least daily** for signs of thrombosis and/or phlebitis. To reduce the risk of catheter-related sepsis and vessel thrombosis blood samples should not be withdrawn from the catheter dedicated to PN therapy. Volumetric infusion pumps, carefully regulated microdrip Buretrols or Solusets, or Dial-a-flow extension sets can be used to ensure accurate PN infusion rates.

Commonly used **stock solutions** for parenteral nutrition include 50% dextrose, 8.5% or 10% amino acids, and 10% or 20% lipid emulsion. Sample calculations for PN are presented in Box 14.10. Other commonly used additives include electrolyte, vitamin and trace mineral mixtures. Parenteral formulas must be compounded aseptically. The use of sterile, empty 3 or 4 L bags with 2 or 3 lead transfer sets (Baxter All-in-One 4 L bag; Baxter Healthcare Corp., Deerfield, IL, USA) facilitates mixing.

To maintain a suitable solution **pH for lipid solubility**, components should be added in the following order: glucose, amino acids and then lipids. Solutions should be refrigerated prior to use and vitamins and trace elements added just prior to administration.

Glucose solutions provide 3.4 kcal/g and are hypertonic at concentrations >5%. Five and 10% glucose solutions alone cannot provide adequate calories for the sick foal and would require infusion rates of 35 and 18 L/day, respectively, to provide a 50 kg foal with 120 kcal/kg/day. When initiating parenteral alimentation, glucose infusion begins at 10 g/kg/day and can be increased at a rate of 1 g/kg/day up to 15 g/kg/day.

Lipid emulsions are isotonic, contain primarily long chain triglycerides and provide approximately 9–11 kcal/g. The addition of lipids to PN formulas is associated with a decreased incidence of vessel thrombosis that may be related to the decrease in total osmolality of the PN solution or a protective effect of lipids on vascular endothelium. Lipid infusion rates begin at 1 g/kg/day and can be increased up to 4 g/kg/day.

When insulin-resistant, sepsis-induced hyperglycemia restricts glucose administration in sick neonates, lipids can be used to provide up to 30–60% of non-protein calories. Impaired lipid clearance during sepsis or associated with prematurity may respond to **heparin administration** which augments lipoprotein lipase activity. Heparin can be given as a bolus at 10 units/kg or added to the PN solution at a rate of 1 unit/mL.

Lipid emulsions are not routinely administered to human infants with marked hyperbilirubinemia. Elevated concentrations of free fatty acids associated with lipid administration compete with bilirubin for albumin-binding sites resulting in reduced bilirubin clearance and exacerbation of **kernicterus** (deposition of unconjugated bilirubin in brain cells). Controversy also surrounds the use of lipids in foal neonates with severe pulmonary compromise. There is concern that lipid emulsion interferes with pulmonary microcirculation and gas exchange. Clinical complications associated with lipid administration to foals receiving mechanical ventilatory support, however, are rare. Compared with glucose, lipids are oxidized with a **lower respiratory quotient** (RQ of fat = 0.7; RQ of glucose = 1.0). Use of lipids in the ventilated patient could prove beneficial by reducing metabolic CO₂ production and minimizing ventilation.

The most commonly used **protein solutions** are hypertonic, contain free amino acids with or without electrolytes, and provide approximately 4 kcal/g. Protein solutions are added to the PN formula to provide amino acids and nitrogen for growth and cellular repair. To prevent catabolism of protein for energy the ratio of non-protein calories to nitrogen should be approximately 100 to 200. In neonatal foals protein infusion rates range between 2 and 3 g/kg/day.

Since the daily requirements of **vitamins and trace minerals** are not available for neonatal foals, commercially available human pediatric preparations are commonly used. Potassium supplementation is required by foals not receiving enteral feeds. Foals receiving prolonged, complete PN require calcium and phosphorus supplementation. Only 25–50 mEq/L of calcium gluconate and 5–15 mEq/L of potassium phosphate can be added to PN solution without danger of precipitation. This amount of supplementation is still inadequate to support long-term growth and should be augmented by enteral mineral supplementation.

Parameters listed in Table 14.15 are used to monitor the patient's tolerance of the PN formulation. A foal must be weaned **slowly** onto and off parenteral

Table 14.15 Monitoring procedures for parenteral nutrition

Parameter	Monitoring frequency	
	During initiation of PN	After stabilization
Vital signs	q 4 h	q 8 h
Catheter/vein inspection	q 8 h	q 8 h
Fluid intake/urine output	q 8 h	q 12 h
Body weight	Daily	Daily
Urine glucose	q 6–8 h	q 12 h
Serum glucose	q 6–8 h	q 12–24 h
Serum electrolytes	q 24 h	1–2 \times /wk
Creatinine/blood urea nitrogen	q 24 h	2 \times /wk
Examine serum for lipemia	q 6–8 h	q 24 h
Triglycerides/cholesterol	Baseline	Weekly
Liver enzymes (GGT, LLDH, SAP)	Baseline	Weekly
Bilirubin	Baseline	Weekly
Hydration status:		
PCV/total protein	q 12–24 h	q 2–3 days
Capillary refill time	q 12 h	q 12 h
Leukogram	Baseline	Weekly
Fibrinogen	Baseline	Weekly

nutrition to allow acclimation of neuroendocrine hormones. Life-threatening **hypoglycemia** may develop if IV nutritional support is stopped suddenly or before adequate enteral nutrition has been initiated. Ideally, a foal should be consuming a minimum of 10% BW in milk daily before discontinuing all PN support.

A foal's daily fluid requirements are not met by the PN solution alone, and **additional balanced electrolyte solutions** are needed. Chronic PN administration has also been associated with an increased incidence of systemic **fungal infections** (*q.v.*) in neonatal foals.

RESPIRATORY SUPPORT

Assessment

Evaluation of the foal's respiratory system begins with physical examination to determine whether respiratory disease is present and, if so, what form of respiratory support is indicated. Signs of **respiratory distress** include tachypnea and increased work of breathing characterized by exaggerated abdominal effort, rib retractions, nostril flaring and expiratory grunting. Foals with severe lung disease display more labored breathing when recumbent and prefer to rest with head and neck extended.

Rapid, shallow respirations are common in foals with **restrictive lung disease** and/or **progressive atelectasis** (*q.v.*). Irregular breathing patterns are associated with prematurity and/or hypoxic damage to the central respiratory center. Unfortunately, thoracic auscultation is not a reliable means of assessing pulmonary disease in the foal and may fail to detect atelectasis and interstitial lung disease. Mucous membrane color is a relatively insensitive indicator of hypoxemia since cyanosis develops only after arterial oxygen (O_2)

concentrations are well below 40 mmHg. Hypercapnia has little effect on mucous membrane pallor.

Lateral radiographs obtained with the foal standing or recumbent help to characterize the nature and extent of pulmonary pathology. Diffuse pulmonary infiltrates occur with bacterial and/or viral pneumonia and atelectasis. Cranioventral and caudoventral pulmonary infiltrates are seen with aspiration pneumonia and bacterial bronchopneumonia. Nodular infiltrates suggest discrete abscessation. Ultrasonography is helpful to detect pleural effusion.

Arterial blood gas analysis

Arterial blood gas analysis determines the type and severity of respiratory dysfunction present and dictates the respiratory therapy indicated. The preferred site for arterial puncture is the **great metatarsal artery**. Other sites include the carotid, brachial, facial and femoral arteries. Arterial puncture requires a small 25 G needle attached to a heparinized 1 or 3 mL Luer slip syringe.

Once the sample is obtained, air bubbles should be removed promptly and the syringe sealed with a cork and kept on ice until analysis is performed. Pressure should be held at the puncture site for 3–5 min. An indwelling arterial catheter eliminates repetitive vessel puncture, but is difficult to maintain in an active foal and requires frequent flushing with heparinized saline or the use of a heparin lock.

The **partial pressure of arterial O₂** is usually between 70 and 100 mmHg in the normal foal. Hypoxemia does not contribute to ventilatory drive until it has fallen to pathologically low levels (<40–50 mmHg). However, tissue anoxia develops below an arterial O₂ tension of 60 mmHg.

Hypoxemia ($\text{PaO}_2 \leq 60$ mmHg, with a normal or low PaCO_2) is caused by ventilation–perfusion mismatching, right-to-left shunting (pulmonary or cardiac shunts), low inspired O₂ concentration, and impaired gas diffusion (*q.v.*). Hypoxemia accompanied by elevated carbon dioxide tensions (PCO_2) is usually the result of hypoventilation due to respiratory muscle fatigue, central depression of the respiratory center or neuromuscular weakness.

The main drive to respiration is the **partial pressure of arterial carbon dioxide**. In normal animals, respiration is controlled to achieve levels of CO₂ tensions of 35–45 mmHg. Any condition that decreases ventilation or increases metabolic rate disproportionately to ventilation results in an increase in PaCO_2 concentrations, a decrease in blood pH and respiratory acidosis. Carbon dioxide tensions >65–70 mmHg require mechanical ventilation to correct.

Oxygen therapy

Mild cases of hypoxemia may be improved by repositioning the laterally recumbent foal in **sternal recumbency** to reduce ventilation–perfusion mismatching associated with dependent lung atelectasis. **Persistent hypoxemia** requires oxygen supplementation using an intranasal cannula inserted to the level of the medial canthus. The cannula can be temporarily taped to the foal's muzzle or sutured to the external nares. **Humidified oxygen** is administered using a tank or wall oxygen source or oxygen concentrator and humidifier filled with distilled water.

Oxygen flows between 3 and 10 L/min are regulated using a flow meter attached to the humidifier. The oxygen tubing and cannula should be changed daily and checked frequently for obstruction with nasal secretions. Oxygen flow rates are adjusted to maintain arterial O₂ tensions between 70 and 100 mmHg.

Mechanical ventilation

Persistent hypoxemia that is refractory to nasal insufflation or is accompanied by arterial CO₂ tensions >70 mmHg necessitates **positive pressure ventilatory support**. Mechanical ventilation is time consuming, labor intensive and expensive. Complications associated with mechanical ventilation are presented in Box 14.11. Ideal candidates for mechanical ventilation should have potentially reversible lung disease. Before initiating treatment, the owner should be fully informed of the commitment required.

Short-term manual ventilation can be performed using a self-inflating rebreathing bag (Ambu bag), which can be used with room air or connected to an O₂ source via a reservoir bag to provide oxygen-enriched gases. An oxygen demand valve can also be used to deliver 100% O₂ during brief periods of manual ventilation such as post partum resuscitation. Prolonged periods of positive pressure ventilation require a **mechanical ventilator**.

Effective positive pressure ventilation requires nasotracheal or oral tracheal intubation. The disadvantages of oral intubation include excessive tube mobility and patient discomfort and intolerance. **Nasotracheal intubation** is better tolerated for prolonged periods of time in the conscious foal. Nasotracheal tubes should be a minimum of 50–55 cm long, composed of an inert plastic (preferably silicone) and have high-volume, low-pressure cuffs. Other equipment

Box 14.11 Complications associated with mechanical ventilation

- Air leaks: pneumothorax, pneumomediastinum, pulmonary interstitial emphysema
- Aerophagia, abdominal distension, gastrointestinal dysmotility, ulceration, gastric reflux
- Pneumonia, secondary to introduction of contaminated tracheobronchial secretions
- Asynchronous breathing or "bucking the ventilator", especially when synchronous intermittent mandatory ventilation is not used
- Nasotracheal tube trauma: pharyngitis, laryngitis, rhinitis, chondritis, tracheal stenosis, epistaxis, dysphagia
- Cardiovascular compromise associated with high airway pressures and excessive positive end expiratory pressures
- Bronchopulmonary dysplasia, barotraumas
- Oxygen toxicity
- Inappropriate airway humidification
- Equipment malfunction: delivery of inappropriate tidal volumes, oxygen concentrations, peak airway pressures; nasotracheal tube occlusion

required for mechanical ventilation includes a pressure-cycled or volume-cycled ventilator, an oxygen blender to deliver variable inspired oxygen concentrations, an oxygen analyzer to monitor blender accuracy, an in-line humidifier, and source of oxygen and compressed gas.

Guidelines for initial ventilator settings are as follows: tidal volume = 10–15 mL/kg, respiratory rate = 15–25 breaths/min, $F_{I}O_2$ = 0.4–1.0, proximal airway pressure = 18–25 cmH₂O, end expiratory pressure = 0–8 cmH₂O, I:E ratio = 1:2. Additional programming changes are made according to arterial blood gas analysis.

Foals that continue to resist attempts at positive pressure ventilation require sedation. Low doses of **phenobarbital** (2–5 mg/kg given as a slow IV infusion) are usually quite effective.

Ventilators that allow foals to breathe spontaneously between pre-set ventilator breaths employ a synchronous, intermittent mandatory ventilatory (SIMV) mode. This ability to synchronize mandatory breaths with spontaneous breathing efforts eliminates a great deal of patient anxiety. Foals rarely require sedation when ventilated using SIMV.

To reduce the risk of oxygen toxicity the $F_{I}O_2$ should be reduced to 40 mmHg as soon as possible. The nasotracheal tube should be changed every 24–36 h, or more frequently if secretion accumulation is a problem. Sterile suctioning is performed as needed, but prolonged suctioning is avoided to prevent hypoxia. Arterial blood gases are monitored as needed to evaluate pulmonary function and adjust ventilator settings. A capnograph may be used to measure end tidal CO₂ concentration to reduce the number of invasive arterial punctures required.

Weaning from the ventilator is done slowly by decreasing the $F_{I}O_2$, peak airway pressure, positive end expiratory pressure, and number of ventilator delivered breaths. It is helpful to wean the foal onto continuous positive airway pressure (CPAP) or intranasal oxygen therapy and re-evaluate pulmonary function prior to discontinuing all forms of respiratory support.

Other forms of respiratory therapy

Foals have a **poorly developed cough reflex** and removal of tracheobronchial secretions may be difficult. **Chest coupage** using a cupped hand or electric percussor helps stimulate the natural cough reflex. **Ultrasonic or hydrosphere nebulizers** are used to administer a variety of agents such as saline to help moisten secretions, bicarbonate to act as a mucolytic agent, and bronchodilators to help relieve bronchospasm. **Nebulization followed by percussion** is often quite effective in mobilizing secretions.

Respiratory stimulants are used to treat **periodic apnea** (*q.v.*) and abnormally slow breathing patterns associated with central depression of the respiratory center. Chemical respiratory stimulants should be used **cautiously** in the foal since overdosing leads to excessive CNS, myocardial and gastrointestinal stimulation resulting in agitation, seizures, tachycardia, hypertension, colic and diarrhea. **Doxapram** is a general CNS stimulant with direct effects on the medullary respiratory centers. Although it produces transient increases in respiratory rate and tidal volume, these changes are accompanied by increases in work of breathing and myocardial oxygen consumption, resulting in little

change in oxygen tensions. Doxapram will stimulate ventilation when CNS depression is present, but will not reverse secondary apnea during cardiopulmonary arrest. Doxapram (0.2 mg/kg IV) should not be used in patients suffering from seizures, head trauma, cerebral edema or respiratory failure secondary to neuromuscular weakness.

Caffeine is used most frequently to stimulate the respiratory neuronal activity and increase receptor responsiveness to elevated carbon dioxide concentrations. Caffeine is the safest of the methylxanthines to use. The caffeine loading dose is 10 mg/kg administered orally followed by a maintenance dose of 2.5–3.0 mg/kg PO q 24 h.

Theophylline and **aminophylline**, both xanthine derivatives, are commonly used **bronchodilators** in foals but can also be used to improve diaphragmatic contractility and to treat **periodic apnea** associated with prematurity. Oral dosages and IV infusion rates are not available for the foal and must be extrapolated from the human literature. When calculating doses, 1.0 mg aminophylline equals approximately 0.8 mg theophylline. Adverse drug effects include excessive stimulation of the CNS and myocardium, and diuresis. The therapeutic range of theophylline in humans is 10–20 µg/mL. Therapeutic and toxic concentrations of theophylline have not been established for foals. Drug clearance is decreased and the potential for toxicity increased when these bronchodilators are administered concurrently with erythromycin or cimetidine. Terbutaline and albuterol have also been used for bronchodilation in the foal.

NEONATAL RESUSCITATION

INTRODUCTION

Cardiopulmonary emergencies in foals are the result of respiratory and/or circulatory failure that is usually secondary to systemic disease or failure to adapt during the immediate post partum period. Cardiopulmonary failure results in **hypoxic acidosis** that causes respiratory arrest followed by severe **bradycardia** and eventually asystole.

Cardiopulmonary failure may arise from:

1. Peri partum hypoxia leading to central respiratory center depression and/or myocardial damage resulting in hypoventilation and cardiac failure
2. Primary lung disease leading to hypoventilation and hypoxia
3. Circulatory failure due to septic or endotoxic shock
4. Hypovolemic or hemorrhagic shock
5. Severe metabolic acidosis
6. Hyperkalemia (e.g. uroperitoneum)
7. Vasovagal reflex
8. Hypothermia
9. Congenital cardiac defects.

Both **acute and chronic asphyxia** in the prenatal period may induce damage to multiple body systems. The compromised neonate suffering from the effects

of hypoxia may have **profound central nervous depression**, leading to respiratory center dysfunction and lack of stimulus to breathe, and respiratory acidosis. Metabolic acidosis occurs simultaneously, following the onset of anaerobic metabolism due to poor tissue perfusion. This further exacerbates both the respiratory failure and circulatory failure due to the effects on the hemoglobin-oxygen dissociation curve, the respiratory center and the myocardium.

Resuscitation of the neonate at birth may require no more than stimulation of breathing by methods such as palpation of the nasal mucous membranes, insertion of a finger in the ear, brisk rubbing of the thorax and extension of the limbs. The airways should be cleared manually, and with suction if necessary. **Coupage of the chest** will also help clear the airways. However, **cardiopulmonary resuscitation (CPR)** may be required at any time during the neonatal period, most frequently for severely depressed neonates immediately after birth, but also in foals that develop either respiratory or cardiac failure as a consequence of other diseases.

CPR refers to emergency treatment and initial stabilization. Its goal is to sustain life by providing an oxygenated blood supply to vital organs, in particular the brain and myocardium. The principles of CPR in foals are similar to those applied to other species.

A flow chart for CPR is given in Figure 14.1. The protocol and priorities for CPR can be memorized as **ABC: Airway, Breathing, Circulation**. In addition, emergency measures to address specific problems may also be required. For example, the airways may have to be suctioned to remove meconium, or the

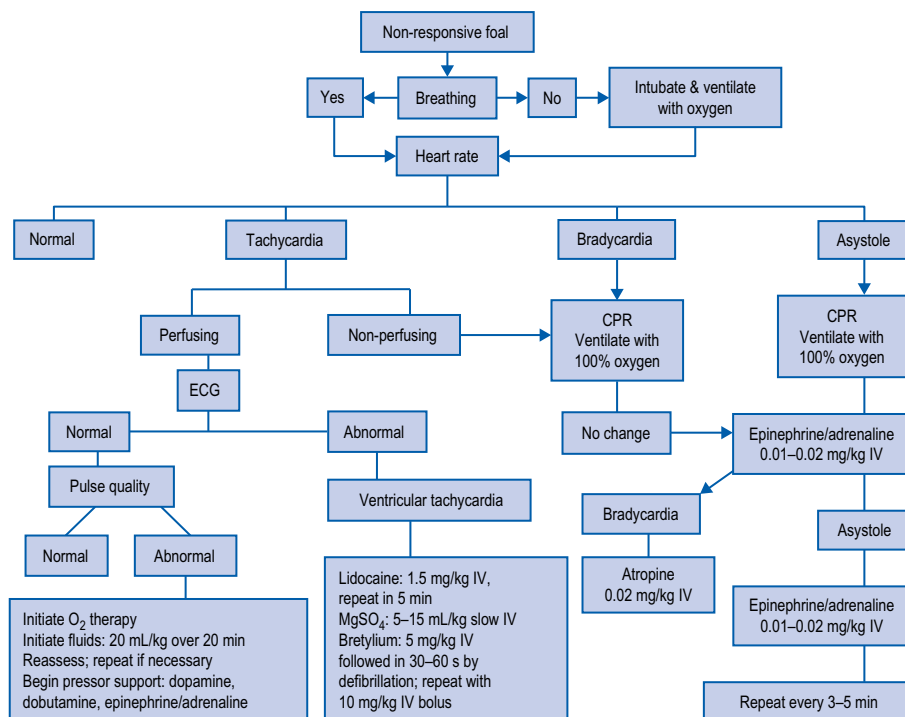

Figure 14.1 Flow chart for cardiopulmonary resuscitation.

stomach may have to be decompressed in foals with gastrointestinal obstruction. Nevertheless, a standardized protocol is most likely to be successful, and support of the respiratory and the circulatory systems must be given priority.

CPR is most likely to have a favorable outcome if a team of trained personnel work together and appropriate equipment is assembled and kept **ready in advance**. Table 14.16 lists the components of a **crash cart** and Table 14.17 details drugs required for CPR.

AIRWAY

Foals may be **intubated** via the nose or the mouth. The nose is preferred if the foal is likely to recover consciousness while intubated. Silicone tracheal tubes of 7–12 mm in diameter and 45–55 mm in length are preferred. Cuffed tubes allow positive pressure ventilation.

To insert the endotracheal tube, the foal should be positioned with its head in extension, and the curve of the tube directed ventrally. Once the tube reaches the level of the arytenoid cartilages it should be rotated to allow the bevelled end to spread the arytenoids. Correct placement is ascertained by compressing the chest and detecting air movement out of the tube. Palpation of the proximal esophagus during intubation also helps ensure proper placement of the tube.

Table 14.16 Equipment required for a neonatal crash cart

Airway	Cuffed silicone nasotracheal tubes (selection of sizes: 7–12 mm diameter, 45–55 mm in length) Suction device and catheters Nasal insufflation catheter and tubing Tracheostomy tube (7–10 mm diameter) Laryngoscope Tapes and suture Air syringe and sterile lubricating jelly
Breathing	Demand valve Ambu resuscitation bag Oxygen supply and equipment Tidal volume meter Heparinized syringes for blood gas samples
Circulation	Electrocardiograph, leads, alcohol spray Indirect blood pressure monitor Board to provide firm support for external cardiac massage Electrical defibrillator Intravenous catheters (selection of sizes: 14–18 G) Syringes, needles and fluid administration sets
Miscellaneous	Surgical gloves Surgical packs, suture and scalpels Floor padding or mattress Heat lamps, hot water bottles and blankets Thermometer Penlight Watch Record sheets and pen Stomach tube

Table 14.17 Dosages for emergency drugs in foals

Drug	Indications	Dosage	Complications
Epinephrine (adrenaline)	Asystole, pulseless electrical activity, bradycardia	Initial: 0.01–0.2 mg/kg IV Subsequent: 0.1 mg/kg IV IT; repeat q 3–5 min	Hypertension, tachyarrhythmias, increased cardiac O ₂ demand
Atropine	Bradycardia not responsive to hyperventilation	0.02 mg/kg IV 0.04–0.06 mg/kg IT Repeat once in 5 min	Tachycardia; increased myocardial O ₂ consumption, exacerbate hypoxia
Bretylium	Ventricular fibrillation, ventricular tachycardia	5 mg/kg IV undiluted followed in 30–60 s by defibrillation; repeat with 10 mg/kg IV bolus	Hypotension, hypertension, tachycardia
Calcium gluconate/chloride	Hyperkalemia, hypocalcemia, hypermagnesemia	10% Ca Gluconate: 0.6–0.75 mL/kg 10% Ca chloride: 0.2–0.25 mL/kg	Rapid infusion produces bradycardia; can result in rapid cell death in presence of hypoxia
Dexamethasone	Shock	5–10 mg/kg IV	Suppress immune function
Dextrose solution: 5–10%	Hypoglycemia, hyperkalemia	4–8 mg/kg/min CRI	Hyperglycemia, hyperosmolality
Dimethyl sulfoxide (DMSO)	Cerebral edema, reperfusion injury	0.5–1.0 g/kg as 10–20% solution given IV over 1–2 h	Concentrated solutions or rapid administration can cause hemolysis
Dobutamine	Hypotension	CRI: 1–20 µg/kg/min	Tachycardia, arrhythmias, hypertension
Dopamine	Hypotension, anuric/oliguric renal disease	CRI: 1–15 µg/kg/min; α-effect (pressor) at low doses; β-effect (inotrope) at higher doses	Tachycardia
Doxapram	Primary apnea, only if ventilation is not available	0.5–1.0 mg/kg IV, sublingual	Ineffective for secondary apnea; increases myocardial O ₂ consumption; overdose can produce seizures
Furosemide	Diuretic: pulmonary edema/oliguric renal disease	1 mg/kg IV/IM CRI: 0.25–2.0 mg/kg/h	Dehydration, hypokalemia, enhances aminoglycoside toxicity
Hypertonic saline (7%)	Hypovolemic hypotension	4 mL/kg IV	Hypernatremia; use in conjunction with polyionic crystalloids
Insulin	Use with glucose to treat hyperkalemia associated with ruptured bladder	0.1 U/kg regular insulin IV with 0.5–1.0 g/kg dextrose IV	Hypoglycemia

Table 14.17 (Continued)

Drug	Indications	Dosage	Complications
Lidocaine	Ventricular fibrillation, ventricular tachycardia	Initial: 1.5 mg/kg IV, repeat in 5 min CRI: loading dose: 1.0 mg/kg IV followed by 20–50 µg/kg/min	Seizures, paresthesia, myocardial depression, circulatory depression
Magnesium sulfate (50%)	Refractory ventricular fibrillation	14–28 mg/kg, diluted to 10 mL in 5% dextrose in water, slow IV push	Hypotension
Plasma	Septic shock; improve oncotic pressure; support immune function	5–15 mL/kg IV over 1–3 h	
Polyionic fluids (non-glucose-containing fluids)	Hypovolemic/septic/hemorrhagic shock	20 mL/kg IV bolus; reassess, repeat if necessary	Fluid overloading exacerbates cardiac failure and may decrease coronary perfusion
Sodium bicarbonate	Hyperkalemia (ruptured bladder), severe metabolic acidosis	0.5–1.0 mEq/kg IV over 1–2 min; repeat once in 5–10 min if indicated	Hypernatremia and hyperosmolality with secondary cerebral hemorrhages, cardiac depression, left shift of oxyhemoglobin saturation curve

CRI, constant rate infusion; IT, intratracheal—via a catheter inserted in an endotracheal tube; IV, intravenous.

Once inserted, the cuff should be inflated until no airflow is detected from either nostril.

Tracheostomy is indicated if there is upper airway obstruction: a longitudinal incision is made on the ventral aspect of the neck, the tracheal ligament is incised, and a small (7–10 mm) tracheostomy tube is inserted between the tracheal rings.

Vacuum suction should be used to clear the airways of secretions, particularly if meconium has been aspirated. This should be performed prior to commencing ventilation, and periodically thereafter. However, excessive suction exacerbates hypoxemia and should be avoided. Suctioning should be followed by oxygen administration.

BREATHING

Mechanical ventilation may be achieved using a self-inflating resuscitation (Ambu) bag or an oxygen demand valve. **Oxygen** is preferred over room air for initial resuscitation. A respiratory rate of 15–25 breaths/min is required. The inspiration phase is continued until a complete chest excursion is achieved, avoiding excessive pressure (20–40 cmH₂O). The passive expiration phase should be two to four times the duration of inspiration. If **external cardiac**

massage is being conducted simultaneously, the rates should be coordinated to give 5–6 breaths per chest compression.

In foals that are breathing spontaneously but inefficiently (e.g. due to respiratory distress syndrome and atelectasis), arterial blood gas analysis is used to identify **hypercapnia**. Alternatively, it may be helpful to assess the spontaneous tidal volume with an appropriate tidal volume meter to determine the need for mechanical ventilation (normal tidal volume = 10–12 mL/kg). Careful evaluation of chest excursion and breathing pattern may be equally informative, and allow prompt identification of foals which will benefit from assisted ventilation.

The respiratory stimulant doxapram is not recommended in respiratory failure unless no form of positive ventilation is available. Doxapram is a CNS stimulant used to stimulate the respiratory center during primary apnea. In secondary (terminal) apnea, the respiratory center is no longer responsive to chemical stimuli, thus doxapram is not efficacious. In those foals in which it is effective in stimulating respiration, doxapram may be counterproductive in that it increases the oxygen demand of the myocardium in the face of prolonged hypoxia.

CIRCULATION

Support of the circulation is aimed at both maintenance of blood pressure and treatment of asystole or specific cardiac arrhythmias. Palpation of **peripheral pulses** and inspection of the **mucous membranes** are the initial means of evaluating perfusion.

An IV catheter should be inserted aseptically and **polyionic fluids** (e.g. Normosol-R, Plasmalyte, 0.9% saline) administered at a modest rate (e.g. 4–6 mL/kg/h) while evaluation of the patient proceeds. Overzealous fluid administration is contraindicated during asystole or non-perfusing rhythm. If volume replacement is necessary to treat severe dehydration, bolus administration is preferred rather than continuous high flow rates.

An **ECG** (*q.v.*) should be obtained. A lead II or base-apex strip is adequate to assess rhythm. Indirect arterial blood pressure is measured from the middle coccygeal artery, using an oscillometric or a Doppler sphygmomanometer.

Cardiac massage

Cardiac arrest is assumed if no palpable pulse is present; **external cardiac massage** should be instituted immediately. It is now known that the effects of external cardiac massage are not on the heart alone, but rather it acts as a **thoracic pump**. Increasing intrathoracic pressure, by compression of the chest, leads to the evacuation of the arteries and veins. Forward flow in the arteries is unimpeded, whereas retrograde flow in the veins is limited by the IV valves.

The primary aim of external cardiac massage is to generate **cerebral blood flow**. Chest compression is unlikely to support oxygenation for extended periods but it is effective in increasing blood flow in the short term. Re-establishing **coronary blood flow** is essential for return to a normal cardiac rhythm. During cardiac compression, coronary blood flow is restricted to the diastolic period. Diastolic aortic pressure determines coronary perfusion.

The foal is placed in **right lateral recumbency**, on a firm surface. External cardiac massage is performed by placing one palm on top of the other hand, and applying pressure **immediately behind the elbow**, in the fourth or fifth intercostal space. The pressure should be applied evenly, with a compression rate of 60–80/min. Approximately 35 kg of pressure is necessary for a 50 kg foal. Excessive pressure may result in rib fractures, visceral damage or pneumothorax.

The administration of **epinephrine/adrenaline** (initial dose 0.01–0.02 mg/kg IV or intratracheally [IT]; subsequent doses: 0.1 mg/kg IV/IT), a strong α -adrenergic agonist, increases arterial wall stiffness and total peripheral vascular resistance. This improves intrathoracic arterial blood flow by reducing the arteries' tendency to collapse. Other α -adrenergic effects include elevating systolic and diastolic pressures while decreasing splanchnic, renal, mucosal and dermal circulation. Epinephrine also has β -adrenergic effects that include increasing myocardial contractility and heart rate and relaxing bronchial smooth muscle. Epinephrine is the drug of choice during asystole because of its ability to improve coronary perfusion pressure. This is achieved by increasing diastolic aortic pressure and by increasing aortic tone.

Internal cardiac massage has been shown to be more effective than external methods in other species. Its use in horses has been described, however it has yet to be widely adopted in the equine neonatal intensive care unit.

Cardiac asystole and arrhythmias

Five **electrophysiologic abnormalities** are associated with cardiopulmonary failure: (1) asystole; (2) ventricular fibrillation; (3) electrical–mechanical dissociation; (4) ventricular tachycardia; and (5) profound bradycardia. An ECG (*q.v.*) must be obtained promptly so that the precise abnormality can be documented, and based on this, rational therapy instituted. The ECG features of these arrhythmias and appropriate pharmacologic agents for their treatment are listed in Table 14.18. Drug dosages are listed in Table 14.17.

Ventricular fibrillation is seen most commonly. **Electrical defibrillation** is the method of choice for treatment. However, this requires specialist equipment and trained personnel. Defibrillation is performed with an initial series of up to three rapid charges: 2 J/kg, 4 J/kg, 4 J/kg. Subsequent defibrillations of 4 J/kg can be performed 30–60 s after administration of epinephrine/adrenaline, lidocaine or bretylium. Large paddles are placed on either side of the heart, ensuring good chest contact.

Lidocaine is an effective pharmacologic agent for the treatment of ventricular fibrillation and ventricular tachycardia. Lidocaine suppresses ventricular arrhythmias by decreasing automaticity and decreasing conduction of re-entrant pathways. The drug prevents recurrence of ventricular fibrillation following conversion. It may be administered in **IV boluses** (1.0–1.5 mg/kg) or injected into the **trachea** via a catheter inserted in an endotracheal tube. This dose may be repeated at 3–5 min intervals. Use in conjunction with defibrillation.

Bretylium prevents recurrence of ventricular fibrillation or ventricular tachycardia (*q.v.*). Bretylium is an adrenergic neuronal blocker and is **synergistic with lidocaine**. Bretylium administered at 5 mg/kg IV can be followed in 30–60 s by defibrillation. If fibrillation persists, repeat with 10 mg/kg boluses. Do not administer more than a total dose of 35 mg/kg. Bretylium alone will

Table 14.18 Cardiac emergencies in foals

	ECG findings	Treatment
Asystole	Flat line	Epinephrine/adrenaline
Ventricular fibrillation	Chaotic (saw-tooth) undulations	Electrical defibrillation Lidocaine Bretylium Magnesium sulfate
Electrical–mechanical dissociation	Normal	Adrenaline
Ventricular tachycardia	Rapid ventricular complexes	Lidocaine Quinidine
Sinus bradycardia advanced 2nd degree and 3rd degree AV block	Infrequent complexes	Ventilate with oxygen Epinephrine/adrenaline Atropine Dopamine

not reverse ventricular fibrillation, but it may be beneficial in that the fibrillation pattern is made coarser and more amenable to correction. Similarly, epinephrine/adrenaline is used to convert asystole to ventricular fibrillation, which is then treated with electrical defibrillation or lidocaine.

Magnesium sulfate can be used for refractory ventricular fibrillation when counter shock, epinephrine/adrenaline, lidocaine and bretylium have been unsuccessful. Administer 14–28 mg/kg diluted to 10 mL in 5% dextrose in water as an IV push.

In **electrical–mechanical dissociation**, cardiac electrical activity is normal but no contraction occurs. Electrical–mechanical dissociation is recognized by a normal ECG accompanied by a blood pressure of less than 50 mmHg.

Epinephrine/adrenaline is administered to attempt to restore cardiac contractility. In the past, calcium was included in CPR protocols for its inotropic action. However, studies in humans have indicated that survival is not improved by calcium administration and it may be detrimental, as calcium influx is an end-stage process in myocardial necrosis. It should be reserved for use in cases with hypocalcemia, and for the treatment of hyperkalemia (e.g. uroperitoneum).

Vagally mediated, profound bradycardia is treated with **epinephrine/adrenaline** (0.01–0.02 mg/kg IV) or **dopamine** (sympathetic atropine: 0.02 mg/kg IV) stimulation; 1–10 µg/kg CRI) or with parasympatholytic agents such as glycopyrrolate or atropine (0.02 mg/kg IV). Most cases of neonatal bradycardia are caused by hypoxia and are treated by hyperventilation with 100% oxygen and epinephrine/adrenaline. Hypoxemia and hypercapnia stimulate the carotid body to increase vagal tone and produce secondary bradycardia. Hyperventilation results in lung inflation and stimulates pulmonary receptors that override the carotid body stimulus.

Occasionally, extreme intestinal distension may be associated with high vagal tone. **Atropine therapy** is indicated when hyperventilation and epinephrine/adrenaline are ineffective. Atropine is administered at a dose of 0.02 mg/kg IV

or 0.04–0.06 mg/kg intratracheally. Concurrent ventilation with oxygen is important since atropine may exacerbate the hypoxic insult by increasing the oxygen demand of the myocardium.

Ventricular tachycardia may occasionally be seen. In these foals, lidocaine is the drug of choice. Quinidine gluconate and bretylium may also be effective.

Cardiac arrhythmias are common in foals with **uroperitoneum** (*q.v.*), associated with hyperkalemia. Ventricular premature contractures, ventricular tachycardia and ventricular fibrillation are seen, but third degree atrioventricular block has been documented most frequently.

In foals in which **electrolyte disorders** are the underlying cause of cardiac arrhythmias, attempts should be made to correct these. Specific measures to reduce serum potassium include the administration of **insulin** (0.5 IU/kg), **dextrose** (2–4 g/unit of insulin used) and **sodium bicarbonate** (2 mEq/kg). Hypocalcemia may enhance potassium's arrhythmogenic effects, and calcium administration may be cardioprotective during hyperkalemia.

Pressure support

The restoration of **effective circulating volume** is essential to maintain blood pressure. Crystalloid (polyionic) or colloidal solutions, plasma or whole blood are all suitable alternatives. **Polyionic solutions** are most widely used, however colloidal solutions and plasma have the advantage that they are maintained in the intravascular space for longer. Fluids should be administered IV at up to 20 mL/kg/h. Hypertonic (7%) saline can be used to increase rapidly the effective circulating volume (see Table 14.17), but it is contraindicated in **renal failure** (*q.v.*), a common problem in asphyxiated and septicemic neonates.

The adrenergic agents **dopamine** and **dobutamine** are indicated if fluid administration alone does not increase blood pressure. Dopamine has dose-dependent effects. At low doses (1–3 µg/kg/min), it produces vasodilatation in the renal vascular beds, mediated through dopaminergic receptors. β₁-Adrenergic effects are induced by moderate doses (3–5 µg/kg/min), and these are responsible for dopamine's positive inotropic action. At high doses (greater than 5 µg/kg/min), α-adrenergic stimulation produces vasoconstriction. This may be detrimental and should be avoided.

Information on dopamine dose rates for foals has largely been extrapolated from other species and further research is required. Human neonates are less responsive to dopamine than adults, and, clinically, it appears that this may be true in foals. Therefore, dopamine administration must be **titrated to effect** in each individual foal.

Dobutamine is a synthetic adrenergic agent that produces strong β₁- and weak α-adrenergic effects. Consequently, it has strong inotropic effects. It is used alone, or in combination with dopamine, to provide pressor support (see Table 14.17).

Epinephrine/adrenaline CRI can also be used. Begin epinephrine/adrenaline administration at 0.1 µg/kg/min and titrate to effect up to 1 µg/kg/min or higher. Monitor for tachycardia.

If there is no response to traditional pressor therapy, **methylthioninium chloride** therapy (0.5–2 mg/kg IV) may be beneficial. Methylthioninium chloride blocks the action of **nitric oxide**, which is a potent vasodilator. **Naloxone**

has also been used to block endorphin-mediated hypotension as occurs during hemorrhagic and septic shock.

SUPPORTIVE THERAPY

The foal's respiratory and cardiovascular problems should be addressed first, but supportive therapy is also important. For example, **furosemide** (1.0 mg/kg IV) is indicated if **pulmonary edema** is present; antibiotic therapy should be instituted as appropriate; and plasma containing antibodies to endotoxin, or drugs such as **flunixin** may be useful.

Metabolic acidosis

In the presence of hypoxia and circulatory failure, **lactic acidosis** develops rapidly as anaerobic metabolism ensues. Administration of **sodium bicarbonate** may be indicated in profound metabolic acidosis. A severe base deficit (≥ 10 mEq/L) must be documented by blood gas analysis prior to administration of bicarbonate.

Acidosis depresses myocardial function, and correction with bicarbonate will improve the effectiveness of epinephrine. However, the use of bicarbonate in CPR protocols is becoming increasingly less popular as a growing body of evidence suggests that it may not be beneficial overall. Complications include metabolic alkalosis, hyperosmolarity, hyponatremia and intracranial hemorrhage. Bicarbonate is metabolized to carbon dioxide; therefore adequate ventilation must be established prior to the administration of bicarbonate in order to prevent the development of respiratory acidosis.

Hypoglycemia

The severely compromised neonate is frequently **profoundly hypoglycemic**. In septic and hypovolemic shock, increased catecholamine secretion and hypothermia may increase glucose utilization, and glucose production decreases in association with hepatic and endocrine dysfunction.

Neonates, particularly premature foals, may have insufficient glycogen stores. In utero, hypoxemia may deplete cardiac glycogen stores, impairing cardiac function during subsequent periods of hypoxemia. Dextrose should be administered IV at 4–8 mg/kg/min in a 5–10% solution for initial stabilization. Serum glucose concentrations can be monitored using a dextrometer, and should be frequently evaluated to guide replacement therapy and prevent post asphyxia hypoglycemia. Hyperglycemia should be avoided as this may exacerbate brain injury.

Body temperature

Neonates have limited ability to regulate temperature. Human neonates will lose 4°C in skin temperature in 5 min, and 2°C in core temperature in 20 min if left naked and wet in ambient temperatures. Similarly, **the wet newborn foal loses a large amount of heat by evaporation**. Newborn foals should be dried with towels.

Radiant heat is the most effective means of maintaining body temperature, and heated pads, hot water bottles (not hotter than can be comfortably held in the hand) and blankets are also useful. Rectal temperature should be monitored frequently (every 10–15 min during initial stabilization) to ensure that the foal does not become hyperthermic under radiant heat.

Cerebral edema and reperfusion injury

Reperfusion injury plays a central role in the pathogenesis of myocardial and cerebral damage induced by cardiopulmonary failure (*q.v.*). Free radical scavenging drugs such as **dimethyl sulfoxide (DMSO)** may help to minimize this process (see Table 14.17).

In foals, the use of mannitol to reduce cerebral edema is controversial. There is concern that it may exacerbate cerebral hemorrhage, which is associated with neonatal maladjustment syndrome. Consequently, mannitol should be avoided.

SURVIVAL FOLLOWING CARDIOPULMONARY ARREST

In human medicine, precise details are known of the prognosis following cardiopulmonary failure, particularly the neurologic outcome and long-term survival and their relationship to the duration of the period of arrest and the **APGAR score** (a clinical assessment used to identify hypoxic babies—see Table 14.9). Unfortunately, such information on long-term outcome is lacking for foals and there are no firm guidelines on the point at which CPR should be abandoned. In other species, neonates are more resistant to the effects of hypoxia than adults, and can survive longer periods of cerebral hypoxia.

In foals, the most useful clinical parameter on which to base termination of CPR is the absence of the **corneal reflex** as this reflects profound CNS dysfunction. It may also be helpful to decide the precise duration for which CPR will be continued in advance (for example 15 or 20 min) as this will ease the final decision to stop resuscitation.

DEVELOPMENT OF A NEONATAL INTENSIVE CARE SERVICE

The four essential ingredients for neonatal intensive care are: (1) facility; (2) laboratory support and equipment; (3) trained personnel; (4) knowledge of foal diseases and intensive care techniques.

THE FACILITY

The level of care can vary from basic supportive nursing care provided in a stall environment to round the clock monitoring in a specially designed facility.

Critically ill foals should be kept in a warm, quiet, well-ventilated but draught-free area, separate from any transient adult horse population. Whenever possible the **mare** should be kept within sight and smell of her foal to reduce neonatal stress and foster good maternal bonding.

Intensive care delivery is facilitated by a few **stall renovations**. Working on a recumbent foal in the presence of the dam requires a large stall (average size 3.7×5.5 m [12×18 ft]) with a sturdy, removable stall partition (approximately 1.2 m [4 ft]) in height. Fenestrated partitions constructed of stainless steel or aluminum are easily disinfected and allow the mare to see and smell her foal without obstructing ventilation.

Although clay and dirt floors provide the best footing for young foals, an easily disinfected surface is preferred. Heavy rubber textured mats are an ideal alternative. Lightweight wrestling mats provide additional padding for recumbent neonates. The ability to pad the walls and floor of a 1.2×1.8 m (4×6 ft) area in a stall corner allows confinement of foals at increased risk for self-trauma.

A centrally placed **swivel hook** in the ceiling above the foal side of the stall facilitates fluid administration, especially when used in conjunction with a coiled IV fluid administration set. Ceiling hooks can be used to suspend heat lamps and oxygen lines entering from either wall outlets or oxygen tanks or oxygen concentrators positioned outside the stall.

Good lighting is essential for reliable evaluation of mucous membranes, sclera and other physical examination parameters as well as for performing a variety of procedures including catheter placement. Easily accessible electrical outlets are mandatory for the wide array of equipment frequently employed during the work-up and care of a sick foal. A small refrigerator is an invaluable storage area for antibiotics and milk. Although a warm water bath can be used to rewarm cold milk and heat fluids, a microwave is more efficient.

Simple **hand washing** remains the most important means of infectious disease control among sick neonates. Therefore, a sink and mild antiseptic soap should be in close proximity of the mare and foal stall(s). Traffic into the foal care area should be limited.

LABORATORY SUPPORT

Foals sick with a variety of problems frequently **stop nursing** and experience varying degrees of hypoglycemia, dehydration and hypogammaglobulinemia (*q.v.*). Rapid evaluation of these parameters is essential to provide basic supportive care. A pocket size, battery-operated **glucometer** provides fast, stall-side glucose determination. A countertop microhematocrit centrifuge and a handheld refractometer will measure PCV and total protein concentration, respectively. Serum IgG concentration can be readily determined using a variety of easily performed assays that include zinc sulfate turbidity, latex agglutination and ELISA technology.

Critically ill foals are **metabolically unstable** and experience a variety of biochemical disturbances that are not apparent from physical examination alone. If serum biochemistries cannot be performed in the clinic, then arrangements should be made with an independent laboratory service capable of providing results within 6–12 h.

Sudden changes in the leukogram, such as leukopenia with a degenerative left shift signaling the onset of septicemia, may require **aggressive changes** in case management. **Same-day hematology** results are desirable. Changes in plasma fibrinogen concentration reflect more chronic trends in a patient's condition and same-day results are not mandatory.

Systemic and localized bacterial infections remain the most common problems of the newborn. The ability to perform bacteriologic cultures and cytology on blood and other body fluids is essential. Identification of offending pathogens and their antibiotic susceptibility patterns helps guide rational microbial therapy.

Hypoxemia and hypercapnia are difficult conditions to identify clinically. Although tissue damage begins once arterial O_2 concentrations decrease <60 mmHg, **cyanotic mucous membranes** only develop at arterial O_2 tensions <40 mmHg. Hypercapnia does not produce any appreciable change in mucous membrane color. Respiratory support is often initiated based on signs of respiratory distress. Arterial blood gas analysis characterizes the type and severity of pulmonary dysfunction and is essential if aggressive mechanical ventilatory support or prolonged respiratory therapy is anticipated.

EQUIPMENT

Equipment needs are dictated by the level of intensive care to be provided. A detailed list of supplies is presented in Table 14.19. Deep straw bedding is satisfactory for weak but ambulatory foals. Recumbent neonates require softer, more absorbent bedding to reduce the risk of **decubital sores**.

The ideal foal bed should be easily moved and cleaned. Options include a heavy-duty inflatable air mattress or twin bed mattress encased in a removable vinyl cover. **Water beds** can be used: they have the advantage of providing a temperature-controlled environment and the disadvantage of being cumbersome and difficult to move. Washable, synthetic fleece pads, available from most hospital supply companies, provide the ideal bedding to prevent pressure sores and can be used on any of the foal beds described. Towels, soft brushes and cornstarch containing baby powder assist in keeping foals dry and clean.

Foals unwilling or unable to nurse from the mare must be fed enterally by bottle, bucket or nasogastric tube, or parenterally using a variety of IV catheters and infusion devices. The mare can be **milked by hand** or with a human breast pump or udder pump. If artificial powdered milk replacer is used, a blender facilitates the mixing process. Foals with an effective suckle and swallow reflex can be fed using a baby bottle and selection of nipples.

Wide, shallow containers are ideal for bucket feeding. Nasogastric tubes should be soft and approximately 50–55 cm in length. Stallion urinary catheters or human enteral feeding tubes can be used as substitutes for commercially available, foal nasogastric tubes. Some form of flow regulating device (e.g. Dial-A-Flow extension set, Soluset, Buretrol, infusion pump) is needed to control delivery of parenteral alimentation.

Weak foals unable to nurse require **fluid therapy** in addition to nutritional support. Catheters should be available in a variety of gauges and lengths and made of low reactivity material such as polyurethane or polyvinyl chloride. In the dehydrated foal, catheters that use a short introduction trocar and guide wire are easier to insert than over-the-needle catheters with long stylets. Fluids commonly used for foals include 5% dextrose, 0.9% sodium chloride, 5% or 2.5% dextrose and 0.45% sodium chloride and a balanced electrolyte solution. Additives frequently required include concentrated bicarbonate, calcium,

Washer and dryer	

¹ SIMV, synchronized intermittent mandatory ventilation.² CPAP, continuous positive airway pressure.³ PEEP, positive end expiratory pressure.

potassium chloride and dextrose solutions. A coiled IV fluid administration set and fleece-lined fluid surcingle facilitate fluid administration in even a barn situation. Plasma and blood transfusions (*q.v.*) require special administration sets with appropriate filters.

Respiratory support covers a wide spectrum of techniques including post partum resuscitation, intranasal oxygen therapy, nebulization therapy, with percussion and mechanical positive pressure ventilation. Effective resuscitation can be performed using a nasotracheal tube and self-inflating resuscitator bag with or without oxygen enrichment or an oxygen demand valve. Intranasal oxygen therapy requires an intranasal or intratracheal cannula, oxygen tubing, and humidifier with flow meter and oxygen source.

An **oxygen concentrator** capable of delivering 5–10 L/min may be an attractive and affordable alternative to having compressed gas or liquid oxygen tanks in a clinic or farm setting. The concentrator requires only an electrical outlet. A variety of nebulizers are available that can be used to deliver solutions containing bronchodilators, mucolytic agents and wetting solutions. Foals in respiratory failure require positive pressure mechanical ventilation using a volume- or pressure-cycled ventilator, oxygen blender, oxygen analyzer, on-line humidification system and continuous supply of compressed air and oxygen.

Hypothermia plagues many sick foals. Correction of hypothermia complicated by severe dehydration and/or septic shock (*q.v.*) requires **volume repletion** in addition to any external warming aids. Ideally, the external environment itself should be warmed and draughts eliminated. To reduce environmental hazards and overheating of the patient, radiant heat lamps should be hung securely and equipped with a thermostat control. IV fluids can be warmed in either a microwave or commercially available insulated fluid jacket. Additional aids include warm water bottles and hot water pads strategically placed under an insulated blanket or blankets warmed in a dryer or commercial blanket warmer.

If **chronic intensive care** is anticipated, an electrocardiograph and indirect blood pressure monitor are recommended. Additional diagnostic aids include an ultrasound machine, preferably a sector scanner with 3, 5 and 7.5 MHz transducers. Ultrasonography is useful to diagnose a variety of problems including cardiac defects, ruptured bladder, umbilical remnant infection and intussusception. Radiography is helpful in evaluating thoracic and abdominal disease and a variety of musculoskeletal disorders including incomplete cuboidal bone ossification, angular limb deformities, and septic arthritis and/or osteomyelitis.

The equipment listed in Table 14.19 represents a comprehensive inventory required by an intensive care facility. If an **ambulatory foal service** is anticipated, the supply list can be reduced to those items required to provide resuscitation, intermittent intranasal oxygen and fluid therapy, plasma administration and enteral nutrition. A suggested pharmacy inventory is presented in Box 14.12.

PERSONNEL

The nucleus of any foal care program is the **support staff**. To maximize the chance of survival, the sick foal must be identified as soon as possible and its

Box 14.12 Suggested pharmacy inventory**Antibiotics, antifungal agents**

- Procaine benzylpenicillin, benzylpenicillin in aqueous solution, or ampicillin
- Amikacin, gentamicin (potentially nephrotoxic)
- Trimethoprim–sulfamethoxazole
- Ceftiofur
- Oxytetracycline (for treatment of contracted tendons)
- Erythromycin
- Clarithromycin (for treatment of *Rhodococcus equi* infections)
- Rifampicin
- Fluconazole (antifungal agent)
- Metronidazole

Gastrointestinal drugs

- Acetylcysteine powder (6 g in 150 mL water as a retention enema)
- Sucralfate
- Ranitidine, cimetidine or famotidine
- Omeprazole
- Antacids
- Bismuth subsalicylate
- DTO Smectite: Biosponge (Platinum Performance Inc.)
- Metoclopramide
- Bethanechol
- Loperamide
- Probiotics
- Lactase tablets

Analgesics, sedatives, anti-inflammatory drugs

- Phenylbutazone
- Flunixin meglumine
- Ketoprofen
- Xylazine
- Detomidine (use with caution in sick neonatal foals)
- Butorphanol
- Dipyrone
- Acepromazine (for mare sedation)
- Dimethyl sulfoxide (DMSO)

Anticonvulsives and other CNS drugs

- Diazepam
- Phenobarbital
- Magnesium sulfate solution
- Thiamine
- Ascorbic acid
- Alpha tocopherol

Box 14.12 continues on page 867

Box 14.12 Suggested pharmacy inventory [continued]

Cardiac and renal drugs

- Lidocaine
- Epinephrine/adrenaline
- Bretylium
- Dopamine
- Dobutamine
- Mannitol
- Furosemide

Miscellaneous

- Oxytocin
- Domperidone
- Bronchodilators: albuterol, clenbuterol
- Caffeine
- Ophthalmic ointments/solutions
- Antibiotic preparation without steroids
- Steroid preparation: prednisolone acetate or dexamethasone
- Atropine
- Acetylcysteine
- Artificial tears
- Fluorescein strips (to detect corneal ulcers)

progress monitored frequently by **trained observers**. Continuing education programs offering information on mare/foal husbandry and foal diseases serve to educate stud farm personnel and hospital attendants and to attract the additional workers required during the foaling season.

The level of care required by even a few critically ill foals can be extremely labor intensive, and a pool of trained, temporary “foal sitters” is essential. Eager volunteers can often be found among preprofessional students in search of veterinary experience. In the academic setting, veterinary students provide invaluable assistance in the neonatal ICU. Additional nursing support can be found in the local community among interested horsemen and women, but reliability and commitment are usually improved if the seasonal positions are offered at wages considered competitive within the horse community.

KNOWLEDGE OF NEONATOLOGY AND INTENSIVE CARE TECHNIQUES

Veterinarians and their attendants interested in providing critical foal care must remain current in their knowledge of foal diseases and critical care methodologies. Veterinarians usually have little difficulty meeting this obligation; however, many practices overlook the tremendous advantage of having one or more well-trained **veterinary nurses**. These individuals should be encouraged to enhance their skills and experience by attending formal veterinary programs and by establishing a close working relationship with their counterparts in the human neonatal nursing field.

	Introduction 1044	

INTRODUCTION

Most horses are produced and kept for athletic purposes although ambitions range from intermittent use for pleasure riding to the extreme demands placed on the elite racing Thoroughbred. Whatever the requirements, **lameness** is the greatest contributor to loss of performance, missed training and attrition of horses, and consequently is the **single most common problem** of equine practice.

Disturbances of the locomotor system have attracted research funds and initiatives such that the equine veterinary literature abounds with advances in diagnostic and treatment modalities. Understanding in this field exceeds that of other domestic species and therefore the services available to horses are similar to those provided for human athletes.

The conditions encountered daily in general veterinary practice range from ill-fitting shoes through developmental conditions to long bone fractures. Accurate diagnosis and understanding of pathophysiology are vital for appropriate early case management. These areas are therefore highlighted in this section. Emphasis is also placed on the management of common problems; more esoteric considerations can be made after additional investigation of the literature or at a referral center.

Despite advances in imaging modalities, diagnostic **local analgesia** remains pivotal in the investigation of equine lameness. Understanding of basic local analgesic techniques is therefore necessary for all who evaluate lame horses.

DIAGNOSTIC LOCAL ANALGESIA

The importance of diagnostic local analgesia in the investigation of equine lameness has been well documented. Typically this involves perineural or

regional analgesia and intrasynovial analgesia although epidural analgesic techniques (*q.v.*) are frequently used for treatment of orthopedic pain.

The judicious use of local analgesia in the investigation of equine lameness should be deferred until a **thorough clinical appraisal**, including assessment of the gait abnormality, limb palpation, etc., has been completed. This is particularly true when the history or performance level suggests that there may be a nondisplaced fracture or serious soft tissue injury.

Fortunately, aberrant distribution of the appendicular nervous system is uncommon in horses. There are few indications for the use of ring blocks or field blocks as diagnostic techniques because they usually produce little more than cutaneous desensitization. However, when aberrant nerve routes are suspected they may be a useful adjunct to perineural analgesia.

When possible, **intrasynovial analgesia** should precede perineural infiltration when involvement of a specific joint, bursa or tendon sheath is suspected, since this will not interfere adversely with the interpretation of subsequent regional blockade. The reverse is, however, not true. Moreover it is acceptable to “leapfrog” with intrasynovial techniques whereas perineural analgesia should be performed in a **sequential manner** beginning distally. Intrasynovial analgesia is usually specific, and periarticular structures such as ligaments and tendons usually retain sensation. There are a few notable exceptions to this generalization, including intra-articular (IA) anesthesia of the distal interphalangeal joint.

Local analgesics are salts of weak bases in aqueous solution. Penetration and diffusion in tissues is determined by their lipid solubility. These salts dissociate in neutral or alkaline areas, and are therefore not as active in acid media, e.g. **infected sites**. The local analgesic cation binds to anionic receptors on the nerve fiber blocking the sodium channels. As a result, sodium entry and depolarization are prevented. This is referred to as a non-depolarizing block. Since the myelin sheath of nerves is both an electrical and pharmacologic insulator, access of local analgesic to myelinated fibers is limited to the nodes of Ranvier and so a higher concentration of agent is necessary to induce anesthesia of myelinated compared with non-myelinated nerves.

Although transmission in all nerve fibers can be blocked by local anesthetics, there is generally a **difference in susceptibility** of various types of nerves. Sensations disappear in order from pain, cold, warmth, light touch, joint proprioception to deep pressure, and return in the reverse order. As a result, when desensitizing a peripheral nerve, **differential blockade** may be produced—pain may be overcome completely (i.e. type A- δ and C fibers are blocked) but motor function and touch (type A- α and A- β fibers) can remain unaffected.

Once the local anesthetic agent has been deposited around a nerve it diffuses from outside toward the center. Small diameter nerve trunks are therefore more susceptible to blockade than large nerves. In addition, since the most distal limb elements supplied by a particular nerve are the core fibers, and therefore blocked last, the most pertinent tests of efficacy are performed as far distal to the site of infusion as possible.

Following vascular removal from a site, agents are detoxified by liver and plasma pseudocholinesterases (principally the former) and metabolites are excreted by the kidneys.

The three most suitable local analgesic agents are:

1. Mepivacaine hydrochloride 2%
2. Lidocaine hydrochloride 2%
3. Bupivacaine hydrochloride 0.5% and 0.75%.

Two per cent mepivacaine hydrochloride is widely used and demonstrates reduced local tissue reaction in equines, particularly with IA infusion. Systemic toxicity is unlikely to be a problem at dose rates up to 10 mg/kg in local infiltration. However, both systemic and local reactions can occur with repeated doses, and inadvertent rapid IV injections can produce initial excitement followed by CNS depression. **Intravenous barbiturate** is the treatment of choice if an **overdose** is suspected.

All local anesthetic agents (with the exception of cocaine) cause **peripheral vasodilatation**, thereby enhancing vascular absorption, although the intensity of response varies with the site of injection, dosage and between individual agents. The duration of action of mepivacaine and lidocaine is reported to be as short as 45–60 min. However, clinical experience suggests that these times are frequently exceeded and there are reports that effects persist for up to 3 h. **Bupivacaine** has a duration of action of up to 6 h and is therefore a useful agent when sedation is required for administration of a diagnostic block.

The **duration of action** of all agents is prolonged by the addition of a vasoconstrictor, e.g. epinephrine/adrenaline hydrochloride. Systemic toxicity is also reduced but at a price, since prolonged local exposure will increase the effects of tissue irritation at the site of injection. Epinephrine/adrenaline at 1 in 50 000 dilution results in **local tissue ischemia** and necrosis. Generally 1 in 100 000 or 1 in 200 000 is adequate and will almost double the duration of local anesthetic action, but even at these concentrations the subsequent production of white hairs at nerve block sites can be a problem, and epinephrine/adrenaline is generally avoided.

Clean injection techniques are essential when performing perineural local analgesia, and aseptic technique is mandatory for IA procedures or for performing regional nerve blocks that can inadvertently enter a synovial cavity. Appropriate aseptic technique requires **full surgical skin preparation**, and wearing sterile surgical gloves. Studies have shown that it is not necessary to clip the hair over the injection site, but with a heavy haircoat or gross contamination of the area it may be advisable to do so. Many experienced practitioners still routinely clip before synovial injection.

A **new vial** of local anesthetic should be used for intrasynovial analgesic administration.

Many of the inflammatory reactions that occur following local analgesic techniques are probably due to poor technique including **iatrogenic contamination**. While antibiotics are not usually necessary when intrasynovial analgesia is undertaken, if conditions are less than ideal or repeated injections are required, they can be added. It is important to select antibiotics that **do not precipitate** when mixed with the local anesthetic agent (i.e. 2% lidocaine mixed with penicillin or ampicillin). The aminoglycosides **gentamicin** (300 mg) and **amikacin** (250 mg) can be mixed with local anesthetics without precipitating and they maintain their antibiotic efficacy in the mixture. Consequently, they are used regularly, particularly when there is a concern about potential contamination or when sepsis is already present.

PRACTICAL ASPECTS OF DIAGNOSTIC LOCAL ANESTHESIA

General

The minimal amount of **restraint** conducive to good technique and personal safety is recommended. When the technique in question is most easily performed with the limb weight bearing then an assistant lifting another leg is often the most effective option. A twitch can be employed when necessary and in some circumstances sedation may be required.

There are obvious difficulties in interpretation of local analgesia of a sedated animal, and a sedative with a shorter duration of action than the local anesthetic should be utilized. **Intravenous xylazine** (*q.v.*) is often the drug of choice, although almost any sedative or sedative combination can be employed if bupivacaine is used. When xylazine or another α_2 -agonist is used, the sedation can also be reversed with an appropriate antagonist such as **atipamezole** or yohimbine to allow for earlier re-evaluation. Nervous horses can be sedated with low doses of acetylpromazine (0.02 mg/kg IV or 0.04 mg/kg IM). The drug should be administered before evaluating the horse's baseline lameness, as the sedation can actually facilitate the examination and augment lameness.

For injection around **deep nerve trunks**, e.g. median nerve or tibial nerve, and for difficult intrasynovial infusions or fractious horses, a small SC bleb of local anesthetic greatly facilitates the procedure. Eliminating patient movement increases the accuracy of placement and reduces iatrogenic damage.

During intrasynovial techniques, accuracy of placement can be ensured by aspirating synovial fluid before infusion although this is not possible in all locations. It is **not necessary** to withdraw the same volume of synovial fluid as of the local analgesic agent to be infused. When synovial fluid cannot be aspirated, careful movement of the needle can also be used to confirm IA or intrasynovial placement. This can usually be supported by observation of the site as injection proceeds. **Ultrasound** can also be invaluable in guiding difficult intrasynovial injections, e.g. the coxofemoral joint.

There is general agreement that approximately 5–10 min should be allowed for regional blockade to be effective and 15–30 min for intrasynovial analgesia. However, there is significant variation in these times between sites and between individual patients, e.g. some intrasynovial techniques have shown responses in <5 min and some proximal (large) perineural blocks may take >30 min for full effect. During this time the horse is usually walked quietly to become accustomed to the desensitized area and to provide diffusion of intrasynovial anesthetic agents before reassessing the animal's gait and, where appropriate, the quality of the block.

Evaluation of the efficacy of perineural local analgesia requires knowledge of the zones of cutaneous innervation provided by individual nerves together with the deeper structures supplied. Whenever possible both should be evaluated.

Individual techniques

Details of forelimb and hindlimb regional and intrasynovial analgesia are given in Table 15.1.

Table 15.1 Techniques for diagnostic local anesthesia

Site	Needle	Volume ¹
FORELIMB REGIONAL ANALGESIA		
Palmar digital nerves		
SC between the mid-pastern and the proximal border of the cartilages of the distal phalanx, immediately palmar to the medial and lateral palmar digital arteries or SC just distal to the proximal border of the cartilages of the distal phalanx, immediately palmar to the medial and lateral palmar digital arteries	0.5 × 16 mm (25 G × 5/8")	1–1.5 mL (avoid larger volumes to prevent spread through fascial planes to the dorsal branches of the palmar nerves)
Site	Structures desensitized	
SC between the mid-pastern and the proximal border of the cartilages of the distal phalanx, immediately palmar to the medial and lateral palmar digital arteries or SC just distal to the proximal border of the cartilages of the distal phalanx, immediately palmar to the medial and lateral palmar digital arteries	Navicular bone, navicular bursa, collateral sesamoidean and distal sesamoidean impar ligaments, insertion of the distal sesamoidean ligaments, distal DDFT and associated digital synovial sheath, insertion of the SDFT, digital cushion, palmar laminar corium and corium of sole and frog, palmar solar and variable amounts of dorsal distal phalanx, collateral cartilages, most of the distal interphalangeal joint, collateral ligaments of the distal interphalangeal joint, palmar aspect of the proximal interphalangeal joint, skin over the heel bulbs	
Site	Needle	Volume¹
Palmar nerves at the level of the proximal sesamoids (abaxial sesamoid block)		
SC immediately palmar to the medial and lateral palmar arteries over the abaxial surfaces of the proximal sesamoid bones or SC immediately palmar to the medial and lateral palmar arteries at the base of the proximal sesamoid bones	0.5 × 16 mm (25 G × 5/8")	2–3 mL
Site	Structures desensitized	
SC immediately palmar to the medial and lateral palmar arteries over the abaxial surfaces of the proximal sesamoid bones or SC immediately palmar to the medial and lateral palmar arteries at the base of the proximal sesamoid bones	As noted for palmar digital nerves plus remaining content of the hoof, middle phalanx and associated soft tissues, proximal and distal interphalangeal joints, distal and palmar aspects of proximal phalanx and associated soft tissues, distal sesamoidean ligaments, occasionally portions of the metacarpophalangeal joint, skin over medial lateral and palmar aspects of the pastern and variable areas of skin dorsally from coronary band to proximal phalanx	

DDFT, deep digital flexor tendon; SDFT, superficial digital flexor tendon.

¹ All volumes of local anesthetic agent are for 2% mepivacaine hydrochloride.

(Continued)

Table 15.1 (Continued)

Site	Needle	Volume ¹
Low palmar (a) and palmar metacarpal (b) nerves (low four-point block, low volar block)		
(a) Just dorsal to the DDFT and palmar to the suspensory ligament at the level of the button of the second and fourth metacarpal bones (or slightly higher if the digital sheath is distended) medially and laterally in the subcutaneous space	0.7 × 25 mm (22 G × 1")	2–3 mL
(b) Immediately distal to and at the depth of the buttons of the second and fourth metacarpal bones	0.5 × 16 mm (25 G × 5/8")	1–2 mL
Site	Structures desensitized	
(a) Just dorsal to the DDFT and palmar to the suspensory ligament at the level of the button of the second and fourth metacarpal bones (or slightly higher if the digital sheath is distended) medially and laterally in the subcutaneous space	As noted for abaxial sesamoid block plus the entire metacarpophalangeal joint and associated tendons and ligaments, proximal sesamoid bones and associated soft tissues, distal third metacarpal bone, digital synovial sheath and enclosed flexor tendons, branches of the suspensory ligament and their insertions, skin over the dorsal aspect of the proximal phalanx and skin over most of the fetlock, but some skin sensation may be present over the dorsal surface of the fetlock	
(b) Immediately distal to and at the depth of the buttons of the second and fourth metacarpal bones		
Site	Needle	Volume ¹
High palmar (a) and palmar metacarpal (b) nerves (high four-point block, subcarpal block)		
(a) Medially and laterally adjacent to the DDFT palmar to the suspensory ligament in the proximal metacarpus beneath a heavy fascial layer	0.5 × 16 mm (25 G × 5/8")	2–3 mL
(b) Axial to the heads of the second and fourth metacarpal bones and adjacent to the suspensory ligament	0.7 × 25 mm (22 G × 1")	3–5 mL
Site	Structures desensitized	
(a) Medially and laterally adjacent to the DDFT palmar to the suspensory ligament in the proximal metacarpus beneath a heavy fascial layer	As noted for the low four-point block plus the DDFT and SDFT, accessory ligament of the DDFT, suspensory ligament, metacarpal bones and associated interosseous ligaments, skin over the palmar metacarpus. The carpometacarpal and middle carpal joints may be blocked inadvertently	
(b) Axial to the heads of the second and fourth metacarpal bones and adjacent to the suspensory ligament		
Site	Needle	Volume ¹
Lateral palmar nerve block (high two-point block)		
Laterally at a point midway between the accessory carpal bone and the head of the fourth metacarpal bone through the palmar border of the accessorimetacarpal ligament. Anesthetic must be injected beneath the flexor retinaculum	0.7 × 25 mm (22 G × 1")	5–6 mL

Table 15.1 (Continued)

Site	Structures desensitized	
Laterally at a point midway between the accessory carpal bone and the head of the fourth metacarpal bone through the palmar border of the accessorimetacarpal ligament. Anesthetic must be injected beneath the flexor retinaculum	Can be used in conjunction with the high medial palmar nerve block (high two-point block) to block the structures noted for the high four-point block with a lower risk of inadvertently blocking the middle carpal and carpometacarpal joints. The carpal canal may be blocked unintentionally.	
Site	Needle	Volume ¹
Median (a) and ulnar (b) nerves		
(a) Medially, 5 cm below the elbow joint, in dense fascia at a depth of 2–3.5 cm, adjacent to the caudomedial border of the radius and the median artery in the angle between the superficial pectoral and flexor carpi radialis muscles	1.1 × 38.1 mm (19 G × 1.5")	10–15 mL
(b) Beneath the antebrachial fascia, at a depth of 1–1.5 cm in the groove between the flexor carpi ulnaris and ulnaris lateralis, approximately 10 cm (one hand's breadth) proximal to the accessory carpal bone on the caudal aspect of the forelimb	0.9 × 38.1 mm (20 G × 1.5")	10–12 mL (as withdrawn an additional 2 mL is injected)
Site	Structures desensitized	
(a) Medially, 5 cm below the elbow joint, in dense fascia at a depth of 2–3.5 cm, adjacent to the caudomedial border of the radius and the median artery in the angle between the superficial pectoral and flexor carpi radialis muscles (b) Beneath the antebrachial fascia, at a depth of 1–1.5 cm in the groove between the flexor carpi ulnaris and ulnaris lateralis, approximately 10 cm (one hand's breadth) proximal to the accessory carpal bone on the caudal aspect of the forelimb	In addition to structures blocked with a high four-point block, the radiocarpal, middle carpal and carpometacarpal joints and associated carpal ligaments, carpal canals and enclosed tendons, and distal radius	
Site	Needle	Volume ¹
FORELIMB INTRASYNOVIAL ANESTHESIA²		
Navicular bursa³		
Palmar midline through the digital fossa between the bulbs of the heels, parallel to the bearing surface until contact is made with the navicular bone. Radiographic control or ultrasound guidance is required to confirm location	1.2 × 89 mm (18 G × 3.5")	2–4 mL
Site	Needle	Volume ¹
Distal interphalangeal (coffin) joint⁴		
Either adjacent to the common digital extensor tendon or through the tendon on dorsal midline, and 1.5 cm proximal to the coronary band; direct the needle distally and toward the mid-sagittal plane	1.1 × 38.1 mm (19 G × 1.5")	3–6 mL

² Alternative methods of intrasynovial anesthesia of the forelimb and hindlimb have been described in the literature for many of these sites.

³ More than five different approaches to the navicular bursa have been described and compared in the literature.

⁴ Lateral and palmar approaches to the distal interphalangeal joint have also been described.

(Continued)

Table 15.1 (Continued)

Site	Structures desensitized	
Distal interphalangeal (coffin) joint⁴		
Either adjacent to the common digital extensor tendon or through the tendon on dorsal midline, and 1.5 cm proximal to the coronary band; direct the needle distally and toward the mid-sagittal plane	Analgesia of the distal interphalangeal joint is not specific for IA pain and can eliminate pain associated with many conditions of the foot including navicular syndrome and sole pain	
Site	Needle	Volume ¹
Proximal interphalangeal (pastern) joint⁵		
1.5 cm from the midline and below the palpable palmar condylar eminence of the first phalanx; insert the needle underneath the extensor tendon directed distally and toward the mid-sagittal plane	0.9 × 38.1 mm (20 G × 1.5")	4–5 mL
Site	Needle	Volume ¹
Metacarpophalangeal (fetlock) joint⁶		
Into the palmar pouch through or adjacent (proximal or distal) to the collateral sesamoidean ligament	0.9 × 25 mm (20 G × 1")	5–7 mL
Site	Needle	Volume ¹
Digital flexor tendon sheath⁷		
Proximal to the proximal sesamoids and palmar annular ligament, and adjacent to the DDFT <i>or</i> On the palmar aspect of the pastern distal to the palmar annular ligament at the level of the proximal interphalangeal joint	0.9 × 25 mm (20 G × 1")	5–7 mL
Site	Needle	Volume ¹
Middle carpal and carpometacarpal joint		
Medial or lateral to the extensor carpi radialis tendon and sheath with the limb flexed <i>or</i> Adjacent to the ulnar/fourth carpal articular palmarolaterally with the limb extended	1.1 × 38.1 mm (19 G × 1.5") 0.9 × 25 mm (20 G × 1")	5–8 mL

⁵ Dorsal midline and palmaroproximal injection sites have also been described.

⁶ A dorsal approach to the metacarpophalangeal joint is often utilized to distend the joint prior to arthroscopic surgery, and can be used diagnostically as well.

⁷ An alternative approach made axial to the midbody of the proximal sesamoid bone through the annular ligament with the fetlock joint flexed is particularly valuable when the sheath is not distended and is difficult to palpate proximal or distal to the annular ligament.

Table 15.1 (Continued)

Site	Structures desensitized	
Medial or lateral to the extensor carpi radialis tendon and sheath with the limb flexed <i>or</i> Adjacent to the ulnar/fourth carpal articular palmarolaterally with the limb extended	The carpometacarpal and middle carpal joints reliably communicate. Palmar pouches of the carpometacarpal joint can desensitize the origin of the suspensory ligament and the proximal palmar metacarpal region	
Site	Needle	Volume ¹
Antebrachiocarpal joint		
Medial or lateral to the extensor carpi radialis tendon and sheath with the limb flexed, <i>or</i> Adjacent to the radius proximal to the accessory carpal/ulnar carpal bone articulation palmarolaterally with the limb extended	1.1 × 38.1 mm (19 G × 1.5")	5–8 mL
	0.9 × 25 mm (20 G × 1")	
Site	Needle	Volume ¹
Carpal sheath		
Palmarolaterally just proximal to the accessory carpal bone between the lateral digital extensor and the ulnaris lateralis tendons <i>or</i> On the palmaromedial aspect of the proximal metacarpus between the DDFT and accessory ligament of the DDFT	0.9 × 38.1 mm (20 G × 1.5")	5–7 mL
Site	Needle	Volume ¹
Cubital (elbow) joint⁸		
Immediately cranial or caudal to the lateral collateral ligament distal to the lateral epicondyle of the humerus <i>or</i> Caudolateral approach cranial and distal to the olecranon process directing needle craniomedially into the caudolateral joint pouch	0.9 × 38.1 mm (20 G × 1.5")	10–15 mL
	1.1 × 38.1 mm (19 G × 1.5")	
Site	Structures desensitized	
Immediately cranial or caudal to the lateral collateral ligament distal to the lateral epicondyle of the humerus <i>or</i> Caudolateral approach cranial and distal to the olecranon process directing needle craniomedially into the caudolateral joint pouch	A needle placed just caudal to the lateral collateral ligament enters the bursa of the ulnaris lateralis muscle and this bursa does not always communicate with the joint	

⁸ A number of modifications of these approaches to the cubital joint have been reported.

(Continued)

Table 15.1 (Continued)

Site	Needle	Volume ¹
Scapulohumeral (shoulder) joint		
Through the notch between the cranial and caudal eminences of the greater tubercle of the humerus, needle directed caudomedially	1.2 × 89 mm (18 G × 3.5")	15–25 mL
Site	Structures desensitized	
Through the notch between the cranial and caudal eminences of the greater tubercle of the humerus, needle directed caudomedially	Occasionally a communication exists between the joint and the intertubercular bursa	
Site	Needle	Volume ¹
Intertubercular (bicipital) bursa		
Needle directed proximomedially from a distal position just cranial to the humerus and proximal to the deltoid tuberosity Ultrasound guidance is valuable	1.2 × 89 mm (18 G × 3.5")	7–8 mL
Site	Structures desensitized	
HINDLIMB REGIONAL ANALGESIA		
Plantar digital nerves		
As for the forelimbs	As for the forelimbs	
Site	Needle	Volume ¹
Plantar nerves		
As for the forelimbs, performed in abaxial or basesamoid positions with additional anesthetic solution injected dorsally lateral and medial to the long digital extensor tendon to anesthetize the dorsal metatarsal nerves	0.5 × 16 mm (25 G × 5/8")	1–2 mL
Site	Structures desensitized	
As for the forelimbs, performed in abaxial or basesamoid positions with additional anesthetic solution injected dorsally lateral and medial to the long digital extensor tendon to anesthetize the dorsal metatarsal nerves	As for the forelimbs	
Site	Needle	Volume ¹
Low plantar (a), plantar metatarsal (b) and dorsal metatarsal (c) nerves		
As for the forelimbs (a, b) with additional anesthetic solution injected dorsally lateral and medial to the long digital extensor tendon to anesthetize the dorsal metatarsal nerves (c)	0.5 × 16 mm (25 G × 5/8")	1–2 mL

Table 15.1 (Continued)

Site	Structures desensitized	
As for the forelimbs (a, b) with additional anesthetic solution injected dorsally lateral and medial to the long digital extensor tendon to anesthetize the dorsal metatarsal nerves (c)	As for the forelimbs	
Site	Needle	Volume ¹
High plantar (a), plantar metatarsal (b) and dorsal metatarsal (c) nerves (subtarsal block)		
(a, b) Distal to the tarsometatarsal joint and axial to the second or fourth metatarsal bone; inject as withdrawing	1.1 × 38.1 mm (19 G × 1.5")	10 mL
(c) Dorsally lateral and medial to the long digital extensor tendon or a dorsal ring block performed	0.7 × 25 mm (22 G × 1")	2–3 mL
Site	Structures desensitized	
(a, b) Distal to the tarsometatarsal joint and axial to the second or fourth metatarsal bone; inject as withdrawing (c) Dorsally lateral and medial to the long digital extensor tendon or a dorsal ring block performed	Can be associated with unintended penetration of the tarsometatarsal joint and tarsal sheath. Infiltration of the origin of the suspensory ligament is often substituted for this nerve block, but is also associated with inadvertent penetration of the tarsometatarsal joint	
Site	Needle	Volume ¹
Tibial (a) and peroneal (b) nerves		
(a) Medially or laterally, 10 cm proximal to the calcaneal tuber, cranial to the calcaneal tendon, caudal to the DDFT beneath the crural fascia at a depth of 1–1.5 cm	0.9 × 38.1 mm (20 G × 1.5")	10–15 mL
(b) Laterally, 10 cm proximal to the point of the hock, 2–3 cm deep to the crural fascia in the groove between the long and lateral digital extensor muscles	1.1 × 38.1 mm (19 G × 1.5")	8–10 mL deep and an additional 4–6 mL as withdrawn to anesthetize the superficial branch
Site	Structures desensitized	
(a) Medially or laterally, 10 cm proximal to the calcaneal tuber, cranial to the calcaneal tendon, caudal to the DDFT beneath the crural fascia at a depth of 1–1.5 cm (b) Laterally, 10 cm proximal to the point of the hock, 2–3 cm deep to the crural fascia in the groove between the long and lateral digital extensor muscles	Deep structures distal to the tarsus, tarsal joints and associated tendons and ligaments, and tarsal sheath, calcaneal tendon. Skin sensation is lost over the plantar pastern and heels, but may persist medially and caudally

Table 15.1 (Continued)

Site		
HINDLIMB INTRASYNOVIAL ANALGESIA²		
Distal to the tarsus		
As described for the forelimb		
Site	Needle	Volume¹
Tarsometatarsal joint		
Laterally, proximal to the head of the fourth metatarsal bone; needle directed dorsally and distomedially	1.1 × 38.1 mm (19 G × 1.5")	4–6 mL
Site	Structures desensitized	
Laterally, proximal to the head of the fourth metatarsal bone; needle directed dorsally and distomedially	The tarsometatarsal joint occasionally communicates with the distal and proximal intertarsal joints and the tarsocrural joint, and anesthetic may also enter the tarsal sheath. In addition, distal outpouchings may anesthetize the origin of the suspensory and plantar proximal metatarsal regions	
Site	Needle	Volume¹
Distal intertarsal joint		
Medially, in the depression between the central, second and third tarsal bones and below or through the palpable edge of the cunean tendon	0.7 × 25 mm (22 G × 1")	3–4 mL
Site	Needle	Volume¹
Tarsocrural and proximal intertarsal joint		
Craniomedial aspect of the tarsocrural joint immediately medial or lateral to the saphenous vein or Plantarolateral approach between the tibia and the calcaneus	0.9 × 38.1 mm (20 G × 1.5")	10–20 mL
Site	Structures desensitized	
Craniomedial aspect of the tarsocrural joint immediately medial or lateral to the saphenous vein or Plantarolateral approach between the tibia and the calcaneus	The tarsocrural and proximal intertarsal joints reliably communicate	
Site	Needle	Volume¹
Cunean bursa		
Medially from the distal edge of the cunean tendon proximally under the tendon	0.7 × 25 mm (22 G × 1")	4 mL

Table 15.1 (Continued)

Site	Needle	Volume ¹
Tarsal sheath		
Medially or laterally over the deep digital flexor, proximal to the calcaneal tuber and cranial to the calcaneal tendon	1.1 × 38.1 mm (19 G × 1.5")	7–8 mL
Site	Needle	Volume ¹
Femoropatellar joint⁹		
Below the apex of the patella, between the middle and lateral (or medial) patellar ligaments, needle directed caudally or caudoproximally	1.1 × 38.1 mm (19 G × 1.5")	20–30 mL
Site	Structures desensitized	
Below the apex of the patella, between the middle and lateral (or medial) patellar ligaments, needle directed caudally or caudoproximally	The femoropatellar joint can communicate with the medial, and less often the lateral femorotibial joints. These communications are not reliable	
Site	Needle	Volume ¹
Medial femorotibial joint¹⁰		
Between the medial patellar and medial collateral ligaments, 1–2 cm proximal to the tibia	1.1 × 38.1 mm (19 G × 1.5")	10–20 mL
Site	Needle	Volume ¹
Lateral femorotibial joint¹⁰		
Just proximal to the tibia, between the lateral patellar ligament and the lateral collateral ligaments cranial, through or caudal to the tendon of origin of the long digital extensor tendon	1.1 × 38.1 mm (19 G × 1.5")	10–20 mL
Site	Needle	Volume ¹
Coxofemoral (hip) joint		
The notch between the cranial and caudal eminences of the greater trochanter of the femur, needle directed cranially, distally and medially. Ultrasound guidance facilitates this difficult block	1.2 × 152 mm with stylet (18 G × 6")	15–25 mL

⁹ The femoropatellar joint can also be approached laterally.

¹⁰ Alternative approaches to the medial and lateral femorotibial joints have been described.

OSTEOLOGY

STRUCTURE AND FUNCTION OF BONE

Four major functions of bone can be identified. The tissue provides:

1. The supportive and protective framework of the body
2. The levers by which muscles effect locomotion
3. Reservoirs of inorganic elements and fat
4. Red blood cells and many types of white blood cells.

To function as a skeleton, the bones must be stiff, and bone is one of the hardest substances in the body.

Bone derives from the embryonic mesenchyme, developing either by endochondral ossification or by intramembranous ossification. Long bones have specialized sites of endochondral ossification—the growth plates. In both types of ossification the method of bone deposition is the same. Under the influence of increased vascularity, mesenchymal cells differentiate and become **osteoblasts**. These cells line the surfaces on which bone matrix is being deposited. **Osteoid** is the organic portion of bone that is laid down first and later becomes mineralized. Both the production and mineralization of osteoid seams are functions of the osteoblast. The matrix of mature bone is approximately one third organic (mainly osteocollagenous fibers) and two thirds inorganic (hydroxyapatite crystals of calcium phosphate).

Early in its formation bone is described as woven because the collagen fibers are entwined in a haphazard fashion. Fetal bone and the first bone produced at sites of fracture repair have a high woven component. In certain specialized localities, such as dental alveoli or osseous labyrinths, woven bone persists into maturity. However, woven bone is usually gradually replaced by lamellar bone in which the collagen fibers are organized into layers.

According to the density of lamellae, bone may be classified as compact (**cortical**, dense) or spongy (**cancellous**, trabecular). Lamellae may be piled in one plane, but more typically they are ordered according to the Haversian system in which between 4 and 20 layers of bone describe concentric rings around a central canal containing blood vessels. Each Haversian unit is called an osteon. The principal cell of mature bone is the **osteocyte**. Osteocytes function to preserve the integrity of bone matrix. They respond to certain stimuli to release calcium and are also capable of bone destruction. The specialized cell for bone destruction is, however, the **osteoclast**.

The external, non-articular surfaces of bones are covered by **periosteum** consisting of an outer fibrous layer permeated by blood vessels and nerves and an inner osteogenic layer. Periosteum derives from the periosteal bone collar, which supplies osteoblasts to the periphery of developing bones. At that stage it is a highly vascular structure, but in adulthood it is a relatively loose covering of connective tissue containing mostly venules and capillaries. Nonetheless the periosteum retains osteogenic potential if injured. At certain sites, e.g. ligament, tendon or capsular insertions, modified periosteal fibers called **Sharpey's fibers** penetrate cortices providing firm anchorage. Endosteum is similar to periosteum, but is thinner and lines the medullary cavity of the bone.

Vascularity of bone is maintained through a medullary and periosteal blood supply, and the blood supply to bone differs between mature and immature states. Generally the blood supply to immature bone is more extensive. In developing bones with active growth plates the epiphysis and metaphysis have separate supplies because most vessels do not traverse the cartilaginous plate. There are transphyseal vessels in large epiphyses. The epiphysis is supplied by a network of vessels entering at articular margins circumferentially—an arrangement particularly vulnerable to trauma. The metaphyseal side of the growth plate is supplied by a similar arborization of vessels entering via numerous foramina. These anastomose with branches of the nutrient artery before coursing perpendicular to the active growth plate. Periosteal vessels supply the outer third of forming cortical bone of the diaphysis. In mature bone significant periosteal supply persists only at sites of firm fibrous attachments.

The principal supply to long bones is via a main nutrient artery which enters the diaphyseal cortex at a fascial attachment, passes through the cortex to the medulla and then divides into ascending and descending branches. These subdivide to supply intramedullary bone, sites of hematopoietic marrow plus the inner two thirds of all cortical bone. The metaphyseal ends of long bones are supplied by the proximal and distal metaphyseal arteries that persist from the immature state. Blood flow through cortical bone is mainly centrifugal, i.e. from medullary cavity to periosteum, with an intravascular pressure gradient between vessels at the two sites. Blood supply to flat and irregular bones is much more diverse than that to long bones, with multiple afferent and efferent points.

Marrow is the term used to describe the soft substance occupying the intertrabecular spaces of spongy bone. Marrow in the fetus and neonate is primarily hematopoietic (red). In the adult the marrow of long bones becomes primarily fatty (yellow) but does contain primordial stem cells. In the mid-shaft of some long bones the medulla has no spongy bone present and is termed the medullary cavity.

MODELING AND REMODELING OF BONE

Bone is a unique material that can change shape as it grows in a process called **modeling**. It can also regenerate itself through **remodeling**, in which the bone is activated and areas are resorbed and reformed. Bone responds readily to the complex forces on the skeletal system that cause small deformation of the bone, but superimposed on the mechanical requirements of bone is the need for it to fulfill its metabolic role, specifically in calcium homeostasis. Bone is therefore subject to adaptive activity in response to a wide range of biochemical influences, principally hormonally mediated. There are three major hormones (*q.v.*) that affect the activity of bone cells:

1. **Parathyroid hormone (PTH)** is secreted by the parathyroid glands from cells highly sensitive to the calcium concentration in blood. PTH (*q.v.*) is the principal hormone regulating plasma calcium levels. Its action on bone is to increase resorption thus elevating blood calcium.
2. **Calcitonin** is secreted by C cells of the thyroid gland, which are also sensitive to plasma calcium concentration. Calcitonin (*q.v.*) is inhibitory to

PTH and disables osteoclasts, therefore acting to decrease blood calcium levels.

3. **Cholecalciferol** (vitamin D₃) is both ingested and, catalyzed by ultraviolet radiation, synthesized in the epidermis. The principal purpose of vitamin D₃ (*q.v.*) is to provide sufficient extracellular calcium and phosphorus for mineralization to take place, and its chief role is increasing intestinal absorption of these.

The interactions of these three hormones are complex. In addition, their effects on bone cells can be modified or overridden by many other factors including the effects of other hormones, age, nutritional status, pathologic processes and biomechanical influences.

Although the basic blueprint for their overall structure is genetically predetermined, bones will **model** and **remodel** according to the use to which they are put or as a result of disease processes. In the course of normal activity a bone is intermittently loaded causing intermittent deformations of its structure. This physical property is at least part of the stimulus enabling bones to maintain mechanical competence. Excessive strains, either absolute or relative to the state of the bone under load, can be the cause of structural deterioration and ultimate failure.

The end stage of the modeling/remodeling adaptation is a function of antagonistic processes: resorption of existing bone and formation of new. In normal bone, equilibrated with its environment, there is still a constant need to replace damaged tissue. In compact bone, osteoclasts bore through existing **Haversian systems**, which become filled in by secondary osteons. In cancellous bone, the same occurs in large trabeculae but the smaller ones ossify by appositional deposition on their surfaces. With a decrease in customary strain levels, osteonal replacement rate increases but more bone is resorbed than is laid down. Consequently, cortices become porotic and can also become progressively thinner due to endosteal resorption.

Excessive strain levels cause damage to bone matrix, which stimulates replacement. The first phase of this involves bone resorption, further weakening the structure. If activity levels persistently outstrip the ability of a bone, or area of a bone, to remodel then defects in structure may progress to failure. This is the phenomenon sometimes referred to as exercise/stress adaptation mismatch or **stress fracture**. Candidates for such injuries are **immature animals** subjected to physiologically abnormal levels of exercise, perhaps with inappropriate training, or **high performance athletes** that undergo a change in training regimen for which they were unprepared. A series of studies at the University of Pennsylvania has provided an excellent example of the failure of bone remodeling to keep pace with athletic training.

Young Thoroughbred racehorses exercising at speed often develop a syndrome of **bucked shins** (*q.v.*) due to repetitive motion injury associated with high-strain cyclic fatigue of the third metacarpal bone, and can develop a **stress fracture** up to a year after the original injury. **Adaptive exercise programs** (*q.v.*) involving high-speed exercise in small doses can change the geometric properties of the bone and reduce the incidence of fatigue failure by changing the shape and substance of the bone.

Grooves and prominences on the outer surfaces of bones develop in adaptation to the pressure from overlying muscle bellies or tendons and the pull from soft tissue attachments, respectively. Mature periosteum can be reactivated by increased vascularity to form new bone at, or close to, sites of injury. Subchondral bone is also subject to remodeling in the face of repetitive functional overloading. This reduces its compressibility, undermining its ability to absorb shock, and so contributes to the vicious circle of **osteoarthritis** (*q.v.*).

The ultimate mechanical failure of bone is exemplified by **fracture**. The immediate response at a fracture site is an **acute inflammatory reaction** (*q.v.*) to soft tissue disruption and periosteal tearing, and to the necrosis caused by vascular compromise of the fracture ends. The **inflammatory phase** is succeeded by the **reparative phase** during which the initial hematoma is invaded by capillary buds (the process of granulation) that deliver mesenchymal cells enabling organization to occur. A **callus** is formed comprising fibrous tissue, cartilage and immature woven bone. The proportion of bone increases steadily, and with it the stability of the fracture site improves. The final step in healing of bone is the **remodeling phase** during which, through osteoclastic and osteoblastic activity, mature lamellar bone is produced. On occasion, fracture ends can be rigidly stabilized, permitting primary bone formation in which cutting cones of osteoclasts traverse the fracture gap and filling takes place via Haversian remodeling, bypassing the fibrocartilaginous callus stage.

BONE INFECTION (OSTEOMYELITIS, OSTEITIS)

Bone infection can cause **periosteitis**, **osteitis** or **osteomyelitis**, depending on the depth of involvement. When the infection is initiated in the **periosteum** and outer cortex the term **osteitis** or osteoperiostitis is used, and when the infection begins in or extends into the **medullary cavity** the term **osteomyelitis** is more appropriate. An acute inflammatory process is provoked leading to edema, thrombosis and ischemic bone necrosis. Infective material travels through the Haversian and Volkmann's canals, spreading the process. Extension into epiphyses and joints is possible because of the communication between metaphyseal and epiphyseal vessels.

As the disease progresses, **scar tissue** forms. Necrotic bone is sequestered by osteoclastic activity and becomes encapsulated by dense sclerotic bone (**involucrum**). Inflamed periosteum lays down new bone. If the process is not arrested then **pathologic fractures** may result from physiologic loads applied to bone with a compromised infrastructure.

Etiology

Infection occurs by **hematogenous spread** of organisms, via direct local trauma to bone or by extension of infection into bone from an adjacent septic focus. Osteomyelitis following bacteremia is most common in foals. The physal regions in the long bones of foals are predilection sites for bacterial localization, probably because of the slowing of blood flow in metaphyseal end vessels. Traumatic wounds (*q.v.*) are common in horses and are frequently complicated by infection and bony injury. Such conditions favor the development of sequestra, which occur at various sites, particularly in the lower limbs. Sequestrum formation requires both avascularity and infection.

Clinical signs

Particularly in the early stages, lameness and pain on palpation of the affected site are evident. Associated soft tissue swelling may subside with time or with antibiotic therapy, or may become fluctuant. In cases of open wounds, chronic, purulent discharge is an indication of sequestration or the presence of a foreign body. In cases of extensive osteomyelitis or in those that are secondary to bacteremia, there may be signs of systemic response such as general malaise, pyrexia, neutrophilia and hyperfibrinogenemia.

Diagnosis

Clinical signs can be highly suggestive but **radiography** is the definitive diagnostic procedure. Osteomyelitis may however be radiographically **silent** in the early stages and optimal radiographic definition is necessary to maximize diagnostic sensitivity. The first signs are typically **mottling** within the trabecular pattern, which progresses to areas of distinct radiolucency within the bone. Lesions are frequently discrete and with chronicity become surrounded by the radiodense involucrum. **Sequestra** are separated from the parent bone by radiolucent halos and they may increase in radiodensity. Periosteum adjacent to a site of bone infection may lift off the surface and produce palisading new bone.

Ultrasonography can also be valuable in identifying osteomyelitis and sequestrum formation. Ultrasound is particularly valuable for early identification of periosteal inflammation and subperiosteal fluid accumulation associated with infection or for evaluating areas that are difficult to evaluate radiographically such as the scapula.

Osteomyelitis has an intense uptake pattern with standard nuclear **scintigraphy**, and specialized nuclear imaging techniques including white blood cell labeling and radiolabeled ciprofloxacin can also be used to identify bone infection in difficult cases such as vertebral osteomyelitis. **Computed tomography** (CT) can also provide improved localization of osteitis lesions by eliminating superimposition in cross-sectional images. **Magnetic resonance imaging** has been found to be more sensitive for osteomyelitis than CT or radiography.

Treatment

The objectives of treatment are to **remove necrotic bone fragments**, to debride remaining tissue surfaces and to eliminate infection. Sequestra generally require surgical removal because elimination of infection at such sites is often impossible by medical means alone. Pathology resulting from direct trauma tends to be superficial and in accessible locations. These cases generally carry a good prognosis and often require minimal parenteral antibiotic therapy. Osteomyelitis resulting from hematogenous seeding of bacteria frequently involves less accessible and/or more vulnerable sites. Surgical debridement of septic physal lesions is indicated but carries the risk of long-term **physal dysplasia** (*q.v.*).

Parenteral antibiotics are recommended in these cases are mandatory and should preferably be selected according to the results of blood culture or culture of needle aspirates from lesions. Prolonged courses of bactericidal drugs are necessary. Regional antibiotic administration using intramedullary, IV or IA techniques can also be used effectively to eliminate the infection.

THE DISTAL (THIRD) PHALANX (P3, COFFIN BONE)

See Diseases of the foot (*q.v.*) (Table 15.2).

THE MIDDLE PHALANX (SECOND PHALANX, SHORT PASTERBONE, P2)

Fractures

Etiology

Fractures of the middle phalanx (P2) are usually **comminuted**, occur most frequently in the hindlimbs and are most common in athletic Quarter Horses. Calks and rims to augment traction may predispose to P2 fractures.

Simple fractures usually involve one or both plantar/palmar eminences, but longitudinal fractures can occur, most often in the frontal plane. Fractures are thought to be the result of compression, bending and torsional forces associated with abrupt stops and turns. **Palmar/plantar eminence fractures** presumably occur due to hyperextension of the proximal interphalangeal joint and tensile forces transmitted from soft tissue insertions. Comminuted fractures probably occur due to the complex forces generated with the digit moving relative to a fixed hoof position.

Clinical signs

Sudden onset of severe lameness at exercise is usual. Quite often the rider will report hearing a crack. In instances where the fracture occurs at apparently low-level exercise it is presumed that a stress fracture had previously weakened the bone. Limited swelling above the coronary band develops quickly. Pain, crepitus and instability can be elicited by palpating and manipulating the lower pastern. Simple fractures are generally less obvious. Palmar/plantar process fractures may be detectable by applying pressure directly over the site.

Diagnosis

Dorsopalmar, lateromedial and several oblique radiographs are required to effectively evaluate the fracture configuration.

Treatment

Simple fractures are best treated by a **lag screw technique** with or without arthrodesis of the proximal interphalangeal joint and the prognosis is favorable if repair is performed without delay. Most cases require a proximal interphalangeal **joint arthrodesis** and numerous effective arthrodesis techniques have been described.

Comminuted fractures are often amenable to internal fixation with a proximal interphalangeal joint arthrodesis. When the distal interphalangeal joint is not involved the prognosis is better than with biarticular fractures because of the ability of horses to perform with an arthrodesed proximal interphalangeal

Table 15.2 Fracture stabilization for transport to treatment facility

Limb involved	Fracture location	Stabilization method recommended
Forelimb or hindlimb	Distal phalanx	None
Forelimb	Middle phalanx Proximal phalanx Proximal sesamoids and distal metacarpus	Light bandage up to carpus. Dorsal splint from carpus to toe. Align dorsal surfaces of the cannon bone and phalanges with toe extended <i>or</i> Kimsey Leg Saver Splint
Forelimb	Mid to proximal metacarpus Carpus Distal radius	Robert-Jones bandage (<i>q.v.</i>) extending to the axilla Rigid splints from elbow to the ground secured with duct tape or other non-elastic tape
Forelimb	Ulna Humerus Neck of scapula	Padded bandage extending to the elbow Rigid splint from elbow to the ground to fix the carpus in extension
Forelimb	Mid to proximal radius	Robert-Jones bandage extending to the axilla Rigid splints to prevent abduction of the limb
Forelimb	Body of scapula	None
Hindlimb	Middle phalanx Proximal phalanx Proximal sesamoids and distal metatarsus	Light bandage up to hock. Plantar splint from tarsus to toe. Align sole surface, plantar fetlock and flexor tendons <i>or</i> Kimsey Hindlimb Leg Saver Splint
Hindlimb	Mid to proximal metatarsus	Lighter version of Robert-Jones bandage extending to point of hock. Rigid splints using the calcaneal tuber as a functional extension of the metatarsus
Hindlimb	Tarsus Tibia	Thick Robert-Jones bandage extending up to stifle. Rigid splint to prevent abduction and provide rotational stability
Hindlimb	Femur	None
Hindlimb	Pelvis	None
Limb involved	Splint placement	
Forelimb or hindlimb	NA	
Forelimb	Single dorsal splint. Use minimal padding and secure splint with duct tape and/or cast material	
Forelimb	Two splints placed caudally and laterally from the elbow to the ground	
Forelimb	Single splint caudally from the elbow to the ground	
Forelimb	Two splints. One placed caudally from the elbow to the ground. One placed laterally extending up the lateral aspect of the chest and taped securely around the forelimb and chest	
Forelimb	NA	
Hindlimb	Single plantar splint with sole flat against the splint and the fetlock flexed. Secure splint with duct tape and/or cast material. Can wire splint to the toe for longer applications	
Hindlimb	Two splints placed caudally and laterally from the calcaneal tuber to the ground	
Hindlimb	Single lateral splint extending from the ilium to the ground (preferably angled to match angle of the hock and stifle, or a straight 15–20 cm board splint)	
Hindlimb	NA	
Hindlimb	NA	

NA, not applicable.

Information derived from Bramlage, L.R. (1996) *First aid and transportation of fracture patients*, in Nixon, A.J. (ed) *Equine Fracture Repair*, W.B. Saunders, Philadelphia, pp. 36–42.

joint. In severely comminuted cases internal fixation may not be an option and if healing can be achieved it is invariably accompanied by osteoarthritis. Long-term casting with transfixation pins or the use of an external fixation device will be required to salvage a horse for pasture or breeding soundness.

Euthanasia (*q.v.*) is often elected in severe cases when both articular surfaces are involved and the horse does not have value for breeding. If the blood supply has been compromised, salvage may not be feasible. Blood supply can be evaluated using standard radiography, computed tomography (CT) or fluoroscopy in conjunction with vascular contrast injections.

Palmar/plantar process fractures can be stabilized by lag screw fixation, but osteoarthritis often develops and arthrodesis of the proximal interphalangeal joint is usually recommended. Casting is necessary regardless of the treatment selected, but duration of casting should be kept as short as possible to avoid associated complications.

Periarticular new bone formation (high ringbone)

Periosteal new bone formation on the dorsal, medial and lateral surfaces of the second phalanx is one manifestation of the condition known as **phalangeal exostosis** or ringbone. Where this involves distal second and proximal third phalanges it is called **low ringbone** (*q.v.*), and where proximal second and distal first phalanges are involved, **high ringbone** (*q.v.*). Depending on whether the interphalangeal joints are involved or not the ringbone may be articular or non-articular. Articular ringbone is dealt with in the subsection on arthrology (*q.v.*).

Etiology

Non-articular (or periarticular) ringbone affects both front and hind limbs. The periosteitis is presumably triggered by **tearing of fibers** of soft tissue attachments, e.g. common digital extensor tendon or collateral ligaments, or by direct external trauma. Depending on the time and nature of the insult, cases may present with acute or chronic lameness or with no associated lameness.

Clinical signs

In **acute cases**, sudden onset, moderate to severe lameness develops. There is increased digital pulse amplitude and often a discrete area around the pastern that is sensitive to pressure. Absence of solar pain is a useful aid to locating the site of pain. In **chronic cases** lameness is usually low grade and may be gradually progressive. If considerable exostosis has developed this will be palpable.

Diagnosis

Lameness is alleviated by palmar/plantar perineural analgesia at the basilar sesamoid or abaxial sesamoid level. Some cases will improve following a palmar/plantar digital nerve block. Intra-articular analgesia (of P1/P2 and P2/P3 joints) should differentiate articular and non-articular cases. Radiography is necessary for diagnosis and periosteal new bone should be assessed for signs

of activity. Acute cases may not show radiologic changes for 3–4 wk following injury. Nuclear scintigraphy will identify active bone involvement. Ultrasound should be considered to evaluate soft tissue structures and joint stability.

Treatment

In **non-articular** cases, rest is the only appropriate therapy available. Immobilization of the lower limb is advisable, and if there is associated joint instability cast immobilization may be required. Box confinement is necessary for 4 wk, followed by a further 2 or 3 mo of controlled exercise depending on the age and activity of the lesion. The prognosis for non-articular cases is generally favorable.

THE PROXIMAL PHALANX (FIRST PHALANX, LONG PASTERBONE, P1)

Fractures

Simple proximal phalanx (P1) fractures include fractures involving one fracture plane in which the fragment is too large to be classified as a chip fracture. Proximodorsal and proximal palmar/plantar P1 IA fractures are addressed in the subsection on arthrology (*q.v.*).

A variety of configurations of simple P1 fractures occur routinely including **sagittal** fractures and **dorsofrontal** fractures. Comminuted fractures of the proximal phalanx are also common racehorse injuries, but can also occur as accidents during other activities. These range in complexity and are classified as having mild, moderate or severe comminution.

Etiology

Depending on the configuration, the cause of fracture may be combined compressive/torque forces, hyperextension of the fetlock or ligamentous avulsions. Comminuted fractures can result from either internal compressive/torque forces or external trauma.

Clinical signs

Most fractures involve the **proximal articular surface** and therefore sudden onset joint pain is likely. However, if articular surface involvement is marginal the lameness may not be severe and may abate quickly. Some fetlock **joint effusion** can usually be detected and pain on palpation might be elicited if pressure is applied across the fracture plane.

Short dorsofrontal fractures are usually identified in the chronic stages because these horses can train reasonably well with the injury and only display an intermittent low-grade lameness. Similarly, palmar/plantar process fractures and incomplete sagittal fractures that extend only a short distance from the articular facet (and perhaps involve only the dorsal cortex) can be missed in their acute phase and identified later as the cause of a chronic lameness. Larger frontal and complete sagittal fractures (emerging at the P1/P2 articulation or at the lateral or medial cortex) usually present with more severe signs and are therefore easier to diagnose quickly.

Extreme lameness, crepitus, massive distension of the fetlock joint and rapid development of soft tissue swelling are hallmarks of **comminuted fractures**.

Diagnosis

Radiography is the definitive diagnostic procedure and several projections are required to adequately map out the fracture plane or even to find the fracture line if there is minimal displacement. On the standing dorsopalmar projection, proximal to distal obliquity removes superimposition of the proximal sesamoid bones on the proximal P1 articulation. Two radiolucent lines are often seen. These should not be confused as two fractures; they are often the **deficits in each cortex** caused by the same fracture.

Non-displaced incomplete fractures will sometimes require full lameness work-up before they are diagnosed. Occasionally, cases of lameness caused by P1 fractures will be alleviated by regional analgesia of the palmar/plantar nerves at abaxial sesamoid level, but most will only be obliterated by analgesia of the palmar/plantar plus palmar metacarpal/plantar metatarsal nerves at distal splint bone level (**low four-point block**) (*q.v.*). In the hindlimb the pastern and fetlock may receive additional innervation from the dorsal metatarsal nerves, which can be blocked either side of the long digital extensor tendon at the same level (**low six-point block**).

There is significant risk of developing a **catastrophic fracture** when horses with incomplete fractures are evaluated for lameness following a regional nerve block. If there is a history or there are clinical signs consistent with fracture, radiographs should be taken prior to performing regional nerve blocks. In addition, nuclear scintigraphy can be helpful in detecting fractures that are not apparent radiographically.

Treatment

Short, simple, incomplete sagittal fractures will usually heal with rest, but lag screw repair is often elected to facilitate rapid return to work. Longer incomplete fractures and simple complete sagittal fractures require internal fixation, usually with compression using lag screw techniques. Incomplete fractures have been reported to heal well when immobilized with external support. However, if an articular surface is involved, the risk of displacement and/or subsequent osteoarthritis will be reduced by rigid internal fixation. The prognosis for simple fractures is good, especially if fixation can be performed in the acute stage.

Dorsofrontal P1 fractures are relatively uncommon and are almost exclusively seen in the hindlimbs. Incomplete fractures are managed conservatively with controlled exercise. Displaced or complete non-displaced fractures are managed surgically using lag screws.

In cases with **moderate comminution** in which the number and position of fragments is known, reconstruction with several appropriately directed screws is recommended. A buttress plate may be necessary if cortical deficits persist. Surgical repair using internal fixation is generally feasible if there is at least one intact strut spanning the length of the bone. Combined with protracted casting, such cases carry a reasonable prognosis. If it is not possible to

reconstruct the distal articular surface it may be feasible to perform a proximal interphalangeal joint arthrodesis during the same surgery.

On occasion the comminution and/or soft tissue disruption (e.g. sesamoidean ligament attachments) will be so severe that surgical repair cannot be contemplated. In these cases, **prolonged immobilization** in a transfixation cast or the use of an external skeletal fixator may permit salvage as a breeding animal but provide only a fair prognosis for survival. Otherwise euthanasia is indicated.

Periarticular new bone formation

Distal P1 can be involved in high ringbone as described above (*q.v.*). The distal limbs, and P1 in particular, are predilection sites for periosteal reactions that occur as part of the hypertrophic osteopathy syndrome (Marie's disease) (*q.v.*). In addition, palmar/plantar periosteitis sometimes develops secondary to injury to the distal sesamoidean ligaments. Rest is required for this reaction to resolve and the long-term consequences relate more to soft tissue pathology than that of bone.

THE PROXIMAL SESAMOID BONES

The proximal sesamoid bones are an integral part of the suspensory apparatus and of the metacarpophalangeal joint itself. Injuries are **common**, particularly in racehorses.

Sesamoiditis

Sesamoiditis is an imprecise term used to describe a variety of **remodeling** changes of the proximal sesamoid bones, which are usually, if not invariably, secondary to inflammation of associated soft tissues. It remains debatable whether sesamoiditis exists as a clinically definable disease of bone or whether it is a bony manifestation of what is essentially a disease of soft tissue.

Etiology

All components of the fetlock are subject to high strains during extreme extension, which occurs during load at exercise. Tearing of the fibrous attachments to the sesamoid bones can produce **bony pathology (enthesopathy)** at those sites. This may result from a single severe episode of **desmitis** or from repetitive smaller injuries.

Clinical signs

By the time sesamoid pathology develops, lameness has frequently become chronic, although the process may have been initiated by an acute desmitis causing sudden onset lameness. Pain can sometimes be elicited by pressure applied over the sesamoid bones, and large bony proliferations (enthesophytes) may be palpable. Associated ligamentous damage may also be apparent grossly or ultrasonographically.

Diagnosis

Lameness is localized to the fetlock area by regional analgesia (*q.v.*). Although palmar/plantar nerve blockade at abaxial sesamoid level would not be expected to desensitize the region, an effect from local infiltration is possible. Similarly, it is possible for local anesthetic injected into the fetlock joint to diffuse extra-articularly and desensitize adjacent tissues. Most cases however require a low four-point nerve block to relieve the lameness. **Standard radiographic views** of the fetlock are needed but the most informative are the dorsolateral—palmaromedial and dorsomedial—palmarolateral oblique projections profiling the two bones individually.

Changes include new bone formation on the abaxial and basilar surfaces of the bone, changing its contour, and poor/disorganized trabeculation. An increase in the size and number of the vascular channels is another reported abnormality, but its significance is questioned. **Vascular channels** can usually be differentiated from fractures based on their radial orientation. Changes are often confined to single sesamoid bones but may affect both bones in the same limb or bones of more than one limb. **Dystrophic mineralization** in adjacent soft tissue may be an additional finding.

A thorough **ultrasound evaluation** of the fetlock and pastern regions is indicated to determine the extent of the associated soft tissue injuries. Nuclear scintigraphy may be required to differentiate chronic changes from active bone remodeling.

Treatment

Changes in the sesamoid bones detected on radiographs are **permanent** once formed. Treatment centers on suppressing the inciting inflammatory process. Confined rest is indicated at first, possibly with the administration of a non-steroidal anti-inflammatory drug (NSAID), e.g. **phenylbutazone**, and **cryotherapy**. Complete healing (in as far as this is achieved) requires a prolonged period of inactivity reflecting the primary role of ligamentous injury. Once chronic lameness is accompanied by radiographic changes, the prognosis for a return to full athletic performance is guarded.

Osteopenia

Although technically not a disease, the **demineralization of bone**, which is consequent to **protracted disuse** (e.g. when a limb is immobilized in a cast) can be detected earlier in the proximal sesamoid bones than at other sites. The process is reversible but the vulnerability to pathologic fracture should be considered when planning the rehabilitation of long-term orthopedic patients.

Fractures

Sesamoid fractures occur commonly in racehorses due to excessive tensile forces and direct trauma.

Fractures—general

Etiology

The proximal sesamoid bones are subjected to bending and marked tensile forces by virtue of their role in the suspensory apparatus. Asynchrony of these

forces, as might occur following abnormal foot placement or in a fatigued horse, can lead to failure of the bone's infrastructure. Predisposing weakness in the bone due, for example, to osteopenia (*q.v.*), sesamoiditis (*q.v.*) or juvenile bone in foals, may lead to a fracture under physiologic loading. Interference with a thoracic limb from a hind foot is also thought to be the cause of some forelimb fractures.

Sesamoid fractures also occur in young foals when they are turned out in pasture, especially following a prolonged period of stall confinement. The signs are often remarkably subtle. In foals, these fractures frequently form a bony union, and displaced fractures result in the appearance of an elongated sesamoid. Minimally displaced fractures will heal with rest alone.

Clinical signs

With **complete fractures**, sudden onset lameness is accompanied by rapid development of local soft tissue inflammation and usually distension of the fetlock joint. If the animal is weight bearing there will be a marked reduction in extension of the affected fetlock. Flexion of the fetlock joint and pressure applied over the injured bone elicit pronounced withdrawal reactions. Many cases are not diagnosed in the acute phase and therefore present with chronic, low-grade lameness. Horses with **small apical fractures** are typically only mildly to moderately lame unless there is a concurrent suspensory ligament injury.

Diagnosis

Diagnosis is based on results of a complete lameness examination and radiographs. Lameness is localized to the fetlock by regional and/or IA anesthesia. Dorsopalmar, standing and flexed lateromedial and oblique radiographic projections are required for full evaluation. Lateromedial projections taken with proximodistal obliquity may assist in the imaging of some lesions. For example, with abaxial fractures **special views** (lateral proximal–medial distal or medial proximal–lateral distal oblique projections) may be necessary to identify the lesions and determine whether the fracture has an **articular component**. A thorough **ultrasound evaluation** is indicated to evaluate the integrity of the suspensory apparatus.

Fractures—apical and abaxial

Apical fractures are the most common proximal sesamoid bone fractures, and are frequently articular. If they involve less than a third of the bone they respond well to **surgical removal**, performed arthroscopically or via a small arthrotomy. Ultrasound evaluation of the suspensory branch is required to determine the length of postoperative convalescence.

Abaxial fractures are avulsion fractures involving the insertion of the suspensory ligament and can be articular or non-articular. Smaller abaxial fragments that involve the dorsal articular surface are amenable to arthroscopic removal. Others may be extra-articular avulsions within suspensory ligament insertions and both conservative treatment (i.e. rest for up to 6 mo) and removal have been described, but most horses perform successfully without surgery. Only extremely large fragments require internal fixation.

Fractures—axial

Axial fractures along the longitudinal axis of the proximal sesamoid bone have been described in association with condylar fractures of the cannon bone. They are generally non-displaced and can heal with conservative treatment. Diagnosis requires high quality dorsopalmar radiographic images.

Fractures—mid-body, basal and comminuted

Transverse fractures through the body of the proximal sesamoid bone may be apical, mid-body or basal. They occur in a horizontal plane across the bone, involving the dorsal articular surface.

Treatment of transverse sesamoid fractures

For apical fractures in which the proximal fragment is less than one third of the size of the whole bone, early surgical removal offers a reasonable chance of success. Careful dissection from the attachment to the suspensory ligament is imperative. Mid-body fractures involve disruption of the suspensory apparatus but can be repaired by lag screw fixation or a self-compressing cannulated screw technique using a combined clamp and drill guide placed across the fracture. Cerclage, transfix-cerclage and suture techniques using wire or polyethylene cable are also reported, and may provide similar or even improved repair strength. Surgical repairs may be supplemented by the use of cancellous bone grafts (*q.v.*). Alternatively the latter may be employed alone in conjunction with external fixation. Fractures repaired with internal fixation benefit from the support of a cast. As an ultimate salvage procedure, fetlock arthrodesis is also possible.

Articular basal fragments can be removed arthroscopically. Horses with basilar fractures have a fair prognosis for return to racing following arthroscopic fragment removal when a portion of the base is involved. Small non-articular basilar fractures typically require conservative management because removal involves excessive soft tissue damage. Large basal fractures, particularly those involving the entire base of the sesamoid, comminuted fractures and those with marked displacement have been reported to have a guarded prognosis due to associated soft tissue damage and difficulties associated with removal or repair. The severity of distal sesamoidean ligament desmitis (*q.v.*) observed with large fractures may also be associated with a poor outcome.

Osteomyelitis

Osteomyelitis of the axial border of the proximal sesamoid bones can occur associated with a septic desmitis (*q.v.*) of the intersesamoidean ligament. Patients usually present with a chronic, moderate to severe lameness localized to the fetlock area by regional analgesia. Destructive lesions at the attachment of the intersesamoidean ligaments are evident on dorsopalmar and palmar proximal–palmar distal oblique (skyline projection) radiographs and increased bone turnover can be demonstrated by nuclear scintigraphy. The intersesamoidean ligament can be evaluated with ultrasound and/or via

palmar/plantar fetlock arthroscopy and digital sheath tenoscopy. Treatment with long-term systemic and regional antibiotic administration in conjunction with surgical curettage is recommended, but the prognosis is guarded to poor.

THE THIRD METACARPAL/METATARSAL (CANNON) BONE

Condylar fractures

Condylar fractures are parasagittal fractures of the distal end of the third metacarpal or metatarsal bone.

Etiology

Fractures through the distal condyles of the third metacarpus (MC3) and metatarsus (MT3) are relatively common in racehorses. There are a number of theories regarding the pathophysiology of these injuries including accumulated subchondral bone damage, fatigue failure with the accumulation and coalescence of small parasagittal microcracks, asynchronous rotation of the cannon bone, and pre-existing articular or suspensory ligament injuries. Thoroughbreds wearing toe grabs are more likely to develop fatal condylar fractures.

The **lateral condyle** is much more commonly involved than the medial. Fractures are classified as complete or incomplete and displaced or non-displaced. Most fractures emerge at the ipsilateral cortex a variable distance up the bone. However **spiraling fissures** as far as the proximal articular surface do occur, particularly with medial condylar fractures and/or in the hindlimb. Medial condylar fractures are also associated with an occult Y-shaped configuration in the mid-diaphysis.

Clinical signs

Because of the weight-bearing location, most horses with condylar fractures are moderately to severely lame. However, non-displaced, incomplete fractures of the cannon bone may not be detected as acute conditions and are sometimes found only after a full investigation including nuclear scintigraphy. Fetlock joint effusion is expected with condylar fractures, as is exacerbation of the lameness by fetlock flexion. Most cases however become **acutely lame** during or immediately after exercise, rapidly develop a fetlock joint effusion and have an obviously painful distal cannon bone. With displaced fractures crepitus can be palpated and may be accompanied by fetlock instability.

Diagnosis

Incomplete fractures of the cannon give rise to a lameness that will improve with IA fetlock analgesia, or four/six-point (low or mid cannon) nerve blocks (*q.v.*). Nuclear scintigraphy may also be of use in detecting lesions. If there is any suspicion that a fracture may exist, radiography should precede regional analgesia techniques. Trotting horses with incomplete fractures under the effect of local anesthetic runs a significant risk of worsening the injury.

Standard radiographic views are required using cassettes long enough to include the full length of the cannon bone and the fetlock joint. Fractures that

do not clearly emerge at lateral or medial cortices should be further investigated with differing angles of obliquity to determine the presence or absence of a proximally spiraling fissure. Small Y comminutions at the palmaro/plantarodistal extremities of condylar fractures frequently go unrecognized in conventional projections. These can adversely affect the prognosis and can be highlighted with a 125° dorsodistal–palmaroproximal oblique view. This view can be obtained by flexing the fetlock, or by elevating the extended limb.

Radiographs, ultrasound and even arthroscopy should be used to look for other associated injuries including axial sesamoid fractures, osteoarthritis, palmar and plantar erosive lesions of the condyles and suspensory ligament desmitis. Computed tomography can be used to precisely define three-dimensional fracture configuration prior to repair to allow accurate implant placement when proximal spiraling is suspected.

Treatment

Most condylar fractures should be reduced and stabilized by lag screw fixation or using a self-compressing cannulated screw system. Simultaneous arthroscopic evaluation can improve articular alignment. Some clinicians recommend conservative treatment of incomplete non-displaced fractures, but residual defects in the distal articular surface of the cannon bone are likely to result in osteoarthritis. With prompt and accurate repair the prognosis for complete non-displaced condylar fractures is good.

The prognosis for horses with **displaced condylar fractures**, regardless of treatment, is much poorer for return to athletic performance. Prognosis is also adversely affected by associated articular comminution or with subchondral erosive lesions in the palmar/plantar cannon bone. Spiral fractures often require plate fixation, and a minimally invasive technique of plate application has been described.

Diaphyseal fractures

Etiology

Almost invariably, significant external trauma is necessary for the strong diaphysis of third metacarpal/metatarsal bones to break. In **foals** the cause is often **trampling by the dam** while adult horses often present with a history of being kicked. The fractures are frequently open because the lack of soft tissue protection over the bone allows external objects or internal fragments to penetrate the skin easily. For the same reason the fractures are often complicated by **damage to vital structures**, in particular the palmar/plantar vessels and nerves. Fractures can assume a variety of configurations from simple fissures to severely comminuted fractures.

Clinical signs

Horses are usually non-weight-bearing and the fracture readily palpable, if not visible. Caution should be exercised in the examination of patients since **self-inflicted trauma** in a fractious animal can easily render a previously repairable fracture hopeless. Complete but non-displaced fractures may be more difficult to identify.

Diagnosis

Clinical signs enable the diagnosis to be made in the majority of cases. If treatment is an option, radiographs are required to delineate fracture planes. However it is often most sensible to transport the horse to a center capable of performing the necessary surgery rather than taking preliminary radiographs. A **full-limb splint** (see Table 15.2) should be immediately secured to the limb before moving the horse.

Treatment

There may be good cause to recommend euthanasia: gross contamination, severe comminution, volatile patient temperament and prohibitive costs are all valid reasons. If treatment is attempted, internal fixation is required in most cases. Non-displaced fractures in foals have been reported to heal in casts but the risks (and expense) of protracted full limb casting usually do not justify such an approach. Some comminuted proximal fractures in foals can be managed with transfixation casting.

Double plating is usually necessary in front limbs whereas single dorso-lateral plating may be sufficient in MT3, which has a more obvious tension side. **Autologous bone grafting** (*q.v.*) is indicated if there are cortical deficits. Even after fixation numerous complications can prevent a successful outcome, e.g. contamination leading to osteomyelitis, implant failure or poor quality bone production at the repair site.

Dorsal cortical disease (bucked shins and dorsal cortical fractures)

A number of clinicopathologic entities comprise the syndrome variously referred to as **dorsal cortex disease**, **dorsal metacarpal disease**, **bucked shins**, **sore shins** and **shin splints**.

Etiology

Juvenile horses subjected to rigorous race training are at particular risk of developing the disease, which is one manifestation of an exercise/stress adaptation mismatch. It has been reported that up to 70% of young Thoroughbreds in race training will experience **bucked shins**, but the condition also appears to be more common among horses training on harder surfaces in North America.

This is a **fatigue injury** of bone and usually occurs in **2-year-olds in early training**. Failure occurs as a result of repetitive motion injury associated with high-strain cyclic fatigue when the required adaptive bone modeling and remodeling cannot keep pace with the level of work the horse is undertaking. Classical training schedules induce bone formation on the dorsomedial surface of MC3 due to high strain events of bending of MC3. The new bone formation is an appropriate response to repetitive motion injury of MC3, and it is the underlying injury that needs to be prevented.

In 3 and 4 yr olds there appears to be a specific manifestation of cortical stress fractures occurring obliquely, dorsolaterally and at the junction of middle and distal thirds of the bone. The location suggests that these injuries happen secondary to earlier remodeling of the dorsomedial cortex, which may

then leave the dorsolateral cortex vulnerable to fracture propagation. Dorsal cortical fractures are seen in horses that previously experienced bucked shins. Catastrophic complete midshaft MC3 fractures can occur when horses with pre-existing dorsal cortical fractures are exercised at speed.

Clinical signs

Acute cases will have **increased skin temperature** over the dorsal cannon and be **sensitive to palpation** there, particularly following exercise. Swelling can also occur. Lameness is often minimal and may show only as a bilateral shortening of stride or simply as poor performance. The condition is much more common in MC3 than in MT3. Signs typically predominate in the limb that is on the **inside of the horse's usual running direction**. Chronic cases develop visible and palpable callus and a lameness that waxes and wanes with work and rest.

Diagnosis

In early cases, clinical signs precede radiographic changes and a tentative diagnosis can be made from the clinical findings and the appropriate age-training relationship. It is usually not possible to be site specific in desensitizing the area with **regional analgesia** (*q.v.*). Lesions can be subtle and require high definition radiography to be detected. Zones of cortical osteolysis appear on dorsopalmar and oblique projections, succeeded by periosteal new bone formation. Dorsolateral cortical fractures typically run distoproximally, but proximodistal and complete saucer fractures are also seen regularly. Nuclear scintigraphy may assist in detecting changes earlier than radiography.

Treatment

Mild cases respond to rest until signs of acute inflammation have subsided. More severe cases may need longer periods of rest and some horses reportedly never return to previous performance levels. Horses that buck their shins and stop training may **re-buck** when reintroduced to training, and **modifications in training** are preferable to complete rest when horses can be maintained in work.

Cortical stress fractures that show no tendency to heal by second intention are amenable to fixation with a unicortical screw and/or to surgical osteostixis (where small holes are drilled through the bone). Although **osteostixis** alone can lead to healing, a combination of screw fixation and osteostixis is probably the most reliable surgical treatment. However, surgical treatment of dorsal cortical stress fractures is not always indicated. Stress fractures that involve the distal or proximal ends of the bone typically develop much more callus and require less intervention than the indolent fractures in the middle of the bone. The optimal candidate for surgical treatment is a horse with an obvious fracture line with minimal healing response and distinct associated clinical signs.

Extracorporeal **acoustic shock wave treatment** using a single 2000 pulse dose at high energy has also been used to facilitate fracture repair (*q.v.*), but should be used with caution due to resulting analgesic effects that could allow a horse to return to work before the fracture has healed, possibly predisposing to catastrophic MC3 fractures.

Prevention involves **modifications in training** (*q.v.*) that allow the bone to model and remodel, changing the inertial properties of MC3 to resist bending in the dorsopalmar direction. Research has shown that **high-speed exercise** in small doses is highly protective against bucked shins, while long galloping exercise increases the risk for bucked shins. Horses that do not develop bucked shins in their early training also do not develop stress or saucer fractures or midshaft MC3 fractures.

Palmar/plantar cortical disease (incomplete palmar cortical fractures and avulsion fractures at the origin of the suspensory ligament)

Trabecular disruption and palmar/plantar cortical deficits are sometimes found in conjunction with injury to the **origin of the suspensory ligament**. **Avulsion fractures** are the extreme example. Generally confined rest followed by controlled exercise for a total of 3–6 mo offers a good prognosis, but refractory cases may respond to **acoustic shock wave treatments** (*q.v.*) or **surgical forage (osteostixis)** of the affected cortex. It is essential to perform an ultrasound evaluation in conjunction with radiographic imaging to determine the severity of injury to the suspensory ligament itself (*q.v.*).

Surgical treatments reported for unresponsive cases of **desmitis** at the origin of the suspensory ligament that may be considered with associated avulsion fractures include: ultrasound guided suspensory desmoplasty (surgical fasciotomy and splitting), tibial neurectomy (hindlimb), or plantar metatarsal neurectomy and fasciotomy (hindlimb) (*q.v.*). Similarly, injections of bone marrow, extracellular matrix (ACell Vet™ Powder), stem cells or growth factors have also been advocated for proximal suspensory desmitis with or without associated avulsion fractures (*q.v.*).

Incomplete longitudinal palmar cortical fatigue fractures of the third metacarpus are relatively common and can extend proximally to involve the joint. They are usually associated with radiographically visible sclerosis of the palmar cortex and are therefore thought to be stress fractures. They occur most often in young horses in race training. Lameness can be mild to severe, and diagnosis is based on response to local analgesia, dorsopalmar radiographic projections revealing sclerosis and a longitudinal fracture line on the palmar medial cortex. Some cases are initially detected with nuclear scintigraphy. Ultrasound should be performed to rule out an associated soft tissue injury. Most horses respond to rest for 3–6 mo.

THE SECOND AND FOURTH METACARPAL/METATARSAL (SPLINT) BONES

Exostosis (splints)

A **true splint** forms as a result of tearing of the **interosseous ligament** between the second or fourth and third metacarpal/metatarsal bones and is therefore centered over the groove between the splint bone and the cannon bone. In addition, a large number of exostoses occur in response to direct trauma to the periosteum, usually on the abaxial aspect of a splint bone, and

these are referred to as **false splints**. The term **blind splint** refers to interosseous ligament inflammation and swelling on the axial surface of the splint that is difficult to detect on physical examination.

Etiology

Splints occur more frequently **medially** and in the **forelimbs**, reflecting preferential loading at these sites. The splint bones articulate with the carpometacarpal and tarsometatarsal joints and are load bearing bones (the fourth metatarsal bone has only a small articulation). Excessive intrinsic stresses cause **tearing of fibrous attachments** between the splint bones and the cannon bone, provoking an inflammatory process (desmitis, periostitis) that can progress to ossification. The new bone production will ultimately fuse the splint to the cannon bone and eliminate the source of irritation.

Direct external trauma that injures periosteum also initiates new bone formation. Such exostoses occur more frequently laterally and in hindlimbs, reflecting their traumatic etiology. Some of these “false splints” are calluses at the site of splint bone fracture. Encroachment by the associated new bone growth onto the adjacent suspensory ligament or into the carpometacarpal/tarsometatarsal is a potential complication.

The condition is most common in **young horses**, particularly those that have recently started **vigorous training**. **Hard ground** predisposes to the condition in any age of horse. **Poor conformation** also contributes to development of metacarpal exostoses, either by elevating strain on the interosseous ligament (medial splints are common in horses with offset carpi or bench knees) or by predisposing to interference (toe-out conformation predisposes horses to wing-in and interfere). With age, metacarpal fusion occurs in most horses without clinical evidence of inflammation, and active true splints are uncommon in older horses.

Clinical signs

Splints often occur suddenly with a **primary soft tissue swelling** that is typically much larger than the underlying bony enlargement. The area is painful and often warm in the early stages. The degree of lameness varies from none to moderate.

Diagnosis

Clinical signs are usually diagnostic. Sometimes there is doubt over the contribution of a splint to lameness, in which case the innervation to the site can be blocked with reasonable specificity by injecting local anesthetic (*q.v.*) around the palmar metacarpal/plantar metatarsal nerve, axial to the head of the affected splint bone. Radiographically, oblique views are the most useful to detect the true size of the splint and its degree of activity. Dorsopalmar projections can give an idea of axial encroachment. Radiographic examination is necessary if joint involvement is a concern. Ultrasonography is indicated to investigate associated soft tissue pathology, particularly when new bone production appears to be interfering with suspensory function. Scintigraphy is a sensitive indicator of splint bone remodeling.

Treatment

Rest is the most important component of the treatment regimen for acute splints and this often requires stall confinement for 6 wk. This lay-up period is almost always sufficient to allow clinical resolution although a small bony lump often persists permanently. Many cases are not strictly rested because it is well known that some splints arise, remodel and settle without causing appreciable lameness. However, failure to impose a strict regimen is a common reason for some splints becoming chronically troublesome or unusually large.

The inflamed area should be treated aggressively with **topical cold therapy** applying ice (or an effective alternative cryotherapy technique) at least two times daily for 30 min. Anti-inflammatory medication, administered parenterally (e.g. **phenylbutazone**) or topically (e.g. dimethyl sulfoxide [DMSO] plus a corticosteroid), along with pressure wraps can also be of benefit. **Intralesional corticosteroid** or hyaluronan (hyaluronic acid/sodium hyaluronate, *q.v.*) administration can also reduce inflammation and prevent excessive new bone production.

Occasionally there is justification to excise the splint surgically along with the distal extent of the metacarpal/metatarsal bone, because of a refractory inflammatory process, for cosmetic reasons or because it is impinging on the suspensory ligament. Counter-irritation, in particular the use of pin-firing, has enjoyed considerable popularity as a therapy for splints but evidence of its efficacy remains anecdotal. In cases of traumatically induced splints, protective splint boots or wraps should be used during future exercise.

Fractures

Etiology

Splint bone fractures can be divided into two types: fractures of the distal third and fractures of the proximal and middle thirds of the bone. **Distal third fractures** are typically caused by intrinsic forces, and are usually thought to be the result of abnormal tension on the bone as a result of hyperextension of the fetlock, pre-existing changes in the elasticity of the interosseous ligament and/or suspensory desmitis (*q.v.*). There are strong fascial attachments from the distal end of the splint bones to the suspensory apparatus. The resulting fractures are simple and closed, are more common in the forelimbs and usually occur medially. They usually occur in older racehorses. **Fractures of the middle and proximal thirds** are usually the result of external trauma, e.g. kicks from other horses. These fractures are frequently open, comminuted and lateral.

Clinical signs

Instability of the distal third fracture fragments may sometimes be palpable in the acute phase but more often the presenting signs are those of the associated suspensory desmitis (the majority of these patients do have suspensory desmitis). Lameness is usually low grade. A periosteal reaction occurs relatively quickly and can be felt as a discrete area of hard swelling separate from the suspensory ligament. The more proximal fractures present with acute lameness, with heat, swelling and pain over the fracture site. Often there is an

associated wound that develops serosanguineous, then purulent, discharge. Probing the wound may reveal the presence of small fragments. Sometimes fractures are not presented acutely, but only after failure of the wound to heal because of sequestration. By this time a significant callus may have formed.

Diagnosis

Standard radiographic views are necessary for full evaluation but the appropriate oblique projection is usually the most informative.

Treatment

For distal fractures, when there is considerable displacement or infection, surgical removal of the distal fragment is recommended (amputation or segmental ostectomy). Conservative management is otherwise usually effective, especially considering the fact that any active soft tissue injury will require an extended period of rest. Bony or fibrous union will usually occur during a 2–4 mo rest period, and the length of convalescence is dictated by the degree of suspensory desmitis.

Non- or minimally displaced fractures of the middle third of the splint bone can be managed conservatively, but fracture displacement or sequestration of bone fragments often dictates surgical removal. Surgery can involve removal of the fracture and the entire distal splint (amputation) or of the fracture fragments only (segmental ostectomy). Efforts should be made to resolve any associated infection prior to surgery to avoid spreading the infection. Up to two thirds of the length of the splint can be removed.

Several considerations apply to the management of **proximal fractures**. Conservative management may result in a satisfactory outcome, but the repair is slow and often impeded by infection, sequestration and instability of fragments such that non-unions with massive fibrous callus formation can occur. **Surgery** is therefore often indicated to expedite healing.

Unfortunately, removal of proximal splint bones can result in **carpal/tarsal instability** (the exception being the fourth metatarsal bone which can be completely removed without creating instability). As a result, fractures involving the proximal one third of the bone may require surgical stabilization. However, fixation of an unstable proximal fragment to the cannon bone has the disadvantage of removing the normal independent movement of small and large metacarpal/metatarsal bones and should be avoided when possible.

The most biomechanically desirable repair is achieved by application of a small plate across the fracture line without engaging the third metacarpus, after removal of sequestra and contaminated debris. If removal of the distal splint is necessitated, a small reconstruction plate can be contoured from the remaining splint bone onto the cannon bone to restore the length of the lever arm of the splint bone and prevent avulsion of the head of the splint bone. Such an approach is especially important for the most proximal fractures in which disruption of the articulations of the splint bones has occurred. If the proximal segment of bone is stable, segmental ostectomy has also been reported to be effective. That technique has the advantage of avoiding the extensive incision and dissection associated with amputation, or the risks of infection associated with implants.

THE CARPAL BONES

See Carpus, (*q.v.*).

THE ACCESSORY CARPAL BONE

Fractures

Etiology

The etiology of carpal fractures remains unclear. Although direct external trauma cannot be ruled out, many **accessory carpal fractures** are thought to be the result of forces exerted by soft tissue attachments to the bone. **Ligamentous avulsions**, usually from the dorsoproximal border, can develop if the carpus is hyperextended. Larger fractures are generally thought to occur when the limb is weight bearing and in slight flexion, such as may happen during a fall after a jump. In addition to the biomechanical forces associated with ligamentous attachments, these fractures may occur as a result of the bone being crushed between the cannon bone and the radius during the fall.

Clinical signs

Small avulsion fractures often show few acute signs. There may be localized inflammation proximal to the bone associated with low-grade lameness.

Dorsoproximal fractures that involve the **articular surface** can result in radiocarpal joint effusion. Larger fractures can occur horizontally across the proximal third of the bone, but by far the most common configuration is a frontal plane (vertical) fracture through the proximal and distal borders, usually along a line palmar to the line of the groove for the ulnaris lateralis tendon. **Sudden onset** of moderate to severe lameness is associated with localized swelling and severe pain on flexion of the carpus. Before distraction of the fragments occurs, crepitus may be detected. **Synovial distension** of the carpal sheath/canal characteristically develops (*q.v.*). Compartment syndrome affecting this canal (*q.v.*) is frequently noted as a potential sequel to fracture of the accessory carpal bone, but many horses do not develop this complication.

Diagnosis

Radiography is required to confirm the diagnosis. Lateromedial projections of the carpus are the most useful for detecting and defining the fracture. Flexed views are useful for assessing instability.

Treatment

While surgical procedures have been described for fixation of frontal plane fractures, surgery probably does not improve the prognosis beyond that obtained with conservative treatment. Attempts to reduce and compress the fracture frequently result only in a fibrocartilaginous repair, and this will occur with confined rest for an average of 6 mo. As a result, conservative management is generally recommended.

The initial phase of rehabilitation should be complemented by a full limb **Robert Jones bandage** (consisting of a heavy, multilayered bandage with each

layer about 2.5 cm (1 inch) thick and secured with gauze and the final diameter approximately three times the diameter of the limb) to **minimize motion at the fracture site**. Many cases return to athletic performance, but others are complicated by residual radiocarpal osteoarthritis or carpal canal syndrome. Surgical resection of a portion of the flexor retinaculum may be required to return the horse to athletic performance. Ulnar neurectomy has also been reported but the benefits are not well documented. Avulsion fractures require similar periods of rest. Intra-articular **fracture fragments** (avulsion chip fragments off the proximodorsal aspect of the bone) should be removed arthroscopically.

THE RADIUS

Osteochondroma

The caudomedial metaphysis of the distal radius is a predilection site for **solitary osteochondroma** formation. An osteochondroma is an **exostosis** (*q.v.*) that is continuous with the cortex of the bone and covered by cartilage. Osteochondromas typically develop immediately proximal to the caudal distal radial physis, often medial to midline.

Etiology

Osteochondromas are thought to develop due to separation of a portion of a border of the physis during development. They can occur in a number of long bones and have even been reported in intramembranous bones, but the **radius** is the most common location. The separated chondrogenic tissue establishes a separate focus of endochondral ossification that forms the bony protrusion. Osteochondromas possess a cortex and medullary cavity and are covered by a cartilage cap. Unlike the condition of hereditary multiple exostosis, single osteochondromas do not appear to have a hereditary factor.

Clinical signs

Presenting signs tend to be those of compartment syndrome of the carpal flexor canal (*q.v.*), i.e. effusion of the carpal sheath, pain on carpal flexion and a mild to moderate intermittent lameness that increases with exercise. Despite the presence of lesions in juveniles, most growths are identified in adult horses. The onset of lameness may be insidious, reflecting a gradual increase in pressure within the canal and impingement on the deep digital flexor tendon (DDFT). Large exostoses are palpable and are usually medial on the caudal radius surface.

Diagnosis

Lameness should be responsive to median and ulnar nerve blocks or, more specifically, to intrasynovial analgesia of the carpal canal. The diagnosis is generally confirmed by radiography, revealing an exostosis from the cortical surface 2–4 cm proximal to the residual physeal scar. Lateromedial and/or slightly oblique radiographic projections of the distal radius project the lesions best. Ultrasound evaluation of the carpal canal is indicated as DDFT

tendinitis is commonly responsible for much of the observed lameness, and the irregular bone contour will also be visible.

Treatment

Although rest or intrasynovial **corticosteroid treatment** will provide a respite in the lameness, resumption of exercise is likely to result in recurrence. Therefore, surgical relief of the compressed carpal canal is indicated. Flexor retinaculum release should be complemented by removal of the osteochondroma and debridement of any torn fibers of the DDFT. Most lesions can be identified and removed endoscopically. Periosteal reaction does not usually complicate recovery and recurrence of the lesion is rare. Prognosis for return to performance is good.

Exostosis of the caudal perimeter of the radial physis (physeal remnant spikes)

Recently, endoscopic evaluation of the carpal canal has identified a syndrome very similar to osteochondroma involving **tenosynovitis** of the carpal synovial sheath (*q.v.*) caused by small physeal remnants or physeal spikes from the caudal distal radius. These exostoses can cause traumatic injury to the DDFT.

Etiology

Exostoses of the caudal perimeter of the radial physis are structurally different from radial osteochondromas (*q.v.*), lacking the distinctive cartilage cap, and are located directly at the level of the physis. They are essentially the sharp edges of an irregular bone remodeling process of the caudal surface of the distal physis that developed at the time of physeal closure.

Clinical signs

Patients typically present with a history of intermittent mild to moderate effusion of the carpal synovial sheath associated with exercise and there may be moderate lameness with exercise. The effusion may resolve rapidly after exercise.

Diagnosis

Regional perineural (median and ulnar) and intrathecal anesthesia of the carpal sheath should be used to confirm that lameness is associated with the sheath.

Radiographs will reveal **sharply angular exostoses** originating from the caudal cortex of the distal radius at the level of the closed physis. The lateromedial and flexed lateromedial projections are most revealing, but high quality images are required as these exostoses are more difficult to identify than osteochondromas. In addition, endoscopic evaluation of the canal may be necessary to verify that there is a bony spike intruding into the canal because of the undulating nature of the caudal distal radial physis. These exostoses can usually be differentiated from osteochondromas (*q.v.*) radiographically

based on location, and they are also histologically different, lacking a cartilage cap.

Treatment

Tenoscopic removal is recommended, and damaged fibers of the DDFT should be debrided. Simultaneous endoscopic release of the carpal retinaculum may improve recovery rates. The prognosis is good for return to athletic performance.

Enostosis-like lesions (bone islands)

Enostosis-like lesions are focal or multifocal intramedullary radiopacities that have been identified and reported in many long bones, including the radius.

Etiology

The etiology of these **bony densities** remains largely unknown. There has been speculation that they may result from disruption of the medullary vasculature, or infarction ischemia and subsequent bone sclerosis. They can occur in horses of all ages, breeds and performance categories.

Clinical signs

The lesions have been associated with mild to severe lameness in some cases, but other horses are sound and the lesions are an incidental finding. There may be multiple lesions and different long and flat bones can be involved simultaneously.

Diagnosis

These lesions are often first identified on scintigraphy performed when lameness is not abolished with regional anesthetic techniques. On scintigraphic evaluation the lesions are associated with mild to intense uptake. Radiographically the radiopacities range from subtle to very distinct areas of medullary sclerosis, usually on the endosteal surface.

Treatment

Treatment involves stall rest for 2–3 mo, followed by additional paddock rest. Systemic NSAID treatment may be indicated initially depending on the degree of lameness. Repeat lameness evaluation, radiographs and/or scintigraphy should be recommended before returning the horse to work. The prognosis appears to be excellent, although few reports of long-term follow-up are available.

Traumatic periosteitis of the craniodistal surface

Etiology

Periosteitis can be provoked at any site by **impact trauma**. The craniodistal radius is a common site because it is exposed with carpal flexion during the

ascent phase of a jump. Periosteitis at this site also occurs as a result of adjacent **sepsis** in the **extensor tendon sheaths** (*q.v.*). These synovial structures are prone to penetrating injuries, particularly in jumping horses.

Clinical signs

Regardless of the etiology, periosteitis is often accompanied by a local **tenosynovitis** (*q.v.*). This tends to be significantly more severe if sepsis is involved. Reduced and painful carpal flexion may be evident. Periosteal new bone may be palpable and painful to pressure.

Diagnosis

Establishing the inciting process in cases of periosteitis is important in selecting the appropriate treatment. **Synovial fluid analysis** should allow acute sepsis to be differentiated but the distinction between chronic septic and traumatic synovitis is less dramatic. Generally, periosteal reactions following trauma occur more locally, more quickly and are more painful to pressure. Radiographically, lateromedial and craniocaudal oblique projections of the distal radius and carpus are needed for thorough evaluation of the new bone formation and can yield clues regarding etiology. Traumatic reactions tend to be more focal and layered whereas septic reactions tend to be more widespread and palisading. An ultrasound evaluation of the flexor tendons and associated synovial sheaths is also critical.

Treatment

Periosteitis secondary to direct trauma generally responds well to confined rest for a period of 6 wk. Supplemental topical cold therapy and systemic NSAIDs are also indicated. The exostoses persist but are inactive. In the case of sepsis, primary treatment should address the infection (*q.v.*).

Fractures

Etiology

External trauma is responsible for fractures involving the **shaft** of the radius, and these fractures are among the most common **catastrophic fractures** seen in horses. The fracture can be complete or incomplete, transverse or oblique, articular or non-articular, simple or comminuted and open or closed. Most are **oblique, complete and comminuted**. They are often open because of the nature of the impact, e.g. kick, or because fragments penetrate the skin medially where there is no muscular protection.

Foals can develop **physeal fractures** involving the proximal or distal extremity. Although stress fractures of the radius are uncommon, racehorses do occasionally develop fatigue fractures of the radius, and these can occur bilaterally.

Clinical signs

Generally, radial fractures are easily identified on physical examination because of their severity. There is often an associated wound from the initial

injury or due to penetration of sharp fracture fragments. Incomplete non-displaced fractures involving the proximal articular surface may be less apparent but will still usually present with an acute lameness that can be localized to the elbow by careful observation of gait, palpation and manipulation. Rarely, fissure fractures occur causing more subtle lameness. In these cases, pain and swelling can sometimes be detected by palpation.

It is particularly important to carefully evaluate and confine horses that have a history of **acute lameness following a kick**. These horses may have a **non-displaced radial fracture**, and their lameness often improves quickly. However, if they are turned out in pasture the fracture can displace with **minimal exertion**. Stress fractures are difficult to identify on physical signs alone.

Diagnosis

Clinical signs are frequently diagnostic. In the less obvious cases distal fractures may respond to a median nerve block and proximal articular fractures to IA elbow analgesia. Scintigraphic scans may reveal sites of increased bone turnover and are particularly useful for identifying stress fractures. Radiography is essential to accurately map out severe fractures, but may be better left until the horse has been transported to a hospital capable of advanced internal fixation techniques. Incomplete fractures or fissure lines may require several angles of obliquity before the fracture line is crossed and can be recognized. Chronic fissures may be visible because of bone resorption or an adjacent endosteal/periosteal reaction.

If an **incomplete fracture** is suspected but is not visible initially, radiographs taken several days later may reveal the fracture line and/or an endosteal/periosteal response. The horse should be **restrained** in cross-ties, a tie-stall or a sling pending the results of these recheck radiographs. Alternatively nuclear scintigraphy can be used to confirm the diagnosis.

Treatment

Complete, displaced fractures require internal fixation. The limb should be immobilized immediately with appropriately sized caudal and lateral splints to avoid the fracture becoming open (see Table 15.2). Appropriate external coaptation is essential if fracture repair is being considered. Specialist facilities and expertise are required for repair but even then the prognosis for adult horses is guarded and worsens the greater the comminution, contamination and size of patient. There are very few reports of successful repair of complete radial fractures in adult horses, but radius fractures in foals carry a much better prognosis.

Both physeal and midshaft diaphyseal fractures have a good prognosis in foals, and single or double plate fixation is generally required. Incomplete non-displaced fractures can respond to conservative management but this generally necessitates 12–16 wk of strict confinement. In patients with a suitable temperament cross-tying or maintaining the horse in a sling to prevent recumbency is feasible and useful for the first 8 wk. Stress fractures have a good prognosis, and should be managed with stall followed by paddock rest for a total of 3–4 mo.

THE ULNA

Fractures (olecranon fractures)

Etiology

Olecranon fractures are very common long bone fractures, and in adults most frequently result from kicks by other horses. Avulsions of the proximal apophysis can occur in foals from excessive tension on the triceps.

Clinical signs

Sudden onset lameness, often mimicking a radial nerve paralysis (*q.v.*), is characteristic of ulnar fractures. With **displaced fractures** the elbow is typically dropped in position and the horse is unable to fix the carpus (unable to bear weight). With incomplete and non-displaced fractures the horse may stand normally, but will usually show lameness. There is usually swelling over the injury. Fractures can be simple or comminuted and may or may not involve the articular surfaces. The degree of lameness varies between cases. Often there is an associated wound on the lateral surface of the limb and probing this may reveal bone fragments. Crepitus may also be detected.

Diagnosis

Clinical signs are often highly suggestive of fracture. Where the possibility of fracture exists it is advisable to obtain radiographs without delay. Mediolateral projections with the limb held protracted provide the most information, but a craniocaudal projection should also be obtained. It is important to include the whole olecranon on the films. In a young foal, it can be difficult to verify whether the apophysis is normal, but images of the opposite leg can be helpful for making this determination.

Treatment

The horse should be **splinted** prior to transport for further diagnostic evaluation or for surgery, otherwise it will struggle during transport being unable to weight bear on the limb. Effective splinting requires only a caudal splint to fix the carpus (see Table 15.2), and it is not necessary or advantageous to attempt to stabilize the elbow itself.

Although certain non-displaced, non-articular fractures will heal with conservative treatment, **internal fixation** is preferred for the majority of olecranon fractures. The site lends itself excellently to the tension band principle of repair, and a narrow dynamic compression plate applied to the caudal surface is usually the treatment of choice. Some proximal avulsions in juveniles are amenable to pin and wire fixation, and some non-displaced, nonarticular fractures in foals can be managed conservatively with confinement and splinting. Although proximal fragments can be difficult to stabilize and severe comminution occasionally complicates implant application, generally these fractures carry a good prognosis, especially if treated early. If fracture fragments are missing, a locking plate may improve stability of the repair.

The potential of **contaminated wounds** of the lateral radius to lead to elbow joint sepsis (because of the relationship of the ulnaris lateralis tendon to

the joint capsule) should always be considered. Assisted recovery from anesthesia (pool or sling) can prevent early catastrophic implant failures.

THE HUMERUS

Fractures

Fractures of the humerus are relatively uncommon, but occur most frequently in foals and weanlings and racing Thoroughbreds. Fractures can be incomplete/complete, open/closed, simple/comminuted and displaced/non-displaced, but most are **complete, closed and displaced**.

Etiology

External trauma is the usual cause of complete fractures although stress-related fractures are also seen regularly in the racing Thoroughbred. In the case of **tubercle fractures** trauma may be from a kick. Foals sometimes sustain trampling injuries from their dam, and many weanlings present with a history of flipping over backwards during halter breaking. Diaphyseal fractures in adults are the least common and tend to result from propagation of a stress fracture or the forceful impact of a heavy fall at speed. Fractures of the **deltoid tuberosity** usually occur as a result of a kick.

Clinical signs

These are dependent on the site and nature of the fracture. **Tubercle fractures** are typically lateral and sometimes associated with a wound. Patients are weight bearing but very lame and display the guarded, slow limb protraction characteristic of shoulder lameness. Cranial extension of the shoulder joint is resented. **Deltoid tuberosity fractures** are also often open, but tend to be associated with less lameness. **Diaphyseal fractures** are of variable configuration but tend to be oblique and/or spiral. Cases are usually non-weight-bearing with massive soft tissue swelling and a dropped elbow stance. Crepitus may be palpable or audible with the assistance of a stethoscope. Disability is sometimes compounded by a radial nerve paralysis (*q.v.*). Distal fractures may involve the condylar surface and have associated joint effusion.

Stress fractures in racehorses are usually associated with a history of lameness, but the lameness may be transient or intermittent, and nuclear scintigraphy should be pursued in horses with that history.

Diagnosis

Clinical signs are diagnostic in the worst cases. Radiography provides the definitive diagnosis. Mediolateral and craniomedial–caudolateral oblique projections with the limb extended are required. Ultrasound can also be valuable in evaluating humeral fractures, especially those involving the tubercles or the deltoid tuberosity. It is very difficult to assess the status of the **radial nerve** prior to surgery because there is no autonomous sensory zone for the radial nerve in horses.

Stress fractures or an associated endosteal response may be visible on radiography, but these fractures are more commonly diagnosed with nuclear scintigraphy.

Treatment

Prognoses for humeral fractures range from good to hopeless. **Deltoid tuberosity fractures** and **tubercle separations** are amenable to fragment removal when small or to lag screw repair when large. Non-displaced deltoid tuberosity fractures can be managed conservatively with a good prognosis.

Occasionally the muscle mass surrounding the humerus and the hemorrhage and swelling that occur in these tissues offer enough support for healing of diaphyseal fractures to take place by **second intention** even in adult horses, but the end stage can involve considerable deformity. Conservative management involves confining the horse to a small stall, and horses that are putting weight on the injured limb have a better chance of a successful outcome. Internal fixation has been successful in foals and yearlings, either by plating, intramedullary stack pinning, or intramedullary interlocking nail fixation. As with many fractures, the chances of success are inversely related to the size of the patient.

Stress fractures have a good prognosis with prolonged stall and paddock rest (3–4 mo). These horses should not be returned to training until the fracture is healed since they are at high risk for developing a complete catastrophic humeral fracture.

Enostosis-like lesions (bone islands)

Enostosis-like lesions identical to those described in the radius (*q.v.*) can also be detected in the humerus. These should be differentiated from endosteal callus formed in response to a stress fracture (stress fractures are typically proximocaudal or distocranial in location).

THE SCAPULA

Fractures

Etiology

Fractures of the scapula are uncommon and usually occur due to external trauma from a fall or a kick. Stress fractures and resulting complete fractures of the scapula are also seen in racehorses. **Supraglenoid tubercle fractures** can occur with avulsions of the origin of biceps brachii and coracobrachialis muscles or due to direct trauma (*q.v.*). Comminuted fractures of the glenoid can arise when the humerus is driven proximally.

Clinical signs

These vary according to the severity of the injury. Lameness ranges from mild in the case of small tubercle fragments to non-weight-bearing in the case of glenoid and scapular neck fractures. Manipulation and deep palpation will usually locate the area of discomfort, and crepitus is sometimes detectable. Fractures of the spine can lead to sequestration of fragments with chronic sinus formation. Neck fractures may cause damage to the suprascapular nerve.

Diagnosis

Mediolateral radiographic projections with the limb extended provide the best images of distal fractures. Scapular spine fragments may be highlighted

by tangential craniocaudal projections. Fractures through the body require high exposures to penetrate the depth of both forelimbs and should be interpreted cautiously because of the superimposition of thoracic structures and the contralateral scapula. Ultrasound can provide better image detail of many fractures in adults. Stress fractures are usually diagnosed on the basis of nuclear scintigraphy.

Treatment

Many fractures of the spine and body respond to conservative management with the exception that **sequestra** typically **require removal**. Plate fixation of unstable fractures of the body has been reported, utilizing the scapular spine to provide sufficient length for screw insertion.

Many **supraglenoid fractures** are amenable to internal fixation using tension band techniques with screws and wires and/or plates. Transection of the biceps brachii tendon has been reported to prevent postoperative implant failure. Early removal of small supraglenoid tubercle fragments can be successful, but in long-standing cases and in other types of fractures, degenerative scapulohumeral joint disease usually limits success to salvage for non-athletic purposes. Internal fixation of neck fractures is technically feasible in foals. Stress fractures should be managed with prolonged rest.

Enostosis-like lesions (bone islands)

While less commonly reported than those of the radius and humerus (*q.v.*), enostosis-like lesions can be detected in the scapula, and have been associated with similar lesions occurring in the ribs and other flat bones.

THE CALCANEUS (FIBULAR TARSAL BONE)

Osteomyelitis—calcaneal tuber

The prominent calcaneal tuber is prone to traumatic injury and subsequent infection.

Etiology

Calcaneal tuber lesions are often caused when the horse kicks a solid object or is kicked by another horse. Foals can also develop infections of the apophyseal growth plate secondary to hematogenous bacterial spread.

Clinical signs

There are often draining wounds present over the point of the hock, and osteitis generally causes moderate to severe lameness and swelling. Tarsal tenosynovitis may also be noted.

Diagnosis

Both radiography and ultrasound should be considered to confirm the diagnosis and determine the extent of involvement. Lateromedial, flexed

lateromedial and plantaroproximal–plantarodistal (skyline) radiographic views should be obtained.

Treatment

Effective treatment requires **prolonged antibiotic therapy** both systemically and regionally (antibiotic perfusions, *q.v.*). Surgical debridement of infected soft tissues and bone is also frequently necessary. These cases can be very difficult to resolve and generally require prolonged treatment, but they can be managed successfully.

Osteitis—sustentaculum tali

Distension of the tarsal sheath (**thoroughpin**) (*q.v.*) is sometimes associated with new bone formation on the sustentaculum tali.

Etiology

Inflammation of the sustentaculum surface is the trigger factor and can result from direct trauma, e.g. fractures, or tenosynovitis of the adjacent tarsal sheath. Septic tenosynovitis is particularly liable to provoke a proliferative reaction. It is also possible for a systemic bacteremia to seed the sustentaculum causing an osteomyelitis.

Clinical signs

The predominant sign is of **massive tarsal sheath distension** accompanying lameness. Hock flexion is likely to exacerbate the lameness.

Diagnosis

Lameness should improve with intrasynovial analgesia of the sheath (*q.v.*). Bone proliferation is often visible on lateromedial and dorsomedial–plantarolateral oblique radiographic projections but the optimal image is obtained with the flexed plantaroproximal–plantarodistal (skyline) view. Ultrasound should be performed to evaluate the DDFT and the tarsal synovial sheath.

Treatment

Initial treatment should be directed toward the inciting cause, but surgery is often indicated. Early aggressive therapy is required to manage **septic tenosynovitis** (*q.v.*) of the tarsal sheath. Systemic and regional antibiotic therapy is required if infection is present, and sheath lavage with tenoscopic exploration is usually performed in conjunction with surgical debridement of osteomyelitis lesions or traumatic fractures. However, once new bone formation has occurred, the prognosis for athletic performance is poor since surgical removal of the proliferations is often followed by regrowth. Surgical release of the tarsal retinaculum can minimize pain associated with compression of the DDFT in the tarsal groove. Deep digital flexor tenotomy has been described to salvage severe cases, but more recent work suggests that this aggressive technique may be unnecessary for successful management of these difficult cases.

Fractures

Fractures are not common, but a variety of **calcaneal fractures** can occur, including **Salter–Harris type 1 separation** of the tuberal growth plate, chip fractures from the plantar surface and fractures through the body of the bone. The latter are often open and may involve the talocalcaneal or proximal intertarsal articulations.

Etiology

External trauma is the usual cause.

Clinical signs

Fractures are accompanied by local swelling and pain consistent with their severity. **Chip fractures** are frequently associated with open wounds and soft tissue inflammation localized around the plantar border. They may sequester and become a source of chronic purulent discharge. Lameness is typically apparent in the acute phase but often subsides with the resolution of soft tissue swelling. Therefore, at the time of presentation there may be little or no pain. **Physeal fractures** in foals result in a loss of hock extension (dropped hock) due to interruption of the insertion of the gastrocnemius muscle. **Body fractures** may cause similar loss of function if the fragments are significantly displaced. **Open, articular fractures** are likely to develop tarsocrural joint sepsis.

Diagnosis

Standard radiographic projections are required to delineate the fracture, with lateromedial and oblique views being the most informative. Special projections may also be indicated.

Treatment

Chip fractures can be left if they retain a blood supply and are not associated with infection. Otherwise they should be removed surgically via an approach either side of the superficial digital flexor tendon (SDFT). Generally the prognosis is good but some are difficult to locate dorsal to the tendon, and osteomyelitis of the tuber calcaneus has been encountered.

Fractures involving **small fragments** can be repaired by lag screw fixation if accessible, whereas fractures of the body or epiphysis must be stabilized using the tension band principle. Generally, the more complicated the repair needed, the worse the prognosis. An associated septic tarsocrural joint requires appropriate therapy, perhaps more urgently than the fracture itself.

THE TIBIA (CRUS)

Physeal fractures

Etiology

Physeal fractures can be caused by external impact or by intrinsic compressive/tensile forces during exercise. Injuries can involve the proximal or distal

physes, or the tibial crest. Fractures of the proximal tibial physis are particularly common.

Clinical signs

Fractures are usually obvious because of the degree of swelling, pain and loss of function. In the case of proximal and distal separations the limb will deviate markedly distal to the line of separation. Horses with tibial crest avulsions are often non-weight-bearing because of the inability of the quadriceps muscle to fix the patella.

Diagnosis

Craniocaudal and lateromedial radiographic projections are necessary to determine the configuration of the fracture.

Treatment

Except in the minimally displaced distal fractures (in which full limb casting might be considered) internal fixation to stabilize the fragments is generally indicated. The technique is variable according to the biomechanical needs of individual cases. **Salter Harris type 2 fractures** with a lateral metaphyseal component frequently occur in the proximal epiphysis of foals up to the age of 18 mo. These lend themselves to repair by internal fixation (plating, cross pinning, screws and wires) via a medial approach and generally carry a good prognosis. Conservative management can be considered for some non-displaced fractures of the proximal tibia. Fractures of the distal tibial physis that require internal fixation can be repaired with cross pins.

Tibial crest avulsions require tension band fixation to oppose the pull of the quadriceps. This is often best accomplished with a plate applied to the cranial aspect of the tibia. Tibial stress fractures should be managed with strict rest to avoid catastrophic bone failure.

Diaphyseal fractures

Etiology

Extrinsic and intrinsic forces are implicated in the development of tibial diaphyseal fractures, but external trauma from a kick is a common cause. They can be complete or incomplete and may involve either or both articular surfaces. Medial overriding of fragments can create an open fracture because of the limited soft tissue protection on that side. The proximal caudolateral cortex is a predilection site for **stress fracture** in the immature athlete.

Clinical signs

Complete fractures present with sudden onset, severe lameness, crepitus and swelling. Incomplete fractures can be more difficult to detect. There is frequently a history of acute onset lameness with little to find clinically. Some cases will display a localized pain reaction to pressure applied over the bone surface medially. Swellings associated with callus formation may become apparent later.

Diagnosis

Complete fractures are readily diagnosed on the basis of clinical signs. Incomplete fractures may be evident radiographically, but this is not invariable. Nuclear scintigraphy offers a good method of detecting these. At a minimum, craniocaudal and lateromedial radiographic projections are a prerequisite to surgery for complete fractures. For the detection of **incomplete fractures** high definition, multiple, oblique films should be examined.

Treatment

Severely comminuted diaphyseal fractures are a **devastating injury** and euthanasia is indicated. Other fractures may lend themselves to internal fixation, particularly in foals, usually with plates applied craniolaterally and craniomedially.

As with all proximal limb fractures, success is more likely the smaller the patient. The prognosis for complete tibial fractures in adults remains guarded to poor despite studies designed to improve plating and interlocking nail techniques. Incomplete fractures that can be seen on radiographs are frequently spiraling and these are best treated by interfragmentary compression in foals, but conservatively in adults. For less extensive fissures conservative treatment is generally indicated although the potential for incomplete fractures to become complete should always be considered, and tie-stall or sling restraint may be indicated.

Enostosis-like lesions (bone islands)

Enostosis-like lesions identical to those described in the radius (*q.v.*) can also be detected in the tibia. These should be differentiated from endosteal callus formed in response to a stress fracture.

THE FIBULA

The fibula is normally vestigial in the horse. Complete fibulas have been reported as a congenital finding in Shetland ponies and miniature horses, and have also been associated with development of **angular limb deformities**. In those cases, an osteotomy should be performed in conjunction with periosteal elevation and/or transphyseal bridging (*q.v.*).

Fractures

Fractures of the fibula are not common. The bone forms from a variable number of ossification centers, and persistence of these, in some individuals, can lead to a mistaken diagnosis of fracture. Usually, multipartite bones will be bilaterally symmetrical. Even in cases of genuine fracture the clinical consequences are few and they are usually managed conservatively. Mild and transient lameness may be seen.

THE PATELLA

The patella is a **critical component** of the quadriceps apparatus, acting as a lever arm for extension of the stifle.

Fractures

Etiology

Direct trauma to the cranial stifle with the limb in flexion is the most commonly recognized etiology. **Avulsion fractures** are also seen, particularly at the apex, and presumably result from contraction of the quadriceps muscles. Other configurations include sagittal (usually medial to the ridge), transverse and comminuted fractures.

Clinical signs

Depending on the fracture configuration, lameness varies from moderate to non-weight-bearing. Local soft tissue inflammation will usually be present together with femoropatellar joint effusion in articular fractures. Pain and possibly crepitus will be elicited by palpation or manipulation. Horses with small avulsion fractures can present with minimal lameness, but may have marked joint effusion. Flexion usually exacerbates the lameness.

Diagnosis

Intra-articular analgesia of the femoropatellar joint (*q.v.*) will typically improve lameness caused by articular fractures. Lateromedial, caudocranial and flexed cranioproximal–craniodistal (skyline) radiographic views are essential to accurately define the fracture. The latter view can be obtained in the standing horse by flexing the limb and holding the cassette against the horizontal tibia while directing the beam proximodistally. Ultrasound can also be valuable in defining fracture configuration, as well as in determining soft tissue involvement.

Treatment

The least complicated cases, i.e. small non-articular and non-displaced fractures, will heal with a fibrous union given sufficient stall confinement. Sagittal fragments up to one-third the surface area of the patella are small enough such that their removal will not interfere with quadriceps action or femoropatellar mechanics and this is a reasonable option with a good prognosis if performed early.

Fragments off the base of the patella should be removed. Most fracture fragment removals can be performed arthroscopically. In other cases, including complete displaced transverse fractures and large sagittal fragments, internal fixation, usually by lag screw technique, is necessary to restore congruity of the articular surface. These repairs have a relatively high failure rate due to the large distracting forces experienced by this bone. Minimally displaced sagittal, transverse and comminuted fractures should be managed conservatively with prolonged stall rest.

Apical fragmentation

Fragmentation, roughened contour or subchondral lucency at the apex (distal end) of the patella, is occasionally identified on lateromedial radiographs. Many of these lesions develop following **medial patellar ligament desmotomy**

for upward fixation of the patella (*q.v.*). Clinically, the lesions may be associated with lameness, responsive to IA femoropatellar analgesia (*q.v.*), and fibrous thickening of the joint capsule may be palpable. A high success rate has been reported with arthroscopic removal of fragments and debridement of the affected area. Medial patellar ligament desmotomy should be avoided when possible as it apparently creates joint instability or patellar malalignment. Most horses with upward fixation of the patella can be managed more conservatively.

THE FEMUR

Physeal fractures

Etiology

Fractures of the femur are quite common in **foals**. Unbroken, fractious youngsters are prone to epiphyseal fractures when restrained and panicking. Trampling by the dam has also been incriminated in the etiology. Proximal physeal fractures are more common than coxofemoral luxations due to the unique anatomy of the equine hip, including a strong accessory ligament of the head of the femur.

Clinical signs

Animals are usually non-weight-bearing unless there is only minimal displacement. There is typically local pain and swelling at the site of fracture, including a marked **gonitis** (*q.v.*) in the case of distal physeal fractures. Crepitus can often be detected on limb manipulation.

Diagnosis

Distal fractures can be imaged radiographically using flexed lateromedial and craniocaudal projections. **Proximal fractures** require powerful radiographic units and a recumbent patient for adequate penetration and diagnostic images. With capital femoral physeal fractures, the radiographs should be closely evaluated to ensure that the femoral head is secure in the acetabulum (round and accessory ligaments are intact) before recommending surgical repair.

Treatment

Non- or minimally displaced fractures can heal with conservative management given sufficient stall confinement. Otherwise treatment requires internal stabilization and an amenable fracture configuration. Lag screw techniques, buttress plating and Rush pinning of distal epiphyseal fractures have been successful. Proximal physeal fractures have been successfully repaired using pins, cannulated screws, the dynamic hip screw plating system, and other techniques. The prognosis is always guarded for athletic potential but is best in small patients.

Diaphyseal fractures

Etiology

External trauma is the usual cause. In adults the energy dissipation associated with the massive trauma frequently causes severe comminution.

Clinical signs

Non-weight-bearing lameness associated with massive soft tissue swelling of the thigh is characteristic. There is usually excessive mobility of the limb on manipulation and crepitus may be felt or heard. The limb may appear shortened due to overriding of fragments. If the femoral vessels are damaged **massive hematomas** can form, and horses will occasionally exsanguinate.

Diagnosis

Clinical signs are often diagnostic and they may be all that is available since radiography of the adult femoral shaft is largely restricted to referral hospitals.

Treatment

In foals, ponies or very small adults intramedullary pinning and double plating have been successful. In larger animals there is usually no realistic prospect of successful repair, and euthanasia is indicated if the fracture cannot be managed conservatively.

THE PELVIS

Fractures

While the incidence of pelvic fractures has been reported to be low, recent improvements in diagnostic imaging techniques have revealed that there is a **relatively high incidence** of pelvic fractures in all types of horses.

Etiology

Fractures through the **iliac shaft or wing** are the most commonly diagnosed pelvic fracture and are usually associated with the trauma of a fall. **Tuber coxae** fractures can occur with direct impact against a solid object, and these commonly occur when horses charge through **narrow doorways**. Pubic, acetabular and ischial fractures tend to occur in younger horses and may occur during forced abduction of the hindlimbs. Spontaneous stress and complete fractures are also well documented in racehorses and can result in catastrophic injury on the track.

Clinical signs

Tuber coxae fractures ("knocked-down hip") present with local soreness but low-grade lameness, which is usually short-lived. The fragment may be detected by palpation and there is usually a visible asymmetry of the tuber coxae. Sometimes these fractures are open and associated with sequestration and chronic drainage. The signs of other fractures are dependent on the configuration. The worst cases with bilateral comminution will be recumbent. Horses with unilateral fractures have moderate to severe lameness and quickly develop muscle atrophy of the ipsilateral proximal muscle masses.

Asymmetry of the bony landmarks may also be obvious. Rocking the horse from side to side or manipulation of the ipsilateral limb may allow crepitus to be felt or heard. If the fracture splits the pubic symphysis, bilaterally shortened

strides will be evident. **Damage to adjacent vessels** can cause severe or fatal blood loss. Perineal edema in females suggests damage to obturator vessels.

Diagnosis

Definitive diagnosis of a pelvic fracture can be challenging. Clinical signs provide the most important diagnostic features. A **rectal examination** is useful and can reveal otherwise undetectable fragment instability, hematoma formation or, in the chronic case, callus formation. Although a technique for standing ventrodorsal radiographic projections exists, it requires powerful machines and purpose-designed cassette holders to perform without undue radiation hazard. Nonetheless, it can be useful in removing the uncertainty of tentative diagnoses.

Full radiographic evaluation requires ventrodorsal projections obtained under general anesthesia. For this reason it is generally recommended that acute cases are given time to stabilize before the procedure is undertaken. Ultrasound has proven to be invaluable in the diagnosis of pelvic fractures and also facilitates monitoring healing following diagnosis. Both transcutaneous and transrectal exams should be performed. Scintigraphy can also be useful for diagnosis of pelvic fractures, particularly for stress fractures when hindlimb lameness is detected without localizing signs. Unfortunately scintigraphy can be inconclusive and a negative scintigraphic examination cannot rule out even serious pelvic fractures in the acute stage of these injuries.

Treatment

There are currently **no surgical techniques** available to repair pelvic fractures in horses. Fracture fragments sequestered from the tuber coxae may require surgical excision.

For most pelvic fractures, conservative treatment involving **prolonged stall confinement** is the only option available. When unstable pelvic fractures are suspected the risk of **vessel laceration** should be considered, and tying an amenable horse for the first month of confinement can reduce the risk of fatal hemorrhage.

Simple tuberal or iliac fractures have a good prognosis. As a general rule, comminution, fragment overriding and involvement of the acetabulum are poor prognostic signs, but exceptions are frequent. Most horses can at least be salvaged for breeding although it is wise to check that the **pelvic dimensions** have not been compromised when determining suitability of a mare for breeding. The duration of stall confinement is usually at least 2–3 mo, but should ultimately be determined based on ultrasound monitoring, as well as clinical and/or radiographic evidence of fracture healing.

ARTHROLOGY (DISEASES OF JOINTS)

INTRODUCTION

Joint disease is one of the most common problems encountered in equine practice and can be broadly divided into five groups:

1. Developmental
2. Degenerative

3. Traumatic
4. Septic
5. Miscellaneous.

There is considerable overlap between each of these groups.

Diagnosis of joint disease may involve a variety of **diagnostic aids** including (most commonly) local analgesia, radiography and synovial fluid analysis. Nuclear scintigraphy and other computer-assisted imaging techniques are becoming more widespread in availability, but are still primarily confined to referral centers.

ANATOMY

Joints are composed of supporting soft tissues, an articular cartilage surface and a subchondral bone foundation. The soft tissues surrounding a joint include ligaments and tendons. However, of most importance to the understanding of joint disease is the role of the **joint capsule**, which consists of an outer fibrous layer and an inner synovial membrane. These closely linked structures contribute much of the nutrition and sensation to the joint. The fibrous portion of the joint capsule is rich in nerve terminals, through which most **joint pain** is detected. The synovial membrane is the source of many of the components of joint fluid, including **hyaluronan** (*q.v.*), and acts as a permeability barrier that controls synovial fluid composition. Many of the destructive enzymes responsible for articular cartilage damage arise from the synovial membrane, and the structure also plays an important role in phagocytosis.

The articular surface is generally composed of hyaline cartilage, which is divided into four layers. The arrangement of these layers, which are constructed mainly of chondrocytes, collagen fibrils and proteoglycans, imparts much of the characteristic strength, elasticity and resistance to compression of articular cartilage. The **superficial layers** of articular cartilage receive nutrition from the synovial fluid, while the deeper layers of immature cartilage receive nutrition via the vascular supply of the subchondral bone. Articular cartilage has no nerve supply and provides little shock absorption. Most shock absorption occurs in the bone and periarticular soft tissues.

The **subchondral bone** provides support for the articular cartilage. This bone has a rich blood supply and is capable of providing limited repair of articular cartilage when exposed to the joint surface.

Several forms of **lubrication** operate within joints. Synovial membrane lubrication occurs by a process known as **boundary lubrication**, and hyaluronan is primarily responsible for this. Cartilage on cartilage lubrication uses both boundary and hydrostatic lubrication. A glycoprotein aids in cartilage boundary lubrication. At higher loads, however, boundary lubrication is inadequate and **hydrostatic lubrication** takes over, operating by formation of a fluid film composed of joint fluid and interstitial fluid from the articular cartilage that keeps the articular surfaces apart.

DEVELOPMENTAL JOINT DISEASES

The broad category of developmental disorders includes osteochondrosis (including osteochondritis dissecans [OCD]), subchondral bone cysts,

cuboidal bone malformations, cervical vertebral malformation, juvenile arthritis and some angular and flexural limb deformities. Osteochondrosis and angular limb deformities are discussed in more detail in the section on developmental orthopedic disease (*q.v.*).

Osteochondrosis

The most commonly recognized developmental joint disease is **osteochondrosis** (*q.v.*) which is a developmental orthopedic condition characterized and defined by a disturbance in **endochondral ossification**. **Osteochondritis dissecans (OCD)** refers to those cases of osteochondrosis in which a **cartilage flap** is formed.

The appearance of clinical signs associated with osteochondrosis can sometimes be delayed many years, particularly if only mild lesions have occurred and the horse has been allowed to mature before vigorous exercise has commenced. Cases appearing in older animals often present with osteoarthritis (*q.v.*); however, the location and appearance of lesions indicate a long-standing osteochondrosis lesion.

All breeds of horses are affected, and it is important to remember that **any articular surface** can be affected, including vertebral articulations, frequently with more than one joint affected. For these reasons, any evaluation of lameness in young horses, particularly if bilateral, should include osteochondrosis as a differential diagnosis.

Clinical findings

The most prominent clinical sign in cases of osteochondrosis is **effusion** of at least one affected joint. Effusion may not always be evident in the contralateral joint, even when radiographic evidence of disease exists. Lameness is variable, but is usually only mild to moderate. The lameness may be difficult to completely abolish with IA local anesthesia. **Muscle wasting** is often evident in long-standing cases of shoulder and stifle osteochondrosis.

Diagnosis

The age and breed of the horse, its size and sex, and the presence of joint effusion can suggest a diagnosis of osteochondrosis. Intra-articular blocks (*q.v.*) may be necessary to localize the lameness. Confirmation of a diagnosis of osteochondrosis is usually made by radiography. If clinical signs are only apparent in one limb, the **contralateral joint** should always be radiographed. The horse should also be closely examined for abnormalities in other joints. A **neurologic examination** (*q.v.*) may be indicated to determine whether cervical vertebrae have been affected in severe cases.

Treatment

Conservative and **surgical** management have been investigated. Conservative therapy consists of restricting the horse's exercise, slowing the growth rate, and ensuring there are no dietary vitamin or mineral deficiencies or excesses. Excessive feeding of grain should be avoided. Conservative therapy can be successful in carefully selected cases, but is dependent upon the site and

severity of the lesion, how early in the course of the disease the lesion is detected and whether any osteochondral fragmentation or elevation of cartilage has occurred. Up to 12 mo convalescence may be required, and joint effusion and lameness may be present for a considerable period of this time.

The role of **drainage** of the joint and **IA corticosteroid injections** is controversial. In cases of osteochondrosis in which osteochondral fragmentation or loose cartilage flaps have not developed, corticosteroids may provide short-term relief from clinical signs of lameness and joint effusion. However, it is unclear if corticosteroids aid the recovery process and they may hasten the development of cartilage detachment. **Intra-articular hyaluronan** (*q.v.*) or long-term **IM polysulfated glycosaminoglycan (PSGAG)** (*q.v.*) therapy may improve the prognosis in selected cases. However, if severe effusion is present and there is radiographic evidence of fragmentation or undermining of cartilage then surgery is the preferred option if an athletic career is anticipated.

Arthroscopic surgery is the technique of choice. There are estimates that up to 70–80% of appropriately selected cases respond to arthroscopic debridement of osteochondrosis lesions. Of course, prognosis depends on the extent of the lesion, the joint involved and the degree of associated osteoarthritis. Improvement in clinical signs is often evident within weeks of surgery. **Postoperative care** depends on the surgical findings, but generally consists of 4 wk of stall confinement, then 4 wk of hand walking, followed by paddock rest for another 8–16 wk. This can be modified to suit the individual lesions and programs of the affected horse. If required, some horses, primarily those with small intermediate ridge OCD or plantar fetlock lesions, can resume exercise within a week of surgery.

New techniques that may replace simple surgical debridement are being developed. These include stabilizing the OCD flap lesion with absorbable pins to facilitate healing, tissue engineered cartilage constructs to repair the articular surface, and osteochondral autograft transplantation using Mosaic-Plasty or OATS™ (osteochondral autograft transfer system) technologies.

Osseous cyst-like lesions

Osseous cyst-like lesions or **subchondral bone cysts** are most frequently identified in the **medial femoral condyle** of the femur; however, they also occur regularly in many other sites, including the fetlock, pastern, elbow and carpal joints, and cysts can develop in any joint. The etiology of bone cysts is uncertain, but they may be related to dietary abnormalities and may have a similar pathogenesis to OCD (*q.v.*). Trauma to the articular surface can also result in cyst formation.

Conservative therapy can be successful in some cases, but many of these horses will develop **osteoarthritis** (*q.v.*). Surgical evacuation of the cyst contents is the most common surgical technique used when access to the cyst is feasible. **Intralesional corticosteroid** injection without surgical enucleation has recently gained popularity for treatment of medial femoral condyle cysts. Intralesional corticosteroids may slow the progression of cysts if detected at an early stage of development. Improved treatment options are being investigated in an attempt to improve prognosis in these cases. These include cylindrical press-fit osteochondral allografts/autografts, tissue engineered cartilage

constructs, mesenchymal stem cell transplantation and growth factor enhanced repair techniques.

There are several conditions in young horses that can mimic cysts, including lytic areas in the ulnar carpal bone or incomplete development of the distal first phalanx seen in yearling Thoroughbreds. It is important to differentiate conditions that may be “normal”, or at least clinically insignificant, from those that can result in lameness.

Incomplete or defective ossification of the carpal and tarsal bones

This condition arises as a result of **delayed ossification** of the carpal and tarsal bones and has been suggested to be a result of prematurity, hypothyroidism (*q.v.*) or a variation of normal ossification rates. Lack of ossification of the cuboidal bones in these joints and uneven pressure distribution result in collapse and deformation of the cartilage; with subsequent ossification, the bones are permanently deformed. In the carpus, an angular limb deformity often develops, while a flexural deformity occurs with tarsal collapse (**curby, sickle-hock**) (*q.v.*). In severe cases clinical signs are usually present at, or soon after, birth. In less severe cases, particularly with tarsal bone collapse, a diagnosis may not be made until much later when mild osteoarthritis is detected.

Radiographic examination will confirm either delayed ossification or subsequent deformation and wedging of the cuboidal bones. If a diagnosis is made early, before permanent deformation of the bones has occurred, treatment should be instituted. This consists of straightening the leg and applying well-padded splints or a fiberglass tube cast. Splints should be lightweight to allow the foal to ambulate well, and can be made out of PVC pipe or formed using cast material. In young foals, splints should be reset daily, and casts should be changed every 3–7 days to accommodate the rapid growth occurring at this time and to prevent flexor tendon laxity that can be a major complication of cast application in very young foals. When splints are applied bilaterally, the foal may initially require assistance to stand and nurse at regular intervals.

The prognosis is guarded once bone deformity is identified radiographically. Some horses become sound, but others are left with a chronic osteoarthritis and permanent limb deviation. In mild cases of tarsal bone collapse affecting only the distal intertarsal and tarsometatarsal joints **arthrodesis** can eliminate the associated lameness, particularly if there is no or minimal deviation of the limb.

Young horses can also develop osteoarthritis of the distal tarsal joints, presumably as a result of defective development of the articular cartilage in these joints. This may be a manifestation of OCD. These horses present at a young age with clinical and radiographic evidence of **juvenile bone spavin**.

OSTEOARTHRITIS/DEGENERATIVE JOINT DISEASE

Etiology

Osteoarthritis (OA) or **degenerative joint disease** (DJD) is actually a group of disorders that are defined and characterized by **progressive deterioration** of the **articular cartilage**. Cartilage degeneration is usually associated with

changes in the adjacent soft tissues and subchondral bone, but the term implies progressive and permanent deterioration of the articular cartilage. A wide variety of etiologic factors have been shown to cause osteoarthritis, including trauma, osteochondrosis, IA fractures, chronic low-grade trauma and septic arthritis (*q.v.*), although in many cases no predisposing factors can be identified. In many patients osteoarthritis probably develops due to chronic low-grade articular trauma occurring as a result of joint instability, ligamentous or capsular damage, poor conformation or action, or wear and tear over many years of strenuous athletic activity. In some cases no obvious predisposing factors can be found.

Despite the wide variety of initiating causes, there is considerable commonality in the reactions of the articular tissues. Once the normal architecture of the cartilage is altered, a **vicious cycle** of events begins. The changes that occur include a loss of cartilage elasticity, a decrease in aggrecan or proteoglycan content, and liberation of degradative enzymes. The end result is damage to the articular surface and remodeling of the subchondral bone. In many cases, osteoarthritis can progress to the extent that subchondral bone will fragment from articular surfaces.

Pathophysiology

The articular changes at the cellular level have been well described in a number of review articles. Osteoarthritis can involve changes in the soft tissues surrounding the joint, the articular cartilage and the subchondral bone, but many of the pathologic changes identified also involve the synovial membrane. The initial response is inflammatory, with production of increased amounts of relatively normal synovial fluid. As the inflammatory changes progress there is an increase in the protein levels, as well as an increase in leukocyte numbers and a decrease in viscosity of the joint fluid due to reduced hyaluronan concentrations.

Inflamed synovium is capable of releasing degradative enzymes such as collagenases, proteases and glycosidases, as well as prostaglandins and superoxide radicals. Much of the **pain** associated with joint disease apparently occurs as a result of stimulation of nerve fibers within the synovium.

Grossly, the articular cartilage becomes softened and fibrillated. There may be **cartilage splitting** and fragmentation extending to complete erosion and loss of articular cartilage in the most severe cases. Structural changes include loss of proteoglycan and glycosaminoglycan content, as well as collagen degradation.

Subchondral bone damage results when full thickness articular cartilage damage has occurred. Grossly there is softening of the bone and fragmentation. Subchondral bone damage has been suggested as a cause, rather than a result, of articular cartilage degeneration in young horses whose joints are subject to inappropriate loading during training. However, this is presumably a less frequent cause of osteoarthritis than are primary changes in the synovium and articular cartilage.

There are three basic theories about how cartilage degeneration is initiated in osteoarthritis. First, it has been suggested that trauma stimulates a **biochemical degradative response** in the joint and resident chondrocytes either contribute to this process or are unable to respond adequately to protect the

cartilage from the insult. Second, **excessive mechanical forces** may play a determining role with resulting failure of the articular cartilage. Third, **repetitive concussion** produces changes in the subchondral bone, and cartilage changes develop secondarily. It should be noted that these so-called “biomechanical and biochemical theories” of joint destruction are not mutually exclusive: each of these processes is likely to occur in most cases of osteoarthritis depending on the primary initiating factor. There is a growing trend to suggest that osteoarthritis arises exclusively as a result of changes in the subchondral bone, but the etiology of osteoarthritis is so complex that a single pathologic mechanism is unlikely.

Diagnosis

Initial diagnosis of osteoarthritis is often based on clinical signs (Box 15.1). Horses usually present with a low-grade, chronic lameness. If a fracture has been superimposed on the osteoarthritis, lameness may be more severe. Many horses have reasonably **advanced degenerative changes** before the owner or trainer detects clinical signs. Effusion in the affected joint is variable, with no, or only minimal, distension detected in many cases. For example, due to anatomic constraints, effusion is rarely detected in the distal intertarsal or tarsometatarsal joints.

Response to **flexion tests** (*q.v.*) can often be informative, but a negative response does not rule out the possibility of osteoarthritis. For example, the “**spavin test**” (*q.v.*) for osteoarthritis of the hock can be a useful ancillary diagnostic procedure and is relatively easily standardized between operators. In contrast, many horses with mild carpal osteoarthritis will not respond positively to a carpal flexion test.

Flexion tests of the fetlock must be interpreted carefully, as many horses, particularly older animals, will show some degree of lameness after fetlock flexion, and flexion of the fetlock also affects the proximal and distal interphalangeal joints. Furthermore, variability in pressure applied and duration of flexion makes comparison between operators very difficult. Individual veterinarians should be **consistent** in performing the fetlock flexion test and correlate the response observed with the pathology subsequently detected. Mild pressure for 30–60 s is generally recommended.

Box 15.1 Osteoarthritis—diagnosis

Clinical signs

- Lameness
- Look for joint swelling, pain
- Assess flexion tests

Anesthesia, regional and IA

Radiography

- New bone formation, enthesophytes, lysis, sclerosis

Arthroscopy

- Response to treatment

Diagnostic regional and/or IA local analgesia (*q.v.*) are typically required to localize lameness to a particular area. Scintigraphy may be required to identify some subtle osteoarthritis responsible for a decline in performance without lameness. Radiography is indicated to evaluate the extent of bone involvement, but arthroscopy and MRI can provide information about the articular cartilage.

Synovial fluid analysis is of limited assistance in making a diagnosis of osteoarthritis, however the potential exists for great advances in this area as research continues for a simple, reliable, and accurately interpretable test. Both **serum and synovial fluid biomarkers** are being investigated. Some of the numerous serum and synovial biomarkers being evaluated in horses include: collagenase-1 activity, glycosaminoglycan, aggrecan metabolites, cartilage oligomeric matrix protein, carboxy-terminal propeptides of type II collagen, cross-linked telopeptide fragments of degraded type I collagen, and neutrophil elastase 2A. Work to date suggests that marked fluctuations can be detected with physiologic processes and sampling interventions and careful interpretation of data will be essential.

At present, color and viscosity of the synovial fluid remain as useful indicators of joint pathology. Normal joint fluid is clear to very light yellow in color. The darker yellow (xanthochromic) the fluid appears, the more likely it is that articular pathology is present. In severe cases of osteoarthritis the fluid can appear reddish in color.

Treatment

Treatment should be designed to eliminate the cause of the osteoarthritis whenever possible, for example OCD lesions or joint sepsis (Box 15.2). Articular cartilage has a limited ability to repair, and response to treatment is usually dependent on the severity of the cartilage injury. Partial thickness articular cartilage damage does not repair but full thickness damage can heal as a result of metaplasia of the granulation tissue that forms in the defect. However, the replacement cartilage is fibrocartilage not hyaline cartilage, with lower aggrecan content and little or no type II collagen.

It is important to recognize and to inform clients that **osteoarthritis cannot be cured**. However, a number of management practices can be utilized effectively to keep horses in athletic performance. **Long periods of rest** may also be indicated in conjunction with other treatments, and utilized when the horse's training program allows.

Box 15.2 Osteoarthritis—treatment summary

- Arthroscopy and joint lavage
- Rest
- Medical therapy
 - NSAIDs
 - Corticosteroids
 - Hyaluronan (IA, IV)
 - Polysulfated glycosaminoglycan (IM, IA)
 - Atropine (IA)

Arthroscopy and joint lavage

In severe cases, or where IA fractures are present, **arthroscopic surgery** should be considered. This allows for removal of loose fragments of bone and cartilage, debridement of degenerative cartilage down to healthy subchondral bone, and a thorough flushing of the joint to remove degradative enzymes and cartilage particles. **Diagnostic arthroscopy** should be considered even if a radiographically identifiable lesion is not present. Experimental evidence suggests that creating full thickness cartilaginous lesions and/or penetrating the subchondral bone plate (i.e. microfracture techniques allow access to cancellous bone without compromising the subchondral bone plate) can enhance cartilage repair. Newer resurfacing techniques including autologous grafting (*q.v.*) are likely to come into clinical use in the near future.

Medical therapy

Medical therapy can be utilized alone or in conjunction with surgery, and includes the use of NSAIDs, corticosteroids, PSGAGs and hyaluronan (*q.v.*). The appropriate use and action of these drugs is similar for all forms of joint disease.

Prior to injection of any substance into a joint (*q.v.*), **meticulous aseptic surgical preparation of the skin surface** must be performed. Evidence suggests that adequate disinfection can be achieved without clipping or shaving the hair provided adequate scrubbing time is allowed, but clipping may still be necessary with a long haircoat and/or excessive contamination. Sterile surgical gloves are recommended for all IA injections.

The most potent anti-inflammatory medications used to treat osteoarthritis are **corticosteroids** (Table 15.3). Their actions are complex and include

Table 15.3 Corticosteroids used in treatment of osteoarthritis

Corticosteroid	Standard concentrations	Typical IA dose per joint ¹	Duration of response ²
Betamethasone acetate/sodium phosphate ³	6 mg/mL	3–18 mg	3 mo
Triamcinolone acetonide	6, 10 and 40 mg/mL	3–18 mg up to 40 mg ⁴	Up to 3 mo or more
Methylprednisolone acetate ⁵	20 and 40 mg/mL	80–120 mg	Up to 6 mo
Dexamethasone sodium phosphate	5 mg/mL	15–25 mg	1 wk–2 mo
Dexamethasone isonicotinate	1 and 3 mg/mL	9–15 mg	Up to 3 mo
Isoflupredone acetate	2 mg/mL	5–20 mg	3 mo
Triamcinolone and dexamethasone combined		10–40 mg triamcinolone and 15 mg dexamethasone	More potent initial response, 3 mo or more

¹ The dose ranges vary widely and are somewhat arbitrary.
² The duration of response can be very variable, depending on the severity of the condition, the nature of the horse and the joint being medicated. The approximate times given above relate to a best-case scenario.
³ Not currently available on the market.
⁴ Reduce if multiple joints are injected. It is advisable not to administer more than a total of 18–80 mg per horse because of a possible risk of inducing laminitis. No research is available to accurately set this limit.
⁵ Methylprednisolone acetate may have prolonged detection times in some horses; it also has the most detrimental effects on articular cartilage, and should probably be avoided in high-motion joints.

stabilization of lysosomal membranes (decreasing the release of degradative enzymes), inhibiting prostaglandin, free radical, interleukin-1 and collagenase release, and decreasing vasodilation, edema formation and fibrin deposition. They also suppress leukocyte function, as well as inhibiting other inflammatory pathways. The deleterious effects of corticosteroids are considered to be a result of decreases in proteoglycan content and cartilage elasticity, which can result in cartilage degeneration. However, recent studies have shown that **triamcinolone** (*q.v.*) has very few adverse effects when administered IA and the potent anti-inflammatory effects of this medication are well documented.

Provided corticosteroids are not used in large doses, frequently over long periods, or in an attempt to treat severe IA fractures, the beneficial effects of their use generally outweigh the deleterious consequences. Corticosteroids are often used in combination with hyaluronan. Long-acting agents, such as **methylprednisolone acetate**, can result in improvement for up to 6 mo. Recommended doses of methylprednisolone acetate are 60–80 mg in smaller joints such as the fetlock and carpus, and 120 mg in larger joints. Short- to medium-acting corticosteroids, primarily betamethasone acetate (3–18 mg per joint), dexamethasone isonicotinate (10–15 mg per joint) and dexamethasone (20 mg per joint), can give relief for several weeks up to approximately 3 mo.

Triamcinolone acetonide is one of the most commonly used corticosteroids for IA use in competition horses. The amount of triamcinolone recommended varies from 6 to 40 mg per joint, but many practitioners limit the total quantity of triamcinolone to 18 mg per horse in an effort to avoid the development of laminitis (*q.v.*).

All corticosteroids are readily detected during routine drug testing procedures for racing and competition (*q.v.*). Sufficient time must be allowed following injection to ensure the drug has been excreted prior to competition. Veterinarians must stay current with information regarding detection times of these medications.

Hyaluronan, also referred to as **sodium hyaluronate** or **hyaluronic acid** (HA), is a component of articular cartilage and synovial fluid, and is produced by both synoviocytes and chondrocytes. Hyaluronan is a polyanionic non-sulfated glycosaminoglycan. Under physiologic conditions hyaluronic acid is anionic and can be appropriately referred to as hyaluronate or hyaluronan. Articular surfaces are covered with a fine layer of hyaluronan, which exerts resistance to cartilage compression while still retaining its elasticity. Hyaluronan also confers viscoelastic as well as lubricating properties to normal synovial fluid, and is responsible for the boundary lubrication of synovial membranes. It creates a steric barrier at the synovial membrane, and inhibits release of prostaglandins and free radicals.

Exogenously administered HA is thought to stimulate production of endogenous HA by resident synoviocytes, provide anti-inflammatory benefits, and supplement the action of depleted or depolymerized endogenous HA, but additional documentation of these claims is warranted. Intravenous HA appears to decrease lameness and synovial effusion in horses with synovitis. A number of different hyaluronan products are commercially available for administration to horses (Table 15.4). The properties of HA are listed in Box 15.3.

Table 15.4 Hyaluronan products commercially available for administration to horses

Hyaluronan can be given IA or IV. The IA route may be preferred if the lameness has been localized to a specific joint. The IA dose is 20 mg per injection site, and the injection can be repeated in 2–3 wk if clinically indicated. This medication is commonly used **in combination with an appropriate corticosteroid**. The combination can be mixed and injected in the same syringe. Intravenous injections of 40 mg are given once weekly for 3–4 wk often

Box 15.3 Properties of hyaluronan**Molecular weight**

The molecular weight (MW) of synovial fluid hyaluronan has been estimated at approximately 2–6 million Daltons. The MW of hyaluronan has been used to compare the relative merits of different hyaluronan products. However, the measurement of MW of hyaluronan products can be difficult and produce misleading results. Contamination of the hyaluronan with proteins and nucleic acid can result in artificially high MW readings. The advantage of higher MW products is not well documented, but higher MW may result in longer duration of effect.

Protein

The measurement of protein concentration in hyaluronan is an indication of purity of the substance. Pure hyaluronan is free of protein. It is acknowledged that it is virtually impossible to totally eliminate all extraneous protein; however, it is suggested that the lower the level present, the less synovial reactions are likely to occur.

Viscosity

It has been suggested that the higher the viscosity of the hyaluronan product used, the more beneficial it will be in terms of assisting in lubrication and shock absorption within the joint.

followed by a maintenance program of decreasing frequency, or given 1–2 days prior to an event. By **combining corticosteroids with the IA administration of hyaluronan** many practitioners have observed a better and longer lasting improvement when compared with corticosteroids alone. Hyaluronan alone is only effective against mild to moderate synovitis.

Two forms of polysulfated polysaccharide medications for intramuscular administration are currently registered for equine use: **polysulfated glycosaminoglycan (PSGAG)** and **pentosan polysulfate**. These agents are reported to have anti-inflammatory properties and anabolic effects on cartilage, to prevent catabolism, to promote hyaluronan synthesis and to have beneficial vascular effects on the joint.

The PSGAG, Adequan (Boehringer Ingelheim), is supplied in an IA or IM ampule. It has chondroprotective and anti-inflammatory effects in osteoarthritic joints, and it is commonly used postoperatively when there is significant cartilage loss. Adequan is reported to inhibit degradation and stimulate synthesis of cartilage matrix, thereby meeting the requirement of cartilage matrix synthesis stabilization, which is deemed most important in the treatment of osteoarthritis. However, the nature and magnitude of its anabolic effects are controversial, while the anti-catabolic effects are more generally accepted. Adequan is a semi-synthetic heparinoid. It is a mixture of highly sulfated glycosaminoglycans, the major component of which is chondroitin sulfate. The product is made from an extract of bovine lung and trachea modified by sulfate esterification. Intramuscular Adequan is recommended at

500 mg (1 mg/kg) every 4–7 days for a total of 4–7 injections. While there are few objective data to support the effectiveness of IM PSGAG, there is a great deal of anecdotal backing. Intra-articular administration has been associated with inflammation and a reduced resistance to infection, and 250 mg of Adequan should be co-administered with 125–250 mg of amikacin sulfate if the IA route is used. Many practitioners have discontinued use of IA Adequan to avoid complications.

Pentosan polysulfate (Pentosan Equine; Nature Vet; 250 mg/mL; 6 mL), is supplied in an IM formulation, but is not licensed for use in the US. Pentosan polysulfate has been used in human medicine as an anti-thrombotic and anti-lipidemic agent for the last three decades and recently its potential as a disease-modifying anti-arthritis agent has been explored. It appears to have chondroprotective but no analgesic properties. Pentosan polysulfate is a linear polysulfated polysaccharide derived from plant extracts. It is prepared from the plant product xylan and contains linked beta-D-xylopyranoses attached to glycoside chains. Pentosan polysulfate has also been used in canine patients with osteoarthritis. In dogs the optimal dosage regimen is 3 mg/kg q 5–7 days by SC injection. In horses, it has primarily been used in Australia, and the dose has been extrapolated from this canine data to 2–3 mg/kg once weekly for 4 wk, repeated after 3 mo as required. Occasional local reactions to IM injection of this product have been observed.

A number of **oral medications** are currently available that are claimed to be of benefit in the management of osteoarthritis. These primarily consist of **chondroitin sulfate** and/or **glucosamine sulfate/hydrochloride**. The efficacy of these products is not well established although there is increasing evidence of their effectiveness. Glucosamine may increase proteoglycan synthesis by chondrocytes as well as having anti-inflammatory properties. Chondroitin sulfate is also reported to have anti-inflammatory and chondroprotective benefits. There is currently debate regarding the efficacy of the two different glucosamine salts on the market (glucosamine sulfate versus glucosamine hydrochloride) but the salt form simply provides the delivery vehicle and the real issue of importance is that of product purity.

Both glucosamine and low molecular weight chondroitin sulfate are absorbed after oral administration to horses, but the levels achieved in the target joint remain unclear. There also appears to be considerable individual variation in clinical results observed following this form of supplementation. When supplementation is used, a reputable product should be selected since many of the glucosamine and chondroitin sulfate products currently on the market do not contain the products listed on the label.

NSAIDs act by inhibiting prostaglandin-mediated activity in the joint, thereby decreasing the pain and inflammation associated with joint disease. Certain NSAIDs **inhibit anabolic activity** in chondrocytes and have deleterious effects, while others **stimulate matrix synthesis**. Clinically, there is little evidence of detrimental effects in the joint even following chronic administration, and these medications are very useful in management of equine joint disease. Nevertheless, there is recent evidence that chronic phenylbutazone administration does suppress proteoglycan synthesis and may potentiate cartilage damage. **NSAIDs should be used judiciously in athletic horses with osteoarthritis.**

The least expensive and most commonly used NSAID is **phenylbutazone** (*q.v.*), which can be given PO or IV. One recommended dosing interval consists of 4.4 mg/kg twice daily for 1 or 2 days, then 2.2 mg/kg twice daily for 3–5 days, then 2.2 mg/kg once daily as required. Toxicity, including gastrointestinal ulceration and renal papillary necrosis, can occur rapidly if the higher dose rate is used for long periods, particularly if the horse is suffering from dehydration or has pre-existing renal or gastrointestinal disease. Toxicity may manifest as protein loss, colic and diarrhea (*q.v.*). A good response is obtained with phenylbutazone when treating **low-grade lameness**. It can assist in resolving clinical signs of lameness when acute inflammation is present, but in chronic lameness clinical signs usually return when medication is withdrawn. As a result **long-term administration** is sometimes indicated to maintain a horse in athletic work. Long-term administration does not usually have adverse effects providing the drug is given at the correct dose and the horse remains well hydrated, but owners should be instructed to monitor the horse for evidence of toxicity. Phenylbutazone can have a prolonged detection time following even short-term use or administration of a single dose, and breed/performance regulations should be observed.

Other drugs in the NSAID group that are used in horses include flunixin meglumine, ketoprofen, carprofen, acetylsalicylic acid, naproxen, meclofenamic acid, vedaprofen, eltenac, etodolac and indometacin. **Meclofenamic acid** (Arquel) is considered to have a wide margin of safety. It has been shown to have similar analgesic properties to phenylbutazone, but may take several days administration to reach peak therapeutic levels. Newer agents such as **meloxicam** are very useful, particularly in foals. They have potent anti-inflammatory and analgesic properties. They are reported to be much less ulcerogenic than traditional NSAIDs. Meloxicam can be given at a rate of 1 mL/75 kg IV or 1 mL/50 kg PO once daily in horses.

Other medications

Dimethyl sulfoxide (DMSO) has anti-inflammatory and antibacterial properties. It can be used as an IA medication, and has significant anti-inflammatory benefits when applied topically. There is some in vitro evidence of detrimental effects on matrix metabolism, but no cartilage pathology was detected following administration in vivo.

Diclofenac is a phenylacetic acid NSAID that has been approved for **topical use**. **Surpass** (IDEXX Laboratories) is a 1% diclofenac sodium cream in a liposomal formulation for locally enhanced targeted delivery. Clinical field trials performed to obtain FDA approval in the US suggest that this medication, applied twice daily, improved lameness and joint mobility of horses with osteoarthritis, and the product has been released for veterinary use.

Atropine sulfate is used regularly in equine practice to **reduce synovial effusion** at a dose of approximately 4–15 mg per joint. A potent anticholinergic, atropine may work by reducing blood supply to the synovium, but there is little objective evidence of its effectiveness. If blood supply is restricted a poor healing response could result. Atropine therefore may be more suitable for use in managing chronic tendon sheath effusions. Doses should be limited to no more than 15 mg total body dose to avoid **gastrointestinal side effects**, and horses should be monitored closely for colic following treatment with IA atropine.

Prognosis

The prognosis for horses with osteoarthritis is dependent on the severity of the disease process, as well as a horse's individual tolerance to pain. No long-term cure can be expected in any case of osteoarthritis since hyaline cartilage does not heal effectively, and many cases require long-term medication to remain in work. Many horses can function adequately as performance horses, despite the presence of osteoarthritis. In more severe cases the best outcome that can be hoped for is for the horse to remain useful as a breeding horse, or be "pasture sound".

TRAUMATIC ARTHRITIS

Traumatic arthritis and degenerative arthritis (*q.v.*) are usually closely linked. There are some occasions when a single traumatic incident, such as a displaced IA fracture, will initiate development of arthritis. More commonly, low-grade repetitive trauma initiates a destructive cycle that results in osteoarthritis. This process is commonly observed in the carpus and fetlock of racehorses, but may be seen at any site. Traumatic arthritis also involves synovitis, capsulitis and articular cartilage damage and it is therefore very difficult to differentiate chronic traumatic arthritis from other causes of osteoarthritis.

SEPTIC (INFECTIOUS) ARTHRITIS

Etiology

Entry of bacteria into a joint can occur as a result of hematogenous spread, penetrating injuries, extension from adjacent soft tissue or osseous lesions, as a consequence of IA injection or as a complication of surgery.

Septic arthritis in foals is often referred to as **joint ill** (*q.v.*). In such cases, a focus of infection can usually be found elsewhere in the foal, such as an infected umbilicus (**navel ill**) (*q.v.*). Foals with bacterial arthritis (*q.v.*) are frequently immunocompromised and multiple joints can be affected simultaneously. Spread of infection is usually via the hematogenous route.

In adult horses, penetrating injuries and injections are the most common cause of septic arthritis. Drugs such as PSGAG (Adequan) and corticosteroids are most frequently associated with infections (Box 15.4). Septic arthritis can occur in any joint. **Iatrogenic septic arthritis** occurs more often than it should and is typically caused by *Staphylococcus aureus* (*q.v.*), which is one of the most common and most resistant joint infections to manage. It is important not to examine any wound, particularly one near a joint, with ungloved fingers, and all IA injections should be performed using strict aseptic technique. The hands are a common source of *S. aureus*, and this organism can also be present in high levels in the nasal passages of some individuals.

Clinical signs

Appearance of clinical signs can often be delayed for several days after the initial bacterial contamination, and this delay can be prolonged up to 14–21 days after corticosteroid injections. Unfortunately any delay is likely to diminish the response to therapy. Horses with septic arthritis are usually **severely**

Box 15.4 Septic arthritis following intra-articular drug administration**Corticosteroids**

- Corticosteroids suppress white cell and other inflammatory responses to infection
- The ability to overcome infection is greatly reduced
- Clinical signs may not be evident until 3–21 days following the injection
- Clinical signs are often mild initially
- If in doubt, suspect sepsis following a corticosteroid injection.

Polysulfated glycosaminoglycan (PSGAG, Adequan)

- Adequan suppresses joint defense mechanisms
- Similar infection risk as observed with corticosteroids
- Less ongoing suppression of inflammation following advent of infection
- Administer with amikacin sulfate.

(**grade IV/V**) **lame**, with pain on palpation or flexion of the affected joint. There is usually **marked effusion of the joint** and a thickened joint capsule. However, there may be no obvious signs of swelling early in the course of the infection in upper limb joints, such as the shoulder, or joints with limited ability to distend, such as the pastern or tarsometatarsal joints.

Affected horses are often depressed and have a decreased appetite. They may be pyrexia. There can, however, be **considerable variation** in the severity of clinical signs. If the joint capsule is still open following traumatic injury, and there is continual discharge of synovial joint fluid there will often not be as much lameness or effusion detected, although there may be periarticular swelling.

Sometimes a low-grade chronic septic arthritis and synovitis occurs. Affected horses are moderately lame, but have severe synovitis and effusion, as well as pain on palpation of the joints, which are often very warm to touch. Such horses may respond temporarily to treatment but frequently relapse. They are usually only moderately depressed, and often have only a slight temperature rise, to approximately 38.1–38.6°C (100.6–101.5°F).

The typical **clinical signs** of septic arthritis are:

1. Heat, swelling, pain
2. Usually severe lameness
3. Variable pyrexia
4. Variable depression
5. Variable peripheral white cell changes.

Pathophysiology

Once an infection is initiated the synovial membrane responds by becoming inflamed, resulting in increased accumulation of synovial fluid and liberation of **degradative enzymes**. Inflammatory cells, particularly neutrophils, rapidly infiltrate the joint, releasing free radicals and other destructive enzymes. These enzymes result in depletion of proteoglycans and collagen from the articular cartilage matrix, and subsequently cause erosion of the articular surface. The formation of fibrin clots in the joint further compromises synovial

membrane function, provides a supportive environment for bacterial proliferation, and interferes with appropriate nutrition of the articular cartilage.

If full thickness cartilage loss occurs and bacteria penetrate the subchondral bone, a septic osteomyelitis (*q.v.*) will develop. Conversely, osteomyelitis or septic physisitis can extend into a joint and initiate a septic arthritis. In such cases, the radiographic abnormalities in the subchondral bone are much more severe early in the course of the disease than would be expected if septic arthritis had been the initiating factor.

Diagnosis

There are few causes of lameness as severe as that observed with joint sepsis; these include hoof abscesses (*q.v.*) and fractures. Therefore when a patient is reluctant to weight bear, and fracture and digital infection have been excluded, it is quite likely that joint sepsis is present. Diagnosis should be based on clinical signs, joint fluid analysis and radiography.

Infected joint fluid will usually have a turbid serosanguineous or seropurulent appearance and a watery consistency. Chronically infected joints will have flocculent synovial fluid. Strong consideration should be given to a diagnosis of joint sepsis when a **synovial fluid** aspirate has a **protein** of $>3\text{ g/dL}$ (often $>4\text{ g/dL}$) and/or a **white cell count** $>5000/\mu\text{L}$ (often $>30\,000/\mu\text{L}$), of which 80% are **neutrophils**. Cell counts of $>30\,000/\mu\text{L}$ with $>90\%$ neutrophils are considered virtually pathognomonic for bacterial infection (although some other severe inflammatory conditions can result in cell counts in this range). However, lower values do not preclude a diagnosis of septic arthritis, especially when there is a history of steroid use. Other analyses that have proven valuable include **glucose concentrations** (expect levels below serum glucose with sepsis), **pH** (expect acidic pH, often <6.9), and **lactate** concentrations (expect elevated levels, typically $>5\text{ mmol/L}$, but levels are also elevated following uncomplicated corticosteroid injections). Other reliable markers of joint infection are likely to be identified in the near future.

Samples should be submitted for bacteriology and cytology. Culture of organisms from infected joints can often be unrewarding; however, inoculation of enhancement broths and submitting both aerobic and anaerobic samples for culture can improve recovery rates. In addition, polymerase chain reaction (PCR) analysis is a very sensitive technique for detecting the presence of bacterial DNA and identifying organisms, but it also has a high false positive rate from contaminants or from non-viable organisms.

Joint fluid analysis reveals:

1. Turbid, watery and color altered (slightly red tinged to dark red or cloudy)
2. In severe cases, purulent fluid
3. Protein $>3.0\text{ g/dL}$
4. WBC $>5000 \times 10^6/\mu\text{L}$ (usually $>30\,000 \times 10^6/\mu\text{L}$)
5. Neutrophils $>90\%$
6. Culture important but often negative despite active infection.

Radiography may reveal evidence of gas within a joint or fractures associated with the sepsis or its initiating factors. Radiographic imaging is particularly valuable in conjunction with contrast studies to determine whether a wound

has penetrated a synovial structure. In long-standing cases evidence of **severe secondary osteoarthritis** may be apparent radiographically. Radiographs are indicated early in the course of disease. When this step is neglected, subsequent images often reveal findings that would have significantly altered either the treatment or the prognosis or both. Such findings include the presence of foreign bodies, osteomyelitis, sequestration or obvious disruption of the articular surface. In utilizing **radiography**, it is important to note that:

1. Radiographs should always be taken as part of the initial examination.
2. Soft tissue changes may be all that is identified initially.
3. Evidence of IA degenerative damage is a poor prognostic sign.
4. Intra-articular osteomyelitis suggests a poor prognosis.
5. Repeat radiographs are recommended at least every seven days during treatment.

Specialized **scintigraphic examinations**, including radiolabeled WBC scans and ciprofloxacin labeled scans, can provide valuable diagnostic tools in challenging cases of infection, but could delay initiation of therapy.

Treatment

Primary treatment for septic arthritis is summarized in Box 15.5. **Early and aggressive** treatment is required in order to eliminate the causative organisms and remove damaging inflammatory products from the joint. Treatment can be either **medical** or **surgical**; however, a combination is usually required. It is important to recognize that septic joints are an emergency and often require prolonged medication, and possibly repeated surgical intervention, if a successful outcome is to be achieved. Owners should be advised of this before treatment is instituted.

Initial **emergency treatment** should usually consist of broad-spectrum systemic antibiotics and NSAIDs, arthroscopic examination of the joint, lavage with large volumes of balanced electrolyte solution, regional limb antibiotic perfusion when feasible, and IA antimicrobials. Initial antibiotic selection should be based on the most likely pathogen (i.e. *Staphylococcus* spp. if the infection is iatrogenic), and on susceptibility patterns in the practice area.

Systemic antimicrobials are always indicated (Box 15.6). Ideally, antibiotics should be selected on the basis of culture and sensitivity patterns. Before this information is available, or when culture is unsuccessful, a broad-spectrum

Box 15.5 Primary treatment for septic arthritis

- Systemic antibiotics and anti-inflammatory drugs including NSAIDs
- Surgical lavage and drainage, followed by ongoing treatment either via indwelling catheter or via arthrotomy incisions
- Regional limb perfusion with antibiotics daily or every 2–3 days
- Intra-articular antibiotics daily or every 2–3 days
- Repeat large-volume (10 L) lavage in 1–5 days if not improved
- Horses with septic arthritis may require treatment for months

protocol should be initiated. A combination of penicillin and gentamicin, or potentiated sulfonamides can be used depending on resistance patterns in the particular practice area. Antibiotic therapy should be continued for at least 2 wk after clinical signs have resolved. However, up to 3 wk, additional treatment is recommended in foals, where a focus of infection is often located distant from the site of joint sepsis and also needs to be located and treated appropriately.

If *S. aureus* infection is suspected and there has been no response in 48 h with routine broad-spectrum antibiotics, consideration should be given to

Box 15.6 Commonly used systemic antibiotics for septic arthritis

- Preferably dependent upon sensitivity pattern
- Administer for ≥ 2 wk after significant improvement in clinical signs
- Often require 3 wk IV/IM followed by 3 wk orally
- Adverse gastrointestinal reactions not uncommon.

Penicillin

- Procaine benzylpenicillin still very useful, but long-term IM therapy a problem
- Avoid under dosing
- Intravenous crystalline penicillin good for initial high levels.

Gentamicin

- Give 6.6 mg/kg IV once daily for an adult horse
- Concentration-dependent efficacy
- Nephrotoxicity a possible but uncommon complication
- In vivo effectiveness against *Staphylococcus* spp. is very disappointing.

Trimethoprim-sulfonamide

- Can be used orally (paste or powder), IV or IM
- Considerable resistance has been detected in some practice areas
- More useful orally for ongoing long-term treatment, particularly when susceptibility testing supports its use
- Susceptible horses can develop colitis.

Ceftiofur

- Appears to have good penetration into bone
- Can be used IV or IM in conjunction with gentamicin
- No advantage to concurrent use of penicillin
- Susceptible (stressed) horses may develop colitis.

Flucloxacillin

- Use 20 mg/kg IM four times per day
- Expensive, but well tolerated
- Extremely effective in vivo against *S. aureus*.

Enrofloxacin

- Broad-spectrum including *Staphylococcus* spp.
- Concentration-dependent efficacy
- Intravenously once daily 7.5 mg/kg
- Orally.

using **flucloxacillin** either systemically if the expense can be justified, or IA. Alternatively, **enrofloxacin** can be administered, but it should be avoided in neonates due to associated cartilage damage in developing joints.

Non-steroidal anti-inflammatory drugs are also recommended for their anti-inflammatory and analgesic effects; **phenylbutazone** or **flunixin meglumine** is often used. Patients should always be monitored for NSAID toxicity, kept well-hydrated and appropriate **anti-ulcer medications** (e.g. **omeprazole** paste s.i.d.) administered when indicated. Concerns about potential detrimental effects on cartilage matrix metabolism are probably unwarranted considering their well-documented beneficial anti-inflammatory effects.

If possible, **arthroscopic** examination of the joint should be performed. This enables a thorough examination and removal of any fibrin clots and other debris. Most importantly it allows **extensive lavage** of the joint. High-volume (≥ 10 –20 L) frequent lavage of infected joints is critical for effective treatment. Following arthroscopic examination and lavage, an **arthrotomy** can be performed in many cases to facilitate postoperative drainage. The arthrotomy incisions are typically left to heal by second intention, but delayed closure of the arthrotomy incision may reduce subsequent complications. Open joint wounds should be protected by **sterile bandages**, which may need to be changed twice daily if extensive discharge occurs.

When arthroscopy cannot be performed, lavage via a 10–14 G catheter needle or cannula should be performed. Ingress and egress portals should be placed on either side of the joint (or in multiple locations in large joints) and 5–20 L of **balanced polyionic solution** such as lactated Ringer's solution flushed through the joint. Saline should be avoided when possible, as it not physiologic and has been shown to be more detrimental to chondrocyte and synoviocyte function. DMSO can be added as a 5–10% solution for its anti-inflammatory and analgesic benefits. There is some evidence that DMSO is damaging to articular cartilage matrix metabolism, but no gross pathology was detected following its administration in a clinical study. During flushing, the egress cannula/s should be occluded periodically to allow distension-irrigation of the joint.

In refractory cases **continuous lavage** can also be of benefit. An IV fluid administration set-up can be used, with extendable tubing and the end of the drip set entering the joint. This technique is used when appropriate drainage portals are present or have been created to allow free egress of fluid. Lavage solutions can be flushed through under gravity flow for 24–48 h or longer if required, but dedicated nursing care is required to avoid complications. Similarly, indwelling ingress catheters can be used to administer continuous or periodic IA antibiotics. Closed suction drainage can effectively remove inflamed synovial fluid, but also requires careful monitoring to avoid ascending infections.

The use of **IA medications** is generally well accepted. In the past the main objection to their use was that they would create synovitis (*q.v.*), resulting in more damage to the articular cartilage. However, in view of the severity of the disease process induced by the sepsis, the additional synovitis, when it occurs, is probably minimal. Drugs that are known to be irritating should be avoided. The advantage of IA medication is that higher drug levels are present in the joint than can be achieved via systemic administration. The most frequently used IA drugs are **amikacin** (250 mg–1 g IA) and **gentamicin** (300–500 mg IA).

High levels of IA medication can be maintained with the use of IA **antibiotic-impregnated polymethyl methacrylate (PMMA) bone cement**. This can be formed into beads and left within the joint to elute antibiotic. However, recent studies suggest that PMMA beads can damage articular cartilage. Other antimicrobial-impregnated **biodegradable drug delivery systems**, such as collagen, DL-lactide-glycoside copolymers, and plaster of Paris implants have also been described and tested.

Another practiced method for achieving high levels of antibiotics in the joint and surrounding tissues is **regional limb perfusion**. This can be performed by placing a tourniquet on the leg and injecting antibiotics IV, IA or into a medullary cavity in a location distal to the tourniquet. The tourniquet is maintained in place for 30 min following injection. The intramedullary technique is considered particularly beneficial when there is osteomyelitis at the end of a long bone. The injection portal can be left in place so that regular treatments can be performed, and prolonged treatment is usually essential in such cases.

In refractory cases, consideration should be given to **arthrodesis** when feasible. This has the effect of eliminating the joint space and synovial membrane and is occasionally the only means of resolving the problem.

Supportive care should include providing support to the opposite limb and foot to avoid breakdown and/or development of **laminitis** (*q.v.*). Physical therapy should also be initiated including passive range of motion exercises to avoid restrictive joint capsule fibrosis.

Prognosis

The earlier treatment is initiated, the better the chance of successful resolution (Box 15.7). If **sepsis** has been present for 14 days or more the chances of successful long-term resolution are low. Even if the infection is controlled, **cartilage damage** may be severe enough to render the horse chronically lame. Consideration needs to be given to the long-term usefulness of the horse before continuing aggressive treatment in horses that do not respond well initially.

The long-term prognosis can be very good if the infection is controlled early. Several months rest should be provided after any episode of septic arthritis (*q.v.*) to allow the articular cartilage to regain normal extracellular matrix form and function. This **exercise hiatus** should be implemented even if the condition appears to have resolved rapidly with no obvious, immediately apparent adverse effects. Radiographs prior to resuming exercise are also indicated to assess whether any long-term adverse effects have resulted.

Box 15.7 Septic arthritis—summary

1. Early diagnosis and treatment is the key to success
2. There is a requirement for aggressive, often long-term treatment
3. Clients must be advised of prognosis and potentially escalating costs
4. Immediately advise the livestock insurance company when the condition is detected.

MISCELLANEOUS JOINT DISEASES

Immune-mediated joint disease

Immune-mediated joint disease (*q.v.*) is infrequently encountered in the horse, but should be suspected if synovitis is present in multiple joints and no specific etiology can be determined. Synovial fluid analysis will be consistent with a non-infectious inflammatory arthritis. **Polysynovitis** has been documented with **systemic lupus erythematosus** or an immune reaction to *Streptococcus* spp. (*q.v.*) or *Rhodococcus equi* (*q.v.*) infection.

Treatment with systemic **prednisolone** can be effective if instituted before secondary cartilage damage occurs. A suitable dose rate for oral prednisolone therapy is 1 mg/kg b.i.d. for 7 days, then 1 mg/kg s.i.d. for 7 days, and reducing to 1 mg/kg every 2–3 days for 2–3 wk. Longer periods of therapy may be required to prevent recurrence.

Calcinosis circumscripta

Calcinosis circumscripta manifests as **abnormal calcification** in or adjacent to the joint capsule, and usually occurs as a result of trauma. It is often found in close association with joints, particularly the stifle joint. The calcification is often oval in shape, and is well circumscribed from surrounding tissue. Clinically these calcifications present as firm, non-painful, subcutaneous swellings. The masses have a characteristic radiographic appearance. Removal is recommended if the lesion is large or interfering with joint function. The prognosis is usually good after surgical removal.

Synovial hernia

Herniation of the synovial membrane through a defect in the fibrous joint capsule usually occurs as a result of trauma, but may not become clinically apparent for some time after the initial traumatic episode. A hernia appears as a soft, subcutaneous swelling that is non-painful. Injection of contrast media into the hernia or the joint will reveal a communication between the two, and the communication can also often be documented with ultrasound. The most successful resolution is obtained with surgical repair.

A **synovial hernia** should be differentiated from a **ganglion** (*q.v.*). The latter is a cystic structure containing mucinous material, with no discrete synovial lining, also found in close association to a joint or tendon sheath but not appearing through a defect in the joint capsule. Histologic evaluation is often required to differentiate accurately between these conditions. Treatment for a ganglion is also surgical removal.

DISEASES OF SPECIFIC JOINTS

Scapulohumeral (shoulder) joint

Diagnostic **IA anesthesia**, ultrasound and radiography are usually required to confirm a diagnosis of shoulder lameness. Scintigraphy may also be required to localize the problem, and contrast arthrograms are occasionally necessary to identify cartilage lesions. Intra-articular anesthesia (*q.v.*) is performed through

a needle placed between the cranial and caudal eminences of the greater tubercle of the humerus. Joint fluid should be aspirated prior to injection. Lameness can improve within 15 min, but up to 1 h should be allowed before deciding on a negative result. In some horses the intertubercular (bicipital) bursa communicates with the shoulder joint.

Lateral radiographs can be obtained in the standing horse. The affected leg is simultaneously extended and pulled downward as far as the horse will allow. The plate is held against the affected joint and the beam directed from the opposite side of the horse, under its neck. In this position the articular surface of the joint should overlie the radiolucent shadow created by the trachea. Many horses with shoulder lameness will resent the limb being pulled forward as far as is necessary to obtain good standing radiographs. Oblique radiographs can also be obtained if fractures of the supraglenoid tubercle or lateral tuberosity are suspected. **General anesthesia** may be required to obtain high quality radiographs, and is essential for craniocaudal views.

Scapulohumeral **osteochondrosis** (*q.v.*) usually manifests as a chronic low-grade lameness that may be greatly exacerbated by exercise. The shoulder tends to be one of the most severely affected joints with OCD. Affected horses are reluctant to allow extension of the limb and muscle atrophy is often evident. Conservative treatment is only successful in approximately 20% of cases. Arthroscopic debridement of the lesions improves the prognosis, but the success of arthroscopic surgery is dependent on the location of the lesion and the severity of associated osteoarthritic changes. Instrument access to some lesions on the medial aspect of the humeral head or deep in the glenoid cavity can be difficult to achieve resulting in limited ability to debride the lesion. Intra-articular medication consisting of 20–40 mg of hyaluronan (*q.v.*) can be of benefit.

Intra-articular fractures of the supraglenoid tubercle are relatively common, and horses typically present with severe lameness of acute onset. There is often a history of the horse having run into an object, taking most of the impact on the shoulder. There is usually pain and swelling evident on palpation. Conservative management will result in a very high incidence of **severe osteoarthritis**. Surgical management, consisting of internal fixation or fragment removal, can result in athletic soundness. Best results are observed following removal of smaller fragments via arthrotomy. Larger fragments create more of a problem, as the joint can become unstable following removal. Reasonable results can be achieved following removal of large fragments, but internal fixation has been used more successfully. Fracture reduction can be difficult and the pull of the biceps brachii can result in fixation failure. Consequently, partial or complete transection of the biceps in conjunction with internal fixation has been advocated.

Luxation of the scapulohumeral joint occurs primarily as a result of trauma, although severe osteoarthritis and remodeling, or muscle atrophy occurring as a result of “sweeny” (*q.v.*), can predispose to this. Ponies and miniature horses appear to be at a higher risk for luxation. Since the shoulder has no collateral ligaments, and joint stability is maintained by the joint capsule and surrounding musculature, luxation occurs without ligamentous disruption. Affected horses have a severe lameness, and palpation usually demonstrates luxation. Radiography may be required to confirm the diagnosis if severe swelling has

occurred, and is also useful in determining whether any associated fractures are present. Reduction can be extremely difficult, almost invariably requiring general anesthesia. Once reduced, the incidence of relaxation is surprisingly low, but owners should be advised of this possibility.

Cubital (elbow) joint

Intra-articular fractures of the olecranon are the most commonly diagnosed problem affecting the elbow joint. Horses often have a “dropped elbow” appearance due to loss of triceps function, but this must be differentiated from other upper forelimb fractures, and from radial nerve paralysis. Surgery consisting of internal fixation with either a bone plate or a tension band technique can result in an excellent outcome (*q.v.*). Radiography is essential and the prognosis is dependent on the configuration of the fracture and the age of the horse.

Osteochondrosis and **subchondral cystic lesions** (*q.v.*) are diagnosed infrequently in the elbow. Osteoarthritis is also encountered less commonly in the elbow but may be under diagnosed. Diagnosis of elbow problems is usually reached following IA anesthesia and radiography. Intra-articular blocks can be performed using several alternative approaches but the joint is often approached immediately caudal to the lateral collateral ligament. Radiographic signs are often minimal in osteoarthritis of the elbow, and any remodeling should be considered significant. **Bone cysts** of the elbow are usually detected on a craniocaudal radiographic view.

Prognosis for athletic soundness in cases of bone cysts is guarded, but may be improved if extra-articular surgical debridement can be achieved. Intra-articular medication is usually required if the animal is to pursue an athletic career following development of osteoarthritis in the elbow joint.

Carpus

The carpus is a complex high-motion joint comprised of the **antebrachio-carpal** (radiocarpal), **middle carpal** (intercarpal) and **carpometa-carpal** joints. The most common abnormality occurring in this joint is traumatically induced osteoarthritis, which often occurs in association with chip or slab fractures in racehorses.

Lameness resulting from carpal lesions can vary in severity from barely detectable to non-weight-bearing. **Effusion** in the middle carpal and/or antebrachio-carpal joints is usually evident after joint damage has occurred. This is detected as swelling over the joint space medial to the extensor carpi radialis tendon or between the extensor carpi radialis and the common digital extensor tendon. Effusion can also be detected over the palmar lateral surface. The degree of effusion can be variable, and in some instances, particularly following a lay-up period with an injury involving the antebrachio-carpal joint, effusion may not be evident even when a fracture is present.

Response to **flexion tests** (*q.v.*) can also be unreliable in determining whether a carpal lesion is present. While a positive response to flexion is usually reliable, a negative response does not preclude the presence of a carpal lesion.

Although a tentative diagnosis of a carpal injury can often be based on clinical observations, **IA anesthesia** (*q.v.*) is frequently required to localize the source of pain. The middle carpal and carpometacarpal joints reliably communicate and they are anesthetized simultaneously. This can be done through a dorsal approach 1 cm medial or lateral to the extensor carpi radialis tendon with the leg held in flexion, or the joint can be blocked through the palmarolateral pouch with the limb in a standing position. Response should be evaluated after 5–10 min, although up to 30–40 min may be required before a negative result can be confirmed. The distopalmar outpouchings of the carpometacarpal joint can result in inadvertent anesthesia of the proximal suspensory ligament and proximal metacarpus. Similar techniques are used for the antebrachiocarpal joint, which rarely communicates with the other joints.

A minimum of **eight radiographic views** is recommended for complete evaluation of the carpus. These are a lateromedial, flexed lateromedial, a dorsopalmar view, 45° dorsomedial–palmarolateral and dorsolateral–palmaromedial obliques, and a skyline (dorsoproximal–dorsodistal) view of the proximal and distal row of carpal bones, and of the distal radius. The skyline views are very useful, and will often identify lesions that are not evident on any other projection. The dorsopalmar view can identify stress fractures in the proximal metacarpus, and on rare occasions can reveal unusual fractures in the carpal bones. Accurate interpretation of subtle radiographic lesions in the carpus requires experience.

Osteoarthritis

Osteoarthritis of the carpus can be evident in any age, breed or performance category and is probably the most common carpal problem. In racing Thoroughbreds carpal joint disease is seen frequently in younger horses. Clinical signs of osteoarthritis in the carpus frequently go undetected until an IA chip or slab fracture occurs (*q.v.*) and the degree of lameness increases dramatically. Differentiation of osteoarthritis from fractures is often difficult since the two problems are linked. Response to medical therapy for osteoarthritis (*q.v.*) can be variable, with relief of clinical signs ranging from weeks to 6 mo. Repeated treatments are usually indicated. Once fractures occur, arthroscopy is clearly indicated. However, arthroscopic evaluation can also be recommended for horses with unresponsive inflammation in the absence of radiographic abnormalities. CT and MRI scans can also provide important diagnostic information in those cases.

A debilitating syndrome of carpometacarpal osteoarthritis has been described in older performance horses. Arabian and Quarter Horses seem to be predisposed to this condition and carpal trauma appears to be the initiating factor. Conservative management offers a poor prognosis for return to use, and a method of carpometacarpal arthrodesis, similar to that used in the distal hock joints, has been reported with excellent clinical results.

Chip and slab fractures

Osteochondral fragments (**chip**) and **slab fractures** are almost invariably the end stage of a **chronic** low-grade degenerative process initiated by **repetitive loading trauma**. As the disease progresses, the subchondral bone becomes lytic and weakens, eventually resulting in a fracture. Most fragments develop

dorsally. The characteristic location of these fractures can be explained by a combination of factors, including maturity of the horse, conformation and direction of racing. The role of OCD-like changes as a predisposing factor to carpal fractures should be considered, particularly for bilaterally symmetrical lesions. The most common sites are the **medial aspect of the distal radial carpal bone, the medial aspect of the proximal third carpal bone, the lateral aspect of the distal radius, and the proximal aspect of the intermediate carpal bone**. Frequency of fracture at these locations varies between different racing breeds. Multiple fractures may be present in one joint, or be present in both antebrachiocarpal and middle carpal joints. Lesions are often bilaterally symmetrical. For this reason it is recommended that **both carpi** be radiographed routinely when carpal joint disease is present.

Fractures of the **palmar carpal bones** are much less common, and are frequently associated with significant lameness. Horses resent carpal flexion, which tends to impinge on the fragment. Diagnosis is complicated by multiple overlapping lines of the palmar borders of the carpal bones, and CT may be required to confirm fracture location.

Frontal plane slab fractures, which by definition involve both proximal and distal articular surfaces, occur primarily in the third carpal bone. Again, degenerative changes usually predispose to this type of fracture. **Sagittal plane slab fractures** are also most frequently identified in the third carpal bone, but are much less common than frontal slab fractures.

Arthroscopic surgery is usually recommended as the treatment of choice for management of osteochondral fractures. At the time of surgery, any additional fractures can be identified, fracture fragments and degenerative cartilage removed, and the joint thoroughly flushed. Postoperative complications are minimal, and horses can usually return to work 1–6 mo after surgery, depending on the severity of lesions. Approximately 85–90% of horses undergoing arthroscopic surgery of the carpus will be able to return to athletic competition. The prognosis is considered better for lesions in the antebrachiocarpal joint compared to the middle carpal joint. Postoperative IA medication is occasionally recommended, but is not essential for a successful outcome. Palmar carpal fragment removal can be performed arthroscopically or via a small arthrotomy.

Conservative therapy can also be successful, however the time required out of training, the increased requirement for IA medication and a poorer long-term prognosis should be considered if this form of therapy is selected. Many chip fractures will heal with irregularity of the articular margin, which predisposes to more severe OA and re-fracture.

The prognosis for carpal osteochondral fragments is influenced by the severity and location of lesions. When bilateral lesions are present, the prognosis is determined by the severity of the worst lesion.

Many slab fractures are amenable to internal fixation using a lag screw technique or self-compressing screws, and this can usually be performed using arthroscopic guidance. If the fragment is severely displaced and cannot be reduced by carpal flexion, an arthrotomy may be required. **Displaced slab fractures** require internal fixation if the horse is to remain competitive, and the results after this surgery are generally good. Some non-displaced slab fractures do heal with conservative management, while some slab fractures are too thin to support fixation and necessitate removal.

Other articular fractures

Longitudinal fractures of the proximal third metacarpal bone extending into the carpometacarpal joint are occasionally detected (*q.v.*). A similar condition is seen less frequently in the **proximal metatarsus**. There is frequently pain on palpation of the dorsal aspect of the proximal metacarpus. Lameness will be improved or abolished with a middle carpal block (*q.v.*). Conservative therapy is usually effective but surgical management with internal fixation or osteostixis (*q.v.*) may be indicated depending on the pain associated with the fracture, its severity, and chronicity. Intra-articular fractures of the second and fourth metacarpal (splint) bones require internal fixation for the best long-term prognosis. Untreated IA fractures of the splint bones can result in severe osteoarthritis of the carpometacarpal joint and may necessitate arthrodesis (*q.v.*).

Intercarpal ligament damage

Another carpal injury regularly diagnosed in athletic horses is damage to the **medial palmar intercarpal ligament**. This ligament extends between the second and third carpal bones and the radial carpal bone and resists dorsomedial displacement of the radiocarpal bone. Damage ranges from complete rupture to mild disruption of fiber alignment and fraying of the edges of the ligament. Lameness resulting from this damage is inconsistent, and changes are usually seen in association with carpal chip fractures or other joint pathology. Horses typically present with variable forelimb lameness, which has frequently been present for some time. There is usually minimal swelling in the affected joint, and localization requires IA anesthesia. No consistent radiographic abnormalities are evident; however, longer-term signs of osteoarthritis may become evident due to low-grade instability in the joint. Confirmation of the diagnosis is by arthroscopic evaluation, although MRI should also be capable of detecting ligament damage. The condition is usually treated by resting the horse; however, the rate of recurrence is high. Intrinsic repair of the ligament is facilitated if part of the ligament remains intact, when compared to cases with complete rupture. Intra-articular corticosteroids may be required to maintain the horse free of lameness but should be avoided during initial rehabilitation.

A syndrome of **lateral palmar intercarpal ligament avulsion** has also been reported as a clinically significant source of lameness. Treatment involves arthroscopic debridement and rest, and the prognosis for return to athletic competition is good.

Osseous cyst-like lesions (subchondral bone cysts)

Bone cysts can occur in any of the carpal bones or proximal metacarpus. They range in size and can even completely occupy the space within the cuboidal bones. The prognosis for athletic soundness is poor. These cysts should be differentiated from cystic looking areas that are often apparent within the ulnar carpal bones of young Thoroughbred horses, but which resolve with maturity. Incidental cyst-like lesions can also be observed in the second carpal bone and in the base of the second metacarpal bone that are not associated with lameness.

Incomplete ossification of the carpal bones

Carpal bone collapse can occur in young foals, usually as a result of incomplete ossification of the carpal bones in **immature** or dysmature neonates

(*q.v.*). Left untreated, incomplete ossification often progresses to collapse of the cartilage/bones and resulting **angular limb deformity**. Once collapse occurs, treatment is limited to restriction of exercise and the use of tube casts to support the limb, and the condition carries a somewhat guarded prognosis for future athletic performance.

Accessory carpal bone fractures

Fractures of the **accessory carpal bone** are thought to result from direct trauma, hyperextension injuries, or when the bone is crushed between the radius and metacarpus (*q.v.*). These fractures usually result in marked lameness, swelling and severe pain with carpal flexion. The most common configuration is a frontal plane (vertical) fracture through the proximal and distal borders. These fractures have a surprisingly good prognosis when treated conservatively, despite the obvious non-union that develops. Affected horses can resume a normal athletic career following up to 12 mo rest. Attempts at internal fixation are usually unsuccessful. Complications of these fractures include carpal canal syndrome (*q.v.*) and tenosynovitis.

Metacarpophalangeal/metatarsophalangeal (fetlock) joint

Diagnosis of fetlock lesions is generally based on clinical findings and diagnostic regional nerve blocks or intrasynovial anesthesia. Many horses, particularly older horses and those that have had some degree of training, will have a positive **fetlock flexion test** (*q.v.*). Interpreting the significance of such a reaction can be difficult. Lameness originating in the fetlock can often be abolished with IA anesthesia (*q.v.*). A number of alternative injection techniques have been described including dorsal, proximopalmar and distopalmar approaches as well as an approach through the collateral ligament of the proximal sesamoid.

Radiographic evaluation of the fetlock requires careful attention to positioning and exposure. **Five views** should always be taken. These include dorsopalmar/plantar, lateromedial, flexed lateromedial, dorsolateral–palmaromedial and dorsomedial–palmarolateral oblique views. The dorsopalmar/plantar view should be taken with the beam angled down approximately 30° from the horizontal and centered on the joint space, which has the effect of elevating the sesamoids and thereby providing a clear view of the articular surface of the joint. Additional views of the fetlock include a 125° dorsodistal–palmaroproximal (extended dorsopalmar view), and 45° lateroproximal–mediodistal and 45° medioproximal–laterodistal oblique projections. A partially flexed horizontal beam dorsopalmar view can be substituted for the extended dorsopalmar/plantar view if the horse is not in too much pain for flexion.

Synovitis/capsulitis and supracondylar lysis ("osselets")

A precise definition of **synovitis–capsulitis** as a clinical condition is difficult. These horses generally present with either a slight thickening of the joint capsule and/or an increase in joint fluid pressure. These changes are of uncertain significance in some cases, although distension in the fetlock joint is an indication that some abnormality has occurred. In young athletes, synovitis may be a result of abnormal stresses being placed on the joint, and the joint subsequently adapts without more serious injury. However, the distension will

often remain as a permanent record of previous joint damage. In other cases the joint damage can progress and become clinically significant. Horses usually resent fetlock flexion, and are noticeably lammer for 10 strides or more after fetlock flexion. In the initial stages of this condition, no radiographic abnormalities are detectable. If the problem progresses, radiographic signs of osteoarthritis may be present.

Virtually **every young racehorse** will experience this syndrome. The presumed etiology of synovitis–capsulitis is chronic low-grade trauma to the joint capsule and articular surface. Fibrosis in the joint capsule develops, and restricts the range of motion. Lameness is not always evident with this condition, and when capsulitis–synovitis is the sole abnormality, lameness is usually mild. It is important to realize that **chronic capsulitis–synovitis** with effusion is frequently encountered, particularly in performance animals, and may not be contributing to any lameness present at the time of examination. Therefore IA anesthesia (*q.v.*) is recommended to localize the lameness and provide information about the likelihood of a positive response to IA medications.

Treatment for acute cases consists of systemic anti-inflammatory medication for 2–3 wk and 6–12 wk of rest or modified exercise. In most cases, IA medication consisting of hyaluronan and/or corticosteroids (*q.v.*) is indicated, particularly if an exercise program is to be continued. The prognosis is variable, as ongoing trauma necessitates continuous medication and each horse responds differently to the discomfort associated with this condition.

Chronic synovitis can result in erosion of the palmar articular surface. Presumably this occurs as a result of chronic elevation in joint fluid pressure. The condition is identified on radiographs and is referred to as **supracondylar lysis**. The prognosis for these horses is considered guarded by some, although the radiographic change is occasionally seen in horses not displaying any clinical signs. There is no effective treatment but management with IA corticosteroids and hyaluronan is indicated.

Osteochondrosis

Osteochondrosis (*q.v.*) of the fetlock can manifest in several different forms. Lesions involving the **dorsal aspect of the distal third metacarpal/metatarsal bone** (originally referred to as OCD of the **sagittal ridge** of the third metacarpal and metatarsal bones) are the most commonly recognized form of this disease. **Palmar and plantar osteochondral fragments** of the proximal phalanx, and **dorsal osteochondral fragments from the proximal first phalanx** may also represent forms of osteochondrosis. The condition previously referred to as palmar/plantar OCD or palmar/plantar condylar necrosis is apparently traumatically induced and no longer considered to be a manifestation of osteochondrosis.

Osteochondrosis of the dorsal aspect of the distal third metacarpal/metatarsal bones is seen commonly in pre-sale yearling radiographs and is often of little long-term clinical significance. It is also seen in older horses, sometimes as an incidental finding. While the exact significance can be difficult to determine, it is important to assess the degree of effusion in the joint, evaluate lameness and determine if there is any radiographic evidence of a flap of cartilage or underlying subchondral bone damage. All four fetlocks should be radiographed when lesions are identified in one joint.

If there is flattening of the sagittal ridge with no associated clinical signs then no surgical treatment is required. Horses <18 mo of age should usually be managed conservatively at that time as many lesions show improvement radiographically. However, if there is evidence of a flap, or effusion or lameness then arthroscopic examination is indicated. The prognosis following debridement is usually good, providing the entire lesion is treated. Access can be difficult in some cases.

Osteochondral fragmentation of the proximal phalanx

Proximal phalanx (P1) fractures are frequently observed in horses. The most common type is a small osteochondral fracture from the **medial eminence** on the **dorsal proximal aspect of P1**. Fractures from the lateral eminence also occur, and occasionally fractures are found both medially and laterally. These fractures appear to result from impingement by the distal third metacarpal bone that occurs during hyperextension of the joint during high-intensity exercise.

Fractures are frequently seen in association with **chronic proliferative synovitis**, which can also produce abnormal stresses on proximal P1 with impingement during exercise. It has been suggested that some of these fragments are a manifestation of osteochondrosis, particularly when they are identified in yearlings and non-racing breeds, but most fragments are presumed to be of traumatic origin.

Clinical signs vary from no detectable problems to moderately severe lameness. There can be joint effusion and pain on flexion. Intra-articular anesthesia is sometimes required to identify the fetlock as the source of lameness. Confirmation is by radiography. Some P1 fractures are first identified on pre-sale radiographs, and the interpretation of such a finding can be difficult. While some P1 fractures will cause few problems, in the majority of cases some degree of lameness and/or synovitis will be evident. In most instances a non-union develops, and continual movement of the fragment results in pain and inflammation in the joint. Bilateral fractures are common, and the contralateral fetlock should always be examined. The forelimbs are far more frequently affected than the hindlimbs.

If lameness and/or inflammation are present, arthroscopic removal of the fragments is recommended. The prognosis after removal is good to excellent. Affected horses can resume training from 6 to 16 wk after surgery, depending on the extent of cartilage damage.

Palmar and plantar fragments from proximal P1 are more often identified in the hindlimbs than the forelimbs, and are more commonly seen in Standard-breds and Warmbloods. These lesions often appear to be a manifestation of OCD (*q.v.*), although there is increasing evidence that many are avulsion fractures at the insertion of the distal sesamoidean ligaments. The fragments are usually located in the joint capsule between P1 and the base of the sesamoids. They most often occur medially, but can occur laterally or biaxially.

The degree of lameness and effusion associated with these lesions is often only slight, with a gait abnormality only evident at high speeds. Intra-articular anesthesia is often required to locate the lesion, and examination at high speeds after anesthesia may be required to confirm that the lesion is contributing to lameness. The diagnosis is confirmed radiographically. The fragment of bone may only be clearly evident on a lateromedial projection centered on

the base of the sesamoids, or a dorsoproximolateral–palmarodistomedial or dorsoproximomedial–palmarodistolateral oblique projection. The fragments can be difficult to detect on standard 45° oblique projections.

Prior to treatment, it should be determined whether the fragments are causing a clinical problem. In many cases the lesion is detected on survey radiographs and may not be a cause of lameness. However, if lameness is identified as arising from the affected joint, then treatment is by arthroscopic removal. Not all fragments at this site are IA, as some are buried in the joint capsule, and surgery can be challenging. The use of an electrocautery probe or radio frequency technology can facilitate removal. The prognosis after arthroscopic removal is good.

Larger palmar or plantar eminence fractures can result in more severe lameness in the acute phase. These are often traumatic in origin, although large OCD lesions may occur. In acute fractures heat, swelling and pain are evident at the fracture site. However, after this acute phase the degree of lameness may be minimal, although there is usually some obvious thickening of the area. Intra-articular fragments require surgical treatment if athletic soundness is required. Lag screw fixation can be performed if the fragment is large and acute. In many cases, by the time a diagnosis is made an obvious non-union has developed. In such cases removal using an extra-articular approach is usually indicated. The prognosis is generally good, even for larger fragments.

Chronic proliferative synovitis (villonodular synovitis)

Chronic proliferative synovitis refers to an increase in size of the bilobed synovial pad (plica) in the dorsal aspect of the fetlock joint at the distal aspect of the metacarpus. The proliferation occurs as result of **repetitive trauma** from the proximal aspect of the first phalanx that occurs with hyperextension of the fetlock during strenuous exercise. As the tissue increases in size, damage may also occur on the proximal aspect of P1, including cartilage erosion and chip fractures. The forelimbs are affected far more frequently than the hindlimbs, and chronic progressive synovitis is often an underrated cause of fetlock problems in athletic horses.

Villonodular synovitis may represent a progression of chronic proliferative synovitis, being much larger and more pedunculated. This form of the disease can usually be detected on palpation of the joint.

These horses are usually lame, but often the gait deficit is not readily detectable. Trainers may comment that the horse has been unwilling to “stretch out”, or has been reluctant to perform or “faded” during a race. The lameness is usually chronic and is frequently bilateral.

There is usually moderate to severe **pain on flexion**, and a markedly positive response to a fetlock flexion test. Intra-articular anesthesia may be required to localize the lameness to this joint. The diagnosis can usually be confirmed with radiographs and/or ultrasound. Plain radiographs reveal a characteristic dishing of the dorsal distal aspect of MC3 (“cut-out”), just distal to the level of the attachment of the joint capsule. There may also be areas of dystrophic mineralization apparent in this defect. The lesion is typically identified on lateromedial radiographs, but can be obscured if even a small amount of obliquity occurs. The opposing aspect of P1 is often roughened, or a chip fracture may be present. Ultrasonographic evaluation can also be used

to confirm the diagnosis and provide a more accurate assessment of the size of the synovial villi. In some instances contrast radiography with 50 mL air or 10–15 mL of positive contrast agent is used to confirm the diagnosis.

Non-surgical treatment, such as IA corticosteroids and alterations in training, can resolve the problem in its early stages, but is often ineffective for advanced cases. A short-term beneficial response may be observed, but clinical signs frequently recur. Arthroscopic surgery is considered the definitive treatment for this condition. The enlarged synovial membrane is removed and any lesions on P1 can also be treated at this time. The response to surgery is excellent, with some horses returning to athletic activity within 4 wk of surgery. Recurrence appears to be uncommon.

Luxation

Luxation of the fetlock joint usually occurs as a result of direct trauma, especially when a horse gets its foot trapped. Diagnosis is usually not difficult. Radiographs are indicated to determine if the luxation is exclusively the result of soft tissue disruption or if concurrent osseous lesions have occurred. Medial and lateral stressed views will confirm joint instability. Ultrasonography is used to evaluate the extent of the soft tissue injury and is the optimal way to identify less extensive collateral ligament injuries. Closed luxations are best treated by external immobilization with a fiberglass cast for up to 12 wk. The prognosis can be good, and some animals are able to resume athletic careers. Recurrent luxation and osteoarthritis are the most frequent complications. Implantation of synthetic mesh to replace the ruptured collateral ligament has been described, and may be indicated with recurrent luxations, but has also been associated with infection.

With **open luxations**, the wound should be thoroughly debrided and the joint flushed. Primary closure can be attempted, but if severe contamination has occurred then the joint is best left either partially or completely open. Casting is then required (again for up to 12 wk), although frequent changes are required until the soft tissue injuries have resolved. The prognosis for these horses is guarded, but some do become useful athletic animals. Septic arthritis, relaxation and osteoarthritis are the major limiting factors.

If severe injuries such as extensive fractures or rupture of the suspensory apparatus (*q.v.*) have occurred in association with the luxation, then arthrodesis may be indicated, either as the initial management option or later when any soft tissue lesions have resolved.

Palmar/plantar condylar necrosis

Subchondral bone damage in the **distal palmar aspect of MC3** has been identified as an athletic injury. Originally considered to be a manifestation of osteochondritis dissecans (OCD), these lesions appear to develop due to focal impact from the base of the proximal sesamoids during strenuous exercise. Young horses are most often affected, and are presented for severe lameness that has often recurred despite rest or other treatments. A diagnosis is made based on clinical signs, response to intrasynovial anesthesia, and radiography. Scintigraphy is very sensitive at detecting these lesions in the early stages. Linear or crescent-shaped lucencies (“flattening”) of the palmar or plantar

aspect of the condyles are usually identified on the flexed lateromedial radiographic projection or can be seen on the 125° dorsodistal–palmaroproximal or flexed dorsopalmar/plantar views. The flattening corresponds to severe cartilage erosion and subchondral bone damage. Treatment is unrewarding in most cases, and a very guarded prognosis should be given.

Proximal interphalangeal (pastern) joint

Osteoarthritis of the pastern joint is also commonly referred to as degenerative joint disease, or **high ringbone**, and can be seen in any age or breed of horse. Lameness is usually chronic and low grade. There is typically a positive response to distal limb flexion. In long-standing cases there is often palpable bony enlargement around the pastern joint. Effective regional anesthesia may be achieved by desensitizing the palmar nerves at the abaxial border of the sesamoids. Intra-articular anesthesia can be used for added specificity. Radiography is required to confirm a diagnosis of osteoarthritis.

Early stages of ringbone can often be effectively managed with a combination of IA medication, low dose NSAID therapy and ensuring that the horse is shod correctly with a **well-balanced foot**. A good response will often be obtained initially with this therapy, particularly with IA corticosteroids and hyaluronan. Repeated medication will be required for long-term management. Surgery, consisting of arthrodesis, can provide permanent relief. Arthrodesis can be performed using a number of different surgical techniques. One technique involves placing three parallel 5.5 mm diameter lag screws across the joint space. The screws enter the distal dorsal aspect of P1 and exit through the caudal proximal aspect of P2. Postoperatively the leg is placed in a cast for several weeks.

Fractures

Chip fractures are diagnosed infrequently in the pastern. Any aspect of the pastern can be affected. Most cases appear to be the result of direct trauma, but OCD may also produce fragmentation. A chronic, low-grade lameness is usually present. If the fracture is dorsal, lateral or medial, some swelling may be evident. Many of these fractures result in non-unions, and if lameness persists after rest, surgical removal is indicated. This can be done via arthroscopy or arthrotomy, depending on location and size. The most common complication is long-term osteoarthritis, even though the joint may appear to be relatively healthy at the time of surgery. In severe cases arthrodesis may be indicated.

Osteochondrosis

OCD (*q.v.*) should be considered in the differential diagnosis in young horses, particularly when more than one joint is affected. OCD of the pastern can be very painful and rapidly progress to severe osteoarthritis. Conservative therapy of pastern OCD is usually unrewarding. Most horses require arthrodesis if lameness is to be resolved. Bone cysts can also be found, and multiple cysts are often associated with severe osteoarthritis. The prognosis for these is also poor without arthrodesis as surgical access is very difficult, if not impossible. An extra-articular approach is often the best means of surgically debriding these cysts.

Luxation

Luxation of the pastern joint usually occurs as a result of acute trauma. These are usually medial or lateral luxations. Acute cases that can be reduced effectively can be treated by cast application. However, the results are disappointing. Most pastern luxations either cannot be reduced by closed manipulation or reluxate readily after reduction. Surgical arthrodesis is therefore considered the treatment of choice. Many cases will spontaneously ankylose over a period of 2–4 yr if surgery is not performed.

Subluxation

Subluxation (dorsal or palmar/plantar) can also occur, and is more common in the hindlegs and in younger horses. The etiology is uncertain, but may be related to flexural deformities or deep digital flexor tendon (DDFT) contracture. Subluxation can also occur as a result of reduced weight bearing due to chronic lower limb pain or as a result of acute trauma.

A surgical technique that involves severing the medial head of the DDFT in the hindleg has been reported for resolving dorsal subluxation associated with excessive tension on the DDFT. Conservative treatment can also be effective and includes ensuring relief from low-grade pain if present and dietary management, ensuring that a well-balanced ration is provided and that rapid growth rates are avoided. Arthrodesis provides definitive management.

Distal interphalangeal (coffin) joint

See Diseases of the foot (*q.v.*).

Sacroiliac joint (sacroiliac subluxation/strain/osteoarthritis)

The sacroiliac joint is a true diarthrodial joint although it has virtually no movement and the joint cavity is only a cleft. It is stabilized by the dorsal interosseous and ventral **sacroiliac ligaments**, the sacrosiatic ligament and the iliolumbar ligament. This joint provides the attachment between the pelvis and the axial skeleton, and as such it has to transfer both weight-bearing and propulsive forces.

Injury to the sacroiliac joint is a common problem and source of lameness, particularly in Standardbred racehorses, but diagnosis is challenging. Stresses that produce joint motion may produce subluxation of the joint. These include falls or repeated trauma from strenuous exercise. Apparent prominence and asymmetry of the tuber sacrale reflects previous injury to the sacroiliac joints (**hunter's bump**) or muscle atrophy.

Definitive diagnosis is very difficult. In the **acute stage** of injury the horse is usually lame. Lameness may be manifest as a bilateral shortness of stride or unilateral lameness. Pain can often be elicited with manual pressure applied over one or both tubera sacrale or the surrounding muscles.

A technique for ultrasound-guided **periarticular** administration of local anesthetic has been described to facilitate confirmation that the sacroiliac joint is the source of lameness. This same approach can be used to inject corticosteroids therapeutically. Nuclear **scintigraphy** can be helpful diagnostically in equivocal cases. Ultrasonography is useful to detect damage to the dorsal

sacroiliac ligament or to rule out pelvic fractures. A rectal examination can be used to detect crepitus associated with the subluxation, and to obtain ultrasound images of the ventral sacroiliac ligaments. Radiographs may be required to evaluate associated pelvic fractures.

Lameness can resolve with prolonged rest although some asymmetry with protrusion of one or both tubera sacrale is likely to persist. Asymmetry of the tubera sacrale should be differentiated from muscle atrophy, and many horses with asymmetry do not have sacroiliac subluxation. The prognosis is poor for full recovery due to risk of repeated injury, and return to work should be regulated to minimize this risk.

Chronic pain associated with the sacroiliac joints can result in poor hindlimb impulsion with a tendency to move closely or to plait behind, reluctance to jump, a history of poor performance or much less commonly overt lameness. Other potential causes of lameness should be eliminated before diagnosing this condition. Scintigraphy is particularly valuable for facilitating diagnosis, but images should be interpreted conservatively. Occasionally, irregular widening of the sacroiliac joints can be appreciated radiographically, with or without new bone formation on the caudal aspect of the joint. This may be associated with enlargement of the articular surfaces. Ultrasonography may also be useful for assessment of the dorsal sacroiliac ligament. Affected horses are usually best kept as fit and well muscled as possible and may respond to long-term NSAID therapy. The presence of radiographic abnormalities warrants a guarded prognosis.

Coxofemoral (hip) joint

Abnormalities of the hip joint are infrequently diagnosed in the horse, but **many may be overlooked** due to difficulties associated with localizing lameness in this area. Diagnosis usually relies on the exclusion of lower limb problems, the presence of muscle wasting around the pelvis, and radiography, ultrasound or nuclear scintigraphy. Intra-articular anesthesia can be used to localize the lesion; however, it is a difficult block to perform and ultrasound guidance is often warranted.

The most frequently reported problem is **fracture of the pelvis** (*q.v.*) extending into the acetabulum. This results in moderate to severe lameness, and profound muscle wasting soon develops. Scintigraphy can be valuable, but can also provide false negative results. Pelvic radiography may be required to confirm the presence of an IA fracture, but the risk of recovery from anesthesia often precludes obtaining radiographs in the acute phase of injury. Ultrasound provides a valuable alternative for evaluating the acetabulum and pelvis. Rest for up to 6 mo may result in improvement in some cases; however, the majority of horses remain lame with severe muscle wasting.

Osteochondrosis (*q.v.*) has been reported in the coxofemoral joint. Conservative treatment is frequently used; however, arthroscopic examination of this joint has been described and may improve the outcome. In general, OCD of this joint appears to carry a poor prognosis.

Other conditions include **luxation** of the coxofemoral joint. Luxation is seen more commonly in **miniature horses**, ponies and younger horses. The condition occurs much less frequently in horses than in other species, presumably due to the unique anatomy of the equine hip including an accessory ligament

of the head of the femur. When luxation does occur, the prognosis for recovery is generally poor. Some luxations can be reduced under general anesthesia, but this is ineffective if the rim of the acetabulum is fractured. In appropriate cases, such as miniature horses, femoral head resection can result in a satisfactory outcome, and several other stabilization techniques have also been described for these patients. Osteoarthritis, hip dysplasia, round ligament rupture and joint infection are infrequently observed and also carry a poor prognosis.

Genual (stifle) joint

The stifle is a complex joint that consists of three compartments: the femoropatellar and the medial and lateral femorotibial joints. Diagnosis of stifle abnormalities currently relies on clinical signs including the presence of joint effusion, response to IA anesthesia, ultrasound, radiography and diagnostic arthroscopy. The femoropatellar and medial femorotibial joints communicate in most animals; however, to ensure that adequate local anesthesia has occurred, they may need to be blocked separately. The femoropatellar joint is routinely blocked by injection either medial or lateral to the middle patellar ligament below the patella, but can also be blocked using a lateral approach. The medial femorotibial joint is approached between the medial patellar and the medial collateral ligaments 1–2 cm proximal to the tibia. The lateral femorotibial joint is injected caudal to the lateral patellar ligament or caudal to the long digital extensor tendon just proximal to the tibial plateau.

Osteochondrosis

Osteochondrosis (*q.v.*) **of the stifle** most frequently affects the lateral trochlear ridge of the distal femur, but other sites can be affected, including the medial trochlear ridge, the intertrochlear groove and the patella. Most horses with OCD present for effusion and/or lameness. Radiography and ultrasound are used to confirm the diagnosis. Radiography can reveal a similar clinically silent lesion in the contralateral limb. **Arthroscopic debridement** has significantly improved the outcome over conservative management techniques. However, success rates are dependent on case selection. When there is no evidence of associated osteoarthritis, the lameness associated with osteochondrosis will often improve dramatically shortly after surgery, with resolution of effusion occurring soon after.

Osseous cyst-like lesions

Subchondral bone cysts are most frequently identified in the medial femoral condyle. The lateral condyle and proximal tibia are infrequently affected. Cysts are commonly detected bilaterally. Conservative therapy may be successful in managing small cysts or those with minimal articular involvement. However, the success rate for animals returning to full athletic function may be as low as 20%. An **arthroscopic approach** is recommended for surgical management. The cyst is opened, evacuated and curetted back to healthy subchondral bone. Cancellous bone grafts used to pack the cyst defect following arthroscopic surgery have not improved the surgical prognosis, and forage has been associated with postoperative enlargement of the cyst. Unfortunately, surgical management has failed to return many horses to athletic performance, and treatment

with intralesional injection of corticosteroids has recently been advocated. While this may limit the growth of cysts in young horses and provide short-term relief from lameness, it is less successful in resolving well-established cysts. Newer resurfacing techniques including a combination of bone and chondrocyte grafting with growth factor administration or autogenous stem cell injections may provide better surgical outcomes.

Upward fixation of the patella

Upward fixation of the patella occurs when the medial patellar ligament hooks over the medial trochlear ridge of the femur. Affected horses are unable to flex the limb. The etiology is obscure but appears to be related to conformation, the age and condition of the horse, and poor muscle tone. Horses in very **poor condition**, as well as young horses and those with a straight hindlimb conformation, are predisposed to upward fixation.

Diagnosis is based on the characteristic appearance of the horse, which **maintains the leg in extension with the fetlock flexed**. The condition can be bilateral. Flexion can occur suddenly as the ligament is dislodged, and the condition should not be confused with stringhalt. Subtle forms of this problem consisting of **delayed patellar release** or **intermittent upward fixation** can be more difficult to diagnose. Horses can be worked on an incline to detect any hesitation or jerky movement of the patella. Radiographs and a complete ultrasound evaluation should be performed to rule out concurrent problems including fractures and patellar ligament desmitis.

Treatment of upward fixation of the patella consists of **improving muscle tone** where possible, either by improving the overall condition of the horse, or by exercise to improve quadriceps femoris muscle tone.

In young horses, aggressive treatment should be delayed to determine if the horse will grow out of the problem. Injection of a **counterirritant**, usually 2% iodine based in almond oil, or a **sclerosing agent** such as 5% ethanolamine oleate, into the middle and medial patellar ligament and quadriceps muscles has been used very effectively to reduce ligamentous laxity. Other clinicians inject the medial patellar ligament and distal area of muscle with dexamethasone. The use of conjugated estrogens, which presumably act to reduce ligament tension, has also been found to be effective. Estradiol benzoate or estradiol cypionate (10 mg/450 kg) is administered IM once a week for 4–5 wk to treat this condition. **Most horses will respond to conservative treatment.**

In severe cases in which the patella remains locked, injection of 20–30 mL of **local anesthetic** into and around the medial patellar ligament will often resolve the immediate problem.

In non-responsive or recurrent cases **surgery** should be considered. This consists of cutting the medial patellar ligament. This is best done in the standing horse under local anesthesia, so that the medial ligament is clearly defined. The response to this surgery is usually very good, but the surgery has been associated with patellar instability and subsequent development of apical patellar fractures. Because of the potential for patellar instability after this surgery, the horse should be rested for 6–8 wk, and gradually reintroduced into training. One of the major complications of this surgery is fragmentation of the articular cartilage and subchondral bone at the apex of the patella, in the region of attachment of the middle patellar ligament (*q.v.*). This occurs as

a result of altered biomechanical forces induced by sectioning of the medial patellar ligament. Affected horses have an effusion and low-grade lameness. Arthroscopic surgery is required to remove the fragments if the clinical signs are to resolve (*q.v.*). For this reason medial patellar desmotomy should only be undertaken when non-invasive treatments have failed or when severe clinical signs are present.

An alternative surgical approach has been described in which the proximal third of the medial patellar ligament is split percutaneously to induce a localized desmitis and thickening. The technique has been shown to be effective and allows rapid return to normal activity following surgery.

Luxation and/or subluxation of the patella

Luxation and/or subluxation of the patella, usually in a lateral direction, is seen most often in ponies and miniature breeds of horses, and it is usually **congenital**. With luxation, the quadriceps femoris is disarmed and the foal is unable to lock the stifle joint, resulting in a very characteristic crouching stance. Palpation and radiography will indicate that a luxation has occurred.

Treatment consists of **surgical imbrication** of the fascia on the side opposite to the luxation, with a release incision on the side of the luxation. Trochleoplasty may also be required with trochlear hypoplasia. The prognosis is guarded. Severe OCD lesions of the trochlear ridges can predispose to this problem, but usually only a subluxation will occur with OCD-induced luxation.

Meniscal and cruciate injuries

Meniscal and cruciate injuries usually result in chronic lameness that can be difficult to diagnose and to manage. A preliminary diagnosis can be made on the basis of IA anesthesia as well as radiographic and ultrasonographic imaging studies. Arthroscopy should be used to confirm the diagnosis, and can often provide a more accurate prognosis for the horse. In selected cases meniscal tears can be effectively managed following arthroscopic trimming providing osteoarthritis has not progressed too far.

Osteoarthritis of the patella

Osteoarthritis is seen predominantly in older horses and is commonly a result of trauma or chronic soft tissue injuries, such as collateral ligament or meniscal damage. Some cases benefit from arthroscopic surgery and follow-up corticosteroid medication.

Tarsus (hock)

The hock is a complex articulation comprising numerous joints including the **tarsocrural**, **talocalcaneal**, **proximal and distal intertarsal** (talocalcaneal-centroquartal, centrodistal) and **tarsometatarsal** joints. The tarsocrural and proximal intertarsal joints reliably communicate. The proximal and distal intertarsal joints also communicate in some horses, but this does not guarantee that medication will flow readily from one joint to another.

Most movement in the hock occurs in the tarsocrural joint, which also has the largest joint space. Very little movement occurs in the lower joints. The different joints will be discussed separately.

The tarsocrural joint

Osteochondrosis

The tarsocrural joint comprises the articulation between the distal tibia and the talus (tibial tarsal bone) and calcaneus (fibular tarsal bone). The most commonly detected abnormality in this joint in young horses is **OCD** (*q.v.*). Sites of occurrence in decreasing order of frequency are the **distal intermediate ridge of the tibia**, the **lateral trochlear ridge** of the talus, the **medial malleolus** of the tibia, and the **medial trochlear ridge** of the talus. Affected horses typically present for joint effusion (**bog spavin**), with varying degrees of lameness. Radiography will usually reveal characteristic OCD lesions. The contralateral leg should routinely be radiographed.

The success rate for treatment using conservative or surgical therapy is similar to that seen with OCD in other joints. Conservative therapy, consisting of confinement and dietary management, can result in resolution of clinical signs in approximately 40% of horses. However, many horses will continue to have joint effusion for long periods of time, and osteoarthritis (*q.v.*) can develop.

Osteochondritis dissecans lesions (*q.v.*) are readily operated on, usually using **arthroscopic** techniques. Surgery will be successful in resolving the effusion and lameness in >80% of joints, depending on the location of the lesion and severity of any associated cartilage damage. The **contralateral limb** should be examined arthroscopically if joint effusion is present without radiographic signs, or if radiographic lesions are present without clinical abnormalities. Following removal, resolution of clinical signs of effusion usually takes 4–6 wk. In some horses effusion persists, and IA hyaluronan and/or a corticosteroid may be required.

When OCD lesions are detected in **young horses** (i.e. yearlings) prior to training, the lesions should be removed, even if no associated clinical signs are evident. Left untreated, these lesions can predispose to the development of wear lines and full thickness cartilage erosion once training commences. The secondary changes are often of more consequence than the original OCD lesion.

Effusion in the tarsocrural joint, commonly referred to as **bog spavin** (*q.v.*), can occur in any age or breed of horse. Osteochondritis dissecans is the most frequent cause of bog spavin in younger horses, but in the absence of OCD, the etiology is frequently obscure. Chronic effusion can also occur subsequent to trauma, or septic arthritis (*q.v.*). Resolution of a chronic bog spavin can be difficult even when no underlying pathology can be identified. Confinement and systemic anti-inflammatory therapy may decrease the effusion, but it will frequently recur once treatment is discontinued. Intra-articular corticosteroid, atropine and hyaluronan therapy (*q.v.*) following drainage of the effusion may be successful in resolving the effusion. In refractory cases arthroscopic examination of the joint is indicated.

Fractures

Other abnormalities in the tarsocrural joint are uncommon. **Intra-articular fractures**, luxations and lacerations are seen as a result of trauma. Osteochondral fractures of the lateral malleolus are usually an indication of joint trauma, not of OCD. Treatment of these fractures may require internal fixation if large fragments have occurred, but removal of smaller fragments is recommended. Often

the position and size of the fragment and extensive soft tissue attachments mean that an arthrotomy directly over the fragment is required for removal. The prognosis can be good, but if there has been significant soft tissue trauma associated with the fracture osteoarthritis can develop. There can also be partial subluxation of the joint at the time of fracture, resulting in collateral ligament damage and secondary new bone formation, and ultrasound evaluation is warranted.

The proximal intertarsal joint

The **proximal intertarsal** joint contributes only a small amount of movement and few isolated abnormalities occur. A small portion of this articulation can be examined arthroscopically from the tarsocrural joint. It is relatively common for osteoarthritis of the distal joints to simultaneously affect the proximal intertarsal joint and this can be difficult to manage. Treatment is aimed at controlling clinical signs through the use of IA medication, but the tarsocrural joint will also be exposed to the medication. Arthrodesis of this joint is usually not recommended.

Fractures of the central tarsal bone

Fractures of the **central tarsal bone** occur infrequently, and detection may require multiple radiographic views or nuclear scintigraphy. Conservative treatment of non-displaced fractures has been reported to produce satisfactory results, but can result in non-union and osteoarthritis. Lag screw fixation or a technique using a cannulated self-compressing screw can be successful, providing displacement is minimal.

The distal intertarsal (centrodistal) and tarsometatarsal joints

The **distal intertarsal (centrodistal) and tarsometatarsal joints** primarily consist of the articulations between the central and third tarsal bones, and the second, third and fourth tarsal bones and metatarsal bones, respectively. They are both “**low motion**” joints.

Osteoarthritis (bone spavin)

The primary problem detected in the distal tarsal joints is **osteoarthritis**, or **bone spavin** (*q.v.*). This condition presumably results from **repetitive trauma** to the articular surfaces, and is seen most commonly in racing and western performance horses, particularly Standardbreds and Quarter Horses. Older horses are most frequently affected, and poor hindlimb conformation appears to be a significant risk factor. However, younger horses that have had only light training are sometimes affected and in these animals it is likely that the changes are a manifestation of developmental orthopedic disease such as incomplete ossification of the tarsal bones (*q.v.*).

Affected horses most often present because of **hindlimb lameness**; however, the presenting complaint may be of **back pain** or **poor performance**. Pacers and trotters may lose their gait (“break”) and gallop during races. Some horses have extensive new bone production medially (**Jack spavin**) and may respond to manual pressure over the medial joint surface (a “**Churchill test**”).

A “**spavin test**”, in which the hock is flexed for 1.5–2 min before the horse is trotted off, is a useful means of precipitating lameness. If osteoarthritis is suspected, diagnostic IA anesthesia (*q.v.*) is indicated. This is achieved by

injection into the tarsometatarsal joint immediately proximal to the head of the fourth metatarsal bone, while the distal intertarsal joint can be anesthetized through the space formed by the fused first and second tarsal bones and the third and central tarsal bones. Local anesthesia is important in confirming the hock as a site of lameness.

If a diagnosis is made early in the course of the disease, radiographic signs may be absent or minimal. This is occasionally referred to as **blind** or **occult spavin**. As the disease progresses, radiographic evidence of osteoarthritis often becomes apparent in these horses. Radiographic evidence of osteoarthritis includes the formation of spurring of the articular margins, subchondral bone lysis and sclerosis and decrease in width of the joint space; osteoarthritis can eventually progress to complete obliteration of the joint spaces.

Treatment is dependent on the severity of abnormalities, and the age and expected use of the horse. Initial treatment is aimed at controlling the clinical signs associated with the disease. This can often be satisfactorily achieved with IA injection of a long-acting corticosteroid. Injection of 120–200 mg of **methylprednisolone acetate** often results in improvement in clinical signs for between 1 and 6 mo. Addition of hyaluronan or PSGAGs to the injection is not routinely recommended, primarily due to space limitations in these joints. Corrective shoeing is occasionally advised. This usually consists of elevating the heels and rolling the toe; however, the contribution of these changes to improvement in clinical signs is uncertain. **Ankylosis** can occur in some joints, but this is difficult to predict and may take many years to occur.

When medical therapy fails to give satisfactory results, **arthrodesis** of the joint may be indicated. Both the distal intertarsal and tarsometatarsal joints are routinely fused, even if radiographic abnormalities are present in only one site at the time of surgery. Surgical arthrodesis is best achieved by drilling three holes across the articular spaces from a single entry point. A medial approach is used for this technique and a cunean tenectomy is usually performed simultaneously. Postoperative analgesics are used for up to 6 wk, and a controlled exercise program instituted to promote arthrodesis. Rapid improvement in clinical signs is seen in some cases. Stabilization usually occurs within 6 mo, but up to 12 mo may be required before complete freedom from lameness is evident. A laser technique has also been described for arthrodesis of the distal tarsal joints.

Chemical ankylosis with injection of sodium monoiodoacetate into the affected joints has been suggested as an alternative technique. The recommended dose rate is 100 mg diluted in 2 mL injected IA. Arthrodesis usually occurs within 6 mo, but again, up to 12 mo may be required. However, this procedure has been associated with several potentially serious complications. Prior to injection, contrast studies must be performed to ensure there is no communication between the distal and proximal hock joints or tarsal sheath and also to confirm that the needle is in the joint. The technique can be very painful, and appropriate analgesia including epidural morphine is necessary. Incorrect preparation or storage of the sodium monoiodoacetate can also create problems, and severe sepsis and degeneration can result. Due to the severity of these complications this procedure is not currently recommended.

Other treatments that are used in managing osteoarthritis of the distal tarsal joints include cunean tenectomy, extracorporeal shock wave therapy, and partial tibial and deep peroneal neurectomy. The prognosis for athletic

performance with spavin is guarded, which may explain the large number of different management techniques that have been advocated.

Osteoarthritis can also affect any of the other articulations of the hock, including the tarsocrural joint and the talocalcaneal joint.

Fractures of the third tarsal bone

Fractures of the **third tarsal bone** occur infrequently. They are usually managed in a similar fashion to central tarsal bone fractures (*q.v.*); however, arthrodesis of the distal intertarsal and tarsometatarsal joint can also provide good results if there is not excessive instability of the fracture fragment.

Tarsal bone collapse

Tarsal bone collapse or incomplete/defective ossification of the carpal and tarsal bones (*q.v.*) is a condition usually diagnosed in young foals, in which the third, central or both tarsal bones are crushed and displaced cranially. There can be considerable variation in the severity of this condition. Less severely affected cases may not be diagnosed until training commences, and in some cases a degree of athletic soundness can be achieved with IA medication. The etiology appears to be related to prematurity/dysmaturity and associated incomplete ossification of the central and third tarsal bones at birth. Affected foals may be reluctant to stand, have angular limb deformities, or run with a bunny-hopping gait. Radiography is necessary for an accurate diagnosis. Treatment is limited to minimizing the severity of the changes by supporting the limb with splints or tube casts. Ankylosis may eventually occur; however, most foals have a poor prognosis for long-term soundness.

Tarsal luxation

Luxation of the hock can occur as a result of traumatic damage to one or more joints. Fractures are frequently present with tarsocrural luxations, while severe soft tissue damage occurs with luxation of the distal joints. Treatment is dependent on the amount of stability present at the time of examination. If obvious instability is present, internal fixation may be indicated. If the joint can be reduced and is reasonably stable, which is often the case with luxation of the lower joints, then application of a full limb fiberglass cast can be effective. Many joints subsequently undergo ankylosis, but some horses can continue to be athletes when only the lower joints are affected.

DISEASES OF THE FOOT

INTRODUCTION

The foot is the **most common site of lameness** in horses of all types and activities. Although the hoof is relatively strong, the ratio of a horse's body weight to the weight-bearing surface of the feet is very high, and as a result each foot is continually subject to concussion, stress and trauma.

To understand, diagnose and treat conditions of the foot it is important to have a sound knowledge of its functional anatomy and physiology. Developing a technique of careful, methodical and thorough examination of the foot is of great value in diagnosis. The foot is not an easy structure to examine because

it is encased in a relatively rigid outer hoof capsule and it is necessary for the clinician to develop skills in the use of hoof testers, hammer and hoof knife. In many cases, alterations in the hoof capsule offer clues to underlying problems and these can be detected with careful observation. A fairly consistent indication that there may be a problem is **increased heat** in the foot or feet and/or **increased digital pulses**. The extent of the increase is often related to the severity of the inflammation produced by the underlying condition.

It is also important to have a good appreciation and understanding of the **art and science of farriery** and the value of corrective and therapeutic shoeing as part of the treatment of all kinds of lameness. A good working relationship and communication between the veterinarian and farrier is essential for prevention and treatment of lameness.

LAMENESS DIRECTLY ASSOCIATED WITH TRIMMING AND SHOEING

Quicking (nail prick, hot nail)

Quicking occurs at shoeing when a nail penetrates the sensitive structures of the foot. It occurs most commonly if the horse is restless or fractious, the hoof wall is particularly thin, broken or flared, the shoe is too small, too large a nail has been selected, and/or the nail is simply misdirected.

Clinical signs

Pain and hemorrhage may occur at the time of penetration or when the nail is clinched. Lameness, if present, usually occurs immediately and may persist for 24–48 h accompanied by pain on percussion over the affected area. If infection occurs, the lameness will increase over a 24–48 h period.

Diagnosis

Diagnosis is based on clinical signs and an associated history of recent shoeing. Hoof tester evaluation can be used to locate the offending nail.

Treatment

Quicking rarely gives rise to serious complications. Once the nail is removed and the nail hole irrigated with an antiseptic such as **povidone-iodine**, additional treatment is usually not necessary and lameness will subside after 2–3 days. Appropriate tetanus vaccination status (*q.v.*) should be confirmed. If the hole is infected it is important to establish adequate **drainage**.

Close nail (nail bind)

A close nail occurs when the nail of the shoe is driven close to, but not into, the sensitive structures of the foot resulting in pressure, inflammation and discomfort. A properly placed nail can also cause the problem if the shoe shifts, causing pressure on adjacent sensitive structures.

Clinical signs

Lameness is rare at the time of shoeing, but becomes apparent within 1–4 days. Pain can often be elicited with percussion or hoof tester pressure over the

clinch of the offending nail, and frequently that nail will emerge through the hoof wall slightly higher than the other nails. A close nail rarely results in infection.

Diagnosis

Diagnosis is based on the history and clinical signs.

Treatment

The offending nail should be removed or, if this is not possible, the shoe should be removed. Lameness will usually subside within a few days. If removal of the nail is accompanied by a discharge, or if lameness persists, the wound should be treated as an abscess (*q.v.*).

Over-lowering of the hoof wall (excessive trimming)

Varying degrees of lameness can result if the hoof wall is **trimmed too short**, i.e. below the level of the sole. In these cases lameness is the result of the sole of the foot becoming excessively weight bearing. In some cases, lameness may result from direct damage to the sensitive structures themselves during the trimming process. Over-lowering of the hoof wall is often accompanied by excessive sole trimming, which can cause damage and remodeling of the third phalanx.

Clinical signs

Lameness will be evident almost immediately, or within 24 h of trimming. The degree will vary depending on the extent of damage or pressure on the sensitive structures, and the conformation of the foot.

Clinical signs in the front feet are usually the most obvious. The horse will usually adopt a **laminitic type gait**. If more than one foot is affected this condition can look like acute laminitis.

The lameness will be increased on hard or stony ground and improved on soft ground. A pain reaction can be elicited by pressure with hoof testers over the sole. In severe cases there may be slight serum discharge at the sole/white line junction.

Diagnosis

Diagnosis is based on the history of **recent trimming**, and clinical signs.

Treatment

The horse should be rested on a soft surface or the feet can be placed in protective bandages/boots. Shoeing with a seated out shoe is advisable to take pressure off the sole. In some cases, a **rim pad** between the shoe and the hoof wall may be necessary. The rim pad, however, should not extend onto the sole. Sole pads should be avoided in these cases as they may result in increased pressure on the sole. Most cases will show a marked improvement within 1 wk; more severe cases may take longer. The prognosis for a complete return to soundness is good providing sensitive structures have not been severely damaged.

Sudden changes in hoof length and/or balance

Lameness can arise if an overgrown, neglected foot or a severely unbalanced foot is trimmed back to a normal length and balance in one trimming. The lameness is probably due to a sudden change in the stresses placed on the structures of the foot and the limb.

Clinical signs

Clinical signs will vary depending on the degree and type of change in length and balance of the foot, and the number of limbs involved. If lameness occurs it will usually be apparent very shortly after trimming and will increase if the animal is exercised.

Diagnosis

Diagnosis is based on the history of trimming of overgrown or unbalanced feet.

Treatment

One to 2 wk of paddock rest to allow the feet and limbs to adapt to the new stresses is usually all that is required. If the lameness is severe, box/stall rest and a course of NSAIDs should be given, followed by a gradually increasing controlled exercise program.

Dumping (dubbing)

Dumping is a term given to **excessive rasping** of the outside of the hoof wall, usually at the toe, but it can extend all the way around the wall. It is most often done to make the foot fit a shoe that is too small, or in an attempt to try and trim back an overlong toe, and is most commonly seen in the front feet. This should be differentiated from under cutting the toe, which is an accepted method of shortening the toe and reducing break over. Dumping has several adverse affects:

1. The cross-sectional area of the bearing surface of the hoof wall is reduced and so the shoe will come to rest on the sole, resulting in sole pressure, and the nail holes will invariably be inside the white line, resulting in a higher risk of quicking the horse.
2. If dumping is excessive at the toe or has been present for a long period of time an apparent “reverse rotation/angulation” or “**negative plane**” of the distal phalanx can occur. On lateromedial radiographs of the foot the distal border of the distal phalanx slopes downward at the heels. This results in stress on the dermal laminae at the heels.

Clinical signs

Feet that have been markedly dumped have a characteristic “bull nose” appearance when viewed from the side. The front feet are more commonly affected. Dumping does not always result in lameness. Where lameness is the result of excessive sole pressure or a hot nail, the clinical signs are as for these conditions (*q.v.*). Where it is due to stress on the dermal laminae at the heels the lameness is usually bilateral, accompanied by shortening of the anterior phase of the

stride, and increased when the animal is turned in the direction of the affected foot or feet. There may be no palpable increase in the digital pulses or heat.

A pain response can often be elicited by pressure with hoof testers on the **posterior third** of the foot. A palmar digital nerve block will reduce or abolish the lameness in most cases.

Diagnosis

Diagnosis is based on the appearance of the feet and the clinical signs. In chronic cases lateromedial radiographs may reveal “**reverse angulation**” of the distal phalanx and this is usually accompanied by a “beak-like” projection of horn at the toe of the foot.

Treatment

The shoe should be removed and the wall at the toe trimmed from the ground surface **with reference to radiographs**. The feet should then be shod with wide webbed shoes fit to prevent excessive wear of the dorsal hoof wall, full at the quarters, and the branches should extend slightly beyond the weight-bearing surface at the heels. The horse should be rested until the lameness subsides and then started on a gradually increasing exercise program.

Prognosis is generally good providing the condition has not been present for a long period of time and permanent changes have not occurred in the dermal laminae or distal phalanx.

CONDITIONS OF THE HOOF CAPSULE

Hoof wall cracks

Cracks in the hoof wall can be divided into two categories based on site of origin:

1. Cracks that originate at the **ground surface**, often referred to as **sand cracks**. These rarely extend to the coronary band, involve the deeper structures of the foot or result in lameness. They are usually due to hoof wall overgrowth, training barefoot on hard surfaces, or excessive drying of the hoof, and they frequently involve more than one foot.
2. Cracks that originate at the **coronary band**. These can extend part way down the wall (**incomplete**) or all the way down to the ground surface (**complete**). They can arise due to injury to the coronary band but more commonly they are the result of abnormal stress on the coronary band from hoof imbalance, an overlong concave dorsal hoof wall, or excessive concussion.

In addition to being classified by their site of origin and length, cracks are also characterized by their location at the **toe, quarter, heel or bar**, by orientation with **vertical** and **horizontal** cracks, and by their depth, being either **superficial or deep**. Unstable cracks can cause hemorrhage and can result in infection.

Clinical signs

A **hoof wall crack** is usually obvious on visual inspection of the hoof, but the hoof often fails internally before the crack is visible on the external surface (**blind crack**). Many hoof cracks do not result in lameness, unless the crack is

deep and extensive enough to allow movement of the edges, which causes pinching of the underlying laminar corium, or if the crack becomes infected.

There is often a painful response to pressure applied along the coronary band above the crack, or when hoof testers are applied in the region of the crack. Hoof testers can also be used to assess the degree of instability of the crack. **Hemorrhage** may be evident from the crack, especially after exercise, and bleeding indicates involvement of the sensitive laminae. Purulent discharge indicates infection of underlying structures.

Diagnosis

Diagnosis is based on the clinical signs including response to diagnostic analgesia. In long-standing hoof cracks, or where there is infection, radiograph the distal phalanx for evidence of bone resorption or osteomyelitis, which would affect prognosis.

Treatment

Treatment varies with the location of the crack, the degree to which the crack has invaded sensitive tissues, and whether or not the crack is infected. Small cracks extending from the ground surface of the foot usually only require trimming, balancing and shoeing of the affected foot or feet.

Treatment of larger, **incomplete cracks** is aimed at preventing the crack from extending any further while it grows out, and involves trimming and balancing the foot, **floating** the hoof wall below the crack and shoeing with a bar shoe. The term “floating” refers to trimming the ground surface of the displaced heel shorter than the rest of the hoof wall so that it will not bear on the shoe. This allows transfer of load away from the crack to the frog and remaining wall. Some individuals recommend grooving a **horizontal line** in the hoof wall across the end of the crack; however, this is often not successful in preventing progression of the crack. The technique may be more successful when the hoof is grooved with a **hot file**.

With **superficial cracks**, if the foot is balanced and the horse restricted from strenuous activity, shoeing with a bar shoe will often resolve the problem. With deeper incomplete cracks one of the stabilization methods described for complete cracks may be required.

Treatment of a **complete crack** is aimed at stabilizing the crack to allow solid wall growth from the coronary band. The foot should be trimmed and balanced and breakover eased. The crack should then be pared out to its full depth and length to expose and remove any necrotic or infected tissue and to prevent overlapping of the edges, which would perpetuate the crack. **Heel cracks** are typically associated with proximal displacement of the heel bulb on the side of the crack and can often be managed by floating (*q.v.*) the heel on that side and shoeing the horse with a complete bar shoe or a heart-bar shoe.

Similarly, with **quarter cracks**, the location of the crack typically corresponds to a raised area in the contour of the hairline at the coronary band. Lowering the wall under the crack allows the heel to relax down into a more normal position, encourages normal hoof growth at the coronary band, and reduces the shearing forces that originally created the crack. Removing the shoe, floating the heel and applying frog pressure with a frog support pad for

24–48 h before reapplying a shoe will often allow the raised area to straighten out (relax). Soaking the feet or applying moist bandages can facilitate this process.

The most common techniques for treating a hoof with a complete crack include a combination of a **bar shoe** and **frog support**. In some cases a method of supplemental wall stabilization is required to immobilize the crack. These should generally be applied/tightened with the foot weight-bearing in the case of a toe crack and non-weight-bearing in the case of a quarter crack.

Stabilizing techniques include:

1. A contoured metal plate technique in which one or two plates or sections of hose-clamp are screwed to the hoof wall and tightened.
2. A drill and wire or lace technique done either in a shoelace pattern through holes drilled in the hoof wall at right angles to the crack, or in a figure of eight pattern through two staggered holes drilled in the hoof wall, starting at the ground surface and running upwards, on either side of and parallel to the crack. This technique is most effective for incomplete cracks that do not extend up to the coronary band.
3. Staples placed through the insensitive hoof wall at right angles to the crack.
4. Acrylic hoof wall repair or patching. This should only be performed **after all infection has been resolved**, and the sensitive structures have begun to cornify. In most cases patching is not necessary and can be avoided to prevent complications. When it is performed, the crack is opened to its full depth and length and filled with hoof repair material such as Equilox. A number of synthetic hoof repair materials that bond to the hoof wall have been developed, and some of these materials mimic the consistency of the hoof wall. A pipe cleaner can be used to create a space under the acrylic to allow for drainage of any residual infection, and antibiotics can also be incorporated in the repair material. Because of the high temperatures created during the hardening process of many hoof repair materials they should not be applied directly to sensitive structures, and care should be taken to cool the foot during the hardening process. Some of the newer products such as Equi-Thane Adhere are not as exothermic. A patch of hoof repair material, or a plate and screws, should be applied across the filled crack to strengthen the repair.

The length of time required for healing of a crack is related to the rate of growth of new hoof wall from the coronary band, which is approximately 0.6 cm/mo. In some cases complete healing may take a year or longer.

The prognosis is good for complete healing of superficial cracks not involving the coronary band and for early, uncomplicated cracks involving the coronary band. For long-standing cracks, infected cracks, or cracks accompanied by deformity of the coronary band, the prognosis for complete healing is not as good, and recurrence is common. Identifying and eliminating the biomechanical cause of the crack will reduce the recurrence rate.

Corns

Corns are **bruises** of the sensitive corium and the sole at the angle between the wall and the bars (the “seat of corn”). They are most common in the medial angle of the front feet.

Etiology

The underlying problem when corns develop is that an isolated section of the sole and not the adjacent hoof wall, bars or other supporting structures is receiving pressure during weight bearing. Common causes are:

1. The shoe is left on for too long and, as the foot grows, the heel branches of the shoe are progressively pulled forward off the wall onto the angle of the sole.
2. Improper shoeing, particularly if the shoe is fit short and tight at the heels to prevent the horse from inadvertently pulling the shoe.
3. Excessive weight bearing at the heels, such as the horse with low heels, or the addition of heel calks or studs to the shoe.
4. The heels have been left long and allowed to run forward in an effort to align the pastern.
5. Crushed heels accompanied by a “negative third phalanx plane” in which the distal border of the third phalanx slopes downward at the heels.

Chronic corns can also develop when the wall at the heels is so low and weak that it collapses inward and puts pressure on the “seat of corn”, and chronic corns are also detected during the early stages of ossification of the collateral cartilages (sidebone) (*q.v.*).

Clinical signs

The degree of lameness varies depending on the severity of the bruising. Usually there will be bilateral forelimb lameness, with shortening of the anterior phase of the stride and a toe-first landing. Lameness will typically increase with circling and on a hard or uneven surface, and decrease on a soft surface. After removal of the shoe and light paring of the sole, bruising may be evident at the angle between the wall and the bars. Most horses show a pain reaction to gentle pressure in this area.

Corns can be:

1. **Dry**—the surface of the horn is dry but stained red, brown or yellow
2. **Moist**—with more severe bruising the horn over the corn area is moist due to serum seepage from the damaged corium beneath it
3. **Suppurating**—if the corn becomes infected the horn over the area may be a bluish color or there may be a discharge of pus.

Diagnosis

Diagnosis is based on the shoeing history, clinical signs and the appearance of the corn. Radiographic examination of the distal phalanx can be of value in chronic corns to ascertain whether concurrent ossification of the collateral cartilages or pedal osteitis (*q.v.*) exists.

Treatment

Where shoeing is the cause of the corn, the shoe should be removed to provide relief from pressure and pain. Removing a thin layer of sole horn over the corn relieves pressure, but paring out all of the discolored horn is unnecessary (unless suppurative) and weakens the area further. Reshoeing with a shoe fit full may be all that is required along with adequate rest. Heel calks or studs are contraindicated. Infected corns should be treated as for solar abscesses (*q.v.*).

Chronic corns due to low weak/collapsed heels can be very difficult to resolve. Hoof wall that has collapsed onto the seat of corn should be removed enough to relieve pressure. The foot should be shod with a full fit shoe and breakover facilitated. In addition, materials such as Equi-Pac or commercial dental impression material can be used to create “load sharing” with the intent of using more of the caudal sole, bars and frog for support. However, the material should be trimmed away from the bruised angle of the sole.

The prognosis for simple corns is good, but chronic corns due to collapsed heels have a more guarded prognosis.

Bruised soles

Bruised soles are bruises in the sole other than at the “seat of corn”. They are more common in the front feet.

Etiology

Bruising can be the result of direct trauma to the sole from stones or rough ground, or a displaced or small shoe. Horses with a misalignment between the hoof capsule and distal phalanx, including a clubfoot or long toe/low heel conformation, are more prone to sole bruising. In addition, excessive paring of the sole, and dropped soles following laminitis (*q.v.*), predispose the horse to bruising.

Recurrent or **chronic bruised soles** may be associated with bony changes to the distal border of the distal phalanx such as pedal osteitis (*q.v.*) or solar margin fractures. Recurrent or chronic bruising at the toe may be indicative of pain elsewhere causing the horse to overload its toe.

Clinical signs

The degree of lameness with sole bruising is quite variable. There is usually a history of sudden onset of quite severe lameness associated with a stone bruise. In cases of recurrent or chronic bruised soles there is often a history of intermittent forelimb lameness. Heat in the foot and increased digital pulse are not consistent findings. The gait adopted by the horse depends on the area affected. Careful examination of the sole may reveal discoloration/bruising in an unpigmented sole or a softer area of horn in a pigmented sole. This discoloration may take several weeks or longer to reach the solar surface, and if the trauma is very recent these changes may not be apparent. **Pain reaction** can usually be elicited by finger pressure or gentle pressure with hoof testers, in the area of the bruise.

Diagnosis

Diagnosis is based on the history, clinical signs and foot conformation, but differentiating sole bruising from other causes of foot lameness can be very challenging.

Radiographic examination of the distal extremity is advisable in cases of persistent severe lameness to rule out fractures or other pathology. In cases of recurrent or chronic sole bruises **pedal osteitis** (*q.v.*) may be detected.

Treatment

Rest is the best form of treatment if the bruise is the result of a single traumatic incident. In cases of recurrent or chronic bruised soles, any predisposing foot

conformation abnormalities should be corrected when possible. The farrier should trim the hoof and place the shoe to bring breakover back toward the distal phalanx, and the weight-bearing surface of the heels should be “backed up” so that support is moved palmarly. Removal of any “live sole” in an effort to shorten the toe should be avoided.

The foot can be shod with a Natural Balance Shoe or with an egg-bar shoe extending back as far as the bulbs of the heels and giving support to the posterior structures of the foot. If necessary to correct the hoof-pastern axis, a **wedge pad** can be used to raise the heels, but this may further decrease the rate of heel growth and possibly contribute to further collapse of the heels. Not all cases of long toe/low heel conformation respond to corrective shoeing; allowing the horse to go barefoot may result in the fastest improvement in conformation, but a horse with sole bruises may not be able to tolerate this.

For horses that are not sensitive to hoof testers in the caudal portion of the foot, dental impression material can be used to load this part of the foot, effectively unloading the bruised front area of the foot.

The use of **complete sole pads** under the shoe has been recommended in some cases. However, if pads are applied to a flat sole they effectively bring the sole closer to the ground and possibly exacerbate the problem. Protective sole pads can also be applied by riveting them at the toe to create a void that will relieve any pressure between the pad and the sole.

The prognosis in the case of a single traumatic incident is good. With recurrent or chronic bruised soles, particularly if the feet do not respond to corrective shoeing or there is concurrent pedal osteitis, then the prognosis is guarded.

Keratoma

Keratoma (*q.v.*) is an uncommon condition involving development of an aberrant keratin mass that originates from the epidermal horn-producing cells of the hoof and extends between the hoof wall and the distal phalanx. While these masses have some clinical characteristics of a benign tumor, they are primarily composed of keratin and squamous epithelial cells.

Keratomas typically form in the epidermal laminae on the inside of the hoof wall and usually originate at or near the coronary band. As the keratoma grows distally it acts as a space-occupying mass, and the resulting pressure on the distal phalanx can cause marked bone resorption. Keratomas tend to occur in the toe or quarter and any foot can be affected.

Etiology

The majority of cases are caused by injury or chronic irritation to the coronary band. However, some cases appear to develop spontaneously, and often the cause cannot be determined.

Clinical signs

Signs vary depending on the size and position of the keratoma. The hoof wall may develop an abnormal buttress shape and lameness may or may not be present. When present, lameness appears to be due to pressure on the dermal laminae and distal phalanx from the growing mass. On examination of the foot, a deviation of the white line toward the center of the foot will often be identified. Once the keratoma has grown down to the bearing surface of the

hoof it causes a break in the continuity of the sole-wall junction that can allow infection to enter, and recurrent abscesses may develop. Pain will usually be elicited by pressure with hoof testers over the area.

Diagnosis

The initial diagnosis of keratoma is based on the clinical findings and, in particular, the deviation of the white line. Radiographic examination of the distal phalanx often reveals a focal area of osteolysis adjacent to the keratoma and increased soft tissue density of the hoof wall. CT or MRI can be used to determine the extent of the mass, and ultrasound can also be utilized to identify the origin of a keratoma at the coronary band. Differential diagnoses include true neoplastic conditions as well as septic osteitis (*q.v.*) of the distal phalanx, and the radiographic changes that occur with keratomas should also be differentiated from the normal crena found at the toe of the distal phalanx.

Treatment

Complete surgical removal of the abnormal growth is necessary and this often requires removing the entire overlying hoof wall. This can be done by making parallel cuts through the full thickness of the hoof wall on either side of the mass and reflecting the horn upward toward the coronary band. Alternatively the keratoma can be resected through a hole made in the hoof wall using a large **Galt trephine**. With either technique it is important to identify the origin of the growth and to make sure all of the aberrant tissue is removed.

Following surgery the foot should be wrapped in sterile bandages until a dry horn cuticle has formed, and then shod appropriately to address any instability created by the hoof wall resection. In some cases this will necessitate a bar shoe, in others a metal band similar to that used to treat complete hoof cracks may be required to adequately stabilize the hoof wall postoperatively.

The prognosis depends on the size of the keratoma and the extent of the damage to the surrounding structures, but is generally good. However, recurrence is expected following incomplete surgical removal.

INFECTIONS OF THE FOOT

Abscesses

Abscesses are the result of **infection** gaining entry to the soft tissues of the foot. This is commonly the result of a penetrating wound through the sole, frog or white line. Infection can also gain entry to the foot through hoof capsule defects such as sand cracks and white line separations, or pressure/traumatic injuries such as corns, sole bruises and lacerations.

The sequelae vary depending on the depth of penetration of the infection and the structures of the foot involved.

Abscesses can be divided into two general groups. **Group 1 abscesses** (sub-solar abscesses) are the result of shallow penetration of infection through the hoof capsule. Infection is trapped between the horn (epidermis) and the corium (dermis). The build-up of purulent exudate between the corium and the relatively rigid horn results in an increase in pressure in the foot, pain, and the spread of infection along the line of least resistance. Infection **under the sole** tends to spread backward toward the “seat of corn”; infection under the

wall will usually spread upward to the coronary band (**gravel**), and infection under the frog tends to spread to the heel bulb—skin junction.

Group 2 abscesses are the result of infection penetrating into the deeper structures of the foot and are potentially far more serious. Penetration of the solar surface in the anterior third can result in infection of the corium and/or distal phalanx. Infection penetrating to the middle third leads to the most serious abscesses and can result in infection of the DDFT, digital sheath, navicular bursa, navicular bone and possibly the distal interphalangeal joint. Penetration to the posterior third can result in chronic abscesses forming in the digital cushion, or infection of the collateral cartilages ("**quittor**" [*q.v.*]), while penetration to the white line can result in infection spreading up to and involving the coronary band ("**gravel**"), or to the collateral cartilages. Pain associated with group 2 abscesses is usually the result of infection and destruction of the deeper structures of the foot. These two groups are not mutually exclusive, and untreated group 1 abscesses can progress to group 2 status.

The clinical signs, diagnosis and treatment of septic navicular bursitis, septic arthritis of the distal interphalangeal joint, and quittor (*q.v.*) are covered under the appropriate headings.

Clinical signs

There will often be a history of an **acute onset of lameness**, which may or may not be associated with a known history of foreign body penetration of the foot. The severity and the type of lameness will vary depending on the area of the foot affected and the length of time from onset. At rest, the horse will often point or rest the affected foot. In the early stages, when moving, it will tend to place the foot in a manner designed to keep weight bearing off the affected area. There will be a **marked pain reaction** to light percussion with a hammer or gentle pressure with hoof testers in the region of the abscess.

As the abscess develops, the horse will usually become lamer, the uneven loading of the foot will tend to disappear, and the horse will weight bear only on the toe. Percussion or pressure with hoof testers anywhere on the foot will produce a pain reaction.

Black spots, cracks, soft areas of horn or horn bruising may be found when the shoe is removed and the foot searched. Pus may be found discharging from old nail holes, the edges of the sole or frog or from the coronary band. In group 2 abscesses there will often be a rapid development of severe lameness within 2–3 days of onset.

Diagnosis

Abscesses are **one of the most common causes of severe lameness** in general equine practice. Diagnosis is based on the history and clinical signs. These horses are typically severely lame, with **palpable heat** and **bounding digital pulses**. The site will usually be very sensitive to hoof testers, and often a small black track can be found with careful evaluation of the solar surface. Black, gray or brown colored pus discharging from the foot usually indicates a group 1 abscess and creamy white or yellow colored pus, sometimes blood-stained, is more characteristic of a group 2 abscess.

Radiographs are used to assess the involvement and degree of damage to the deeper structures. Inserting a blunt-ended, malleable probe in the wound tract or injecting a positive contrast agent through a flexible catheter into the

tract can be used to define radiographically the extent and depth of the penetration. If a foreign body such as a nail is found in situ it should ideally not be removed until the foot has been radiographed so that the structures involved can be assessed. However, it is also important to prevent damage from progressive penetration of a nail or other foreign body, so decisions regarding when to pull the nail should be made according to the situation.

Treatment

Group 1 abscesses (subsolar abscesses and gravel)

The first step is the **rapid establishment and maintenance of drainage** by careful paring away of the horn around the abscess tract. Where no abscess tract is evident, but an abscess is still suspected, the use of a **poultice** is advocated. Poultices that encourage the hoof horn to absorb water and become softer should be used. Several different poultices can be used effectively including commercial products such as **Animalintex** that are soaked in hot water and applied to the bottom of the foot under a bandage. Another useful poultice consists of a combination of 2 parts wheat bran and 1 part Epsom salts. Alternatively the foot can be packed with **ichthammol** (sulfonated bitumen). In addition, **foot soaks** containing warm water with dilute povidone-iodine solution and saturated with Epsom salts can encourage drainage and help to eliminate infection, but chronic foot soaking should be avoided.

Once the tract is identified at the sole surface, it should only be enlarged enough to establish adequate **drainage** and allow for **effective irrigation**, and once drainage has been established there is often a rapid improvement in lameness. The debrided surface of the foot should be lavaged with a mild antiseptic solution such as **4% povidone-iodine**, and the foot covered with a **dry impervious dressing** that should be changed daily. This can usually be done with the animal standing, but an abaxial sesamoid nerve block may be necessary to allow adequate debridement.

Submural abscesses that have tracked up and are discharging at the coronary band (gravel) usually respond to removal of the lower portion of under-run wall with frequent through and through flushing of the tract with dilute povidone-iodine. Significant debridement at the coronary band should be avoided as this could result in damage to germinal tissues. Persistent cases may require hoof wall resection under general anesthesia.

Systemic antibiotics are of little value in the treatment of most group 1 abscesses, since in most cases a protective layer of horn covers the corium in the infected area, and antibiotics are unlikely to reach the site of infection at any therapeutic level. However, if there is evidence of cellulitis or swelling around the coronet or pastern region, antibiotic therapy is indicated. **Tetanus prophylaxis** is critical (*q.v.*).

Group 2 abscesses (deep penetrating injuries)

With group 2 abscesses, areas of infected and necrotic corium and/or bone should be removed by **debridement and curettage**, and all underrun areas of cornified tissue should be resected. This is often most easily achieved under general anesthesia, and hemorrhage can be minimized with the use of a tourniquet. A sterile, dry, impervious dressing should then be applied to the foot and changed regularly.

In severe cases that will require long-term treatment, a shoe with a **removable treatment plate** can be applied to the foot to protect the sole while allowing ready access for treatment and reducing the length of time for which the horse requires expensive sterile dressings. In addition, a “**sugardine**” **dressing**, consisting of white granular table sugar mixed with povidone-iodine solution to make a paste, can be applied to the draining area to absorb suppuration and keep the adjacent sensitive tissue dry and healthy.

Systemic antibiotic therapy is indicated in the treatment of many group 2 abscesses in addition to removal of infected tissue. Broad-spectrum antimicrobial coverage such as trimethoprim–sulfamethoxazole 30 mg/kg PO b.i.d. is often appropriate, but bacterial culture and sensitivity results should be used to modify antibiotic selection with more serious and deeper infections. In all cases of abscesses, tetanus vaccination status should be determined and **tetanus prophylaxis** administered if necessary (*q.v.*).

Prognosis

If all the underrun, infected and necrotic material has been removed, the wound will be dry and start to heal within 2–4 days (group 1 abscesses) or 2–3 wk (group 2 abscesses). Once the wound has healed and a firm, dry layer of horn has formed over the corium, the foot can be shod with a flat, broad webbed shoe and a sole pad to protect the sole if required.

The prognosis for group 1 abscesses is good providing treatment is instigated early and all infected tissue is removed. In group 2 abscesses, the prognosis is guarded to poor depending on the extent of the deeper structures involved and the duration of infection.

Septic navicular bursitis

The most common cause of infection of the navicular bursa is **foreign body penetration** through the middle or palmar third of the frog or solar surface of the foot. The shape of the collateral sulci of the frog almost seems to direct nails and other sharp objects toward the bursa, and **all puncture wounds** of the foot should be considered to be potentially serious. Infection can also be introduced iatrogenically with bursal injection or aspiration.

This is a **very serious problem**, and should be dealt with on an **emergency** basis. Infection rapidly spreads to involve the navicular bone and DDFT, frequently resulting in severe irreversible damage. Spread of infection to involve the distal interphalangeal joint can also occur.

Clinical signs

There is usually a **sudden onset of marked lameness** that gets progressively worse within 24–48 h. Foreign body penetration of the foot may or may not have been recognized, and occasionally the foreign body will still be present when the horse presents for evaluation. Often the horse will only weight bear on the toe of the foot and will point the foot at rest. There will usually be a painful reaction to pressure on the DDFT over the middle phalanx, and in more advanced cases a sinus tract may be evident. These horses will also usually respond painfully to flexion of the distal interphalangeal joint, and a palmar digital nerve block (*q.v.*) will improve but not eliminate the lameness.

Diagnosis

Diagnosis is suggested by a history of foreign body penetration and the associated clinical signs.

Radiographic examination can be very useful for determining which synovial structures are involved. A single **nail puncture** can contaminate the navicular bursa, distal interphalangeal joint and digital tendon sheath at the same time. Plain radiographs are taken first; if a puncture tract is found, radiographs should be taken with a blunt-ended malleable probe gently inserted in the tract or with a contrast agent injected along the tract to identify the structures involved. Several radiographic projections (a minimum of two orthogonal views) should be taken to determine accurately the position of the probe or contrast agent.

Plain radiographs may not show much in the early stages although a loss of definition of the navicular bone on a dorsoproximal–palmarodistal oblique projection and possible damage to the flexor surface on a palmaroproximal–palmarodistal oblique projection may be noted. In more advanced cases, osteomyelitis of the navicular bone and secondary osteoarthritis (*q.v.*) may be evident. Normal radiographic findings do not rule out a diagnosis of septic navicular bursitis, and synoviocentesis may be required to confirm involvement. Synovial contrast studies can also be used to confirm a penetrating injury.

Treatment

Rapid treatment is essential. Local debridement and systemic antibiotics are usually unsuccessful if the bursa has been punctured. Traditional surgical treatment involves the establishment of **drainage** and removal of all necrotic and infected material using the “street nail operation”.

Under general anesthesia with the affected limb uppermost, and a tourniquet applied, a **sterile probe** is inserted along the puncture tract, and the entire tract is dissected out. A portion of the central part of the frog and digital cushion is removed to reveal the DDFT. A window is made in the tendon over the navicular bone to expose the navicular bursa. All the infected and necrotic tissue is removed and the bursa thoroughly flushed. A cancellous **bone graft** (*q.v.*) can be placed in the defect to encourage granulation. The wound is packed with sterile gauze and the foot bandaged. **Tetanus prophylaxis** (*q.v.*) and broad-spectrum **systemic antibiotics** should be given. The packing and bandage should be changed daily and any further necrotic tissue debrided. Using this surgical approach, the healing period may be prolonged to 6 mo or longer, and the prognosis for a complete return to soundness is poor. The longer the condition has been present before instigation of treatment, the poorer the prognosis becomes.

Endoscopic examination of the navicular bursa has essentially replaced the street nail procedure as the technique of choice for treating acute infectious navicular bursitis. For this surgery, the horse is placed under general anesthesia, and the arthroscope is introduced into the bursa from the medial or lateral side. A cannula or instruments can be introduced through the wound on the bottom of the foot. The bursa is extensively lavaged and any lesions are debrided. Once examination is complete, the puncture tract on the bottom of the foot should be enlarged and debrided to prevent abscess formation. Postoperative management is similar to that with the more invasive

street nail procedure (*q.v.*), but healing is more rapid and prognosis appears to be significantly improved with the endoscopic lavage technique.

Septic arthritis of the distal interphalangeal joint

Infection of the distal interphalangeal joint can occur as a result of **foreign body penetration** of the foot, as an extension of infection from the navicular bursa, or by iatrogenic introduction associated with aspiration from or injection into the joint.

Clinical signs

The condition is characterized by severe, often non-weight-bearing lameness. There may be swelling over the dorsal coronary band from periarticular soft tissues and joint effusion. There will be marked pain on flexion of the joint or pressure over the joint.

Diagnosis

Diagnosis is based on the history and clinical signs. It can be confirmed by arthrocentesis (*q.v.*). Typically the synovial fluid will be cloudy and turbid with low viscosity. With an established infection, the white blood cell count will be $\geq 20\,000/\text{mm}^3$ (often $>40\,000/\text{mm}^3$) with neutrophils the predominant cell type (characteristically these are degenerate neutrophils). The synovial protein levels will be $\geq 2\text{ g/dL}$ (usually $>4\text{ g/dL}$), and the pH and glucose levels will be decreased (pH often <6.9 and glucose levels significantly below those detected in serum).

A positive **bacterial culture** from the synovial fluid confirms the diagnosis, but it is often difficult to obtain a positive culture with synovial infections and a negative culture certainly does not rule out a diagnosis of septic arthritis (*q.v.*). Sample collection in a nutrient broth or use of antimicrobial removal devices can improve culture success rates. Both aerobic and anaerobic culture should be requested. PCR techniques for identifying bacteria are also gaining in popularity.

Radiographic examination can be helpful to assess the degree of damage to the joint structures. In the early stages, joint effusion may cause a widening in the joint space, and in the later stages areas of bone lysis and periarticular and periosteal proliferation may be seen. Other imaging techniques including CT, MRI or radionuclide imaging using labeled white blood cells can also be of value in cases where diagnosis is difficult.

Treatment

The treatment is as for other forms of **septic arthritis** (*q.v.*). It is generally considered that treatment of this joint is particularly difficult, but the use of arthroscopic evaluation and lavage certainly facilitates effective treatment. The prognosis is generally guarded.

Quittor

Quittor is the term used to describe infection and necrosis of the **collateral (ungual) cartilages of the distal phalanx**. The condition is seen most often,

but not exclusively, in the front feet of the **heavier breeds** of horses. Infection usually gains access to the cartilage via extension from the sole, wall or frog, or from a wound at the coronary band in the region of the collateral cartilage. Since the cartilage is **poorly vascularized**, the body is not able to mount an adequate defense against infection and the condition becomes chronic.

Clinical signs

Lameness may not be present at the time of examination but there will almost always be a history of **intermittent lameness** occurring in the same limb and accompanied by swelling and purulent discharge from the region of the cartilage above the coronary band. Lameness will usually subside following discharge. In many cases, the initial injury or infection that caused the condition may have occurred several months before the first bout of lameness. On examination of the foot, evidence of previous/healed sinus tracts may be found. In long-standing cases there may be permanent damage and deformity of the foot and persistent lameness.

Diagnosis

Diagnosis is based on the history and clinical signs. The number and position of the **sinus tracts** can help to differentiate quittor from submural or subcoronary abscesses (*q.v.*), in which there will usually only be one, if any, sinus tract at the level of the coronary band. Radiographic examination may show areas of ossification of the cartilage. Contrast injections or placement of a sterile flexible metal probe in the fistulous tract can be performed to identify the course of draining sinus tracts, and to rule out foreign body involvement.

Treatment

Systemic or local antibiotics used alone may cause a remission of clinical signs, but unless all of the infected cartilage is removed it will act as a focus for reinfection.

The recommended treatment is to establish **drainage** and to remove **all infected material**. This is best performed under general anesthesia with a tourniquet applied to the limb, but can be done standing. Two surgical approaches are described and are frequently used in combination. An elliptical incision is made through the skin above the coronary band over the cartilage and the infected material is removed through the skin flap. This approach tends to heal quickly, but it does not allow good access to deep-seated infection extending below the coronary band. In the second approach, a hole is drilled through the hoof wall over the affected cartilage giving better access and visualization. The hoof wall can be opened using a large **Galt trephine**. Usually a combination of both approaches is required to effectively debride all of the affected tissue, and the coronary band should be preserved in all cases. **Necrotic cartilage** can be recognized easily by its purple-bluish color. New methylthioninium chloride can also be used to define the tracts and identify necrotic tissue. In addition, great care must be taken to avoid penetration of the distal interphalangeal joint capsule during surgery.

Following surgery, the wound is packed with sterile gauze and the foot bandaged. **Tetanus prophylaxis** (*q.v.*) is required. The bandage should be

changed daily until there is no more discharge and the exposed corium has formed a dry protective cuticle. Healing is slow and reinfection can occur.

Prognosis for a complete return to performance is good for acute cases following complete excision of the necrotic cartilage. However, in long-standing cases and in cases where the foot has become deformed, prognosis for complete soundness is guarded.

Thrush

Thrush is an infection of the **frog and its sulci** that results in degeneration of the horn and the production of **foul smelling gray/black discharge**. In severe or neglected cases the infection can spread to involve the underlying corium. Most commonly it is found in the hind feet.

The degeneration of the horn is due to infection with keratolytic bacteria and fungi; multiple organism infections are most common. *Fusobacterium necrophorum*, one of the organisms responsible for foot rot in cattle, is often isolated when cultures are performed.

Predisposing causes of thrush include wet unhygienic stable conditions, lack of routine foot care, prolonged confinement/lack of regular exercise, overgrown, ragged frogs, and long contracted heels that produce deep sulci.

Clinical signs

Thrush does not typically cause lameness unless the infection spreads to involve the sensitive structures of the foot. In those cases, lameness may be accompanied by swelling of the lower limb. There will be a moist, dark, offensive smelling discharge in the central and collateral sulci and the frog may be **ragged and undermined**. There may be pain on pressure over the frog, and the surface may bleed when being cleaned.

Cases of “**deep thrush**” involving the central sulcus occur even in arid climates can, and often be overlooked. The central sulci will appear closed like a thin slit in the frog, and when probed the depth of the sulcus will extend all the way to the hairline. When opened, the sulcus is usually quite undermined with tracks running over most of the caudal third or more of the frog. These cases resemble early canker (*q.v.*).

Diagnosis

Diagnosis is based on clinical signs and the **distinctive characteristics** of the discharge. Culture is usually not necessary as multiple bacteria are involved, and systemic antibiotics are not generally administered. Thrush must be differentiated from canker (*q.v.*).

Treatment

Debridement of all the infected tissue is important and cases involving the sensitive tissues may require regional anesthesia. Following this, **aeration** of the affected tissues is important and an antiseptic or astringent agent, e.g. povidone-iodine, tincture of iodine, 10% formalin, dilute bleach or oxytetracycline spray, can be applied. Prolonged application of astringents should be avoided as they can damage sensitive structures.

Predisposing factors should be eliminated. The horse should be moved to a clean, dry environment and regular foot care adopted including daily cleaning. In many cases, improved foot balance incorporating more natural frog pressure and regular exercise will eliminate the problem. In severe cases involving the sensitive tissues systemic antibiotics may be indicated, and should provide coverage for anaerobic bacteria, i.e. **IM procaine benzylpenicillin** 25 000 IU/kg IM b.i.d.

The prognosis is good providing there is not extensive involvement of sensitive structures. Of course, prevention should be encouraged for performance horses that are stall confined since proper foot hygiene, regular exercise and **clean stabling** will usually eliminate the problem.

Canker (necrotic pododermatitis)

Canker is a chronic hypertrophic **moist pododermatitis** resulting from infection of the epidermal tissues of the foot. The nature of the infection is not fully understood, and although a number of bacteria have been identified in clinical cases, none has been confirmed as the causal agent. Nevertheless, Gram-negative anaerobic bacteria are consistently identified in the epidermal tissues, and both *Fusobacterium necrophorum* and *Bacteroides* spp. (*q.v.*) are thought to be involved.

The infection causes the production of rapidly growing, friable, filamentous fronds of horn. Canker usually starts in the **frog region** but, if it is not recognized or is left untreated, it can spread to involve the sole and wall. It occurs most commonly in the hind feet, and traditionally draft breeds have been over-represented. However, front feet and non-draft breeds are also regularly affected.

This condition is reported as being rare, however isolated cases do occur and the incidence appears to be increasing. The condition is predisposed to by **unhygienic stable conditions and poor foot care**, but it can occur in clean well-managed stables. The most common risk factor is prolonged exposure to **moisture**, and the condition is seen much more regularly in humid climates or swampy environments.

Clinical signs

Lameness may not be present in the early stages of the disease but develops once neglected infection involves the corium. Lameness can become quite severe and is often accompanied by swelling of the lower limb. Initially, the frog may appear normal but on closer examination there is a **crust** over its surface that is loose and friable and easily splits with slight pressure. Beneath the crust the swollen corium is covered in soft, moist, creamy white, filamentous fronds of horn with a **cottage cheese like, foul smelling exudate**. The proliferative appearance of the frog helps to differentiate canker from thrush.

Diagnosis

Diagnosis is based on the typical clinical signs and can be confirmed histologically with evidence of epidermal hyperplasia, inflammation, intracellular edema, dyskeratosis and necrosis.

Treatment

Once established, canker can be a very difficult condition to treat successfully, and early recognition of the condition dramatically improves success rates.

Horses should be moved immediately to a **clean, dry environment**. Treatment involves removal of the infected horn tissue to allow application of topical antimicrobial medications. This can be done standing under local anesthesia and sedation or under general anesthesia. A tourniquet applied to the limb improves visualization. Superficial and wide debridement of grossly infected horn tissue should be followed with persistent **topical antimicrobial therapy** with metronidazole or antimicrobial mixtures as described (*q.v.*).

Care should be taken not to remove or damage too much of the underlying normal corium as this can result in **permanent hoof deformities**. Surgical debridement and hemostasis can be facilitated with the use of a surgical laser. Some individuals have also reported success with the use of cryotherapy with liquid nitrogen to manage these cases. **Tetanus vaccination** status should be confirmed.

Meticulous postoperative care with topical antimicrobial therapy is essential for successful treatment of these cases. Using **dry, sterile, waterproof dressings**, the foot should be bandaged so that pressure is applied to the wound. Alternatively, a shoe with a **treatment plate** can be applied to reduce the cost of daily bandaging, but pressure should still be applied to the frog and sole under the plate. The dressing should be changed daily, and the area treated with topical **metronidazole, chloramphenicol, or a combination of ketoconazole with rifampicin and DMSO**. To treat the foot topically with metronidazole, a 2% ointment can be used or tablets can be crushed and mixed with water to form a paste. The combination of ketoconazole, rifampicin and DMSO, referred to as “**phycofixer**”, is made by dissolving 7.5 g of ketoconazole in 100 mL of heated 0.2 normal HCl in a fume hood. This is added to 4.8 g of rifampin in 400 mL of DMSO, and can be sprayed directly on the affected areas.

Systemic antibiotics including effective coverage for anaerobic bacteria should be considered if lameness is severe or if there is evidence of cellulitis or swelling in the pastern area.

Despite great care being taken in the debridement and postoperative care of this condition, recurrence is common and will usually be apparent within 3–7 days. Regular rechecks and repeated debridement may be necessary before canker can be controlled. Healing tends to be prolonged. **NSAIDs** should be administered to try and encourage weight bearing.

The prognosis is good if the condition is not too widespread but it is important to persevere with treatment. Prognosis is guarded if the condition is widespread and long-standing.

HOOF WALL SEPARATION

Seedy toe

The term **seedy toe** describes a hoof wall separation that occurs as a sequel to **laminitis** (*q.v.*). This separation starts between the dermal and epidermal laminae when rotation or sinking of the distal phalanx occurs, creating

a thickened, stretched or separated white line at the toe. The space is filled with poor quality **soft crumbly horn** and enough separation can occur to allow infection to penetrate between the dermal and epidermal laminae, resulting in submural abscesses. Some of the resulting hoof deformity can be addressed by trimming and/or shoeing the foot to move the breakover point into position with the distal phalanx. This will relieve tension on the DDFT and tends to minimize the separation at the toe as the hoof grows down.

The term **seedy toe** is also occasionally used to describe the condition of **white line disease** (*q.v.*).

White line disease

The definition and etiology of white line disease are not well established. As a general term, white line disease refers to hoof wall separations at or near the white line that are not due to chronic laminitis. More specifically, white line disease has been described as a **keratolytic process** on the solar surface of the hoof, characterized by a progressive separation of the inner zone of the hoof wall.

The **white line** of the hoof is the junction between the horn of the sole and the soft white horn of the epidermal lamellae, but in most cases of white line disease the separation is not truly in the white line but in the non-pigmented deeper layers of the epidermis, or in the non-pigmented horn at the junction between the stratum medium and stratum internum of the epidermis. This junction can be damaged by mechanical trauma, nutritional deficiencies, excessively wet or dirty environments, dry conditions producing exceptionally dry feet, microorganism invasion or a combination of these conditions.

Hoof wall separations begin at the ground surface and **spread upward** underneath the hoof wall. It is thought that this progressive separation occurs as a result of infection with **anaerobic keratolytic bacteria, fungi or yeasts**, which gain access to the area at the ground surface. These organisms slowly digest the horn of the epidermal laminae and, as the epidermal horn is broken down, the distal phalanx loses its attachment to the hoof wall and can rotate. It is possible that the organisms cultured are all secondary invaders once the keratin becomes exposed by other environmental or mechanical factors.

Clinical signs

Lameness is not usually present in the early stages of hoof wall separations, but the separation will be evident on visual examination and probing the crumbly horn typically reveals a **cavity with separation of the outer hoof wall** from the laminae. The lesion can occur anywhere on or superficial to the white line around the diameter of the foot, and one or more feet can be involved. In severe cases the separation can extend from the weight-bearing surface all the way up to the coronary band. Typically a “**cigarette ash**” type discharge will be found around the edges and in the depth of the lesion, as a result of horn destruction.

Lameness will be evident when the separation is extensive enough to cause instability and some degree of rotation of the distal phalanx. Lameness can be quite marked with the horse adopting a laminitic gait. On examination, the sole may be dropped and there may be evidence of sole bruising and a painful response to pressure from hoof testers. Undermined areas of hoof wall will produce a hollow sound when tapped with a hammer.

Diagnosis

Diagnosis is based on the clinical signs and the insidious nature of the lesion. Radiographic examination is important in order to assess the extent of the separation, to determine whether there is rotation of the distal phalanx, and to detect evidence of **pedal osteitis** (*q.v.*), all of which will affect the treatment and prognosis.

Treatment

The condition is usually refractory to conservative methods of treatment, and treatment of hoof wall separations requires **complete removal** of all the undermined wall and infected, necrotic horn. Infectious agents involved in this condition thrive in an **anaerobic environment**; therefore it is essential to **remove** the entire **undermined hoof wall** to expose the infected area. The edges of the normal horn should be tapered so that no lip is left under which infected material could remain.

In some cases quite large areas of hoof wall may need to be removed and the distal phalanx will require support that can be provided using a properly fit heart-bar shoe. The defects should generally not be replaced with hoof repair material in the early stages of treatment, as this will recreate an anaerobic environment. Some **medicated hoof acrylics** containing metronidazole powder may overcome this problem and allow earlier hoof wall repair. However, if the distal phalanx is supported, and the horse is not lame, hoof repairs for cosmetic purposes are discouraged, as they tend to recreate the anaerobic environment that encourages continued infection.

The laminae in the infected area are usually covered in a protective horn cuticle. Old or necrotic horn over this layer should be carefully debrided and the surfaces treated with an antiseptic solution such as povidone-iodine or dilute bleach. If possible, the foot should be shod with a full bar shoe, or a heart-bar shoe to try and support the foot until the hoof wall regrows. Where a large amount of hoof wall has been removed it may not be possible to fit a conventional shoe. A glue-on shoe can be used, or a shoe can be supported by attaching it with clips screwed into sections of normal wall. Alternatively, the foot can be left bare and the horse kept on a soft dry surface until the hoof wall regrows.

The prognosis is good providing that the distal phalanx and the corium have not been severely damaged. Treatment and healing can be prolonged, so the earlier in the course of the disease treatment is instigated, the better the chances of success. Horses should be monitored closely for evidence of recurrence. **Moisture extremes** (too wet or too dry) apparently provide the optimal environment for the horn-digesting microorganisms that contribute to this condition, so horses should be moved to a different environment when possible. Nutritional supplements including biotin and methionine may also be of benefit in horses with poor quality hoof wall.

CONDITIONS OF THE DEEPER STRUCTURES OF THE FOOT

Fractures of the distal phalanx

Fractures of the **distal phalanx** are a relatively common cause of lameness, and they often occur during exercise, particularly with racing, and may be

associated with hoof imbalance, uncoordinated action or direct trauma from a hard or rocky working surface. Many horses will present with a history of kicking an unyielding object, and these fractures can also arise secondary to other conditions such as foreign body penetration, laminitis, osteomyelitis, nutritional deficiencies or pedal osteitis (*q.v.*).

Seven basic types of fractures are recognized:

1. **Type 1:** Non-articular fracture of the palmar or plantar process (wing fracture).
2. **Type 2:** Abaxial articular fracture that extends from the distal interphalangeal joint (DIP joint) to the lateral or medial distal border (articular wing fractures). These are reported to be the most common fracture type.
3. **Type 3:** Sagittal articular fracture that divides the distal phalanx into two approximately equal parts.
4. **Type 4:** Extensor process fracture.
5. **Type 5:** Articular or non-articular comminuted fracture.
6. **Type 6 adult:** Non-articular fracture of the solar margin. These have also been reported to be the most common fracture type.
7. **Type 6 foal:** Non-articular solar margin fracture of the palmar or plantar process. These fractures are thought to be the result of shear forces generated by tension from the DDFT or by compression.

Extensor process and solar margin fractures most often occur in the front feet and these can be bilateral. There is controversy regarding the etiology of fragmentation of the extensor process, particularly in bilateral cases. Some authorities consider these to be separate centers of ossification and manifestations of osteochondrosis (*q.v.*).

Clinical signs

Type 2, 3 and 5 fractures will usually have a history of sudden onset of non-weight-bearing lameness. In some cases the horse may be unwilling to put the foot to the ground for several days following the onset. Lameness with non-articular fracture may not be as severe, and the lameness associated with extensor process and solar margin fractures can be quite subtle.

Articular fractures and fractures of the extensor process produce distension of the DIP joint and pain on flexion of this joint. A painful response will usually be detected with gentle percussion or pressure with hoof testers in the region of the fracture. There may be a painful response to digital pressure over a fractured extensor process, and if a large extensor process fracture has been present for some time the hoof wall at the toe may become more pointed or buttress shaped (**buttress foot**, **pyramidal disease**).

Diagnosis

The history and clinical signs may be indicative, but diagnosis is confirmed by **radiography**. Many different oblique projections may be required in order to demonstrate a fracture and to accurately determine its configuration. Artifacts can mimic fractures, and the foot should be well prepared and the sulci packed prior to taking radiographs. Initially the fracture line may not be radiographically evident and in these cases the foot should be radiographed again

in 7–14 days. Alternatively, **nuclear scintigraphy** or **CT** can identify these fractures, and CT is also invaluable for differentiating between type 1 and 2 fractures when the fracture line extends close to the articular surface.

Radiographic examination can help differentiate separate centers of ossification at the extensor process from true extensor process fractures. The former are usually small, round, smooth edged, and sit immediately proximal to the extensor process. Radiographic examination is also important to assess the degree of osteoarthritis (*q.v.*) that may have developed as a sequel to articular fractures.

Treatment

The treatment selected will depend on the type of fracture, the age of the animal and the purpose for which it is used.

For fractures that do not extend into the joint a **conservative approach** will often produce good results. Conservative treatment involves rest, trimming and balancing the foot, and shoeing to stabilize the hoof wall so that it can function like a cast. A number of different shoeing options have been effective including application of a bar shoe with stout quarter clips, a continuous rim shoe, or a bar shoe with cast material applied around the hoof wall. Another alternative is a commercially available Equine Digital Support System P3 and Navicular Bone Fracture Plate for treating distal phalanx fractures. This shoe provides excellent stabilization of the foot, and articular fractures have been successfully treated with this shoe and solid plate combination.

These different approaches are all designed to **limit hoof expansion** and decrease distraction during weight bearing. Releasing tension on the DDFT by raising the heels can also improve comfort and healing with distal phalanx fractures. With the commercial fracture plate system the heels can be raised with adjustable wedge rails that are attached to the shoe with screws placed inside of the nail groove to facilitate turning.

Regardless of the style of shoe selected, it should be reset every 4–6 wk; at least until bone union has taken place (6–12 mo). Even after healing has taken place, the foot may need to be permanently shod in this manner to prevent refracture.

Cast material preventing hoof wall expansion will need to be discontinued earlier in the treatment protocol to prevent permanent hoof contracture. If a long enough period of rest is given after the therapeutic shoe is removed and this is followed by a slowly increasing, controlled exercise program to allow for bone remodeling, refracture is less likely to occur and a return to conventional shoeing is possible.

Many **type 2 and 3 fractures** can be managed conservatively as described for non-articular fractures. Complete hoof casts have also been used in the treatment of type 2 and 3 fractures to give better immobilization, but tend to be associated with more complications. Surgical treatment, using lag screw fixation or cannulated self-compressing screws, has been recommended in early type 2 and 3 fractures to ensure more rapid and efficient healing, particularly in horses over 3 yr old and in performance horses. The risk of **sepsis** and other catastrophic complications is high, and the prognosis for return to athletic performance is still somewhat guarded.

Small **extensor process fractures** can be treated conservatively, but larger fractures should be managed surgically. Most fragments can be removed arthroscopically, although very large fragments may require arthrotomy or in some cases immobilization with lag screw fixation.

Solar margin fractures occur with athletic performance on hard ground or often develop secondary to other conditions such as laminitis and foreign body penetrations. Treatment in these cases is aimed at the primary condition. Where solar margin fractures occur without concurrent problems, conservative treatment consisting of rest is usually successful, and strict immobilization with specialized bar shoes is typically not necessary. The fractures may heal, be resorbed or persist without clinical signs. **Type 6 fractures** in foals usually heal with 8 wk stall confinement alone, but adequate healing should be confirmed radiographically prior to turnout.

The prognosis for a complete return to soundness is influenced by fracture type (particularly whether or not it is articular), degree of displacement, the age of the horse and the foot affected. In general, the prognosis is better in young horses (≤ 3 yr) and in hind feet rather than front feet. The prognosis for non-articular fractures is generally good providing the animal is given an adequate period of rest and slowly reintroduced to exercise. The prognosis for articular fractures is more guarded because of the rapid development of osteoarthritis that can occur. Prognosis for type 2 and 3 fractures may be improved by surgical treatment in the early stages. Fractures that occur as a result of osteomyelitis (*q.v.*) generally carry a poor prognosis.

Fractures of the navicular bone

Complete fractures occur infrequently, but are seen most often in the front feet. They usually result from direct trauma from exercising on hard or stony ground, or from kicking a solid object. Pathologic fractures also occur as a result of bone demineralization associated with navicular syndrome (*q.v.*) or secondary to osteomyelitis (*q.v.*). The most common complete fractures of the navicular bone are simple, vertical or slightly oblique sagittal fractures close to the central ridge of the bone. Comminuted and transverse fractures of the navicular bone occur more rarely.

Small fractures of the distal border occur more regularly and are typically detected in association with navicular degenerative changes. These fragments may be due to avulsion fractures or may actually be the result of new bone formation in adjacent diseased soft tissue structures. Fractures should also be differentiated from congenital non-fusions that are occasionally identified, and may not be associated with lameness.

Clinical signs

With **complete fracture**, there is usually a history of **sudden onset of severe lameness**. In some cases, the horse will only bear weight on the toe of the foot. Usually there will be a marked painful reaction to flexion of the DIP joint. A painful response can also often be elicited by pressure with hoof testers across the posterior third of the hoof wall. After 2–3 wk the degree of lameness usually lessens but can be exacerbated by flexion of the DIP joint or by exercise.

Diagnosis

Diagnosis is based on history and clinical signs. A palmar digital nerve block (*q.v.*) will often improve the lameness, however a negative response to the nerve block does not rule out a fracture of the navicular bone.

Diagnosis can be confirmed with radiography. Great care should be taken in the preparation of the foot before the radiographic examination, and the **sulci of the frog** should be packed so that **radiolucent air artifacts** are not mistaken for fractures. At least two radiographic projections demonstrating the fracture line are necessary before a definitive diagnosis is made. Fracture lines always end at the bone margins, while lines from the sulci of the frog will typically extend above or below the navicular bone.

Although rare, congenital bipartite and tripartite navicular bones can be distinguished from fractures radiographically by their smooth rounded edges and the overall symmetry of the bone. They can occur bilaterally, and the opposite distal extremity should be radiographed simultaneously.

Treatment

Conservative methods for managing complete navicular fractures involve **prolonged rest** (6–8 mo), combined with trimming and balancing of the foot and shoeing with a bar shoe that does not contact the frog but is fit with quarter clips or a complete rim and has a rolled toe. Alternatively, trimming and balancing the foot and shoeing with a graduated raised heel shoe, fit long in the heels and fashioned with quarter clips, can be tried. There is also a commercial and adjustable Equine Digital Support System P3 and Navicular Bone Fracture Plate system that eases breakover, releases tension on the DDFT and eliminates frog contact. Once shod, the horse is given a minimum of 2 mo of stall rest followed by a gradually increasing, controlled exercise program.

The prognosis for return to athletic soundness is **very poor**. Whatever method of conservative treatment is used, healing will be slow and occur by fibrous union because of the difficulty in immobilizing the fracture. The fracture line will always be evident radiographically and complete soundness is uncommon. Some horses have been returned to performance with a palmar digital neurectomy, but many of these horses develop osteoarthritis of the distal interphalangeal joint, and there is an increased risk of catastrophic failure of the DDFT in those patients.

Surgical treatment by lag screw fixation has been successful in the treatment of a few select navicular bone fractures and resulted in a bony union without excessive callus formation. Repair should be performed as soon as possible after the fracture has occurred to reduce secondary changes. The surgical technique is complicated and sophisticated equipment is required, but several successful cases have been reported.

Osteoarthritis of the distal interphalangeal joint (low ringbone, degenerative joint disease)

This condition resembles osteoarthritis (*q.v.*) in other joints, and it can develop as a result of poor forelimb conformation, foot imbalance or excessive concussion. It also develops in association with other primary conditions causing

instability or joint incongruity such as articular fractures of the distal phalanx, fractures of the navicular bone, osseous cyst-like lesions and navicular syndrome (*q.v.*).

Clinical signs

Lameness is very variable and somewhat non-specific. Lameness may be unilateral or bilateral and will often be increased by trotting on a hard surface, or circling in the direction of the affected limb or limbs. The horse may show a painful reaction to flexion of the distal extremity and lameness is subsequently increased. In some cases, distension of the DIP joint may be palpable just proximal to the coronary band on the dorsal aspect of the limb.

Diagnosis

Definitive diagnosis can be difficult. It is based on clinical signs and history, particularly if there is a history of previous fracture of the distal phalanx or navicular bone.

In most cases, palmar digital nerve block (*q.v.*) will result in a partial improvement in lameness, and an abaxial sesamoid block in a marked improvement or abolition of lameness. A dorsal ring block may be required to eliminate the lameness. Intra-articular anesthesia of the DIP will also improve or eliminate the lameness. Of course, these techniques will also block many other causes of foot lameness, and scintigraphy can be useful in localizing the lameness to the coffin joint.

Changes of osteoarthritis may not be evident radiographically unless severe. A lateromedial projection of the foot is the most useful to demonstrate subtle changes: these include **bone remodeling** and **osteophyte formation** on the dorsal and palmar aspects of the articular margins. Care must be taken to distinguish periarticular changes on the extensor process from true articular changes. Increasing availability of MRI for the distal extremity should improve our detection of early lesions that cannot be detected radiographically.

Treatment

Treatment involves **trimming and shoeing** to correct any obvious foot and hoof–pastern axis imbalance if possible, and to ease breakover. A rocker motion shoe made of steel or aluminum or constructed from double-nail pads can be used to minimize the joint movement required with each stride, and consequently reduce the associated pain. This should be combined with rest, or low dose NSAIDs and a gradually increasing, controlled exercise program.

The systemic use of **hyaluronan** and/or **polysulfated glycosaminoglycan** (*q.v.*) may reduce inflammation in the joint and provide some relief. In addition, IA treatment with hyaluronan, with or without corticosteroids, can be of value in returning these horses to athletic performance. While use of IA corticosteroids has to be balanced with knowledge of their potential adverse effects, in chronic cases these medications have been found to be of value in treatment of this otherwise career limiting condition. Arthrodesis of this joint is difficult and is generally not recommended except for salvage.

Prognosis for a complete or sustained return to soundness is guarded, particularly in cases with obvious radiographic changes.

Desmitis of the collateral ligaments of the distal interphalangeal joint

Injury to the **collateral ligaments** has been identified as a source of severe lameness, typically involving a single forelimb. Medial or lateral collateral ligaments can be affected and they can be simultaneously involved, but **medial desmitis** has been reported more frequently. The lameness can be subtle or severe enough to be seen at a walk. These patients typically have a history of an acute onset of lameness that is not improved with an initial period of stall rest. The desmitis may develop due to a single misstep or with repeated unbalanced landings in which the distal phalanx either slips or rotates, straining the collateral support ligament. Poor footing is a risk factor.

Diagnosis

Soft tissue swelling and pain can be detected in patients with injury to the body or origin of the collateral ligaments; however, many injuries occur at the insertion and are confined to the hoof capsule. Most horses will improve with regional palmar digital anesthesia and/or with IA anesthesia of the distal interphalangeal joint (*q.v.*). **Ultrasound** is probably the method of choice for diagnosis and can be used to detect desmitis involving the origin or body of the collateral ligament, while characteristic radiographic findings include subtle osteolysis or bony irregularity around the insertion of the collateral ligament on the third phalanx. Contrast enhanced **CT** and **MRI** are also valuable for confirming these lesions.

Treatment

Treatment consists of **strict stall rest**, followed by a gradual return to controlled walking exercise over 2–6 mo. Well-balanced wide-web shoes should provide improved support for the joint and reduce strain on the ligament. The prognosis for return to athletic performance is considered fair, although evidence of gross joint instability or associated osteoarthritis is a poor predictive indicator.

Pyramidal disease (buttress foot)

The terms pyramidal disease and buttress foot are used somewhat loosely to describe changes in the appearance of the coronary band and subsequent growth deformities of the toe. **Pyramidal disease** is a term used to describe the triangular distortion of the dorsal hoof wall and coronary band that is frequently the result of new bone growth and subsequent soft tissue reaction in the region of the extensor process of the third phalanx.

The term **buttress foot** is used interchangeably, referring to dorsal hoof wall swelling at the coronary band resulting in a conical deformity of the toe from the coronary band to the weight-bearing surface. Horses with upright conformation, or forward broken hoof–pastern axis, are more prone to develop pyramidal disease.

Etiology

One proposed cause of **extensor process periosteitis** and resulting distortion of the dorsal hoof wall is excessive strain on the insertion of the common or long digital extensor tendon or of the extensor branches of the suspensory ligaments. This results in soft tissue inflammation and fibrosis, reactive periosteitis and enthesophyte formation. Large fractures of the extensor process, advanced osteoarthritis of the distal interphalangeal joint with proliferative exostosis (low ringbone), and keratomas (*q.v.*) can also cause pyramidal distortion of the dorsal hoof wall.

Clinical signs

The clinical signs are clearly dependent on the cause of the hoof deformity. When it is associated with excessive soft tissue strain, there is usually a moderate to severe lameness, accompanied by a shortening of the stride and a tendency for the heels to land first. There may be swelling at the dorsal coronary band and a pain reaction to digital pressure in this area and to flexion of the DIP joint.

In the more chronic stages, the degree of lameness is variable; the swelling at the coronary band will be obvious and firm to the touch, and a painful reaction may or may not be elicited by pressure. Due to the enlargement of the coronary band, the hoof wall develops a **bulge** on the dorsal surface, which will eventually extend down to the bearing surface as the hoof wall grows, giving the foot a distinctive V shape.

Diagnosis

Diagnosis is based on the history and the clinical signs, and can be confirmed by local anesthesia and radiography.

Lameness may improve following palmar digital nerve block, but there should be a marked improvement following an abaxial sesamoid block.

With pyramidal disease resulting from extensor process periosteitis, radiographic examination in the early stages may show no changes other than soft tissue swelling in the area of the extensor process, unless the strain has resulted in a fracture. In the later stages **new bone** and **enthesophyte formation** will usually be obvious.

Treatment

If there is an **extensor process fracture** this should be treated appropriately as described in the section on fractures of the distal phalanx (*q.v.*).

In the early stages, if there is no fracture, the horse should be **stall rested** and treated with systemic anti-inflammatory medications such as phenylbutazone 2 mg/kg PO b.i.d. Immobilization has also been recommended. Rest should be followed by a slowly increasing, controlled exercise program, and the foot trimmed, balanced and shod to ease breakover. In the later stages, once new bone growth is established, lameness may be permanent and **long-term** NSAID treatment or IA corticosteroids may be required to return the horse to any level of work.

The prognosis for a complete return to soundness is guarded in the early stages and poor in the advanced stages.

Phalangeal exostosis (low ringbone)

The term **ringbone** (*q.v.*) was coined to describe bony enlargement of the phalanges below the fetlock joint. The terms **high** and **low** ringbone are used to differentiate between bone production around the proximal and distal interphalangeal joints respectively, while the terms **articular** and **periarticular** ringbone distinguish between new bone production involving the joint and that strictly involving the joint perimeter.

Navicular syndrome (navicular disease, caudal heel syndrome, caudal heel pain)

Navicular syndrome is one of the most common causes of chronic forelimb lameness and it is also one of the most controversial.

The syndrome is generally progressive and usually affects both front feet, while the hind feet are rarely involved. Conventionally, lameness in these patients has been attributed to the navicular bone, the navicular bursa and/or the adjacent DDFT; however, current research suggests that other soft tissue structures may also be involved.

The term “**caudal heel pain**” has gained popularity since it tends to draw attention away from the navicular bone itself, and integrates all of the soft tissue structures thought to be involved in this condition. All breeds and all work categories of horse can be affected, but Quarter Horses and Thoroughbreds appear to be predisposed, while Arabians and ponies are rarely affected.

Etiology and pathogenesis

While a number of different theories have been developed, the proposed **causes remain speculative**. Although historically described as a single disease, it is likely that navicular syndrome includes a variety of different clinical entities, and this could explain the difficulty we have encountered in trying to define a precise etiology. Primary **DDFT tendinitis** (*q.v.*) is usually not included under the heading of navicular syndrome, but can be difficult to differentiate without advanced imaging techniques.

The principal theories are as follows:

1. **Vascular:** The suggestion is that as a result of reduced blood flow, from thrombosis or atherosclerosis of the arterioles supplying the navicular bone, there is ischemic necrosis of the bone, and pain. This theory has fallen into disfavor since histopathology has not confirmed the presence of thrombosis or areas of infarcted bone.
2. **Biomechanical:** This theory suggests that navicular syndrome is the result of non-physiologic forces on the navicular bone such as repetitive concussion, vibration, overloading, or pressure from the DDFT, provoking either a navicular bursitis or increased bone turnover and remodeling.
3. **Degenerative:** It is proposed that changes occurring in the fibrocartilage, subchondral bone, flexor cortex and the synovial fluid of the navicular bursa are similar to those occurring in osteoarthritis (degenerative joint disease) of synovial joints.
4. **Developmental:** This concept is based on observations regarding soft tissue structures in the heel region of pathology specimens from horses

with navicular syndrome. Observations have led to speculation that an increased vascular supply associated with thicker collateral cartilages as well as more fully developed digital cushions may allow improved dissipation of concussion in horses with “good feet”. In addition, abnormal shearing forces between the impar ligament and the DDFT are thought to lead to painful inflammation in the heels of horses with “bad feet”. Recent work suggests that **regular exercise** is essential for development of healthy foot architecture in horses as they mature.

The above theories point to **abnormal conformation** and **foot imbalance** as predisposing factors in the development of the condition. Abnormal foot conformations implicated are:

1. **Broken back hoof–pastern axis**—probably the most common, and almost always the result of long toe/low heel imbalance
2. **Upright pastern**
3. **Feet smaller than normal** in relation to body size
4. **Mediolateral foot imbalances**
5. **Sheared heels.**

Clinical signs

There will often be a history of **intermittent and progressive forelimb lameness** involving one or both forelimbs. On examination, the degree of lameness can be variable and may initially appear to be unilateral, but on further examination, such as circling or flexion tests, is usually found to be **bilateral**. The degree of lameness may be the same in both forelimbs, resulting in a very short “**pottery**” forelimb gait. Lameness is usually accompanied by shortening of the anterior phase of the stride, with the toe of the foot contacting the ground first. Affected animals are inclined to **stumble** and there is often marked **wearing of the toe** of the shoes.

At rest, the horse may “point” the most severely affected foot, or alternately point one foot and then the other. In advanced cases the horse may adopt a “rocking horse” stance with the forelimbs placed in front of and the hindlimbs placed behind their normal position.

If the condition has been present for some time, the affected foot or feet will have **changed in shape**. Because of lack of normal use of the posterior third of the foot, the foot becomes smaller, narrower, and higher in the heels. A marked disparity in shape may be evident between the front feet. A painful response may be elicited with hoof tester pressure applied across the heels, or across the middle third of the frog to the opposite heel. Flexion of the DIP joint often produces a painful reaction and a significant increase in lameness. An increase in lameness may also follow extension of the DIP joint. The palmar hoof or hoof extension **wedge tests**, in which the frog or toe regions are temporarily elevated on a block, also frequently exacerbate the lameness.

Diagnosis

A tentative diagnosis based on the history and clinical signs should be confirmed by local anesthesia and subsequent diagnostic imaging studies.

A **palmar digital nerve block** (*q.v.*) will usually produce a marked improvement, or abolition of the lameness, and lameness will often become more obvious in the **opposite forelimb**.

Intra-articular anesthesia of the DIP joint will also usually significantly improve the lameness, presumably due to diffusion of anesthetic to the area or to the palmar digital nerves that are located subsynovially in the DIP joint. The volume of local anesthetic placed in the DIP joint may influence the time required for the block to improve lameness in horses with caudal heel pain, but research suggests that it is difficult to differentiate between DIP joint and caudal heel pain on the basis of IA anesthesia alone.

Navicular bursal blocks can also be used to confirm a diagnosis of navicular syndrome, but these are more difficult to perform and are usually performed in conjunction with bursography or with medication of the bursa.

Lameness caused by disease of the DDFT within the digit often fails to improve with analgesia of the palmar digital nerves, the DIP joint or the navicular bursa, but does typically improve following an abaxial sesamoid nerve block. Intrathecal analgesia of the digital sheath can also be used to identify horses suspected of having an injury of the digital portion of the DDFT.

For radiographic examination of the navicular bone a minimum of three radiographic views are needed: **dorsoproximal–palmarodistal** oblique view, **lateromedial** view, and a **palmaroproximal–palmarodistal oblique** (flexor) projection. Great care should be taken in the preparation of the foot prior to radiography to avoid imposition of artifacts.

Radiographic findings associated with navicular syndrome include an increase in number and change in shape (from a normal cone shape to rounded or mushroom shapes) of the **synovial fossae** on the distal border of the navicular bone; the presence of synovial fossae (regardless of shape) in the distal border of the wings and proximal border of the navicular bone; areas of radiolucency or **cyst formation** within the navicular bone; thinning or roughening of the flexor cortex (flexor view); loss of normal trabecular pattern in the medullary cavity; remodeling of the proximal and/or distal border; **enthesophyte formation** on the proximal border of the wings of the navicular bone (spurs); and avulsion fractures of the distal border of the navicular bone.

The degree of lameness and radiographic abnormalities are often poorly correlated. In fact, many of the radiographic findings associated with navicular disease are found in sound horses, and no single radiographic feature is diagnostic. Similarly, the absence of radiographic abnormalities does not rule out a diagnosis of navicular syndrome. Radiographic findings should be assessed in conjunction with the clinical findings and the results of local anesthesia.

Alternative diagnostic imaging methods that facilitate evaluation of soft tissue involvement have become increasingly popular. Magnetic resonance imaging provides optimal anatomic detail, and its increased use has confirmed the frequent involvement of the DDFT in horses with caudal heel pain. Computed tomography provides excellent three-dimensional detail of the bone and, when used with contrast injections, can provide excellent soft tissue detail. Ultrasound can be used to evaluate a narrow portion of the DDFT, impar ligament and navicular bursa by imaging these structures through the bottom of the foot. Appropriate **preparation of the foot** with thinning of the frog and soaking the foot improve image quality.

Scintigraphy can be used to localize the area of involvement in the foot, but it often does not provide much anatomic detail, and there is a high incidence

of false positives. Bursography is occasionally used to confirm effective injection of the navicular bursa, and it can also give valuable information regarding cartilage pathology and adhesion formation. Thermography can be used to assess relative blood flow to the region, but must be performed under appropriate temperature controlled conditions, and should not be over interpreted. Endoscopic evaluation of the navicular bursa has been described, but is usually reserved for penetrating injuries to the foot.

Treatment

Selection of treatment for navicular syndrome depends on the stage of the disease process and the duration and degree of lameness. **Correction of any foot abnormality or imbalance** should always be the first line of treatment. The trimming and shoeing technique used depends on the individual animal's conformation.

The most common foot imbalance predisposing to navicular disease is the **long toe/low heel** resulting in a backward broken hoof-pastern axis. This configuration places excessive stress on the DDFT and navicular region, and can result in development of **underrun heels**. Some correction can often be achieved with corrective trimming and shoeing. Underrun **heels should be trimmed** to move support for the hoof back under the foot. The hoof-pastern axis can be realigned using wedged heels, wedge pads or rails as necessary. Leaving underrun heels long in an effort to align the hoof-pastern axis naturally only forces the heels to grow farther forward. **Breakover**, or the last part of the hoof to leave the ground, should be moved back using appropriately designed and placed shoes (this will reduce tension on the DDFT). The **toe should be trimmed** as short as is practical, and the horse shod with a commercial Natural Balance shoe or in a wide webbed egg-bar shoe extending back to meet a line dropped vertically from the bulbs of the heels.

Over time the use of bar shoes in low-heeled feet can crush the caudal region of the frog and offer little weight-bearing support to the third phalanx. The use of a **frog insert** can help by redistributing weight over more of the foot, and will also provide better support to the heels on soft ground. The feet should be trimmed and shod every 6 wk until the desired correction is achieved. In some cases, the heels are so low and collapsed that even supporting the heel structures will not encourage development. In those cases, it is recommended that the shoes be removed, the collapsed portion of the heels trimmed, and the horse kept on a very soft surface until enough strong wall has grown at the heels.

When the horse is very lame, or the disease is advanced and the feet have become small and upright, it may be more beneficial to shoe the horse with a wide webbed, graduated raised heel shoe with a rolled toe and fit well beyond the weight-bearing surface at the heels to give some support. This shoe will lift the heels mechanically to take tension off the DDFT and help straighten the hoof-pastern axis. However, because of the increased thickness of the shoe at the heels, there may also be increased pressure and wearing of the wall at the heels.

Wedge pads or wedge rails added to the Equine Digital Support System shoe can also be utilized to elevate the heels. While the chronic use of wedge pads has been associated with further collapsing already weak heels, this

problem can be minimized through the use of sole loading materials such as Equi-Pac or dental impression material. By incorporating the sole in weight bearing, loading of the hoof wall at the heels is reduced, protecting that area.

In some cases of navicular syndrome, particularly in the early stages, correction of the foot imbalance combined with a gradually increasing exercise program is all that is necessary to return the horse to athletic performance. Other cases may also require medical and/or surgical intervention.

Intrasynovial medication of the DIP joint or of the navicular bursa is used regularly to manage these patients. Typically, a combination of corticosteroid and hyaluronan (*q.v.*) is used. Results and duration of effect vary between patients, but can be outstanding with even long-term improvement in lameness recorded in some horses. If necessary the treatment can be repeated, and careful aseptic technique should always be used.

NSAIDs are used routinely, although they are **largely palliative**. In chronic cases with advanced bony remodeling changes, the use of oral NSAIDs can be invaluable for returning horses to work. These patients should be monitored for adverse systemic effects. The anti-inflammatory effects of these drugs can also be beneficial in management of acute cases of caudal heel pain, although the benefits must be weighed against the **adverse effects** of encouraging increased loading on the affected area, particularly when DDFT involvement is suspected.

Vasoactive drugs and hemorheologic agents have been used extensively in an effort to improve circulation to the foot. With increasing evidence that thrombosis and ischemia are not responsible for the development of navicular syndrome, use of these medications has been questioned. Recent data indicate that orally administered isoxsuprine hydrochloride, pentoxifylline and propentofylline are poorly absorbed and do not increase blood flow to the foot. Nevertheless, there is considerable clinical as well as research evidence that these medications can be beneficial, and practitioners continue regularly to recommend their use. Oral warfarin therapy for navicular syndrome has largely gone out of favor.

Other systemic medications that are routinely used include IV **hyaluronan** (Legend), IM polysulfated glycosaminoglycan (Adequan), and oral feed supplements such as glucosamine HCl and chondroitin sulfate. In addition, intravenous tiludronate, a bisphosphonate used to normalize bone metabolism, has been shown to be beneficial in treating some horses. This drug currently requires FDA approval for use in the USA.

Palmar digital neurectomy is the most commonly performed surgical technique used to manage horses with caudal heel pain. It is **purely palliative**, and should probably be considered a last resort when more conservative methods of management are no longer effective. Palmar digital nerve block should always be carried out before a neurectomy is considered in order to assess the likely results of surgery. Owners should be informed of associated risks of injury as well as of the possibility of nerve regrowth or painful neuroma formation.

Desmotomy of the medial and lateral collateral (suspensory) ligaments of the navicular bone is also used as a surgical treatment. Under general anesthesia the ligaments are sectioned on the medial and lateral aspects of the pastern just below the level of the pastern joint. The effects of this treatment are not well documented and clinical improvements may actually be due to

sectioning of sensory nerve fibers. Variable results have been reported, and clinical improvement is usually short term.

Other treatments that have been described include shock wave therapy, desmotomy of the accessory ligament of the DDFT, temporary chemical neurectomy or percutaneous cryoneurectomy, surgical drilling of cysts and acupuncture.

Prognosis for a complete return to soundness is good in the early stages, providing the condition is recognized and treatment is instigated at that stage. The prognosis is guarded once the disease is established, and poor in the advanced stages when the lameness is persistent and there is radiographic evidence of cortical and medullary erosion involving the flexor surface of the bone.

Laminitis

Laminitis (or **founder**) is a complex systemic metabolic disease that results in **acute degeneration of the laminae** that form the supportive bond between the distal phalanx and the hoof wall. Occasionally, simple mechanical overloading of the laminae can cause the same changes.

Because laminitis is a **systemic disease**, all four feet are often involved to some extent, but the condition is usually more severe in the front feet. Ponies are more often affected than horses, but laminitis in the horse tends to be more severe and life threatening.

The disease can be divided into three phases: the **developmental phase** when the trigger factors initiate the complex pathway of events that lead to disintegration of the lamellar attachments and changes in the foot; the **acute phase** from the onset of clinical signs until the **chronic phase** begins; and the chronic phase when there is either 48 h of continual pain or evidence of distal phalanx rotation and/or sinking.

Etiology and pathogenesis

There are many **predisposing factors** that can trigger the development of laminitis. These include alimentary carbohydrate overload with grain starch (grain founder), lush grass overload on fructan rich pasture (grass founder), obesity, endometritis, retained placenta or severe systemic infection, colic, stress and/or exhaustion, ingestion of toxins, hormone imbalances, systemic or IA administration of corticosteroids, and viral respiratory disease. Horses with **equine Cushing's disease** (*q.v.*) caused by a pituitary adenoma and those with peripheral insulin resistance are also predisposed to developing laminitis.

Over-exercise on hard ground (road founder) and excessive weight bearing on one limb due to an injury or a surgical procedure in the opposite limb can cause the same changes to occur in the foot as a result of mechanical overload.

The pathogenic mechanisms involved in development of laminitis are not fully understood, but recent work performed by the Australian Equine Laminitis Research Unit (AELRU) has contributed substantially to our understanding of the pathogenesis of this difficult disease. The primary pathology identified with development of laminitis involves a **failure of attachment** between the dermal and epidermal lamellae, ultimately resulting in a loss of the attachment between the hoof wall and distal phalanx. This failure specifically involves the **lamellar basement membrane**.

AELRU have identified molecular up-regulation of **lamellar matrix metalloproteinase-2 (MMP-2)** as a critical early event in the pathogenesis of laminitis. Structural components of the lamellar basement membrane are targets of the activated MMP-2, and the increased proteolytic activity promotes degradation and structural failure of the hoof lamellae at the dermo-epidermal junction. The basement membrane and anchoring filaments connecting the epidermal cells to the basement membrane may be the primary targets for MMP activity. In fact, enzymatic separation of basement membrane from lamellar epidermal cells is well underway before clinical signs of laminitis are apparent. Targeted inhibition of MMP-2 has the potential to prevent laminitis, but preventive strategies must be in place early to avoid permanent structural damage.

In addition to MMP activation, there is also substantial evidence that **peripheral insulin resistance** during stress, injury or infection could contribute to laminitis through **glucose deprivation**. Adequate glucose levels are required for maintenance of lamellar integrity, and glucose deprivation may contribute to the dermo-epidermal separation that characterizes laminitis. Inadequate glucose levels can result in depletion of the normal hemidesmosomes required to support epidermal cell attachments to the basement membrane, and similar reductions in the number or size of these crucial supporting structures have been observed with naturally occurring laminitis. Medical conditions contributing to the loss and failure of hemidesmosomes through insulin resistance and subsequent glucose deprivation, such as pituitary pars intermedia dysfunction (Cushing's disease, *q.v.*), may contribute to laminitis development.

An alternative hypothesis regarding the pathophysiology of laminitis proposes that digital hypoperfusion during the developmental stage of laminitis leads to ischemia and separation of lamellar tissue. Shunting of blood through arteriovenous anastomoses, vasoconstriction and perivascular edema are thought to contribute to the vascular compromise. Recent reports indicating that digital and laminar blood flow is increased during episodes of acute laminitis, as well as evidence that digital vasoconstriction is protective during the developmental stage of laminitis, do not support this vascular compromise theory of laminitis.

If the developmental phase is severe or prolonged, there will be laminar degeneration and breakdown of the epidermal–dermal **laminar bond** that suspends the distal phalanx within the hoof. Since the dorsal laminae are usually more severely compromised, the distal phalanx loses its dorsal support first. This, combined with the downward force of the body weight and the pull of the DDFT, results in the **distal phalanx rotating** down at the toe. The amount of rotation depends on the extent of the laminar degeneration. In severe cases, rotation can take place within a few hours of the onset of clinical signs.

In extreme cases, where all or virtually all of the laminae are involved, there is total loss of support for the distal phalanx and it “sinks” within the hoof (vertical distal displacement). In many cases, a combination of rotation and **sinking** may be present.

Clinical signs

The clinical signs vary depending on the severity of the attack. Most often both front feet are involved. In the acute phase, there will usually be a **sudden**

onset of signs. In severe cases, the horse may lie down for long periods and be reluctant to rise. There may be increased respiratory rate, muscle tremors and sweating. In milder cases, the gait is short and stilted and it can be difficult to lift a forefoot.

When standing, the front feet are usually held out in front of their normal position to transfer the weight to the heels and the hind feet are tucked under the body to take weight off the front feet. The back is usually arched and the muscles of the back and quarters are tensed, which may give the impression of a back injury. When the horse moves it will place the heels of the affected feet to the ground first in an exaggerated manner (**laminitic gait**), and it may show hyperflexion and short steps with the hindlimbs, which can be mistaken for a hindlimb problem.

On examination, the feet will usually be **hot**, particularly around the coronary band, and there will typically be a marked increase in **digital pulse strength**. A painful response can usually be elicited using light pressure with hoof testers over the sole. In horses with rotation of the distal phalanx the foot is usually most sensitive over the toe, while “sinkers” or horses with vertical displacement of the distal phalanx tend to be sore over the entire sole. Areas of bruising may be evident.

In the **chronic phase**, the degree of rotation and/or sinking of the distal phalanx influences the degree of lameness. With a mild to moderate degree of rotation, initially the sole is pushed down and becomes flat or slightly convex (**dropped sole**) and there will be increased sensitivity to light pressure in this area. There will be a slight depression at the dorsal coronary band. Over time, the foot will develop characteristic changes due to the disparate growth rates between toe and heels, associated with the position of the bone and compromised blood supply. The dorsal hoof wall becomes concave, the heels grow long, and there will be distinct **laminitic rings** around the wall. These are growth rings that are wider apart at the heels than they are at the toe. The white line also becomes wider as the laminae are stretched.

With severe rotation of the distal phalanx, which is often accompanied by some degree of sinking, lameness will be severe and the horse may be recumbent for long periods, often resulting in development of **decubitus** ulcers. There is usually a soft semicircular bulge of the sole just in front of the point of the frog indicating imminent prolapse of the distal phalanx. Serum may be oozing from the surface of the bulge, or the horn may break to reveal the corium covering the bone.

In complete vertical displacement without rotation of the distal phalanx, the degree of lameness may initially subside markedly and the horse may even weight bear evenly. Often, the only external feature will be a distinct depression at the coronary band all the way around the foot. However, the lameness eventually increases accompanied by discharge and separation of the hoof wall at the coronary band.

Diagnosis

Laminitis can often be mistaken for other conditions, such as muscle injuries, colic and back pain. Diagnosis is based on the history and on the characteristic clinical signs.

Serial radiographs should be taken, starting as soon after the onset of the condition as possible. These are very useful in assessing if, and to what extent, rotation has taken place and in subsequently monitoring the progress of the case and selecting treatment. A lateromedial view with one marker placed at the apex of the frog and a second linear marker taped to the front of the hoof wall from the hairline down is the most helpful. A horizontal dorsopalmar view can detect medial to lateral rotation.

Treatment

Each case must be considered individually. The selection of treatment will depend on the predisposing factors and the severity and duration of the disease.

Acute laminitis should always be treated as a **medical emergency** since changes can take place within a matter of hours of the onset of the disease. It is important to instigate intensive therapy as soon as possible to prevent these changes occurring.

Treatment is aimed at removing the initiating cause, preventing or reducing the degree of pedal bone rotation or sinking, as well as minimizing delivery of “trigger factors” to the foot. **Forced exercise is contraindicated** as it places stress on an already weakened lamellar attachment apparatus causing further damage; however, once appropriate treatment has begun the horse should be allowed limited free movement whenever possible. Nerve blocks are not recommended because the degree of pain relief that they produce can result in increased weight bearing and movement, which in turn will cause further damage to the lamellar attachments.

Medical therapy of laminitis should include aggressive treatment of the primary disease process. Unfortunately there is no known treatment protocol that can effectively arrest the development of laminitis, although there is ongoing research investigating methods of inhibiting MMP activation. **Stall or small paddock rest** should be continued to prevent further damage.

Antimicrobial and **antiendotoxin** therapy are indicated when bacterial infection or endotoxemia are suspected. **Non-steroidal anti-inflammatory medications** including phenylbutazone, flunixin meglumine or ketoprofen are usually indicated to reduce inflammation and pain. Horses with acute laminitis will usually require at least 2 wk of NSAID therapy. Chronic administration of large doses of NSAIDs should be avoided due to risk of adverse systemic effects, and also because the analgesic effects of the NSAIDs may encourage the horse to ambulate more, increasing damage to the already compromised lamellar attachments. When NSAIDs are required for long periods, weekly fecal occult blood, PCV and creatinine levels should be performed to monitor for systemic toxicity.

Continuous cryotherapy using a slurry of ice and water for 48 h during the developmental and acute stages of laminitis can be used as a preventative strategy. Up-regulation of MMP enzymes is thought to contribute to the pathogenesis of acute laminitis, and cryotherapy applied during the developmental stage of laminitis can **limit MMP activity**. In addition, cold-induced vasoconstriction may limit delivery of laminitis trigger factors such as

cytokines and bacterial products. Aggressive cryotherapy for 24–48 h using boots containing ice and water or circulating cold water can effectively prevent development of acute laminitis in horses with conditions that put them at risk of developing acute laminitis.

Therapy designed to increase blood flow to the foot, including hot water footbaths and vasodilating drugs such as isoxsuprine hydrochloride, acepromazine and nitroglycerin, is **contraindicated** during the developmental phase of laminitis as it may increase exposure to circulating trigger factors and activate MMPs. Use of these therapies later in the management of laminitis is currently debated. There is little evidence that they do effectively increase blood flow to the foot, and the benefits of increasing laminar blood flow are not well established. However, acepromazine may also encourage a horse in pain to spend more time down, consequently protecting the lamellar attachments.

Hoof care and mechanical support are absolutely critical for effective management of laminitis at all stages. The goal of hoof care is to minimize damage to the lamellae by minimizing the forces that produce rotational or vertical displacement of the distal phalanx. The forces favoring displacement include the weight of the horse, the pull of the DDFT and leverage on the hoof wall, especially at the toe.

In the **developmental and acute phases** of laminitis the goal is to prevent distal displacement of the distal phalanx by providing optimal support for the distal phalanx. In these early stages shoeing is usually not indicated, but if the horse is already shod, removing the shoes may also be **contraindicated** as this often increases discomfort.

Stress on the wall and damaged laminar structures can be minimized by increasing the dimension of the weight-bearing surface by transferring weight from the wall to the **caudal solar surface** of the foot. Specifically, the frog and caudal sole can be recruited for weight bearing through application of dense Styrofoam pads, frog support pads and/or the use of soft supportive bedding materials like sand or peat moss. The toe can be unweighted by beveling or rockering it with a rasp, or by beveling the foam pad. Foam pads cut from sheets of very dense Styrofoam insulation provide an economical and effective method of supporting these patients. The pads can be applied using duct tape and flexible adhesive bandaging material. Alternatively a commercial system using a cuff with wedge pads and rubber impression material is available (Redden Ultimates) and provides excellent support.

Once the disease has become chronic, treatment is aimed at preventing further laminar damage and rotation or sinking of the distal phalanx, minimizing infection and necrosis, and resolving any systemic problems. Eventually an attempt should be made to re-establish normal alignment between the third phalanx and the wall and sole. Therapeutic trimming and shoeing are extremely important in the treatment of **chronic laminitis**.

The methods chosen will depend on the individual animal and the degree of damage in the foot. What will be effective in one animal may not be effective in another. Discussion and collaboration with the farrier and reference to lateromedial radiographs of the feet are essential in the selection of hoof management techniques.

The fundamental principles to follow when designing a treatment plan should include the following:

1. Utilize as much of the palmar aspect of the ground surface as possible for support.
2. Avoid removing sole, particularly under the toe of the distal phalanx.
3. Bring the breakover back toward the toe of the distal phalanx (in this context breakover refers to the last part of the foot or shoe to leave the ground).
4. Raise the heels when necessary to reduce tension from the DDFT, but continue to trim the heels to re-establish the relationship between the distal phalanx and the sole.

In mild cases with only **slight rotation**, removal of the shoe, trimming of the toe to reduce its fulcrum effect, lowering the heels to start realignment of the distal phalanx and maintaining the horse on a soft surface may be all that is required. Realignment of the distal phalanx, hoof wall and sole is brought about gradually by trimming based on serial radiographs. Some animals are more comfortable if frog support is continued or they are shod with a flat wide-webbed shoe with a rolled toe.

Where there is a **moderate degree of rotation**, the hoof wall at the toe should be trimmed back more radically to reduce the fulcrum effect, but use caution to avoid compromising sole thickness under the toe of the distal phalanx. The heels should be trimmed and a variety of shoes can be applied, with or without the addition of early frog support, depending on the response of the horse.

Different types of shoes that have been used effectively include flat wide-webbed shoes, full-bar shoes, egg-bar shoes, reverse shoes (these allow more radical removal of the hoof wall at the toe, but should never be used if the laminae are still friable as they can induce further rotation), glue-on shoes of any configuration, Equine Digital Support System (EDSS) shoes, heart-bar shoes, and steel or plastic adjustable heart-bar shoes. The **heart-bar** and adjustable heart-bar shoe should be used with caution. These are shoes with a built-in frog support bar that puts varying degrees of pressure on the frog depending on how it is made. These shoes require considerable experience to fit correctly, they do not compensate for growth or changes in hoof capsule to bone alignment, and more damage can be done with an incorrectly fitted heart-bar shoe than any other shoe or no shoe at all.

One of the most effective techniques for shoeing horses with **chronic laminitis** and moderate to severe rotation involves application of a shoe that transfers weight bearing to the palmar aspect of the foot and provides optimal support for the third phalanx. Hoof testers should be used first to confirm that the caudal third to half of the sole is relatively pain free, and a commercial shoeing system marketed by Equine Digital Support System Inc. can often be used with excellent results. The EDSS system includes a shoe that automatically reduces the length of breakover, a sole pad, wedge rails and frog inserts with various elevations, as well as dental impression material. The system offers a highly adjustable shoeing method that effectively allows the horse to dictate what feels best. The shoe and pad are designed to protect the toe of the distal phalanx and improve circulation by creating a gap between the anterior sole and the foot surface of the pad. The system seems to facilitate **minimizing**

NSAID doses, and free movement can be encouraged at this stage of treatment as the system provides dynamic support to the distal phalanx instead of static pressure. If the wall cannot effectively hold nails, or the horse cannot tolerate the concussion, the shoe can be applied using a cuff and screws placed into the insensitive wall.

A common problem in chronic laminitis is **recurrent abscess formation** and septic pedal osteitis (*q.v.*). Abscesses should be drained, and infected bone debrided as needed. Distal limb perfusion with broad-spectrum antimicrobials may help to resolve distal phalanx infections, and topical application of a mixture of povidone-iodine and sugar ("**sugardine**") (*q.v.*) is also commonly recommended to encourage drainage. If there is radiographic or clinical evidence of **seroma** formation (a sterile accumulation of serum) or infection under the hoof wall, a **dorsal wall resection** may be required. This involves removal of all undermined hoof wall, facilitates drainage, and encourages new hoof growth. Infected and necrotic laminae are removed and the foot bandaged with frog support until the laminae have produced a dry protective cuticle. The hoof wall resection technique was very popular at one time and was probably over utilized. Removal of the dorsal hoof wall is no longer recommended in horses with acute laminitis. However, the principles behind the procedure are still valid for management of chronic laminitis with extensive laminar damage and can benefit some horses.

Transection of the DDFT has also been advocated for treatment of horses with laminitis. The rationale behind performing the tenotomy is that it will reduce the pull of the DDFT and decrease shearing forces on the lamellae. In addition, the surgery facilitates lowering of the heels to realign the distal phalanx. Guidelines for when to perform the surgery are not well defined. In general the surgery is used in management of chronic recurrent laminitis cases, and it is usually considered a salvage procedure. Reported results have varied between practices, and this may reflect the timing of the procedure. The tenotomy can be performed in the mid-metacarpal or mid-pastern region. **Transection of the accessory ligament of the DDFT** (carpal or inferior check ligament desmotomy) has also been advocated to reduce tension on the DDFT in less severely affected horses.

Coronary grooving is a technique in which a groove extending from the medial to the lateral quarter is created through the hoof wall parallel to the coronary band and approximately 1.5 cm below the hairline. The groove extends to the depth at which soft translucent horn is visualized. The theory behind this technique is that it will relieve pressure on the dorsal coronary band and promote new hoof wall growth. In addition, grooving the area of the hoof wall associated with the extensor process in an effort to relieve pressure and suppuration created by rotation of the distal phalanx has provided pain relief in some cases.

The **prognosis** in laminitis should always be considered guarded and depends to a large extent on the degree of internal damage that has taken place and the number of feet involved. Horses that recover from one attack tend to be prone to further attacks. It is always important to find the initiating cause in order to try and eliminate this from the animal's environment or management. In cases of severe rotation or sinking, particularly if more than one foot is involved, or where extensive infection or necrosis of the feet

occurs, prognosis is very poor and destruction on humane grounds may be necessary.

Ossification of the collateral cartilages of the distal phalanx (sidebone)

Ossification of the collateral cartilages is most often found in the front feet in heavier breeds of horses. Ossification usually starts at the cartilage–bone junction or can originate at a separate location in the center of the cartilage, and is thought to be part of the normal aging process.

It is not unusual to find some degree of **sidebone** formation on radiographs of older horses, or young draft horses without associated lameness. Ossification is typically more extensive in the lateral than the medial cartilage. Excessive, abnormal or premature ossification can occasionally cause lameness. Increased loading and/or concussion on the collateral cartilages may predispose to ossification, and these tend to occur as a result of poor foot conformation or improper trimming and/or shoeing. Occasionally direct trauma to the cartilage can result in an area of ossification.

Clinical signs

Lameness associated with sidebone is considered to be rare, and when present it is usually thought to be associated with an inflammatory reaction at the onset of ossification or with excessive ossification. Recent evidence from detailed anatomic studies of healthy and diseased feet suggests that well-developed collateral cartilages and their associated vascular architecture may be critical for dissipation of concussion within the hoof capsule. Future studies may confirm that pliable, non-ossified collateral cartilages are essential for long-term pain-free locomotion.

In the early stages, lameness associated with sidebone development is often slight but will be increased on a hard or rough surface or when the horse is turned in the direction of the affected foot. Pain may be elicited on pressure with hoof testers over the heels. Paring of the foot may reveal hemorrhage at the “seat of corn” on the affected side(s). Lameness usually subsides given rest.

If the cartilage becomes **extensively ossified**, lameness may be more marked, and there is often pain on palpation of the area as well as a loss of pliability of the cartilage. With loss of normal expansion accompanying extensive ossification, the hoof wall from the heels to mid-quarter on the affected side(s) tends to become more upright and the coronary band bulges in this region.

Diagnosis

The diagnosis is based on clinical signs and shape of the foot in advanced cases. It should be confirmed by uniaxial or biaxial palmar digital nerve blocks and with radiographs. Radiographic evidence of ossification of the collateral cartilages does not necessarily mean that this is the cause of lameness and the findings should be correlated with the clinical signs and the results of nerve blocks (*q.v.*).

Occasionally what appear to be “**fractured**” sidebones may be identified radiographically. Usually these are actually separate **centers of ossification**, but traumatic fractures have also been described.

Treatment

Foot imbalance should be corrected and the feet shod with a flat, wide-webbed shoe with a rolled toe, fit wide at the quarters and heels, and extending beyond the weight-bearing surface at the heels to support the posterior foot and encourage expansion. Combined with 6–8 wk rest this may be successful in the early stages.

In more advanced cases, treatment is mainly palliative and includes correction of any foot imbalance and shoeing as above, making sure that there are no nails behind the mid-quarters. **Long-term NSAIDs** may be necessary. Grooving or thinning the hoof wall at the quarters and heels may encourage expansion and reduce pain, but does tend to weaken the foot.

The prognosis for a complete return to soundness is good in the early stages, and guarded to poor if ossification is extensive.

Pedal osteitis

By strict definition, the term **pedal osteitis** refers to inflammation of the distal phalanx, and this diagnosis has commonly been made to explain chronic forelimb lameness. However, pedal osteitis is actually a very poorly defined condition that was traditionally diagnosed on the basis of radiographic evidence of bone demineralization, new bone formation and widening of the vascular channels in the distal phalanx.

These radiographic changes have been attributed to persistent trauma occurring as a result of **abnormal foot conformation**, including long toe/low heel imbalance, flat thin soles and clubfoot or when concavities or flares have developed in the external hoof wall. However, demineralization can also develop secondary to other conditions of the foot, such as abscesses, hoof wall cracks, laminitis and corns. In addition, there is considerable variation in the appearance of the distal phalanx between horses, and demineralization is probably over diagnosed. Furthermore, once radiographic demineralization of the distal phalanx develops, it tends to persist, and it is difficult to document active inflammation or bone resorption without scintigraphy.

Clinical signs

The clinical signs usually attributed to pedal osteitis are varied. The degree and type of lameness will vary depending on the initiating cause, the area of bone affected, and severity of damage. There will often be a marked increase in lameness on a hard or uneven surface and a decrease in lameness on a soft surface. There may be diffuse areas of bruising evident in the sole, and a painful response to pressure with hoof testers in these areas.

Diagnosis

There is increasing evidence that lameness is often incorrectly attributed to “pedal osteitis”, and many experts do not think that there is a discrete clinical syndrome associated with inflammation of the distal phalanx.

Radiographic changes in the distal phalanx include areas of demineralization around the solar margin, widening of the nutrient foramina at the solar margin, new bone growth on the solar margin of the wings and occasionally type VI fractures of the solar margin. Since many of these radiographic findings are found in sound horses and will persist indefinitely once they do develop, their significance should be assessed in conjunction with clinical signs and results of local anesthesia.

Treatment

Treatment depends on the cause, and should be aimed at the primary condition when that can be determined. If there is associated severe or chronic bruising, shoeing changes should be implemented and the horse should be rested until lameness subsides.

CONDITIONS OF THE HEELS

Sheared heels

The condition of sheared heels involves a loss of structural integrity of the tissue between the medial and lateral heels, and is probably a more common cause of lameness than is generally recognized.

The structural breakdown between the medial and lateral heels appears to occur as a result of **uneven loading** of the heels and disproportionate use of one heel. When the foot is examined from behind with the foot in a weight-bearing position, the bulb of the heel on the affected side is higher, and wall of that heel is longer. In severe cases the heels can be manipulated to displace them, confirming shearing of the structures between the two heels. This condition can be caused by a single incident of severe uneven loading but is usually the result of persistent slight uneven loading due to mediolateral foot imbalance.

Sheared heels are usually the result of **improper trimming** and/or shoeing, and poor conformation is often a contributing factor. Once the condition is created it tends to be perpetuated, since a disproportionate amount of the weight-bearing load tends to be shifted onto the affected heel when the hoof contacts the ground, displacing it further upward. The use of heel calks ("stickers") or studs will exaggerate this effect.

Horses with long toe/low heel imbalance are more prone to develop sheared heels because of the already weak heel structure. Sheared heels may also follow long-term corrective trimming for a conformational defect in young horses, or occur as a result of a painful lesion elsewhere in the foot or limb that causes an alteration in the way the foot contacts the ground. Front feet are usually more severely affected, and the medial heel is most commonly displaced proximally.

Clinical signs

Lameness is usually insidious in onset, but the degree depends on the duration and severity of the deformity. The anterior phase of the stride will be shortened with the toe of the foot contacting the ground first. The affected heel may be seen to strike the ground first on landing and to move proximally

relative to the other heel. The central sulcus of the frog appears unusually deep, with the heel bulb on the affected side higher than the other. The hoof wall at the heel and quarter on the affected side is steeper, and on the non-affected side it will usually be flared. In severe cases, the hoof wall on the affected side may be rolled under the foot.

On manipulation, the heel bulbs may be able to be displaced in opposite directions proximally and distally and the horse will usually react painfully to this manipulation. However, with chronic upward displacement of one heel, it can be difficult to detect instability with manual manipulation. A painful reaction may also be elicited by pressure with hoof testers across the heels or from mid-frog to the opposite quarter. Radiographs are indicated to rule out other problems.

Diagnosis

Diagnosis is based on the clinical signs and characteristic appearance of the foot. There will usually be a marked improvement in, or abolition of, lameness following palmar digital nerve block (*q.v.*).

Treatment

The aim of the treatment is to restore normal foot balance and shape and relieve pain. Since each animal is an individual and may react in different ways, no set technique for correction can be applied, but guidelines can be considered.

In mild cases, the heels should be trimmed to the same length and a **bar shoe** fit to stabilize the heels. In more severe cases, the affected heel should be trimmed or “floated” so it will not make contact with the shoe, and in time the horse’s body weight will push the heel back down into alignment. To encourage more rapid realignment of the heels prior to shoeing the foot can be maintained overnight in a “**foot-soak bandage**” (consisting of water-soaked wrap material or commercial baby diapers applied to the foot with an impervious covering of duct tape) with a frog support insert (i.e. Lily Pad). If there is a flare on the unaffected side, this should be rasped to try and return the wall to a normal angle. This can rarely be achieved in one trimming. The foot is shod with a **full bar shoe**. When the hoof wall on the affected side is rolled under, the shoe should also be fit wide at the heels and quarters on the affected side to give support and encourage the wall to grow down without collapsing. Trimming and shoeing may be required several times in advanced cases before balance is restored.

The prognosis is good in most cases although some horses may require a prolonged period of corrective trimming and shoeing. If there has been severe structural damage, the prognosis is guarded and permanent shoeing with a full-bar shoe may be necessary.

Avulsion of the hoof wall at the heel

This is a separation of a portion of the hoof wall from the underlying structures at the heels. It may involve the corium and coronary band. The most common causes include standing on or kicking a sharp object, trapping the

foot in wire, prolonged foot imbalance or incorrect removal of the shoe. It can also occur secondary to submural infection. Avulsions can be complete or partial.

Clinical signs

The degree of lameness will vary depending on the position and extent of avulsion and the depth of the injury. With an **acute avulsion**, the horse will often be very lame, resenting any examination of the foot. In **chronic cases**, lameness is usually less marked unless there is involvement of deeper structures. Wound healing may be evident but this is often delayed by infection.

Diagnosis

The diagnosis is usually straightforward but careful examination of the foot is needed to determine the full extent of the injury.

Radiographic examination can be of value in assessing involvement of deeper structures. Contrast radiography can be useful.

Treatment

In cases of **acute partial avulsions**, attempts at repair rarely work, and it is best to completely remove the separated portion of hoof wall. This is best done under general anesthesia so that the damaged area can be assessed and thoroughly cleaned. The exposed corium should be lavaged with an antiseptic solution and the area packed with a non-caustic antiseptic astringent agent such as "sugardine" (*q.v.*). The foot should then be dressed and bandaged, and the bandages changed every 2–3 days until protective cuticle has formed over the corium.

In cases of **complete heel avulsions** where there is involvement of the sensitive corium, any remaining separated pieces of hoof wall should be removed, the corium cleaned and debrided and any wounds in the coronary band sutured. The wound should be packed, and dressed as above. The use of a **foot cast** covering the entire hoof and extending up to the level of the pastern is often recommended to reduce the amount of movement, which can delay healing. If secondary infection occurs, the presence of the cast makes it difficult to detect and treat.

Once a **firm dry cuticle** has formed, a full-bar shoe can be applied to the foot with an extension in the area of the avulsion to give added support. Hoof repair materials can be used to fill the defect and protect the area, but should be used with caution since covering the area prevents inspection and cleaning, and can create an ideal **anaerobic environment** for bacterial infection.

Where there is evidence of infection and/or involvement of deeper structures, chronic heel avulsions should be treated as described previously for group 2 hoof abscesses (*q.v.*).

The prognosis depends on the extent of the avulsion and the structures involved. In cases of partial avulsions the prognosis is usually good. Where there is damage to the coronary band and dermal laminae the prognosis is more guarded.

Heel bulb lacerations

Because of their distal location on the limb, the foot and pastern regions are particularly susceptible to trauma. Lacerations are most frequently found over the bulbs of the heels. These heel bulb wounds usually involve one heel and appear as an inverted U, and they often occur when the horse kicks at or steps on a sharp-edged object such as barbed wire or roofing sheet metal. **Overreaching** with a hind foot can also result in serious injuries. Open wounds quickly become contaminated with feces, urine and dirt.

Diagnosis

The diagnosis is straightforward but careful examination of the foot is needed to determine the full extent of the injury. Possible complications include coronary band injury, arterial laceration, nerve damage, collateral cartilage injury (could result in quittor) as well as joint capsule penetration (*q.v.*). The integrity of the DIP joint, navicular bursa and digital sheath should be assessed. Radiographs can be taken to assess involvement of deeper structures.

Treatment

Carefully evaluate wounds and consider potential complications prior to initiating treatment. The branches of the laceration may extend through the coronary band, but there is seldom much loss of tissue—it is usually pulled loose as a flap. As the horse moves, these wounds alternatively gape open and close, and this constant motion will result in delayed healing and excessive granulation tissue (**proud flesh**) (*q.v.*).

Usually a combination of **suturing** and stabilizing the repair in a **foot cast** (*q.v.*) will provide the best cosmetic and functional end result. Fresh clean wounds can be closed primarily, but delayed primary closure generally is recommended for the acute contaminated laceration.

SOFT TISSUE INJURIES AND DISEASES

INTRODUCTION

Soft tissue injuries and diseases, apart from injuries to the flexor tendons and suspensory ligaments, have previously been underestimated as causes of lameness or poor performance. It should always be borne in mind that when there has been trauma to a joint or bone it is likely that there is **concurrent soft tissue pathology**. Advances in diagnostic techniques, notably local analgesic techniques, diagnostic ultrasonography and arthroscopy, have made us more aware of the incidence and importance of these injuries, either alone or in conjunction with bone pathology.

DISEASES OF THE SUSPENSORY APPARATUS

Superficial digital flexor tendinitis in the metacarpal/metatarsal region

Superficial digital flexor tendinitis is predominantly an injury affecting one or both forelimbs of horses that work at speed, especially racehorses and

advanced level event horses. However, any type of performance horse can be affected. It is considered to be an **overstretch injury** and muscular fatigue is probably a predisposing factor. Foot imbalance and conformational abnormalities may be underlying factors, aggravated by sudden alterations in ground conditions or irregular surfaces. It is likely that multiple episodes of submaximal strain induce **microdamage** that accumulates and predisposes to eventual injury. Lesions can range from minor tearing to complete tendon rupture.

Clinical signs

There is usually **localized heat with swelling** from fluid accumulation or palpable thickening of the superficial digital flexor tendon (SDFT). Pain can often be elicited by direct palpation of the margins of the tendon. Lameness may be present but is frequently absent in mild injuries, and this emphasizes the need for diligent observation to pick up subclinical injuries.

The **degree of swelling** is often proportional to the severity of the injury, but core lesions tend to swell less than peripheral injuries. In mild cases, clinical signs often resolve with confinement to box rest and application of a bandage, with or without cold therapy, but the potential significance of the underlying lesion should not be overlooked, and these horses should have an ultrasound evaluation before returning to work.

Diagnosis

Diagnostic ultrasonography is essential to assess the extent, type and severity of injury, and to monitor progress. One important caution is to recognize that examination of a recent SDFT injury may not reveal the full extent of the injury. If the SDFT appears only slightly enlarged or even normal on ultrasound, but clinical signs suggest that there could be an injury, the horse should be managed conservatively and the examination **repeated** in 3–7 days.

In most cases both forelimbs should be assessed since lesions are frequently **bilateral** although overt clinical signs may only be detectable in one limb. High quality images are essential for accurate diagnosis and prognosis. Abnormalities that can be detected include enlargement of the tendon, poor definition of one or more of its margins, and a reduction in echogenicity in a localized or more diffuse area (e.g. a central, anechoic core lesion or a diffuse hypoechoic area involving the entire cross section of the tendon). High-resolution images and experience in evaluating these images are critical for accurate interpretation.

Treatment

The aims of treatment are to reduce inflammation and pain, minimize further damage, restore normal fiber alignment as soon as possible, promote increased speed of healing and enhance the quality of the repair tissue. However, even under optimal conditions the **repair tissue** will not be as strong as an undamaged tendon.

A prolonged period of stall rest with gradually increasing controlled exercise is required for adequate healing to occur. **Scheduled exercise**, which usually involves walking in the early stages, stimulates optimal collagen fiber

alignment. Healing should be monitored with ultrasound on a regular basis (30–60 days) in order to determine when increased exercise is warranted. Uncontrolled turnout should be avoided. Appropriate rehabilitation is probably the most important aspect of treatment, and must be performed regardless of the other treatments that are used.

NSAID medications, cryotherapy with ice and/or cold water, pressure/compression wraps, topical DMSO and therapeutic ultrasound can help to reduce inflammation, swelling and pain. The use of systemic and intralesional corticosteroids should generally be avoided as they appear to retard healing.

Surgical options for managing SDFT injuries include **percutaneous tendon splitting**, in which ultrasound-guided incisions are made into the lesion. By evacuating the area of hemorrhage, reducing lesion size and possibly enhancing resolution of inflammatory edema, this procedure may be helpful in the acute stage of central core lesions. **Transection of the accessory ligament of the SDFT** (superior check ligament desmotomy) has been reported to reduce the incidence of re-injury in some horses, and is considered most valuable for Standardbred racehorses. **Annular ligament desmotomy** can be beneficial in the management of distal SDFT tendinitis in which the tendon is constricted by the palmar annular ligament.

Various drugs including intralesional hyaluronan, PSGAGs (*q.v.*) and most recently ACell Vet Powder (a derivation of extracellular matrix of swine urinary bladder) have been used to improve the quality of the repair tissue. In addition, bone marrow, stem cell and growth factor (i.e. insulin-like growth factor) injections are currently being advocated. Bone marrow injections are likely to provide high concentrations of **growth factors** as well as some **primordial stem cells**. Vet-Stem Inc. offers stem cell therapy technology on a commercial basis. The injured horse's fat is collected and mailed to the company, where stem cells are isolated, concentrated and sent back to be injected into the tendon injury. Treatment within 28 days of injury is recommended to minimize fibrosis. Additional research is needed to document the benefit of these treatment modalities.

Prognosis is dependent on the severity of the initial injury. Severe injuries result in **peritendinous adhesions** (*q.v.*), which predispose to re-injury. Repair tissue is mechanically inferior to normal tendon tissue and the incidence of re-injury is high. Once returned to performance, the horse should always be maintained as fit as possible for the work it is required to do.

Superficial digital flexor tendinitis in the pastern region

In the pastern region the SDFT divides into two branches that encircle the DDFT before inserting on the palmar aspect of the middle phalanx. Injury to the SDFT in this area may be a sequel to a previous injury in the metacarpal region, or occur in isolation. It occurs much more commonly in the forelimb than in the hindlimb.

Clinical signs

There is usually associated lameness, greater in degree than a comparable injury to the SDFT in the metacarpal region, and **localized heat, pain and swelling** on the palmar lateral and/or medial aspects of the pastern. Usually

only one branch is affected. In the acute stage there may be lameness that is improved or alleviated by perineural analgesia of the palmar (abaxial sesamoid) nerves but no detectable swelling.

Diagnosis

The diagnosis is confirmed ultrasonographically: the affected branch is enlarged, its margins may be poorly defined and it is of irregular echogenicity. This should be differentiated from injury to a distal sesamoidean ligament, DDFT tendinitis, or peritendinous trauma (*q.v.*).

Treatment

The same principles of treatment apply as for SDFT tendinitis in the metacarpal region (*q.v.*). The incidence of re-injury is very high, regardless of the method of management.

Deep digital flexor tendinitis

Deep digital flexor tendinitis in the metacarpal or metatarsal region is less common than SDFT tendinitis but is seen alone, or in association with the palmar (plantar) annular ligament syndrome. Subtle lesions of the dorsal margin can also be seen in association with desmitis of the accessory ligament of the DDFT.

Clinical signs include localized heat, swelling and pain and associated lameness; in some cases there is no detectable enlargement of the DDFT and in others the degree of swelling is too extensive to determine definitively, with palpation alone, which structures may be involved. Involvement of the DDFT within the digital sheath can result in **distension of the tendon sheath** and marked lameness.

Diagnosis is generally confirmed using diagnostic ultrasonography, although tenoscopic evaluation of the digital flexor tendon sheath may be required to appreciate some linear tendon defects. The same treatment principles apply as for SDFT tendinitis (*q.v.*); the incidence of re-injury is high.

Deep digital flexor tendinitis in the **pastern region** or in the **foot** occurs more frequently. There is localized swelling on the midline of the pastern region and associated heat and swelling although lesions further distally may have no detectable palpable abnormalities. There may be associated distension of the flexor tendon sheath. There is usually associated lameness.

Pastern lesions are confirmed ultrasonographically. The appearance of the DDFT is dependent on the **angle** of the transducer head, and hypoechoic areas should be interpreted with great care. Injuries within the hoof capsule typically require specialized ultrasound techniques, MRI, or contrast enhanced CT imaging for diagnosis.

Treatment is prolonged rest and rehabilitation. Intralesional therapy with stem cells on ACell have been used to improve the quality of repair tissue. The prognosis for return to sustained full athletic function is guarded.

Deep digital flexor tendinitis progressing to partial or complete rupture can occur following **palmar digital neurectomy**. Pre-existing pathology in the DDFT and/or flexor cortex of the navicular bone may be predisposing factors. Following rupture, there is **marked swelling** in the palmar aspect of the

pastern, severe lameness and often subluxation of the distal interphalangeal joint. The horse appears to walk on its heel. The prognosis is grave.

Accessory ligament of the deep digital flexor tendon (inferior check ligament) desmitis

The accessory ligament of the DDFT or **check ligament** is a substantial supporting structure in the forelimb that is similar in diameter to the DDFT itself. It arises from the palmar carpal fascia and joins the DDFT in the mid-metacarpal region. In the hindlimbs it is generally much smaller and less prone to injury.

Clinical signs

Injury almost invariably results in sudden onset of lameness during work. Localized swelling (medial and lateral), heat and pain develop within the following 24 h. Lameness usually resolves relatively quickly, long before healing is complete.

Diagnosis

Diagnosis can be confirmed ultrasonographically, and healing monitored with serial examinations.

Treatment

Treatment is as for SDFT tendinitis (*q.v.*). Uncontrolled turnout will result in exacerbation of the injury, but **controlled exercise** is important to minimize the risk of adhesion formation. Horses are often able to resume work within 6 mo. The prognosis for future athletic function is fair. Severe injuries may be associated with the development of adhesions and a secondary flexural deformity of the metacarpophalangeal joint, or SDFT tendinitis. These patients, and horses with chronic recurrent desmitis, may benefit from desmotomy of the accessory ligament.

Palmar/plantar annular ligament desmitis

The **palmar annular ligament** traverses the palmar aspect of the digital tendon sheath at the level of the fetlock joint. The annular ligament with the sesamoid bones and intersesamoidean ligament create an inelastic fetlock canal around the SDFT, DDFT and digital sheath. The annular ligament is in part contiguous with, and attaches to, the digital sheath so that they appear as one structure on ultrasound. This ligament maintains the position of the flexor tendons.

The ligament itself can be injured by direct trauma or with hyperextension of the metacarpophalangeal (or metatarsophalangeal) joint. Direct trauma can cause thickening and contraction of the ligament, effectively reducing the diameter of the fetlock canal. Desmitis is often grouped with other conditions including tenosynovitis of the digital sheath (*q.v.*), SDFT or DDFT tendinitis, adhesions between the sheath and tendon and combinations of these problems under the heading of **palmar annular ligament syndrome** (*q.v.*) or constriction of the annular ligament.

Clinical signs

There is localized heat, swelling (resulting in a **bulge** on the palmar aspect of the limb at the level of the ligament, as opposed to the notch observed with primary tenosynovitis) and pain. Lameness is variable in degree and can be due to the desmitis or due to compression of the flexor tendon or restriction of free movement of the tendons.

Diagnosis

Diagnosis is based on clinical signs and ultrasonography. With acute injury there is enlargement of the ligament and focal or diffuse areas of reduced echogenicity. All other structures should be examined carefully to exclude concurrent injury.

Treatment

Treatment involves rest, NSAIDs, bandaging, cryotherapy and topically applied anti-inflammatory agents (e.g. DMSO). The period of rest required is variable. Usually localized swelling persists. Sometimes **local adhesions** develop, resulting in recurrent lameness.

Suspensory ligament desmitis—body and branch lesions

The **suspensory ligament** originates from the proximal palmar aspect of the third metacarpal bone and the palmar carpal ligament in the forelimb, and it originates from the plantar aspect of the third metatarsal bone in the hindlimb. The ligament divides in the mid-metacarpus/tarsus, and the resulting medial and lateral branches insert on the ipsilateral proximal sesamoid bones. Extensor branches are given off and join the extensor tendons. With respect to routine injury the suspensory ligament can conveniently be divided into its proximal third and the remainder of the body and branches. Injuries of the proximal part of the suspensory ligament are considered separately.

Sprain of the body and/or branches of the suspensory ligament is usually seen in horses that work at speed and/or race over fences, although **localized** soreness of the suspensory ligament branches is regularly detected in dressage horses. Straight hindlimb conformation and/or hyperextension of the metacarpophalangeal (metatarsophalangeal) joints and/or foot imbalance may predispose to injury of the suspensory apparatus.

Clinical signs

There is usually **palpable enlargement** of the body and/or one or both branches of the suspensory ligament with associated heat and localized pain. In some cases **swelling is so extensive** initially that identification of individual structures by palpation is difficult, especially if there is a concurrent fracture of the distal second or fourth metacarpal bones. When detected, lameness is often not proportional to the extent of the injury but may be **worse on soft ground**. There is usually pain on passive flexion of the metacarpophalangeal (metatarsophalangeal) joint and accentuation of lameness following flexion. In some horses there is concurrent pain associated with the metacarpophalangeal joint.

Diagnosis

Diagnosis is based on clinical signs and ultrasonography. Unfortunately, there is considerable variation in the normal appearance of the suspensory ligament, including an inconsistent amount of muscular tissue, and images must be interpreted with care. Lesions often persist for a long time ultrasonographically and serial imaging is less useful for predicting when a horse may be returned to work compared with SDFT lesions. Nevertheless, some improvement including a reduction in the cross sectional diameter of the ligament may be observed and **serial ultrasound** examination is strongly recommended even after the horse returns to work.

The second and fourth metacarpal bones should be evaluated radiographically together with the proximal sesamoid bones to eliminate the possibility of concurrent fracture, sesamoiditis or mineralization within the ligament.

Treatment

The same principles of treatment apply as for SDFT tendinitis (*q.v.*). There is a high incidence of recurrent injury.

Suspensory ligament desmitis—proximal

Proximal suspensory desmitis refers to lesions in the suspensory ligament in the proximal third of the metacarpus (or metatarsus). This is a **common injury in athletic horses** from many disciplines, and it is associated with either a sudden or insidious but often transient onset of lameness. With hindlimb involvement the lameness is often more severe and persistent.

Clinical signs

Since the suspensory ligament lies between the bases of the second and fourth metacarpal (metatarsal) bones there is frequently no detectable enlargement of the ligament, although further distally its margins may feel slightly rounded. There can be localized heat with or without distension of the medial palmar vein.

Pain can often be elicited by pressure applied over the origin of the suspensory ligament. Lameness varies from mild to moderate and usually improves considerably with rest. Lameness is typically worse on soft surfaces, especially with the affected limb on the outside of a circle. The condition can be **unilateral or bilateral**, in which case the horse may present for a loss of action.

Diagnosis

Pain should be **localized** to the proximal metacarpal (metatarsal) region using perineural analgesia although interpretation of these blocks can be complicated by diffusion and inadvertent synovial analgesia. In particular, care should be taken to eliminate the middle carpal and tarsometatarsal joints as potential sources of pain.

Diagnosis is confirmed ultrasonographically but requires high quality images for accurate interpretation. There may be enlargement of the suspensory ligament, poor definition of one or more of the margins, ectopic mineralization, loss of fiber pattern, a central hypoechoic lesion and/or a more

diffuse decrease in echogenicity. Comparison with the contralateral limb is often useful.

The proximal metacarpus/metatarsus should be examined radiographically, together with the carpus or tarsus to exclude the possibility of an avulsion fracture at the origin of the suspensory ligament, a palmar cortical fatigue fracture, and/or osteoarthritis of the middle and/or carpometacarpal or tarsometatarsal joints (*q.v.*).

Treatment

Treatment consists of **prolonged stall rest** with gradual introduction of controlled exercise. The speed of recovery is often proportional to the duration of lameness prior to inception of treatment and to the severity of the injury. Recurrent injury in hindlimb proximal suspensory desmitis is common and prognosis is generally poor.

Many of the treatments discussed for SDFT tendinitis (*q.v.*) can be used for proximal suspensory injuries. **Extracorporeal shock wave treatment** has been particularly successful in management of chronic unresponsive injuries (Box 15.8).

Owners should be cautioned to allow the horse **adequate time** to heal before returning it to work since shock wave therapy also provides analgesia. Intralesional bone marrow, stem cell and ACell Vet Powder (a commercially marketed derivation of extracellular matrix of swine urinary bladder) injections have also been advocated, and there is some preliminary evidence that lesions heal more rapidly and effectively. Infiltration of proximal suspensory lesions with 2% iodine in almond oil has been used for many years, but creates considerable scarring.

Surgery may be necessary in unresponsive cases. **Suspensory desmoplasty** (surgical fasciotomy and splitting) can be performed with ultrasound guidance on the front or hind limbs. Alternative surgical interventions including tibial neurectomy, neurectomy of the deep branch of the lateral plantar nerve and fasciotomy of the deep plantar metatarsal fascia have all had some reported success in returning horses with hindlimb proximal suspensory desmitis to athletic function.

Proximal suspensory desmitis often occurs **concurrently** with some other cause of lameness or in association with poor foot balance. Obviously, all problems diagnosed should be addressed.

Complete breakdown of the suspensory apparatus

Traumatic rupture of the suspensory apparatus during racing or training is uncommon in Europe but relatively common in racehorses in the US. It is often **catastrophic** since extreme hyperextension of the metacarpophalangeal joint ensues, with potential disruption of the blood supply to the distal limb.

Loss of the suspensory apparatus can occur with fracture of the proximal sesamoids, disruption of the body or branches of the suspensory ligament, rupture of the distal sesamoidean ligaments, metacarpal fracture, rupture of the intersesamoidean ligament or with a combination of those injuries. Traumatic disruption of the suspensory apparatus is also seen in **young foals**

Box 15.8 Extracorporeal shock wave therapy

- Acoustic pressure waves with peak pressures of 10–100 MPa
- Rapid pressure rise times of 30–120 ns
- Variable pulse frequencies
- Dose-dependent effects on bone and soft tissues
 - Analgesia
 - Hemorrhage and hematoma formation
 - Increased regional blood flow
 - Microfracture of cortical bone
 - Stimulation of osteogenesis
- **Radial** shock waves expose broad areas of tissue
 - Low peak pressures and shallow depth of penetration
- Radial shock waves generated:
 - **Pneumatically**
- **Focused** shock waves converge on a target point guided by ultrasound or radiography
 - High peak pressures and greater depth of penetration
- Focused shock waves generated:
 - **Electrohydraulically**
 - **Piezoelectrically**
 - **Electromagnetically**
- Exact mechanisms of action are unknown
- Various treatment protocols are used ranging from one to three treatments at 3–14 day intervals
- Equine conditions treated with shock wave therapy include:
 - Proximal suspensory desmitis
 - Superficial digital flexor tendinitis
 - Osteoarthritis of distal tarsal joints and interphalangeal joints
 - Stress fractures
 - Bucked shins and dorsal cortical stress fractures of the metacarpus
 - Navicular syndrome.

running out in pasture, and this is usually associated with fracture of both sesamoids.

Immediate emergency treatment is essential to prevent vascular trauma by maintaining the metacarpophalangeal joint in flexion. This may be achieved by application of a specially designed commercially available splint (**Kimzey Leg Saver Splint**) or by attaching a wood splint to the sole of the foot and strapping this to the palmar aspect of the metacarpus.

The prognosis for athletic function is grave. However, if the blood supply and skin are intact, some horses are salvaged for breeding, usually by performing a metacarpophalangeal joint arthrodesis. Conservative management with long-term splinting has also been used successfully.

Degenerative suspensory ligament desmitis or atraumatic degeneration and breakdown of the suspensory ligaments associated with hyperextension of the fetlock joints is a progressive degenerative syndrome recognized in

horses that have intense workloads as well as in older broodmares. This syndrome also occurs spontaneously in certain breeds (**Peruvian Paso**, **Andalusian**). The hindlimbs are most commonly affected, and it is usually bilateral (can be quadrilateral) and unresponsive to treatment, although shoeing the horse with flat shoes with long heel extensions can provide some support for the fetlock. Horses may only appear stiff initially, but lameness can become quite severe.

The etiopathogenesis of this problem is unclear, but there is no sex, age or work-related predisposition in Peruvian Pasos. In that breed, the degenerative changes and progressive enlargement are typically most severe in the branches, and the disorder often involves all four limbs. A genetic component has not been confirmed, but the etiology of this condition may be different in Peruvian Pasos than that in older horses with a history of heavy exertion.

Distal sesamoidean ligament desmitis

There are three distal sesamoidean ligaments, the paired **deep** or **cruciate**, the paired **middle** or **oblique** and the **superficial** or **straight**. With the advent of improved ultrasonographic equipment and expertise, injury to these structures has been recognized as an important source of lameness problems in performance horses. Ultrasonographic evaluation of the soft tissue structures over the palmar/plantar pastern is quite complex, and results should be interpreted with appropriate reference to normal anatomy and common artifacts. MRI can also be valuable in identifying these injuries. These ligament injuries should be differentiated from tendinitis (*q.v.*) of the medial and lateral branches of the SDFT in the pastern region.

There is usually some degree of lameness and associated enlargement of the palmar aspect of the pastern, and some horses will have digital sheath effusion. The lameness should improve following an abaxial sesamoid nerve block. Many horses will also improve with a palmar digital nerve block, presumably due to diffusion. It is usually not possible to determine which structure is involved with palpation alone.

Treatment involves a **prolonged period of rest** and rehabilitation (with corrective trimming and shoeing as appropriate). The incidence of re-injury is relatively high.

Injury to the middle distal sesamoidean ligaments is the most common, and tends to be associated with moderate to severe lameness. Enthesopathy at the site of insertion on the palmar aspect of the proximal phalanx is a common incidental radiographic abnormality. Desmitis of the straight distal sesamoidean ligament is an unusual cause of lameness, and usually involves the forelimbs when it occurs.

MISCELLANEOUS TENDON AND LIGAMENT INJURIES

Gastrocnemius tendinitis

The gastrocnemius tendon lies caudal to the SDFT in the mid-tibial region and then passes laterally and cranially to insert on the calcaneal tuber beneath the SDFT. The **intertendinous calcaneal bursa** is interposed between the tendons

of the SDFT and the gastrocnemius, while the **subtendinous calcaneal bursa** (or gastrocnemius bursa) is located deep to the gastrocnemius tendon near its insertion. The proximal part of the gastrocnemius tendon contains some muscular tissue and has an irregular echogenicity but, when it has assumed a position dorsal to the SDFT, has a more uniform echogenicity. Tendinitis of the gastrocnemius is unusual, but should be included among differentials for upper hindlimb lameness.

Clinical signs

With tendinitis there is usually slight to moderate enlargement in the region of the **Achilles tendon** (which includes the gastrocnemius and soleus tendons), with or without localized heat. It is usually difficult to elicit pain by palpation, and lameness varies from mild to severe. There can be associated distension of the calcaneal bursa/bursae, with or without a capped hock appearance.

Diagnosis

Lameness is usually improved by perineural analgesia of the tibial nerve (although this may reflect local diffusion of local anesthetic). Diagnosis is confirmed ultrasonographically.

Treatment

Mild cases may respond adequately to conservative treatment of box rest and controlled walking exercise for 3–6 mo but moderate to severe lesions carry a guarded prognosis for return to full athletic function. Ultrasonographic abnormalities of the tendon usually persist.

Biceps brachii tendinitis

The proximal tendon of biceps brachii attaches to the supraglenoid tubercle of the scapula and passes over the intertubercular groove of the humerus enclosed within the intertubercular (bicipital) bursa. At the level of the humeral tubercles the tendon has distinct lateral and medial lobes that are connected by an isthmus, and the tendon is partially cartilaginous.

Tendinitis of the biceps brachii from an **athletic injury** occurs most often in racehorses and results in acute onset lameness of variable severity. The tendon can also be injured traumatically. There may be focal pain induced by firm pressure applied over the region of the tendon and intertubercular bursa, or pain induced by manipulation of the upper forelimb, especially retraction. Lameness is **characteristically improved** by analgesia of the intertubercular bursa (*q.v.*).

Diagnosis is confirmed with ultrasound, although radiographs are warranted to rule out an underlying bony injury. Mild injuries may be difficult to identify since the curvature of the normal tendon creates artifacts, and images should be interpreted cautiously. The medial and lateral lobes of the biceps brachii tendon should each be evaluated. Biceps tendinitis should be differentiated from injury to the infraspinatus tendon and/or bursa (*q.v.*).

Treatment consists of box rest and controlled exercise for 3–6 mo. Intra-synovial injection of hyaluronan and/or corticosteroids can reduce the synovitis. Endoscopic as well as open surgical evaluation of the intertubercular bursa and underlying bone has also been described. Serial ultrasonographic examination may be useful to monitor healing. The prognosis for return to athletic function is guarded.

Luxation of the superficial digital flexor tendon

The SDFT of the hindlimb becomes flattened and wider as it passes over the tuber calcaneus, and it is held in position by strong medial and lateral fascial attachments. **Luxation or dislocation** of the SDFT from the point of the hock is an uncommon injury, but it can occur with racing, strenuous exertion (i.e. endurance) or trauma. The luxation is usually lateral.

Clinical signs

Displacement of the SDFT is usually a **sudden onset** injury; the SDFT slips off the tuber calcaneus and lies laterally, or less frequently, medially. It can remain mobile and slip on and off the tuber calcaneus. The unstable position of the SDFT in the acute state often results in lameness and **considerable apprehension**, and the horse may appear very distressed.

Usually considerable swelling develops within the initial 24–48 h, and this makes accurate palpation of the tendon increasingly difficult. However, if NSAIDs are used to control the development of swelling, the tendon may remain **more mobile** and cause more distress. Ultrasound can be used to determine the extent of soft tissue injury, while radiographs are recommended to rule out bone involvement. In some cases the tendon is only subluxated and unstable, and those horses have a better prognosis for future soundness.

Treatment

Although replacement of the SDFT and surgical stabilization has been attempted using various techniques, the results are often disappointing and generally require long-term cast immobilization. With conservative treatment (stall rest) pain-related lameness usually resolves, although the horse may be left with a mechanical gait abnormality. This does not necessarily significantly impair jumping ability.

Plantar ligament desmitis (curb)

The plantar ligament originates at the top of the tuber calcis, runs down the plantar aspect of the calcaneus and inserts on the distal tuber calcis, the plantar aspect of the fourth tarsal bone and fourth metatarsal bone and the plantar fascia. **Curb** is associated with thickening of the plantar distal aspect of the tarsus. However, it is important to confirm what structures are involved in horses that have thickening in this location (or a so-called “**curby**” appearance) as many conditions can mimic curb. In fact, the term **curb** is often used more generally to describe a whole collection of plantar tarsal soft tissue injuries including SDFT tendinitis, injury to the peritendinous/periligamentous tissues, and long plantar ligament desmitis.

Clinical signs

Racing Standardbreds are the most commonly affected, and poor hindlimb conformation, especially a **sickle hock conformation**, may predispose to ligament injury. There is usually localized heat and swelling and pain on palpation. Lameness is often absent, but if present is usually mild.

Diagnosis

Initial diagnosis is based on clinical signs but care should be taken to differentiate the swelling from a prominent base of the **fourth metatarsal bone** or from synovial effusions. Ultrasonography is necessary to differentiate a curb involving the plantar ligament from **subcutaneous edema, peritendinous/periligamentous inflammation** or **SDFT tendinitis**, and radiographs can be used to identify horses with **tarsal collapse**, which can also produce a curby appearance.

Horses with “curb” or swelling over the plantar aspect of the fibular tarsal bone are actually more likely to have swelling and injury of peritendinous and periligamentous tissue and/or SDFT tendinitis than an injury of the plantar ligament.

Treatment

Treatment for plantar ligament desmitis typically involves rest, or moderation of the exercise program, and local application of cold and topical anti-inflammatory agents such as DMSO. Rarely is there recurrent lameness, but some swelling may persist. With peritendinous/periligamentous inflammation, local treatment with corticosteroids and Sarapin (an extract of the pitcher plant) may be effective. Substantial SDFT injuries will require longer rehabilitation and ultrasound monitoring before return to work.

Supraspinous ligament desmopathy

The supraspinous ligament caudal to the withers region consists of a strong cord of white fibrous tissue attached to the summits of the dorsal spinous processes. Sprain of the supraspinous ligament causes **acute onset back pain** often associated with localized thickening and sensitivity to palpation, and results in a restricted gait. Tearing of the attachment can result in linear radiopacities proximal to the summits of one or more dorsal spinous processes. In association the horse may develop some atrophy of the longissimus dorsi muscles. Focal hypoechoic areas may be detected in the ligament using diagnostic ultrasonography.

Treatment is a prolonged period (3–6 mo) of rest; ultrasound therapy may be beneficial in the acute stages. Prognosis is usually fair to good.

DISEASES AND INJURIES OF ARTICULAR SOFT TISSUE STRUCTURES

Intercarpal ligament desmitis

Small ligaments cross the dorsal aspects of both the proximal and distal rows of carpal bones, attaching to each bone. Pulling or tearing of the attachments

results in periosteal new bone formation or **enthesopathy**. This is rarely associated with clinical signs, since the new bone is far removed from the joint margins. However, the development of enthesopathy probably reflects mild instability of the carpus that may predispose to osteoarthritis. Enthesopathy should be differentiated from periarticular osteophyte formation (*q.v.*). If enthesopathy is detected radiographically the radiographs should be examined carefully for modeling of the articular margins.

Several palmar carpal ligaments connect the proximal and distal rows of carpal bones on the palmar aspect of the joint. A large **medial palmar intercarpal ligament** attaches the radial carpal bone to the second and third carpal bones, and a lateral ligament joins the ulnar to the third and fourth carpal bones. **Desmitis** of one (or both) of these ligaments is associated with moderate to severe lameness and/or effusion of the middle carpal joint. Lameness is usually improved following IA analgesia.

Diagnosis is made by arthroscopic evaluation of the joint. The entire joint should be assessed for concurrent damage. The injury occurs most commonly in racehorses but has been seen in other performance categories.

Treatment involves rest and rehabilitation, although the prognosis for return to full athletic function without recurrent injury is guarded.

Collateral ligament injury

Most diarthrodial joints are supported medially and laterally by collateral ligaments. Sprain of a collateral ligament can occur within the body of the ligament and/or at the site(s) of bony attachment. Injuries to the collateral ligaments are most commonly recognized in the femorotibial, tarsocrural, distal interphalangeal and metacarpo/metatarso-phalangeal joints, and include desmitis, insertional desmopathy, avulsion fractures and rupture.

There is usually an **acute onset of lameness**, the degree being proportional to the severity of the injury. **Desmitis** (*q.v.*) may result in localized soft tissue swelling, heat and focal pain, with pain on passive manipulation of the joint (especially rotation).

Lameness is usually not immediately improved following IA analgesia of the joint (unless there are concurrent IA lesions), but is improved by local perineural analgesia or by local infiltration. In a suspected case of collateral ligament desmitis an **ultrasonographic** evaluation should be performed. **Radiography** should be performed to exclude other concurrent damage, and “stressed views”, in which medial to lateral force is applied to the joint during image acquisition, can confirm joint instability and ligament damage. Secondary insertional desmopathy may not become radiographically apparent until 2–3 wk after the onset of lameness. If lameness is severe the axial stability of the joint should be assessed carefully, and stressed radiographs obtained, in order to assess better the integrity of the collateral ligament and the possibility of subluxation of the joint.

In some cases no clinical signs referable to the collateral region can be detected clinically but **nuclear scintigraphy** subsequently indicates increased bone activity or blood supply at the site of collateral ligament attachment. Several weeks later, new bone formation may be apparent.

Treatment is prolonged (many months) rest, preferably stall rest combined with controlled exercise. If there is discernible joint instability with

a metacarpophalangeal joint collateral injury, some external support may be required. **Rupture of the collateral ligament** can be treated conservatively by immobilization of the limb in either a Robert-Jones bandage or a cast, or with surgical implantation of an implant.

Avulsion fractures occur most commonly in the metatarsophalangeal and metacarpophalangeal joints with displacement of a fragment from one or more of the plantar (palmar) processes of the proximal phalanx. If the fragment is displaced or a significant proportion of articular surface is involved, it should either be removed (if small) or stabilized by internal fixation (if large). Prognosis depends on the degree of articular damage and of damage to the collateral ligaments. Fracture of the lateral malleolus of the distal tibia can also occur due to an avulsion fracture of the lateral collateral ligament of the tarsocrural joint. Treatment usually involves surgical removal of the fragment or conservative management. The prognosis is good.

Cruciate ligament injury

The cranial cruciate ligament attaches to the lateral wall of the intercondylar fossa of the femur and to the tibia just cranial to the intercondylar eminence. The caudal cruciate ligament lies medially and attaches to the cranial part of the intercondylar fossa of the femur and to the region of the popliteal notch of the caudal tibia. Both structures are extrasynovial, not within the femorotibial joints, but between the synovial sacs of the medial and lateral compartments. Associated pain may not be alleviated with IA analgesia of either compartment but it is often improved.

Cranial cruciate ligament damage is recognized far more frequently than caudal cruciate ligament damage. Other structures, including the menisci, collateral ligaments and articular cartilage, are often damaged in horses with cruciate injuries.

Lameness is usually sudden in onset and relatively severe, although it can be insidious in onset and less severe. There may be palpable distension of the medial femorotibial, lateral femorotibial or femoropatellar joint capsule. Flexion of the stifle is usually resented; the horse may avoid flexion by exaggerated lifting of the limb. Manipulation of the stifle usually accentuates lameness. Lameness may be improved by IA analgesia of the medial and/or lateral compartments of the femorotibial joint. A drawer sign cannot usually be elicited in the conscious horse.

Ultrasonographic evaluation of these ligaments is extremely difficult. Radiographic abnormalities associated with cranial cruciate ligament injury include remodeling of the tibia, avulsion fracture of the intercondylar eminence and cranial displacement of the tibia. However, many horses will have no radiographic abnormalities. In chronic cases, there may be evidence of **secondary osteoarthritis**, as well as remodeling of the intercondylar fossa of the femur. Nuclear scintigraphy can reveal increased bone activity at one of the attachment sites. A definitive diagnosis is made with arthroscopic evaluation. The cranial cruciate ligament is most easily assessed from the lateral femorotibial joint, while the caudal cruciate ligament is best viewed through cranial and caudal approaches to the medial femorotibial joint. The prognosis for athletic function is guarded.

Meniscal injury

The crescent-shaped medial and lateral menisci are composed of fibrocartilage, and are interposed between the femur and tibia. They are stabilized by substantial cranial and caudal meniscal ligaments.

Lameness associated with **meniscal injury** can be sudden or gradual in onset and is usually moderate to severe when recognized. There may be distension of the femorotibial joint capsule and pain on manipulation of the joint. Lameness is usually substantially improved by IA analgesia of either the lateral femorotibial joint (lateral meniscus) or the medial femorotibial joint (medial meniscus).

Care must be taken in interpreting radiographs since apparent narrowing of one side of the femorotibial joint space can be a positional effect. Occasionally there is **sclerosis** of the subchondral bone of the tibial plateau of the affected side and infrequently mineralization of the affected meniscus. In long-standing cases there may be radiographic evidence of secondary osteoarthritis.

Ultrasound is very effective in evaluating the menisci, and should be recommended routinely. Diagnosis can often be confirmed with arthroscopic evaluation of the meniscus and the meniscal ligaments. The cranial meniscal ligaments are visible with cranial approaches to the joints; however, only the cranial and caudal poles of the menisci themselves can be viewed arthroscopically, and some pathology will be missed. Tears should be debrided when indicated. Damage to the meniscus or cranial meniscal ligament appears to warrant a guarded prognosis for return to athletic function.

Patellar ligament injury

The medial, middle and lateral patellar ligaments attach to the patella and the tibial tuberosity/crest and are effectively the tendons of insertion of quadriceps femoris and biceps femoris. Injury to one or more ligaments usually results in acute onset mild to moderate lameness, pain on pressure applied over the affected ligament and pain on manipulation of the stifle. Intra-articular anesthesia may not improve the lameness but local infiltration of anesthetic often will. Diagnosis can be confirmed with ultrasound. Treatment consists of rest with rehabilitation, and the prognosis is usually good.

Impar ligament desmitis

The **distal sesamoidean impar ligament** attaches to the distal border of the navicular bone and to the flexor surface of the distal phalanx. Injury to this ligament can be difficult to differentiate clinically. Associated lameness is likely to be improved by perineural analgesia of the palmar digital nerves or intra-synovial analgesia of the navicular bursa. Ultrasound images obtained through the frog following meticulous flattening of the surface with a hoof knife as well as **soaking** the foot overnight, can detect impar ligament injuries, adhesions and/or bursal distension. However, the optimal imaging technique to detect impar desmitis is probably MRI.

Discrete osseous or mineralized opacities distal to the distal border of the navicular bone are often identified radiographically. These may represent an

avulsion fracture from the distal border of the navicular bone, mineralization of a hematoma in the impar ligament or dystrophic mineralization within the ligament (*q.v.*). The clinical significance of these changes is unclear, however they are seen with higher incidence in horses with navicular syndrome (*q.v.*).

Intersesamoidean ligament injury

The intersesamoidean ligament (also referred to as the **palmar/plantar ligament of the fetlock**) attaches to the palmar and axial surfaces of the medial and lateral proximal sesamoid bones, and the flexor tendons glide across this surface. With fetlock extension the intersesamoidean ligament is under significant tension and compression as the suspensory apparatus restricts dorsiflexion.

Injuries to this ligament, including desmitis and enthesitis, have been recognized and associated with lameness. Horses can develop areas of bone lysis along the axial insertion sites of the intersesamoidean ligament with enthesitis, or avulsion fractures may be detected. Lameness is generally moderate. Severe injuries, including rupture and abaxial displacement of the proximal sesamoids, can also develop and can occur in association with complete breakdown injuries. Infectious desmitis and osteomyelitis can develop with puncture wounds or hematogenous inoculation (*q.v.*).

Lameness should be improved by **perineural analgesia** (*q.v.*) of the palmar (at mid-metacarpal level) and palmar metacarpal nerves. Intra-articular analgesia of the metacarpophalangeal joint and digital sheath will frequently improve but not eliminate the lameness. Diagnosis is usually based on diagnostic ultrasonography and radiography, although lesions have also been diagnosed via tenoscopy of the digital sheath or localized with scintigraphy. With insertional damage there may be radiographic evidence of radiolucency on the axial surface of the proximal sesamoid. The collateral ligaments of the proximal sesamoid bones can also be injured.

TENDON LACERATIONS AND RUPTURES

Suspensory apparatus lacerations

Clinical signs associated with tendon lacerations depend on what tendon is involved and whether the tendon is partially or fully transected. **Transection** of the SDFT typically results in **sinking of the fetlock** while transection of the DDFT allows the **toe to turn up**.

Tendon healing is compromised by a poor blood supply, concurrent contamination, and the biomechanical forces that create a gap between the lacerated tendon ends regardless of the repair technique utilized.

For a successful outcome, **radical aggressive treatment** is required. The wound must be thoroughly cleaned and debrided and the nature of the tendon injury assessed. The site of the lesion (metacarpus/metatarsus or pastern), the condition of the ends of the tendon and the degree of contamination will influence to some extent what method of repair is instituted.

Alternatives include attempts to repair the tendon with **specialized suture patterns** (e.g. locking-loop and 3-loop-pulley) using monofilament nylon,

polypropylene or polydioxanone; gap healing with multifilament scaffolds such as Dacron or carbon fiber; cast immobilization; splint immobilization or fitting raised and elongated heel shoes. Newer techniques, including semi-cylindrical biodegradable plates sutured to the transected tendon, are being investigated and appear to be significantly stronger than sutured tenorrhaphies. Frequently a combination of these different techniques is employed.

Prognosis depends on the tendon (or tendons) involved (extensor tendons have a much better prognosis than flexor tendons), the site of the injury (injuries entering tendon sheaths have a much more guarded prognosis), the degree of contamination, and whether a forelimb or hindlimb is affected. Prognosis for salvage for breeding is good; prognosis for return to full athletic function is more guarded. Repair of flexor tendon lacerations has a reported success rate of 11–18% for return to athletic function. There are no repair methods that provide adequate tensile strength for primary tendon healing.

Superficial digital flexor tendon rupture

Complete rupture of the SDFT is relatively uncommon. It occurs more often in forelimbs than hindlimbs and results in sinking of the fetlock.

Treatment requires **elevation of the heel** to bring the ends into apposition, application of a splint or cast for up to 3 mo and a prolonged period (often 12 mo) of rest. Implants such as carbon fiber or Dacron to provide a multifilament scaffold have been reported to enhance the speed and quality of repair, but they also dramatically increase the risk of infection. The prognosis for athletic function is poor but the horse may be salvaged for breeding.

Deep digital flexor tendon rupture

Rupture of the DDFT is uncommon and usually occurs as a sequel to previous palmar digital neurectomy (*q.v.*). Rupture is probably predisposed by pre-existing tendon damage, adhesions and bone remodeling. Rupture rarely occurs with advanced navicular degenerative changes when a neurectomy has not been performed. Once the tendon ruptures there is swelling on the palmar aspect of the pastern and lameness is generally severe. The foot is placed on the ground heel first, and the toe flips up with weight bearing.

The prognosis is hopeless for return to athletic function. Immobilization of the distal limb for 8–12 wk may allow sufficient healing to take place to salvage the horse for breeding, but most cases will require humane euthanasia.

Common digital extensor tendon rupture

Rupture of the common digital extensor tendon occurs in **young foals** and can be **congenital** or **acquired**. The etiology is poor understood, but there may be a heritable component. It results in a characteristic soft tissue swelling in the associated tendon sheath on the dorsolateral surface of the carpus, often occurs bilaterally, and is frequently seen in foals with **flexural deformities** of the carpus or fetlock. The ends of the tendon can usually be identified on palpation, and can also be seen with ultrasound. Foals are often able to stand normally or may appear bowlegged, but **knuckle forward** at the fetlock as they

walk. The intact lateral digital extensor tendon often allows them to move normally at slow speeds, but the gait deficit becomes more noticeable as they move quickly.

Treatment for this condition is **conservative**, and surgery to repair the tendon is not necessary. The use of bandages to reduce swelling and support the carpus is recommended and **stall confinement** is advised. A well-padded splint can prevent knuckling, but should be changed regularly and removed periodically to prevent tendon laxity. The prognosis is excellent. Associated flexural deformities may require more aggressive management and carry a more guarded prognosis.

Extensor carpi radialis tendon rupture

Rupture of the extensor carpi radialis tendon also usually occurs in **young foals** and can be congenital or traumatic. It results in soft tissue swelling on the dorsal proximal aspect of the carpus. The ends of the tendon can usually be identified on palpation, and can also be seen with ultrasound. Mild lameness may be observed.

Treatment is conservative with stall confinement for 6–8 wk and the prognosis is excellent. Although immobilization of the limb using a **Robert Jones bandage** (*q.v.*) or a cast may facilitate repair, flexor tendon laxity is likely to develop.

Gastrocnemius rupture

Rupture of the gastrocnemius, with or without rupture of the SDFT (the combination is referred to as the **Achilles tendon**), is a rare injury resulting in severe lameness and an inability to extend the hock. This condition also occurs in foals with flexural deformities or following overexertion. With complete rupture the hock is dropped even at rest, and as the horse attempts to weight bear the hock drops further while the stifle extends (loss of reciprocal apparatus).

If the entire Achilles tendon is lost, the horse cannot support weight on the limb. There is localized soft tissue swelling proximal to the hock and/or lateral to the stifle. With **partial rupture** the signs are more subtle with moderate lameness and an exaggerated hock drop. With **complete rupture** the prognosis for athletic function is very poor and the prognosis for survival is guarded.

Most surgical treatments to salvage the horse for breeding have failed, but some horses have been managed successfully with full limb support. Partial rupture should be managed with protracted stall rest.

TENDON SHEATHS

Digital flexor tendon sheath tenosynovitis

The digital flexor tendon sheath extends from the junction of the third and fourth quarters of the metacarpus (or metatarsus) to the distal pastern and encloses the SDFT and DDFT.

Mild distension of the tendon sheath, proximal to the metacarpophalangeal (metatarsophalangeal) joint, and sometimes distally as well, is a

common incidental finding, particularly in the hindlimbs. Such non-articular “windpuffs” or “windgalls” may fluctuate according to the amount of work the horse is doing, the hardness of the ground and the environmental temperature. Bandaging the horse while it is stabled may control their size.

Enlargement of the tendon sheath may also be due to thickening of the sheath wall which can result in a firm nodular swelling at the proximal reflection of the sheath wall, or in a somewhat loculated appearance to the enlarged sheath, and a slight notch at the level of the palmar (plantar) annular ligament. The latter two features occur more commonly in hindlimbs than in forelimbs.

Sudden onset of distension of a digital flexor tendon sheath associated with heat, pain on flexion of the fetlock and moderate to severe lameness can be due to tenosynovitis. Diagnostic ultrasonography should be performed to exclude the possibility of concurrent tendon pathology. Unfortunately, some longitudinal tendon defects may not be detected with ultrasound.

Most cases respond relatively rapidly to **local application** of cold pressure bandaging and systemic NSAIDs. Topically applied DMSO and IV hyaluronan therapy (*q.v.*) may also be beneficial. If lameness persists, **intraheathal** injection of a corticosteroid and/or sodium hyaluronan should be considered. The prognosis for acute cases is good provided that the injury is solely due to tenosynovitis and does not involve structural damage of the sheath wall or damage to supporting structures. When other structures are involved, healing can result in **intraheathal adhesion formation**, peritendon sheath fibrosis and/or effective constriction by the palmar (plantar) annular ligament (**complex tenosynovitis**). Intraheathal adhesion formation can be diagnosed either by ultrasonography or radiographic contrast studies and may necessitate surgical treatment.

Treatment of chronic cases of tenosynovitis can be challenging. Initial management usually involves drainage of fluid and intraheathal injection of hyaluronan and corticosteroids. Horses that do not respond or that have ultrasonographic evidence of complex tenosynovitis are surgical candidates. A tenoscopic approach is typically recommended as this allows diagnostic evaluation, as well as annular ligament desmotomy when indicated, and resection of granulation tissue masses and adhesions.

Palmar/plantar annular ligament syndrome (annular ligament constriction, stenosing palmar ligament desmitis)

The palmar annular ligament passes around the palmar aspect of the digital flexor tendon sheath. It is contiguous with it on the most palmar aspect of the limb, and attaches to the proximal sesamoid bones.

Overextension of the metacarpophalangeal joint can result in overstretching of the ligament and associated annular ligament **desmitis** (*q.v.*) with thickening.

Similarly, **distension** of the digital flexor tendon sheath and/or tendinitis and **tendon swelling** within the sheath can result in effective constriction by the relatively inelastic palmar annular ligament creating a notch on the palmar aspect of the limb, often best assessed when the limb is clipped. Slight notching can also be an incidental finding of no current clinical significance.

Clinical signs

Lameness associated with constriction by the palmar annular ligament may be insidious or acute in onset and varies from mild to severe. Often these patients have a history of **persistent lameness** that does not respond effectively to rest. Lameness is usually improved, but rarely alleviated, by intrathecal analgesia; perineural analgesia of the palmar and palmar metacarpal nerves is usually required to eliminate the lameness.

Diagnosis

Diagnostic ultrasonography is useful to assess the size of the ligament and its structural integrity, the thickness of the sheath wall and associated fibrosis, the presence of intrathecal adhesions and the presence of associated tendon pathology. The latter warrants a guarded prognosis. Adhesions have also been identified using radiographic contrast, but that technique has largely been replaced by ultrasound.

Treatment

In the absence of adhesions, **closed palmar annular ligament desmotomy** may result in resolution of lameness, but in most cases breakdown of adhesions is required. This can be performed tenoscopically or with an open incision into the sheath.

Prognosis is fair to guarded. Postoperative administration of intrathecal and IV hyaluronan (*q.v.*) may help to reduce reformation of adhesions. Deep digital flexor tendinitis (*q.v.*) occasionally occurs following constriction by the palmar annular ligament and carries with it a guarded prognosis for return to full athletic function.

Tarsal sheath distension (thoroughpin)

The tarsal sheath extends from approximately 7 cm proximal to the medial malleolus of the tibia distally to about the proximal third of the metatarsus, and surrounds the DDFT (or more correctly the lateral digital flexor tendon). It lies in close apposition to the sustentaculum tali of the calcaneus. Enlargement of the tarsal sheath is colloquially referred to as **thoroughpin** (*q.v.*).

Clinical presentation

Distension is visible in the distal caudal crus. The filling extends laterally proximal to the tuber calcaneus between the common calcaneal tendon and the tibia, and tends to be somewhat less prominent medially. Occasionally swelling extends further distally and is detected medial to the DDFT in the proximal metatarsal region. Mild distension may be seen without other associated clinical signs. The swelling must be differentiated from the caudal outpouching of the tarsocrural joint capsule and from distension of the intertendinous calcaneal bursa. Some horses develop an acquired or adventitious bursa between the DDFT and the Achilles tendon, and this can be difficult to differentiate clinically from true distension of the tarsal sheath without ultrasound or contrast radiography.

Chronic distension without associated lameness or obvious significant pathology is quite common and does not require treatment, but these cases must be distinguished from other causes of tenosynovitis that do cause lameness, including trauma, DDFT injury and infectious tenosynovitis (*q.v.*).

Diagnosis

Sudden onset lameness can coincide with **acute distension of the tarsal sheath** either symmetrically due to tenosynovitis or hemorrhage or asymmetrically associated with partial rupture of the sheath wall. Occasionally there is associated DDFT tendinitis (*q.v.*).

Diagnostic ultrasonography and contrast radiography help to elucidate which structure is involved and should be used to evaluate the integrity of the DDFT and sheath wall. Contrast radiography can also be useful. Standard radiographs including dorsomedial–plantarolateral oblique and flexed plantaroproximal–plantarodistal views of the calcaneus should routinely be obtained, particularly to assess the sustentaculum tali. Proliferative bone production and dystrophic mineralization of the sustentaculum tali are poor prognostic indicators.

Treatment

Sudden onset tenosynovitis is treated conservatively with stall rest, topical DMSO and NSAIDs, with or without intrathecal short-acting corticosteroids. More chronic cases and acquired adventitious bursae may require surgical intervention, but the prognosis in those cases is guarded. Tenoscopy may be useful to assess damage, treat infection, and facilitate treatment of lesions on the sustentaculum tali.

Carpal sheath distension

The carpal synovial sheath surrounds the DDFT and SDFT within the carpal canal and extends from approximately 10 cm proximal to the carpus to the proximal third of the metacarpus. The carpal canal encloses the sheath and is formed dorsally by the palmar ligament of the carpus, medially by the accessory ligament of the SDFT, laterally by the accessory carpal bone and associated ligaments, and palmarly by the flexor retinaculum, palmar metacarpal fascia and caudal antebrachial fascia.

Clinical signs

The distended sheath protrudes laterally along the distal antebrachium and both medially and laterally between the DDFT and the check ligament. Distension of the carpal sheath develops due to tearing of the accessory ligament of the SDFT, idiopathic synovitis, proximal tendinitis of the DDFT or SDFT, tearing of the flexor tendons at their myotendinous junctions, infection, trauma with intrathecal hemorrhage, fracture of the accessory carpal bone, exostosis of the caudal perimeter of the radial physis, or due to an osteochondroma on the caudal aspect of the radius.

Lameness is variable depending on the initiating cause and severity of the distension. Horses with **intrathecal hemorrhage** can show a very severe

lameness. Passive flexion of the carpus usually produces a painful response and can accentuate the lameness. Lameness is generally improved following intrathecal analgesia.

Diagnosis

Ultrasonographic, radiographic and endoscopic examinations help to determine if there is underlying pathology that will influence treatment and prognosis. Radiographs should be evaluated for evidence of exostoses of the caudal perimeter of the radial physis, or so-called “**physeal remnant spikes**”.

Treatment

If no primary lesion can be identified then administration of short-acting corticosteroid and hyaluronan into the sheath, controlled hand walking for 4–6 wk, and **cryotherapy** is the treatment of choice. Prognosis is fair. Corticosteroids should not be used if a tendon lesion is identified, and tendon involvement warrants a more guarded prognosis.

Osteochondromas (*q.v.*) and radial exostoses are removed surgically, often using a tenoscopic approach, and prognosis is good. Distension of the carpal sheath secondary to an accessory carpal bone fracture (*q.v.*) may require transection of the palmar carpal retinaculum in order to relieve compression of the soft tissue structures in the canal.

With increasing use of endoscopic evaluation of the carpal sheath, exostoses of the caudal perimeter of the radial physis have been increasingly recognized as a cause of tenosynovitis and lameness. Lesions that penetrate the carpal synovial sheath and impinge on the DDFT can be managed by tenoscopic removal.

Horses with **complex tenosynovitis** involving chronic enlargement of the sheath and/or desmitis of the DDFT or SDFT may benefit from endoscopic evaluation of the sheath, surgical debridement and tenoscopic release of the carpal canal. Division of the carpal flexor retinaculum to decompress the carpal canal should also be performed when osteochondromas are removed, or if there is evidence of chronic flexor tendon compression in the canal.

Extensor carpi radialis, common digital extensor and lateral digital extensor tenosynovitis

The **tendon sheath** of the extensor carpi radialis starts approximately 10 cm proximal to the carpus and extends to the middle of the carpus. It is traversed by a dorsal annular ligament and extensor carpi obliquus. The tendon sheath of the common digital extensor begins approximately 8 cm proximal to the carpus and ends at the proximal metacarpus, and is crossed by two dorsal annular ligaments. The tendon sheath of the lateral digital extensor tendon starts approximately 8 cm proximal to the carpus and extends to the proximal metacarpus. It is traversed by an annular ligament.

Direct trauma (e.g. hitting a fence) is a common cause of tenosynovitis (*q.v.*), and the more dorsal tendon sheaths of extensor carpi radialis and the common digital extensor tendon are more commonly affected. Idiopathic and infectious tenosynovitis also occurs regularly.

Clinical signs

Tenosynovitis results in a **longitudinal soft swelling** that may be subdivided by the annular ligaments. The swelling should be differentiated from other soft tissue swellings including an acquired or false bursa, distension of the antebrachiocarpal or middle carpal joint capsules, joint capsule damage with secondary synovial membrane herniation, or diffuse soft tissue swelling. Ultrasound may be required to make this differentiation. The enclosed tendon may or may not be enlarged. Usually there is no associated lameness unless the distension is extreme or the result of septic tenosynovitis (*q.v.*).

Diagnosis

Additional information may be obtained from ultrasonographic evaluation. Usually this is a cosmetic rather than a functional problem.

Treatment

In most cases of idiopathic tendon sheath effusion treatment is unnecessary except for cosmetic reasons. With traumatic injury, topical DMSO and cold therapy may be beneficial in the acute stage. Intrasynovial corticosteroids, hyaluronan and/or atropine may be helpful in the absence of any concurrent tendinous pathology.

Occasionally, following a severe injury, there may be considerable synovial proliferation and adhesion formation requiring surgical intervention. Sepsis requires aggressive medical and surgical treatment.

Tendon sheath infections

Infection of a tendon sheath can occur as a result of a penetrating injury or hematogenous spread of infection; in some cases the etiology is unknown. Infection typically results in a sudden onset of severe lameness, associated with distension of the involved tendon sheath.

Diagnosis is confirmed by synovial fluid analysis using similar tests and interpretation to those used in the diagnosis of septic arthritis (*q.v.*). Specifically, fluid with an elevated total protein (>40 g/L), a leukocytosis ($>20 \times 10^9$ cells/L) and a neutrophilia (80% neutrophils) would be considered virtually pathognomonic for bacterial infection. Gram stain and bacterial culture, including anaerobic samples, should be performed.

Early aggressive therapy is essential but even then the prognosis is guarded. Treatment should include **aggressive lavage** of the sheath, on at least one and often several occasions. Effective lavage to remove bacteria-laden fibrin clots and debris can be performed via incisions in the proximal and distal aspects of the sheath and/or via tenoscopy. **Synovial resection** can be performed simultaneously, and is particularly valuable if the infection has been present for more than 2 or 3 days. Indwelling drains and continuous infusion antibiotic pump systems can be useful but require excellent nursing supervision.

Broad-spectrum systemic antimicrobial medication should be combined with local therapy including direct intrathecal instillation and/or distal limb

perfusion techniques. NSAIDs should be administered. Intrathecal hyaluronan can help to reduce adhesion formation if infection can be eliminated.

Tarsal sheath infections

In addition to the conventional routes of sheath infection outlined previously, **tarsal sheath infections** also develop as a sequel to **osteitis** of the sustentaculum tali or tuber calcanei. Osteitis (*q.v.*) has also been reported to occur secondary to infections of the tarsal sheath. The prognosis in these cases is guarded. Surgical management is warranted and may require endoscopic evaluation and lavage or cutting the thickened tarsal retinaculum to decompress the tarsal canal; even tenectomy/tenotomy of the DDFT has been reported.

BURSAE

Intertubercular (bicipital) bursitis

Due to its embryologic origins and function, the intertubercular bursa is more appropriately considered to be a tendon sheath. It is a large structure that surrounds the tendon of biceps brachii in the region of the intertubercular groove of the humerus, and extends from the level of the supraglenoid tubercle distal to the humeral tubercles. Occasionally there is communication between the tendon sheath and the joint capsule of the scapulohumeral joint, and this should be considered when interpreting responses to intrasynovial anesthesia.

Aseptic synovitis of the intertubercular bursa is comparatively rare (*q.v.*). There is usually pain induced by pressure applied over the bursa, or by retraction of the limb. Lameness is moderate to severe and generally improved following intrasynovial analgesia. The area should be examined ultrasonographically for evidence of concurrent biceps brachii, infraspinatus or supraspinatus tendon pathology. Intralesional corticosteroids and/or hyaluronan can be beneficial.

Mineralization within the intertubercular bursa can occur as a sequel to a fracture of the supraglenoid tubercle, and warrants a guarded prognosis for athletic function.

Septic intertubercular bursitis also occurs, either with or without history of a puncture wound. In foals the bursa can be infected hematogenously. Intertubercular bursal infection should be differentiated from septic infraspinatus bursitis. Aggressive treatment is essential for a successful outcome and should include thorough lavage and/or surgical debridement, systemic and local antimicrobial drugs and NSAIDs as required. Prognosis is guarded.

Calcaneal bursitis (capped hock)

A small subtendinous calcaneal bursa (or gastrocnemius bursa) is interposed between the tuber calcaneus and the insertion of gastrocnemius, and a large intertendinous calcaneal bursa is interposed between the tendons of the SDFT and the gastrocnemius, extending from approximately 10 cm proximal to the

hock to the mid-tarsal level. There is also a subcutaneous bursa over the point of the hock, and with slight repetitive trauma or a single more severe traumatic episode, horses also acquire an **adventitious** or false bursa subcutaneously over the tuber calcanei, resulting in a **capped hock** appearance.

Distension of the bursa interposed between the SDFT and gastrocnemius tendons is often associated with gastrocnemius tendinitis, but can result in a capped appearance to the hock. There is usually associated lameness in those cases.

Diagnosis is based on clinical signs, response to local analgesia and ultrasonographic evaluation. An acquired bursa is usually more localized and is usually only a **cosmetic defect** unassociated with lameness and no treatment is necessary. If the horse repetitively kicks the walls, consideration should be given to padding the walls. Protection of the hocks by **hock guards** may be useful when the horse is traveling.

Infection of any one of the bursal structures over the point of the hock can result in serious complications. Infection is usually caused by a penetrating injury or occurs as a complication of septic osteitis of the tuber calcanei (*q.v.*). Radiographs should be taken to determine bone involvement, and bone infection is associated with a poor prognosis. Aggressive medical and surgical management of the bursal infection is warranted. Endoscopic evaluation and lavage of the intertendinous calcaneal bursa has been reported for management of both infectious and non-infectious bursitis.

Olecranon bursitis (shoe boil, capped elbow)

As the result of repetitive trauma an acquired (false) bursa can develop over the point of the elbow resulting in a semi-firm to fluctuant soft tissue swelling. The bursa under the triceps brachii is not involved. This is usually merely a **cosmetic defect** and does not compromise function unless it becomes infected. It usually results from trauma from a shoe, either when the horse is lying down or when the shoe hits the elbow during exercise, and it is most common in draft breeds and gaited horses.

The use of a “**shoe boil ring/boot**” (“sausage boot”) may help to prevent further trauma, and can resolve the problem in acute cases. In some cases draining the accumulated fluid and injecting corticosteroids and/or atropine can improve the cosmetic appearance, but strict asepsis is critical to avoid infection. Irritants including 7% iodine have been injected into the area in an effort to induce fibrosis, but can worsen the problem. Surgical resection has been reported, but is usually unnecessary.

Navicular bursitis

The navicular bursa (or **podotrochlear bursa**) is interposed between the palmar (plantar) aspect of the navicular bone and the dorsal aspect of the DDFT. In some cases lameness associated with caudal-heel syndrome can be alleviated with intrasynovial analgesia of that bursa despite the absence of detectable radiographic or CT abnormalities within the navicular bone. In those cases an isolated navicular bursitis may be the source of the lameness.

Soft-tissue-phase nuclear scintigraphy can support the diagnosis, and an ultrasound examination performed through a meticulously prepared frog may confirm synovitis and bursal distension. However, concurrent DDFT pathology should be excluded via MRI or contrast enhanced CT before this isolated diagnosis can be made definitively. In many cases intrabursal hyaluronan and corticosteroids will alleviate the lameness, although the problem will reoccur in some horses.

Atlantal bursitis (poll evil)

The atlantal bursa lies dorsal to the atlas on the midline between the nuchal ligament and the rectus capitis dorsalis. Occasionally synovial proliferation with or without mineralization has been seen in association with neck pain and/or an abnormal head carriage.

Infection of the bursa, so-called “**poll evil**”, is now a rare condition. In the past it was seen, especially in draft breeds, in association with ill-fitting tack. Although any bacterium may be involved, *Brucella* spp. (*q.v.*) should always be considered and ruled out due to the risk for zoonotic infection. Treatment of either condition is surgical. Prognosis depends on the chronicity of infection and presence or absence of associated osteomyelitis (*q.v.*).

Supraspinous bursa infection (fistulous withers)

The supraspinous bursa lies dorsal to the dorsal spinous processes of the cranial thoracic vertebrae. Infection of the bursa results in localized swelling and pain. In advanced cases the bursa may rupture producing localized cellulitis and/or infectious osteitis of the dorsal spinous processes.

Determination of *Brucella abortus* serum titers and both aerobic and anaerobic bacterial culture should be performed. Radiographs should be taken of the dorsal spinous processes of the thoracic vertebrae. Horses that test seropositive for *Brucella* (*q.v.*) are more likely to have evidence of vertebral osteomyelitis.

In very early cases local and systemic antimicrobial drugs may be successful; in most advanced cases **surgical intervention** involving radical excision of the affected soft tissue and spinous processes of affected vertebrae will be required. Treatment with **strain 19 *Brucella* vaccine** and with **clofazimine** has also been reported. Prognosis is fair in lesions treated early, but guarded to poor in advanced cases.

Trochanteric bursitis (whorlbone disease)

The large trochanteric bursa is positioned between the tendon of the accessory head of the middle gluteal muscle and the cranial portion of the greater trochanter. Bursitis is usually diagnosed clinically (particularly in Standard-breds) in horses that respond painfully to pressure over the greater trochanter of the femur. Most horses develop **trochanteric bursitis** during racing or training, but it has also been reported to result from direct trauma. Confirmation of this diagnosis should entail reduced lameness and/or improved comfort following a bursal block as well as ultrasonography. In fact bursitis has

not been well documented since the advent of the routine use of diagnostic ultrasound.

When diagnosed, it is thought to be secondary to another cause of lameness in the lower hindlimb or in the forelimbs that has altered the horse's gait and produced strain on the gluteal muscles. Treatment traditionally involves injecting the soft tissues around the area with an iodine counterirritant. Alternatively, Sarapin and/or corticosteroids have been injected into and around the bursa. Rest and NSAID therapy are also appropriate.

Cunean bursitis

The cunean bursa is located between the cunean tendon (the medial tendon of the tibialis cranialis muscle) and the tarsal bones.

Lameness has been attributed to cunean bursitis as an isolated etiology, particularly in **Standardbred racehorses**, but many of these patients are also reported to have cunean tendinitis. Diagnosis requires confirmation that the lameness is improved following local anesthesia of the bursa alone. Radiographs must be taken to rule out associated osteoarthritis of the distal tarsal joints, and ultrasound can also be used to determine the degree of effusion and/or tendon involvement. It is difficult to confirm that joint disease is not contributing to the lameness without advanced imaging techniques such as scintigraphy and MRI.

A **syndrome** involving inflammation of the cunean tendon, bursa and other soft tissues over the medial hock has been described in Standardbreds in race training. No radiographic abnormalities are detected (often referred to as **blind** or **occult spavin**), and the inflammation appears to be the result of overwork particularly on hard surfaces. In these cases joint inflammation is likely to be the principal source of pain.

Treatment involves rest or reduced training, NSAIDs, cold therapy, local and/or intrabursal injection with corticosteroid, Sarapin and/or hyaluronan. Cunean tenectomy is often performed, particularly when tendon involvement or tarsitis is suspected.

Carpal hygroma

Hygroma is the name given to a fluid-filled swelling on the dorsal aspect of the carpus that develops as a result of direct trauma. It is a common injury resulting in a diffuse swelling that should be differentiated from enlargement of a tendon sheath, distension of the carpal joint capsules or a synovial herniation. Ultrasound and contrast radiography may be required to confirm the diagnosis and identify communication with other synovial structures.

Hygromas are a **cosmetic blemish** unless very large, and usually there is no functional compromise. In the acute stage topical anti-inflammatory agents and bandaging can help to reduce the swelling. Fluid drainage and injection of corticosteroids and/or atropine can reduce the effusion but the swelling often recurs. If the swelling is the result of repetitive low-grade trauma (e.g. hitting the stable door), preventative measures such as padding the door should be performed. En bloc surgical excision, injection of irritants (i.e. Lugol's iodine) or incisional drainage have been recommended for

unresponsive cases, but can result in a worse cosmetic appearance and complications.

DISEASES OF MUSCLE

Fibrotic or ossifying myopathy

Fibrotic or ossifying myopathy is a cause of mechanical hindlimb lameness. The condition usually involves injury to the semitendinosus, semimembranosus and/or gracilis muscles, and is thought to be a sequel to **muscle fiber damage** that inhibits the normal action of the muscles. It occurs most commonly in barrel racing horses and stock horses but can occur as a result of **repeated injections**, and an underlying **neuropathy** is suspected in some cases.

Fibrosis and/or mineralization within these muscles is usually palpable and results in a characteristic gait at the walk. The cranial phase of the stride is abnormally short, the foot of the affected limb being abruptly slapped to the ground (**goose stepping gait**). The lameness is very characteristic for the condition, tends to be most pronounced at a walk, and does not appear to be associated with any pain.

Diagnosis is based on clinical signs and can be confirmed ultrasonographically. Ultrasound also facilitates determination of the muscles that are involved. The condition should be differentiated from stringhalt (*q.v.*) and other types of neuromuscular dysfunction.

Surgical treatment involves resecting or transecting the affected tissue or cutting the tibial and/or tarsal insertions of semitendinosus tendon. Surgery is most effective in cases with primary semitendinosus involvement. In some cases the gait deficit recurs, but other horses are permanently improved.

Muscle strain

Muscle strain may be easy to diagnose acutely but can be a relatively difficult condition to diagnose when chronic. The most commonly affected muscles are the pectorals, biceps brachii, brachiocephalicus, gluteals, semimembranosus, semitendinosus, gracilis, biceps femoris, gastrocnemius and sartorius.

In the acute stage, there is usually **sudden onset lameness** associated with focal pain, with or without abnormal muscle tension and localized heat and swelling. Strain of the longissimus dorsi muscles also occurs relatively frequently and usually results in an overall shortness of gait. Ultrasound is valuable to evaluate the extent of muscle tearing and seroma or hematoma formation. Thermography can help to identify affected superficial muscle groups but should be performed under appropriate temperature controls. Scintigraphy can be useful for identifying muscle damage, and can identify areas of deep muscle injury.

Treatment includes rest combined with NSAIDs and physiotherapy, e.g. therapeutic ultrasound and massage. Both the duration of rest and the prognosis depend upon the severity of the injury. Only if muscle damage is severe or extensive are there significant elevations in serum muscle enzyme concentrations.

Post-anesthetic myopathy and neuropathy

Inappropriate positioning of a horse during general anesthesia (*q.v.*), inadequate padding beneath the horse and a persistently low blood pressure are contributing factors for the development of a **traumatic post-anesthetic myopathy** and/or **neuropathy**. Hypoperfusion due to pressure and/or hypotension is thought to be the primary cause.

Clinical signs

Clinical signs are generally not evident until the horse tries to stand up and can even be delayed for several hours after recovery. Myopathy results in **extreme pain** and the horse usually becomes very distressed and may sweat profusely. Affected muscle groups are usually hard.

The most commonly affected muscles are the triceps and the gluteals, but any muscles may be affected, whether or not they were under pressure during anesthesia, and bilateral involvement is common with hindlimb adductor myopathies. A generalized myopathy has also been recognized. If the triceps are affected the horse is usually reluctant to bear weight on the limb and stands with the elbow dropped, mimicking radial nerve paralysis. Radial nerve paralysis or neuropathy can also occur as a sequel to general anesthesia (*q.v.*); however, in those cases there will be much less evidence of pain. A **mixed syndrome** of myopathy and neuropathy is also seen.

Diagnosis

A diagnosis of myopathy can be confirmed by measurement of **serum muscle enzymes**. There is generally a moderate rise in creatine kinase (CK) and aspartate aminotransferase (AST) following general anesthesia.

In the very acute stages of myopathy there may be only a slight further elevation of these enzyme concentrations, since when the horse first stands the affected muscles may be relatively poorly perfused. In a normal, asymptomatic horse, 1 h after standing following general anesthesia, CK concentration is usually less than 2000 IU/L, whereas in a horse with clinical signs of myopathy, CK concentrations will usually exceed 10 000 IU/L. Characteristic ultrasound findings include increased echogenicity of the affected muscle with loss of the normal striations.

Treatment

Treatment aims to relieve pain and distress and to ensure adequate muscle and renal perfusion. It consists of **analgesics** usually in the form of NSAIDs (e.g. phenylbutazone 4 mg/kg IV, flunixin meglumine 1 mg/kg IV), sedatives (acepromazine 0.04 mg/kg IV, detomidine 0.01 mg/kg IV, butorphanol 0.02 mg/kg IV), corticosteroids (e.g. dexamethasone 0.1 mg/kg IV) and **balanced polyionic electrolyte solutions** administered IV. It may be helpful in severe cases to sling the horse. Fluids are indicated if there is severe muscle damage grossly, discolored urine or dehydration. Prognosis is fair to good in mild to moderate cases; prolonged recumbency is a very poor prognostic indicator.

Preventative measures include appropriate padding of the operating surface, positioning the horse to avoid pressure on susceptible muscle groups and to avoid rises in intracompartmental pressure, and **maintenance of adequate blood pressure**.

Compartment syndrome

Compartment syndrome is an unusual cause of acute severe lameness, usually the result of **direct trauma** to a muscle group contained within a closed non-compliant fascial compartment. Edema and hemorrhage can result in a marked elevation of pressure within the fascial compartment. If there are major vessels or nerves passing through the compartment the elevated pressure may result in occlusion of vessels and myonecrosis as well as a compromise in blood flow to the more distal limb, and/or neuropathy.

Provided that there is no compromise in blood flow the horse can respond adequately to analgesic and anti-inflammatory treatment; however, if blood flow is compromised then it may be necessary to perform a **fasciotomy**. This type of compartment-like syndrome can occur in the caudolateral muscles of the **antebrachium**.

Exertional rhabdomyolysis

Exertional rhabdomyolysis (*q.v.*) (also referred to as **tying-up**, **azoturia** and **Monday morning disease**) is a common muscle disorder in the exercising horse. The term covers a wide range of related diseases associated with exercise, and numerous causes have been proposed. Specific etiologies have been identified in some cases, for example polysaccharide storage myopathy, mitochondrial myopathy resulting from a deficiency in NADH coenzyme Q reductase, glycogen branching enzyme deficiency in Quarter Horse foals, and a defect in skeletal muscle excitation-contraction.

The condition can occur after strenuous exercise, e.g. endurance racing or after the steeplechase phase of a three-day event, particularly when there is a sudden increase in the duration or intensity of exercise (**sporadic exertional rhabdomyolysis**). Other horses are prone to repeated episodes of exertional rhabdomyolysis and may have an underlying muscle abnormality (**chronic exertional rhabdomyolysis**). Nervous horses, especially fillies, are predisposed. Episodes can occur after minimal exercise. Two heritable causes of chronic exertional rhabdomyolysis have been identified so far: **recurrent exertional rhabdomyolysis** and **polysaccharide storage myopathy**.

Clinical signs

Horses usually exhibit a stiff gait, muscle cramping, pain and reluctance to move. The **gluteal muscle mass** is the most commonly affected. Clinical signs vary depending on the degree of muscle damage. The horse takes progressively shorter strides and may be extremely reluctant to move. It becomes distressed and in pain. There may be patchy sweating. The horse may paw and look at its flanks. The affected muscle group(s) is usually firm. In severe cases the urine may be abnormally dark due to **myoglobinuria**.

Diagnosis

Diagnosis is confirmed by measuring raised serum concentrations of the muscle enzymes CK and AST (normal levels CK 35–125 IU/L, AST 80–400 IU/L). Following an attack of equine rhabdomyolysis, peak concentrations of CK are reached 2 h later and decline relatively rapidly within the next 2 days; peak concentrations of AST are reached approximately 24 h after the onset of clinical signs and decline more slowly over 7–10 days. However, peak concentrations of CK and AST are not always directly correlated with the severity of clinical signs. A horse with moderately severe clinical signs may have a CK concentration of 15 000 IU/L at 2 h, declining to 7000 IU/L at 24 h. Corresponding maximum AST concentration may be 4000 IU/L at 24 h.

The condition should be differentiated from colic and laminitis (*q.v.*). Muscle biopsies can be used effectively to differentiate between sporadic exertional rhabdomyolysis, recurrent exertional rhabdomyolysis, polysaccharide storage myopathy and various other myositis conditions (*q.v.*).

Treatment

The horse should not be moved since this may exacerbate muscle damage. Treatment consists of analgesics, NSAIDs, dantrolene sodium (2–4 mg/kg, PO) and sedation with acepromazine to reduce anxiety and improve circulation (but acepromazine should not be used until the horse is rehydrated). Intravenous or intragastric DMSO is commonly recommended, and in most cases IV fluid therapy is indicated to ensure adequate renal perfusion and excretion of myoglobin. Most horses are alkalotic, and bicarbonate therapy is not advised. The convalescent time is dependent on the severity of the attack.

Preventative measures include regular exercise, vitamin E, selenium and electrolyte supplements, and appropriate concentrate feeding for the amount of work being performed. In some horses the condition is recurrent, and a urinary fractional electrolyte excretion (FEE) (*q.v.*) should be performed. If abnormal FEE values are detected, the diet should be adjusted accordingly, usually by supplementation with sodium and/or potassium chloride and/or calcium carbonate. Affected horses should always be warmed up slowly, regularly exercised and turned out whenever possible.

Recurrent exertional rhabdomyolysis

Recurrent exertional rhabdomyolysis (*q.v.*) is an inherited, intermittent, stress-induced defect in the regulation of muscle contraction. This defect is responsible for a subset of the cases of chronic rhabdomyolysis that are diagnosed, and the condition primarily affects racing Thoroughbreds and Standardbreds. Apparent trigger factors include female gender, stress, high starch diets and heavy training. Often episodes are noted following a training session in which the horse was held to a slow gallop.

Affected horses have intermittent elevations in serum CK, episodes of muscle stiffness and a history of poor performance. Diagnosis can be based on exercise testing and muscle biopsies.

Treatment should **avoid prolonged stall rest**. Prevention includes avoiding stress-related trigger factors and appropriate dietary adjustments. Concentrate feeds that are low in starch and high in fat appear to be beneficial.

Polysaccharide storage myopathy

Another subset of horses with chronic exertional rhabdomyolysis have an inherited disorder in glycogen storage apparently resulting from enhanced insulin sensitivity. **Polysaccharide storage myopathy (PSSM)** is seen primarily in Quarter Horses, draft horses and related breeds. In contrast to horses with recurrent exertional rhabdomyolysis, horses with PSSM tend to be very calm and sedate.

The clinical signs are similar to those detected with any form of exertional rhabdomyolysis, but some horses develop rhabdomyolysis without any history of exercise. Muscle atrophy and an abnormal stiff gait are often detected with this condition, and diagnosis can be confirmed with biopsy. Replacing high carbohydrate grain in the diet with rice bran or other specially formulated diets with a high lipid content can minimize the clinical signs. **Regular, regulated exercise** regimens are critical for these patients.

Nutritional myodegeneration (nutritional myopathy, nutritional muscular dystrophy, white muscle disease)

This is a condition, detected primarily in foals, that is caused by a dietary deficiency of **selenium or vitamin E**. Both cardiac and skeletal muscle are affected. **Young foals** typically die acutely, but older foals may present with signs of lethargy and dysphagia. The skeletal muscle form of the disease is more responsive to treatment, which should include supplementation with selenium and vitamin E as well as appropriate supportive care.

Hyperkalemic periodic paralysis

Hyperkalemic periodic paralysis is an **autosomal dominant trait** affecting horses descending from the Quarter Horse sire, IMPRESSIVE. A DNA test to detect the point mutation from mane or tail samples is available, and horses that are homozygous for the mutation are most prone to serious clinical effect.

The defect prevents normal function of voltage dependent skeletal muscle sodium channels, and typically results in intermittent episodes of weakness and muscle fasciculations. The **defective sodium channels** fail to inactivate appropriately, allowing an excessive persistent depolarization, and elevations of serum potassium are typical during an episode. The severity of clinical signs varies widely and can be influenced by a number of external factors including stress, temperature, diet, exercise and anesthesia.

Treatment in acute episodes is directed toward lowering serum potassium levels by administering solutions containing 0.2–0.4 mL/kg of 23% calcium gluconate diluted in 1 L of 5% dextrose. Alternatively 5% dextrose alone or combined with sodium bicarbonate can be given. Long-term control involves management to reduce dietary potassium and regular exercise, and may require administration of acetazolamide (2–4 mg/kg, PO, q 8–12 h) or hydrochlorothiazide (0.5–1 mg/kg, PO, q 12 h).

Peroneus (fibularis) tertius—rupture or avulsion of the origin

In the horse, the peroneus (fibularis) tertius, along with the SDFT, is an integral part of the **reciprocal apparatus** of the hindlimb, mechanically flexing the

hock when the stifle is flexed. It originates in the extensor fossa of the distal femur, bifurcates distally and inserts on the proximal aspect of the third metatarsal bones, as well as the calcaneus and third and fourth tarsal bones.

Rupture is usually **traumatic** due to overextension of the hock joint (i.e. if the limb is trapped) or when a **full-limb cast** is applied to the hindlimb. Disruption can also occur with a **laceration**. It often initially results in lameness although the horse is able to bear full weight on the limb. The reciprocal apparatus is disrupted so that the hock can be passively extended while the stifle is flexed, and this maneuver creates a characteristic **dimple in the Achilles tendon** on the caudal aspect of the thigh. As the limb moves forward the stifle flexes, but the hock does not. The appearance is pathognomonic but the diagnosis can be confirmed ultrasonographically.

With **avulsion** of the origin of the muscle, which usually occurs in foals and also involves the long digital extensor muscle, lameness can be severe initially, and radiographs should be taken to confirm avulsion of the extensor fossa.

Treatment is prolonged stall rest and the prognosis is favorable for healing and for return to work. Over 70% of horses are reported to return to their previous level of exercise following an average of 8 mo of rehabilitation, but performance horses and horses with additional structures injured simultaneously are much less likely to return to work. Ultrasound should be used to monitor healing before returning affected horses to work.

Quadriceps femoris rupture

Quadriceps femoris has four heads that originate from the ilium and the femur and insert on the patella. **Rupture of quadriceps femoris** is an unusual catastrophic injury that prevents the horse from extending the stifle, and the horse will be unable to bear weight. The site of rupture is usually readily palpable. There is no viable treatment although the horse can be temporarily maintained in a sling, and the prognosis is poor.

Myotonia

Myotonia congenita is a rare skeletal muscle disease characterized by an extremely stiff hindlimb gait. Clinical signs are usually evident within the first few months of life. The hindquarters are often unusually well muscled. Percussion of the muscles results in characteristic dimpling due to prolonged contraction. The condition may be inherited but that has not been definitively demonstrated.

Characteristic histopathologic changes can be confirmed, but the diagnosis is best made with electromyography. There is no effective treatment, but in most cases the signs do not progress after a year of age.

Shoulder instability

Loss of stability of the shoulder (so-called “**shoulder slip**”) is usually the result of a **collision** with another horse or a solid object, resulting in damage to elements of the brachial plexus. The horse tends to place the foot more axially than normal and as the limb starts to bear weight the shoulder appears to

bulge outward due to loss of collateral support. The development of muscle atrophy or areas of patchy sweating may help to elucidate which nerves are involved.

Prognosis depends on the nature of the nerve injury; speed of improvement is a helpful indicator.

Suprascapular nerve injury (sweeny)

Injury to the suprascapular nerve—usually resulting from direct trauma to the point of the shoulder, overstretching or a poorly fitting harness collar—can result in **profound atrophy** and **paralysis** of the infraspinatus and supraspinatus muscles. This condition is colloquially referred to as **sweeny**, and the horses classically present with a **withered appearance** of the upper forelimb and a prominent scapular spine.

While many reports have described lameness, lateral instability of the shoulder and abduction of the shoulder joint with weight bearing with this condition, the instability may be due to simultaneous damage to the brachial plexus. A presumptive diagnosis is made based on clinical evidence of muscle atrophy, and electromyography can detect denervation at about 7 days post injury.

Most cases respond to conservative management with **stall rest** and NSAIDs although improvement may take up to a year post injury. If the nerve has been transected no treatment is effective. Surgical management has been described, and originally entailed removing a notch from the scapula to decompress the nerve, but there were reports of serious complications including scapular fracture. Current modifications involve simple resection of the tendinous band that lies superficial to the suprascapular nerve. Timing of surgical intervention is complicated by the delayed improvement observed even in horses that respond well to conservative therapy, and the prognosis for return to athletic performance is good with both conservative and surgical management.

Serratus ventralis muscle rupture

The serratus ventralis is composed of cervical and thoracic portions that originate from the cervical vertebrae and ribs and converge to insert on the medial surface of the scapula to form the sling support that suspends the thorax between the forelimbs. **Rupture of the serratus ventralis** is a catastrophic but rare injury that occurs with dorsal impact over the withers and neck, or when a horse jumps off of an elevation. Usually both sides of the muscle sling are affected, the thorax is dropped so that the proximal borders of the scapula are prominent above the dorsal spinous processes of the withers, and the horse exhibits extreme pain.

Sling and intensive nursing support provide an alternative to euthanasia for managing these cases, but prognosis for athletic performance is poor.

DEVELOPMENTAL ORTHOPEDIC DISEASE

INTRODUCTION

Developmental orthopedic disease (DOD) (*q.v.*) is a comprehensive term that integrates a wide variety of conditions affecting the skeleton of **growing horses**.

These conditions are caused by a number of interrelated factors, many of which are poorly defined. Developmental orthopedic diseases became a recognized entity in 1985 when a survey conducted by Ohio State University suggested that many of the orthopedic problems in young horses were the result of nutritional deficiencies or imbalances. Being multifactorial these diseases appear to have genetic, environmental and nutritional components.

Trauma can affect the relatively **weak growth centers** of the developing limb and result in developmental abnormalities (e.g. angular limb deformities). Similarly, nutrient excesses (e.g. excess mineral supplementation) and rapid growth (excessive protein and energy) often exacerbate musculoskeletal disorders. Of course **genetic factors** also regulate growth rate, and a lack of careful genetic monitoring can result in the introduction and propagation of disorders that become impossible to eliminate (e.g. osteochondrosis, *q.v.*).

The musculoskeletal system is in a **constant state of turnover** or change throughout life; the rate of turnover is greatest early in life, during the growth phase. Skeletal growth is most rapid in the first few months of life and slows through the first year until growth plate closure. Because the metabolic activity of the musculoskeletal system is so great early in life, the skeletal system is more susceptible to insult, both physical and metabolic.

This section covers the salient features of the pathogenesis of developmental orthopedic disease and provides a review of osteochondrosis, osseous cyst-like lesions, incomplete ossification of the cuboidal bones of the carpus and tarsus, physitis and angular and flexural limb deformities.

OSTEOCHONDROSIS

Osteochondrosis (*q.v.*) is a developmental orthopedic condition defined as a disturbance in **endochondral ossification**, a process that is responsible for the coordinated differentiation of cartilage-producing cells called chondrocytes. Any disruption in this sequence of events can result in the retention of poorly differentiated growth cartilage.

The structure of the joint surface is weakened by retention of this immature cartilage, resulting in necrosis and fissure formation extending to the articular surface. Damage to the articular surface causes inflammation, which is defined by the term **osteochondritis**.

In some horses, a cartilage flap will detach from the underlying bone, creating a lesion known as **osteochondritis dissecans (OCD)** (*q.v.*). A “dissecans” lesion commonly forms as a result of trauma acting on poorly developed cartilage and leads to the formation of a cleft extending from the articular surface to the subchondral bone. These cartilage flaps have been described as **type I lesions** and develop at or near the center of a convex joint surface. At some locations, such as the distal intermediate ridge of the distal tibia, abnormally developed cartilage may fracture along the cleft line resulting in the formation of an **osteochondral fragment**. The latter abnormality is defined as a **type II lesion**.

Pathogenesis

Epiphyseal cartilage is converted into bone through the process of **endochondral ossification**. The process through which cartilage is replaced by bone in the developing epiphysis is identical to that occurring in metaphyseal growth

plates. This process is accomplished as chondrocytes proliferate, mature and advance through four histologic zones to produce the extracellular matrix that defines this specialized tissue. Chondrocytes must progress through the **resting, proliferating, hypertrophic** and **calcification zones** in an orderly fashion to develop and function normally. The calcified layer is subsequently replaced by **bone**. If any of the events involved in endochondral ossification are altered to a significant degree, osteochondrosis can occur.

Histologically, an area of **necrotic cartilage** is typically the first identifiable sign of an osteochondrosis lesion. When the epiphyseal cartilage becomes necrotic, ossification cannot occur and the “cartilage template” ultimately is retained as a region of **thickened cartilage**. Because cartilage is avascular, its metabolic needs must be met by diffusion of nutrients from the synovial fluid. Consequently, chondrocytes in the deeper zones of abnormally thickened cartilage are deprived of nutritional support due to the increased distance between these cells and the synovial fluid. This further compromises normal cartilage development.

At the cellular level, important factors thought to be responsible for osteochondrosis include abnormal chondrocyte metabolism, abnormal coding for cartilage matrix production, and biomechanical forces leading to irregular articular loads. As it is likely that these factors participate concurrently in the etiology of the condition, osteochondrosis should be considered to be a **multifactorial disease**.

The metabolic requirements of cells involved in endochondral ossification are met by delivery of nutrients via the systemic circulation and by diffusion through the synovial fluid. Articular cartilage lacks a blood supply and must receive its nutrients by diffusion through the synovial fluid. In contrast, epiphyseal cartilage has a direct blood supply from vessels located in the perichondrium, a thin continuation of the periosteum over the extremities of bone. **Perichondrial blood vessels** penetrate and supply the epiphyseal cartilage through cartilage canals. This source of blood is vitally important during the early stages of cartilage development. If it is **disrupted** prior to the normal time frame required for epiphyseal development, ischemia and necrosis can result and produce lesions consistent with osteochondrosis.

Adequate production of normal **extracellular matrix** is essential to the development of the epiphyseal cartilage and the formation of bone. Chondrocytes are capable of producing many different types of matrix molecules, including collagen, proteoglycans and glycosaminoglycans. These molecules must be produced in the right order, location and arrangement to allow endochondral ossification to proceed normally. Disruption of this complex process due to **abnormal genetic makeup** or **cellular injury** may result in lesions consistent with osteochondrosis.

Because osteochondrosis lesions are noted to occur in consistent locations within each affected joint, **biomechanical influences** are presumed to play a role in their development. Some investigators hypothesize that physiologic trauma during development results in focal stresses on specific areas of developing articular cartilage, which leads to abnormal development of the tissue.

Etiology

Osteochondrosis has a **multifactorial etiology**. The proposed causative factors include **genetic factors** that affect **weight gain** and **growth rate**, **nutrition**,

heredity, type and intensity of exercise and **trauma**. A positive relationship has recently been identified in Standardbred and Warmblood horses between the occurrence of osteochondrosis in the tarsocrural joints and body weight at birth and during the growth phase. Furthermore, **rapid weight gain** has been noted to facilitate the development of osteochondrosis in the femoropatellar joints of Warmblood horses.

Diets that include appropriate amounts of **calcium, phosphorus, copper** and **zinc** tend to reduce the incidence of musculoskeletal problems. Feeding excessive amounts of calcium and phosphorus, however, is contraindicated as a combination of decreased exercise activity and excessive intake of calcium and phosphorus is associated with the development of multiple developmental orthopedic diseases, including osteochondrosis and irregular physal closure. **Copper** participates in the function of the enzyme lysyl oxidase, which is essential in appropriately cross-linking pyridinoline in collagen. Collagen is a vital component of the cartilage matrix, and diets containing less than adequate amounts of copper result in reduced **collagen cross-linking** and, consequently, an increased incidence of osteochondrosis. Copper supplementation in mares during pregnancy and in foals after birth appears to reduce the incidence of osteochondrosis, especially involving the distal intermediate ridge of the tibia. Although copper is not the only important factor in the etiology of osteochondrosis, it is important to consider evaluating dietary copper in instances in which the incidence of osteochondrosis is excessive.

Other important dietary elements to take into account are **digestible energy** and **protein**. Diets containing high percentages of carbohydrate and protein have been associated with developmental abnormalities for many years. Excessive carbohydrate intake appears to disturb the balance between serum concentrations of **insulin** and **thyroid hormones** (T3 and T4) (*q.v.*) and disrupt their coordination of cartilage development leading to abnormal chondrocyte differentiation. In contrast, diets containing excessive amounts of protein do not appear to have similar detrimental effects on development; these diets cause only minor changes in the growth plates.

Although there is no conclusive evidence to support a role for **genetic factors** in the development of osteochondrosis, the role of genetic makeup has been suggested by heritability studies. These studies have shown that osteochondrosis of the tarsocrural joint may depend on genetic background and that the development of these lesions may in fact depend on progeny rather than environment.

The effect of **exercise** on development of osteochondrosis is controversial. The results of controlled studies do not support the hypothesis that increased exercise activity early in life is associated with development of osteochondrosis. Moreover, when low exercise and high exercise programs were compared in Thoroughbred foals, osteochondrosis lesions were significantly more common in the low exercising population of foals, indicating a possible protective effect of high-intensity short-duration exercise. Furthermore, in foals presumed to be genetically predisposed to develop osteochondrosis of the femoropatellar and femorotibial joints, exercise did not appear to influence the development of lesions, rather exercise altered the appearance and distribution of the lesions.

Trauma and **biomechanical loads** appear to play a role in the progression of an osteochondrosis lesion into a “dissecans” lesion (*q.v.*) or into an osseous

cyst-like lesion (*q.v.*). More convincingly, exercise-induced trauma may explain the consistent location of osteochondrosis lesions in the various joints, suggesting the influence of physical factors in the pathogenesis. It is generally accepted that physiologic loads applied to defective cartilage or abnormally high loads exerted on normal cartilage can lead to osteochondrosis.

Incidence

Osteochondrosis is estimated to affect 5–20% of foals, although the occurrence rate may be much higher in certain breeds. All breeds of horses may be affected, however the majority of cases have been recognized in racing breeds. It was reported recently that 50% of horses undergoing surgery for osteochondrosis of the femoropatellar joint were Thoroughbreds. Osteochondrosis primarily affects diarthrodial joints and occurs more frequently in male than female horses.

It is important to remember that any articular surface may be affected, including vertebral articulations, with more than one joint frequently being involved. For this reason, evaluation for **any lameness** in young horses, particularly if bilateral, should include OCD as a differential diagnosis. The most common sites are the distal intermediate ridge of the tibia, the lateral and medial trochlear ridges of the talus, the lateral and medial trochlear ridges of the femur and, less commonly, the humeral head, the glenoid surface of the scapula, and the metacarpo/tarso-phalangeal and proximal interphalangeal joints.

Clinical signs and diagnosis

Generally, osteochondrosis lesions causing clinical **lameness** occur in horses <3 yr of age, although some horses remain asymptomatic until later in life. The latter presentation is particularly common when only mild lesions exist, and the horse has been allowed to mature before vigorous exercise has commenced. Older horses may present with degenerative arthritis, with the location and appearance of bony lesions being consistent with a diagnosis of long-standing osteochondrosis.

The most prominent clinical finding in horses with osteochondrosis is **effusion** in at least one affected joint. Effusion may not always be evident in the contralateral joint, even though radiographic evidence of disease exists. Lameness is variable, but is usually only mild to moderate. The lameness may be difficult to abolish completely with IA injection of local anesthetics. Muscle wasting is often evident in horses with long-standing osteochondrosis of the shoulder or stifle.

The age of the horse, its size and sex, and the presence of joint effusion are factors that can indicate a probable diagnosis of osteochondrosis. Confirmation of a diagnosis of osteochondrosis is usually made with **radiography**. In OCD, articular cartilage becomes thickened and usually does not mineralize, therefore it appears radiographically as a defect in the articular surface. Even when clinical signs are only apparent in one limb, the **contralateral** joint should always be radiographed. The horse should also be closely examined for abnormalities in other joints. A **neurologic examination** and cervical radiographs may be indicated to determine whether cervical vertebrae have been affected.

Common radiographic findings in horses with osteochondrosis include discrete osteochondral fragments, defects in the contour of the articular surface (flattening or depression), irregularly shaped lucent areas in the subchondral bone, subchondral bone sclerosis surrounding the lucent areas, and secondary osteoarthritis. Despite the presence of lameness and effusion, osteochondrosis lesions of the shoulder and stifle may not be readily identified radiographically. In these cases, the diagnosis can ultimately be made by investigating the joint via **arthroscopy**. It is important to note that lesions identified by radiography are not always clinically significant. Radiographic findings must be interpreted in light of the clinical signs.

Treatment

Conservative therapy consists of restricting the horse's exercise, slowing the growth rate, and ensuring that there are **no dietary vitamin or mineral deficiencies**. Excessive feeding of grain should be avoided. Conservative therapy is successful in 20–50% of cases, depending upon the site and severity of the lesion. Up to 1 yr of convalescence may be required, and joint effusion and lameness may be present for a considerable period of this time. Intra-articular injection of hyaluronan and systemic administration of polysulfated glycosaminoglycans do not appear to have any effect on the long-term outcome if combined with conservative treatment. Injection of corticosteroids into an affected joint is contraindicated.

Surgical treatment is usually recommended for horses with OCD and consists of removal and debridement of detached or abnormal cartilage to induce subchondral bone capillary bleeding. This facilitates the initiation of a repair process that, in the majority of cases, eventually leads to the formation of functional **fibrocartilage**. **Arthroscopic** surgery is preferred over arthrotomy, because of the ability to observe and operate on multiple sites within a joint, reduce surgical trauma and minimize postoperative complications. Approximately 70–80% of horses with OCD respond favorably to arthroscopic surgery. Improvement in clinical signs is often evident within weeks after surgery.

Postoperative care consists of 4 wk of stall confinement, then 4 wk of hand-walking, followed by paddock rest for an additional 8–16 wk. This can be modified to suit the individual lesions and training program of the affected horse. If required, some horses, primarily those with small lesions of the distal intermediate ridge of the tibia, can resume exercise within 10–14 days of surgery.

Because osteochondrosis is often associated with some degree of **osteoarthritis**, clients need to be informed of the potential for the persistence of lameness and need for medical management after surgery. Early surgical management will help retard the development of osteoarthritis, thereby producing a less painful and more functional joint. The **prognosis** in appropriately managed patients is generally favorable.

Prevention

Measures designed to reduce the incidence of osteochondrosis and other developmental problems should be directed at the etiology as understood. However, considering the gaps in our understanding of the etiology of osteochondrosis, such measures cannot always be specific. Although the influence

of inheritance on the expression of osteochondrosis is unknown for most forms of OCD, in most cases it would be prudent to **avoid breeding** to horses that have shown the propensity to produce foals with osteochondrosis. Nevertheless, there are many highly productive lines of athletic horses that do have a high incidence of OCD, and it is not realistic or even rational to suggest that those genetic lines be eliminated.

Foals up to 1 yr of age should be allowed to exercise freely for at least 12 h/day and forced exercise should be avoided. Strict guidelines concerning diet are difficult because of the different types and quality of feed available and because individual foals respond differently to different diets. The best recommendation is to have a reliable laboratory analysis of feeds performed followed by consultation with a recognized equine nutritionist. Similar attention should be given to the diet of gestating mares. Moreover, it is important always to avoid over-supplementation of mineral/vitamin mixes.

OSSEOUS CYST-LIKE LESIONS

Osseous cysts (*q.v.*) occur most frequently in the **medial femoral condyle** within the stifle joint, but also occur in other sites, including the pastern and elbow (cubital) joints and carpal bones. Potentially cysts may occur in any joint. These lesions are characterized by infolding of articular cartilage into the underlying cancellous bone. The **infolded cartilage** then becomes **necrotic** and its matrix remains non-mineralized. Because the affected area lacks a blood supply, the normal repair processes cannot occur.

The etiology of bone cysts is uncertain but may be related to dietary abnormalities and may have a similar pathogenesis to OCD (*q.v.*). Several theories have been proposed to explain the origin of subchondral bone cysts, including a **disturbance** in the normal process of **endochondral ossification** similar to that in classical osteochondrosis. In support of this theory is the fact that osteochondral disease may lead to cyst formation. It also has been proposed that subchondral bone cysts are caused by **direct trauma** to the articular surface leading to full thickness cartilage degeneration. Experimentally, cysts can be induced by linear incision of the articular cartilage and penetration of the subchondral bone. In contrast, cysts do not form if only the articular cartilage is damaged. Because cysts are generally site specific, it is thought that certain joint surfaces are vulnerable to this disease due to the **biomechanical forces** acting at specific sites.

Bone cysts may or may not be associated with clinical **lameness**. Cyst-like lesions close to the articular surface are more likely to cause lameness than those deep within the bone. The treatment of choice is surgical evacuation where access to the cyst is feasible. Conservative therapy may be successful in some cases, but many horses treated conservatively develop long-term degenerative joint disease.

INCOMPLETE OR DEFECTIVE OSSIFICATION OF THE CARPAL AND TARSAL BONES

Delayed ossification of the carpal and tarsal bones in newborn foals may be a result of **prematurity/dysmaturity**, hypothyroidism (*q.v.*) or a variation of

normal ossification rates. Lack of ossification of the cuboidal bones in these joints results in collapse and deformation, and subsequent development of joint abnormalities. In the carpus an angular limb deformity occurs, whereas a flexural deformity appears in the hock.

When the tarsal bones are involved, the most prominent clinical sign is the development of a characteristic **“bunny hopping” gait** that is usually present at, or soon after, birth. Radiographic examination will reveal the presence of one or more abnormal bones in these joints. The cuboidal bones are usually collapsed, incompletely ossified and may show varying degrees of fragmentation. If a diagnosis is made early and the deformity is not severe, effective treatment can be as simple as exercise restriction and application of full limb bandages to provide support. In more advanced cases, straightening the leg with the foal under general anesthesia and applying a full limb or tube fiberglass cast (*q.v.*) should be considered.

In young foals, the cast will need to be changed initially every 7–10 days or more often to accommodate the rapid growth occurring at this time. This treatment will only be successful if instituted prior to degenerative changes occurring in the joint. When the diagnosis is delayed or the angulation of the limb is severe, surgical treatment is recommended. Surgical correction of the resulting angulation deformities includes growth acceleration and retardation procedures that are more thoroughly discussed elsewhere in the text. The prognosis is somewhat guarded, as some horses become sound, but many are left with a chronic lameness.

PHYSITIS

Physitis is traditionally defined as a generalized inflammatory response of a **growth plate**. The disease occurs with biphasic age peaks, typically detected between 3 and 6 mo in the distal metacarpus/metatarsus, and between 8 mo and 2 yr of age in the distal radius and occasionally in the distal tibia.

There is still controversy regarding whether to classify physitis as an inflammatory process or a disturbance of endochondral ossification. Regardless, in its acquired form, physitis is most likely to result from compressive forces producing **Salter–Harris type V physeal fractures**, and can be classified as a developmental orthopedic disease. Because of the higher load applied to the medial aspect of the forelimb, these fractures tend to propagate in a medial to lateral direction.

During the delicate phase of active growth, **nutritional imbalances** associated with heavy feeding programs that include diets rich in concentrate feed can predispose to excessive weight gain and weakening of the epiphyseal cartilage template. The growth plates enlarge in response to inflammation and excessive load bearing, which cause subperiosteal osteogenic cells (osteoblasts) to initiate new bone formation. Horse owners will often complain of physeal enlargement without any other clinical signs. These mildly affected cases are usually transient and can be effectively managed with rest and a balanced **low energy** diet. In more severe forms, enlargement of the physis may be accompanied by local heat, pain and variable degrees of lameness.

The diagnosis is usually clinical, but lateral and dorsopalmar/plantar radiographs show characteristic changes: the physis is thicker and more irregularly undulating than normal, and the metaphysis may show sclerosis and flaring. The disease is usually self-limiting but treatment includes retardation of growth, low doses of phenylbutazone, and restricted exercise.

It is particularly important to reduce energy intake and body weight, but the **nutritional balance** of the diet (*q.v.*) must be maintained. Feed analysis and consultation with a nutrition specialist are advised. Several feed companies are developing diets specifically designed to manage foals with this type of developmental problem. The prognosis is usually good. Foals with this disease should be monitored for development of flexural and angular limb deformities.

ANGULAR LIMB DEFORMITIES

The term angular limb deformity refers to limb deviations that occur in a frontal plane and are lateral or medial deviations along the long axis of the limb. The deformities can be **congenital** or **acquired**, and they most commonly involve the carpus, tarsus and metacarpo/metatarsophalangeal joints. Foals may develop these problems after birth because of the interplay of the aforementioned factors involved in the pathogenesis of developmental orthopedic disease.

Valgus deformities are those in which the limb deviates laterally, distal to a reference point (in other words, the angulation distal to the reference point is away from the midline of the body). In **varus** deformities the limb deviates medially distal to the reference point (in other words, the angulation distal to the reference point is towards the midline of the body). The terms valgus and varus are adjectives and should precede the nouns they describe; however, in common usage they are usually applied following the noun that they modify (i.e. "carpus valgus").

Deformities of the **carpus** and **tarsus** are most often valgus, with a lateral deviation of the limb below the carpus or tarsus, and less commonly varus. A combination of valgus and varus deformities will produce a so-called "**wind swept**" appearance. Deviations associated with the **metacarpo/metatarsophalangeal** joints can be either valgus or varus. Angular deformities arising from curvature of the diaphysis of the metacarpus and metatarsus also have been reported.

Most foals are born with a slight **bilateral carpus valgus** and outward rotation of the forelimbs. This is considered **normal** and should correct within 7–10 days of birth. Should this fail to occur the foal needs to be critically observed since correction of angular limb deformities must be implemented within the period of active growth. The majority of growth in the distal radial and tibial physes occurs within the first 6–8 mo of life, whereas the distal metacarpal/metatarsal physes are active from birth to 3 mo of age.

As a general rule, each of the following differentials should be considered in any foal that presents with an angular limb deformity:

1. Laxity of periarticular soft tissues
2. Incomplete ossification of the cuboidal bones and collapse

3. Disproportionate growth at the level of the physis
4. Metacarpal/tarsal bone displacement
5. Diaphyseal curvature (MC3, MT3).

The pivot points of **acquired angular deviations** are usually in either the epiphyses or physes on either side of the joint. The deviation can also be centered over the cuboidal bones when hypoplasia is present. Angular deviation due to ligamentous laxity is usually congenital, although it also can occur following prolonged limb immobilization.

Visual inspection may demonstrate both rotational and angular deformities. For this reason the clinician should examine the foal by standing directly in front of the dorsal aspect of the limbs and positioning the hooves directly under the proximal aspect of the limb. The same principles apply for hindlimb evaluations except that the examiner views the foal from the rear. Gait assessment is aimed at evaluating hoof breakover in order to implement the most appropriate corrective trimming or shoeing measures. Manipulation of the limb may induce complete or partial correction of the deformity in cases of ligamentous laxity or cuboidal bone hypoplasia.

Dorsopalmar/plantar radiographs are valuable to determine the pivot point(s) and deviation angle of the deformity. In addition, hypoplasia of the cuboidal bones, usually the ulnar, third and fourth carpal bones and the central and third tarsal bones, can be identified from radiographs. In long-standing cases there may be radiographic evidence of **degenerative joint disease**, which influences prognosis. Sufficient length of the appendicular skeleton must be included on the radiographs proximal and distal to the clinical site of the deformity so that lines can be drawn along the axis of the long bones on either side of the joint. For this purpose, long narrow cassettes (18 × 43 cm) are commonly used. The lines will intersect at the site of angulation in deviations caused by a single deformity. However, perfect radiographic positioning of bones proximal and distal to the pivot point is frequently impossible because of rotation of the distal limb. In addition, appropriate positioning of the two intersecting lines is often very subjective. An alternative technique for determining the pivot point has been described using lines drawn through the physes and the joint spaces. In a normal limb these lines will be parallel, but in an affected foal the lines will deviate at the level of the deformity. Again, accurate positioning of these lines is very subjective.

In most cases, **conservative** management is successful in treating angular limb deformities. Stall rest or limited small paddock turnout and corrective shoeing and trimming will resolve the deformity by altering weight-bearing patterns. To address **carpus valgus** problems, the clinician can elect either to apply commercially available glue-on shoes with dorsomedial hoof extensions or to over-trim the lateral hoof wall. Although trimming has been used successfully for many years, glue-on shoes are preferred because they do not affect **hoof balance**. Deformities that can be improved by manipulation (i.e. those deformities due to ligamentous laxity or cuboidal bone hypoplasia) may benefit from splints or tube casts (*q.v.*). **Pressure sores** are a common complication of external support when applied to irreducible deformities and are extremely difficult to treat or manage.

External coaptation will not resolve angular deformities due to disparity in growth rates at the physis. Angular deformities associated with epiphyseal or physeal dysplasia or ligamentous laxity can resolve spontaneously.

Surgical correction should be attempted if the deformity is severe, if the degree of angulation is increasing rapidly, if conservative therapy has failed, or if inadequate time is left for conservative therapy to be effective before closure of the physis occurs. Surgical correction of deformities arising from the epiphysis or physis involves **growth retardation** by **transphyseal bridging** or **growth enhancement** by **hemicircumferential periosteal transection and elevation** (periosteal stripping). Diaphyseal curvature of the metacarpus or metatarsus that is identified before 1 mo of age can be treated with periosteal transection and stripping of the distal metacarpal/tarsal physis and the entire concave surface of the bone. In older foals, an osteotomy will be required.

There is some evidence that **periosteal stripping** may not be as effective as originally purported. However, additional research needs to be performed to determine accurately the effectiveness of this technique. The difficulty has been identifying an appropriate model to represent naturally occurring angular limb deformities in order to allow accurate comparisons between treated foals and untreated controls.

Regardless, surgery needs to be performed well before cessation of metaphyseal growth to be of benefit. This requires intervention before approximately 6 wk of age for metacarpo/metatarsophalangeal joint deformities and 4–6 mo of age for deformities of the carpus and tarsus. Therefore, once deemed necessary, the surgery should be performed promptly. Occasionally, however, surgical correction has been achieved at the metacarpus/metatarsus and carpus/tarsus as late as 3–4 mo of age and 9–14 mo of age, respectively.

Correction of $>20^\circ$ has been reported for carpal valgus but $8\text{--}15^\circ$ is a more reasonable expectation; anticipated correction at the metacarpo/metatarsophalangeal joints should be more modest, approximately $5\text{--}8^\circ$. The rotational deformity usually corrects with the angular limb deformity, although if left too long part or all of the rotation may become permanent. Correction of angular and rotational deformities following physeal closure can be achieved by an **ostectomy** or **osteotomy** and a variety of different derotational, step (frontal and sagittal plane), and wedge ostectomy/osteotomy techniques have been described for use in horses. These are generally considered to be salvage procedures.

FLEXURAL DEFORMITIES (CONTRACTED TENDONS)

A flexural deformity represents a deviation in the sagittal plane and is detected as a **persistent hyperflexion** of a joint region. Flexural deformities are most commonly encountered in the distal interphalangeal joint, the metacarpo/metatarsophalangeal joint and the carpus. These deformities are commonly referred to as **contracted tendons**, even though true tendon contracture is unlikely to be the cause of the problem.

With flexural deformities, the soft tissue structures of the palmar and plantar limb are affected such that the limb is held in varying degrees of flexion. The forelimbs are more frequently affected, and the problem can involve one or more limbs at the same time. The true cause and method of development of

flexural deformities remain unknown, although horses with acquired deformities (those that develop after birth) often share similar factors to those associated with the **developmental orthopedic disease** complex (*q.v.*).

Many foals are born with mild **digital hyperextension** characterized by flaccidity of the flexor tendons, which causes the toes of the front hooves to elevate off the ground during weight bearing. Most of these deformities are **self-limiting**, and correction occurs during the first two weeks of life as muscle and tendon tone improves. Tendon laxity may be more severe and excessive toe elevation causes load bearing to occur on the bulbs of the heel or pastern leading to soft tissue abrasion. This condition can be successfully treated by applying **heel extensions** until muscle and tendon tone improves.

Congenital flexural deformities

Multiple factors have been implicated in the **congenital form** of the disease including intrauterine positioning, ingestion by the mare of certain toxins such as locoweed, collagen cross-linking defects, equine hypothyroidism/goiter and unidentified predisposing genetic factors. Congenital flexural deformities can be due to hyperflexion or, less commonly, hyperextension due to flaccid or relaxed flexor muscles and tendons. Some of these deformities can cause dystocia or difficult foaling.

The most common congenital flexural deformity occurs at the level of the **distal interphalangeal joint and fetlock**. These deformities are appropriately classified according to the joint involved. The contracture associated with the DDFT involves the distal interphalangeal joint (coffin joint) and the contracture associated with the SDFT affects the metacarpophalangeal joint. The two need to be carefully differentiated since the prognosis for the latter is generally worse. Careful palpation of the flexor tendons should be completed with the foal in a weight-bearing and non-weight-bearing position to determine which of the flexor tendons is most involved. Involvement of both SDFT and DDFT to a similar degree can occur. Congenital flexural deformity of the **carpus** is also fairly common, and can occur as part of a generalized limb contracture involving several joints.

If the foal can stand, and the limbs can be manually extended into a normal position, the prognosis is favorable for resolution with temporary **splinting** with stiff PVC splints or splints constructed from synthetic casting material applied to the back of the leg over a heavy wrap. Splints can cause **pressure sores** (*q.v.*), thus they require careful application for only a few hours each time, maintaining an accurate schedule. Analgesia is also important, but **NSAID use** should be monitored carefully to avoid complications such as gastric ulceration or renal papillary necrosis. More severe forms may require **surgical correction**, which is described below in the section on acquired flexural deformities (*q.v.*).

The empirical use of **IV oxytetracycline** has been reported to cause laxity of tendons and ligaments and can be used for the early treatment of these conditions. The mechanism of action is unknown, but is thought to relate to receptor binding or calcium chelating properties of the antibiotic. Two different courses of therapy have been used: 1 g IV repeated for 3 consecutive days, or 3 g once followed by a second identical dose if correction is not observed. The

lower dose is advocated by some because of decreased risks of reported renal toxicity, diarrhea and excessive laxity of the other normal joints.

Flexural deformities occurring at the level of the **carpus** usually carry a poor prognosis. Foals born with this condition hold the carpus in permanent flexion and are often unable to stand. **Careful evaluation** of these cases should be undertaken to determine whether surgical correction is even feasible. Commonly, contracture of the carpal joint capsule and associated ligaments accompanies that of the carpal flexor tendons, eliminating the chance for successful surgical treatment even after complete carpal flexor tendon transection.

Rupture of the common digital extensor tendon (*q.v.*) can be congenital or acquired, unilateral or bilateral; the cause is unknown but it has been observed to develop in foals with congenital flexural deformity of the carpus (*q.v.*). A characteristic swelling will be located over the tendon sheath at the dorsolateral aspect of the carpus. Foals knuckle over at the fetlock when walking, and appear “over at the knee” when standing. **Temporary full limb splint application** prevents knuckling over and allows the tendon ends to fibrose and eventually return to complete function. Surgery is not required.

Acquired flexural deformities

Acquired flexural deformities are included in the classification of developmental orthopedic disease and share many pathogenetic factors with osteochondrosis (*q.v.*) and other growth related abnormalities. Fast-growing horses on a **high plane of nutrition** are often affected. Furthermore, foals on a poor plane of nutrition that are subsequently introduced to good quality feed often develop flexural deformities. Other important factors include pain caused by osteochondrosis, septic arthritis, physitis and trauma. Pain in one limb will cause abnormal weight bearing on the contralateral limb, resulting in a flexural deformity.

Foals typically develop evidence of **distal interphalangeal joint deformities** between 1 and 4 mo of age. This is in contrast to deformities of the metacarpophalangeal joint that usually occur around 1 yr of age. This difference is thought to be associated with the disparity in growth between the distal and proximal portions of the forelimbs. Distal limb growth is nearly complete by 3 mo of age, whereas distal radius growth continues for much longer. During the rapid growth phase, bone lengthening is not paralleled by passive elongation of the DDFT and SDFT, which are thought to be restricted by their respective accessory (check) ligaments.

The DDFT inserts on the flexor surface of the third phalanx, therefore a decrease in its length will lead to dorsiflexion of the distal interphalangeal joint. Conversely, the superficial flexor tendon bifurcates into medial and lateral branches just distal to the metacarpophalangeal joint. These branches insert on the palmarodistal aspect of the proximal phalanx and the palmaroproximal aspect of the middle phalanx. A shortened superficial flexor unit, therefore, causes the pastern area to be drawn palmarly and the metacarpophalangeal joint to dorsiflex creating the “knuckled forward” appearance. It is believed that this problem mainly relates to the SDFT, but the DDFT and suspensory ligament can concurrently be involved.

Flexural deformity of the distal interphalangeal joint (club foot syndrome)

Increased angulation and shortening of the dorsal wall and elongation of the heels give a typical conformation termed “**club foot**”. The disease may progress so that the angle of the dorsal wall with the ground exceeds 90°, with the heels and frog no longer touching the ground and the dorsal wall becoming concave.

Very severely affected foals will walk on their dorsal hoof wall. These foals are classified as having a **type II deformity**, whereas when the dorsal hoof wall is less than perpendicular to the ground, foals are said to have a **type I deformity**. This classification may aid the clinician in formulating a prognosis because type II problems have a poorer treatment outcome even with aggressive treatment such as surgery.

The diagnosis is based on appearance and palpation of a taut DDFT with the limb in extension. Radiographs of the distal interphalangeal joint will identify abnormal joint angulation, and in chronic cases remodeling of the distal phalanx and secondary changes in the distal interphalangeal joint.

Appropriate **dietary management** should be implemented. This needs to begin with the mare’s diet so that milk production is limited. **Exercise** should be controlled so that some exercise is given but excessive exercise at pasture is eliminated. Mildly affected animals respond to gradually lowering the heels and systemic non-steroidal analgesics (where necessary) to control pain and enhance weight bearing.

Non-steroidal analgesics must be used with caution in foals because they can cause gastrointestinal ulceration. The risk of gastrointestinal ulceration (*q.v.*) should be minimized by using the non-steroidal analgesic at the lowest dose required for the shortest duration possible to achieve the desired clinical effect (1–2 mg/kg **phenylbutazone** q 12–24 h, but up to 4 mg/kg has been recommended); anti-ulcer medication, e.g. omeprazole paste (GastroGard) 4 mg/kg s.i.d., can be used concurrently to reduce the likelihood of gastrointestinal symptoms related to non-steroidal analgesics.

Moderately affected animals (i.e. those with angulation approaching or slightly greater than 90°) and mild cases that fail to respond to non-invasive therapy usually require **desmotomy** of the accessory ligament of the DDFT (inferior check ligament) possibly supplemented by an extended toe shoe. Severely affected animals may require **DDFT tenotomy** performed in the mid-metacarpus or mid-pastern as a salvage procedure.

The prognosis for return to athletic function is usually good for animals that do not need a DDFT tenotomy, but may vary with the intended use of the horse and age at which surgery is performed; in Standardbreds the prognosis for racing after an inferior check ligament desmotomy is reportedly poor for foals operated on >5–8 mo of age.

Flexural deformity of the metacarpophalangeal/metatarsophalangeal joint

The prognosis for this deformity is generally poorer than that associated with the distal interphalangeal joint. Severity may be classified as mild if the

metacarpo/metatarsophalangeal joint is more upright than normal but dorsiflexion is not present; moderate if intermittent dorsiflexion is present; and severe if the joint is in permanent dorsiflexion.

As with conditions involving the distal interphalangeal joint, the diagnosis is principally based on appearance. **Palpation** of flexor tendons and suspensory ligament with the limb in maximal extension should assist in defining the principal structures involved. Radiography of the fetlock joint should be performed prior to treatment to detect the presence of secondary changes that may affect the prognosis.

Mildly affected animals respond to treatment involving **dietary management** to decrease growth rate, **phenylbutazone** to control pain, and **shoeing** with elevated heels with or without a toe extension. Exercise should be restricted and controlled but should not be eliminated. Moderately affected horses respond to similar conservative therapy in combination with surgery. There is considerable debate as to the relative efficacy of desmotomy of the superior and inferior check ligaments in the treatment of this condition. Determining which structure is involved by palpation may assist the surgeon in deciding which surgery to perform, but the use of the *inferior* check ligament desmotomy is generally recommended in mildly affected animals. Horses with more pronounced deformities may or may not respond to corrective shoeing together with both superior and inferior check ligament desmotomies. Superior check ligament desmotomy can be associated with seroma formation (*q.v.*) and infection if postoperative management is not careful, and tenoscopic techniques have been developed to minimize these complications.

The prognosis for return to athletic function in mild and moderately affected animals is favorable, but it is poor when the deformity is severe.

INTRODUCTION

There have been many developments in the science of training and fitness testing of horses over the last 40–50 years. Many of the research findings on blood lactate, heart rate and hematology in the exercising horse are of clinical relevance to veterinarians. The following sections provide an overview of the normal physiology and biochemistry of the equine athlete, both at rest and during exercise.

Veterinarians are frequently asked to examine horses that are either destined to be athletes or are not performing well. The main factors that contribute to good athletic performance include the structure and function of the respiratory, cardiovascular and musculoskeletal systems. It is not the purpose of this chapter to give details of all abnormalities of these or other body systems that affect performance, such as lameness and respiratory disease. The emphasis is rather on those **techniques** that are routinely used to assess performance, such as hematology and electrocardiography, and some new techniques based on the application of measurements made during or after standardized exercise tests. Some of these techniques are now routinely performed in large and successful racing stables. Unfortunately, veterinarians have been slow to apply many of the practical aspects of recent findings on exercise and performance in horses. This may be due to a lack of information on applied aspects of the many research findings in this area. One aim of the following sections is to review the research and present aspects of its practical application.

There are three principal aims of the application of science to training horses.

1. To develop techniques for **testing fitness** of horses for competition. Exercise testing may contribute to the financial success of training establishments in several ways. These include:
 - (a) Early identification of horses with **inferior stamina**. This information can hasten their removal from the stables, or identify limitations to performance in young horses even before they have commenced racing.
 - (b) Repeated tests evaluate **improvement or deterioration** in fitness during training. Information gained in one preparation can be used to assess the fitness attained in subsequent preparations.
2. To design training programs that **maximize fitness**, reduce the incidence of injury and improve results in competition. Heart rate measurements during exercise and blood lactate concentrations after exercise can provide a guide to ideal training speed for development of stamina. This enables adjustments to the training routine in order to increase fitness without overtraining the horse.
3. To evaluate horses with **poor performance**.

Many of the techniques referred to in this chapter have been validated both in the laboratory and on the racetrack in Europe, USA and Australia. Moreover, similar techniques have been used by human athletes and sports science laboratories for decades and are now part of the daily routine of human athletic training. It has taken time to adapt and develop suitable protocols for horses.

It is hoped that this chapter increases veterinarians' understanding of the normal physiology and biochemistry of exercise in equine athletes and illustrates the limitations of some of the traditional methods of assessment of equine performance. This chapter also points the way ahead to the application of new techniques for monitoring fitness in horses.

BIOCHEMISTRY OF EXERCISE AND FATIGUE

ENERGY SOURCES

The processes of muscular contraction and relaxation require **adenosine triphosphate (ATP)** as an energy source. Hydrolysis of ATP to adenosine diphosphate (ADP) and a phosphate molecule liberates heat and energy. The energy is used in the process of actin–myosin crossbridge cycling in skeletal muscle cells, and muscular contraction and relaxation. The nature of the myosin ATPase enzyme in the muscle cell determines the twitch characteristics of a muscle fiber, and characterization of muscle fibers according to their actin–myosin ATPase activity forms the basis of **muscle fiber typing**.

The horse has very **small stores of ATP** within its muscles. These stores are quickly exhausted at the onset of exercise. In order for a horse to sustain exercise, it must be able to replenish ATP at a rate compatible with usage. The ability to utilize and regenerate ATP is a major factor limiting performance. There are several metabolic pathways that have the potential to contribute to ATP resynthesis. The relative importance of each pathway to overall ATP production is determined by the **intensity and duration** of exercise.

The immediate sources of substrate for **ATP resynthesis** are high energy phosphate molecules stored within the cell. These substrates are most important at the onset of exercise, and during times of extreme energy demand, such as the sprint at the end of a race. **Creatine phosphate (CP)** represents the largest pool of high energy phosphate in the muscle. CP can donate a phosphate group directly to ADP. Thus, ATP regeneration is rapid, but CP stores are too small to support more than a few seconds of exercise. During times of **extreme energy demands**, a high energy phosphate group may be transferred from one molecule of ADP to another. One molecule of ATP is produced with one molecule of adenosine monophosphate (AMP), which is metabolized to inosine monophosphate and eventually ammonia.

Sustained exercise demands an energy supply beyond that available in stored phosphate bonds. This demand is met by the energy available in fuel stores derived originally from feeds. There are two primary energy sources: carbohydrate and fat. **Carbohydrate can be metabolized aerobically (using oxygen) or anaerobically (without oxygen). Fats are metabolized aerobically.** Proteins have a minor contribution as an energy source during exercise.

AEROBIC METABOLISM

When the demands for energy are low, aerobic metabolism is capable of meeting the requirements for ATP resynthesis. Aerobic metabolism is the primary

pathway by which ATP is regenerated during **endurance-type exercise**. Aerobic metabolism also contributes greatly to the energy supply during high intensity exercise such as galloping. Anaerobic metabolism makes up the deficit in total energy resynthesis during high intensity exercise.

Aerobic metabolism is the process by which fats and carbohydrates are oxidized, culminating in the production of ATP, carbon dioxide and water. The oxidation of substrates produces hydrogen ions. Pairs of hydrogen ions are accepted by coenzymes **nicotinamide adenine dinucleotide (NAD)** and **flavin adenine dinucleotide (FAD)**, which are reduced to NADH and FADH. These coenzymes transport the hydrogen atoms to the enzymes of the respiratory chain, which are located within the **mitochondria**. These enzymes, the cytochromes, have electron transport functions and are capable of delivering electrons derived from oxidizable substrates to oxygen. In the process, derived energy is stored as ATP. Three moles of ATP are formed from each mole of NADH entering the respiratory chain, and two moles of ATP from each mole of FADH.

Fat is stored in **depots** around the body and as **triglycerides** within muscle cells. Mobilization of fat from the depots occurs under hormonal influence. Non-esterified fatty acids (NEFA) are transported to the muscle by the circulation, and move into cells along a concentration gradient.

Carbohydrates are stored in the muscle and liver in the form of glycogen. Glycogenolysis is activated by **epinephrine (adrenaline)**. Glucose, transported to the cell by the bloodstream, can also be oxidized to produce energy.

Fatty acids enter the mitochondria and undergo a process known as **beta-oxidation**, which results in the production of hydrogen and acetyl coenzyme A (acetyl CoA). Acetyl CoA enters the tricarboxylic acid (TCA) cycle, where it is metabolized to produce four pairs of hydrogen atoms and CO₂. Acetyl CoA is also the entry point of amino acids to the TCA cycle.

Glycogen and glucose are metabolized to pyruvate in the **Embden-Meyerhof pathway** by a process known as **glycolysis** that results in the production of hydrogen ions that can be accepted by NAD and FAD. Pyruvate may be metabolized to acetyl CoA, and enter the TCA cycle when sufficient oxygen is available. The oxidation of 1 mole of NEFA of average composition yields approximately 138 moles of ATP. One mole of glycogen is oxidized to produce 37 moles of ATP. The oxygen cost of oxidation of NEFA is approximately 10% higher than the cost of glycogen oxidation.

Glycogen and blood glucose are the substrates **immediately available** for aerobic metabolism. Mobilization of NEFA requires a considerable time, and their contribution as a substrate for aerobic metabolism increases as the duration of exercise increases.

The capacity of the horse to generate energy aerobically is primarily limited by the **availability of oxygen** in the working muscle. Potential limitations include the function of the upper airways, lungs and cardiovascular system, erythrocyte numbers, and capillarity and fiber diameter within the muscle. The concentration of enzymes in the muscles appears to be in excess of the levels required to fully metabolize the oxygen delivered by the blood.

Training enhances the capacity for oxygen delivery to the muscle, therefore increasing the capacity of the animal to generate energy aerobically. Mitochondrial density and enzyme concentrations also increase.

ANAEROBIC METABOLISM

At the onset of exercise, the delivery of oxygen to the muscles does not instantaneously reach the level required to support aerobic metabolism. Approximately 30 s of exercise is required before **maximal aerobic activity** is achieved. During this time, there is an increase in heart rate and ventilation, an increase in the oxygen carrying capacity of the blood as the splenic erythrocyte reserve is mobilized, and redirection of blood flow to the skeletal muscles. Increases in body temperature may enhance enzyme activity. During this period, the **deficit** in energy production is met by **anaerobic metabolism**. During intense exercise, the maximal accumulated oxygen deficit can be measured, and this measure reflects the anaerobic capacity.

When **insufficient oxygen** is available to support the activity of the TCA cycle and respiratory chain, or when the rate of pyruvate production is very high, pyruvate may act as a recipient of hydrogen atoms from NADH, resulting in the production of ATP and lactate. No oxygen is required in this reaction.

One mole of glycogen yields three moles of ATP when metabolized anaerobically. When glucose is the substrate, two moles of ATP are produced, as one mole of ATP is used to phosphorylate the glucose on its entry to the cell. In contrast to the reactions of aerobic metabolism, which occur in the mitochondria, the processes of anaerobic metabolism occur in the cytoplasm.

Lactate diffuses from muscle cells to the bloodstream and is transported to the liver where it is oxidized to pyruvate by NAD in the cytoplasm. The pyruvate is converted to glycogen and stored in the liver in an energetically expensive series of reactions. Fatty acid oxidation may provide the energy used in these reactions. During exercise, mobilization of liver glycogen stores helps to maintain blood glucose concentrations. Lactate ions are also metabolized aerobically in slow twitch muscle fibers during and after exercise.

Anaerobic metabolism reaches its peak capacity within 20–30 s of the onset of exercise. It is best viewed as a **supplement to aerobic metabolism** that enables the total demands for energy to be met. The balance between aerobic and anaerobic metabolism depends on the rate at which NADH can be oxidized. For carbohydrate metabolism to continue, a supply of NAD is required. Resynthesis of NAD can be viewed therefore as a key step in ATP generation. As the duration of exercise increases, or as speed falls, the contribution of anaerobic metabolism to the overall energy equation becomes smaller.

In a horse galloping over 1200 m, aerobic metabolism accounts for approximately 65% of the ATP generated. Demands for ATP resynthesis during exercise at a velocity slower than 18 s/200 m (11 m/s, or 650 m/min) can be almost fully met by aerobic metabolism in most horses. Post-competition measurements of blood lactate concentrations in **showjumpers** have shown that anaerobic metabolism is significant in that form of exercise.

FATIGUE

Fatigue can be defined as the failure to maintain a desired power output during exercise. Many factors contribute to the development of fatigue, and the importance of individual contributors depends on the intensity and duration of the exercise. At a biochemical level, the most important factors are **depletion**

of high energy phosphate reserves, changes in metabolite concentrations, and the depletion of glycogen stores. Depletion of intracellular ATP will also inhibit the cell membrane sodium–potassium pump, so there is accumulation of potassium in the extracellular fluid. Cycling of calcium between the cytosol and the sarcoplasmic reticulum will also be compromised, and fatigue is associated with **increased calcium ion concentration** in the cytoplasm.

During endurance exercise, the biochemical cause of fatigue is **depletion of glycogen reserves** in the muscle. Muscle biopsy studies have shown that muscle fibers are recruited progressively as glycogen stores in other fibers are exhausted and their power output decreases. When all fibers have depleted their glycogen reserves, exercise must stop. The oxidation of fatty acids alone is not sufficient to maintain the required power output, although the energy held in fat stores would support many days of continuous slow exercise. However, increased use of fatty acids as a substrate for aerobic metabolism has the effect of sparing glycogen reserves and increasing the potential duration of exercise. Aerobic training **enhances fat utilization** by increasing the concentrations of enzymes involved in fat metabolism and increasing mitochondrial volume.

Appropriate training will increase the capacity of the horse to use fatty acids as a substrate. The value of **glycogen loading**, of proven benefit to human endurance athletes, remains unclear in the horse. It is possible that the very large glycogen stores that are found in equine muscle may approach the limit of storage capacity. Hyperthermia, dehydration and electrolyte imbalances (*q.v.*) also contribute to fatigue and the “**exhausted horse**” syndrome during prolonged exercise.

The **accumulation of lactate** in the cytoplasm is a characteristic of cells generating energy **anaerobically**. Traditionally, the development of **intracellular acidosis** resulting from the production of lactic acid by anaerobic metabolism has been believed to be a major factor contributing to fatigue. However, at physiologic temperatures, reduced intracellular pH has little direct effect on muscle contraction and fatigue. Glycolysis may provide a high and sustainable supply of ATP without causing muscle fatigue.

The development of fatigue during high intensity exercise is related to **oxygen delivery** to the muscles. Oxygen modulates intracellular metabolism to influence the rate of change of metabolites—mainly inorganic phosphate (P_i)—and may affect fatigue by influencing the rate of P_i accumulation. In muscle cells, an increase in P_i may reduce crossbridge force production and myofibrillar Ca^{2+} sensitivity, and inhibit Ca^{2+} release and/or reuptake. When oxygen delivery is limited, there is greater reliance on substrate-level phosphorylation for ATP resynthesis, resulting in disruption of metabolic homeostasis and a decline in developed tension. Studies in humans have found that hypoxic conditions that decreased aerobic capacity had no effect on performance for sprints of up to 60 s, and had very little effect on sprints of up to 120 s, indicating that maximal human running speeds for short- and intermediate-length sprints are relatively unaffected by large reductions in aerobic power. The ability to maintain power output at a time when aerobic capacity was decreased suggests that additional metabolic energy must have been derived from anaerobic sources during exercise in hypoxic conditions, that maximal metabolic power outputs during sprinting under normoxic conditions are not

limited by rates of anaerobic metabolism, and that human running speed is largely independent of aerobic power during all-out sprints lasting less than one minute.

PRINCIPLES OF TRAINING

INTRODUCTION

Successful performance of a horse in an athletic event will depend on its **adaptation to the physical demands** of the event. The degree of adaptation will depend on inherited characteristics of heart size ($q.v.$), muscle fiber types and other factors. It will also depend on adaptations that occur in response to the stimulus of regular exercise, or training. A key aim of training the horse is **increasing fitness** in order to **delay the onset of fatigue during exercise**. In some events, such as dressage and showjumping, **skill** is also likely to be a very significant factor influencing performance.

The development of fatigue during exercise is likely to be multifactorial. The body of research in exercise physiology encompasses five general models to explain the processes affecting performance:

1. The **cardiovascular/aerobic model** of fatigue is based on the idea that increasing the ability of the muscles to utilize oxygen, thus delaying the onset of lactate accumulation in the blood, will delay the onset of fatigue.
2. The **energy supply/energy depletion model** is based on the idea that fatigue during high intensity exercise may be due to the inability to supply ATP at a sufficient rate to support exercise.
3. The **muscle recruitment (central fatigue)/muscle power model** holds that brain concentrations of serotonin (and perhaps dopamine, acetylcholine and other neurotransmitters), alter the neural drive to exercising muscles, or that reflexes generated in the exercising muscles reduce recruitment of alpha motor neurons at the level of the spinal cord.
4. The **biomechanical model** states that biomechanical characteristics of the muscle (such as the capacity to act as a spring), affect the demands for force production, and therefore limit metabolite accumulation and heat production.
5. According to the **psychological model**, the ability to sustain exercise results from a conscious effort.

Physical fitness is associated with the capacity of the horse to do work. Therefore, in order to achieve fitness, it is necessary to enhance the function of all systems that may limit work capacity. Physical training that increases the work capacity of the horse must impact on one or more of the factors that contribute to fatigue. As **the ability of the horse to use and regenerate ATP is a vital factor limiting performance**, achieving an increase in the capacity of the horse to generate and utilize ATP is a key aim of training. In addition to enhancing energy generation capacity, training should increase the strength of the muscles, tendons and skeleton, enabling the horse to generate higher work outputs without succumbing to injury.

Other factors that limit performance, in particular skills and psychology, are beyond the scope of this chapter. **Skills training** may result in improvements in **gait** that result in increased efficiency of movement and a decrease in energy demands. In addition, training of this type may improve the **psychological condition** of a horse, making it more willing to work. The benefits of physical training can easily be undone by **inadequate provision of rest** periods before competition, so that the horse becomes tired and disinterested in competing.

AEROBIC TRAINING

In order to design a **training program** aimed at improving energy economy, it is necessary to know the contribution of the various metabolic pathways to ATP resynthesis in the athletic endeavor for which the horse is being trained.

Aerobic metabolism makes a significant contribution to ATP resynthesis during exercise of any intensity. **All horses** being trained for any purpose require aerobic training as part of their program. In events that require relatively low rates of energy turnover, such as dressage or endurance riding, aerobic metabolism can satisfy the demands for ATP resynthesis. As exercise intensity increases, the contribution of anaerobic metabolism becomes relatively more important, supplementing the energy produced aerobically to meet the total energy requirements for exercise.

When anaerobic metabolism makes a significant contribution to energy generation, a horse will be unable to sustain exercise as **metabolic changes in the muscle will result** in the onset of fatigue. If the capacity of a horse to generate energy aerobically is increased, its reliance on anaerobic metabolism to generate energy during exercise at a given intensity will be decreased. Therefore, the onset of fatigue will be delayed.

The **maximum work capacity** is determined by the sum of the aerobic and anaerobic capacities. Therefore, training that enhances anaerobic capacity will enhance performance in horses working at maximal intensities.

There are several **basic principles** that apply to training. Training will produce changes in the function of all parts of the body, but most importantly in the musculoskeletal and cardiovascular systems. In order to produce changes in a specific system, that system must be stressed in the training process. This has been described as the **overload principle**. However, it is important to avoid fatiguing the animal during training. It is therefore beneficial to have a method of measuring **training intensity**.

The changes produced by training are influenced by how often the horse is trained, the duration of training and the training intensity. Training-induced changes will be **lost** if a horse ceases regular exercise, although **maintenance training** programs will preserve the adaptations.

Aerobic training results in increases in circulating **blood volume** and **stroke volume**, which produce an increase in the amount of oxygen transported to the muscle. Within the muscle, there is an increase in the capillary distribution to individual muscle fibers, and fiber cross-sectional area. Mitochondrial volume, enzyme concentrations and myoglobin concentration increase within the cell. Training also appears to increase intracellular **glycogen stores**.

The metabolic cost of exercise is largely unaffected by training. A horse working at a given submaximal speed has a set requirement for oxygen delivery. As stroke volume increases during training, heart rate will fall. **Heart rate provides the best indicator of the intensity of aerobic training**, and heart rate changes can be used to monitor aerobic fitness.

The **aerobic capacity of a horse can be increased** by training at a relatively low intensity. Exercise at a heart rate approximately 50% of maximum appears to be sufficiently intense to maximize gains in aerobic power (maximum heart rate in the horse is in the range 195–240 bpm). Regular monitoring of the heart rate allows the training intensity to be increased as the horse becomes fitter. Exercise that results in heart rates in the range of approximately 70–90% of maximum is likely to be associated with **metabolic changes** in the muscle. These changes promote development of buffering capacity in muscle cells.

Training sessions aimed at enhancing aerobic power should last for at least 30 min. Where horses are being trained for endurance riding, at least one session per week should be in excess of 1 h in duration, in order to ensure that mobilization of NEFA has occurred in the fat depots of the body.

Skeletal remodeling is an important factor contributing to the maintenance of soundness through training and competition, and should be considered an important goal in this stage of training. Because the intensity of work is low during aerobic training, the skeleton is not exposed to extreme stresses. Only a minimal increase in the exercise intensity is required to promote bone remodeling. Although increases in aerobic capacity are rapid, morphologic changes in the skeleton and muscle occur more slowly. This must be considered when planning the **duration of the aerobic component** of the training program.

Once a horse has achieved a high aerobic capacity, specific training is not required to maintain it. The higher intensity work given to train the anaerobic system will maintain aerobic power. If a horse is not undertaking high intensity work, relatively low intensity exercise such as trotting will enable it to maintain considerable aerobic capacity.

ANAEROBIC TRAINING

Anaerobic training is often the most neglected aspect of training. During this phase, the aim is to increase the **capacity of the anaerobic pathways to generate ATP**, and to increase the capacity of the muscle to cope with changes in metabolite concentrations and intracellular acidosis.

The point at which anaerobic work should be introduced to the training program is debatable. At least 4–6 wk of aerobic work appears to be necessary to provide an appropriate level of background fitness. However, many human athletes include an anaerobic component from the onset of training. As they become fitter, the anaerobic proportion of the total training load is increased. Some horse trainers believe that excessive low intensity training of racehorses results in a loss of speed.

An appropriate **training load** to stress the anaerobic system is one that results in post-exercise blood lactate concentrations in the range 4–10 mmol/L. Heart rates in the range of 85–95% of maximal are also appropriate. At this exercise

intensity, anaerobic metabolism is making a significant contribution to energy generation. The resulting metabolic changes cause an increase in sprint capacity and an increase in intramuscular buffering capacity, which enables the horse to sustain intense exercise for longer periods.

It has been suggested that exercise eliciting a heart rate of 200 bpm should be sufficient to generate lactate concentrations in the range 4–10 mmol/L. However, some horses working at this speed will have lactates either higher or lower than this range. In some horses, the target heart rate will be appropriate and may be used as an approximate guide when lactate measurement facilities are not available. New technology that combines simultaneous measurement of heart rate and velocity with a global positioning system (GPS) has great potential for improving the monitoring of exercise intensity during horse training.

During anaerobic training, the horse can quickly become fatigued. Measuring blood lactate concentrations to monitor workload enables the trainer to avoid fatiguing the horse. **Training-related anorexia** is generally seen in horses working frequently at an intensity that generates blood lactate concentrations greater than 10–15 mmol/L. In addition, an excessive anaerobic training load may result in glycogen depletion in the muscles, and a “tired” horse. Regular **light training days** should be provided to enable the horse to replenish its glycogen stores.

The optimal amount of anaerobic exercise in each training session and the optimal frequency of training sessions have not been determined. When the exercise intensity is closely controlled by regular blood lactate analysis, horses can cope with an exercise volume far in excess of the amount that has traditionally been considered the limit. However, in general, it would be unwise to regularly use very high intensity exercise training on more than two days per week.

Speed is an important factor contributing to the occurrence of injuries. Working horses uphill increases the intensity of exercise at a given speed, enabling an appropriate training stimulus to be generated at lower speeds, and minimizing the risk of injury. However, there has been a report that uphill treadmill exercise also increases the severity of exercise-induced pulmonary hemorrhage after intense exercise. Excessive use of training at speeds >900 m/min in Thoroughbred horses increases the risk of injury.

For horses involved in events where maximal exercise intensities are reached, **speed training** is the final component of the training program. The aim of this phase is to increase maximum speed and strength, and to increase stores of high energy phosphates. In order to achieve this, high speeds, generally higher than mean race speed, are required. Traditionally, sprint training of racehorses has been limited to a few maximal sprints at the end of training gallops. In human athletics, interval training techniques with up to six repetitions in each session have been used.

During the sprints, the horse should not reach the point of fatigue. A **fatigued horse** is unable to work at maximum speed, and therefore does not receive the appropriate training stimulus. In addition, the **risk of injury** is increased in a fatigued horse because gait becomes abnormal. The amount of sprint training required to achieve the maximum performance benefit in the horse is unknown. The distance over which the horse is sprinted

should equal, or slightly exceed, the distance over which it will sprint during competition.

TRAINING FOR SPECIFIC PURPOSES

Racehorses

The discussion of training above provides general guidelines to **racehorse training**. The duration of each phase of training must be balanced between the time required to optimize performance and the costs of keeping a horse in training. As a general rule, a program consisting of 4 wk slow aerobic training, 4 wk medium pace and 2 wk sprint training can be considered as a bare minimum. The sprint training component includes skills work such as practice starts from stalls. Approximately 4 days before the race, the workload should be decreased to enable the horse to **replenish intramuscular glycogen** stores.

Horses that have achieved race fitness do not require intensive training in order to maintain fitness. Low intensity exercise with weekly gallops appears to be sufficient. In Standardbreds, which may race at intervals of <7 days, racing may be the only high intensity exercise required.

Endurance horses

As a general rule, **training volume** is the key to success in preparing endurance horses. The more training exercise given to a horse, the greater the improvements in performance. Some training sessions must be long enough to ensure that mobilization of fatty acids occurs (at least 1 h). Initially, low intensity exercise should be given to increase aerobic capacity and stimulate bone remodeling. Once preliminary aerobic training is completed, an appropriate training speed is 80–100% of speeds in endurance races.

A characteristic of **elite endurance** athletes is that lactate does not begin to accumulate in the blood until the intensity approaches that generating maximal heart rates. Training intensities that generate lactate can shift the lactate accumulation point closer to the maximum heart rate. All endurance horses should receive some anaerobic training. Many endurance riders are reluctant to allow their horses to canter or gallop, as they believe this may teach them bad habits for the race. If the trainer is reluctant to increase the speed of exercise, beneficial results may be obtained by working the horses at lower speeds up hills or on inclined treadmills. Treadmill training is a regular feature of many top class human athletes.

One to two weeks before an event, the horse should be given one training session where at least half the distance of each race leg is covered. The greater the distance covered in this session, the greater the benefits to performance. During the week prior to the event, **training should be tapered** to ensure that intramuscular glycogen stores are maximized.

Dressage

Skill training is far more significant in **dressage horses** than fitness training. The skill training to which the dressage horse is subjected should result in the development of adequate fitness.

Showjumpers

Post-competition blood lactate concentrations in **showjumpers** approach 10 mmol/L, indicating that anaerobic metabolism makes a significant contribution to energy generation. Training sessions are generally limited to 20–30 min of jumping or other work.

Eventers

Horses involved in **cross-country events** generate high lactate concentrations in the blood. In the steeplechase stages, the work intensity is similar to that of racing. Therefore eventers should benefit from programs designed to increase aerobic and anaerobic capacity. A highly successful training program involves 60–90 min of conditioning 6 days per week. Most of the work is given at a hard trot or steady canter, with two to three easy gallops over approximately 1000 m. In the final weeks before the event, the horses are given several steeplechase sessions at approximately 800 m/min.

INTERVAL TRAINING

Interval training has achieved widespread acceptance with Standardbred trainers, and is commonly used by human athletes. The aim of interval training is to **increase the volume of work** done in an individual training session. In order to achieve this, **exercise is provided in bouts, with a recovery period** between each bout.

There are five factors to be considered in designing an interval training program. These are:

1. The intensity and duration of each interval
2. The number of repetitions
3. The rest interval between bouts
4. The type of activity during the rest period
5. The frequency of training.

The final program depends on the goal of training. Where the **anaerobic system** is the target, intervals are generally conducted at 10% below race speed. Recovery between bouts does not need to be complete. **Heart rate monitors** are commonly used to measure recovery, with a heart rate of approximately 120 bpm the goal. The distance of each interval does not appear to be particularly important. Where enhancement of **sprint capacity** is the aim of training, the horse must be fully recovered before a heat is commenced. Trotting a horse between exercise bouts will result in a more rapid fall in blood lactate concentration than walking or cantering.

Flexible interval training programs tailored to meet individual requirements can produce good results. However, repeated high intensity interval training can also cause overtraining in racehorses, with weight loss and loss of performance.

OVERTRAINING

Overtraining can be defined as an **imbalance between training and recovery**. Overtrained animals appear fatigued and stale. Their performance

deteriorates and they may lose weight. Short-term overtraining can be corrected by rest for a period of days to weeks. Where the severity of the overtraining is greater, a recovery period of several months is required.

Overtraining appears to be associated with dysfunction in the neuroendocrine system. The **blood cortisol response** to intense exercise is reduced in overtrained horses. The syndrome is not associated with exhaustion of the adrenal glands (*q.v.*). Rather, there is a downregulation of the hypothalamic response (*q.v.*) to the exercise stimulus. The syndrome cannot be diagnosed by routine hematology or biochemistry in resting horses.

HEMATOLOGY OF HORSES IN TRAINING

INTRODUCTION

Routine blood testing is used by trainers in a variety of ways. Many of the claims of the usefulness of blood tests have been overrated. Blood testing can be used routinely to check the health status of the animals in a stable. However, this becomes expensive where large numbers of horses are involved, and the costs of such a program may well exceed any benefits that are gained.

Blood tests should be considered as a **diagnostic aid** in evaluating loss of performance, as they can be used to identify horses suffering from subacute diseases that may impair performance. In addition to the direct loss of performance, the stresses associated with racing may exacerbate a pre-existing condition, with the result that far more severe problems develop. This is particularly true of horses with respiratory disease.

Many trainers use routine blood testing in the belief that it will enable them to assess the fitness of their horses and estimate their performance in competitive events. Although certain hematologic changes do occur as a result of training, **hematologic evaluation cannot be used as a guide to fitness**, or to identify horses that will win races. In a comprehensive study of Thoroughbred horses conducted in Australia in the late 1970s, attempts were made to correlate the pre-race hemogram with subsequent performance. From the results it was apparent that no relationship existed between the hemogram and subsequent racing performance. Similar results have been found in a subsequent study of Standardbreds.

The usefulness of hematologic evaluation as an indicator of fitness is limited by the variability in the results obtained. The sources of variability are: the state of the horse; the handling of the sample; variation in the normal values recorded in different laboratories; and individual variations between horses. Erythrocytes, as a step in the oxygen transport chain, represent a potential limitation to performance. However, many other factors affect performance in a healthy horse, and the blood cannot be considered the key limiting factor. **Transport of horses** can have a significant effect on their blood indices.

RED BLOOD CELLS

The horse holds a large store of erythrocytes in its spleen. Under stimulation of the sympathetic nervous system, the spleen contracts, injecting the stored cells

into the circulation and resulting in an increase in the hematocrit. Splenic contraction occurs in anticipation of or during exercise. However, changes in the hematocrit (*q.v.*) are minimal following endurance exercise unless dehydration has occurred. Hematocrit values >0.55 L/L, and plasma protein concentrations >90 g/L in endurance horses are signs of **potentially dangerous fluid loss**.

The **act of blood sampling** may be sufficient to cause mobilization of the splenic erythrocyte pool in some nervous horses. This can result in large increases in the hematocrit. Because the temperament of the animal is a variable that cannot be controlled, comparison between horses becomes meaningless.

In order to minimize the variation in results obtained in multiple tests conducted on the one animal, **conditions of sample collection should be standardized**. Minimal restraint should be used, and the same person should collect the sample on each occasion. The sample should be collected **before** the horse is fed or exercised. Feeding is associated with an increase in hematocrit and plasma protein concentration, and a fall in serum potassium concentrations.

Stallions tend to have a higher hematocrit than geldings or mares. The hematocrit in Thoroughbreds is usually higher than in other breeds. Red cell numbers increase as a horse becomes fitter, and as it ages. In general, training results in an increase in erythrocyte numbers and total blood volume. However, changes in horses undergoing endurance training are minimal. Species and state of training must be considered when analyzing erythrocyte values.

Poor performance has been reported in racehorses with a resting hematocrit <0.36 L/L. If abnormally low red cell indices or hemoglobin concentration are suspected, collection of a blood sample within 5 min of a fast gallop should be used to confirm the condition. Normal hematocrit after a fast gallop is in the range 55–70 L/L.

In horses used for endurance exercise, the lower limit of normality may be considered to be 0.30 L/L. Resting hemograms are a useful aid in the detection of **anemic horses**. In such animals, the hematocrit is lower than the lower limit of normality at the laboratory conducting the analysis. In addition to poor performance, signs include pale mucous membranes and a rough coat.

Two common causes of **anemia** (*q.v.*) in horses are **chronic inflammation**, which causes bone marrow suppression, and a **heavy parasitic burden** (*q.v.*), which causes increased blood loss. **Subclinical infections**, which have the potential to impair performance, may cause bone marrow suppression. Because reticulocytes do not appear in the bloodstream, a **bone marrow biopsy** (*q.v.*) is required to determine whether anemia is regenerative or non-regenerative. Anemia is rarely due to a primary iron deficiency, and **iron supplements should not be considered** a treatment for the condition. The animal must be examined to determine the underlying cause. Iron supplementation has been associated with severe **phlebitis** when injections are incorrectly administered. Fatalities have also been reported to occur following iron injections. Erythrocytes require 5–7 days to mature. It is therefore very optimistic to expect that any treatment for anemia is going to help the performance of the horse in a race two days later.

It has long been argued that **polycythemia** (*q.v.*) is the mechanism or hallmark of overtraining syndrome in Swedish Standardbred trotters. However,

a longitudinal study of overtraining that included a control group failed to confirm that overtraining causes red cell hypervolemia.

If the resting hematocrit is in the normal range, no further interpretation can be made from the results. There is no relationship between resting hematocrit and the post-exercise hematocrit, which can be 55–70 L/L.

WHITE BLOOD CELLS

Increases in leukocyte numbers may be indicative of the presence of a variety of conditions that may decrease performance. **Increases in neutrophil numbers are generally associated with bacterial infection.**

Lymphopenia is a common finding in any animal with chronic disease. Monocyte numbers generally decrease during acute inflammation, but may increase when inflammation becomes chronic. Lymphopenia may also be associated with **corticosteroid administration** (*q.v.*).

Leukocyte numbers also increase **following exercise**. An increase in neutrophils, persisting for 4h following a vigorous training gallop, has been reported. A **post-exercise lymphocytosis** also occurs due to the release of lymphocytes from the spleen during mobilization of the erythrocyte store. These factors should be considered when interpreting the results of tests performed on samples collected soon after exercise.

Stress in endurance horses during an event is associated with a progressive neutrophilia and lymphopenia. A neutrophilia with a significant left shift and lymphopenia are signs of exhaustion in endurance horses. Stress of training is often diagnosed if a “high” ratio of neutrophils to lymphocytes is measured. **There is no basis for this diagnosis.** Moreover, the extreme stress of overtraining syndrome is not associated with any abnormality of the red or white blood cell counts.

PLASMA PROTEINS

Maximal exercise causes an **increase in total plasma protein** concentration due to fluid redistribution that decreases plasma volume. This change in plasma volume also contributes to the high hematocrit found in horses after maximal exercise.

Plasma **fibrinogen** may be elevated in animals with mild to moderate inflammation that is not associated with a leukocytosis or neutrophilia.

ELECTROLYTES

Alterations in electrolyte concentrations can seriously affect performance, but these are unlikely in healthy horses in training if appropriate supplements of sodium chloride are used in the diet. **There is no indication for any need for potassium supplementation** in racehorses. **Hypochloremia** will be found in endurance horses during and after competition because of the high chloride concentration in equine sweat.

Calcium supplementation of diets has been advocated on the basis of low blood calcium concentrations. However, blood calcium is carefully controlled by the body. In addition, calcium concentrations are affected by plasma

protein concentrations, as approximately 50% of blood calcium is bound to plasma protein. Calcium levels will be lower in hypoproteinemic horses.

Training appears to have little effect on plasma electrolyte values. However, **during high intensity exercise**, there are large increases in plasma sodium and potassium concentrations, with smaller increases in calcium and phosphate. Bicarbonate concentration decreases. These changes persist for approximately 1 h after exercise, and are normal expectations.

During exercise, electrolytes are lost in the **sweat**. However, these changes may not be reflected in plasma electrolyte concentrations until significant losses have occurred. Therefore, **use of 50–100 g salt (NaCl) supplementation** (*q.v.*) in the feed is recommended for the exercising animal, with greater supplementation in horses undertaking long distances of training exercise in hot environments.

Electrolyte supplements are commonly used to replace losses in sweat. A horse that is sweating heavily will lose large amounts of chloride. In order to maintain electrical neutrality, the horse will retain bicarbonate, and metabolic alkalosis may develop. **Electrolyte supplements** for endurance horses should be **high in chloride and low in bicarbonate**.

Bicarbonate supplements for horses following high intensity exercise are of dubious value as the horse is physiologically well adapted to neutralizing post-exercise acidosis. There is no evidence that supplements with high bicarbonate buffer prevent **tying up** (*q.v.*), and their inappropriate use could contribute to high plasma bicarbonate concentrations in horses presented for pre-race testing.

ENZYMES

Enzymology can provide useful information regarding tissue damage. Serum creatine kinase (CK) and aspartate aminotransferase (AST, SGOT) are elevated in horses with exertional rhabdomyolysis. However, they are often elevated following exercise, although signs of muscle damage may not be evident on examination. CK peaks 3–5 h after exercise, then declines over 24 h. AST peaks at around 24 h, and declines more slowly. Very high serum CK concentrations have been found in normal horses, and horses may have myopathy without elevated serum enzymes.

Gamma-glutamyltransferase may increase as a result of training. Over-training or training stress is not associated with abnormalities of serum enzymes.

ELECTROCARDIOGRAPHY

Electrocardiography (*q.v.*) is frequently used by veterinarians involved in assessment of performance horses. The most common reasons for examining the electrocardiogram (ECG) of an equine athlete are to **investigate arrhythmias and poor racing performance**. ECG has also been used to estimate heart size by calculation of the heart score. The ECG is also used in horses to measure heart rate and investigate the cardiac rhythm during and after exercise as part of examinations for poor athletic performance. The popularity of the ECG as a tool for diagnosis of poor racing performance and estimation of heart size

varies in different countries. Detailed discussions on cardiology can be found elsewhere (*q.v.*).

TECHNIQUE

The **limb lead system**, based on Einthoven's triangle (*q.v.*), is usually employed. Most normal values for equine ECGs have been produced with this system. Electrodes are placed on the skin in standard limb positions. On the forelegs, the electrodes are placed on the posterior aspect of the radius. On the hindlegs, the electrodes are placed on the anterior aspect of the tibia. Other lead systems have been described, such as the XYZ leads, which attempt to create an orthogonal lead system that can be used for vectorcardiography. Unfortunately there is little information available on XYZ vectorcardiography in normal horses and horses with heart disease. The limb lead system has been used for vectorcardiography in the horse, although there are criticisms of this technique in quadrupeds.

For investigation of **arrhythmias**, a simple alternative to the bipolar limb leads is the **Y lead, or base to apex lead**. This lead places a positive electrode (e.g. the LA lead) on the skin over the xiphoid process of the sternum, and the negative electrode (e.g. the RA lead) on the ventral chest in front of the manubrium or at the right jugular furrow. This lead gives a high amplitude signal, and the record is less likely to be disturbed by movement of the horse. This lead is ideal for the routine examination of arrhythmias.

The skin does not need to be clipped. Alligator clips can be attached directly to the skin after application of a suitable **electrode gel**. Horses usually tolerate this technique if the points of the teeth on the alligator clips are filed down. Alternatively the leads can be connected to tin plates held against the skin with clips or elastic straps.

Recordings are made at 25 mm/s, with the horse standing quietly. The heart rate of the resting horse can increase from 30–40 bpm to ≥ 100 bpm very quickly due to excitement or fear. High heart rates abbreviate the PQ and QT intervals, and P waves also lose their notching.

A good technique for examining the ECG is to identify the **P waves** first. The P wave of the equine ECG can vary greatly from beat to beat, but this variation is normal. Notching is frequent, so that the P wave is divided into two components, P1 and P2. P2 is frequently of higher amplitude than P1. It is thought that P2 is due to activation of the atrial septum. Changes in heart rate also dramatically affect the shape of the P waves, due to alterations in vagal tone. Normal P wave duration is < 0.16 s.

Absence of the P waves may indicate hyperkalemia (serum $K^+ > 6$ mmol/L), atrial fibrillation (*q.v.*), sinus arrest or junctional rhythm. **Sinus arrest** (*q.v.*) is rare in horses. Junctional rhythm refers to a rhythm originating at the atrioventricular node, with P waves buried in the QRS complex, which is traveling toward the base of the heart as well as to the bundle branches in the ventricular septum.

COMMON ARRHYTHMIAS IN HORSES

Second degree atrioventricular block and **sinoatrial block** (*q.v.*) are characterized by dropped beats. Both arrhythmias are regarded as normal in the resting horse. This has been attributed to a high vagal tone, and the arrhythmias

disappear during exercise. The presence of **dropped beats** immediately after exercise may also be associated with vagal dominance during cardiac deceleration, and are probably not significant.

Sinus bradycardia, a resting heart rate of ≤ 24 bpm, has been described as abnormal in racehorses and as a cause of poor performance. The resting heart rate in horses is greatly dependent on the degree of relaxation of the subject. However, some horses with sinus bradycardia (*q.v.*) have a history of **collapse**, possibly due to cerebral anoxia. The prognosis for this condition is poor if it is accompanied by an arrhythmia.

Third degree atrioventricular (AV) block (complete heart block) occurs occasionally in racehorses. This arrhythmia is associated with organic heart disease or severe drug toxicity, and rarely is caused by very high vagal activity. It is usually associated with poor race performance.

Atrial fibrillation, recognized by the absence of P waves or the presence of “flutter” (f) waves, and irregular R–R intervals, is probably the most common arrhythmia causing poor race performance. It is important to differentiate atrial fibrillation from the ECG affected by muscle twitching. Normal P waves can be identified on the tracing affected by muscle twitching. Atrial fibrillation (*q.v.*) can often be successfully converted to sinus rhythm with **quinidine sulfate**, with many affected horses returning to racing. It has been suggested that a P wave duration >0.16 s after conversion may indicate atrial disease.

Ventricular premature contractions (VPC), or ectopic beats, are generally described as being evidence of myocardial disease. The QRS wave is widened and bizarre in comparison to the normal wave. If the ectopic beat occurs before the sinus impulse, there is often a following compensatory pause. Alternatively, the ectopic beat may occur between two normal beats in resting horses, and sinus rhythm remains undisturbed. An extra beat is inserted in the rhythm.

Ectopic beats generally become more frequent during exercise and also become more frequent during heart rate slowing after exercise. It has been suggested that if ectopic beats (*q.v.*) occur infrequently, the prognosis may not be poor. The prognosis is poor if they occur frequently. VPC is one of the few arrhythmias in which a period of rest may be beneficial, and re-examination some months later is therefore justified.

Ventricular tachycardia (VT) refers to four or more ventricular extrasystoles at a rapid rate with regular rhythm. The QRS complexes in VT are normal in appearance. They are usually associated with myocardial disease (*q.v.*). Both VPC and VT can be found in horses with sepsis, hypoxia, viral disease, electrolyte imbalance and metabolic disease, and can be due to drugs such as digitalis and halothane.

ASSESSMENT OF HEART SIZE

Horses with severe heart disease may develop chamber hypertrophy, as in other species. Vectorcardiography and echocardiography can be used to investigate the presence of **ventricular hypertrophy**.

Measurement of **heart size** by ECG in healthy horses is popular with some veterinarians and horse trainers. This technique involves calculation of the heart score. **Heart score** is the mean of the QRS durations in the three bipolar limb leads, expressed in milliseconds. Proponents of the technique emphasize

that heart rates must be ≤ 42 bpm, consistency of the horse's stance, and a standardized approach to measurement of the duration of the QRS complex. The form of the QRS wave can differ between horses and leads. Guides for the measurement of QRS duration in the different QRS wave forms have been published. The original study on this subject reported a correlation of 0.89 between heart score and the weight of the heart at post mortem. Unfortunately there have been no other published studies that confirm this finding. A recent study found **no significant correlation** between heart score and left ventricular wall measurements obtained echocardiographically.

The results of several investigations into the relationship between **heart score** and **race performance** are contradictory. Some studies have shown weak correlations between heart score and racing performance. Coefficients of determination in those studies indicated that 16–23% of the variability of racing performance was attributable to variability of heart score. However, other studies have shown no significant correlation between heart score and racing performance. An electrocardiographic and echocardiographic study of Thoroughbred yearlings in Ireland found no relationship between heart score and ECG measures of heart size and later racing performance in 125 2-yr-olds and 127 3-yr-olds. The study concluded that selection of young racehorses on the basis of heart score is unlikely to be successful. It seems that assessment of heart size by ECG is an inappropriate technique for prediction of athletic performance.

Assessment of young racehorses by echocardiography is now commonplace. Detection of **cardiac defects that could limit performance** is an important role for this examination. As well, indices of ventricular size are correlated with maximal oxygen uptake.

Measurement of the **whole-body oxygen transport** by measurement of maximal rate of oxygen consumption, or measurement of blood lactate variables during standard exercise tests, offers greater chances of success when trying to identify limitations to performance. In human sports science, these measurements frequently have coefficients of determination $\geq 50\%$ for running performance in events that are energetically similar to horse races. In Standardbred racehorses in Sweden, exercise tests with measurement of total red cell volume, heart rate and blood lactate after exercise have yielded encouraging results. Maximal trotting velocity was significantly correlated with several variables. Running speed and racing performance of Thoroughbreds has also been significantly associated with blood lactate response to exercise, with coefficients of determination of 40–50%.

T WAVES IN THE PERFORMANCE HORSE

The nature of the T wave in the ECG of the resting racehorse has been proposed as a means of assessment of horses with poor race performance. The presence of certain abnormal T wave forms has been suggested as a diagnosis of **myocarditis** (*q.v.*), or “heart strain”. Normal and abnormal T waves have been described, based on the shape and direction of the T wave in six selected leads. However, recent studies have confirmed that abnormal T waves are not associated with poor performance. T waves do change in some horses during training, but this development does not reflect heart disease.

HEART RATE DURING EXERCISE

MEASUREMENT OF HEART RATE

The resting heart rate in the horse is generally in the range 25–50 bpm. In human athletes, the resting heart rate taken first thing in the morning is used as a guide to fitness and health. Highly trained human athletes, especially endurance athletes, have very low resting heart rates. If the resting heart rate is abnormally elevated, this could indicate loss of fitness, illness or “over-training”. Unfortunately it is difficult to use resting heart rate in horses as a measure of increasing fitness because the resting heart rate is subject to great fluctuation due to excitement. For example, **resting heart rate can fluctuate** between 25 and 120 bpm over a 30 s period, depending on the degree of excitement, fear or alarm.

It is therefore necessary to evaluate **heart rates during exercise** to assess fitness in racehorses. Heart rate measurements during exercise are important because there is a very close relationship between heart rate and metabolic rate. Many **heart rate meters** designed for use in exercising horses are now available. These meters use electrodes that are placed under the girth. Some meters have leads connecting directly to the receiver, which is designed to strap on to the saddle or jockey’s leg. Others have remote receivers that can be worn on the wrist. A jockey can then keep an eye on the horse’s heart rate while the horse is working. The meters also have a memory function, enabling later evaluation of the heart rates. Telemetric ECG can also be used to measure heart rates during exercise. This technique has the advantage of enabling simultaneous evaluation of the ECG during and after exercise.

HEART RATE AND SPEED

There is a **linear relationship between heart rate and speed** of submaximal exercise. This pattern is common to all horses during exercise. However, the actual heart rates that any horse records at the trot or slow canter can vary greatly, depending on age, fitness and health of the horse. The heart rate during slow work can also be elevated in horses with lameness or illness.

For all horses there is a work speed that does not result in an increase in heart rate. A plateau occurs, and no further increases in heart rate occur, regardless of increases in speed. The highest heart rate that can be recorded in such a test is called the **maximum heart rate** (HR_{\max}). Maximum heart rates in horses are generally in the range 195–240 bpm. Each horse has its own individual HR_{\max} , and the HR_{\max} is not influenced by training. There does not seem to be any relationship between a horse’s maximal heart rate and its fitness. However, it would be expected that racehorses with the higher velocities at which maximal heart rate is attained would have superior performance.

HEART RATE AND METABOLIC RATE

Heart rate is a good estimate of the relative amount of oxygen that is being used by the horse during exercise at slow and moderate work speeds. The relationship between relative heart rate and oxygen consumption during

submaximal exercise on an inclined treadmill is very close. The relative oxygen consumption (% of maximal) is equal to 1.6 times the percentage of maximal heart rate, minus 65. For example, a horse exercising at 75% of maximal heart rate is exercising at approximately 55% of maximal oxygen consumption. The speeds at which 100% of maximal heart rate and maximal oxygen consumption are attained are similar. Therefore improvements in maximal oxygen uptake will be reflected in lower heart rates during submaximal exercise, and a higher velocity at which the maximal heart rate and oxygen uptake are achieved.

EFFECTS OF EXERCISE

During **swimming**, heart rates may be as high as 180–200 bpm when horses are forced to work hard in the pool. Heart rates as low as 120–130 bpm have also been recorded.

Heart rates at **onset of slow exercise** can be erratic, taking several minutes to achieve a steady rate. This may reflect excitement, or can be related to a physiologic phenomenon in horses whereby the heart rate increases quickly at the start of exercise and then decreases after this initial “overshoot” to a lower rate over the next few minutes.

At the **start of fast exercise**, the increase in heart rate is very rapid. Within 30 s, the heart rate can be greater than 200 bpm. The rate of increase in heart rate at the commencement of exercise depends on the use of a “warm-up” period. With inadequate or absent warm-up, heart rates increase more slowly after the commencement of exercise. Such slow kinetics of heart rate would limit oxygen transport during the first 30 s of intense exercise. This causes a higher accumulated oxygen deficit during a race at maximal speeds, and would limit performance because the relative dependence on anaerobic ATP resynthesis would be greater.

RECOVERY PERIOD

After exercise, heart rates decrease rapidly in the first minute, and then continue to decline at a slower rate. Results of several studies demonstrate that **recovery heart rates** are lower after a standard exercise test as a result of training. However, routine use of recovery heart rates to assess fitness is not advised. The results can be easily influenced by excitement, and unless the exercise is carefully controlled on a treadmill, differences in intensity of exercise performed will make the results very difficult to interpret. Lack of standardization of the horse’s activity both during exercise and during the recovery period makes useful interpretation of recovery heart rates very difficult.

Some advocates of interval training also contend that recovery heart rates are a guide to whether or not horses should continue with further workouts. A recovery heart rate of 120 bpm or less has been suggested as indicating that the horse is sufficiently recovered for more fast work. However, this approach must be used with caution, as heart rates less than 120 bpm can be found in horses 5 min after racing. There is no evidence that 5–10 min recovery heart rates after fast exercise are a good guide to recovery of body temperature or acid-base status.

Post-race heart rates can be used as a guide to inadequate recovery, as heart rates that remain elevated post exercise are a warning sign. Veterinarians who are requested to check horses that may have performed poorly in races should **routinely check** the heart rate and rhythm. Heart rates that remain >130 bpm for 5–10 min after exercise suggest a poor recovery. Such a result could indicate that the horse is not fit enough, or that the horse may have clinical problems such as atrial fibrillation, respiratory infection or lameness (*q.v.*). Dysrhythmias should be identified, and followed up with ECG for accurate diagnosis.

Evaluation of heart rate recovery is a vital part of the assessment of horses during **endurance rides**. Horses with abnormally elevated heart rates at checkpoints are not allowed to continue. Specific rules differ nationally, but generally require that heart rates are <55 – 60 bpm 30 min after arriving at the checkpoint. Endurance riders should ensure that their horses are accustomed to the approach of strangers to measure heart rates, so as to eliminate the **effect of excitement** on recovery heart rates during competition.

WARM-UP EXERCISE

Warm-up prior to strenuous exercise, such as 5 min trotting, ensures a more rapid increase in heart rate and oxygen uptake at commencement of strenuous exercise. This is beneficial for horse performance, as the horse is more rapidly able to mobilize the transport of oxygen to the skeletal muscles, so minimizing the accumulated oxygen deficit. All horses should undergo a trot and canter warm-up before gallops and racing. Many Standardbred horses in Australia are now given two warm-ups prior to racing. Horses are often jogged for 2400 m 30–60 min before racing, and again 5–10 min before racing. Some trainers also let the horse exercise at near racing speeds for 200–300 m 5 min before the race.

Unfortunately, Thoroughbred horses do not always have the opportunity for adequate warm-up prior to racing. This omission probably contributes to premature fatigue and so **limits performance**. Fatigue causes inefficient locomotion, and therefore gait abnormalities may occur, possibly contributing to soft tissue trauma during races. Obviously it can be very difficult to give an adequate warm-up before some Thoroughbred races, especially when the start is near the saddling enclosure. There is still much to learn about the best intensity and duration of warm-up exercise for horses, and the ideal interval between the warm-up and the subsequent exercise.

TRAINING

There is a predictable effect of training on heart rate during slow exercise, but little change in either maximal heart rate or resting heart rate. During sub-maximal exercise, heart rate falls by approximately 20–30 bpm. This means that, at a set speed of exercise resulting in heart rate less than HR_{\max} , training will decrease the heart rate at that speed by approximately 20–30 bpm, or more. Therefore the horse can work at faster speeds at the same heart rate. The increase in blood volume is thought to contribute to this physiologic response to training. Stroke volume increases, and so the same cardiac output can be maintained with a lower heart rate.

Several other factors can influence heart rate during submaximal exercise. If the horse developed lameness, muscle soreness, respiratory infection or another illness, the heart rates at the same speed could increase. Likewise, if the horse stopped training, the loss of fitness during detraining would be reflected in a higher heart rate during slow exercise.

FITNESS TESTS

The heart rate of Thoroughbred horses during slow exercise on a racetrack can vary enormously due to excitement. It is therefore very difficult to conduct a standard exercise test in that environment. The results of exercise tests are more reliable when the tests are conducted on treadmills, and then only in horses which have been adequately accustomed to treadmill exercise, so reducing the effect of excitement.

Heart rate measurement during **treadmill fitness tests** usually employs a stepwise exercise test. These tests involve measurements at several slow work speeds. The treadmill speed is increased every 1–2 min, and heart rate is recorded in the last 10–15 s of the exercise at each speed. Graphs of treadmill speed versus heart rate are then plotted. Several indices of performance have been suggested. Most popular is V_{200} , **the treadmill velocity that results in a heart rate of 200 bpm**. Other workers use similar indices, such as V_{140} and V_{160} . If the fitness of different horses is to be compared, the velocity at which the horse reaches a speed corresponding to maximal heart rate should be measured (V_{HRmax}).

V_{200} has also been calculated using **racetrack exercise tests** in trotters. The horses were exercised over 1000 m at four increasing submaximal speeds, with the driver maintaining a constant speed during each run. The fastest speed was chosen so that it would result in a heart rate of just >200 bpm.

An alternative index of fitness based on heart rate measurement during exercise is calculation of HR_{10} , the heart rate at a constant speed of 10 m/s. This index is suitable for trotters, pacers and other horses that can be exercised at a set speed (10 m/s) for 3000–4000 m. Both this index and V_{200} calculated from a racetrack exercise test are negatively correlated with maximal trotting speed over 1000 m. A low heart rate response to the exercise tests was associated with faster 1000 m times, with coefficients of determination of 55% and 36%, respectively.

Several studies have described simple field tests for galloping horses. Exercise testing on a treadmill allows strict control over environmental conditions and test protocol, as well as permitting a large range of testing procedures. However, it cannot take into account many factors in the normal competition environment, such as the effect of rider and tack, terrain, surface and wind resistance. Treadmill exercise testing also requires expensive, sophisticated equipment. The major advantage of field-based exercise testing over treadmill testing is that the measurement can take place in the horse's usual competition or training environment. In addition, field-testing precludes the need to transport a horse to a specialist laboratory and obviates the need for periods of acclimation to treadmill exercise.

Typically an exercise test involves a series of exercise steps at predetermined speeds and durations, with constant velocity of exercise during each step. Inability to standardize exercise and track surface conditions often limits the interpretation of results from field tests. Comparison of results obtained from

different tracks is also difficult, because variations in track geometry, surface and condition can significantly affect the responses to exercise. Furthermore, gait and physiologic variables are significantly affected by differences in track conditions.

The following field exercise test was used to assess **fitness in 3-day event horses**. Each horse was given dressage work 20–30 min before the test. The exercise test was performed after a uniform warm-up of 5 min trotting, and consisted of four bouts of exercise on a 450 m undulating grass track at progressively increasing speeds, with a recovery of 400 m at the trot between each repetition. Target speeds for each step were 250 m/min (trot), 350 m/min (slow canter), 450 m/min and 600–650 m/min. Horses were timed with a stopwatch over each step to determine average velocity, and riders were asked to maintain a consistent speed if possible during each step of the exercise test. Heart rates were recorded, and then related to velocity for each step of the test in order to calculate V_{200} .

It has been suggested that heart rate meters should be used as a guide to the intensity of exercise during training. At heart rates of 130–150 bpm, horses can undertake prolonged exercise without fatigue due to the accumulation of lactate and hydrogen ions in the skeletal muscle. However, prolonged exercise at such heart rates is likely to be limited by dehydration, electrolyte disturbances and hyperthermia.

Some workers recommend that medium intensity work should be carried out at exercise speeds that produce heart rates of 200 bpm. This is based on work that implies that HR_{200} is the work rate at the “anaerobic threshold”. It has been demonstrated that training horses at exercise intensities that result in blood lactate concentrations of 6–12 mmol/L results in an increase in muscle buffering capacity. This response will help limit fatigue during intense exercise.

BLOOD LACTATE MEASUREMENT

LACTATE PRODUCTION

Accumulation of lactate in muscle cells and in the blood is a **normal consequence of fast exercise** in the horse. At low speeds, the horse is able to generate sufficient energy by catabolism of glycogen, glucose and fat. This metabolic process uses oxygen to generate ATP and is referred to as **aerobic**. At higher speeds, aerobic metabolism does not regenerate ATP quickly enough.

Exercise at speeds greater than approximately 700–800 m/min recruits fast twitch skeletal muscle fibers. These fibers can be classified as being highly oxidative or highly glycolytic in nature. At fast speeds, recruitment of fast twitch, highly glycolytic muscle fibers results in accumulation of **lactate anions and hydrogen ions** in the muscle cells, due to the contribution of **anaerobic glycolysis** to ATP resynthesis. Both these ions diffuse into the extracellular fluid. It is generally thought that the stimulus for anaerobic glycolysis in skeletal muscle fibers during fast exercise is a limitation to the supply of oxygen at the cellular level.

The production of many molecules of lactate and hydrogen ions results in **acidosis** of both the muscle cell and the blood. The increasing acidity of

muscle cells is implicated in fatigue during intense exercise. In any horse at top speed for approximately 800 m, the accumulation of lactate and the concomitant cellular acidosis has a negative effect on energy production by anaerobic glycolysis. The rate of ATP production is decreased, and the animal reduces speed.

NORMAL BLOOD LACTATE CONCENTRATIONS AT REST AND AFTER EXERCISE

Resting blood lactate concentration in the horse is approximately 1–1.5 mmol/L. At low speeds this value does not change greatly from the resting value. At moderate speeds lactate begins to accumulate in the blood. Accumulation of lactate in blood occurs most quickly when the work speed is faster than that at which blood lactate is approximately 4 mmol/L. This work speed at which blood lactate is 4 mmol/L is often referred to as the **anaerobic threshold**, or the speed at onset of accumulation of blood lactate (OBLA). It is also frequently referred to as VL_{a4} . VL_{a4} is therefore the work velocity which results in a blood lactate of approximately 4 mmol/L. This value is derived from inspection of graphs of exercise speed (on the X axis) plotted against blood lactate concentration (on the Y axis).

At speeds greater than VL_{a4} , **lactate accumulates rapidly** in the blood. The general relationship between velocity and blood lactate is therefore usually described as exponential. However, if sufficient steps are used in the exercise test, the relationship is described by two straight lines, with an obvious velocity at which the blood lactate begins to accumulate in blood.

LACTATE CLEARANCE

After a race, blood lactate concentrations are usually >20 mmol/L. It is normal for the blood and muscle lactate concentration to gradually decrease over a 1–2 h period after a race or fast work. Acidosis of muscle and blood is a normal result of fast work, and this **acidosis is rapidly reversed** by the horse's own metabolism. It is not necessary to medicate horses with salts such as sodium bicarbonate and citrate, which are marketed to prevent acidosis in racehorses. Horses do not become chronically acidotic in training. Any acidosis is due to a temporary accumulation of lactate and protons, a **normal physiologic response** to fast exercise. Acidosis is not a cause of tying up (*q.v.*).

The rate of decrease in blood lactate after exercise is affected by the activity during this period. For example, blood lactate decreases more quickly after strenuous exercise if the horse is trotted, rather than walked. The slowest rates of blood lactate clearance are found in horses that do not walk or trot at all after the exercise. However, prolonged slow exercise after racing or other fast exercise is likely to compromise recovery of normal body temperature, and is not normally recommended.

LACTATE AS AN ENERGY FUEL

Lactate can be used as a fuel for energy in muscle fibers with high oxidative capacities. These fibers are found in the skeletal muscle and in the heart,

where lactate can be used as a fuel aerobically. Some lactate can be used as a fuel during exercise. The role of lactate as an energy substrate at various speeds in horses is not known, although it is probably not an important fuel source during slow work.

LACTATE AND FITNESS

Many studies of horses trained on both treadmills and on racetracks consistently demonstrate that **training results in lower blood lactate concentrations** at the same work speed. The speed at which blood lactate begins to accumulate rapidly, VL_{a4} , also increases. The horse is able to work at a higher speed without accumulating lactate and without becoming acidotic.

VL_{a4} (*q.v.*) is a common measurement in human athletes to estimate **endurance fitness**. VL_{a4} tests are also suitable for any athletic horse as a means of measuring increasing stamina with training. If more than one horse is tested, measurements of VL_{a4} enable comparisons of the relative stamina in each horse. VL_{a4} measurements every 2–3 wk also enable measurement of changes in fitness through the training program. However, VL_{a4} measurements have the disadvantage of requiring several blood collections and analyses. A simple, one-step exercise test can be designed to give the same information (see Box 16.2). Details of the design and conduct of such tests for horses are outlined below (*q.v.*).

LACTATE ASSAYS

When blood is collected for lactate assays, it should be added to tubes containing a suitable anticoagulant and inhibitor of glycolysis. **Fluoride and oxalate combinations** are suitable, as the blood stores well at room temperature for at least 2 days in those chemicals. However, if possible, blood should be stored in a **refrigerator or on ice** until analysis. Individual laboratories should be consulted concerning ideal storage conditions, as different centers use different techniques to conduct the analysis.

Lactate assays can also be conducted on plasma. However, plasma and whole blood lactate concentrations in blood collected after exercise are not equivalent. Plasma lactate concentrations are 140–150% of concentrations found in whole blood, due to **unequal distribution** of lactate between plasma and erythrocytes in horse blood after exercise. Plasma and whole blood lactate concentrations should therefore **not be directly compared**.

In the past, lactate assays have been complicated and not readily available. The analysis of plasma or serum for lactate concentration has been greatly simplified by the development of rapid analyzers.

LACTATE AND TRAINING

Blood lactate measurements are a common feature of the normal training routine of many human athletes. The rationale is that training should be very efficient, neither too strenuous nor too low in intensity. Many human athletes are constantly subjected to blood lactate measurements in their training

for this purpose. This helps to maximize fitness and minimize the risk of overtraining.

This technology has not been widely applied to the training of horses. However, the technique does offer advantages. Since horse racing is an exercise that depends on anaerobic and aerobic capacities, it is important to train the muscles to metabolize glycogen anaerobically (for speed) and to resist fatigue. It has been suggested that if horses are trained at speeds that constantly produce high concentrations of lactate in muscle during training, there is a risk of overtraining and associated loss of performance and interest in racing. This risk may be reduced by giving racehorses more exercise that produces only moderate increases in blood lactate concentrations, in the range 4–10 mmol/L.

EXERCISE TESTS

INTRODUCTION

There is no better test of racing ability than **performance** on the racetrack. However, some owners and trainers of racehorses appreciate having an approximate guide to their horse's ability based on scientific measurements. Also, veterinarians are often requested to assess racehorses with poor race performance. In the past, tests such as blood analysis in resting horses and ECGs for heart score measurement were popular in some countries. Unfortunately, these approaches are of limited use. In one study of 131 racehorses presented to a university clinic for poor performance, all hematologic and plasma biochemical results were within the laboratory's normal ranges.

A superior approach is to assess changes in **physiologic variables during and after exercise**, using techniques commonly employed in human exercise laboratories. This approach may well be applicable to racehorses as well as to human athletes.

The basis of these tests is usually measurement of **blood lactate and/or heart rate response to a standard exercise test**. Exercise tests conducted at treadmill facilities may also incorporate measurements of body temperature, respiratory gas exchange (oxygen consumption and carbon dioxide output), blood volume, arterial blood gas tensions, hematology and serum biochemistry. Such tests may greatly assist the diagnosis of poor performance problems in horses, when combined with the usual complete clinical examination in the resting horse. Recently, the **endoscopic assessment of upper airway function** during gallop exercise on a treadmill has become part of the assessment of horses with suspected upper airway problems (*q.v.*), and for assessment of responses to upper airway surgery.

Exercise tests may consist of assessment of the physiologic response to a single bout of exercise, or may involve tests in which the horse undertakes a series of steps at gradually increasing speeds. The one-step approach to exercise testing has also been validated in human athletes. Multi-step tests are standardized so that results can be compared. The tests can be continued until the horse cannot keep pace with the treadmill, so that the responses to exercise at submaximal and maximal intensities are assessed.

STANDARD BRED RACEHORSES

A simple, **multi-step exercise test** for Standardbred racehorses (Box 16.1) enables measurement of VLa_4 (*q.v.*).

It is also possible to measure fitness with a **one-step exercise test** (Box 16.2). In this test, the horse must work over a set distance at an even, set speed. In fit

Box 16.1 The multi-step exercise test for Standardbred racehorses

1. Suitable, standardized warm-up routine
2. Four workouts over 1000 m (5 furlongs). Suitable velocities for these four steps are 550, 650, 700 and 750 m/min. The time for each 1000 m is recorded, ensuring that the pace is even throughout the work
3. Collect blood 3 min after each step.

The driver should attempt always to use the same speeds in each exercise test. A speedometer can be used to help standardize this important aspect of the test. Bicycle speedometers can be fitted to the sulky. Horses should walk for a set period of time between each of the four steps. Three to 5 min would be suitable. It is important that the time period between each heat is kept constant for all horses in all tests.

When the results have been returned from the laboratory, a plot of speed versus lactate is drawn. By drawing a line horizontal to the 4 mmol/L level, the VLa_4 can be calculated directly from the graph. In trained Standardbred pacers, VLa_4 ranged from 615 to 705 m/min in a similar exercise test.

The blood lactate response to a four-step exercise test described above will depend on many factors. These include:

1. The inherent ability of the horse
2. Stage of training: the blood lactate response to the exercise test will gradually decrease as the horse gets fitter; the VLa_4 therefore increases
3. Type of training used: endurance training is more likely to more rapidly lower the lactate values than is pure sprint training
4. Length of the track on which the test is conducted
5. Type of track, e.g. undulations and track surface
6. The velocities of the four steps of the exercise test, and constancy of the horse's pace during the test
7. Time after exercise that the blood sample is collected: this factor should be kept constant in each test
8. Warm-up and warm-down procedure used
9. Correct storage of blood sample.

It is important that an attempt be made to **standardize** points 4, 5, 6, 7, 8 and 9 in particular, so that the procedure is the same each time an exercise test is performed.

Veterinarians interested in using these tests in Standardbred horses should develop their own exercise test routine on the client's racetrack, as the results will differ on tracks of different surface and length.

Box 16.1 continues on page 1087

Box 16.1 The multi-step exercise test for Standardbred racehorses [continued]

In general, the horses with the best **stamina** (lowest lactates during exercise, or highest VLa_4) in an unfit state are also the horses with the best stamina after training. It is therefore possible to test young horses, or horses just entering training, to get some idea of which horses in a group are likely to be poor performers. However, until a trainer has the results from many exercise tests on many different horses, and is confident in the results, no horse should be retired from the stable on the basis of the exercise test results.

Box 16.2 The one-step exercise test for Standardbred racehorses

1. Standard warm-up procedure, for example jogging for 5 min
2. Standard mile (1600 m) time, for example 2 min 16 s, at an even pace (4×34 s quarters)
3. Standard warm-down procedure before taking blood sample at 3 min after exercise
4. Store blood in refrigerator or in ice

The obvious disadvantage of this one-step test is that minor variations in the time for the mile (1600 m) will affect the results. For example, if the horse works at 2 min 12 s or 2 min 20 s, the results are not valid for that test, and the test has to be repeated. In a four-step test, the speed of each step is not so crucial.

The blood lactate response to this exercise test will vary considerably. The fittest horses will generate lower lactates at this speed than less fit horses.

or nearly fit Standardbred racehorses, it is suggested that the guidelines are followed closely for best results. The one-step test in Box 16.2 is too difficult for unfit horses. They should be tested using a mile rate of 2 min 40 s (40 s quarters).

THOROUGHBRED RACEHORSES

Thoroughbreds can also be tested on the racetrack, following the principles outlined above for Standardbred horses. However, one-step testing of Thoroughbreds is a much more difficult task. The exercise test requires the horse to work at a set speed (approximately 15 s per furlong [200 m]) over a set distance. This is harder to achieve in Thoroughbreds than in Standardbreds.

Thoroughbreds have been tested by conducting a **two- to three-step test** (Box 16.3). This test can be repeated on successive days, or over a 7-day period. A graph of blood lactate concentration versus time for the 1000 m (5 furlongs) is then drawn, using at least three data points. Horses with **superior race performance** have **lower blood lactate concentrations** at work speeds in the range tested. Horses with consistently high blood lactate responses in this test are generally poor performers, despite the best of training. Their poor performance may be due to their inherent structure of heart, lung and muscle.

Box 16.3 The two- to three-step exercise test for Thoroughbreds

1. Suitable warm-up trot and canter, as per normal training routine
2. The horses work on firm ground over 1200 m (6 furlongs). The jockeys are asked to accelerate to a speed of 14–16 s per furlong from the 6 furlong mark, and then maintain that speed for 5 furlongs
3. The time for the last 1000 m (5 furlongs) is recorded
4. A blood sample for lactate analysis is collected 3–5 min after exercise

The results of this track test sometimes produce blood lactate values that do not fit the expected pattern. The inability to have strict control of the rate of acceleration at the start of the gallop can contribute to this problem. Horses that accelerate more quickly at the start of the gallop will have unusually high lactates. Likewise, horses that vary their speed of galloping or pull against restraint by the jockey during the 5 furlong workout will also have unusually high lactate values, which should be ignored.

Any decision on the results of a track exercise test should be based on results from at least three or four separate tests, eliminating any high lactates that do not lie close to a line of best fit for at least three data points.

It may also be due to disease of the respiratory tract or heart (*q.v.*). If there is no evidence of any disease causing poor oxygen transport to the muscles, then it must be concluded that the horse does not have the optimal physiologic make-up for racing.

EXERCISE TESTS AND THE HEMOGRAM

Exercise tests can be used to help diagnose anemia (*q.v.*) in racehorses. The resting hemogram can be **highly variable** in an individual horse, and there is no predictable relationship between hematologic findings in resting horses and the hematologic findings after maximal exercise. In English Thoroughbred racehorses, the mean hematocrit 3–14 min after 6 furlong (approximately 1200 m) races averaged 59% (SD 3%). After longer races, mean hematocrit values were 63% with 95% confidence limits of approximately 54–70%. There is no relationship between race performance and post-maximal exercise hemogram in the Thoroughbred. A correlation has been demonstrated between total red cell volume (RCV) and performance of Swedish trotters. Measurement of RCV necessitates measurement of plasma volume and post-exercise hematocrit.

Collection of blood 5–10 min after fast exercise at or near racing speeds can help with the diagnosis of anemia in those horses with low hemograms at rest. Published data suggest that horses with a 10 min post-race hematocrit <50% are probably anemic. Veterinarians should establish their own **standardized protocol** for checking post-exercise hemograms, and establish their own normal values in a range of horses. The hematocrit gradually decreases after exercise, so a constant time of blood collection post exercise must be used.

TREADMILL EXERCISE TESTS

Treadmill exercise tests are usually employed to assess **stamina**, or endurance fitness, by measuring heart rate, blood lactate and oxygen consumption (maximal aerobic capacity) during exercise. There has only been one report of measurement of anaerobic capacity in horses. Obviously **anaerobic capacity** will be a major contributor to the **strength and sprinting ability** of a horse. The best test of sprinting ability and acceleration is a time trial on a racetrack.

Stamina is an important component of successful racing over all distances, but it is of course particularly relevant to middle and longer distance racing. Performance in Quarter Horse racing is unlikely to be greatly dependent on stamina however, as the events are completed in less than 24 s.

Exercise tolerance tests are conducted by exercising horses at set treadmill speeds and angles, and measuring the body's physiologic responses to that exercise. Superior horses cope with the exercise more easily, and the response to a set amount of exercise changes with training. In general, the horse that is able to maintain a high work rate **without reliance on anaerobic energy production** has superior stamina.

A simple exercise test for **race-fit horses** is as follows. The treadmill angle is set at 6° (or a 1 in 10 slope). The horse is trotted for 2 min (at 4 m/s), followed immediately by 2 min slow cantering (6 m/s). The horse is then walked on the treadmill for 4 min, and then given 2 min exercise at 10 m/s.

Blood is collected into fluoride oxalate tubes 3 min after the finish of the exercise test, and is analyzed for whole blood lactate concentration. As horses get fitter, they produce less blood lactate in response to a standardized exercise test. Race-trained Thoroughbred horses with blood lactates >8 mmol/L after the test described above have definite limitations to stamina, and are unlikely to be good racehorses. Racehorses with superior stamina, or endurance fitness, have blood lactate concentrations of <4 mmol/L after the test.

Incremental treadmill exercise tests, with measurements of heart rate and blood lactate at various speeds, can also be conducted. Such tests enable calculation of indices of fitness such as V_{200} and VL_{a4} ($q.v.$). Collection of blood at each speed necessitates stopping the treadmill after each step, or placement of an IV catheter. Sterile heparinized saline solutions can be used to maintain catheter patency during the tests. Such tests are now common at research centers with treadmills for assessment of poor performance. Measurements of heart rate, blood lactate and oxygen consumption are usually conducted during submaximal exercise and during exercise at maximal intensities.

LIMITATIONS OF TREADMILL TESTS

It should be remembered that all tests of fitness using blood lactate analysis during or after submaximal exercise are an assessment of the **endurance fitness**, or stamina, of the horse. The results have little relevance to the ability of a horse to accelerate quickly at the start of a race, or to the top speed of a horse over 2 furlongs (400 m). These factors are, of course, of great importance to the ability of racehorses in events lasting 2–8 furlongs.

Stamina is a vital component of all racehorses except the Quarter Horse. Stamina, or “staying” ability, is obviously more important in the longer distance events. Performance in Standardbred and Thoroughbred races depends on many factors, but **both stamina and sprinting ability** are paramount. A horse with superior speed, strength and acceleration but only moderate stamina may still win races, especially over the sprint distances. Likewise, at the other end of the spectrum some horses have superior stamina, but poor speed over 2–3 furlongs. These horses cannot be expected to perform very well in Thoroughbred or Standardbred races.

It should not be expected that results of treadmill tests will detect very small differences in fitness between horses. For example, it would not be possible to distinguish between 20 horses of similar grading, even though there might be several lengths between them at the end of a race. Fitness tests that try to classify horses on the basis of their stamina should be restricted to rating a horse as having good, average or poor stamina, dividing populations of racehorses into large subsections.

The blood lactate response is therefore a **guide to ability**, and the other factors that contribute to racing success must not be ignored. However, a treadmill study of 12 English Thoroughbred racehorses indicated that 47% of the variability in *Timeform* rating (a handicap rating system) was due to variability in their blood lactate response to treadmill exercise, using a test similar to that described above. The better horses had a lower blood lactate after treadmill exercise at 10 m/s on a treadmill inclined at 10%. Similar results have been reported in trotting horses. The **blood lactate response to exercise** is a very important determinant of likely success or failure on the racetrack.

MEASUREMENT OF MAXIMAL OXYGEN CONSUMPTION

Measurement of the maximal rate of oxygen consumption is performed as part of exercise tests at many clinics. The **maximal rate of oxygen consumption ($VO_2\text{max}$)** is expressed as mL O_2 /min/kg. In fit racehorses, the range is approximately 125–190 mL/min/kg. This value expresses the ability of the horse to **transport oxygen from the atmosphere to the skeletal muscle mitochondria and use it to regenerate ATP**.

The value of $VO_2\text{max}$ for any horse depends on the product of **maximal cardiac output** and the **amount of oxygen** extracted from the arterial blood supplying all tissues during exercise. Of course, during exercise the majority of the arterial blood is directed to the active skeletal muscle. Rates of maximal oxygen consumption increase by 15–20% with training, mainly due to increases in **stroke volume**.

In human athletes, $VO_2\text{max}$ is highly correlated with performance in many running events. Running ability of Thoroughbred horses racing over 2000 m on an 800 m track was moderately correlated with $VO_2\text{max}$ ($r = 0.45$) in one study. It is highly unlikely that horses with $VO_2\text{max}$ values in the lowest three deciles are destined for good performances on the racetrack in events lasting more than 60 s. Standardbreds with superior performance also had higher maximal oxygen uptakes than values in a group of horses with inferior performance.

CONCLUSIONS

In conclusion, exercise tests on racetracks are more suitable for pacers and trotters, but are difficult to apply in Thoroughbreds. Treadmill exercise tests are generally superior to track tests, as the test conditions are easily standardized. Most horses become accustomed to treadmill exercise after 3–5 exposures to the routine. Treadmill exercise tests facilitate examination of metabolic, cardiovascular, hematologic and respiratory responses to exercise. As well as being a useful research tool for the study of equine exercise, such tests can be used routinely to monitor fitness and assess performance potential in equine athletes. Field tests can be used to assess fitness, but standardization of the exercise test protocol can be more difficult. However, field tests have the advantage of being conducted in the horse's own environment, and veterinarians should explore ways of using field fitness tests to assess equine athletes, using measurements of heart rate and/or blood lactate concentration.

EFFECTS OF TRAINING ON BONE

INTRODUCTION

It is over 200 years since the relationship between mechanical stress and bone structure was first appreciated. In 1892, the German anatomist Julius Wolff reported that “every change in the function of a bone is followed not only by certain definite changes in its internal architecture, but in its external conformation as well, in accordance with mathematical laws”. Since then some elegant studies have been carried out in both humans and animals to investigate the response of bone to a variety of biomechanical situations. However, it is only more recently that any investigations on racehorses have been undertaken to try and monitor the effects of training.

The specific effects of exercise on bone have been shown to depend not only on the animal's age but also on the duration and intensity of training. This section deals with some of the specific responses that take place in cortical bone of young Thoroughbreds following maximal exercise (galloping) and in their practical application to problems of exercise-induced lameness (e.g. shin soreness).

BONE BIOMECHANICS

Bone has a dual role, to support the body (**skeletal homeostasis**) and act as a source of calcium (**mineral homeostasis**). It is a dynamic tissue in which changes continue to take place throughout life to maintain optimal strength and to adapt to external forces. This involves a continual and coordinated activity of forming (by osteoblasts) and removing (by osteoclasts) bone, which is termed remodeling. The actual structure of bone is very complex, but its basic make-up is a collagen framework hardened by hydroxyapatite mineralization to give it strength.

The skeleton of the horse reflects the load-bearing competence of its individual components; in other words bones are capable of adapting to the prevailing biomechanical stresses (**load bearing**). In racehorses, the extent of load

bearing is essentially determined by the training regimen to which they are subjected. The objective of training is to increase skeletal strength while limiting the possibilities of exercise-induced injury.

Although the actual mechanisms of response to loading are poorly understood, it is clear that bone readily adapts either to imposed stress or to the lack of any stress by forming or losing tissue. **Bone hypertrophy (modeling)** occurs when stress is applied. Lack of exercise has been shown, particularly in humans, to be one of the most significant factors in stimulating bone turnover, initially seen as remodeling but leading eventually to osteoporosis. The withdrawal of any functional loading of the bone also results in rapid loss, although this can be reversed by exposure to short daily periods of suitable dynamic loading.

The effects of loading and unloading of bone are well known, but the means by which the specific signals are recognized at the cellular level are not yet understood. It is now believed that there is a limiting strain range called the **minimum effective strain (MES)** that turns these mechanically controlled responses “on” and “off”. It has been suggested that, to switch on a modeling response, $\sim 1500\text{--}3000\ \mu$ strain (microstrain) is required. However, a much smaller threshold strain range ($\sim 100\text{--}300\ \mu$ strain) is necessary for the mechanical control of remodeling.

It has also been shown that bone requires stimulation by appropriate strain rates for optimal maintenance of strength. Bones resist compression twisting and bending in many directions and can be trained to resist these forces. A dose–response curve has been produced that shows strains below a certain peak magnitude are associated with bone loss while those above that level not only protect the existing bone tissue from resorption, but also provide an **osteogenic stimulus** resulting in deposition of an amount of new bone proportional to the degree of “overstrain” engendered. Once a loading regimen has been repeated so that it is recognized by the bone, subsequent repetitions apparently do not affect the nature or magnitude of the adaptive response. This, of course, has important connotations for training of racehorses in trying to reduce exercise-induced lameness by limiting excessive amounts of fast work.

POOR SKELETAL CONDITIONING AS A CAUSE OF “WASTAGE”

The principal aim of any training program is to condition all the systems of the body to maximal athletic performance while achieving the minimum of damage. Knowledge of the effects of training and the ability to maximize potential in relation to the muscular and cardiorespiratory systems is now quite extensive. However, while appreciating the importance of training effects on bone and joints, there is very little published information available. This is regrettable when one considers that surveys of “wastage” by insurance companies and in the racing industry have highlighted lameness and orthopedic conditions as being the most important cause of losses.

The most serious cause of exercise-induced lameness in young Thoroughbred horses in training is associated with **sore shins** (bucked shins, dorsal metacarpal disease) (*q.v.*). This condition is particularly common in 2-yr-olds during their first year of training. It has been recognized for over a hundred years as being

associated with uni- or bilateral lameness after fast work on hard ground. The pathogenesis is not completely understood, but it involves both damage to the periosteum of the dorsal cortex and microdamage to the underlying cortex.

Despite its frequency, little seems to have been done to reduce the incidence of **sore shins** (*q.v.*). The condition is particularly common in the USA, Canada and Australia, but is less commonly seen in the UK. Surveys in the USA indicate a 65–70% incidence; in Australia the incidence is at least 70%; while in the UK two surveys estimated the incidence at $\leq 17\%$. Shin soreness causes wastage through lost time during training and therefore appearances on the racetrack. Periods of absence from training vary greatly, but range from 1 to 6 mo, and a small percentage of horses are lost to racing completely. Although many horses only go shin sore once, the problem can recur both in 2- and 3-yr-olds. In the more chronic form of the condition **stress fractures** (*q.v.*) of the dorsal cortex occur that significantly prolong recovery and predispose to further bouts of lameness.

There is no single answer or therapeutic panacea for shin soreness, but research is being carried out to identify the specific conditions and intensity of exercise required to trigger the condition, so that training programs can be adjusted to reduce susceptibility.

METHODS FOR ASSESSING BONE QUALITY

It is necessary objectively to assess and sequentially to monitor changes in bone strength in order to follow the effects of training on cortical bone in racehorses. The non-invasive measurement of **bone quality** in the horse has traditionally involved the use of **radiography**. There are now some other modalities available to evaluate cortical bone quality and strength. These include **ultrasound speed** in bone, which gives an estimate of its stiffness and elasticity, and **radiation-based assessment**, which gives a direct measurement of **bone mineral content (BMC)** or **bone mineral density (BMD)**.

Quantitative ultrasound (QUS)

The speed of an ultrasonic wave (speed of sound) through bone is related to the modulus of elasticity and the specific gravity of the bone. There is now a simple method for determining ultrasound speed in cortical bone by passing a longitudinal beam of ultrasound between two transducers along the cortex of the third metacarpus. The speed of ultrasound is calculated from the time of flight and the distance between the two transducers in m/s. The precision of this method is $<3.0\%$ and normal values for young racehorses range from approximately 3700 to 4200 m/s.

Radiation-based assessment of bone

An accurate measurement of bone mineral mass by single photon absorptiometry was developed in the USA in the early 1960s. The principle of the technique is to scan the bone with a narrow beam of low energy photons from a monoenergetic radionuclide source and measure the reduction in attenuation

using a scintillation detector. A direct relationship exists between the number of photons absorbed by the bone and its mineral content. The radionuclide source used for horses is americium-241, which has the photon energy required (60 keV) to penetrate the dense cortical bone of the equine metacarpus. The precision of this technique in the live horse is around 2%. The method takes a little longer than that for ultrasound speed and the limb is required to be surrounded by a soft tissue equivalent material. Normal values for BMC in adult horses range from 8.0 to 10.0 g/cm.

Dual energy X-ray absorptiometry employs two beams of photons: one of higher energy and one of lower energy. This is the most widely used technique for measurement of BMD in man. A portable system is now available for use in the horse.

Invasive methods

There are a number of important invasive methods used to assess bone strength and quality in the horse.

1. Mechanical testing in vivo using rosette strain gauges, or on excised bones to measure Young's modulus and ultimate strength
2. Microradiographic and histomorphometric examination of bone to study the static changes in bone due to exercise, and by using intravital bone labeling to appreciate the dynamic effects of bone turnover
3. In vitro studies of the orientation of collagen in cortical bone using polarization microscopy, which has an important connotation with functional loading.

EFFECTS OF EXERCISE ON BONE

The effects of exercise on cortical bone have been examined in growing (1–2-yr-old) and adult horses at both submaximal and maximal intensities. These studies reveal that submaximal exercise even for prolonged periods (≤ 6 mo) in young and adult horses does not dramatically alter the mass or density of cortical bone in the metacarpus. In contrast, training at high speeds results in significant increases of ultrasound speed in both adult Thoroughbred and Standardbred horses. This increase in ultrasound speed is only approximately 1.5% (~ 50 m/s) and is thought to reflect a small increase in bone density due to a reduction in bone porosity.

Maximal exercise in young Thoroughbreds (15 mo old) at speeds > 12 m/s results in a rise in ultrasound speed, but also more substantial increases in bone mass. This intense type of exercise causes a decrease in **intracortical porosity** that is reflected in high ultrasound speed readings. However, the increase in ultrasound speed is never greater than 1–2% and differs from the non-exercised horses only by 3–4% (≤ 120 m/s). These small changes may have an important effect on bone strength since bone strength is proportional to the density cubed.

A more dramatic change in response to fast exercise is the alteration in **distribution of compact bone** that occurs in young horses. Histomorphometric examination of bone samples from these horses reveals that both modeling

and remodeling of bone have been substantially changed. First, intracortical bone remodeling is significantly reduced by decreasing bone porosity. Second, the cross-sectional morphology of the metacarpal shaft is altered, resulting in greater bone formation on the dorsal periosteal and endosteal surfaces.

It appears that increase in bone formation on the dorsal periosteal surface does not occur at any appreciable rate until speeds greater than 12 m/s are achieved. It has been postulated that the signals that regulate intracortical bone density may be different than the signals that cause the enlargement of the cortex. There is now increasing evidence that important changes in the density of subchondral bone also occur as a result of high speed exercise.

The change in the **shape of the metacarpal bone** due to high speed exercise is important in the adaptation of the bone to the rigors of fast galloping and also helps to reduce the risk of bone damage (shin soreness). The adult Thoroughbred's third metacarpal bone has a thick dorsal cortex compared with that of Standardbreds. This difference between the two breeds is not necessarily genetically related, as there is evidence that the normal growth pattern of the Thoroughbred does not always involve specific enlargement of the dorsal cortex. However, it is clear that intense exercise of young Thoroughbreds will dramatically enlarge the size and shape of the dorsal cortex, compared with non-exercised age-matched controls.

The response of the metacarpus to the forces of compression is to enlarge the cross-sectional area. This reduces local **bone stress**, since stress is equal to the force (load) divided by the area over which the force acts. If the horse's metacarpus were subjected simply to axial compressive forces (no bending) during galloping, then the alteration in cross-sectional area would be uniform. This, however, is not the case, since substantially more bone is laid down on the dorsal cortex than at other sites. We can assume therefore that some bending forces on the metacarpus must occur during galloping in addition to compression. Bending increases the local strain on the dorsal cortex and leads to the preferential enlargement of the bone in this axis. This bending is thought to occur only at the fast gallop, since it has not been possible to measure at slower speeds. The Standardbred's cannon bone does not have an enlarged dorsal cortex, which indicates that the bending forces probably do not occur at the fast trot or pace.

There are a number of other structural factors in bone, which have not yet been investigated, that may be influenced by training. For example, the alignment of collagen fibers within the bone contributes significantly to the compressive strength of the cannon bone. It is feasible that the **collagen formed in trained horses** is better aligned than in untrained horses, thus contributing to the structural strength of the bone. The collagen cross-linkage of bone is also an important factor that can regulate bone mineralization and bone strength. Increases in the number of collagen cross-links may also contribute to the bone strengthening effect of training.

It is clear therefore that **controlled fast work over short distances** will improve the biomechanical strength of the metacarpus of young horses. Further studies are required to determine the minimum amount of fast work that will result in an improvement in the strength of the metacarpus, and also the duration and speed of fast exercise that provides an unacceptable risk of causing bone damage.

SHIN SORENESS—AN EXERCISE-INDUCED INJURY

The cause of shin soreness (*q.v.*) was originally attributed to the tearing of the periosteum and subsequent subperiosteal hematoma. More recently **biomechanical injury** has been proposed as a more likely cause of shin soreness involving a fatigue failure of the bone on the dorsal aspect of the metacarpus. **Microfracturing** in the outer layer of the dorsal cortex is now proposed as the instigating factor leading to local inflammation and pain.

The major risk factors involved in shin soreness in order of precedence are high speed work, immaturity, too much work too soon and low bone strength/density. Over 90% of shin soreness cases exhibit the first signs during the fast work stages of their preparation.

Bone that is repetitively loaded will suffer **fatigue** during which the bone loses strength and will ultimately **fracture**. Bone that is under very large loads will fatigue quickly, whereas bone under smaller loads will take longer to fatigue (the greater the load or strain, the fewer cycles required to cause fatigue). On the other hand the fatigue life of bone is positively related to its density (the denser the bone the more cycles required to cause fatigue).

However, the situation in young racehorses is more complex. We have already seen that the metacarpus of young horses responds to intense exercise by producing **more bone** on its dorsal surface. This bone is of low density initially, as mineralization of the newly formed bone is fairly slow. This bone therefore will have a much **lower fatigue life** than that of fully mineralized bone. For a given load, this bone will deform more than fully mineralized bone, thus setting up large shear forces between areas of new low mineralized bone and older fully mineralized bone. These larger shear forces may result in more rapid fatigue of the bone, which leads to microfracturing. This is followed by an inflammatory reaction resulting in **periostitis** (*q.v.*) with serum oozing underneath the periosteum. The inflammation and damage to the bone matrix stimulates the formation of periosteal new bone (generally woven bone).

TRAINING TO MAXIMIZE BONE QUALITY AND MINIMIZE LAMENESS

Although it is possible to train a horse without the horse going shin sore, it is unlikely that horses can be trained without **some degree of shin soreness** occurring. Alteration of current training and racing practices could result in a reduction of the occurrence of shin soreness, as well as a reduction in many other orthopedic injuries such as carpal chips, traumatic arthritis, etc. (*q.v.*). These, together with improvements in track structure and design, are thought to be the important factors that will affect the incidence of shin soreness in the future.

An **incremental training program** that increases the length, speed and repetition of galloping has been proposed as an alternative training program. It has been shown in other species that small numbers of high intensity loads per day can result in enhanced bone growth. Therefore, the distance over which horses gallop needs only be short (200–400 m). We know that the faster the speed at which this work is done, the greater the bone's response.

In order to control this response and not promote excessive risk of shin soreness, the horses should be started at a slow gallop and the speed progressively increased after periods of 4–5 wk. As galloping speed increases, so does the risk of shin soreness, so close surveillance is required. This type of training program involves a trade off between maximizing the bone response and minimizing the incidence of shin soreness. Acute shin soreness occurs from excessive strain in a bone that is relatively small. As a result of training the bone enlarges, which means for a given load (speed) there will be less strain. The strain in an adult Thoroughbred at full gallop is around 3500μ strain, whereas it may be $\geq 5000 \mu$ strain in a 2-yr-old. If the bone strain is kept at 3000–3500 μ strain during a gallop then the risk of shin soreness should be low.

The proposed advantages of such a training program include a reduction in the amount of shin soreness, and as a result an **improvement in welfare** for the horse. It is envisaged that other types of exercise-induced bone and joint problems may occur less often, which could add substantial benefits. The other factor is that reductions in these orthopedic conditions may greatly enhance the horse's useful racing life and thereby reduce the substantial wastage that occurs in the racing industry.

CONCLUSIONS

In summary, galloping exercise at maximum speeds results in important adaptational changes in the size and shape of the metacarpus to provide extra bone strength. The extent of these changes will vary between individual horses and in some instances the end result will be exercise-induced injury such as shin soreness. Enlargement of the dorsal cortex will also result from shin soreness because the acute inflammation produced activates the periosteum and results in a rapid production of bone. This bone is often a type that will gradually need to be modified to provide suitably strong (organized) bone by the process of remodeling.

SORE BACK IN THE PERFORMANCE HORSE

INTRODUCTION

Sore backs are a common and often underrated problem in performance horses. The conditions involved may be primary or arise secondarily as the result of lameness, faulty tack or inadequate schooling. It is worth remembering that the most common reason for presentation of a back problem is **poor performance** rather than overt back pain.

Diagnosis of back problems is notoriously difficult and always requires a **thorough and systematic examination**. Despite this attention to detail and the application of sophisticated clinical aids, a definitive diagnosis is often only made by elimination of all other conditions.

PATHOPHYSIOLOGY

Specific pathogenesis of many back problems is unknown. However, a thorough knowledge of **functional anatomy** of the spine is the basis of pathophysiology.

It is important to remember that the horse keeps its back almost **rigid** to act as a bridge between the fore- and hindquarters. It then transmits the power or impulsion from the hindquarters to enable increased stride length and performance. The equine spine has been likened to a “**string and bow**” arrangement where the “bow” is the rigid vertebral column and the “string” keeps it under constant tension.

The conformation, type and use to which horses are put can have an important bearing on the injury. For example, specific spinal malformations (e.g. lordosis and scoliosis) tend to predispose to injury through the inherent weakness of the back or “bow” arrangement of the thoracolumbar spine. These conditions place extra strain on the “string” or epaxial muscles of the back, which can lead to recurrent soft tissue injuries. The majority of horses do not have this type of gross deformity, but **mild conformational defects** are common. Those horses that are short-backed with restricted flexibility of the spine tend to exhibit more vertebral lesions than longer-backed animals, which have relatively more suppleness and seem to be more prone to muscular or ligamentous strain. Large-framed animals with comparatively weak-looking quarters appear to be more susceptible to sacroiliac problems (*q.v.*).

There also seems to be an association between the type of back injury and the **sort of work** the horse is involved in. Acute sacroiliac strain or subluxation is more prevalent in horses jumping at speed, whereas overriding of the dorsal spinous process is most common in showjumpers. The incidence of soft tissue damage is much the same in both of these groups and age is not nearly such an important factor in equine back disorders as it is in humans. **Spondylosis deformans** appears more frequently in mares, and overriding of the dorsal spinous processes is most often seen in short-backed Thoroughbred geldings.

Another feature that seems to have a bearing on pathophysiology is the **seat of the injury** itself. Bone damage tends to be centered on the mid-point of the back, while soft tissue injuries are more often seen in the cranial and caudal parts of the thoracolumbar spine. This point can be helpful if no special radiographic facilities are available to differentiate soft tissue from skeletal damage. For example, a common scenario is acute onset of **noticeable discomfort** in the animal's back behind the saddle region (cranial lumbar spine). This would most likely be due to soft tissue damage and could be treated accordingly. In general practice it should be possible therefore to facilitate diagnosis of spinal disorders by carrying out a **thorough clinical examination** and using the ancillary aids available (assessment of muscle-derived enzyme levels, a short course of a non-steroidal anti-inflammatory drug [NSAID] and local anesthesia of the interspinous spaces).

DIAGNOSIS OF BACK PROBLEMS

One of the most difficult aspects of examining horses with potential back problems is being able to assess objectively the site and degree of pain involved. This is further complicated by the marked variation of individuals in their response to pain even on a day-to-day basis (**pain threshold**). As in human patients there is also the involvement of **temperament** as a contributory factor.

It is suggested that impaired performance is sometimes due to a horse trying to “save its back” even though the clinical signs of pain have apparently abated. Horses that keep their backs stiff for any reason are not going to perform satisfactorily as they will lose hindlimb impulsion. Some credence to this idea has been given by inducing stiffness of the back with small injections of concentrated lactic acid into the longissimus dorsi muscles under experimental conditions. The effect of local pain and associated back stiffness produced a noticeable reduction in performance capacity as analyzed by high speed cinematography on a treadmill.

A practical scheme for examining a horse with a potential back injury is given in Table 16.1.

Palpation of the spine

Clinical examination of the horse should be carried out **in stocks or in the box** with the horse in as relaxed a state as possible. To begin with, a test of the horse's reaction to **running a hand gently** along its back from the withers to the base of the tail is made. It is very difficult to palpate more than the tips of the dorsal spinous processes, although in most horses the interspinous spaces can be identified. It should be possible to detect **spasm of the longissimus dorsi** muscles as well as any protrusion or thickening around the summits of the dorsal spinous processes. Thin-skinned or hypersensitive horses will cringe when this is done, but unless there is a really dramatic response

Table 16.1 A practical scheme for examination of horses with a potential back injury (the examination should be standardized as much as possible)

Case history	Assessment of management factors Experience of owners: animal's temperament and ability to perform Time of onset and duration of clinical signs Response to any treatment given, particularly manipulation and NSAIDs
Clinical examination	At rest—visual inspection, palpation, manipulation Rectal palpation At exercise—in hand, lunged, ridden or driven
Radiologic examination	Lateral views of thoracolumbar (T2–L3/4) and sacrococcygeal (S2–Cy4) regions performed in standing position Radiography of lumbosacral (L4–S5) spine carried out under general anesthetic in ventrodorsal plane Linear tomography for sacroiliac lesions
Laboratory examination	Hematologic analysis—whole blood count Biochemical analysis, including muscle-derived enzymes (AST and CK), before and after exercise test
Other aids	Local anesthesia of interspinous spaces Faradic stimulation of muscles for confirmation of soreness Short-term effect of NSAID on performance “Slap test” for evidence of cervical vertebral stenosis causing mild to severe hindlimb incoordination Nuclear medicine (scintigraphy) for bone lesions Thermography for “hot spots” in back muscles Ultrasonography of soft tissue structures of the back

(e.g. kicking out, rearing, grunting) this should not be considered of clinical significance.

Palpation of the tips of the sacral spinous processes in the croup should also be carried out, particularly in horses used for harness racing. Pain may be palpable over the tendinous insertion of longissimus dorsi on the spines of S2 and S3 and in the sacrosciatic ligament. The tail and croup region should be examined for any flaccidity or perineal paralysis, which may be a sign of **neuritis of the cauda equina** (*q.v.*).

When there has been a history of trauma, a **rectal examination** should be carried out to determine the presence of damage to the pelvic canal, sublumbar group of muscles and/or sacroiliac region. If there is active damage to the muscles or ligaments in the sacroiliac region, then pressure exerted above each tuber coxae and on the midline at L4–5 usually produces pain or discomfort.

The next part of the procedure involves alternate **pinching** of the midline of the caudal thoracic and sacral region, in order to make the animal flex (ventroflex or arch) and extend (dorsiflex or dip) its spine. Reluctance to perform this maneuver and **rigidity of the back** are often significant findings, as they may reflect some underlying pain due to soft tissue or lesions of the thoracolumbar spine. Pain or discomfort produced by carrying out these tests is often accompanied by spasm of longissimus dorsi on one or both sides of the back. Areas of pain need to be located as precisely as possible for comparison with the results of any bony abnormalities noted on radiographic examination.

Skin sensitivity over the back and loins has proved an unreliable test as it seems to be so variable between individuals. However, **firm stroking** of longissimus dorsi with a pencil to produce muscular contraction and lateral flexion of the thoracic and lumbar spine is a very useful technique. There should normally be no marked resentment to this test unless there is some painful muscle involvement. If some chronic bony or muscular problem is present in the mid-back, then a reluctance or difficulty in lateral flexion in one or both directions is often seen.

Examination at exercise

Many horses with **chronic back trouble** show a restricted hindlimb action with poor hock flexion and a tendency to drag the toes of one or both hindlimbs. If moderate to severe pain is present a wide straddling hindlimb is usually seen, but in the horse with a low grade, less painful problem the action behind will be very close (**plaiting**).

The animal should be turned as short as possible in both directions with the intention of making it **flex the spine laterally**. If back pain is present and there is loss of suppleness, turning is often difficult, resulting in rather jerky movements and spasm of the back muscles. On backing there is sometimes an initial reluctance to move, then the head is raised, the back is arched more than usual and some spasm of the back muscles occurs.

Another sign of discomfort is the **dragging of the forelimb toes** on moving backwards. Severe lameness in one or both hindlimbs is not usually a feature of a back problem and diagnostic nerve blocks should be used to differentiate this from a genuine thoracolumbar condition. Mild shifting lameness or simply an **unlevel action** of one hindlimb is much more commonly seen.

Flexion tests rarely have any effect on the gait, but can be useful in distinguishing hock or stifle problems.

A session of 10–15 min exercise on the **lunge rein in a sand ring** is useful to assess critically the horse's gait. This also provides an opportunity to see any improvement or deterioration in the action as the horse warms up. Animals with restricted hindlimb gait often show poor tracking of the hindfeet (placement of the hindfeet behind the imprint of the ipsilateral forefoot) and a tendency to drag or plait with the hindtoes. The head carriage may be elevated and the animal looks uncomfortable in its work. A poor action is usually best seen at the trot. Some difficulty is often seen when changing pace along with an inability to lead on the correct leg (disunited). The action behind appears to lack impulsion, and swishing of the tail is often a feature, however tail swishing is not always indicative of back pain.

Finally **the horse should be ridden**, if possible by its regular rider, and with its regular harness, and an assessment made of the action at the walk, trot and canter. If the horse is a showjumper it should also jump over the type of fences that usually cause the most trouble (e.g. combination-type fences). For harness racing horses it is of great benefit to have the animal driven to assess the performance and trotting or pacing gait at fast exercise.

After a period to allow the animal to cool down, it should be exercised in hand again to see if there is any change in action. This is particularly useful in horses with low grade **exertional rhabdomyolysis** (*q.v.*) as they show increased stiffness of the hindquarters.

Differential diagnosis

The list of conditions that may be confused with a genuine back injury (Table 16.2) is deliberately presented *before* the section on conditions affecting

Table 16.2 Conditions to be considered in differential diagnosis of a thoracolumbar disorder

General category	Specific lesions/problems
Temperamental problems	Apparent hypersensitivity of back or "cold back"
Management problems	Poor schooling and equitation Badly fitting tack (saddle, bridle, bit)
Lameness	Forelimb lameness: Bilateral carpal or fetlock damage Navicular disease (e.g. laminitis) Hindlimb lameness: Originating from pelvic region Stifle problem (e.g. partial fixation of the patella) Hock lesion (e.g. spavin)
Hindlimb incoordination	Spinal cord damage in cervical or thoracolumbar regions
Miscellaneous conditions	Head-shaking and dental problems General debility and stiffness Traumatic cervical damage with neck stiffness

Table 16.3 Conditions of the thoracolumbar spine that may directly cause back problems in the horse

General category	Specific lesions
Deformities of vertebral column	Congenital or acquired curvature of the spine (scoliosis, lordosis and kyphosis) Synostosis (congenital vertebral fusion) Sacralization of L5/L6 vertebrae
Soft tissue injuries	Muscle strain of longissimus dorsi and/or sublumbar muscles Strain or damage to supraspinous and sacroiliac ligaments of the back Exertional or cramping of back muscles
Fractures	Dorsal spinous processes—single or multiple overriding fractures Vertebral bodies and neural arch
Other vertebral and articular lesions	Spondylosis deformans Crowding and overriding of the dorsal spinous processes ("kissing spines") Osteoarthritis and fusion of the dorsal spinous, transverse and articular processes Chronic sacroiliac problems (instability and spine formation)

the horse's spine. It is not uncommon for owners to blame poor competitive ability on a condition of the thoracolumbar spine when it is simply due to problems of schooling, rider equitation or poor track. The signs of a "cold back" on tightening the girth or mounting are not necessarily an indication of an underlying spinal problem.

Hindlimb lameness (e.g. a bilateral hock problem) is probably the most common differential diagnosis. Both fore- and hindlimb lameness can result in secondary back soreness and stiffness.

CONDITIONS AFFECTING THE HORSE'S BACK

Specific conditions of the spine

The size and complexity of the thoracolumbar spine of the horse predispose it to a wide range of problems that may lead to locomotor dysfunction. A list of the specific lesions that have been reported to cause directly back pain and discomfort in horses is given in Table 16.3.

Injuries to the **soft tissues** (muscles, ligaments and tendon insertions) are the most common causes of back injuries in horses. These conditions are usually traumatic in origin and carry a hopeful prognosis.

Alleged back problems

There is another category of so-called "back problems", which, despite lay opinions that they are important, have limited anatomic or pathophysiologic evidence to support their occurrence (Table 16.4). It is this latter group that forms the basis of **much controversy** between veterinarians, physical therapists and horse owners. These difficulties are exacerbated by the fact that many horses suffer **low grade and chronic lesions**. The major clinical sign is always

Table 16.4 Conditions alleged to cause back problems in horses for which there is currently no definitive scientific evidence

General category	Specific problems
Vertebral subluxation	Subluxation of thoracic or lumbar vertebral bodies and articular processes Malalignment of dorsal spinous processes in thoracic or lumbar region
Disk injuries	Intervertebral disk prolapse and herniation
Peripheral nerve injuries	Pinching of peripheral nerves to epaxial structures of the thoracolumbar spine

Table 16.5 Techniques known to be used to treat back problems in horses

General category	Individual methods
Rest	Box rest followed by period at pasture
Management	Replace saddle and/or use sheepskin numnah Change stable and work routine Attempt reschooling Attention to rider's equitation
Medical treatment	NSAIDs by oral, parenteral or local injection Muscle relaxants Sclerosing agents injected locally
Physiotherapy	Heat therapy: Infra-red or heat lamp Poultice, charges or counter irritation Shortwave diathermy Light therapy Lasers Solarium Ultrasonic therapy; muscle stimulation; Faradism; cyclotherapy; magnetic field therapy; swimming and hydrotherapy; graduated exercise program often combined with other forms of physiotherapy
Manipulative therapy	Osteopathy/chiropractic in the standing animal or under general anesthetic
"Natural medicine"	Acupuncture Conventional Laser beam therapy Radionics ("black box") Homeopathy Iridology Faith healing
Surgical removal	Compound fracture of withers Overriding dorsal spinous processes

a loss or reduction in performance whatever the underlying pathogenesis; other clinical signs may be more difficult to precisely define.

MANAGEMENT OF BACK INJURIES

The list of treatments for thoracolumbar disorders in horses is extensive (Table 16.5) and many of these methods will be given in combination, either at

the same time or concurrently (e.g. rest, medical treatment plus some form of physiotherapy). As yet there are few lines of therapy that have been objectively assessed for efficacy and there is also no doubt that some of the methods listed are used simply as placebos.

This lack of precise data results in some therapies becoming fashionable with owners and trainers: a few years ago surgery was often requested for back problems, then swimming became very popular, followed by manipulative procedures. It looks now as if the trend for the future may be in natural medicine (e.g. acupuncture). It should also be noted that many of these types of treatment are performed by non-veterinarians; some are qualified physiotherapists, but a considerable proportion are not. However, there appears to be an encouraging trend to set up rehabilitation centers for performance horses where physiotherapy is being used properly and to good advantage.

Much is talked about **manipulation** for treatment of equine back disorders. This line of therapy, which includes chiropractic and osteopathy, is now routinely performed throughout the world. It is reported to give immediate, but transient, relief to horses with back injuries. It does not always address the underlying pathogenesis of the thoracolumbar condition, which may be why recurrence of signs is common. However, it is encouraging to note that in recent times some real science has gone into investigating the potential of chiropractic for therapy and its mode of action, although no critical or controlled trials of its efficacy or the exact mode of its action have yet been published. The technique is performed either in the standing animal or under general anesthesia.

CONCLUSIONS

Back problems are an **occupational hazard** in racing and performance horses. The conditions that may result are often difficult to diagnose accurately, but it is worth remembering that some horses can perform badly without suffering from a back problem, some horses can perform adequately in spite of having a back problem, and spontaneous recovery from many types of back problem is quite common.

Finally, the simple recourse to a period of **rest** followed by a **graduated program of exercise** is all that is required in many cases. This can often be supplemented by various techniques of physiotherapy. Surgery is limited to resection of overriding spinous processes in selected cases where the diagnosis has been confirmed by radiologic examination and local anesthesia of interspinous spaces. Further studies on the biomechanics of the vertebral column and pathology of thoracolumbar injuries are essential to better understand pathogenesis, and from this sounder principles for therapy can be established.

INTRODUCTION

With the advent of **equine protozoal myeloencephalitis** (*q.v.*) and **West Nile virus** (*q.v.*), neurologic diseases of horses have become increasingly significant worldwide. Since the laboratory diagnosis of those two diseases is not straightforward, and other diseases need disparate treatments and offer a different prognosis, there is increasing pressure on clinicians to make the correct clinical diagnosis.

In the neurologic examination of the equine patient, it is important to remember that the objective is to make an “**anatomic diagnosis**”, i.e. establish in which neurologic structures the lesion(s) are likely to be in order to result in the observed neurologic signs.

Mentation, cranial nerve reflexes, cutaneous reflexes, tail and anus function and gait should be carefully examined. Is the lesion **central** (i.e. brain or spinal cord) or in the **lower motor neuron unit** (lower motor neuron cell body, peripheral nerve, neuromuscular junction or muscle)? Can the signs be explained by a **focal lesion** or are they likely to be due to a **multifocal or diffuse disease**? The answer to those questions will dramatically narrow down the possible differential diagnoses and will determine the choice of diagnostic tests.

This chapter aims to provide the equine practitioner with a synopsis of the clinical findings, diagnostic tests, treatment and prognoses for common neurologic disorders.

CONGENITAL AND DEVELOPMENTAL PROBLEMS

HYDROCEPHALUS

The congenital form of hydrocephalus is rare in newborn foals. When it does occur, it is usually due to **cerebral malformation** and accumulation of fluid in the **ventricles**. The head may or may not be grossly enlarged or dome shaped. Most foals with **congenital hydrocephalus** die shortly after birth but cases can be diagnosed later as incidental findings. **Severe dystocia** (*q.v.*) may be associated with the condition if the head is grossly deformed.

Acquired hydrocephalus is also occasionally observed and is usually due to **adhesions** secondary to bacterial meningitis or intracranial hemorrhage. Adhesions obstruct the normal outflow of **cerebrospinal fluid** (CSF). The head is sometimes, but not always, grossly enlarged. Foals with acquired hydrocephalus may be obtunded. As intracranial CSF pressures increase, **seizures** (*q.v.*) may ensue.

CSF analysis in congenital hydrocephalus is usually normal. In acquired cases, it may reflect the primary disease. In foals, the fontanelles of the cranium are not open, thus ultrasonography is not useful. Computed tomography or magnetic resonance imaging is potentially the best means to obtain an **ante mortem diagnosis**.

There is no practical form of treatment with congenital or acquired hydrocephalus. The prognosis for long-term survival is poor.

CEREBELLAR ABIOTROPHY

Cerebellar abiotrophy is suspected to be an inherited disorder with an 8% incidence in some **Arabian** family lines. It is also considered an inherited disorder in Oldenburg light-breed horses and in Eriskay and Gotland ponies. Either gender can be affected. The diagnosis is based on breed, history and clinical signs. The signs may be present at birth, but can be difficult to recognize in foals <1 mo of age. The clinical signs are characterized by **jerky head movements** and **hypermetria/dysmetria**. Affected foals assume a **wide-based stance** at rest and may fall over backwards if asked to back up or elevate the head. As the foal ages, it will appear **strong but ataxic** and continue to exhibit a **rhythmic head bobbing** or head tremors, characteristic of cerebellar disease (*q.v.*). Blindness and gait paresis are not features of this disease.

There are no ante mortem tests. The CSF is normal. There is no treatment and affected foals should be euthanased because they may injure themselves or their handlers. Cerebellar abiotrophy is confirmed at post mortem by a cerebellum that weighs <10% of the weight of the whole brain, histologic evidence of thinning of the granular and molecular layers of the cerebellar cortex and degeneration of the Purkinje cells.

JUVENILE EPILEPSY OF FOALS

Juvenile epilepsy in foals is probably not a form of true inherited epilepsy. It is speculated to be a type of **pediatric seizure** that reflects the neonate's low seizure threshold in response to **temporary derangements**. The temporary derangements can be caused by toxic, metabolic, physical, infectious or circulatory disorders.

A form of **idiopathic epilepsy** is occasionally reported in suckling and weanling foals, in particular those of the **Arabian** breed. Seizures begin between 1 and 12 mo of age. Several seizures may occur immediately prior to presentation. The seizures are characterized by episodes of **sudden loss of consciousness** with or without tonic-clonic activity. Affected foals can experience **temporary central blindness** (which can last a few hours to a few days). **Head trauma** due to thrashing is a common complication. Seizures do not usually persist into adulthood.

Once other causes for seizures have been ruled out, a diagnosis of idiopathic epilepsy can be given. Although the disease is **self-limiting with age**, seizures must be kept under control (Table 17.1) to avoid permanent brain damage or head trauma. Initial anticonvulsant therapy with **diazepam** (5–20 mg IV) repeated two or three times will usually control the seizures. For maintenance anticonvulsant therapy, affected foals should be kept on **phenobarbital** (100–500 mg PO s.i.d. or b.i.d.) for a minimum of 10–14 days, or as long as is needed to avoid recurrence of seizure activity. Treatment with phenobarbital should be dose adjusted so that seizures can be controlled but the foal not overly sedated. Monitoring blood levels of the drug is advised and the **non-toxic therapeutic range** is approximately 5–30 µg/mL. The lowest dose that controls seizures should be used, as phenobarbital may sedate the foal and **discourage nursing**. The dose must be tapered down over 2 weeks before being discontinued, as abrupt discontinuation may precipitate seizures.

Table 17.1 Guidelines for selected anticonvulsant drugs used to treat seizures in adult horses and foals

Drug	450 kg adult horse dose	50 kg foal dose
Initial therapy		
Diazepam	50–200 mg IV slowly	5–20 mg IV slowly repeated 2–3 times
Phenobarbital	2–5 g IV	250–1000 mg IV
Pentobarbital	To effect	150–1000 mg IV
Xylazine	300–1000 mg IV	Not advised
Maintenance therapy		
Phenobarbital	1–5 g PO b.i.d. (monitor blood levels)	100–500 mg PO b.i.d.

Pediatric epilepsy generally subsides as the foal ages, as long as seizure-related brain damage has not occurred. If **blindness** persists in the postictal phase, vision usually returns within a few days after seizure activity is controlled. The incidence of recurrence after puberty is unknown.

CERVICAL VERTEBRAL MALFORMATION

Cervical vertebral malformation (CVM) describes a group of malformations and malarticulation abnormalities of the cervical vertebrae of horses. It is a common cause of **ataxia** (*q.v.*) in horses all over the world and affects any breed of horse, but particularly **Thoroughbreds**. The disease stems from bone and joint malformations and is seen as two broad categories. Younger horses and foals are predisposed to **deformation** of the vertebral bodies with malarticulation and subluxation on flexion, while the spinal cord compression in older horses is generally due to **osteoarthritis** of the caudal articular processes.

The disease in young horses may be a form of a developmental orthopedic disease, i.e. related to **rapid skeletal growth** in genetically predisposed horses. Cervical vertebrae in those animals have lesions of osteochondrosis and epiphysitis similar to those seen in the limbs. Familial predisposition, high dietary energy intake and trauma to the neck probably all play a role, as young, large, fast-growing animals (often males) are affected.

An accident or injury to the neck is sometimes in the history, and clinical signs may have an abrupt onset. Mild to moderately affected horses show **symmetrical ataxia** with circumduction of the **pelvic limbs**, especially when the animal is made to walk in small circles. Proprioceptive deficits, toe dragging, dysmetria and varying degrees of upper motor neuron weakness (assessed by pulling on the horse’s tail at a walk) are also present. Thoracic limb deficits are usually less severe than pelvic limb deficits. The “**slap test**” for laryngeal adduction (*q.v.*) may be absent but there are no cranial nerve deficits. Neck pain or stiffness may be present, particularly in older horses.

The neurologic examination and plain radiographs of the vertebrae (C1–T2), while the horse is standing with the neck in a neutral position, are the most important diagnostic aids. In younger horses plain film radiographs reveal **stenosis of the vertebral canal**, often at C3–4 or C4–5. A corrected **minimum**

sagittal diameter (the ratio of the absolute minimum sagittal diameter of the vertebral canal to the sagittal width of the vertebral body) of <0.5 is highly suggestive of a compressive lesion at C3–4 or C4–5.

Enlarged caudal epiphyses, a caudal extension of the dorsal aspect of the vertebral arch across the ventral articulation site of adjacent vertebrae, vertebral malalignment and degenerative/osteoarthrosis-like changes in the articular processes often coexist. Greatly **enlarged articular processes**, with osteophytes, associated with hypertrophy and fibrosis of synovial membranes and joint capsule, can cause acute onset compression in older horses. **Myelography**, a technique used to assess spinal cord compression by the injection of radiodense contrast medium into the subarachnoid space, may be useful in determining the extent of cord compression and should be performed on horses in which surgical decompression and/or vertebral fusion are being considered.

In a research setting, the radiographic and neurologic deficits may be reversed in young (≤ 1 yr of age) animals by confinement (to limit further injury to the cord) and a severely protein- and energy-restricted diet. On the whole, however, the prognosis for return to athletic function of horses with CVM is poor. Affected horses may become so ataxic that they become a danger to themselves and horse handlers. Humane destruction is then advised. **Surgical fusion** of the vertebrae has been used to treat, and may improve, affected horses, but residual deficits often persist.

OCCIPITOATLANTOAXIAL MALFORMATION

This rare syndrome is thought to be inherited in the **Arabian** and related **Haflinger** breeds. Some affected foals are born dead. Survivors may be neurologically normal at birth then develop degrees of ataxia and paresis. Other surviving affected foals have no neurologic abnormalities but exhibit **restricted head and neck movement**.

Palpable and audible crepitus may or may not be present with manipulation of the head or neck. **Scoliosis** is occasionally present as well. Radiographically, various malformations of the occiput, atlas and axis are apparent. Most often, the dens is hypoplastic and the occiput and atlas are fused. There is no treatment. Surgical attempts at stabilization have generally not been successful. Humane destruction is advised.

EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

Equine degenerative myeloencephalopathy (EDM) is a disease of **young horses** of any breed, although a familial tendency has been observed in certain Appaloosa, Standardbred and possibly Morgan lines. The disease is thought to be related to **vitamin E deficiency** associated with lack of green forage, or the feeding of heat-processed pelleted rations. A history of vitamin E deficiency is, however, not evident in all cases. **Neuroaxonal dystrophy** in the brainstem and spinal cord results in gait abnormalities.

EDM is rarely seen in horses ≥ 4 yr of age. Symmetrical ataxia, hypometria and paresis usually appear in animals ≤ 6 mo of age. The disease is **progressive**, but the clinical signs have generally stabilized after the animal reaches 6–12 mo of age. Signs may be more severe in the pelvic than the thoracic

limbs. Clinically the disease can be difficult to distinguish from cervical vertebral malformation (*q.v.*).

The diagnosis is based on the characteristic clinical signs and lack of abnormal findings on plain cervical radiographs. Decreased serum vitamin E concentrations $\leq 1.5 \mu\text{g/mL}$ are sometimes (but not always) present.

Dietary supplementation with 6000 IU of **vitamin E** can be effective when initiated early. Response to therapy in one study was seen within a few weeks and continued for over a year. **Low selenium supplements** should be chosen in order to avoid selenium toxicities (*q.v.*) when high levels of vitamin E are being supplemented. Large amounts of **fresh green forage** should be made available. The signs may improve or stabilize with therapy, but many animals do not completely recover.

There are no findings on gross pathology, but histologic examination of the brain and spinal cord reveals degenerative lesions such as swollen axons in white and gray matter of the caudal brainstem and spinal cord.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY (NEONATAL MALADJUSTMENT SYNDROME)

Hypoxic-ischemic encephalopathy (HIE) is a manifestation of **perinatal asphyxia syndrome** and in humans is clinically defined as a syndrome of disturbed neurologic function in an infant at or near term during the first week after birth, manifested by difficulty with initiating and maintaining respirations, decreased reflexes, altered level of consciousness, and often seizures.

Foals should have a thorough **physical examination** in case other organs, such as the renal and digestive systems, are involved. Typically, affected foals are **normal at birth** but show signs of central nervous system (CNS) abnormalities within a few hours. However, some foals are obviously abnormal at birth and some will not show signs until 24–36 h of age. HIE is commonly associated with **adverse peri partum events**, including dystocia (*q.v.*) and premature placental separation (*q.v.*), but a fair number of foals have no known peri partum period of hypoxia, suggesting that HIE in these foals results from unrecognized acute or chronic **hypoxia in utero**.

A wide spectrum of clinical signs are associated with HIE and range from mild obtundation with loss of the suck reflex to generalized seizure activity. Rarely, spinal cord disease can be the only presenting sign.

Intensive supportive care (*q.v.*) is critical to the survival of a foal with HIE. Therapy for the various manifestations of hypoxia-ischemia involves control of seizures, general cerebral support, correction of metabolic abnormalities, maintenance of normal arterial blood gas values, maintenance of tissue perfusion, maintenance of renal function, treatment of gastrointestinal dysfunction, prevention/recognition/early treatment of secondary infections and general supportive care. It is important that seizures be controlled as **cerebral oxygen consumption** increases five-fold during a seizure (see Table 17.1). Parenteral antibiotics (2.2 mg/kg ceftiofur IV b.i.d.) are indicated if sepsis is suspected. Nutritional and respiratory support may be necessary. Correction of acid-base, electrolyte and glucose abnormalities is indicated. With intensive supportive care, 75–80% of HIE foals will survive. In survivors, the condition usually stabilizes by 2–3 days of age and improvement is noted by Day 4.

The neurologic signs often resolve in the reverse order in which they appeared. Complete recovery may take up to 3 mo. Failure of passive transfer of **colostral antibodies** concurrent with HIE is associated with a poor prognosis.

INFLAMMATORY AND TOXICO-INFECTIOUS DISEASES

BACTERIAL MENINGOENCEPHALITIS/BRAIN ABSCESS

Bacterial meningoencephalitis is a **suppurative inflammation** of the meninges. The condition is fairly uncommon in Equidae. In the adult horse, it may be associated with **brain abscesses** due to *Streptococcus equi* or *Strep. zooepidemicus*. Bacterial meningoencephalitis in neonatal foals is primarily caused by Gram-negative enteric bacteria (*Escherichia coli*, *Enterobacter* spp., *Salmonella* spp.), or *Streptococcus* spp., *Staphylococcus* spp., *Actinobacillus equuli*, *Klebsiella* spp., *Listeria monocytogenes*, and *Pasteurella* spp. Mixed infections may also occur.

Concurrent systemic illness is usually not evident in the adult horse (although on rare occasions previous infection with *Strep. equi* has been documented). The most common cause in neonates is **generalized septicemia** due to failure of passive transfer of colostral antibodies, and **hematogenous dissemination** of the bacteria to the CNS. In the latter case, a history of omphalophlebitis, polyarthritis, pneumonia, uveitis and other local infections is usually present.

The early signs of **meningitis** are non-specific but usually include fever, anorexia and obtundation. A stiff neck and hyperesthesia may also be present. Passive manipulation of the head and neck can elicit a **pain response**. As the disease progresses, **severe obtundation** or coma, hypertonia of limbs, paresis and tetraplegia are common clinical signs. Opisthotonus, intermittent prolapse of the third eyelid, and seizure activity may be observed.

Affected animals may or may not be **febrile**. It is important to exclude from the differential diagnosis tetanus, hepatoencephalopathy, equine protozoal myelitis, viral encephalitis (*q.v.*) and, in the foal, hypoxic-ischemic encephalopathy (*q.v.*) or metabolic disturbances (glucose or electrolyte and acid-base disturbances).

There are no changes in blood tests that are specific for bacterial infection in the CNS. The specific diagnosis depends on **CSF analysis**. An increased CSF white blood cell (WBC) count (≥ 5 cells/ μ L), represented primarily by neutrophils, an increased total protein and decreased glucose levels (to $\leq 50\%$ of the serum glucose value) are common findings. The CSF, which can be clear or turbid, should be **Gram stained** and cultured for microorganisms, though the results may be unrewarding. In foals with failure of passive transfer, blood or other body fluids should be cultured in an attempt to identify the organism.

Antimicrobial therapy should be based on culture and sensitivity along with the capacity of the drug to cross the **blood-brain barrier (BBB)**. The antibacterial agent should be highly lipid soluble, non-ionized and poorly protein bound to optimize penetration. In the early stages, or if microbial culture of CSF or other body fluids is negative, empiric treatment with bactericidal, IV delivered antibiotics is advised. Recommended antibiotics include **trimethoprim-potentiated**

sulfonamides (20–35 mg/kg IV b.i.d. or t.i.d.), or a third generation cephalosporin (**ceftiofur** 5–10 mg/kg t.i.d.), in combination with **benzylpenicillin** (20 000–50 000 IU/kg IV q.i.d.). Aminoglycosides such as **gentamicin** (6.6 mg/kg IV s.i.d.) could also be given in combination with penicillin, but as meningeal inflammation subsides, they may not penetrate the BBB as effectively. Only the cephalosporins and trimethoprim-potentiated sulfonamides have adequate penetration at all times. Therapy should be prescribed for a minimum of 6–8 wk. Tetracycline does not penetrate the BBB and should be avoided.

Additional treatment with anti-inflammatories such as 1.1 mg/kg flunixin PO or IV b.i.d. is also recommended. Anticonvulsant therapy (see Table 17.1) may be necessary.

Residual neurologic signs may persist or recur after treatment, especially if there is brain or vertebral abscessation. The long-term prognosis for such cases is grave.

WESTERN, EASTERN AND VENEZUELAN ENCEPHALOMYELITIS (WE, EE, VE)

These equine alphavirus encephalomyelitides are of **public health significance** because humans are susceptible hosts. Interepizootic maintenance of the virus depends on reservoir host–mosquito cycling. Reservoir hosts include birds, rodents and reptiles. The virus may persist in these reservoirs and periodically spreads from the focal host to the bird population and is then amplified via bird–mosquito–bird transmission. **Epizootic outbreaks** tend to occur in late summer in warm and humid conditions that favor the mosquito population. **Standing water** favors larval development. Epizootics decline with the onset of cool and dry weather.

The distribution of EE (also known as EEE) (*q.v.*) is primarily across the Atlantic and Gulf Coast regions in the USA. Serious outbreaks have occurred in eastern Canada, the Caribbean Islands, Central and South America. Over the last 30 years, the disease has become less prevalent due to the widespread use of vaccines and mosquito control programs. EE is transmitted to the horse mainly by *Culiseta melanura*, *Aedes sollicitans*, *A. vexans* and *A. canadensis*. EE is associated with a **high mortality rate** (up to 90%). Both humans and the horse are considered “dead-end hosts”.

WE (*q.v.*) occurs primarily across the western and mid-western USA, west-central Canada, Mexico and South America. It is transmitted primarily by *Culex tarsalis*. The mortality rate in the horse is 10–50%.

VE (*q.v.*) occurs primarily across Central and South America, Texas and the southern USA. Mexico was declared free of VE in 1990. Several species of mosquitoes can transmit VE. The wild reservoirs are not identified. Infected horses develop viremia and can serve as an **amplifying host**, i.e. mosquitoes may become infected by feeding on the viremic horse. The mortality rate for VE is 30–90%.

Clinical signs of EE, WE and VE are generally similar and differ only in detail. These diseases frequently affect **younger horses** (1–2 yr of age), although horses of any age can be affected. A low grade infection may be present, characterized by low grade viremia, fever, lymphopenia and neutropenia. A generalized febrile illness may be observed and can be characterized by

anorexia, obtundation, tachycardia, diarrhea (VE), lymphopenia and neutropenia. A few horses may die in this stage of the disease. **Myeloencephalomyelitis** is classically characterized by clinical signs suggesting **diffuse cortical disease**. Affected animals may become obtunded, unresponsive or irritable. Head pressing, leaning on walls or fences, compulsive walking, circling, blindness, lack of menace response, cranial deficits, or an unsteady gait may be present. Clinical signs progress within 12–48 h. Death is usually preceded by recumbency, irregular breathing, cardiac arrhythmias, coma and convulsions. Survivors may recover over a period of weeks but may have residual deficits (“**dummies**”).

Based on clinical signs, the major differential diagnoses for alpha viral encephalitis include West Nile virus hepatoencephalopathy, rabies, equine protozoal myeloencephalitis, cerebrospinal nematodiasis, leukoencephalomalacia and bacterial meningoencephalitis (*q.v.*).

Serology, hemagglutination inhibition, or complement fixation tests are useful adjuncts to the ante mortem diagnosis, but most cases can be diagnosed based on neurologic and CSF examination, with the concurrent presence of a fever. The changes in **CSF analysis** consistent with EE, VE or WE include neutrophilic leukocytosis, increased total protein concentration and xanthochromia. Occasionally CSF eosinophilic pleocytosis may be seen with EE. **Paired serum titers** may also be helpful in supporting the diagnosis, though titers can **cross-react** between EE and WE. Paired serology is necessary for surviving horses in areas where WE prevails.

There is **no specific treatment** for any of these encephalitides. The prognosis for EE is grave, and it is poor for WE and VE.

At necropsy, diffuse meningoencephalitis, patchy congestion and hemorrhage of the brain are present grossly. Occasionally, occipital or cerebellar herniation has occurred due to brain swelling. Histology reveals a combination of neuronal and parenchymal necrosis, hemorrhage and meningitis. Neutrophilic infiltrate or eosinophils may be present.

For **prevention**, killed inactivated **vaccines** containing EEV and WEV are available (e.g. Encevac T, Intervet Inc., Equiloid, Fort Dodge Animal Health or Cephalovac, Boehringer Ingelheim Pharmaceuticals Inc.). Vaccination followed by a 3–4 wk booster is advised. Most manufacturers recommend yearly revaccination thereafter, however in enzootic areas, semi-annual vaccination is recommended. Brood mares should receive a booster 4–6 wk prior to parturition to maximize colostral antibody levels. Foals should be vaccinated at 2, 3 and 4 mo of age and then receive booster vaccinations at approximately 10 mo and every 6 mo thereafter. Breaks in vaccination protection have been documented. One survey reported that 17% of the cases of EE had been vaccinated within the preceding 7–12 mo, and 5% in the preceding 6 mo. **Mosquito control**, such as minimizing areas of standing water around stables, is also necessary.

WEST NILE VIRUS MYELOENCEPHALOMYELITIS

The West Nile virus (WNV) (*q.v.*) is a **mosquito-borne flavivirus** in the Japanese encephalitis complex, and is endemic in Africa and Asia. West Nile virus was first identified in the West Nile district of Uganda in 1937, and has

since been found in other parts of Africa, Eastern Europe, West Asia, the Middle East and the USA. It is maintained in cycles involving birds as vertebrate hosts and mosquitoes as vectors. The virus is transmitted by at least 10 genera of **mosquitoes** and has been identified in more than 100 species of **birds**, notably the American crow. Antibodies or disease have also been shown in humans and an impressive range of animals, from alligators to bears to horses. **Birds appear to be the only animal with sufficient viremia to infect mosquitoes.**

There are significant strain differences between isolates across the world and even between virus isolates within a given geographic region, which may be expressed by **differences in resulting clinical signs**. Genome data strongly suggest that the virus causing the 1999 New York epidemic/epizootic was introduced from the Middle East. Equine cases from the USA, Italy and France reported mainly spinal cord signs.

Clinical signs are referable to an **encephalomyelitis** but can be subtle. Increased rectal temperature, asymmetrical paresis or ataxia, and muscle fasciculations are reported to be the most common clinical signs in horses in the USA. Cases from Israel may show more signs of encephalopathy such as behavior changes.

The most commonly used WNV laboratory test is based on **IgM capture ELISA on serum or CSF**, further confirmed with plaque reduction neutralization. CSF cell counts and protein content can be normal in up to 75% of cases.

Treatment is supportive and includes the use of **anti-inflammatory medications**, e.g. 1.1 mg/kg flunixin PO s.i.d.–b.i.d.; fluids, e.g. maintenance of 30 liters of **lactated Ringer's** per day; **antimicrobials**, e.g. sodium benzylpenicillin 12 500–100 000 IU/kg IV b.i.d.; and **slinging of recumbent horses**. Unlike herpes myeloencephalopathy (*q.v.*), the use of corticosteroids is probably contraindicated.

An **equine vaccine** is available in the USA (West Nile Innovator, Fort Dodge Animal Health) but, rarely, fully vaccinated horses have developed clinical disease. Mortality rates in **horses** with **West Nile** encephalitis are reported to be 20–30% with some survivors having residual deficits. Neuropathologic lesions consist of mild to moderate, non-suppurative polioencephalomyelitis.

RABIES

There are six viruses in the genus *Lyssavirus*, family *Rhabdoviridae*, including rabies. Rabies virus (*q.v.*) is present in most continents except Australia and Antarctica and is restricted from some islands such as UK, Japan and New Zealand by quarantine of animals, although UK regulations for quarantine have been recently eased, and for many countries replaced with vaccination-based controls. There are approximately 700–1000 reported human cases per year worldwide.

In **endemic areas**, the frequency of rabies in livestock coincides with epizootics in the sylvatic reservoirs (skunks, raccoons, foxes and bats). The disease is usually transmitted to the horse via a bite wound from an infected wild animal. Less frequently, horses are infected by the bite of an infected domestic animal such as a dog or cat but the wounds are rarely identified.

After entry, the virus remains localized for periods that vary from days to many months, resulting in a large variability in the incubation period from

weeks to months. After virus multiplication in the connective tissue and muscle at the site of injury, virus is spread by replication in Schwann cells or by axoplasmic transport (it does not replicate in axoplasm). Early replication occurs in dorsal root ganglia and this correlates with the tingling sensation at the bite or scratch site seen in the prodrome of some human cases. After initial replication in the dorsal root ganglia, the virus disseminates rapidly and selectively in the CNS to infect neuronal cells of the brainstem, hippocampus, the subcortical nuclei, the Purkinje cells of cerebellum and limbic cortex. In the second phase, the virus spreads via the **nerves** (not blood) to diverse sites such as the eye, salivary gland, papillae of tongue, heart, hair follicles of skin, and some muscles. The clinical course of the disease is related to the dose and site of inoculation (i.e. proximity to the brain) and pathogenicity of the specific virus strain. In horses, **natural infection is invariably fatal**.

Classically, rabies in the horse (*q.v.*) has been described in two forms, depending on the neural structures predominantly targeted: **dumb** (medulla and the spinal cord), and **furious** (limbic system). In most cases the clinical signs of the specific forms tend to overlap or appear concurrently. The broad range of clinical signs often makes equine rabies difficult to diagnose. Although **aggressiveness** and **indiscriminate attack** are alerting clinical signs, rabies in the horse does not invariably manifest as the furious form. The initial clinical signs often include **progressive ascending ataxia** and paresis, lameness, colic, dysphagia, hyperesthesia or fever. A spectrum of other clinical signs have been described, but loss of tail and anal sphincter tone, and loss of sensory perception of the pelvic limbs often precede death. The disease **rapidly progresses** once clinical signs appear and may quickly render the animal recumbent. Horses usually die of **cardiac or respiratory arrest** 4 days or so after the onset of the clinical signs. Survival up to 10–15 days has been reported, but is uncommon.

Rabies is a **reportable disease** in most countries, and horses showing suspicious signs or with a known exposure to a suspected rabid animal should be isolated and observed.

There is no definitive ante mortem test that is fast enough or accurate enough to be clinically useful. CSF analysis may be helpful, but is not always abnormal in rabid horses. Serology and **positive fluorescent antibody testing (FAT)** on skin, cornea or salivary gland may aid in the ante mortem diagnosis, but false positives, false negatives and difficulties in interpretation hinder their usefulness. The characteristic eosinophilic **intracytoplasmic Negri bodies**, found in the hippocampus and Purkinje cells of the cerebellum at post mortem, are pathognomonic for rabies but are not present in all cases. They are more likely to be present in horses that survive >4 days. Thus, the definitive diagnosis can usually only be made at necropsy, and by FAT on the brain and/or spinal cord. The FAT, which can detect the disease in 98% of infected animals, remains the most accurate test.

The currently marketed inactivated rabies vaccines are thought to be safe and effective. **Annual vaccination** of horses against rabies is recommended in areas where the disease is endemic. Although the horse is moderately susceptible to rabies, transmission from a rabid equid to a human has not been documented. If an **unvaccinated horse** is bitten it should **not** be vaccinated immediately but isolated for 6 mo and vaccinated 1 mo before the end

of quarantine. If at any stage exposure to rabies is confirmed the horse should be euthanased immediately.

Regulations and quarantine protocols for rabies vary between countries and geographic regions within countries. For specific recommendations regarding human and animal post-exposure procedures, practitioners are advised to consult with federal or national authorities and physicians.

EQUINE HERPESVIRUS 1 (EHV-1) MYELOENCEPHALOPATHY

Myeloencephalopathy is caused by **equine herpesvirus 1 (EHV-1)** (*q.v.*), which is the same virus that causes abortions. There is no breed or gender predisposition, but foals are less likely to be affected with neurologic signs. It has been reported in almost all countries and may occur in outbreaks. It has also been seen after vaccination with a modified live virus vaccine. Respiratory disease may or may not precede onset of neurologic signs, and may be associated with abortion “storms” within a herd.

The onset of **EHV-1 myeloencephalopathy** is acute, and the signs are rapidly progressive (over 36–48 h). It can be characterized by **spinal cord signs** alone, or less commonly, in combination with **cranial nerve deficits**. The pathogenesis is suspected to be an immune-mediated mechanism in the endothelium of blood vessels of the CNS. The underlying lesion is a **vasculitis of CNS arterioles**. There is evidence to suggest that EHV-1 (*q.v.*) is neurotropic and as part of its normal life cycle establishes latency in sensory ganglia, specifically the trigeminal ganglion, from which virus can be reactivated.

Horses may be febrile at the onset (41°C). Signs may vary from a subtle abnormal gait to dog-sitting, progressing to recumbency. **Urinary incontinence** and **bladder distension** are common in the early stages. Decreased tail tone and perineal hypalgesia may be present, along with subsequent constipation. Head signs (cranial nerve deficits, obtundation or vestibular signs) are less frequent. Affected horses are **generally** alert and have a **good appetite**. The signs may stabilize quickly or progress over several days. Complications associated with recumbency (bronchopneumonia, decubiti) may occur.

CSF analysis may reveal **xanthochromia** with marked protein elevation (100–500 mg/dL). There are no changes in blood tests that are specific for EHV-1. Virus may be isolated from nasal swabs, transtracheal wash, CSF, endometrial tissues or buffy coat and is **good evidence** for the disease. Poor virus isolation from CNS may be due to virus bound to antibody. A 4-fold or greater rise in serum antibody titer between acute and convalescent samples collected 10–14 days apart is helpful.

The differential diagnosis includes equine protozoal myeloencephalitis, rabies, cervical vertebral malformation, polyneuritis equi, trauma, aberrant parasite migration, sorghum neuritis-cystitis, and perhaps equine degenerative myelopathy (*q.v.*).

There are no specific treatments for EHV-1. **Supportive care** is essential. Deep bedding, laxatives, enemas, manual rectal evacuation, urinary catheterization and antimicrobial therapy for secondary infections (bronchopneumonia, cystitis) may be necessary. The use of corticosteroids in the acute phase (dexamethasone, 0.1–0.25 mg/kg b.i.d. IM or IV for 1–3 days) is controversial but could be attempted if bacterial infection of the CNS has been ruled out.

Corticosteroids also have a depressant effect on lymphocytes, which may be undesirable in cell-associated viral infections such as EHV-1. Since the CNS lesions appear to be immune mediated, vaccination of horses showing neurologic signs could **worsen** the disease.

Recovery may support the validity of the diagnosis of EHV-1 infection. With EHV-1, complete recovery over several days or months is possible, although **residual neurologic deficits** may remain in some cases.

Histopathologic lesions include endothelial necrosis (characterized by accumulation of neutrophils), vasculitis and thrombosis in small arteries along the meninges. White and gray matter of brain and spinal cord may be affected. Multifocal lesions along the neuraxis may be present, in addition to evidence of vasculitis in nasal passages, lungs and endometrium.

The prophylactic value of **EHV-1 vaccines** (*q.v.*) has not been fully evaluated but vaccination in the face of infection cannot be advised. The EHV-1 vaccines probably provide some immunity to the **respiratory disease** but not to infection, thus the virus can still cause abortion or neurologic disease. It also appears that EHV-1 antibodies are involved in the **pathogenesis** of EHV-1 myeloencephalopathy. A regular vaccination program is still recommended (every 3–4 mo) to maintain antibody titers considered protective for the respiratory and abortive form. Stress (shipping, weaning, castration, foaling) and exogenous corticosteroid administration to pregnant mares can result in activation and shedding of EHV-1 in carriers.

PROTOZOAN MYELOENCEPHALITIS

Equine protozoal myeloencephalitis (EPM) (*q.v.*) is due to infection of the CNS with an as yet poorly characterized protozoan parasite. The putative agent has been named *Sarcocystis neurona* (*q.v.*) but the life cycle and natural history remain unclear. It is most commonly seen in horses that have been in North or South America but appears to be rare and has not been shown to cause disease in native, untraveled horses outside of the American continent. There has so far been no report of EPM in donkeys or mules.

Most cases occur during spring and summer and are seen in racing and **performance animals**. Clusters of cases have occasionally been seen, but affected horses appear to be dead end hosts not capable of transmitting the infection.

The disease definitive host is the **opossum**, and secondary hosts include the armadillo, the striped skunk, the **raccoon** and possibly cats. Horse owners should recognize that exposure to opossums poses the major threat to their horses. Exposure to armadillos, skunks, raccoons and especially cats is unlikely to pose a problem.

Most horses develop ataxia, paresis and muscle atrophy (all are often asymmetrical), and occasionally behavioral changes are seen. As the disease progresses, sensory deficits, obtundation, focal sweating, lameness, cranial nerve dysfunction (head tilt, pharyngeal or facial nerve paralysis), monoplegia and reflex loss may be observed. Neurologic signs are generally progressive and then stabilize. Marked **asymmetrical muscle atrophy** may persist.

There is no definitive ante mortem diagnostic test. Routine CSF analysis is often normal. Serology looking for antibodies is useful to rule out disease but has a low positive predictive value. CSF antibodies may be found in the absence

of CNS infection. The combination of clinical signs and a **positive response to therapy** has been used as a presumptive diagnostic tool. Electromyography can help localize lower motor neuron (gray matter) involvement.

At necropsy, a multifocal, non-suppurative myeloencephalomyelitis (with or without different stages of *Sarcocystis* organisms) may be present. There is an apparent topographic predilection for the spinal cord and brainstem. The lesions occur randomly in gray and white matter. Microscopically, widespread perivascular cuffing with inflammatory cells (macrophages and lymphocytes with occasional eosinophils) is present, along with edema, axonal spheroids and necrosis. The organisms may appear as basophilic meronts in rosettes or clusters but are difficult to find, especially if the affected animal has been treated.

Therapy is based on the use of **antifolate drugs**. The only currently licensed drug is **ponazuril** (Marquis), which is formulated as a paste containing 7 doses at 5 mg/kg dose PO s.i.d. The recommended treatment duration is 28 days (4 paste syringes). **Many horses relapse** after therapy is discontinued. The phenomenon may relate to the inability of the drugs to affect the encysted organism. The folic acid inhibiting effect should be monitored by observing the **complete blood count** for neutropenia and/or thrombocytopenia. Caution is advised when treating pregnant mares, as long-term use of these drugs may suppress the developing bone marrow of the fetus.

An **EPM vaccine** (Fort Dodge Animal Health) is licensed. Long-term efficacy studies have not yet been published.

Equine protozoal myeloencephalitis appears to be a treatable, but not necessarily curable disease. Horses with signs localized to the brainstem often respond best to therapy. Euthanasia may become necessary if there is extensive muscle atrophy, ataxia and loss of athletic capability.

TETANUS

Since the advent of routine vaccination of horses against tetanus (*q.v.*), this **highly fatal** disease has become less frequent although isolated cases still occur in most parts of the world. The cause of tetanus is *Clostridium tetani*, a ubiquitous spore-forming rod found in the soil and feces of many animals. The organism requires anaerobic, necrotic conditions, such as those found in contaminated, deep, puncture-type wounds, so that it can vegetate and produce its **potent exotoxin**. The toxin disseminates from the local wound and gains access to the CNS, hematogenously and through the lymphatics, where it localizes in the gray matter of the spinal cord and inhibits the release of inhibitor neurotransmitters, particularly **glycine** and **γ -aminobutyric acid (GABA)**. This “disinhibition” results in **uncontrolled tetanic extensor muscle spasms**.

Most horses showing signs of tetanus have a history of sustaining a laceration to the face, lower limbs or tail, or a puncture wound to a hoof. Enteric infection has been implicated in cases in which a wound could not be identified. The incubation period varies from hours to 2 wk but is usually 7–9 days. The initial clinical signs are characterized by gait stiffness, but generally progress to elevation of the tail head, erect ears, **trismus (lockjaw)**, flare of the nostrils and **prolapse of the third eyelid** (which can often be induced by flicking the muzzle). Difficulty in eating and drinking, muscle tremors and fever often develop. Recumbency rapidly ensues and death occurs due to uncontrolled

Box 17.1 Treatment aims in horses showing clinical signs of tetanus

1. Destroy the organism with cleansing of the local wound and parenteral administration of benzylpenicillin (20 000–50 000 IU/kg IV q.i.d.)
2. Neutralize the toxin with the antitoxin (1500–20 000 IU, SC or IV or IM s.i.d.)
3. Provide sedation and relief from muscle spasms with acepromazine (0.04–0.10 mg/kg IV, IM q 4–6 h), or diazepam (0.01–0.4 mg/kg IV, as needed) in combination with xylazine (0.5–1.0 mg/kg IV or IM)
4. Provide intensive supportive therapy, including IV fluids (e.g. lactated Ringer's solution at a minimum of 30 liters per day), feeding alfalfa cube slurry via nasogastric tubing, moving the animal to a darkened quiet environment, and placing the animal in a sling to prevent falling
5. Muscle relaxants (e.g. methocarbamol, Robaxin-V Fort Dodge, 10–20 mg/kg q.i.d. or diazepam 50–200 mg IV every 6–8 h) may be effective in controlling the muscle spasms and pain in some animals
6. Recumbent horses will require labor-intensive care
7. Anticonvulsant therapy (see Table 17.1) may be necessary
8. Intrathecal tetanus antitoxin is no longer recommended

muscle spasms and convulsions, respiratory paralysis and cardiac arrest. If the disease has not stabilized by Days 3–4, most animals will become recumbent and die by Days 4–5. The mortality is 50–80%.

There is no definitive ante mortem diagnostic test for tetanus. The CSF analysis is normal. Circulating levels of tetanus toxin are very low and difficult to detect. The diagnosis is based on clinical signs and wound history.

Unvaccinated horses that have sustained a wound require both **tetanus antitoxin** (for immediate passive protection) and a **toxoid** booster (for “acquired” longer term protection). A wounded but previously vaccinated horse requires only the tetanus antitoxin. Treatment aims in horses showing clinical signs of tetanus are listed in Box 17.1.

For horses showing signs of tetanus, the prognosis for survival is good:

1. If the initial wound was treated properly and the horse received parenteral antibiotics (metronidazole, 20 mg/kg b.i.d.) and the antitoxin early in the course of the disease
2. If the disease has stabilized and not progressed after 4–5 days
3. If the horse remains ambulatory and able to eat and drink
4. If the animal was vaccinated within 1 yr prior to sustaining the wound.

Tetanus is a **preventable disease**. Pregnant mares should be vaccinated (*q.v.*) with the toxoid 2–4 wk prior to parturition to ensure transfer of anti-tetanus antibodies to colostrum. Newborn foals suffering failure of passive transfer of colostrum should receive one dose of the antitoxin. All horses should probably be vaccinated with the toxoid at 3–4, 6 and 12 mo of age to ensure protection, although there is some concern that this regimen may interfere with the foal's natural development of anti-tetanus antibodies. Tetanus toxoid and tetanus antitoxin can be given at separate sites at one time, to

ensure both immediate and long-term protection. Due to the susceptibility of horses to tetanus and the potential for highly contaminated wounds, yearly vaccination is advised.

TYZZER'S DISEASE (*BACILLUS PILIFORMIS*)

This sporadic disease, named after Ernest Tyzzer who initially described the syndrome in 1917, is caused by *Bacillus piliformis*, a Gram-negative, filamentous bacterium. Affected foals are usually between 1 wk and 1 mo of age. Infection is thought to occur through oral ingestion of the organism from soil, or from feces of another infected mare or foal. **Stress** and **rapid growth** are thought to be predisposing factors.

Affected foals die due to severe fulminant **acute hepatitis** and **hepatoencephalopathy**. Icterus may or may not be present. **Seizures**, often the presenting clinical sign, may not be responsive to anticonvulsant therapy. Foals quickly become comatose, succumbing 24–36 h after the onset of clinical signs. Ante mortem diagnosis of Tyzzer's disease (*q.v.*) is difficult to make because of its rapid progression. Although the organism should be sensitive to penicillin or oxytetracycline, the condition is usually so advanced when clinical signs become apparent that treatment may be ineffective.

At necropsy, the organism is detected by histologic identification of bacteria in the liver. The organism can only be cultured by mouse or chick embryo inoculation. There is little epidemiologic information on this infrequently reported disease, therefore methods for prevention are unknown.

METABOLIC DISORDERS

HEPATOENCEPHALOPATHY

Hepatoencephalopathy is the result of severe liver disease and is thought to cause cerebral signs through:

1. Ammonia acting as a **neurotoxin**
2. Endogenous **diazepines** produced by the small intestine and not metabolized by the liver
3. An imbalance of **GABA and glutamate** (disrupted glutamate transporter and receptor function)
4. **Perturbed monoamine neurotransmission** as a result of altered plasma amino acid metabolism
5. Altered **nitric oxide synthase (NOS)** expression.

In adult horses, hepatoencephalopathy has been reported in association with acute hepatic necrosis due to administration of the tetanus antitoxin (*q.v.*), or with liver disease due to ingestion of the **hepatotoxic pyrrolizidine alkaloid-containing plants** (*q.v.*) e.g. **ragwort** (*Senecio*) or **rattlebox** (*Crotalaria*). In foals, hepatoencephalopathy can be caused by infection of the liver with *Bacillus piliformis* (**Tyzzer's disease**) (*q.v.*), or less commonly with a congenital porto-systemic shunt.

Physical signs of liver failure, such as weight loss, ascites or photosensitization, may or may not be present, depending on the acuteness and duration of

liver dysfunction. **Neurologic signs** consistent with hepatoencephalopathy include anorexia, obtundation or coma, dementia or violent uncontrollable frenzies, compulsive circling or walking, head-pressing, yawning, blindness and ataxia. Horses are often afebrile and have difficulty eating and drinking. Convulsions may develop and, uniquely in the horse, **bilateral laryngeal paralysis** and roaring may occur. The cause for the latter signs is unknown. In foals with congenital portosystemic shunts, intermittent obtundation and ill-thrift have been described.

Elevations in the **serum enzyme activities** of AST, GGT, SDH, ALP, LDH and concentrations of bilirubin and bile acids should be found. Hypoglycemia is common in acute failure, hypoproteinemia if chronic. A systemic inflammatory response may be evident in the presence of **septic cholangitis** or **liver abscessation** (*q.v.*). **Liver biopsy** (*q.v.*) may reveal necrosis, cirrhosis or hepatitis, but in the early stages of liver disease it may be normal.

Treatment for hepatoencephalopathy includes removal of access to hepatotoxic plants and protection from sunlight, **lactulose** (dose not established, but over 100 mL may have an effect) to decrease ammonia absorption, administration of **polyionic dextrose-supplemented IV fluids** (maintenance of 30 liters per day), and feeding a low protein and high carbohydrate diet. Sedation with conventional anticonvulsants (see Table 17.1) may be required. A protective **head helmet** may prevent further injury to the skull, particularly if the horse is head-pressing or is having seizures.

The prognosis is generally poor, particularly for animals with pyrrolizidine alkaloid toxicity. Most animals die within a week to a month or so after the onset of clinical signs. A few adult horses with mild signs of hepatoencephalopathy and cholangiohepatitis may survive if treated.

HYPOCALCEMIC AND HYPOMAGNESEMIC TETANY

Although these conditions are not as common in equids as they are in ruminants, they have been reported from time to time. In horses, tetany due to **low ionized calcium** has been described in heavily lactating, recently transported mares. It is characterized by muscle tremor, paresis, ileus, staggering high-stepping gait, seizures and “**thumps**” (synchronous diaphragmatic flutter) (*q.v.*). Tetany, seizures and death have been described in critically ill foals with profound **hypomagnesemia**.

These conditions can be corrected by IV administration of calcium or magnesium salt solutions, given slowly **to effect**, with continual monitoring of cardiac function during therapy. Some animals may require several days of calcium supplementation in order to replace total body calcium deficits.

TOXIC CONDITIONS

LEUKOENCEPHALOMALACIA (MOLDY CORN POISONING, MYCOTOXIC ENCEPHALOMALACIA)

Leukoencephalomalacia is a toxic disease that has been reported as a sporadic cause of equine mortality throughout the world. It is caused by the toxin of the **mold** *Fusarium moniliform*. This mold grows on cereals (particularly corn)

that have been contaminated prior to harvest. Kernels damaged by drought and insects and harvested under high moisture or humidity are often infested with *Fusarium*. This is a **seasonal disease** (late autumn/fall to early spring). There is no breed or gender predisposition, but usually it does not affect horses <1 yr of age. The clinical disease is characterized by an acute, severe neurologic disorder, hepatic syndrome or sudden death. Mortality ranges from 40% to 84%.

The course of the disease varies from 6 h to a few days. The mortality rate and severity of clinical signs are dose related: high doses subacutely will induce **hepatic syndrome** and small doses chronically will induce **encephalomalacia syndrome** (*q.v.*).

Clinical signs are variable but fall into one of several syndromes. The encephalomalacia or **neurologic syndrome** is characterized by cerebral signs such as anorexia, obtundation, cranial nerve deficits, central blindness (unilateral or bilateral) and mania. Hyperesthesia, ataxia and paresis may occur. Recumbency, seizures and coma ensue. Icterus may or may not be present. The **hepatic syndrome** is characterized by obtundation, icterus, recumbency and coma. Horses with leukoencephalomalacia are usually not febrile. **Sudden death**, in the absence of preceding clinical signs, may occur. The differential diagnosis includes viral (rabies) or bacterial encephalitis, hepatoencephalopathy or cerebrospinal nematodiasis (*q.v.*).

CSF analysis may be normal or may reveal increased total protein, xanthochromia, neutrophilic pleocytosis and negative microbial cultures. Liver enzymes and blood ammonia may be elevated. A peripheral neutrophilia may be present. Culture of the suspected contaminated feed is usually not rewarding, but isolation of *Fusarium* or its toxin from the feed may be supportive. Isolation of the organism or toxin requires specialized laboratories.

There is **no specific treatment** for horses with leukoencephalomalacia. Removal of contaminated food is advised and supportive care is important. Fluid therapy, control of seizures (see Table 17.1) and anti-inflammatory drugs are indicated. The prognosis is guarded for affected animals. Survivors may have residual neurologic defects.

Necropsy reveals macroscopic brain cavitations, hemorrhage, liquefactive necrosis, edema and unilaterally enlarged hemispheres. Microscopic examination of the brain reveals malacia and cavitation in centrum ovale and corona radiata of the brain along with thrombi, vasculitis, edema, cellular infiltration of eosinophils and plasma cells. There are no specific lesions in the liver but mild, diffuse vacuolization of the hepatocytes, diffuse centrolobular hepatic fibrosis and bile duct proliferation may be observed.

YELLOW STAR THISTLE (NIGROPALLIDAL LEUKOENCEPHALOMALACIA)

In horses, ingestion of **yellow star thistle** (*Centaurea solstitialis*) or **Russian knapweed** (*Centaurea repens*) causes necrosis of the substantia nigra and globus pallidus ("**nigropallidal encephalomalacia**"). These plants grow predominantly in Australia and the western USA.

Affected horses have usually been eating the plants for several weeks (especially the thistles) and may become **addicted**. Necrosis of the basal nuclei

causes muscle rigidity in Parkinson's disease, and the clinical signs in horses may have a similar pathophysiology, although **limited to the face**. The muscles of mastication become acutely rigid with excessive jaw tone. The animal cannot chew, open or close the mouth completely. Masseter muscle fasciculation may be present. Horses may attempt to lap up feed and water with the tongue. Aimless wandering, ataxia or compulsive circling can also be seen.

The diagnosis is based on the clinical signs, history and post mortem findings. The disease has been diagnosed by **magnetic resonance imaging**. Although horses can be temporarily maintained on IV fluids or feeding by nasogastric tube, there is no specific treatment. Starvation and dehydration usually ensue. Affected horses should be humanely destroyed.

RYE GRASS AND DALLIS GRASS TREMOROGENIC MYCOTOXICOSES (STAGGERS)

There are several tremorogenic or staggers syndromes of horses. The most common is probably **rye grass staggers**. Rye grass staggers has been reported in New Zealand, Australia, the UK and the USA. The causative mycotoxin, **lolitrem B**, is produced by fungal endophytes that parasitize rye grass plants and seeds. Dallis grass (*Paspalum dilitatum*) poisoning (**paspalum staggers**) has also been described in horses and has been reported in Australia, New Zealand, the USA and Europe. The toxin is contained in the **sclerotia** (ergots) of *Claviceps paspali*, the fungus that parasitizes dallis grass.

Ingestion of mycotoxins usually results in **generalized muscle tremors** or spasms, ataxia, swaying, or head-nodding in horses. Excitement or stress will exacerbate the signs. Initially there is diffuse intermittent, mild muscle tremor that progresses to varying degrees of ataxia with a wide-based stance. Affected horses may sweat, stumble, and become recumbent. Despite the spectacular signs, the condition is **not generally fatal**, providing the horse does not injure itself with a fall. The clinical signs usually resolve with time (over a few hours to several days). Affected horses should be removed from affected pasture and handled as little as possible. **Diazepam** (50–100 mg/450 kg IV) may be required for sedation. The clinical signs reflect vestibulocerebellar, diffuse spinal or peripheral nerve involvement, but definitive neuropathologic changes are not observed at necropsy.

SPACE-OCCUPYING LESIONS

NEMATODIASIS (ABERRANT PARASITE MIGRATION, VERMINOUS MYELITIS)

There is little information available on the incidence of natural (non-experimental) verminous infection of the CNS in horses and mules. However, aberrant migration of *Strongylus vulgaris*, *Halicephalobus deletrix*, *Angiostrongylus cantonensis*, *Setaria* spp., *Draschia megastoma* and *Hypoderma* spp. (*q.v.*) into the brain or spinal cord of horses or donkeys has been described.

These parasites generally cause signs of forebrain or spinal cord diseases, depending on their sites of entry and/or migration. Horses of any age can be

affected. The clinical signs vary from peracute onset of **asymmetric ataxia and paresis**, to forebrain signs with asymmetric cranial nerve deficits. Occasionally signs of diffuse cerebral disease can occur.

The clinical course may be marked by **stabilization** of the signs (for days or weeks) followed by **re-exacerbation**, which may be associated with reactivation, multiplication and migration of the particular parasite within the CNS. Physical examination is usually unrewarding, as the affected animal may not show outward signs of parasitism unless lesions from warble (*Hypoderma* spp.) larvae (*q.v.*) are evident along the back. **Verminous myelitis** can be difficult to diagnose based on the clinical signs alone, but the presence of **eosinophils** and/or **neutrophilic pleocytosis** in CSF is strong supportive evidence. Parasitic larvae or ova are rarely detected in the CSF.

Larvicidal doses of anthelmintics such as **moxidectin** (Quest, Fort Dodge, 0.4 mg/kg once) or **fenbendazole** (10 mg/kg for 5 days), **corticosteroids** (e.g. dexamethasone 0.1–0.2 mg/kg) or non-steroidal anti-inflammatories (e.g. flunixin 1.0 mg/kg s.i.d.–b.i.d.), are beneficial. The prognosis for complete recovery is guarded, as some degree of **residual neurologic deficit** may persist.

TUMORS AND CHOLESTEROL GRANULOMA

Neoplasms of the CNS in horses are extremely rare. The signs include **gait abnormalities** if the tumor involves the spinal cord, or brain dysfunction if the tumor is intracranial. The signs can appear suddenly and progress rapidly; however, in some cases the signs may also be slowly progressive. There is no treatment for any of these CNS tumors.

The most common equine brain tumor, **pituitary adenoma** (*q.v.*), occasionally induces blindness and obtundation. Carcinoma, melanoma and lymphosarcoma (*q.v.*) of the cranial cervical and cranial thoracic spinal cord have caused **Horner's syndrome** (*q.v.*) in horses. Lymphosarcoma, neurofibroma and melanosarcoma (*q.v.*) occasionally infiltrate the sacrococcygeal vertebral canal, entrap the cauda equina and cause cauda equina syndrome.

Up to 20% of older horses have **cholesterol granulomas** (*q.v.*) associated with the choroid plexuses of the lateral and/or fourth ventricles. Although there is potential for expression of ante mortem neurologic deficits associated with these lesions, most are found incidentally at necropsy. They may represent a chronic granulomatous reaction to cholesterol crystal deposition associated with chronic choroid plexus vascular leakage. Mature cholesterol granulomas are generally circumscribed, firm, granular and yellow-brown and can attain an impressive size. Clinical signs have included altered behavior, obtundation, somnolence and reluctance to move, generalized seizures, ataxia, paresis and unconsciousness resulting from direct pressure lesions and secondary hydrocephalus.

TRAUMA

Of all equine neurologic conditions, **trauma to the CNS** is probably most frequently encountered. Horses that have reared, fallen over backwards and landed on the poll may lie in recumbency, semiconscious, for varying lengths of

time. Upon closer inspection, nystagmus, pupillary constriction or dilatation, blindness or facial paralysis may be present. The ears, nostrils, mouth and ocular fundus should be examined for signs of hemorrhage. If the animal is successful on attempts to stand, it may show profound obtundation and a base-wide stance, along with head tilt, circling, leaning toward the affected side or ipsilateral facial paralysis. Occasionally, seizures occur after head trauma.

The **petrous temporal** or **basisphenoid** bones are not uncommonly fractured when horses fall over backwards, and can result in **profuse hemorrhage** from ears and nose and asymmetric vestibular signs. Atlanto-occipital fractures, dens avulsions and cervical vertebral fractures are common in **foals**, whereas adult horses tend to fracture lower cervical and thoracolumbar vertebrae. **Somersault falls** result in hyperextension and hyperflexion injury to the cervical vertebrae. Horses that run directly into a solid object usually injure the thoracic region. Horses that slip and land in a dog-sitting position most often injure the **thoracolumbar spine**.

Horses (or foals) with fractured vertebrae will demonstrate a range of very mild to severe neurologic signs. If spinal cord injury (compression, swelling and edema) has occurred, clinical signs are more likely to be present. Fractures of C1–T2 usually result in **tetraparesis** and **ataxia** in all four limbs. A recumbent horse with a lesion at C1–C3 may not be able to raise its head. A recumbent horse with a lesion at C3–T2 may be able to lift its head but cannot rise into sternal recumbency (but not all horses with cervical fractures follow these rules). Fractures of T3–L6 may cause paraparesis, ataxia and sometimes dog-sitting. Fractures of the sacrum and coccygeal vertebrae often produce fecal and urinary incontinence and gait abnormalities in the pelvic limbs. Depending on the nature and severity of the injury, some degree of asymmetry may be apparent in any of these fractures. Localization of **hyporeflexia** and **loss of sensation** along the neck and trunk may help to approximate the cranial extent of the lesion. **Whole body sweating** may also be present in horses with a broken back or neck. Very occasionally, the Schiff–Sherrington syndrome (**extensor hypertonia**) has been observed in horses and foals with severe thoracic spinal injury.

Plain radiography is helpful in determining the exact site of the fracture but does not directly evaluate the degree of spinal cord injury. Some spectacular looking fractures on plain radiographs may not cause significant spinal cord compression, while other less dramatic fractures do not reflect the severity of spinal cord injury. In addition, it is not always practical to obtain radiographs of the skull, neck or thoracolumbar spine. Therefore, localization of the lesion is often dependent upon the clinical signs. If the horse is not distressed it may be worth waiting for 2–24 h before euthanasing the animal.

CSF analysis can aid in the diagnosis of CNS trauma, but frequently the analysis is not abnormal. The presence of hemorrhage in the CSF is supportive. Collection of CSF from the lumbosacral site is advised if there is any suspicion of elevated CSF pressure associated with a concurrent head injury. In such cases, collection from the **atlanto-occipital** site exacerbates the risk of caudal herniation of the occipital lobes of the cerebrum and cerebellum. As with radiographs, it may not be practical to collect CSF in the field situation. After CNS trauma, the findings on serial neurologic examinations are often of greater diagnostic and prognostic significance.

Medical management of acute CNS trauma is controversial and complicated by the lack of proof of efficacy of many of the commonly recommended drugs. **Corticosteroids** may help reduce spinal cord and brain edema. The use of corticosteroids in CNS injury is controversial and dexamethasone has not been proven to alter outcome. In the peracute stage of injury, IV **dexamethasone** (0.1–0.2 mg/kg) up to 3 times daily for the first 2 days or so has been used. Injured horses, particularly recumbent patients, may thrash and struggle and should be kept sedated with low doses of tranquilizers, e.g. xylazine 0.5 mg/kg IV.

Anticonvulsant therapy (see Table 17.1) may be necessary. One to two standard doses of the diuretics **dimethyl sulfoxide (DMSO)** (1 g/kg as a 10% solution in 5% dextrose) or **mannitol** (slow IV 20% solution at 0.25 g/kg) may be helpful in minimizing acute brain or spinal cord edema. Caution is advised because these agents may exacerbate intracranial hemorrhage, however this undesirable side effect has not been proven in horses. **Mannitol** may be useful if there is a concern about intracerebral pressure.

Clinical trials suggest that **hypertonic saline** (4–6 mL/kg over 10 min, followed by conventional fluids within 1–2 h) can rapidly improve systemic blood pressure. Antibiotics, e.g. **benzylpenicillin** (20 000–50 000 IU/kg IV q.i.d.) may be required for treatment of pneumonia, cystitis (*q.v.*) and decubiti in chronically recumbent neurologic patients. Repair of skull fractures is usually impractical but **surgical decompression** of the spinal cord and stabilization of luxations and fractures could be attempted if the horse's condition continues to deteriorate after medical therapy.

The prognosis for horses with head trauma must be guarded, particularly if **stupor** or coma persists beyond 2–3 days or the **pupils** become fixed and dilated. A **head tilt** associated with a skull fracture may persist although many horses can accommodate quite well. The prognosis for spinal cord trauma associated with vertebral body fractures or luxation is also generally guarded. Patients that remain ambulatory and show only mild ataxia have the best chance of complete recovery, but **residual gait deficits** may persist. In general, if the horse is unsuccessful in its attempt to stand after 3–4 days of recumbency, the prognosis is grave. However, providing spinal cord compression from healing bone or surrounding soft tissue or re-injury does not occur, the spinal cord may heal and the neurologic signs improve with time.

POST-ANESTHETIC CENTRAL NERVOUS SYSTEM DISORDERS

POST-ANESTHETIC MYELOPATHY

This is a rare complication of **general anesthesia** (*q.v.*) and is most commonly reported in heavier (300–470 kg) but younger (6–24 mo) horses in placed dorsal recumbency for routine surgical procedures. Either gender can be affected. Although frequently not documented, the condition is thought to be related to **hypotension** and **vena caval and aortic compression**, which result in hemorrhage, ischemic injury and necrosis of the gray matter, usually in the thoracolumbar spinal cord.

Less frequently, the lesions have also been observed in the cervical spinal cord. Recently **equine cerebrocortical necrosis** secondary to general anesthesia has also been recognized.

The clinical signs appear either immediately upon recovery from general anesthesia (the horse may have an unusually difficult time standing up) or shortly thereafter, and consist of varying degrees of areflexia, hypotonia, paraplegia and analgesia involving the trunk, pelvic limbs, perineum, tail and anus.

Bilateral femoral nerve paralysis (*q.v.*) and **paraplegia** (due to hemorrhage along the femoral nerves) have also been seen after anesthesia and present with nearly identical clinical signs. Reports of CSF analysis with these conditions are rare, but elevation in total protein concentration, neutrophilic and red cell pleocytosis and xanthochromia might be expected.

Aggressive anti-inflammatory therapy (1.1 mg/kg flunixin) and IV **DMSO** (1 g/kg as a 10% solution in 5% dextrose) may be helpful and is advised. Residual, sometimes marked permanent neurologic deficits should be expected.

POST-ANESTHETIC MYONEUROPATHY

Like post-anesthetic myelopathy (*q.v.*), this condition occurs in horses after general anesthesia (*q.v.*) and is thought to be due to **compartmental pressure elevation** affecting specific muscle groups and nerves, systemic hypotension, and resulting ischemic injury. There are degrees of muscle pain and swelling and paresis, usually on the dependent side. Evidence of **neuropraxia** (particularly radial or peroneal nerve paralysis) due to involvement of major nerves at the anatomically affected site may complicate the clinical picture. Elevation of serum muscle enzymes can be dramatic. **Myoglobinuria** (*q.v.*) is often present.

Treatment requires **intensive supportive care** aimed at maintaining hydration and correcting electrolyte and metabolic derangements. Recumbent animals should be placed in a sling or kept in a sternal position. Tranquilization (if necessary using 0.5–1.0 mg/kg xylazine) and analgesics, including NSAIDs such as 1.1 mg/kg flunixin b.i.d., are advised. Furosemide or corticosteroids should be avoided. Topical and/or systemic **DMSO** may be helpful. Massage, hydrotherapy and manipulation of the affected limb may encourage blood flow.

The prognosis is best for animals that remain standing. Some loss of muscle mass may occur with recovery. Adequate padding, elevation of the upper limbs, minimizing general anesthesia time, and maintenance of the mean arterial blood pressure above 65 mmHg will minimize the risk.

CONDITIONS OF THE LOWER MOTOR NEURON UNIT

BOTULISM

Botulism (*q.v.*) is caused by *Clostridium botulinum*, a Gram-positive, anaerobic, spore-forming rod that produces a toxin that acts as a powerful presynaptic blocker of acetylcholine release at the neuromuscular junction and preganglionic autonomic synapses. Progressive muscle weakness results. Horses are **extremely sensitive** to the toxin. All ages can be affected.

C. botulinum produces several types of toxins (*q.v.*) that are each antigenically distinct from one another but have similar effects. Horses are particularly susceptible to types B and C. Type B has been found in the soil along the mid-Atlantic seaboard and in Kentucky, whereas type C is found in Florida and Europe.

There are three major routes of infection: **forage poisoning**, which usually occurs in adults, and results from the ingestion of preformed toxin in grain or silage; **wound botulism**, which occurs rarely in horses and results from infection of a wound (similar to tetanus); and **toxico-infectious botulism**, which is most common in foals. In the latter, the spores vegetate in the gastrointestinal tract, liver abscesses, gastric ulcers, or in wounds and produce the toxin. This toxico-infectious form of botulism in foals has been referred to as the **shaker foal syndrome** (*q.v.*). Increased incidence of infection in foals has been loosely associated with stress and increased fat and steroid content in the mare's milk. Typically, affected foals are **strong and fast growing**. They are usually <8 mo old and often <8 wk old (foals as young as 1 wk have been diagnosed). Cases can occur sporadically or present as outbreaks in a particular geographic area. The incubation period ranges from 24 h to 7 days.

Progression of clinical signs can be rapid, over several hours, or take several days. Onset is marked by **flaccid tetraparesis**, dysphagia and muscle tremor, in both horses and foals. Foals may have milk dribbling from their mouths and nostrils as suckling ability may be impaired by poor tongue tone. Some strains appear to produce more brainstem signs than others. **Dysphagia** with pharyngeal paralysis can be the presenting sign. A weak tongue is common. **Muscle fasciculations** and profound **generalized muscle weakness** may develop. Pupils may be intermittently dilated and slowly responsive to light due to sphincter muscle paresis. Recumbency and hyporeflexia occur in the late stages of the disease. **Aspiration pneumonia** from failure to swallow, urine retention, ileus and constipation are common complications. Intercostal muscle paralysis may lead to death from respiratory failure. Inflammatory lesions in the bowel, such as gastric ulcers, are often seen and could be potential sites of bacterial colonization and toxin production.

In adults, differential diagnoses include pharyngeal or esophageal obstruction, severe dental disease, grass sickness in endemic areas, and other CNS diseases causing dysphagia such as rabies (*q.v.*). Additionally, in foals, hypoglycemia, septicemia and rarely rhabdomyositis/steatitis (*q.v.*) should be considered.

Diagnosis of botulism is presumptive and is based on clinical signs. *C. botulinum* can be cultured from feces or spores and can be found in the intestine, but the organism has also been isolated from normal animals. Detection of the toxin in serum or intestinal content is very difficult because levels are often too low for conventional laboratory methods. **Electromyography** may aid in diagnosis.

Aggressive treatment and intensive supportive care is imperative for survival and can often affordably be given only to foals. A **polyvalent equine type B antitoxin** is available in the USA (Veterinary Dynamics, Templeton, Ca). Best results are achieved when the antitoxin is given early in the disease process. The antitoxin is very expensive but considerably improves the prognosis. Nasogastric tube feeding and assisted respiration may be required to

minimize secondary complications. Wounds should be thoroughly cleansed. **Crystalline penicillin (benzylpenicillin 20 000–50 000 IU/kg IV q.i.d.)** is recommended to further reduce colonization and toxin production in the gut. Procaine benzylpenicillin, tetracyclines and aminoglycosides should be avoided because they may potentiate the paralyzing effects of the toxin.

Forage poisoning is usually fatal in adult horses unless they remain standing. Without supportive care (including mechanical ventilation and antitoxin treatment), mortality approaches 90% for foals ≤ 12 –48 h old. Older foals will die within 72 h. Prognosis is guarded if there is rapid onset of clinical signs (≤ 12 –36 h) and slightly better if the onset progresses over 2–4 days. If the foal recovers, weakness may last up to 3 wk.

Vaccination of pregnant mares with a **botulism type B toxoid** is practiced in some areas where **shaker foal syndrome** is common.

EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease (EMND) was initially documented in the northeastern USA but is now being recognized all over the world. EMND is equivalent to a type of human motor neuron disease and is characterized by the **degeneration** and loss of **motor neurons in the spinal cord and brain-stem** and neurogenic atrophy of skeletal muscle. The etiology is unknown but may be due to oxidative stress. Cases in North America consistently have a history of very limited access to grass and **low vitamin E** levels (*q.v.*), however this is not necessarily the case in European cases.

Clinical signs in classic cases are marked by **symmetrical muscle wasting** and weight loss, muscle trembling, sweating, and extended periods of recumbency. Animals adopt a “tucked up” stance similar to cases of **grass sickness** (*q.v.*), have a low head carriage, and shift weight when forced to stand. Affected horses “walk better than they stand”, probably because of the preferential denervation atrophy of type I fibers. Type I fibers are found in greater proportion in antigravity postural muscles. Denervation and contracture of sacrocaudalis dorsalis medialis, a muscle that has a high proportion of type I muscle fibers, leads to **elevation of the tail**. Excessive lipopigment deposition in the retina can be detected by fundoscopic examination in many affected horses.

The most consistent laboratory findings in EMND have been mild to moderate increases in muscle enzyme activity in the serum and **extremely low values of plasma α -tocopherol** (active form of vitamin E). Intestinal glucose absorption is decreased while results of xylose absorption tests are more normal.

Ante mortem diagnosis is based on the history, clinical signs, laboratory findings (elevated muscle enzyme activity and low plasma α -tocopherol concentration) and the demonstration of neurogenic atrophy in a muscle biopsy of sacrocaudalis dorsalis medialis. Some cases stabilize and regain normal weight with nursing care and administration of vitamin E; however, some of those relapse 3–4 years later.

HYPERKALEMIC PERIODIC PARALYSIS

Hyperkalemic periodic paralysis is characterized by intermittent episodes of muscular paresis and fasciculations, often resulting in recumbency. Exercise,

a period of rest after exercise, stress such as transport or athletic competition, or ingestion of alfalfa hay may precipitate episodes. Episodes are accompanied by a transient increase in **serum potassium** concentration (5.5–9.4 mEq/L) without major acid-base imbalances or high serum activity of muscle-derived enzymes. The disease occurs in young, heavily muscled, stock-type horses such as American Quarter Horses, Appaloosas and Paints and is similar to a well-described human syndrome. It is an inherited disease in the **Quarter Horse**: affected animals in this breed can all be traced to a common sire, and have a **gene defect** affecting sodium channels.

Between episodes, horses appear normal. The onset of a mild attack may begin with **repeated yawning** and intermittent flicking of the third eyelid or facial muscle spasms followed by **fasciculation and tremor** involving muscles of the flank, shoulders and neck. During an episode the horse is alert, appears distracted and reluctant to move, and may stumble and buckle at the knees. A severe episode, perhaps following forced exercise, results in severe tremor and tetany of many muscles with recumbency and sweating. This is followed by a state of flaccidity, possibly with depressed spinal reflexes. Episodes can be initially confused with colic, seizures or exertional rhabdomyolysis (*q.v.*). Attempts to move result in further tremor and tetany, although the horse remains alert. If the horse does not become recumbent, **profound paresis** manifested as gait deficits (swaying or staggering) or paresis of the hindquarters (dog-sitting) may be observed. **Respiratory stridor** is occasionally observed during episodes and has recently been reported in several neonatal foals thought to be affected with the condition. Episodes may last from 30 min to 1 h.

Hyperkalemic periodic paralysis is typically diagnosed by a combination of clinical signs and concurrent **serum hyperkalemia**. Electromyographic (EMG) examination during an episode reveals fibrillation potentials and myotonic discharges in most muscles. **Genetic testing** of tail hairs (Veterinary Genetics Laboratory, Davis) can detect the disease with a high degree of accuracy.

Attacks of tremor and tetany appear to be short lived, although treatment of horses during attacks with **IV fluids** containing calcium, sodium bicarbonate and glucose may shorten an attack. The diuretics **acetazolamide** (0.5–2.2 mg/kg PO b.i.d.) or **hydrochlorothiazide** (0.5 mg/kg PO b.i.d.) may also be effective but the true mechanism of action is unknown. They may stabilize the Na^+/K^+ pump at the level of the muscle membrane. When administered prophylactically, they appear to lessen the frequency and severity of attacks in horses known to be affected with hyperkalemic periodic paralysis. Limiting dietary potassium may also be helpful; low potassium commercial diets are available in some countries.

The severity and frequency of episodes reportedly lessen as the horse ages. The disease may be fatal in some severely affected animals. If an episode is triggered by an **anesthetic agent**, potentially life-threatening complications may be encountered.

MYOTONIA

Myotonia is the clinical sign of a skeletal muscle abnormality that results in a **prolonged contraction** of the muscle cell. Voluntary, mechanical or electrical stimulation of skeletal muscle produces episodes of prolonged contraction.

It has been reported in Morgan horses, Thoroughbreds, Standardbreds, Swedish half-breds, Appaloosas and Quarter Horse foals and in a Welsh pony. Heritability has not been proven in horses but **familial predisposition** is suspected. In other species a chloride channel defect has been demonstrated.

The disease is characterized by **generalized muscle stiffness** that improves with exercise and worsens with cold or anxiety. Hypertrophy of skeletal muscles may be present and production of a “**dimple**” on percussion is characteristic. Muscles of the hindquarters are most severely affected and usually are prominent. The exact cause is not known but the defect is thought to be at the level of the skeletal muscle cell membrane or transverse tubular system.

The clinical diagnosis can be made by seeing and feeling prominent and prolonged muscle contraction with “knotting” or “dimpling” following mechanical percussion. The clinical diagnosis is confirmed by **electromyographic examination**, which reveals bizarre spontaneous electrical discharges from affected muscle membranes.

Affected animals do not appear to be debilitated by the disorder, although limb deformity with contracture may occur. Phenytoin has not been effective in treating horses with myotonia.

SHIVERING, POLYSACCHARIDE STORAGE MYOPATHY AND STIFF HORSE SYNDROME

Three distinct syndromes characterized by hypertonia and hyperreflexia are recognized in horses.

Shivering is a neuromuscular disorder characterized by **abrupt onset excessive flexion** of muscles of the pelvic limbs and tail. Draft horses and Warmbloods are most often affected, ponies very rarely.

A defect in the myotactic reflex arcs or in the upper motor neuron pathways has been postulated. Walking the horse out of its stable in the morning often initiates signs. **Backing affected horses** will usually greatly exacerbate signs. Pelvic limbs are held in a fully flexed and slightly abducted position. Spasmodic contraction of the gluteal and flexor muscles of the limb produces the “shivering” of the muscle bellies which gives the disease its name. The leg may be held in this manner for several minutes. The tail head may be elevated and tremulous. Animals are usually completely normal between episodes.

Affected animals may still be able to work on the flat, but their jumping ability will eventually be impaired. The frequency and intensity of “shivering” episodes may gradually increase and affected muscle groups may waste. The long-term prognosis for athletic function is grave.

Equine polysaccharide storage myopathy (EPSM) is a myopathy recognized most often in draft horses and Quarter Horses. The disease is characterized by the accumulation of excessive glycogen or complex polysaccharides in principally type II muscle fibers.

Horses can present with signs of stiffness and exaggerated pelvic limb action similar to shiverers, or show muscle atrophy, paresis and recumbency. Exertional rhabdomyolysis is one of the most common signs of EPSM in Quarter Horses and has also been found in the other light breeds. The manifestations of EPSM may be subtle, with mild loss of muscle, energy, gait, and/or performance, or they may be catastrophic, leading to spontaneous or

post-surgical recumbency and death. Pathologic findings do not correlate with clinical severity.

The definitive diagnosis of EPSM at this time relies entirely on pathologic findings in muscle biopsies. Following PAS staining for glycogen the diagnosis may be obvious, with numerous fibers containing amylase resistant complex polysaccharide, or it may be subtle, with primary findings being overall atrophy and increased glycogen staining. Testing of pre- and 4 h post-exercise blood samples often reveals a mild to moderate increase in serum CK and/or AST. A specific metabolic defect has not yet been identified in EPSM horses. Clinical signs may improve dramatically with increased dietary fat. Diets low in carbohydrates, such as alfalfa pellets or commercially available diets, should be supplemented with 500 mL of vegetable oil per day.

Stiff horse syndrome may be the equine equivalent of “stiff man syndrome” in humans. It is characterized by muscle rigidity and episodic and often violent muscle cramps. This rare condition is associated with antibodies produced against the enzyme **glutamic acid decarboxylase (GAD)**, responsible for converting the inhibitory neurotransmitter GABA into its active form.

Clinical signs appear to wax and wane and range from mild muscle stiffness to sudden and often violent muscle contractions. Generally there is an insidious onset, and exercise intolerance associated with mild to moderate muscle stiffness may be the only initial clinical sign. This may easily be attributed to a primary myopathy, with pain on muscle palpation, although serum muscle enzyme concentrations remain in the normal range. If untreated, the degree of stiffness seems to progress and episodes of muscle spasms may become apparent. Between episodes the horse may appear normal. Clinical examination is generally unremarkable. Unlike EPSM, biopsies of semitendinosus are unremarkable. The most useful diagnostic test is detection of antibodies against GAD in serum and CSF, run in some human laboratories. Human patients are treated with benzodiazepines and glucocorticosteroid administration but use of these drugs has not been critically evaluated in equine patients.

Attempts should be made to stabilize the disease as good response to therapy with **prednisolone** 1–2 mg/kg has been recorded, although the prognosis is generally poor due to the apparent progression of this condition. There is a **welfare implication** as some of the spasms are likely to be very painful and there is the strong likelihood of disease progression.

STRINGHALT

Stringhalt is a motor disorder that can affect any breed and is of unknown etiology. The disease is characterized by **delayed protraction and excessive flexion of the hock** during progression and may affect one or both pelvic limbs. Possible associations include trauma and degeneration of the sciatic and/or peroneal nerves, generalized distal axonopathy, spinal cord lesions (e.g. EPM) (*q.v.*) and articular lesions within the hock and stifle joints. It occurs in both sporadic and epidemic forms. The **epidemic form** reported to occur in New Zealand and Australia has been associated with ingestion of certain plants, particularly **dandelion** (*Taraxacum officinal*) and **false dandelion** (*Hypochaeris radicata*), suggesting a toxic etiology, but a specific toxin has not been isolated.

Affected horses appear normal at rest but have a **characteristic involuntary hyperflexion and delayed protraction of the hock** when moving. The disorder may be unilateral or bilateral and can vary in severity from a slight exaggeration of normal movement to a motion wherein the rear foot strikes the belly. The limb may remain flexed for several minutes. When both pelvic limbs are severely involved, forward movement is only possible by a bizarre “bunny hopping” action.

With **chronic stringhalt**, there may be atrophy of distal limb muscles. Some horses with the epidemic form of stringhalt also have **thoracic limb involvement** evident as spasticity, toe scuffing and stumbling. In nearly all cases, the signs are exaggerated when the horse is **turning or backing**. The condition is most noticeable after the horse has rested, and cold weather may exacerbate it. **Inspiratory stridor** due to left laryngeal hemiparesis may also occur due to the involvement of the recurrent laryngeal nerves.

No consistent pathologic lesions have been documented in classical stringhalt but the endemic form is characterized by severe distal axonopathy of large myelinated fibers resulting in neurogenic atrophy of abaxial and laryngeal musculature. Why these cases present with hyperflexion and not paresis is not known, but involvement of the feedback system of muscle spindles to spinal cord is thought to be involved.

Stringhalt is diagnosed by the characteristic pelvic limb hyperflexion. The condition must be differentiated from fibrotic myopathy (*q.v.*) in which the foot is jerked suddenly downward and backward before being put to the ground. It must also be differentiated from intermittent upward fixation of the patella (*q.v.*) and the condition known as “shivering” (*q.v.*), which occurs primarily in draft and heavily muscled breeds.

The treatment for sporadic stringhalt consists of the **surgical removal** of the proximal portion (containing the Golgi tendon organs) of the lateral digital extensor tendon as it passes over the lateral surface of the hock. Some cases show an almost immediate improvement, with complete recovery within 2–3 wk. Other cases may take several months for significant improvement to occur and may never show complete recovery. Some cases of sporadic stringhalt may improve with rest. The majority of horses suffering from the epidemic form of stringhalt recover spontaneously without treatment once they are removed from pasture, however this can often be protracted from several weeks to months.

VESTIBULAR SYNDROME (HEAD TILT)

The **vestibular system** consists of receptors within the semicircular canals in the petrous temporal bone, the vestibular nerve that passes through the internal acoustic meatus, and nuclei in the rostral medulla and caudal cerebellar peduncles. The vestibular nerve does not leave the skull. **Acute asymmetric vestibular disease** is often due to head trauma (e.g. fracture of the petrous temporal or basisphenoid bones) or **osteoarthritis** of temporohyoid bones and subsequent hemorrhage into the inner and middle ear canals. Other causes of head tilt in the horse include equine protozoal myelitis, aberrant parasite migration, viral infection, tumors, neuritis of the cauda equina, otitis media interna or lightning strike (*q.v.*). Mycotic lesions of the tympanic bullae

may also extend into the middle or inner ear, involve cranial nerves VII or VIII, and result in facial paralysis and/or head tilt, respectively. An acute idiopathic vestibular syndrome has also been described in horses.

Neurologic signs are due to a loss of ipsilateral extensor tone and an increase in contralateral extensor tone. When unilateral this results in a **head tilt**, leaning and circling toward the affected side, and an ipsilateral ventral strabismus (accentuated by lifting the head). Nystagmus is rare. If present in unilateral peripheral vestibular disease, nystagmus is horizontal and the fast phase is directed away from the side of the lesion. In central disease, the nystagmus can be horizontal, rotary or vertical. Blindfolding the horse will exacerbate the clinical signs and should be done with care. The specific cause can sometimes be determined by radiography of the skull or CSF analysis.

Treatment of vestibular disease should be aimed at the suspected inciting cause. A head tilt attributed to acute trauma or equine protozoal myelitis will probably respond to treatment better than one attributed to otitis media interna or proliferative bony lesions of the hyoid or temporal bones. Many horses will not completely recover, but will accommodate for the visual and proprioceptive deficits, allowing them to function normally. Acute idiopathic vestibular syndrome in horses usually completely resolves.

HORNER'S SYNDROME

Horner's syndrome was first described by Swiss ophthalmologist Johann Horner in 1869. It is an eponym applied to the collection of clinical signs associated with pathology of the **sympathetic nerve supply to the head**. Symptoms can be caused by lesions anywhere in this sympathetic pathway. The horse is **susceptible** to Horner's syndrome because sympathetic postganglionic fibers from the cranial cervical ganglion are superficial as they pass over the caudodorsal aspect of the guttural pouch and course down the neck along the jugular groove, and hence are vulnerable to trauma or infectious conditions.

Common causes of Horner's syndrome in the horse include cervical trauma, guttural pouch infection (*q.v.*), neoplasia (*q.v.*), focal infections, foreign bodies ("choke"), periorbital disease (*q.v.*), perivascular injections and carotid artery ligation. Grass sickness (equine dysautonomia) (*q.v.*) results in **bilateral** Horner's syndrome.

Interruption or loss of sympathetic innervation results in **ptosis**, **droopy eyelashes**, and **enophthalmos** with protrusion of the third eyelid (the latter sign may be quite subtle). Myosis is not consistent in this species. **Sweating**, which may be seen on the side of the face, neck or shoulder, is a very early sign, the pathogenesis of which is not completely understood. If the lesion includes postganglionic sympathetic neurons, i.e. including or rostral to the cranial cervical ganglion, then sweating is restricted to the face.

Diagnosis of Horner's syndrome is made primarily on the basis of clinical signs. Physical examination or radiographs of the head or neck may help to identify the specific site of the denervation. A simple diagnostic test is the administration of **0.5% phenylephrine** (N.B. most commercial eye drops are a 10% solution). Twenty minutes after administration the ptosis and angle of the eyelashes (assess by standing in front of the horse) are significantly reduced.

The **treatment** of Horner's syndrome depends on the underlying cause of the denervation. The appropriate medical or surgical therapy for the inciting cause should be instituted. For example, palpable swellings over the site of perivascular injections should be cold or hot packed. Reversibility of the disorder is related to the seriousness of the neurologic injury. Neuron avulsion, severance, and invasion or destruction by neoplastic or infectious processes would usually be irreversible.

Stretching, contusive and inflammatory injuries (secondary to perivascular injection) may result in transient clinical signs (≤ 48 h) of Horner's syndrome. In general, the prognosis for these cases is good, but complete recovery may require several weeks to months. Horner's syndrome has been known to persist, in rare cases, up to 1 yr.

FACIAL NERVE PARALYSIS

Facial paralysis is fairly common in horses. The facial nerve and its branches (auricular, palpebral, buccal) innervate the ear, eyelids, lips and external nares respectively. Dysfunction of the facial nerve results in **drooping of the ear and lips** on the side of the lesion. The muzzle will lack tone and is therefore pulled to the opposite side. Areflexia of the **muscles of facial expression** is often observed and the animal may be unable to close its eyelid. As a result, **exposure keratitis** and corneal **ulceration** (*q.v.*) may be present. Occasionally, bilateral facial paralysis occurs and the horse will present with severe dysphagia. With chronic paralysis, facial muscle atrophy and hemi-spasm (grimacing) may be seen.

A common cause of facial paralysis is associated with **lateral recumbency** and pressure on the side of the face due to a halter and its metal buckles and rings. Facial paralysis due to recumbency usually only involves the nose and lips, but the ear and eyelid may droop due to direct pressure on the auricular and palpebral nerves. Other conditions, such as a **direct blow**, various **skull fractures** (e.g. mandibular, temporomandibular, petrous temporal, zygomatic arch or stylohyoid bones, or obtundation fractures of the face), or **lacerations** can also directly or indirectly involve the facial nerve. Pathology to the facial nuclei in the medulla oblongata results in facial nerve paralysis. **Equine protozoal myeloencephalitis** (*q.v.*) often causes such a lesion and can produce marked facial paralysis. Central lesions above the brainstem have also been rarely noted to cause ipsilateral facial paresis, due to interruption of corticobulbar tracts.

The **treatment** of facial paralysis is primarily symptomatic. Application of **ophthalmologic ointment** to the affected eye will help prevent keratitis sicca and ophthalmitis. **Anti-inflammatories** (1.1 mg/kg flunixin PO or IV b.i.d.) are useful in the management of facial paralysis due to lacerations and head trauma. **Antifolate antibiotics**, e.g. ponazuril (Marquis, Bayer), are indicated for EPM (*q.v.*).

Facial paralysis due to pressure associated with lateral recumbency will usually resolve in 2–3 days. The prognosis for facial paralysis due to laceration or skull fracture depends on the severity of the injury. In the absence of severe skin laceration, the prognosis is fair, although recovery may be partial or incomplete after weeks or months.

SUPRASCAPULAR NERVE PARALYSIS (SWEENY)

Damage to the suprascapular nerve is commonly due to an accident that involves **direct collision** of the horse's **shoulder** with another object. Typically, the owner may report that the horse ran directly into a tree, fence post or another horse several weeks prior to the onset of the shoulder muscle atrophy. As the suprascapular nerve winds around the front of the scapula, it is especially prone to shoulder impacts.

Damage of the nerve at the cranial border of the scapula results in **atrophy** of the supraspinatus and infraspinatus muscles (**sweeny**). The force of the impact can also involve the brachial plexus (the origin of most of the nerves that supply the shoulder and thoracic limb). If this occurs, in addition to supraspinatus and infraspinatus, other supporting structures, prominently those innervated by the radial nerve, will be denervated. Gait deficits will result due to **laxity of the shoulder joint**. The shoulder may subluxate or "pop" as it slips laterally and the thoracic limb is circumducted during forward motion.

Horses with suprascapular nerve injury treated with stall rest alone have a **good prognosis** for recovery of normal gait and return to performance; however, the recovery period may be prolonged. Shoulder joint instability has been reported to resolve in most horses within 3–12 mo after the original injury, allowing animals to return to pre-injury activities.

Exercise should be **restricted** while the joint is unstable. Surgery probably will result in a faster return to athletic function but should be delayed for several months. Surgery consists of removal of a 1.5 cm section of bone from the front of the scapula to relieve compression on the suprascapular nerve.

RADIAL NERVE PARALYSIS

The radial nerve derives its origin chiefly from the eighth cervical and first thoracic roots of the brachial plexus and innervates the extensor muscles of the elbow, carpus and digits and the lateral flexor of the carpus (ulnaris lateralis).

A common cause of radial nerve paralysis is **direct trauma** to the nerve as it crosses the musculospiral groove of the humerus. Such trauma often accompanies **fractures of the humerus**, kicks or falls on the lateral surface of the humerus or prolonged **lateral recumbency**. Radial nerve paralysis may also be a result of overstretching the nerve by **hyperextension of the thoracic limb**, fractures of the first rib or compression of the nerve by enlargement of axillary lymph nodes, tumors or abscesses in the cranial thorax or tumors of the brachial plexus.

The signs of radial nerve paralysis vary depending upon the degree and location of the injury. Unlike other species, the radial nerve in the horse does not have an autonomous zone.

Lesions at or near the elbow joint result in a "high radial nerve paralysis", which is characterized by a **dropped elbow, scuffing of the toe and inability to extend the distal limb joints**. Affected horses have great difficulty getting up and down and stand with the shoulder extended. The foot is knuckled over at rest and the animal collapses on the limb when forced to bear weight. In severe paralysis, dragging of the limb may damage the dorsal surface of the fetlock.

Lesions of the distal radial nerve result in **knuckling** of the carpus, fetlock and pastern joints. The animal can support weight on the affected limb if the metacarpus and distal limb are held in extension. If the injury occurs at the point of the shoulder secondary to humeral trauma, the suprascapular nerve may be paralyzed causing atrophy of supraspinatus and infraspinatus (sweeny) (*q.v.*). Occasionally, radial nerve paralysis will be accompanied by paralysis of the entire brachial plexus. In this case, the limb shows paralysis of the flexor and extensor muscles and is unable to bear weight.

Mild cases of radial nerve paralysis may present with subtle gait abnormalities. The horse may **stumble** when walking and may show a **sliding motion** of the foot when the limb is extended. Detectable sensory deficits resulting from radial nerve paralysis tend to be vague and vary among patients. Atrophy of triceps brachialis, extensor carpi radialis, ulnaris lateralis and digital extensors is present when radial nerve paralysis has existed for several weeks.

The diagnosis is made on the basis of clinical signs. If traumatic paralysis has occurred more than 2 wk prior to evaluation, needle EMG in the extensor muscles of the carpus and digits may be helpful in defining the extent of denervation.

Treatment is **palliative** and involves stall rest and bandaging with support bandages of the distal limb to prevent trauma to the dorsal surface of the fetlock. If a myopathy accompanies the radial nerve paralysis, anti-inflammatories, hydrotherapy and IV fluid administration may be indicated.

Most cases of **post-anesthetic radial nerve paralysis** resolve spontaneously within 24–48 h. For other types of radial nerve paralysis, the prognosis is guarded to poor and depends largely on the location and extent of the injury. If significant nerve regrowth is required for recovery, the prognosis is grave. Most cases of humeral fracture with associated radial nerve damage are euthanased due to the poor prognosis.

SCIATIC NERVE PARALYSIS

In horses, sciatic nerve paralysis is most frequently associated with misplaced **hypodermic injections** and/or **local abscessation** at the site of the injection. This condition is often seen in foals receiving IM injections. The sciatic nerve supplies both the tibial and peroneal nerves, and so paralysis is characterized by an **inability to flex and advance the limb**, such that it remains hanging behind the animal with the stifle dropped and extended. The dorsum of the foot rests on the ground, with the hock in flexion. The horse can bear some weight on the limbs since the femoral nerve innervates extensors of the stifle. Cutaneous hypalgesia may be present below the stifle.

Systemic administration of **NSAIDs** (e.g. flunixin 1.0 mg/kg s.i.d.–b.i.d.) and topical treatment of the area with hot or cold packs may be helpful. Lavage and drainage is appropriate if there is an abscess. Bandaging the lower limb may prevent further injury to the dorsum of the foot and coronary band. Several weeks of therapy and **nursing care** may be required. The prognosis for complete recovery depends on the persistence of clinical signs and the nature and severity of the injury to the nerve.

FEMORAL NERVE PARALYSIS

Femoral nerve paralysis has been reported in mares after **parturition** (*q.v.*), in horses after **general anesthesia** (*q.v.*), and rarely, after a penetrating wound to the caudal flank. The condition is characterized by **inability to support weight on the limb or extend the stifle** (the femoral nerve innervates the quadriceps muscle). The horse rests the limb with all joints in flexion. With bilateral involvement, the horse assumes a crouched position and has difficulty rising from recumbency. **Quadriceps atrophy** will occur within several weeks. Anti-inflammatories and analgesics are appropriate and some horses may benefit from a sling for support.

The prognosis for this condition must be guarded. Light-framed horses may eventually be pasture sound, but heavy-framed horses often break down in the contralateral limb. The prognosis for bilateral involvement is grave.

POLYNEURITIS EQUI (CAUDA EQUINA NEURITIS)

Polyneuritis equi is a distinct pathologic syndrome characterized by **chronic granulomatous inflammation** of various **nerve roots**, particularly the extradural spinal nerve roots of the cauda equina and cranial nerves. The etiology is unknown. The lesions produced by the disease bear some histopathologic resemblance to experimental allergic neuritis of rats, Coon hound paralysis of dogs and Guillain-Barré syndrome of humans, all of which are suspected to have an **autoimmune basis**. Anti-P₂ myelin protein serum antibodies have been detected in horses with confirmed polyneuritis equi.

Other etiologies that have been proposed include a hypersensitivity reaction following aberrant migration of helminth larvae, equine adenovirus, EHV-1 or equine viral arteritis infections (*q.v.*). There is no breed or gender predilection. The disease usually occurs in mature or aged horses, although it has been described in a yearling filly.

The onset of clinical signs is usually insidious and slowly progressive. In the initial stages of the disease, horses may show signs of **hyperesthesia around the tail head and gluteal region** and may rub and chew at this area. Later, hypalgesia or analgesia of the tail, perineum and penis or vulva and gluteal area will be observed. Tail tone is absent and the urinary bladder, urethral sphincter, rectum, anal sphincter and penis or vulva are paralyzed. This leads to fecal retention and urinary incontinence. The **bladder is atonic**, distended and easily expressed. Dribbling of urine causes scalding of the perineum and inner thighs. In males, the **penis** may be relaxed and protruding, with decreased sensation of the perineal skin. The preputial skin usually retains normal sensory function.

As the disease progresses, **pelvic limb weakness** may occur due to inflammation of the sacral and lumbar nerve roots and extension of the perineuritis to the lumbosacral plexus supplying the gluteal, sciatic and, rarely, the femoral nerves. Gait abnormalities are often subtle and asymmetric. Atrophy of the gluteal, biceps femoris and other muscles can occur. Cranial nerve signs may also be present: V, VII, and VIII are most commonly involved, resulting in atrophy of the temporal and masseter muscles, drooling, dysphagia and sensitivity around the head.

Involvement of the **facial nerve** results in unilateral or bilateral facial paralysis, which may lead to keratitis or corneal ulceration. A head tilt and other signs of cranial nerve dysfunction may also be present. Clinical signs resembling this disease may be seen in cases of instability of the caudal spine due to luxations or fractures, equine herpesvirus myelitis and sorghum intoxication (*q.v.*).

The diagnosis is based on clinical signs and post mortem findings. **CSF analysis** may reveal a mononuclear or neutrophilic pleocytosis and an elevated protein level. EMG abnormalities occur as a result of denervation of affected muscles. Circulating antibodies to bovine P₂ myelin protein have been demonstrated in a limited number of cases.

There is **no effective treatment**. Various routines of antibiotics as well as systemic, epidural and subarachnoid administration of corticosteroids have been attempted unsuccessfully.

Neuritis of the cauda equina is progressive and invariably fatal. Affected horses may be maintained for long periods of time with supportive care including manual evacuation of the rectum and catheterization of the bladder. Due to the severity of clinical signs, the progressive nature of the disease and the poor prognosis for recovery, euthanasia is usually the eventual outcome.

LEAD TOXICITY

Lead toxicity is relatively uncommon in horses, but is still occasionally seen in animals grazing on pastures near smelting industries where aerial fallout contaminates grass and hay. Lead-based herbicides and paint have also been associated with lead toxicosis in horses (see also page 292).

Dysphagia and roaring due to **laryngeal paralysis** (*q.v.*) are classical signs of lead toxicosis in horses and are probably the result of a peripheral neuropathy. Rarely, horses present with profound obtundation, ataxia and recumbency. Lead interferes with normal heme synthesis, thus erythrocytes have a decreased oxygen-carrying capacity. Peripheral and central nervous tissue is affected by the resulting anoxic-ischemic injury.

The diagnosis of lead toxicity based on blood levels of lead is not accurate because blood levels do not reflect total body lead content. Free RBC porphyrin estimations are not strongly correlated with lead levels. Urine lead and δ -aminolevulinic acid (≥ 200 mg/dL) levels are also variable, but **urinary excretion of lead (≥ 1 ppm) after chelation treatment** (*q.v.*) is strongly supportive of the diagnosis.

Horses may or may not be anemic. Basophilic stippling of the RBCs is occasionally present. Tissue analysis for lead, especially bones, liver and kidney, is helpful.

Treatment of horses for lead toxicity (*q.v.*) consists of removal of access to the source, and **chelation therapy** with **calcium sodium EDTA**. A suggested dose for chelation therapy is 50–100 mg/kg calcium sodium EDTA, slowly IV, s.i.d. or b.i.d. for 2 days then repeated as necessary at 3–4 day intervals.

The prognosis is poor for chronically exposed animals or if ataxia, recumbency or profound cerebral signs are present. In the acute stage, mildly affected horses may slowly respond to treatment.

GUTTURAL POUCH DISEASE (CRANIAL NERVES VII, IX, X, XI, XII)

Trauma, surgery or disease (mycosis, empyema, stylohyoid bone fracture) of the **guttural pouch** (*q.v.*) frequently results in neurologic signs because the facial (VII), glossopharyngeal (IX), vagus (X), spinal accessory (XI) and hypoglossal (XII) nerves, cranial cervical sympathetic trunk and ganglion lie in the lining of the guttural pouch.

The neurologic consequences of guttural pouch disorders include **dysphagia** (IX, X), **soft palate paresis and displacement** (IX, X), **laryngeal paresis** (X), **Horner's syndrome** (sympathetic trunk and cranial cervical ganglion) and **tongue paralysis** (XII). Occasionally, fungal plaques in the guttural pouch may spread to involve the facial nerve (VII) and mandibular nerve (a branch of cranial nerve V), which lie in the medial wall of the pouch, resulting in **facial paralysis** and **masseter muscle atrophy**.

The treatment of guttural pouch disease is discussed elsewhere (*q.v.*). In general, the neurologic signs associated with cranial nerve damage due to guttural pouch mycosis are unlikely to improve.

NEUROLOGIC ASPECTS OF "VICES"

INTRODUCTION

Behavioral disorders in the horse are often referred to as "vices" or stereotypical behavior. They are thought to be related to removing the horse from its natural environment (the free range), confining it, and thus interrupting free access to continual grazing and social contact with other horses. They are frequently annoying to owners, and occasionally dangerous for the horse. Treatment broadly consists of attempts to modify the environment, i.e. to improve it to a more natural state. Offering the animal distractions, including companions and toys, may help if major alterations in the environment are not practical. A more detailed consideration of behavioral problems is given in **Chapter 18** (*q.v.*).

CRIBBING

Cribbing (aerophagia, wind sucking) (*q.v.*) is a behavior in which the horse grasps an object (usually a fence or feed bunk) with the incisors and swallows air. **Aerophagia** may be associated with colic (*q.v.*), and cribbers will show **excessive wear on the incisors**. Some horses may accomplish "wind sucking" without grasping onto an object, by simply flexing the neck and "gulping" air.

A behavioral approach to therapy is given in Chapter 18 (*q.v.*). Alternatives that have been tried include cribbing straps, which inflict discomfort when the horse flexes the neck to swallow air and have been said to deter some horses. Surgical treatments include neurectomy of the spinal accessory (cranial nerve XI) nerve or surgical resection of sternocephalicus, omohyoideus and sternothyrohyoideus, all of which are neck muscles that function in the act in cribbing. Long-term follow-up studies regarding the efficacy of these techniques have not been published and some practitioners have observed that horses relearn cribbing, even after the surgery has been performed. These procedures may also leave cosmetic defects at the site of the surgery.

WOOD CHEWING

Wood chewing (*q.v.*) is associated with feeding low-fiber, high concentrate “complete ration” pelleted feeds, and **boredom**. It is often observed in stabled horses, but pastured horses (with access to grass) may also chew trees, fences or shrubs. Cold, wet weather appears to increase wood chewing. **Increasing the roughage** in the horse’s diet is the obvious treatment, but eliminating wood edges or providing toys or companions for stalled horses may also help.

COPROPHAGIA

Coprophagia (eating feces) is normal in foals, but adult horses will avoid eating manure unless they are starving or are very bored. It is esthetically unappealing but, more importantly, may increase the risk of transmission of parasites or bacterial or viral pathogens. Evaluation of the diet for adequate protein and fiber content is advised.

STALL WALKING AND WEAVING

Stall walking and weaving (*q.v.*) appear to be **exacerbated by stress**. The incessant activity causes the horse to spend less time eating, thus weavers and stall walkers often lose body condition. These behaviors are best treated by turning the horse out into a field or pasture. Numerous mood-altering, antipsychotic and sedative drugs have been tried, however improvements are usually temporary. The horse will often revert to weaving or stall walking after the medications are discontinued.

STALL KICKING/PAWING

Stall kicking and/or stall pawing in a horse without signs of colic usually reflect **frustration**. Horses may resent being confined and tend to exhibit these vices especially at feeding time. Stall kicking can cause injury to the horse. The only generally successful management is to turn the horse out to pasture.

SELF-MUTILATION

Self-mutilation usually affects **young stallions** but has occasionally been seen in geldings and mares. The behavior appears to be triggered by a stressful event, such as a major change in the breeding or exercise program, or relocation into a new herd.

Self-mutilating horses **obsessively bite** specific areas of their body (usually the thoracic limbs, flanks, pectoral area, stifle or thighs) and can inflict serious lacerations. Frequently, the horse will stare at the area, squeal, grunt, bite at the air, or spin in circles before biting at its body. Skin biopsies and other diagnostic tests are unrewarding. **Focal neuritis** (*q.v.*), seizures or abdominal pain should be considered as the differential diagnoses.

Treatment for this stereotypical behavior is to alter the environment, feeding, breeding or exercise patterns. A companion such as a goat, pony or barren mare may help. Castration has been suggested but may not be successful.

Antipsychotic or sedative drugs have also been tried, but must be used with caution since they may exacerbate the signs or produce undesirable side effects. Several progesterone hormone preparations have been used in controlling aggressive or hypersexual horses and may be temporarily helpful in managing self-mutilating horses. Sometimes, if a major change in a horse's environment is not possible, animals have been fitted with muzzles or neck cradles, or cross-tied to prevent serious self-injury.

HEAD SHAKING

Head shaking is most often noted in middle-aged horses during spring or summer. The syndrome appears to be progressive in many cases with increases in severity and loss of the characteristic seasonality.

The etiology is unclear but several causes have been suggested including middle ear disorders, ear mites, cranial nerve disorders, guttural pouch mycosis, dental periapical osteitis, allergic rhinitis and vasomotor rhinitis (*q.v.*). However, only very rarely can it be shown that correction of the abnormality leads to elimination of the head shaking.

Clinicians in California have determined that the condition appeared to be **light stimulated** in approximately 60% of affected horses. The close association of the optic and trigeminal nerves in the midbrain may allow optic stimulation to cause referred itching, tingling or electric-like sensations in areas innervated by branches of cranial nerve V, a condition similar to "photic sneezing" in man.

The majority of horses with idiopathic head shaking in one study in the USA showed improvement of signs after oral administration of **cypromethadine** (0.3 mg/kg b.i.d. q 12 h then after 7 days 0.4–0.5 mg/kg q 12 h), a drug with antihistaminic and antiserotonergic properties. This contrasts with studies performed in the UK where cypromethadine alone was ineffective but a **combination therapy** of **cypromethadine** and the sodium channel blocker **carbamazepine** (20–30 mg/kg q 6 h) resulted in very significant improvement in the majority of cases.

Trigeminal neuritis or **neuralgia** may be the basis of the underlying etiology of idiopathic equine head shaking, but no histopathologic lesions have been found. The etiology, as in the human equivalent, is not known. Head shaking is a frustrating syndrome, and although a particular case may respond to single or multiple management or therapeutic measures, the prognosis for cases of idiopathic head shaking is poor.

NARCOLEPSY/CATALEPSY

Narcolepsy is a REM-sleep disorder characterized by excessive daytime sleepiness and **striking transitions from wakefulness into rapid eye movement (REM) sleep** without passing through slow wave sleep. A syndrome that has the clinical appearance of narcolepsy has been noted in older horses (usually when undisturbed, e.g. in the back of a paddock) and has also been seen in newborn light-horse foals. It appears to be familial in some miniature horses.

The clinical signs can range from **buckling at the knees**, usually when the horse is quiet, to **total collapse and areflexia** with maintenance of some eye and facial responses and normal cardiovascular function. The syndrome resolves in some foals.

Demonstrating the existence of narcolepsy in horses by classical electroencephalographic techniques may prove to be very difficult as ongoing work indicates that horses, being prey animals, may normally be able to go into REM sleep directly from a period of arousal (i.e. after having one last look around to make sure there are no predators around).

Canine and human narcolepsy is associated with dysfunction of a group of neurotransmitters involved in sleep regulation and satiety, the **hypocretin** system. In narcoleptic foals, narcoleptic episodes are often associated with nursing, and it is intriguing that the hypocretin system is involved in the regulation of sleep as well as appetite.

The tricyclic antidepressant **imipramine** (1–2 mg/kg b.i.d. or t.i.d. PO) can resolve clinical signs, but is rarely indicated for long-term management.

INTRACAROTID INJECTION

Intracarotid injection is a common **iatrogenic** side effect of attempted jugular vein injection in the horse. Affected animals tend to have a violent and immediate reaction. The risk is relatively high because of the close anatomic arrangement of the carotid artery and the jugular vein in the neck. Attempted venepuncture in the lower half of the neck carries a greater risk. Reported histories of struggling to restrain the horse during venepuncture, difficulty entering the vein, obtaining a pulsatile jet of bright red blood on entering the blood vessel, and sometimes the presence of a hematoma at the injection site, suggest the possibility of accidental intracarotid injection.

The typical description is that the horse “drops off the needle”. The reaction begins while the needle is still in the neck. The horse will rear up on its pelvic limbs and fall on to its back or side. Some horses react by **collapsing suddenly**, dropping to the floor. After the initial reaction the horse may begin to seizure. Some animals may become comatose while others remain conscious but stuporous. The duration of the effects varies. Some animals will remain recumbent for a few minutes before standing and appearing dazed but otherwise normal. Severely affected horses may not regain consciousness. Following the initial violent reaction, other neurologic deficits (such as blindness or seizures) may be seen.

Histologically, lesions are most severe in the rostral brainstem and cerebrum on the ipsilateral side. Cytotoxic effects of the drug lead to endothelial injury, hemorrhagic foci, necrosis with attraction of macrophages and ultimately cavitation.

Treatment is empirical. Therapy should aim to minimize any further injury as a result of the reaction, and to support the animal until fully recovered. The seizing horse may require sedation with **diazepam** or **phenobarbital** (see Table 17.1). Treatment with corticosteroids and diuretics (**mannitol**, slow IV 20% solution at 0.25 g/kg) in the acute phase may help to minimize cerebral edema.

The prognosis is better if the injected substance is water soluble (such as many tranquilizers and analgesics). Intracarotid injection of a lipid-soluble substance (such as certain antibiotic preparations) produces a more serious and longer lasting effect. Animals showing signs of recovery early in the post-injection period have a better prognosis, and those that remain recumbent for prolonged periods have a poorer prognosis. **Residual effects**, such as blindness or varying degrees of incoordination, may be permanent. Neurologic problems secondary to head trauma suffered during the episode can occur.

GRASS SICKNESS (EQUINE DYSAUTONOMIA)

Grass sickness (*q.v.*) is a disease of horses at pasture. Affected animals have lesions of neuronal chromatolysis and loss principally in postganglionic sympathetic and parasympathetic neurons. The disease is prevalent in the UK, in restricted northern areas of continental Europe and in Patagonia, Argentina.

Younger horses (aged 3–8 years) are more commonly affected. Grass sickness is most often seen in horses **permanently at pasture**. Horses kept stabled have been affected, but this is rare. The cause of grass sickness remains elusive despite considerable research effort. Recent studies following the death of the exceptional Group I racehorse, DUBAI MILLENIUM in 2001, have, however, produced some interesting new leads. Fungal toxins have long been suspected but new evidence suggests that a *Clostridium botulinum* toxin (*q.v.*) may be involved in the etiology of grass sickness.

Horses **recently moved** to a farm are more likely to be affected than horses that have been grazing that same pasture for a prolonged period of time. The disease may occur with greater incidence after periods of cool, dry weather together with irregular ground frosts. The majority of cases occur in spring and early summer, with a smaller peak of incidence in the autumn; however, cases may be seen throughout the year. The disease is generally sporadic, but outbreaks have occurred.

Classical clinical signs include dysphagia, anorexia, cachexia, gut stasis, tachycardia, inappropriate sweating, trembling of axial and appendicular muscles, rhinitis sicca and ptosis. Animals that have severe signs have what is called **acute grass sickness**. Clinical signs are related to stasis of the entire gastrointestinal system, which in turn causes distension of the gut lumen with fluid. Abdominal pain is usually mild to moderate.

Gastric and small intestinal distension is frequently seen, and passage of a nasogastric tube may result in **copious reflux** of pungent, green gastric fluid. **Dysphagia** is invariably present at some time. Prehension and mastication of food is normal; however, swallowing of food and water is difficult. Gastrointestinal sounds are decreased. Tachycardia is usually present even in horses that do not appear overtly painful. Horses with acute grass sickness do not recover.

Chronic grass sickness is generally insidious in onset. Dysphagia occurs to a varying degree and, as in the acute disease, swallowing appears to be difficult. **Intestinal stasis** results in a decrease in intestinal sounds and a decrease in fecal production. **Impactions of the large colon** may occur. Tachycardia, patchy sweating and muscle tremors are seen, along with signs of mild to moderate

abdominal pain. Horses may be anorexic, however the cachexia is often more rapid and severe than can be accounted for by lack of caloric intake alone.

The ante mortem diagnosis is based on the clinical examination and ruling out other causes of colic or dysphagia. The administration of **0.5% phenylephrine eye drops** to one eye results, in 20 min, in a significant increase in the size of the palpebral fissure, assessed by measuring the angle of the eyelashes to the head from a frontal view (i.e. the **eyelashes “stand up”**).

There is no treatment for acute grass sickness. Some animals will recover with **very intensive supportive nursing care**, which specifically involves offering a wide variety of palatable foodstuffs. Animals should be encouraged to eat as much as possible. Affected horses will invariably lose significant amounts of weight.

Histologically, the disease is characterized by **chromatolysis** of enteric neurons, pre- and post-ganglionic sympathetic and parasympathetic neurons in the CNS and ganglia, and specific somatic lower motor neurons in the brainstem.

The disease is known as a **dysautonomia** but clinical signs of grass sickness do not fit clearly into an uncomplicated picture of autonomic disease. Cases usually do not have alterations in pupillary diameter, enophthalmos or corneal ulceration due to decreased tear production, or overt orthostatic hypotension. Primary dysautonomias with markedly similar enteric and sympathetic ganglionic lesions exist in cats, dogs, hares and rabbits.

INTRODUCTION

If we examine statues of humans or horses sculpted in ancient Greece or Rome, it is immediately apparent that their creators were masters of anatomy. Similarly, men with scientific minds have studied physiology for centuries. Thus, anatomy and physiology, basic medical sciences, have a long history. Yet the third basic aspect of living organisms in the animal world, behavior, is a relatively new science. Not until the late nineteenth century did medical scientists like Jung, Freud and Adler begin an analytical study of behavior.

Every living creature has adapted anatomically and physiologically to the habitat in which it has evolved. Its behavior too must adapt to the **environment** in which it exists. All three adaptations—anatomy, physiology, and behavior—are essential for survival and propagation of any species. All three are **genetically predetermined**. Thus if an animal enters the world, say a newborn calf, we can accurately predict its anatomic appearance: what it will look like, its approximate size, what its digestive system will be, etc. We can also make accurate predictions regarding its physiology: its normal body temperature, heart rate, gestation period, and so on. Because it is a bovine we can also know how it will behave: its defensive actions, social interactions with other bovines, its courting behavior, its body language of aggression, dominance or submission.

All three characteristics—anatomy, physiology and behavior—are however subject to a certain degree of modification. For example, **malnutrition** may alter the potential anatomy of an animal. Exercise or living at high altitude may cause physiologic changes. Learning after birth will shape its behavior. The behavior of horses, therefore, is to a great extent **programmed prenatally**, but from the moment a foal enters this world learning begins.

THE SCIENCE OF BEHAVIOR

The science of behavior is so new that only in recent decades have we begun to understand its complexities. Until the middle of the twentieth century it was widely accepted that animals behaved according to **instinct**, but human behavior was all learned. Now we know that every newborn animal is endowed with behaviors that are **genetically predetermined**, and will also **acquire behaviors** as a result of learned experiences.

The horse, in the wild, is a **prey animal**, providing a source of food for the large carnivores. The horse evolved in North America, preyed upon by a variety of large felines such as the saber toothed tiger and the cave lion, and a variety of large canines such as the dire wolf. Its primary defense was flight.

Many herbivorous species are equipped with formidable anatomic weapons of defense such as, for example, the horn of the rhinoceros, the tusks of the hippopotamus or wild boar, the horns of a Cape buffalo or musk ox, or bighorn sheep. When threatened, these species lower their heads, charge, and can use their weapons very effectively. The horse, however, is not so equipped. Its defense is to **sprint** away from perceived danger, and its anatomy and physiology are well equipped for flight. The equine cardiovascular system, musculoskeletal system, respiratory system and senses are those of a flight creature. Because it is dependent upon flight to survive in the world, the horse is **uniquely endowed** with behavioral characteristics that must be appreciated and respected if we are to get along with this animal.

BEHAVIORAL CHARACTERISTICS

Horses are the **most perceptive** of all domestic mammals, equipped with hearing, a sense of smell and a tactile sense far exceeding those of humans. Its vision, while inferior to that of humans in color recognition and depth perception (due to the lateral placement of the eyes), is much superior in detecting movement, in night vision, in peripheral vision and in speed of accommodation, which is accomplished by swiftly altering the position of the head.

The **reaction time** of the horse is the fastest of all domestic mammals. As the horse evolved, those that reacted slowly did not survive to reproduce. The **memory** of the horse is the best of all domestic animals. Moreover, horses learn faster than any other domestic animal. The slow-learning ancestors of the horse did not survive.

Interestingly, this timid, flighty creature—this ultimate prey—can be more **swiftly desensitized** to frightening stimuli than other animals. Why? Because

flighty species must quickly desensitize to frightening sensory stimuli once they are determined to be harmless, or else they would be running all the time. There would be no time to eat, drink, rest or reproduce. The fact that horses can be quickly and lastingly desensitized to frightening stimuli is one of the main reasons they are so suitable for **domestication**. In warfare, for hunting, as a draft animal, the horse had to accept endless normally terrifying stimuli.

The horse, one of only a dozen mammalian species which mankind has successfully domesticated, became the most important factor in the spread of cultures and civilizations.

DOMINANCE AND HIERARCHY

Like most domestic animals, with the exception of the cat, the horse is an animal that lives in groups led by a leader, a **dominant mare** as a rule. Horses, then, readily accept humans as surrogate herd members and as herd leaders. This is why, for thousands of years, horses were so useful to mankind. They worked for humans.

Now, a remarkable change has occurred in the industrialized world—the horse is increasingly becoming a companion animal. Indeed, in many cases, the horse has become a surrogate human: a friend, even a child. An animal that throughout history primarily played the role of a slave, now sometimes becomes the master.

Animals that live in groups have what is called a **dominance hierarchy**. This hierarchy is established in varying ways, depending upon the species. In horses the dominance hierarchy is established by **control of movement**. This is a flight species. Horses establish leadership—dominance—by controlling the movement of their peers. This control can be expressed in either of two ways. Movement can be **caused** by the dominant individual: observe how the lead mare **threatens her subordinates**, causing them to yield space. Conversely, movement can be **inhibited** by the dominant individual: observe how a herd sire will drive his harem, then bunch them up and, head swinging from side to side, forbid them to move. **Controlling movement** of the horse is part of every horsemanship training technique. Properly done it causes the horse to view the human handler as a surrogate leader.

Each species has a **body language** unique to that species and instinctively understood by members of that species. That language can be learned by other species, just as humans learn to understand the snarl of a dog, the lowered head and pawing of the bovine, or presented hindquarter and elevated hindleg of a horse. A creature that lives in groups may **signal surrender** by assuming a position of **vulnerability** for the specific species. The dog, therefore, lies down exposing throat and abdomen to signal, “You are in charge. I won’t question your leadership”. Human beings in every culture bow in submission, exposing the back of the head to mankind’s primary defense, the club. Cattle elevate the nose, and horses, which are most vulnerable when grazing or drinking, lower their heads and make mouth movements to signal submission. Head elevated and lips tightly closed, the horse says “I want to flee”. Head lowered and lips loose or licking and chewing means “I accept you as my leader”.

HUMANS, HORSES AND HORSEMANSHIP

Humans domesticated the horse six or seven thousand years ago. The methods we have used to control this animal have been largely **coercive**. Humans are, biologically speaking, a predatory primate: an intelligent, reasoning, tool-using species. Primitive man established his leadership with the use of intimidation and the use of force, a characteristic of the larger primates. It is natural for us to want to control the horse with such methods, especially if we are young, and even more so if we are male. Our species survived prehistorically because the younger males were willing and able and even eager to confront wild beasts.

However, throughout the course of human history, certain men, endowed with special sensitivity, perception and communication skills, were able to control horses in a remarkably superior way. Rather than coercion, they used **persuasion**, implemented by **communicating** with horses in a way that they instinctively understood. A majority of such individuals have been lost to history. A minority recorded their methods in writing, and many of these records still exist. Unfortunately, the horsemanship espoused by these rare and talented people never became popular with the masses that utilized horses regularly.

Then, late in the twentieth century as the horse became increasingly obsolete in the industrialized world as a source of power and transportation, and increasingly a recreational creature, a remarkable thing occurred. It may be considered a **revolution in horsemanship**. Methods once known primarily to the masters became popularized within the horse industry as a whole. This revolution began in an improbable place, within the cowboy culture of the Pacific Northwestern United States. The pastoral agriculture of frontier cultures such as Argentina, Australia and western North America developed horsemanship that was expedient, inexpensive and often crude. Men and horses were cheap and the methods that evolved were often abrupt and sometimes brutal. It is a tribute to the remarkable **adaptability** of the horse that so many dependable and useful horses were produced this way. They are forgiving creatures.

In Spanish colonial California, a form of horsemanship was developed that, although still crude in some respects, was more refined than any other form of native horsemanship. Early in the twentieth century a man named Tom Dorrance, a cowboy and rancher, was influenced by the horsemanship of the "Californios". He mastered and embellished the techniques, developing a great ability to communicate with horses and influence their behavior. A skilled protégé of Dorrance, Ray Hunt, took these methods and went on the road with them, profitably teaching them to the horse-owning public.

Soon other exceptional horsemen, all cowboys or former cowboys but possessing skills not typical of the working cowboy culture, joined what was to become a revolution which would spread all over the world. Men like Pat Parelli, Richard Shrake, Monty Roberts, Buck Brannaman and Dennis Reis, all cowboys from the western USA, would evangelically spread the gospel of gentler and more humane horsemanship. By the mid 1980s the unorthodox methods espoused by these men had spread worldwide, and by the turn of the century they were being accepted by the racing industry and all horsemanship disciplines.

Why did this happen so late? Why didn't it happen a century earlier when the horse was at the pinnacle of its importance to mankind? There are several reasons:

1. The science of behavior—psychology—had finally become accepted and respected by society as a whole.
2. Horses were now owned by educated people. This was the exception a century earlier when, in fact, many horse handlers were actually illiterate, a situation common in developing countries today.
3. The information explosion of the late twentieth century—the Internet, videotapes, books and horse magazines, and clinicians flying by jet all over the world—rapidly dispersed the technological information involved.
4. Finally, and probably most significant, an industry historically dominated by men is for the first time increasingly dominated by women. The solicitous, compassionate, less intimidating and nurturing attitude so many women have greatly facilitates communication with the horse.

This revolution in horsemanship, known by a variety of names originated by the trainers involved in it, is probably best known internationally as “natural horsemanship”. Its methods are by no means natural to the human species, but they are natural to the horse, and utilizing them has enabled us to communicate with the equine as never before.

Feral horses, captured in the wild and never before handled by human beings, are being gentled and accepting a rider in just a few hours time using natural horsemanship. “Outlaw” horses, some of them exceedingly dangerous to handle, are being reformed and turned into safe and useful steeds with these methods.

VETERINARIANS AND NATURAL HORSEMANSHIP

By the year 2005, scores of trainers in all disciplines were using the methods of natural horsemanship and many of them had become teachers and advocates. Veterinarians in equine practice must become familiar with this revolution. Its teachers have produced a few good books and many fine videotapes teaching the methods.

It is incumbent upon the practitioner to become familiar with the great social changes that are occurring. These include recognition of the **human-animal bond**, the increasing role of the horse as a companion animal, the influence of the animal rights movement, and increasing social awareness of the concept of humaneness, a rejection of violence (even as it increases in the popular media) as a means to an end, and a recognition of the intelligence and emotions possessed by our domestic animals.

It is not the veterinarian's role to train horses. But we must be cognizant of what is happening in the industry and encourage our clientele to familiarize themselves with natural horsemanship and to minimize some of the more coercive techniques of restraint that have become traditional in the horse industry. It is our responsibility at least **not to create behavior problems** in

our patients, to attempt to establish rapport with them, and to use the variety of tranquilizing and behavior modifying drugs available to us as needed.

Horses are a **precocial species**, born with all of their senses fully functional and neurologically mature. Their socialization periods and critical learning times occur immediately post partum, and are not delayed as they are in altricial species such as the dog, the cat and the human infant. If horses are not trained during the minutes, hours and days after they are foaled, the most powerful learning times of their lives are being wasted. Teaching breeders this fact and encouraging them to work patiently and formally with newborn foals will ensure gentler future patients for our profession, lessen the likelihood of injury to either horse or human, and help to create a more equitable and profitable relationship between them.

STEREOTYPICAL BEHAVIORS

Stereotypical behaviors, or **stereotypies**, defined as stylized, repetitive, and apparently motor responses or sequences*, or as an intentional, repetitive, non-functional behavior often performed in a rhythmic manner†. They are commonly seen in animals subjected to stressful situations such as isolation or confinement. Examples include feather pulling in caged birds, paw chewing or habitual scratching of the body in bored or confined dogs, repetitive ritualized pacing in caged zoo animals, and tail sucking in cats. In children, nail-biting and pulling out eyebrow or eyelid hairs are examples of stereotypies.

The horse is **particularly susceptible** to such anomalous behaviors because, in domestication, its environment is often drastically different from that which would be natural for the species; namely open, unlimited grasslands, in the company of other horses. Certainly stereotypies are rarely, if ever, seen in wild horses.

Traditionally, the stereotypies of horse have been called “vices”, or, more commonly, “stall vices” simply because they are seen most often in closely confined individuals. In any species, stereotypy is expressed as an **oral activity**, a **locomotor activity** or a **combined activity**. In horses, oral examples include cribbing (crib biting), windsucking, wood chewing, protrusions of the tongue and biting of the flanks (*q.v.*). Locomotor stereotypies are weaving, circling, pawing and stall kicking (*q.v.*). **Cribbing** and **weaving** are probably most commonly seen.

CRIBBING AND OTHER STEREOTYPIES

Cribbing and windsucking

Cribbing (*q.v.*), wherein the horse grasps a horizontal surface with its incisor teeth, flexes its head and neck, pulls back drawn in air and grunts, is very

* Houpt, K.A. (1995) New perspectives on equine stereotypic behaviour, *Equine Veterinary Journal* 27: 82–83.

† McClure, S.R., Chiffin, M.K., Beaver, B.V. (1992) Nonpharmacologic management of stereotypic self-mutilative behavior in a stallion. *Journal of the American Veterinary Medical Association* 200: 1975–1977.

much disliked by horse people. The upper incisor teeth wear excessively and abnormally, and in some cases this dental damage can be extreme. However, cribbing, as a rule, is not nearly as damaging as is popularly believed, and the vehement dislike of the habit by so many horsemen is **disproportionate** to the ill effects produced.

Admittedly certain rare cribbers are so addicted to their vice that they do not eat enough, suffer **malnutrition**, and develop **anatomic changes** in the neck as well as the teeth. However, for generations the damaging effects of cribbing have been greatly exaggerated. The **folklore** associated with it often results in a depreciation of the fiscal value of an otherwise sound and useful horse. For example, it is popularly believed that the cribber, swallowing air, is predisposed to colic. Recent studies reveal that, in fact, **the cribber does not swallow air**. Fluoroscopic studies have revealed that air is expelled when horses crib. The incidence of colic in cribbers is not significantly higher than in the general population. Indeed, chronic gastrointestinal problems may **cause** a horse to crib.

Another long accepted bit of lore is that cribbing can be learned by foals observing the behavior of confined cribbers. Research studies fail to confirm this and it may be that the conditions that predispose to stereotypical behaviors **on a given premise or property** are likely to produce more cribbers. Additionally, there may be a **genetic predisposition** to such behaviors, so if the horses are related, and live in a similar environment, then a high incidence can be expected. It is well recognized that cribbing is more common in certain bloodlines. Therefore the idea of an allelomimetic (imitative) cause for cribbing is invalid at the present time.

Windsucking (*q.v.*) is often considered to be synonymous with cribbing, or a more advanced form of the vice. Cribbing and windsucking can be minimized but rarely controlled completely with muzzles or a variety of “cribbing collars”. One, called a “miracle collar”, is particularly helpful but, again, these measures usually lessen rather than eliminate the problem.

When these vices are so severe as to harm the physical condition of the horse, myotomy of the sternomandibularis, sternothyrohyoideus and omohyoideus muscles (Forssell’s procedure) or a modification of Forssell’s procedure by partial removal of the sternothyrohyoideus and omohyoideus muscles and neurectomy of the ventral branches of the spinal accessory nerves can be used. The modified version of Forssell’s procedure provides a more cosmetic approach.

Wood chewing

When horses are confined and/or deprived of company, wood chewing (*q.v.*) is a common result. Bored, and deprived of the opportunity to graze at will, many horses begin to chew wood, often causing marked damage to fences and stables. Ideally, this vice should be prevented by providing horses with environmental stimulation including the company of other animals, adequate living space, and either constant grazing opportunity or, at least, available grass hay.

Once the wood chewing habit is established, exposed wood surfaces may be protected by sheathing them in metal, by electric wire fencing, or painting them with unpalatable substances. Creosote, which was particularly effective, is no longer used because it is considered to be environmentally unsafe.

However, several commercial products designed to discourage wood chewing are on the market.

Weaving, circling and stall kicking

These stall vices are almost entirely the result of box stall confinement and isolation from other horses. Only a change in environment can prevent or solve weaving, circling and stall kicking. The moment such a tendency is observed, an immediate change may abort the vice before it becomes a fixed stereotype. Young racehorses are especially susceptible to these highly motile vices. Raised in open pastures, energetic and athletic, racehorses are usually confined to box stalls once training commences, and it is understandable how stressful this change in environment can be.

Biting of the flanks

This vice is seen most often in stallions. Biting is particularly offensive because afflicted horses often severely traumatize their flank region. The use of neck cradles, keeping the horse in a tie stall, muzzling, or a protective blanket may physically prevent the habit. Better, a drastic change in environment may be provided, including as large an enclosure as possible, nearby company of other animals, toys, and visual stimulation such as that provided by a constant view of other animals, people or automobile traffic.

Protrusions of the tongue

Although protrusion of the tongue is often a typical stall vice, originating like the others as the result of boredom, confinement and isolation, it is more often a form of **displacement behavior**. Many colts when started in the snaffle are uncomfortable, especially if the rider or driver is rough-handed, and develop the harmless but very unsightly vice of “tongue dragging” or “tongue lolling” or “tongue rolling” or “tongue play”. As soon as it is detected, an immediate change of methodology including removal of the bit and substitution with a hackamore, sidepull or halter may abort the habit. At the very least, a completely different bit should be tried, such as a Mullen Mouth or a Doctor Bristol or other multijointed bit. Consider, too, the hands of the rider.

Horses with confirmed tongue vices are often subjected to such extreme controlling measures as tying the tongue down, tightly tying the mouth closed, and pricking of the tongue. For show horses, spoon bits and nets have been used. Amputation of the tongue is a drastic and inhumane solution that can never be condoned.

DEALING WITH STEREOTYPIES

It is only in recent decades that controlled scientific studies have been done to better understand stereotypies. What has been established thus far is that there is a physiological chemical mechanism involved. It involves the mediation of **endogenous opioids** (endorphins) elaborated as a response to chronic stress, and it is believed that **the addiction displayed by cribbers is to these**

opioids, rather than to the act itself. This has been demonstrated by the administration of opioid antagonists such as **naloxone** and related compounds, which tends to suppress the cribbing behavior, probably due to opioid interference. However, the use of these drugs, at this point, is not clinically applicable.

Confinement has long been considered the most common cause of cribbing, but **isolation** is probably a more significant factor. Horses confined to tie stalls are more confined than those in boxes, but if they have other horses adjacent to them they seem to be less inclined to begin cribbing than those in box stalls. Even in box stalls, horses that can look out and see other horses are less likely to crib. Thus, the more viewpoints available to the stalled horse, the less inclined it is to crib or exhibit other stereotypies. The **more social interaction** that occurs between stabled horses, the better.

Recently, **diet** has been shown to be a factor in stereotypical behaviors. The more **roughage** fed, the busier it keeps the horse, distracting it from misbehavior. Feeding a mixture of **chaff and hay** seems to be even more effective. Also, horses on **straw bedding** crib less. **High concentrate diets contribute to stereotypies** in two ways. First, they reduce the amount of roughage that must be fed and therefore give the horse more idle time. Second, high concentrate/low roughage diets result in periods of food deprivation, and this results in **gastric hyperacidity**, which can cause ulcers (*q.v.*). High levels of dietary concentrate, which is, after all, an unnatural diet for this grassland grazing species, can also alter cecal fermentation, lowering the pH of the cecal contents. It is possible that cribbing increases the production of saliva, which is alkaline. Horses, unlike carnivores that may salivate at the odor or smell of food, only salivate when chewing. Perhaps cribbing, by increasing saliva flow, normalizes the pH of the ingesta in horses fed excessive concentrates. In one study, **foals** began to crib only after concentrates were introduced. Even after weaning, the incidence of cribbing was four times higher in concentrate fed foals.

Social interaction will also reduce the incidence of weaving in horses confined to box stalls. The presence of large mirrors on the walls of box stalls is believed by some caretakers to inhibit the occurrence of stereotypies. If complete confinement is necessary, then as much “outside” time as possible should be provided, and the opportunity to graze and/or to eat hay should be allowed as often as possible.

INTRODUCTION

Equine ophthalmology has always been, and continues to be, an interesting and challenging aspect of equine practice. For both esthetic and functional reasons, disorders of the eye are of great concern to the horse owner. The horse, perhaps more so than other domestic species, can have devastating complications from ocular trauma or inflammations.

Management of ophthalmic disorders in the horse requires knowledge of the anatomy of the structures involved, an understanding of the pathophysiology of the disease process, and an appreciation of the therapeutic options available. This section is designed to aid the practitioner through the diagnosis and management of the common, and not so common, ocular disorders encountered in practice.

Over the 10 years since the first edition of this volume significant advances have been made in equine ophthalmology, as documented in this chapter. And yet, as will be shown below, there are all too many areas where our understanding of the pathobiology of the equine eye is not sufficient to allow rapid and successful diagnosis and treatment of equine ophthalmic disorders from herpetic keratitis at the very front of the eye to retrobulbar neoplasia behind it.

THE ORBIT

ANATOMY

The orbit is the bony fossa that surrounds and supports the eye. It is composed of the frontal, lacrimal, zygomatic, sphenoid, temporal and palatine bones. The supraorbital process of the frontal bone forms the dorsal rim of the orbit, and provides a complete orbital rim. The ventral floor of the orbit is composed of soft tissue, which, along with a large amount of orbital fat, serves to support the globe.

The orbit is in close proximity to the paranasal sinuses. The frontal sinus is located medial to the orbit and extends dorsally and ventrally along the orbit.

The maxillary sinus is ventral and medial to the orbit. The medial canthus of the eye serves as a **reference point for trephination of the maxillary sinus**. A third smaller sinus, the sphenopalatine, which communicates with the maxillary sinus, is also located ventral and medial to the orbit.

Orbital foramina allow for nerve and blood vessel entry into the orbit. These include, with their associated vessels and nerves, the rostral alar foramen (the maxillary artery and nerve), the orbital fissure (the abducens, ophthalmic, trochlear and oculomotor nerves), the optic foramen (the optic nerve and internal ophthalmic artery), the ethmoidal foramen (ethmoidal nerve and vessels), and the supraorbital foramen (the supraorbital nerve and vessels). The first four of these foramina are clustered on the ventromedial wall of the orbit near its apex, and are important when performing **retrobulbar injections for anesthesia**. The supraorbital foramen is located medially in the supraorbital process of the frontal bone, and serves as a landmark for injection for regional anesthesia of the upper eyelid. It can be easily found by grasping the supraorbital process, at the point where it begins to widen, between the thumb and middle finger, and palpating with the first finger.

The orbit also contains the extraocular muscles. The dorsal and ventral rectus muscles rotate the eye around a horizontal axis, while the lateral and medial rectus muscles rotate the eye on a vertical axis. The dorsal and ventral oblique muscles rotate the eye on an anteroposterior axis. The retractor bulbi muscle lies within the cone formed by the rectus muscles and extends posteriorly around the optic nerve. The main diagnostic importance of the extraocular muscles is in **neurologic examination**, as the position of the globe may indicate lesions of certain cranial nerves.

A sheet of connective tissue, the periorbital, lines the orbit. It is reflected to sheathe the extraocular muscles, and extends onto the globe as Tenon's capsule.

ORBITAL DISEASES

Congenital anomalies

Microphthalmia/anophthalmia

Microphthalmia is an abnormally small eye. **True anophthalmos** (the absence of any ocular tissue) is rare, with most cases having some remnants of eye present. Microphthalmia, which results from degeneration or abnormal growth of the optic vesicle, may be pure (nanophthalmia), with a normal but small eye, colobomatous, or complicated with other ocular anomalies. There can also be **associated systemic anomalies**. The absence of a normal-sized eye may result in the failure of the orbit to develop, with subsequent cranial asymmetry.

Clinical signs

Affected animals are generally presented shortly after birth, with the complaint of small or absent eyes. Affected eyes are **frequently blind**. The palpebral fissure is often correspondingly reduced. A common clinical problem can be ocular surface infection since the conjunctival sac is necessarily enlarged given the small globe size.

Treatment

Therapy is seldom indicated. Enucleation may be performed if irritation or excessive ocular discharge is present. Bilaterally affected foals are most frequently euthanased.

Prognosis

Foals affected unilaterally may perform adequately if allowances are made for the vision loss.

Orbital cellulitis

Unlike the dog, the horse rarely develops orbital cellulitis. When it occurs, it is frequently an extension of inflammation from sinusitis, guttural pouch infection, blunt trauma or penetrating orbital wound, dental disease, or an extension of panophthalmitis (*q.v.*).

Clinical signs

Edema of the eyelids and supraorbital fossa is usually severe, and the region is painful on palpation. Ocular discharge is frequently heavy and ranges from serous to mucopurulent. Prolapse of the third eyelid is common, especially if exophthalmos is present. Fever may or may not be present.

Skull radiographs and **guttural pouch examination** (*q.v.*) may aid in identifying a primary cause. Orbital ultrasonography may be useful in locating pockets of exudate or fluid accumulation.

Treatment

Specific therapy for the primary cause, if identified, is indicated. Broad-spectrum systemic antibiotics are necessary. Non-steroidal anti-inflammatory drugs (NSAIDs), such as **phenylbutazone** or **flunixin**, may be useful in relieving pain and reducing the inflammation. A topical lubricant may be required to prevent corneal exposure; antibiotic ointments may be necessary to control secondary infection. Aspiration or drainage of exudate is useful if possible. Warm compresses may also give some relief.

Prognosis

The prognosis will vary according to the initiating cause, but is frequently guarded to poor due to the severity of the inflammation. Optic nerve degeneration may be a secondary complication.

Exophthalmos

Protrusion of the globe may occur with orbital cellulitis or may be seen as the only clinical sign in cases of neoplasia, orbital cysts, or chronic sinusitis with bony proliferation of the orbital wall. Orbital cysts may be caused by larval forms of *Echinococcus* within the orbit, or occur as extensions of cystic sinus proliferations.

Clinical signs

Exophthalmos may be best seen when viewing the eyes from the front. Subtle changes in eye position may be appreciated by comparing the angle of the eyelashes. The globe will resist retropulsion. Skull radiographs, orbital ultrasonography and guttural pouch examination will aid in diagnosis.

Treatment

Treatment varies with the primary cause, as does prognosis.

Enophthalmos

The eye may appear **sunken** in horses that are dehydrated or debilitated, due to shrinkage of the orbital fat pads. The eye will be actively retracted in cases of ocular pain. Loss of sympathetic tone (**Horner's syndrome**) will create an enophthalmos. Orbital fractures may also present with a sunken globe, due to displacement of bone fragments or orbital fat.

Clinical signs

The eye is recessed. Viewing the eye from the front, the angle of the eyelash will aid in detecting subtle changes in eyelid position. Pain will be associated with orbital trauma or lesions of the globe. Miosis (constriction of the pupil) and sweating on the ipsilateral side of the face and neck are seen in Horner's syndrome.

Treatment

Treatment is aimed at the underlying cause.

Prognosis

In most cases the prognosis is favorable, depending on the primary cause.

THE EYELIDS

INTRODUCTION

The eyelids and third eyelid are necessary for protection of the eye, maintenance of normal corneal and conjunctival health, production, distribution and outflow of tears, and the removal of foreign bodies and debris. **Neoplasia** is possibly the most common disease process involving the eyelid (squamous cell carcinoma and sarcoid) and nictitating membrane (squamous cell carcinoma) (*q.v.*).

ANATOMY AND FUNCTION

The eyelids serve to protect the globe and have important roles in the production, distribution and removal of tears. The outer, oily layer of the tears is produced by the Meibomian glands. This oily film decreases tear evaporation and coats the eyelid margins thus preventing epiphora (watering of the eye)

(*q.v.*). Eyelid closure moves the precorneal tear film toward the nasolacrimal puncta, the first components of the tear drainage pathway.

The **vibrissae** are long, tactile hairs of the dorsal and ventral orbit. **Eyelashes**, or cilia, are always present on the upper eyelids but may not be present on the lower eyelids. Both vibrissae and cilia serve a protective role supplying sensory input for the blink response.

The **Meibomian (tarsal) glands** are positioned perpendicular to the eyelid margins. These glands excrete their sebaceous product onto the globe through openings that lie in a furrow at the mucocutaneous junction of both the superior and inferior eyelids.

The superior and inferior lacrimal puncta and respective canaliculi are located within the nasal aspect of the upper and the lower eyelids and serve as the normal route for tear removal.

The eyelids have a **profuse vascular network**. The primary muscles of the eyelid include the orbicularis oculi, levator palpebrae superioris and Müller's muscles. The orbicularis oculi muscle completely encircles the palpebral fissure and is responsible for eyelid closure. The upper eyelid is more mobile than the lower eyelid and thus is responsible for most of the blink response. The levator palpebrae superioris muscle elevates the upper eyelid. The upper and lower eyelids also contain smooth muscle tissue, Müller's muscle, which serves to open the palpebral fissure.

The sensory innervation of the eyelids is derived from branches of the trigeminal (fifth cranial) nerve. The upper eyelid is innervated by the lacrimal, supra-orbital and infratrochlear nerves, which are branches of the ophthalmic nerve. The lower eyelid is innervated by the zygomatic and infratrochlear nerves, which are branches of the maxillary and ophthalmic nerves, respectively. The orbicularis oculi muscle is innervated by dorsal and ventral palpebral nerves, which are distant branches of the facial (seventh cranial) nerve. The oculomotor (third cranial) nerve innervates levator palpebrae superioris, and the sympathetic component of the autonomic nervous system innervates the smooth muscle of Müller via the trigeminal nerve. A **normal palpebral reflex** demonstrates intact trigeminal (sensory) and facial (motor) nerve pathways.

CONGENITAL ANOMALIES

The eyelids of foals are normally open at birth. **Ankyloblepharon** is a persistent fusion of the eyelid margins. The eyelids can usually be separated manually, however insertion of scissors between the eyelids and globe may be necessary to "unzip" the adhesions, without closing the scissor blades. Scarring can occur with adhesion of the lid margin to conjunctiva, resulting in **symblepharon**. Frequent massage and hot compresses should thus be used over the days following separation of lids in a case of ankyloblepharon.

Many other congenital eyelid defects may occur but are very rare. **Eyelid agenesis** may be characterized by epiphora, conjunctivitis and possibly keratitis (*q.v.*). Surgical correction, **blepharoplasty**, may be required.

An imperforate nasolacrimal punctum is uncommon in Equidae, but may cause chronic epiphora. If the canaliculus is present but a membrane obstructs the punctum, the membrane can be surgically removed thus opening the tear outflow pathway.

ABNORMAL EYELID POSITION AND CLOSURE

Entropion is inversion of the eyelid margin toward the eye and usually involves the lower eyelid. Entropion is rare in adult horses but not uncommon in foals. Entropion does not appear to be a familial disease process, but **Thoroughbreds** may have an increased prevalence. The cause is unknown, but affected newborn foals may be slightly enophthalmic (*q.v.*) at birth thus predisposing to the condition. The abnormal eyelid position may resolve as the foal gains body weight and retrobulbar fat.

The eyelid margin may rub against the conjunctiva and cornea causing a painful keratoconjunctivitis characterized by epiphora, blepharospasm (involuntary closure of the eyelids), conjunctival hyperemia and possibly corneal ulceration (*q.v.*). **Treatment** of entropion is by eversion of the eyelid margin. An everting suture pattern (e.g. interrupted Lemberg pattern using 4-0 or 5-0 non-absorbable monofilament suture material) placed in the eyelid skin is a temporary measure but may be sufficient for permanent correction. Surgical removal of a wedge of skin is reserved for severe cases with recurrent entropion following the skin eversion technique or in adults with acquired entropion. A skin incision is made approximately 3–4 mm from and parallel to the eyelid margin. The second incision is spaced as needed to correct the defect. The wedge of skin is removed and the cut edges are opposed with a small diameter, non-absorbable suture material in a simple interrupted pattern.

Ectropion is an eversion of the eyelid margin that is usually secondary to a wound that heals improperly. Surgical intervention is required if the defect causes chronic epiphora, conjunctivitis or exposure keratitis (*q.v.*).

Symblepharon is an abnormal adhesion of the inner conjunctival surface of the eyelid (palpebral conjunctiva) to the conjunctiva overlying the sclera (bulbar conjunctiva). This is a rare condition that may restrict eyelid movement and necessitate surgical intervention.

Ptoxis is a drooping of the upper eyelid due to loss of oculomotor innervation to levator palpebrae superioris or loss of sympathetic innervation to Müller's muscle (Horner's syndrome) (*q.v.*). Absence of oculomotor nerve function is also associated with lateral strabismus. Horner's syndrome is not commonly diagnosed in horses because the clinical signs may be subtle. In addition to ptosis, loss of sympathetic tone can produce ipsilateral miosis, slight enophthalmia and passive elevation of the nictitating membrane, conjunctival and nasal mucosal hyperemia, and an increase in skin temperature with sweat production on the face and neck. If a specific cause is identified, appropriate treatment should be initiated.

Lagophthalmos is an inability to close the eyelids completely. Lagophthalmos may be caused by marked buphthalmos, exophthalmos or facial nerve paralysis. Secondary exposure keratitis is common.

EYELASH DISORDERS

Distichiasis

Distichia are extra cilia that emerge from Meibomian gland openings; they are rare in horses. If present and causing **secondary corneal and/or conjunctival irritation**, the aberrant cilia should be surgically removed with electro- or

cryo-epilation in an effort to prevent regrowth. **Resection of the Meibomian gland** that forms the follicle of the aberrant lash may be found to be a more permanent solution and may cause less postoperative scarring, than procedures that involve manipulating the eyelid margin itself.

Trichiasis

The condition in which facial hair or eyelashes grow toward and irritate the eye is known as trichiasis. Trichiasis is rare in horses but may be caused by previous trauma and secondary cicatrization altering normal adnexal conformation. Clinically significant trichiasis may require blepharoplastic procedures (eyelid surgery).

Ectopic cilia

An eyelash that arises from a Meibomian gland, penetrates the palpebral conjunctiva, and is directed toward the cornea, often causing a persistent corneal ulceration, is called an ectopic cilia. This condition is very rare but has been reported in the horse. **En bloc resection of the cilia and its follicle** with adjunctive cryotherapy of the surgical bed is the treatment of choice.

BLEPHARITIS

Inflammation of the eyelid, blepharitis, may be caused by blunt trauma, an allergic reaction (e.g. insect bites), exposure to intense solar radiation, and infectious agents (e.g. fungal organisms, mites and parasitic larvae).

Solar-induced blepharitis is an inflammatory condition that generally affects horses with minimal periocular pigmentation and may be a **precursor to squamous cell carcinoma**. Solar-induced blepharitis can be reduced and its recurrence prevented by decreasing exposure to high levels of UV radiation. An affected horse can be housed indoors during peak hours of sunlight or, if prevention is not feasible, the susceptible tissues can be tattooed.

Dermatophytosis

Ringworm (*q.v.*) occasionally affects the periocular region. *Trichophyton equinum* is the most common fungal agent that causes clinical disease in horses; however, *T. mentagrophytes*, *Microsporum canis* and *M. gypseum* may also infect Equidae. Lesions are characterized by alopecia, erythema, scaling and crusts. Fungal culture is required for definitive diagnosis. Treatment should include clipping hair and application of topical antifungal agents, e.g. miconazole or clotrimazole cream. In addition, the horse should be isolated and the environment and tack decontaminated using chlorine bleach (1:20) diluted with water.

Demodectic mange

Demodex equi and *D. caballi* (*q.v.*) seldom present clinically significant disease in horses. The mites live within hair follicles and occasionally cause periocular papules, crusts, alopecia and granulomas. Skin scrapings and cytology may reveal the causative agent. A localized manifestation can be treated with **topical**

rotenone ointment. If the lesions become generalized, application of a miticidal dip is indicated.

Cutaneous habronemiasis

Habronema are parasitic gastric nematodes of horses (*q.v.*). Aberrant larval migration of *Habronema muscae*, *H. microstoma* and *Draschia megastoma* causes rapidly developing, raised, **non-healing ulcerative granulomas** containing caseated and calcified particles. Lesions may be pruritic and painful. The medial canthus and/or nictitating membrane are usually affected since the infective larvae are carried by flies (*Musca domestica* or *Stomoxys calcitrans*), which are attracted to moisture at the medial canthus. Definitive diagnosis is by histopathology, which usually reveals granulation tissue, eosinophils, mast cells, neutrophils and intact or fragmented larvae. **Ivermectin** is the treatment of choice and may be administered in conjunction with a topical antibiotic–corticosteroid ointment.

TRAUMA

Trauma caused by sharp objects such as barbed wire and nails is common in horses. A complete ophthalmic examination, including palpation of the facial bones, should be performed in order to ensure that additional ocular or periocular structures are not damaged. The therapeutic goal is the **re-establishment of a functional and cosmetic eyelid**. Attaining the desired outcome usually requires surgical intervention, which may include debridement and primary closure.

Tetanus prophylaxis should be administered prior to corrective surgical procedures. In addition, systemic antibiotics and NSAIDs are indicated pre- and postoperatively. If corneal ulceration or secondary uveitis is present, treatment with topical antibiotic and atropine ophthalmic ointments should be initiated.

If the presenting wound is >12 h old, contaminated or severely edematous, surgical closure should be delayed. The open wound should be managed medically for 12–24 h with application of a dressed bandage which will cleanse the laceration, soften the traumatized tissue and decrease swelling. **Nitrofurazone ointment** can be used for this purpose as it is well tolerated by the eye and inexpensive.

Following induction of general anesthesia (*q.v.*), the surgical site is prepared in a routine manner and the wound thoroughly cleansed. Excessive suture and tissue tension is avoided by conservative debridement and a two-layer closure. The deep, connective tissue layer should be apposed with absorbable suture (e.g. 5-0 or 6-0 chromic gut or polyglactin). Non-absorbable suture should be used in the skin (e.g. 4-0 or 5-0 monofilament nylon, polypropylene or silk) beginning at and restoring the eyelid margin. Small suture material in a simple interrupted pattern will yield the best results. A bandage and stockinette or protective hood with eye cup may be beneficial for 3–5 days postoperatively, especially during the fly season.

Severe tissue loss may necessitate reconstructive grafting procedures, e.g. **sliding H-blepharoplasty**, to re-establish an eyelid margin. Because of the absence of readily moveable facial skin in horses, extensive reconstructive procedures are difficult to perform. Blepharoplastic procedures are more successful when performed on the lower than the upper eyelid since the lower

eyelid normally has limited motility. In addition, the surgeon should restrict dissection of tissue immediately beneath the orbicularis oculi muscle of the upper eyelid since levator palpebrae superioris function is necessary to prevent secondary postoperative ptosis (*q.v.*). A split-thickness **eyelid tarsor-rhaphy** (*q.v.*) (in which the outer parts of the upper and lower lids are joined) may promote uncomplicated healing by relieving postoperative tension.

THE NICTITATING MEMBRANE

ANATOMY AND FUNCTION

The nictitating membrane, or third eyelid, serves to protect the globe, distribute tears, and produce immunoglobulins and part of the precorneal tear film. The caruncle is a small, finely haired prominence within the nasal canthus that may or may not be pigmented. The nictitating membrane has an exposed, palpebral conjunctival surface and a bulbar conjunctival surface that is in contact with the underlying globe. Superficial lymphoid follicles are located on the bulbar conjunctival surface and presumptively produce IgA, which becomes a component of the tear film. The nictitating membrane has an internalized **T-shaped section of cartilage** that serves as structural support. The gland of the nictitating membrane, located at its base, produces a portion of the aqueous part of the tear film and possibly immunoglobulins. The gland's excretory ductules empty their products onto the bulbar conjunctival surface. Movement of the nictitating membrane is passive. As the globe is pulled deeper into the orbit by the retractor bulbi muscles, the nictitating membrane moves across the corneal surface. Sensory innervation of the nasal canthus, caruncle and nictitating membrane is supplied by the infratrochlear nerve, a distant branch of the trigeminal nerve.

TRAUMA

Because of its important functions, the nictitating membrane **should always be salvaged** unless it is irreparably damaged. Absorbable suture material (6-0 chromic gut or polyglactin) should be used to repair conjunctival defects. The surgeon should ensure sutures are placed such that they do not have the potential to cause **secondary corneal ulceration**.

SOLAR-INDUCED INFLAMMATION

The most common tumor of the nictitating membrane is squamous cell carcinoma. Solar-induced inflammation of a non-pigmented nictitating membrane may be a precursor of neoplasia. If avoidance of excessive UV radiation is not practical, the nictitating membrane can be **tattooed**, which may reduce its susceptibility.

FOLLICULAR CONJUNCTIVITIS

Follicular conjunctivitis is uncommon in horses. However, the **nematode** *Thelazia lacrimalis* (*q.v.*) commonly infests the conjunctival sac and nasolacrimal

system. Depending upon the parasitic load, their active serpentine movement may cause **secondary conjunctivitis** or **dacryocystitis** (inflammation of the lacrimal sac) (*q.v.*). Treatment with topically administered, long-acting organophosphorus anticholinesterase compounds is reportedly effective (0.03–0.25% echothiophate [ecothiophate] iodide q 12h, or 0.1% isofluorophate [dyflos] q 12h for 7–10 days). The anthelmintic treatment should be administered in conjunction with an antibiotic–corticosteroid ophthalmic ointment. Since the intermediate host is believed to be the face fly, *Musca autumnalis*, **fly control** may prevent recurrence.

PROTRUSION (ELEVATION) OF THE NICTITATING MEMBRANE

One or both nictitating membranes may protrude more than normal. The specific etiology should be sought and appropriate treatment initiated. Concomitant clinical signs, diagnostic work-up, treatment and prognosis vary considerably depending upon the actual cause. Protrusion may be associated with enophthalmia (*q.v.*), due to passive elevation over a retracted eye, or with exophthalmia (*q.v.*), due to displacement of the nictitating membrane by a space-occupying lesion. Some causes of unilateral protrusion of a nictitating membrane include pain, Horner's syndrome, phthisis bulbi (shrinking of the eyeball), microphthalmia, orbital fractures and a retrobulbar mass (e.g. neoplasia, abscess, cyst, cellulitis or foreign body granuloma) (*q.v.*). Bilateral protrusion of the nictitating membranes can be caused by dehydration, cachexia (loss of retrobulbar fat), tetanus (*Clostridium tetani*) and hyperkalemic periodic paralysis.

THE CONJUNCTIVA

ANATOMY

The conjunctiva is the mucous membrane that lines the eyelids (palpebral conjunctiva) and is reflected onto the surface of the globe (bulbar conjunctiva). The junction between the palpebral and bulbar conjunctiva is called the **fornix**. Ventrally, a fold in the conjunctiva covers the nictitating membrane. Palpebral conjunctiva is adherent to the underlying tissue, but the bulbar and fornix conjunctiva is mobile, to permit free movement of the globe.

The conjunctiva is composed of a non-keratinizing stratified columnar epithelium and an underlying layer of loose connective tissue, the substantia propria. The fornices and palpebral conjunctival epithelium are rich in goblet cells, which produce mucin. This allows for adhesion of the tear film to the ocular surface. The epithelium also contains melanin pigment. This is frequently most pronounced in the limbal and temporal bulbar conjunctiva and on the nictitating membrane. The bulbar conjunctival epithelium is continuous with the corneal epithelium and changes at the limbus, the corneoscleral junction.

The substantia propria contains **many small superficial and deep blood vessels**, allowing for the red appearance of the inflamed conjunctiva. The superficial portion of this layer contains lymphoid tissue that becomes active with **antigen stimulation**. This is particularly prominent on the bulbar surface of the nictitating membrane, adjacent to the limbus and in the ventral fornix. Lymphatic drainage is through the parotid lymph node.

DERMOIDS

Dermoids are choristomas, areas of normal skin tissue growing in abnormal sites, such as the conjunctiva, cornea or eyelids. **Lesions are congenital**, but not known to be inherited in the horse.

Diagnosis is based on the typical appearance of skin, frequently haired, growing on the conjunctiva. Treatment is by excision of the affected tissue. General anesthesia may be indicated, depending on the size and location of the dermoid. Conjunctival closure should be done to prevent herniation of orbital fat. Prognosis is excellent, assuming total excision of dermoid tissue.

CONJUNCTIVITIS

Inflammation of the conjunctiva may be caused by bacterial, viral, fungal or parasitic infections, or due to dacryocystitis or environmental factors, such as trauma, or irritants such as foreign bodies or solar irradiation (*q.v.*). Conjunctivitis must be distinguished from the ciliary flush, or deep hyperemia associated with uveitis or glaucoma (*q.v.*). The normal equine conjunctival flora consists of many bacteria, particularly staphylococci, as well as a variety of fungi.

Bacterial conjunctivitis

Frequently secondary to trauma, local irritants or systemic disease, compromised resistance may allow overgrowth of normal flora or opportunistic pathogens. *Moraxella* spp. may be associated with a primary conjunctivitis.

Diagnosis is based on conjunctival hyperemia and purulent ocular discharge. Culture is indicated in persistent cases or in outbreaks.

Treatment consists of removing the primary cause, if identified. Topical broad-spectrum antibiotics, such as **gentamicin** or triple antibiotic, 3–4 times daily, are usually sufficient to control the infection. Corticosteroids may also speed the resolution of the clinical signs, but should be used with caution if a specific cause of the conjunctivitis has not been identified, and are contraindicated in the presence of corneal ulcers. With uncomplicated bacterial conjunctivitis, prognosis is good with appropriate therapy.

Viral conjunctivitis

Generally seen in association with upper respiratory infections, viral conjunctivitis may be caused by rhinopneumonitis, influenza, adenovirus or viral arteritis infections (*q.v.*). The conjunctivitis is usually not a serious component of the disease, although an **ocular examination** should be carried out to rule out concurrent uveitis (*q.v.*). A **severe hyperemic conjunctivitis** can be the presenting sign in equine viral arteritis (*q.v.*), and this differential diagnosis of conjunctivitis is thus particularly important in countries free of the disease where early diagnosis of an infected animal is critical.

Diagnosis is usually best accomplished with serology. Treatment is non-specific. Topical broad-spectrum antibiotics may be used if secondary bacterial infection occurs. Prognosis for the eyes is good, as the conjunctivitis is usually self-limiting.

Fungal conjunctivitis

Fungal conjunctivitis rarely occurs in the absence of keratomycosis (*q.v.*).

Parasitic conjunctivitis

Habronemiasis

The eye is a common site for habronemiasis (*q.v.*), as the moisture of the medial canthus attracts the flies that act as vectors. Larvae of *Habronema muscae*, *H. microstoma* or *Draschia megastoma* deposited by the flies migrate into the conjunctiva, skin and nasolacrimal system, where they incite an **intense granulomatous reaction**.

Granulomatous conjunctivitis/blepharitis, often at the medial canthus, is typically seen. Nodules are frequently ulcerated, with caseous, often mineralized “sulfur granules” being characteristic. Secondary corneal abrasions are common. Diagnosis may be confirmed by demonstrating larvae in the exudate or in a biopsy of the granuloma. The presence of a marked eosinophilic and mast cell infiltrate is supportive of the diagnosis.

Systemic ivermectin (0.02 mg/kg PO, single dose) is the treatment of choice. Echothiophate 0.03% solution applied topically twice daily is larvicidal. Antibiotics and corticosteroids are helpful in controlling secondary infection and inflammation. The latter is important since an immune reaction against dead larvae can cause severe reactive signs. **Fly control** will reduce re-infestation. **Surgical excision** of granulomas may be required.

Chronic granuloma formation and re-infestation are possible. However, resolution of conjunctival lesions is generally good.

Onchocerciasis

The adult *Onchocerca cervicalis* nematode (*q.v.*) lives in the ligamentum nuchae and produces microfilaria that migrate to subcutaneous tissues. Microfilaria are spread from horse to horse by biting midges (*Culicoides* spp.). Migrating microfilaria frequently reach the eye and adnexal structures. The disease, which includes conjunctivitis, keratitis, uveitis and chorioretinitis (*q.v.*), results from the inflammatory response to dying microfilaria.

Although demonstration of microfilaria in bulbar conjunctival biopsy may support the diagnosis, microfilaria may be found in many **normal horses**. Therefore, diagnosis should also be based on the finding of characteristic lesions. These include **depigmentation** of the lateral limbal conjunctiva, perilimbal keratitis and follicular perilimbal conjunctivitis.

As the dead microfilaria are more pathogenic than the living microfilaria, treatment with microfilaricidal drugs may **exacerbate** the condition. Therefore active inflammation should be controlled prior to antiparasitic treatment, using topical or subconjunctival corticosteroids. Specific therapy includes **ivermectin** (0.02 mg/kg PO, single dose), diethylcarbamazine (4.4–6.6 mg/kg PO daily for 21 days), or echothiophate (0.25% q.i.d. in both eyes for 21–28 days). Ivermectin may be the preferred drug as it is associated with less local inflammatory response.

Prognosis is good for conjunctival lesions. Corneal lesions and uveitis (*q.v.*) may be more chronic and are potentially recurrent problems.

Thelaziasis

Thelazia is a nematode found in the conjunctival fornix. Infections in horses have been attributed to *T. lacrimalis*, *T. skrjabani*, *T. gulosa* and *T. californiensis*. Infection may be common in some areas, but is frequently subclinical. Larger numbers of worms are found in younger horses. The **face fly**, *Musca autumnalis*, serves as the intermediate host.

Most infections show no clinical signs. However, epiphora, photophobia and keratitis (*q.v.*) may be seen along with the conjunctivitis. A seromucoid discharge and follicular conjunctivitis is seen in chronic cases. Nasolacrimal duct obstruction and keratoconjunctivitis sicca (*q.v.*) may also be seen. The worms are large (10–25 mm long) and are readily seen when they are moving. Topical anesthesia will immobilize them, making diagnosis more difficult.

Many anthelmintics may be ineffective for treatment. Topical anesthetics immobilize the worms and may allow for mechanical removal of some of the worm burden. **Echothiophate** may also be effective, given as 0.03% t.i.d. in both eyes. Fly control will reduce re-infestation and spread.

Prognosis is good, as most cases are asymptomatic.

CONJUNCTIVAL NEOPLASMS

Neoplasms include squamous cell carcinoma, hemangioma, angiosarcoma, mastocytoma and melanocytoma.

SYMBLEPHARON

Symblepharon is an **adhesion between the conjunctiva and cornea**, or between two areas of conjunctiva or nictitating membrane. It may be a congenital malformation or be acquired following conjunctivitis, a conjunctival injury or a corneal ulcer.

Diagnosis is based on conjunctival overgrowth of the cornea, or on the presence of adhesions. Treatment depends on the condition of the eye. If vision is possible, **surgical intervention** can be undertaken to excise adhesions. Prognosis is fair to poor, as recurrence is common after surgery.

THE LACRIMAL/NASOLACRIMAL SYSTEM

ANATOMY

The precorneal tear film consists of three layers: the inner mucin layer, produced by conjunctival goblet cells; the middle aqueous tear layer; and the outer oily layer, produced by the Meibomian glands at the eyelid margin. The mucin serves to bond the aqueous film to the hydrophobic epithelial surface, improving wetting ability. The outer oily layer reduces evaporation and prolongs the surface tension of the tear film, stabilizing its distribution. The aqueous portion, which makes up the bulk of tear film, is produced from the orbital lacrimal gland and the gland of the nictitating membrane. The orbital gland is located in the dorsolateral orbit and empties into the dorsal conjunctival fornix through multiple small ducts.

The action of the eyelids during blinking moves the tear film toward the medial canthus, and actively moves tears into the nasolacrimal puncta. There are two puncta, one on each eyelid. The dorsal and ventral puncta are approximately 8 and 5 mm from the medial canthus, respectively.

The puncta open into the canaliculi, which run medially and ventrally under the palpebral conjunctiva. The canaliculi drain into the lacrimal sac, located in the lacrimal fossa. The sac is drained by the nasolacrimal duct, which runs rostrally to the distal nasal meatus. The proximal one third of the duct runs through the lacrimal and maxillary bones. Distally, the duct runs through the lacrimal groove, a sulcus in the nasal wall of the maxilla, then turns ventrally to open on the floor of the nasal vestibule at the mucocutaneous junction. Multiple openings may be present in some animals and all may or may not connect with the nasolacrimal duct.

CONGENITAL ATRESIA

Atresia may occur at any point of the nasolacrimal duct, but is most frequent at the distal meatus.

Diagnosis

Epiphora is an early clinical sign, and may progress to a mucopurulent discharge. The nasolacrimal meatus is often absent. The location of the atresia may be determined by cannulation of the nasolacrimal duct through either punctum or, preferably, by dacryocystorhinography (i.e. flushing of the tear duct with a contrast agent visible on X-ray).

Treatment

Atresia requires **surgical correction** under general anesthesia. Distal atresia can be corrected by approach through the nostril, or through a paramedian incision through the dorsal nostril wall. The duct is identified by **catheterization** through the dorsal punctum, or by distending the duct with fluid. The nasal mucosa is incised through into the duct and the catheter is advanced through the incision. The catheter is sutured in place and left for 3–4 wk to maintain patency. A topical ophthalmic antibiotic–corticosteroid solution will also reduce stenosis during healing.

More proximal atresia may necessitate a conjunctivorhinostomy by which a silicone tube is passed from the ventral conjunctival recess into the nasal passage after production of a stoma using a Steinman pin. After several weeks the new canaliculus becomes endothelialized and the tube can be removed. Postoperative management is as described for distal atresia repair.

Prognosis is fair to good, with distal atresia having a better prognosis for long-term cure after surgery than cases requiring **conjunctivorhinostomy**.

ACQUIRED DISEASES

Nasolacrimal duct obstruction

Acquired nasolacrimal obstructions may be the result of dacryocystitis, facial trauma, or bone remodeling associated with sinusitis, osteomyelitis, dental disease or neoplasia (*q.v.*).

Clinical signs include epiphora, although most cases progress to a mucopurulent ocular discharge. Skull radiographs and contrast studies are indicated. Cases related to dacryocystitis (*q.v.*) are the most easily treated, as discussed below. In other cases, the nasolacrimal obstruction may be of secondary importance until the primary cause is dealt with.

Dacryocystitis

Inflammation, or infection, of the nasolacrimal duct may be unilateral or bilateral and can result from a variety of causes. Foreign bodies such as plant matter or sand, parasites such as *Habronema* spp. or *Thelazia* spp., adnexal neoplasia (most frequently squamous cell carcinoma) and infections of the upper respiratory tract or sinuses are all possible differential diagnoses (*q.v.*). A wide variety of **secondary bacteria** may be involved and cultures of exudate are indicated.

Clinical signs

Clinical signs include conjunctivitis, which may be chronic and/or recurrent in nature, and mucopurulent discharge from the eyes and possibly from the distal meatus as well. Hemorrhagic exudate may also be seen. Differential diagnosis of such a mucopurulent discharge includes an imperforate distal nasolacrimal orifice in a young horse and squamous cell carcinoma in an older animal (*q.v.*).

Treatment

After collection of exudate from the duct for cultures and cytology, the duct should be **flushed thoroughly** to remove the maximum amount of debris and exudate, and to restore patency if possible. It may help to pass a size 5 French catheter to provide optimal flushing. If the catheter can be passed in its entirety, it should be sutured in place for several weeks to maintain patency. If patency cannot be restored, plain radiographs and **dacryocystorhinography** (*q.v.*) should be performed to identify the obstruction and to find any bony changes. Treatment with an appropriate ophthalmic antibiotic–corticosteroid solution will frequently lead to resolution after patency is restored. Systemic antibiotics may also be indicated. If an obstruction resists flushing, treatment with an antibiotic–corticosteroid may reduce the swelling sufficiently to allow flushing of the duct after a few days of treatment.

Prognosis is generally good, depending on the primary cause, although recurrence is possible. Stenosis is possible in chronic cases and may necessitate surgical intervention.

Lacerations

Eyelid lacerations involving the medial canthal area may be associated with severing of the canaliculi or nasolacrimal duct. During the reconstruction of the eyelid, it is essential to **re-appose the duct** to prevent epiphora. This is achieved by catheterizing the duct prior to closure of the wound. This may be done from the nasal meatus if necessary to identify the distal portion of the

duct. The catheter is left in place during closure to maintain apposition, and is sutured in place for several weeks to prevent stenosis during healing. Antibiotics should be given parenterally and topically postoperatively.

Keratoconjunctivitis sicca

Inadequate tear production resulting in **corneal or conjunctival inflammation** is termed keratoconjunctivitis sicca (KCS). KCS is rare in the horse. It may be idiopathic or result from **head trauma** causing skull fractures, facial paralysis or parasitic infection of the lacrimal gland, or occur transiently during general anesthesia. Certain toxins, such as locoweed (*Astragalus mollissimus*), may also cause KCS. It should be noted that tear film deficiencies can be related either to reduced production of the aqueous phase of the tear film or to increased evaporation secondary to a reduction in the lipid layer that exists to reduce evaporation. **Meibomitis** (inflammation of the Meibomian glands, *q.v.*) may result in this evaporative form of dry eye. While differentiation of aqueous deficiency versus evaporative dry eye has been discussed in the literature, it is difficult to achieve in practice, and tear replacement is the treatment of choice in both.

Clinical signs

KCS usually presents as a chronic keratitis, or conjunctivitis, with a dry dull-appearing eye. A mucoid to mucopurulent exudate is frequently present. The low tear production can be documented by **Schirmer tear test**. In this test, commercially available paper strips are placed in the conjunctival fornix and left for 1 min. The amount of wetting of the strip is measured upon removal of the paper. Normal values are 20–30 mm of wetting/min. Use of **topical Rose Bengal** can be valuable in assessing health of the ocular surface since a healthy cornea does not show adherence of the vital dye whereas areas of mucus deficiency demonstrate a punctate staining pattern.

Treatment

Treatment consists of **tear replacement** and control of secondary infection. Tear replacement may be achieved by use of an **artificial tear solution** with a methylcellulose or polyvinyl base several times daily, or a lubricant ointment twice daily. More recently, replacement using carbomer-based lubricants has been successful with a greater residence time on the ocular surface and thus a reduced frequency of application. Acetylcysteine 5% is useful in some cases as a mucolytic agent. Pilocarpine 0.25–0.5% may stimulate tear production. Topical antibiotic therapy for secondary infection should be based on culture results. **Topical corticosteroids** will provide relief from irritation, but should be used with caution because of the risk of corneal ulceration.

Chronic cases, especially those associated with facial paralysis, may benefit from temporary or permanent **tarsorrhaphy** (where the upper and lower eyelids are surgically joined). Parotid duct transposition has been described but is not routinely done.

In acute, idiopathic cases the prognosis is good as the KCS may be transient. KCS associated with trauma or facial paralysis has a more guarded prognosis, as does any case that becomes chronic.

THE CORNEA

ANATOMY

The large, prominent cornea of the horse is horizontally elliptical. It measures 28–32 mm in width, 23–26 mm in height, is 1.0–1.5 mm thick in the center, and 0.8 mm thick at the periphery. The equine cornea is a three-layered structure composed of an anterior epithelium–precorneal tear film complex, a thick collagenous stroma, and a single-layered posterior epithelium (endothelium) with its thick basement membrane. The non-keratinized anterior epithelium consists of basal, wing and stratified squamous cells, and a basement membrane. The major thickness (90%) of the cornea comes from the stroma. The stroma consists of bundles of small diameter collagen fibrils arranged in parallel layers. The posterior endothelium is a single layer of metabolically active cells and a basement membrane, known as **Descemet's membrane**. Attachments of the pectinate ligaments from the iris base to Descemet's membrane can be seen as a gray line at the limbus. The cornea is densely innervated with sensory nerves of the trigeminal nerve.

CONGENITAL ANOMALIES

Dermoids are congenital tumors (choristomas), composed of hair and many other tissue types, that can affect the temporal limbus and conjunctiva in foals. The hairs cause conjunctivitis, keratitis and blepharospasm (*q.v.*). Surgical keratectomy is the therapy of choice.

Persistent pupillary membranes (PPM) can cause varying degrees of corneal opacification and cataract formation due to damage to the endothelium and lens. These membranes normally atrophy by 9–12 mo.

CORNEAL ULCERS

Corneal ulcers are defects in the corneal epithelium that may also involve the stroma, Descemet's membrane and the endothelium. **Every ulcer in a horse is potentially serious** and sight threatening as the equine cornea appears prone to develop infection and heals slowly with extensive scarring. Most ulcers in the horse are associated with trauma. Entropion, ectopic cilia, fly sprays, facial nerve paralysis or anesthesia can also result in corneal ulceration. The risk of bacterial, fungal or mixed infections is quite high in the horse following damage to the corneal epithelium.

Clinical signs

Corneal ulcerations will generally be **painful** and the horse will exhibit photophobia, blepharospasm and increased tearing. The eyelashes will point downwards, rather than being perpendicular to the corneal surface. The corneal surface of superficial ulcers will appear dull, cloudy and roughened. Vascularization may be present in chronic cases. The corneal stroma may appear to be melting in rapidly progressive, infected ulcers. Infiltration of neutrophils into the stroma can cause **abscess formation**. Ulcers that expose Descemet's membrane will appear clear at the deepest portion of the lesion.

The **diagnosis** of a corneal ulcer is made by the application and retention of **fluorescein dye** on the cornea. Corneal scrapings should be examined, as **cytology** will enable the initiation of appropriate medical therapy for bacteria and fungi. Gram-negative bacteria known to be associated with equine corneal ulcers include *Pseudomonas* spp. and assorted coliform bacteria. *Staphylococcus* and *Streptococcus* spp. are Gram-positive bacteria found in infectious equine keratitis. *Aspergillus* and *Fusarium* spp. are common causes of fungal ulceration in the horse. Culture and antimicrobial sensitivity for bacteria and fungi are recommended, particularly in non-responding cases.

Treatment

Once a corneal ulcer is evaluated presumptively by cytology, or conclusively by culture, the objectives of medical therapy must be carefully considered to ensure comprehensive treatment. First, **bacterial and fungal growth must be halted** and the microbes rendered non-viable. Secondary anterior uveitis (*q.v.*) must then be controlled to prevent blinding sequelae. **Corneal perforation** caused by direct microbial extension or endogenous stromal proteolysis must be averted.

Medical therapy almost always comprises the major thrust in ulcer control, although the judicious use of adjunctive surgical procedures may be required in refractory cases. This intensive pharmacologic attack should satisfy the therapeutic objectives and be modified according to its efficacy. Treatment frequently needs to be sustained for weeks or, occasionally, months.

Horses with ocular disease are often in **pain** and topical treatment is usually difficult. Subconjunctival injections and the use of subpalpebral lavage systems are particularly useful in treating severe eye disease in the horse. **Subconjunctival injections** provide a depot of medication (Table 19.1) that leaks slowly from the injection site and, in effect, provides continuous corneal

Table 19.1 Dosages for subconjunctival injections

Antibiotics	
Amikacin	25 mg
Ampicillin	250 mg
Cefaloridine or cefazolin	100 mg
Chloramphenicol succinate	200 mg
Erythromycin	100 mg
Gentamicin	50 mg
Kanamycin	20 mg
Lincomycin	150 mg
Benzylpenicillin	500 000 IU
Tobramycin	5 mg
Antifungal drugs	
Amphotericin	125 µg
Miconazole	20 mg
Nystatin	5000mg
Autonomic drugs	
Atropine (15 mg/mL)	5 mg
Phenylephrine (10 mg/mL)	5 mg

lavage. A **subpalpebral lavage** system can be produced by placing a fenestrated length of silastic tubing (1.65 mm [0.065 inch] outside diameter) in the superior palpebral fornix using a 12-gauge needle or trocar. Sedation, eyelid akinesia, sensory eyelid blocks, and topical anesthesia are generally sufficient for placement. Recently, lavage systems using a placement system into the medial lower eyelid have been advocated as more simple to position than an upper eyelid system, and with the cornea protected by the third eyelid from potential damage from the footplate.

Soft contact lenses are available to fit the horse cornea. In the UK, Veterinary Speciality Products is the main provider (<http://www.sjhailes.co.uk>), while in the USA, Ocularvision (<http://www.ocularvision.com>) is one of a number of retailers. Bandage contact lenses are used to enhance epithelial adhesion in corneal ulcers, and may have a use as drug delivery systems. Tinted lenses are used to cover corneal scarring and have been advocated to reduce light intensity in uveitis (*q.v.*) where photophobia is a problem. Contact lenses should not be used where there is any suggestion of an infectious ulcerative keratitis (*q.v.*).

Antimicrobials

Several antibiotics (see Table 19.1) may also be used topically to treat bacterial ulcers. On the basis of susceptibility testing, most bacterial isolates from equine corneal ulcers are sensitive to **gentamicin**, although more recently gentamicin resistant organisms have led to increased use of fortified preparations or **fluoroquinolone** antibiotics. Antibiotic administration may need to be frequent (q 1 h) in rapidly progressing ulcers. IV **miconazole** (10 mg/mL) has been used successfully topically to treat **fungal ulcers** in horses. It may need to be administered q 1–2 h for several weeks in severely affected eyes. This high frequency of application renders a lavage system almost mandatory in such cases: an indwelling nasolacrimal cannula or a transpalpebral lavage system is most commonly used. Whereas in the past the upper eyelid was most commonly used for these systems, recent reports have suggested use of an indwelling catheter in the lower eyelid, placed medially so that the third eyelid protects the cornea from possible traumatic ulceration caused by the footplate of the lavage system.

Uveitis control

In horses, as in other species, **iridocyclitis** (inflammation of the iris and ciliary body), or anterior uveitis is a usual and expected sequel to ulcerative keratitis. Uveal inflammation is incited through an axon reflex mediated by the ophthalmic branch of the trigeminal nerve that is sensory for the cornea, conjunctiva and uvea. Anterior uveitis in horses with corneal ulcers should be treated by both topical and systemic routes. Phenylbutazone (2 mg/kg b.i.d.), aspirin (50 mg/kg b.i.d.) and flunixin meglumine (0.5 mg/kg b.i.d.) used orally or parenterally are effective in reducing uveal exudation and relieving ocular discomfort. Topical NSAIDs such as **ketorolac** or **flurbiprofen** have been shown to reduce uveitic signs secondary to ulcerative keratitis.

Topically applied anticholinergics, such as 1–2% atropine, may be effective in stabilizing the blood–aqueous barrier through their pupillary dilatation effects. Relaxation of the ciliary muscles also eliminates **ciliary spasm**, a major factor in ocular discomfort. Pupillary dilatation protects the visual axis from

occlusion and may minimize the development of **synechiae** (adhesions). Horses on topical atropine should be watched closely for symptoms of colic. Measurement of girth circumference can be a useful tool to detect gaseous distension of the intestine as a subclinical early sign of **impending gut stasis** as a consequence of topical atropine use.

Collagenolysis prevention

Severe corneal inflammation secondary to bacterial (especially *Pseudomonas* spp.) or fungal infection may result in sudden, rapid corneal liquefaction and perforation. Activation and/or production of proteolytic enzymes (matrix metalloproteinases) by corneal epithelial cells, leukocytes and organisms are responsible for stromal collagenolysis. Acetylcysteine (up to 10%) or sodium EDTA should be instilled hourly, in addition to the other indicated drugs, until stromal liquefaction ceases. Fresh autogenous plasma or serum used topically is also beneficial in reducing the collagenolysis since a number of anti-collagenolytic factors such as α_2 -macroglobulin are to be found in serum. Different matrix metalloproteinases require different factors to inhibit them: some are calcium dependent requiring EDTA, others have zinc as a cofactor necessitating use of acetylcysteine which chelates zinc in the same manner that EDTA chelates calcium. The rich diversity of tissue inhibitors of matrix metalloproteinases (TIMPS) to be found in serum renders this a particularly useful addition to the therapeutic armamentarium of anti-collagenolytic agents.

Inappropriate therapy

Corticosteroid therapy by all routes is contraindicated in the management of equine corneal infections. Even topical corticosteroid instillation, to reduce the size of post-mycotic corneal scarring or vascularization, may be disastrous if fungi remain indolent in the corneal stroma.

Surgical therapy

Keratotomy (or surgical removal of corneal tissue) may prove useful both in the early stage of ulcerative keratomycosis, while infection is confined to the corneal epithelium and anterior third or half of the corneal stroma, and also in later stages of stromal mycosis when the epithelium has healed. Some clinicians suggest **epithelial debridement** with 7% tincture of iodine applied with a cotton-tipped swab to the corneal surface as routine management. Where fungal infection occurs, therapeutic full thickness corneal transplantation has been advocated but clearly this requires referral to a **specialist center** accustomed to performing such surgery.

To augment lost corneal thickness and strength as well as providing ocular surface protection, deep corneal ulcers threatening perforation may require conjunctival or nictitans flap placement. The former requires mobilization of a **conjunctival flap**, which is sutured to the corneal surface at the edge of the ulcer and acts to adhere to and close the corneal deficit. The latter involves suturing the nictitating membrane to the perilimbal sclera or upper eyelid and merely provides physical protection and support. If, as in these latter cases, the apposed conjunctiva adheres to the denuded stroma, drug penetration may be slightly impeded, but ocular perforation will be averted. The use of a conjunctival pedicle flap also has the advantage of continuous serum supply to

the denuded area of cornea with provision of serum matrix metalloproteinases on a continual basis.

Panophthalmitis (inflammation of all tunics of the eye) following perforation through a stromal ulcer has a grave prognosis, and carries a high risk for loss of vision. Medical therapy includes injection of antimicrobial drugs into the anterior chamber, and systemic antibiotics. Whether or not treatment is applied, **phthisis bulbi** (*q.v.*) is likely to result after a chronically painful course. To spare the unfortunate horse this chronic discomfort, enucleation is the humane alternative.

PERSISTENT EROSIONS

Non-healing ulcers characterized by circumferential lips of non-attached epithelium are found in neonatal foals. Causes to be ruled out include entropion, ectopic cilia, keratoconjunctivitis sicca, nictitans foreign bodies, and bacterial, fungal or viral infection (*q.v.*). Treatment consists of removal of the epithelial lip with a soft cotton swab, cautery of the edges of the ulcer with 7% tincture of iodine, and administration of topical autogenous serum, hyperosmotic solutions, and ophthalmic antibiotic/cycloplegic solutions.

Non-healing ulcers have also been reported in the adult. Treatment of these ulcers includes debridement of the redundant epithelium, the use of soft contact lenses, and performing **multiple punctate keratotomies** (MPK). MPK can be performed with topical anesthesia and sedation. A 22–25 gauge needle is pressed into the anterior stroma just enough to indent it. These micro-punctures are made every 0.5–1 mm over the entire ulcer and extended a few mm into the adjacent epithelium. These allow the exposure of the underlying stroma and enhance the production of a more adherent basement membrane.

STROMAL ABSCESES

In cases with a small but deep corneal ulcer, the epithelium may heal over the ulcer bed, **trapping microorganisms** beneath the epithelium. This may permit the growth of the bacteria and result in the formation of a suppurative infiltrate. The resulting keratitis, and secondary uveitis, may be intense.

Clinical diagnosis is based on the finding of a **non-ulcerative keratitis** with a yellow-to-white stromal infiltrate. Cultures and cytology should be based on deep corneal scrapings.

Treatment is as for ulcerative keratitis (*q.v.*), and should include systemic NSAIDs as well as atropine for **cycloplegia** (paralysis of the ciliary body). It may be desirable to repeat corneal scraping (as often as necessary) to prevent re-epithelialization. This will allow increased antibiotic penetration. Antibiotic therapy should be aggressive topically, and the horse may also benefit from systemic antibiotics.

Prognosis is guarded, as the inflammatory response is difficult to control and may run a prolonged course.

NON-ULCERATIVE KERATOUVEITIS

Non-ulcerative keratouveitis is a painful, progressive keratitis characterized by a flesh-colored stromal infiltrate at the limbus. This condition appears to be

immune mediated. It must be differentiated from stromal abscessation. Treatment consists of topically and systemically administered corticosteroids and NSAIDs. The prognosis for recovery is poor.

PUNCTATE KERATITIS

Multiple, superficial, punctate opacities are characteristic of viral keratitis in the horse. Fluorescein dye retention is variable, but Rose Bengal solution is helpful in identifying devitalized cells. Equine herpesvirus 2 has been isolated from affected horses. Treatment with trifluridine or idoxuridine 6 times per day is recommended.

CORNEAL LACERATIONS

Corneal lacerations are common ocular injuries in the horse. They may or may not be associated with **iridal prolapse**. The sclera should be carefully examined for any hidden defects if the laceration involves the limbus. Prompt surgical correction is required to prevent infection and maintain vision. The prognosis for retention of vision is guarded in most cases due to the risk of endophthalmitis (*q.v.*).

THE ANTERIOR UVEAL TRACT

ANATOMY

The uveal tract consists of the iris and ciliary body (**the anterior uvea**) and the choroid (**the posterior uvea**). The iris serves to regulate the amount of light that enters the posterior segment through the central aperture, the pupil. Pupil size is a function of the sphincter muscle, which runs primarily horizontally in the horse, and the dilator muscle which runs radially deep in the iris. The pupil margin is lined by granula iridica at the center of its upper and lower border. These pigmented bodies are extensions of the posterior pigmented iris epithelium, and are frequently vacuolated.

The iris stroma contains melanocytes and fibroblasts as the predominant cell type. The blood supply is derived from the long posterior ciliary arteries, which form an incomplete major arterial circle at the base of the iris, and numerous small radial arteries.

The ciliary body is divided into two portions, the anterior pars plicata and the pars plana posteriorly. The pars plicata is composed of numerous processes that project into the posterior chamber. A double epithelial layer covers the processes, and is responsible for aqueous humor production. The ciliary muscles are responsible for lenticular accommodation, albeit limited, through the zonular fibers. The pars plana is a flat transition zone from the ciliary processes to the peripheral retina. The uveal tract continues posteriorly as the choroid.

CONGENITAL ANOMALIES

Aniridia

Failure of iris development is rare, but has been reported in the Belgian Draft Horse and sporadically in other breeds. The defect is inherited as an autosomal

dominant in the Belgian horse. Although visual acuity appears to be lower in affected horses, the predominant problem is **photophobia** (*q.v.*): without an iris to constrict the pupil in bright light, higher than normal levels of solar irradiation can impinge upon the retina. In these cases the use of **tinted contact lenses** can be helpful.

Persistent pupillary membranes

In normal development, the mesenchymal tissue covering the pupil regresses, leaving the pupillary aperture. Remnants of this tissue may be seen arising from the iris collarette, and are termed **persistent pupillary membranes** (PPM). PPM may attach to the cornea, creating a focal area of edema, to the lens where focal cataracts may result, or bridge the pupil from iris to iris. These may be an incidental finding or be associated with other ocular anomalies. Treatment is usually not indicated. No genetic predisposition is known.

Heterochromia

Pigment variations of the iris may occur and may involve all or part of one eye, or both. Eyes with blue-colored irides are often referred to as **wall-eyes** or **china eyes**. They are most frequently seen in horses such as Paints or Appaloosas that have **excessive white markings of the face**. Pigment variations of the posterior segment of the eye are commonly seen concurrently. **No functional deficit** is associated with heterochromia. One problem that can occur in these eyes with deficient pigmentation is the appearance of what resembles an **iris cyst**, but is in fact stromal hypoplasia of the iris allowing aqueous produced by the ciliary body behind the iris to “balloon” forward the iris tissues, giving the appearance of a cyst.

ACQUIRED UVEAL DISEASE

Uveitis

Intraocular inflammation is a leading cause of blindness in the horse. Uveitis may be acute or, frequently, recurrent. Many etiologies have been implicated in acute cases, including trauma, bacteria (*Leptospira* spp., *Brucella* spp., *Streptococcus equi*), viruses (parainfluenza 3, equine influenza, equine viral arteritis), fungi (*Chlamydia*, *Mycoplasma*), parasites (*Onchocerca cervicalis*, *Microfilaria*, *Strongylus*, *Toxoplasma gondii*), hypersensitivity reactions, phacoanaphylaxis, endotoxemia and neoplasia (*q.v.*). In cases of ocular trauma or endotoxemia/septicemia, the uveitis may be due to a breakdown of the blood–eye barriers without a specific ocular immune response occurring. Uveitis may also be caused by corneal ulcers (*q.v.*). Stimulation of corneal nerve endings initiates an axonal reflex, creating miosis and protein leakage into the aqueous humor.

In infectious or immune-mediated causes of uveitis, antigens encountered by the eye must be processed at distant sites, as there is normally no lymphatic drainage from the eye. In the normal eye the lymphocytes migrate through blood vessels to the spleen where they present antigen to splenic antigen-presenting cells. This so-called “camerosplenic” access allows antigen presentation to occur

in a specific splenic immunologic environment. Here the immunologic conversation between lymphocytes and antigen-presenting cells results in development of a population of Th2 helper T lymphocytes. These lead to an immunologic response which results in the proliferation of antibody-producing B cells and not the cytotoxic and Th1 helper cells that yield the delayed type hypersensitivity reaction. Theoretically, this down-regulates damaging tissue reactions that would lead to profound intraocular inflammation and subsequent blindness. Whether this occurs in practice is unclear—in the inflamed eye sensitized immune cells and a “soup” of inflammatory cytokines are sequestered in the vitreous. The presence of these cells and cytokines may create a recurrent nature to the uveitis, which may be reactivated by these cells if they are challenged by appropriate antigens at a later date.

With regard to **leptospirosis** (*q.v.*), tests have shown that intraocular responses against leptospira occur in a large number of cases of equine **recurrent uveitis**. Recent work on **therapeutic vitrectomy** in equine recurrent uveitis has shown the presence of intravitreal leptospiral nucleic acid by polymerase chain reaction (PCR), confirming that **intraocular leptospira** are associated with a number of cases of equine recurrent uveitis. It may be that vitreally sequestered leptospiral organisms are responsible for the recurrent nature of much equine uveitis. In such a case “**bystander injury**” may be responsible for the ocular findings in uveitis as the immune system responds to these organisms and the intraocular structures are damaged as a result. Another possibility is highlighted by findings of molecular mimicry between leptospiral surface antigens and uveal and posterior corneal antigens. This suggests that immunologic responses to certain leptospiral antigens may also result in responses directed against these cross-reacting intraocular antigens. Another possibility is that in horses subject to recurrent uveitis the uveal response may be exaggerated, or may be lacking in suppressor T cells. In such cases, local derangement in immunoregulation may be the determining factor in the development of equine recurrent uveitis.

Not all cases of acute uveitis result in recurrent episodes. Uveitis after trauma may not recur but it seems that, all too often, a previously inflamed eye can easily become the focus for further inflammation at a later date.

Clinical signs

Active uveitis may show signs of ocular pain, such as blepharospasm, photophobia, epiphora and depression. Decreased vision may or may not be evident. Ocular pain may necessitate sedation and/or palpebral nerve blocks to facilitate ophthalmic examination.

Ophthalmic findings cover a spectrum of clinical signs that vary with the severity of the inflammation. **Low grade uveitis** may show only **ocular hypotony** (decreased intraocular pressure) and **aqueous flare** (turbidity due to increased protein in the aqueous humor). Most cases of uveitis will show some degree of **conjunctival hyperemia**. Deeper ciliary vessels are often injected. **Miosis** (*q.v.*) is a fairly consistent clinical sign. In mild inflammation, where the **anisocoria** (unequal size of the pupils) may not be dramatic, the affected eye will usually show a resistance to dilatation by mydriatics. The iris may appear thickened and edematous. Inflammatory cell infiltrates may contribute to the aqueous flare and may lead to **hypopyon** formation (i.e. pus in the anterior chamber).

The cells may organize with fibrin to form keratic precipitates (adherent deposits on the corneal endothelial surface). **Hyphema** (blood in the anterior chamber) may also be present. Corneal edema (*q.v.*) is commonly present, and usually indicates decreased endothelial cell function due to inflammation. The edema may be generalized, or may begin peripherally and follow ingrowth of corneal neovascularization. Corneal vessels usually indicate chronicity, and may be a branching superficial pattern, or a deep ciliary “paintbrush” type.

Posterior uveitis may be manifested as **chorioretinitis**, often seen as cellular infiltration or edema adjacent to the optic nerve. The vitreous may appear cloudy due to inflammatory cells and proteins. Clumps of these cells may form vitreous “floaters”. With chronicity, the vitreous may liquefy, and the movement of these floaters will become exaggerated. This liquefaction, combined with the organization of vitreal exudates into fibrous traction bands, may lead to **retinal detachment** (*q.v.*).

Other signs consistent with chronicity, or suggestive of recurrent episodes, include increased iris pigmentation, nodule formation within the iris, and synechia formation. **Posterior synechiae**, adhesions of the iris to the lens capsule, are most common, and may be seen as a distorted or immobile pupil, or as pigment deposits on the lens capsule. **Anterior synechiae** (adhesions of the iris to the cornea) are most commonly seen with perforating wounds and subsequent iris prolapses.

Other signs of chronicity or **equine recurrent uveitis** include cataracts (*q.v.*), which may be focal or generalized, lens luxation, and persistent corneal edema. Chorioretinal scarring may also be seen, and the typical “butterfly” lesion of depigmentation and atrophy medial and lateral to the optic disk may be considered a sign of equine recurrent uveitis. Having said that, it would be unwise to fail a horse at pre-purchase examination (*q.v.*) because these butterfly lesions were seen in a case where no other signs of uveitis were present. Recent research associating these lesions with equine herpesvirus infection underlines the possibility that they may occur without uveitic change. Generalized retinal atrophy may follow severe inflammation. Glaucoma can be a complication but generally **phthisis bulbi** (*q.v.*) is a more frequent result of chronic or severe inflammation.

A particularly severe form of uveitis, referred to as **keratouveitis**, is accompanied by a non-ulcerated keratitis, usually characterized by a fleshy corneal infiltrate and marked corneal neovascularization.

Diagnosis

Although a morphologic diagnosis of uveitis may be easy to make based on clinical signs, it is often difficult to ascertain the etiology. **Fluorescein** should be applied to the cornea to rule out ulceration. Systemic involvement should be evaluated by a general physical examination, CBC and serum chemistry panel. Tests for specific etiologic factors, such as conjunctival biopsies for onchocerciasis and serology for viral or bacterial agents, must be interpreted with care, as many normal horses may have *Onchocerca* (*q.v.*), or positive serology titers. Especially in recurrent cases, the episode of uveitis may occur long after the initial infection and an elevated serum antibody titer may not be seen. Extremely high or rising paired sera antibody titers may be supportive of a diagnosis. Comparison of affected horses with normal stablemates may

be useful. Elevated aqueous antibody titers are diagnostic, although collection of the aqueous sample will exacerbate the uveitis.

Treatment

Many cases of uveitis will not have a cause determined and therefore are treated symptomatically. Uveitis should be treated with **anti-inflammatory agents** and **mydriatics/cycloplegics** for symptomatic therapy. In cases where a specific etiology is identified or suspected, specific therapy should be instituted. However, in onchocerciasis, anthelmintic therapy may **exacerbate the inflammatory response** if anti-inflammatory therapy is not adequate.

Initial therapy should be aggressive, and reduced as clinical signs subside. **In the absence of corneal ulcers, topical corticosteroids** are extremely useful. Prednisolone acetate 1% or dexamethasone 0.1% are the drugs of choice, and should be given every 1–6 h, depending on the severity of the uveitis. Frequent therapy may be facilitated by a subpalpebral or nasolacrimal lavage system, which may be used with or without a perfusion pump. **Subconjunctival corticosteroids** are useful to supplement topical therapy if frequent applications are not possible. Methylprednisolone acetate (10–40 mg), triamcinolone acetonide (10–40 mg) or betamethasone (3–5 mg) can be used. Injection volumes should not exceed 1 mL, and may be repeated q 1–4 wk as required.

Systemic corticosteroids may also be beneficial. Dexamethasone may be used at doses up to 20 mg/500 kg PO b.i.d., but prednisone used at 0.8–1.5 mg/kg may be as efficacious, with less risk of corticosteroid-induced side effects. NSAIDs are also very useful. Flunixin meglumine (1 mg/kg IV, IM, PO) or phenylbutazone (3–6 mg/kg IV or PO b.i.d.) is useful in active uveitis. Aspirin (30 mg/kg PO s.i.d.) may be useful in reducing episodes of equine recurrent uveitis. Topical NSAIDs are also available. Suprofen 1% and flurbiprofen 0.03% are potent anti-inflammatory agents and can be used concurrently with topical corticosteroids to achieve an additive effect. Their use in corneal ulceration is controversial.

Atropine is the mydriatic/cycloplegic of choice. Topical or subconjunctival therapy should be aggressive until mydriasis is achieved, at which time it should be reduced to a maintenance level. Mydriasis may persist for several weeks after discontinuing therapy. **Intestinal motility** should be closely monitored if higher dosages are used, as systemic effects have been reported. Although not a useful mydriatic in the normal eye, topical phenylephrine may augment the mydriasis in eyes refractory to dilation.

Any case of uveitis is **potentially blinding**. In cases of equine recurrent uveitis, the prognosis is generally poor, due to the chronic, recurrent nature of the disorder. Cases of acute uveitis may have a fair to good prognosis depending on the cause and severity of the uveitis. Keratouveitis (*q.v.*) generally has a poor prognosis.

Intravitreal implants containing **ciclosporin** in a slow-release formulation have been reported to be efficacious in down-regulating the inflammatory effects of recurrent uveitis but clearly such medication has to be repeated and can only be considered as a control measure and not a cure.

Surgical vitrectomy, on the other hand, has recently been reported to be a useful therapeutic option with long-term resolution of episodic recurrence. Other workers have not had particular success with the technique, but this

difference may be explained by the fact that the German ophthalmologists, who first reported success with the technique, designed and constructed a specific lengthened probe for both mechanical vitrectomy and cataract phacoemulsification. Attempting vitrectomy with a probe designed for the human or small companion eye is doomed to failure since complete removal of all vitreous humor is not possible using equipment designed for smaller eyes. The exact mechanism by which vitrectomy prevents recurrence of intraocular inflammation is still somewhat unclear: it may be that sequestered leptospiral antigen is thus removed, or that the inflammatory “soup” of cytokines and resident immune competent cells in the vitreous is removed.

Hyphema

Anterior chamber hemorrhage may be associated with blunt or penetrating trauma, chronic uveitis with iridal neovascularization, neoplasia or bleeding disorders (*q.v.*). Non-specific treatment includes stall rest and symptomatic uveitis therapy (*q.v.*). Non-clotted blood will clear from the anterior chamber within a few days. Clotted blood may take a few weeks to resorb. Surgical intervention is not indicated in non-clotting hyphema, and only in clotted hyphema if complications such as glaucoma (*q.v.*) are occurring. Tissue plasminogen activator or urokinase may be used to lyse the clot. Prognosis for hyphema in the absence of severe ocular disease is generally good. The presence of persistent hyphema may be a poor prognostic sign in trauma cases.

GLAUCOMA

INTRODUCTION

Glaucoma is an ocular condition characterized by an elevation in intraocular pressure (IOP) that is associated with **optic nerve damage** and eventual **blindness**. The elevation in IOP in most cases is thought to be due to an inability of the aqueous humor to exit the globe. Glaucoma in the horse is considered by some to be rare, but the initial clinical signs are so subtle that the actual incidence of this disease is not known. Equine glaucoma is an **insidious, progressive disease** that produces significant optic nerve damage without overt clinical signs until late in the disease.

ANATOMY AND PHYSIOLOGY OF AQUEOUS HUMOR PRODUCTION AND DRAINAGE

Aqueous humor is produced in the ciliary epithelium by energy dependent and independent mechanisms. The carbonic anhydrase and Na^+K^+ ATPase enzymes are involved in aqueous production. Aqueous humor passes into the posterior chamber, through the pupil into the anterior chamber, and then exits through the iridocorneal angle (conventional pathway), or through secondary (unconventional) outflow pathways, such as the iris vasculature or supraciliary space. Obstruction at the pupil, iris face, iridocorneal angle or any other part of the outflow pathway can result in an increase in IOP. One theory concerning the

apparent low incidence of glaucoma in the horse is that, in spite of the extensive anterior segment alterations that occur in equine recurrent uveitis (*q.v.*), the unconventional outflow pathways are quite extensive and allow for substantial aqueous drainage despite damage to the conventional pathways.

ETIOLOGY AND DIAGNOSIS

Primary glaucoma, a result of biochemical alterations in the iridocorneal angle, has not been definitively diagnosed in the horse. Glaucoma secondary to obstruction of outflow pathways with vascular membranes, inflammatory cells and debris, or tumor cells is more commonly reported.

Horses with **early glaucoma** present with more subtle clinical signs than horses with advanced disease. Early glaucoma has been diagnosed in Quarter Horses, Thoroughbreds, Arabians, Warmbloods, Appaloosas, Tennessee Walking Horses and Welsh ponies. The most commonly reported early signs are generalized corneal edema, deep linear corneal band opacities, and a fixed, dilated pupil. The affected eye is rarely painful or blind. Topically administered corticosteroids can cause the edema to resolve, suggesting an inflammatory component to equine glaucoma, but the IOP remains elevated. The corneal band opacities are found in horses without glaucoma, thus their relationship to the glaucoma is confusing.

Advanced cases of equine glaucoma may have extensive corneal edema, buphthalmos, blepharospasm, and exhibit signs of blindness due to optic nerve damage (*q.v.*).

The normal IOP of the horse ranges from 16 to 32 mmHg with an average of 24 mmHg. **Electronic applanation tonometers** are the most reliable means of determining the IOP in the horse, although digital tonometry can provide rudimentary IOP levels. Auriculopalpebral nerve blocks should be done prior to tonometry to prevent artificially high readings due to pressure on the eyelids during tonometry.

TREATMENT

Therapy is directed at lowering IOP to maintain vision for as long as possible by decreasing aqueous humor production, increasing aqueous humor outflow, and suppressing any inflammation associated with the glaucoma. Medical therapy in cases of early glaucoma in the horse is difficult to manage, and particularly frustrating in the **Appaloosa** breed, which has a particularly aggressive form of glaucoma.

Outflow can be increased with topically administered **parasympathomimetics**, such as 0.03% echothiophate iodide (b.i.d.), or 0.25% demecarium bromide (b.i.d.). These drugs can exacerbate iridocyclitis (*q.v.*) and should be used with caution if inflammation is present. Aqueous humor production can be lowered with 0.5% timolol maleate. Topical 0.03% sodium flurbiprofen and corticosteroids and systemically administered NSAIDs are also beneficial. Topical carbonic anhydrase inhibitors and prostaglandins will be available in the near future for cases of equine glaucoma.

Atropine may be useful in glaucoma in the horse. This is somewhat ironic, given that in all other species the drug is contraindicated in glaucoma.

As noted above, the horse appears to have an unusually high proportion of aqueous outflow through the unconventional outflow pathway—through choroidal spaces rather than the iridocorneal angle—and this outflow is increased by pupillary dilation. Given the secondary nature of most equine glaucoma with iridocorneal angle blockage through inflammatory debris or peripheral anterior synechiae (*q.v.*) closing the angle, increasing this unconventional outflow is a valuable treatment option, although IOP should be monitored during treatment to ensure that atropinization does not increase it.

Surgical therapy may be necessary to control the IOP in refractory cases. Damage to the ciliary body caused by nitrous oxide (cyclocryotherapy) or laser energy (cyclophotocoagulation) is necessary to reduce the aqueous production and lower the IOP in some cases. This may be the therapy of choice in early cases of equine glaucoma. Filtration gonioimplant surgeries to increase outflow of aqueous humor are experimental in the horse. Chronically painful, blind buphthalmic eyes, or eyes in which the glaucoma is caused by an intraocular tumor, should be enucleated or eviscerated with placement of an intraocular silicone prosthesis. In some cases injection of intravitreal gentamicin may be considered but this pharmacobliteration of the ciliary body can result in substantial intraocular inflammation and thus is not recommended in most horses.

THE LENS

ANATOMY

The lens is a spheroidal, transparent, refractive structure suspended from the ciliary body behind the iris by zonular ligaments. The zonule inserts into the equatorial region of the lens capsule, which surrounds the entire lens. The inner surface of the anterior part of the lens capsule is lined by a single layer of lens epithelium. The lens substance comprises lens fibers laid down in concentric layers like the layers of an onion. The fibers are formed by elongation of lens epithelial cells at the lens equator. New fibers are continually formed around the periphery of the lens throughout life, compressing older fibers in toward the center of the lens. The outer area of lens is the cortex, the inner and older region the lens nucleus. The lens undergoes minimal change in refractive power during accommodation in the horse.

CONGENITAL ANOMALIES

Congenital abnormalities of the lens in the horse are rare with the exception of cataract. **Microphakia** refers to a congenitally small lens, which may be seen in association with other developmental abnormalities of the eye. **Coloboma**, or an absence of part of the lens and associated zonule, may also infrequently occur.

CATARACT

Cataracts, or opacities in the lens, are the most common abnormality of the lens. They may be found in foals at birth or be acquired at any age throughout life. **Congenital cataracts** are the most common congenital ocular anomaly in

the horse. They are often bilateral and can be associated with other abnormalities, including microphthalmia and aniridia (*q.v.*).

The cause of cataracts in the horse is rarely determined but the most likely etiologies include heredity, trauma or uveitis. **Focal cataracts** may be seen at the tips of the lens sutures in a Y-shaped configuration, or at the posterior capsule on the central lens axis associated with persistent hyaloid artery in the vitreous. Congenital cataracts may involve only the lens nucleus or be mature and total opacities of the whole lens. **Acquired cataracts**, such as those caused by trauma or uveitis (*q.v.*), may involve any focal area of the nucleus or cortex, and may progress to become total mature cataracts.

Congenital nuclear cataracts rarely progress to become total cataracts after birth. The progression of acquired cataracts in older horses cannot be predicted with any certainty. The discovery of a focal cataract in a previously normal lens is reason for concern about probable progression and deterioration of vision.

Clinically, cataracts can be diagnosed after applying a **topical mydriatic** to the eye. Tropicamide (Mydriacyl, Alcon) 1% applied to the conjunctiva will dilate the pupil in 20 min and enable examination of the lens with either a focal oblique light source or slit beam. The location of most cataracts can easily be determined in this way. Cataracts secondary to trauma or uveitis will have other signs of ocular inflammation—conjunctival injection, corneal edema, aqueous flare, fibrin or hyphema, and in chronic or quiescent cases pigment on the anterior lens capsule or posterior synechiae between the iris and lens (*q.v.*).

The extent of **visual impairment** is proportional to the volume of the lens that is cataractous, and, to some extent, the location of the cataract within the lens. Focal cataracts involving a small area of the lens, suture line cataracts or hyaloid-associated cataracts do not impair vision to a significant extent and require no treatment. Horses affected with cataract may only begin to show visual impairment when large areas of the lens are affected. Horses with congenital nuclear cataracts may have severe visual deficits, especially when the pupil is constricted in bright light. Total mature cataracts cause blindness in the affected eye.

Nuclear cataracts with a peripheral ring of clear cortex impair vision with a small pupil. Application of topical 1% atropine to the affected eye q 72–96 h will maintain mydriasis and often enable useful vision around the edges of the cataract. At present there is no effective medical therapy that will cause regression of cataracts.

The only effective therapy for total mature cataracts is **surgical removal**. Selection of suitable cases is extremely important in improving the chance of a successful surgical outcome. Inherited, congenital or acquired cataracts are the best surgical candidates. Cataracts secondary to previous ocular trauma may be surgical candidates provided there is no evidence of active ocular inflammation prior to surgery. Horses with cataracts secondary to equine recurrent uveitis (*q.v.*) are not candidates for cataract surgery and can be guaranteed to have severe problems after surgery unless vitrectomy is performed as detailed above.

In horses <6 mo of age the cataract can be removed by discission and aspiration of the lens cortex and nucleus after removing the anterior lens capsule. In older horses, the technique of choice for cataract removal is extracapsular with removal of a portion of the anterior lens capsule followed by **phacofragmentation** (the use of ultrasound energy) and aspiration of the cataract. The equipment required for phacofragmentation is available to

many veterinary ophthalmologists, although **special phacofragmentor needles** are needed to cope with the size of the equine eye. This technique uses a small incision at the limbus, which is less traumatic than opening the eye through 180°. Coupled with the use of both systemic and topical NSAIDs and topical corticosteroids, cycloplegics and mydriatics, this technique has improved the success rate for cataract removal in horses. Even with this technique, the proportion of animals with long-term maintenance of vision is significantly lower than with the same technique in dogs. The effects of cataract surgery on vision in the horse are unknown, although owners should be warned that caution is needed if the horse is used for activities such as jumping which involve reasonable visual function.

Complications of cataract extraction in the horse include corneal ulceration, severe chronic uveitis and retinal detachment (*q.v.*). Glaucoma does not appear to be a common complication in this species.

LENS LUXATION

Lens luxation occurs congenitally associated with other ocular anomalies, or secondary to equine recurrent uveitis (*q.v.*) or ocular trauma. Luxations due to equine recurrent uveitis occur after chronic recurrent bouts of disease, and signs of chronic uveitis are always evident. Traumatic luxations require considerable force to break the zonule and dislocate the lens. Other signs of severe ocular damage will also be present. The lens may be luxated anteriorly into the anterior chamber or posteriorly into the vitreous. Anterior lens luxations may be referred to a veterinary ophthalmologist for removal by an intracapsular approach with reasonable results. A posteriorly luxated lens is more difficult to remove surgically and may as well be left in situ.

THE POSTERIOR SEGMENT

ANATOMY

The posterior segment consists of three layers, the retina being innermost, the middle choroid that includes the tapetum fibrosum, and the sclera providing the outer protective coat. The ocular fundus, that portion of the posterior segment that can be viewed by ophthalmoscopy, consists of tapetal fundus, non-tapetal fundus, retinal blood vessels and the optic disk or papilla. The retina consists of the neurosensory retina (the inner 9 layers) and the outer single layer of retinal pigment epithelium (RPE). The photoreceptors within the neurosensory retina are predominantly rods with a ratio of 1 cone to 20 rods.

The horse retina has two areas of increased cone density and visual perception: the “area centralis” for forward binocular vision and the “visual streak” for monocular lateral vision that are 15 mm and 8 mm dorsolateral of the optic disk, respectively.

With large, laterally positioned globes, large oval corneas, horizontal pupils, and a large lens with limited or no accommodation, the horse eye has evolved to provide primarily panoramic views. The horse is thought to see green and yellow colors, but has poor vision for red.

VARIATIONS OF THE NORMAL FUNDUS

Tapetal fundus

The **tapetum fibrosum layer**, consisting of organized lamellae of collagen fibers with their long axes parallel to the retina, can be observed by ophthalmoscopy through the transparent neurosensory retina and RPE. The tapetal fundus is an irregular triangular area in the upper two thirds of the ocular fundus. Its horizontal base is immediately above the optic disk or papilla. Distributed evenly throughout the tapetal fundus are minute black spots (“**stars of Winslow**”) that mark the penetration of individual choriocapillaries through the tapetum fibrosum.

The tapetal fundus color ranges from yellow-green to green-blue. **Partial albinism** of the tapetal fundus occurs occasionally in gray, palomino, light chestnut and Appaloosa horses and frequently with partial iridial heterochromia (*q.v.*). Partial albinism may be demonstrated in the tapetal fundus as yellow areas with red “stars of Winslow”. In some light gray horses the tapetum is hypoplastic or sometimes completely absent, and is often combined with incomplete pigmentation of the non-tapetal fundus permitting direct observation of the underlying choroidal vasculature. Multiple foci of fairly uniform pigmentation occur occasionally in the tapetal fundus and converging lines of pigmentation signal the origin of the vortex venous drainage system.

Non-tapetal fundus

The non-tapetal area occupies the ventral fundus and completely surrounds the tapetal fundus. The normal dark brown-black non-tapetal fundus results from the densely pigmented RPE. At the junction of the tapetal and non-tapetal fundi, the transition of pigmentation of the RPE is often irregular. In the non-tapetal fundus immediately above the optic disk, pigmentation is often limited and irregular, permitting direct visualization of the deeper choroidal vasculature and occasionally the sclera. In lightly pigmented horses with palomino, gray and white haircoats and in the Appaloosa breed, the non-tapetal fundus may have limited pigmentation permitting direct observation of the deeper choroidal vessels against the white scleral background. The periphery of the retina may be seen on ophthalmoscopy at its junction with the ciliary body (the **ora serrata**).

Retinal vasculature

The equine ocular fundus has a **paurangiotic retinal vasculature** pattern consisting of approximately 40–60 small blood vessels that branch dichotomously and extend from the optic disk for only 2–3 disk diameters. Because of the small diameters of these blood vessels, the arteries cannot be distinguished from the veins ophthalmoscopically, but can be separated by high-speed fluorescein angiography. The arteries, which are branches from the short ciliary arteries, are confined to the inner retinal layers and provide the blood supply to only the immediate peripapillary retina and the optic disk. Hence, the majority of the neurosensory retina must exchange its metabolites and oxygen across the RPE from the deeper choroidal vasculature.

Optic disk/papilla

The round to oval optic disk or papilla is situated within the non-tapetal fundus just below the tapetal junction. Its color ranges from red to pale orange to a pale pink. Its surface is irregular, containing limited numbers of small tortuous blood vessels. The edges are usually easily distinguished from the surrounding non-tapetal fundus and occasionally a ventral notch is present. Sometimes, a white scleral rim is seen, usually at the dorsal edge of the optic disk, arising from a lack of the RPE and choroidal vessels. This rim is traversed by the normal peripapillary vasculature. The peripapillary retina may appear thicker and slightly translucent because of its increased thickness. Infrequently medullated nerve fibers emerge with the ventral peripapillary retinal blood vessels, appearing as white to gray irregular tufts or streaks, and must be differentiated from retinal edema and peripapillary chorioretinitis (*q.v.*). The optic nerve exits the eye through a collagenous meshwork in the sclera, the lamina cribrosa.

EXAMINATION OF THE OCULAR FUNDUS

Abnormalities of the equine ocular fundus occur in approximately 10% of the general horse population. The equine ocular fundus is examined most often by direct and indirect ophthalmoscopy; other procedures that can be employed include fluorescein angiography, A- and B-scan ultrasonography, electroretinography, and slit lamp biomicroscopy. The ocular fundus is best examined in a darkened room, with the pupils dilated with 1% tropicamide, and the horse restrained gently but firmly.

DISEASES OF THE RETINA AND CHOROID

Congenital anomalies

Congenital diseases of the ocular fundus include typical and atypical **colobomas** (defects in or absence of tissue due to improper development), and **night blindness** in the Appaloosa. Large typical colobomas involving the optic disk and non-tapetal fundus (at the 6 o'clock position) are associated with failure of the fetal fissure to close, and have been reported in the horse in association with uveal, retinal and lens defects, and blindness. These colobomas contain foci of hyperplastic and dysplastic retina.

Atypical colobomas, affecting the retinal pigment epithelium, affect the ocular fundus in areas other than the 6 o'clock position. They occur infrequently in the non-tapetal fundus and appear as single or multiple foci of reduced pigmentation with sharply defined borders, often in the peripapillary region. Similar RPE defects occur rarely in the tapetal fundus and appear as single to multiple areas of **intense pigmentation**. Vision in affected horses appears unimpaired. There is no treatment.

Congenital night blindness in the **Appaloosa** horse is characterized by visual impairment in reduced illumination as early as 1 mo of age. Day vision is infrequently impaired. Affected animals are unwilling to enter unfamiliar environments with reduced illumination and often injure themselves. The ocular fundi are normal by ophthalmoscopy but electroretinography can

confirm the disease. Breeding of affected animals or their parents is not recommended as the condition may be inherited as a recessive trait.

Inflammatory disorders

Inflammation of the ocular fundus may involve the retina, the choroid and/or the optic disk. The inflammatory process may originate from the optic nerve, the peripapillary retinal and choroidal blood vessels or extend posteriorly from inflammation in the anterior uvea and vitreous. The retina, as modified neural tissue, often shares diseases common to the CNS; the posterior uvea or choroid may be affected with infections of hematogenous origin. Inflammations of the retina and/or choroid have been reported with **equine recurrent uveitis**, various septicemias and bacteremias, toxoplasmosis, Borna disease, trypanosomiasis and onchocerciasis (*q.v.*).

Equine recurrent uveitis (*q.v.*) may have multiple etiologies that include *Leptospira* spp., and is characterized as multiple recurrent bouts of anterior and posterior uveitis. While the anterior segment abnormalities often prevent detailed inspection of the ocular fundus, fundic lesions may appear in as many as 25% of horses affected with equine recurrent uveitis. Often the “butterfly” peripapillary chorioretinitis or chorioretinopathy is associated with the anterior segment inflammation. Confusion occurs when only unilateral or bilateral “butterfly” peripapillary lesions are present. While peripapillary chorioretinitis or chorioretinopathy has been associated with the equine recurrent uveitis complex, it may also occur as a distinct disease. An assessment of *Leptospira* titers (*L. pomona*, *L. icterohaemorrhagica*, *L. hardjo* and *L. autumnalis*) in horses with peripapillary lesions revealed that the majority of horses with increasing titers to *L. autumnalis* developed peripapillary chorioretinopathy within 6–12 mo. The peripapillary lesions have also been produced in ponies inoculated experimentally with *L. pomona*. Similar lesions have been produced by experimental intranasal inoculation with equine herpesvirus type 1 (*q.v.*), and thus peripapillary lesions may be related to herpetic infection and not equine recurrent uveitis.

Active chorioretinitis in the tapetal and non-tapetal fundi appears fundoscopically as slightly raised grayish foci with indistinct edges. Inactive chorioretinitis or chorioretinopathy appears as foci of either reduced or increased pigmentation and in the tapetal fundus areas as either increased or reduced tapetal reflectivity. In the peripapillary region, the retinal vessels in the active phase of inflammation may appear more prominent and raised; in the inactive phase there may be a paucity of vessels. Unless considerable ocular fundus is involved or the optic nerve is affected, visual impairment is not usually demonstrable. Horses with **peripapillary chorioretinopathy** in the absence of anterior segment disease should be carefully monitored for significant changes to the optic disk. Treatment with systemic antibiotics and/or corticosteroids has not demonstrated efficacy for this condition.

Trauma and retinal detachments

Trauma to the head and/or eye is most apt to affect the anterior segment causing anterior uveitis, hyphema and corneal abnormalities. Trauma in foals may

result in **complete retinal detachments**, often complicated by disinsertion at the ora serrata. The condition is usually unilateral and affected foals are usually presented with visual impairment limited to the affected side. The retinal detachment is visible by ophthalmoscopy and appears as a gray translucent membrane extending from the optic disk into the ventral vitreous. Occasionally vitreous hemorrhage is also present. Treatment is not successful.

Neoplasms

Intraocular neoplasms (*q.v.*) affecting the ocular fundus usually originate from the anterior uvea or posteriorly from the optic nerve. Both **malignant melanomas** of the anterior uvea and optic nerve **medulloepitheliomas** occur but are rare in the horse. Both present as space-occupying masses and are usually detected by slit lamp biomicroscopy, ophthalmoscopy and ultrasonography. These conditions are treated by enucleation and exenteration, respectively.

Miscellaneous retinopathies

Fundusoscopic changes of generalized retinal degeneration (pigmentary retinopathy) occur in the horse and signal complete blindness. Scattered throughout the tapetal fundus are dark irregular pigmented foci; despite several reported cases, microscopic examination of the affected eyes has not been reported. **Glaucoma** (*q.v.*) in the horse is being recognized more frequently with the routine **use of applanation tonometry**. Increased intraocular pressure causes degeneration of the retinal ganglion cells, and cupping and atrophy in the optic disk. **Retinal detachments** in horses are also associated with ocular congenital anomalies and fundic inflammation; reattachment of the detached retina secondary to inflammation may follow successful resolution of the initial condition. Small subretinal and/or choroidal hemorrhages in the tapetal fundus are not uncommon in equine neonates and usually resolve quickly without treatment. These hemorrhages may signal trauma or transient hypoxia during parturition.

DISEASES OF THE OPTIC DISK AND NERVE

Several conditions can affect the optic disk and nerve of the horse. Unilateral optic nerve disease may be revealed as slight mydriasis (dilation of the pupil), monocular visual impairment or blindness, occasional stumbling (primarily on turning), and reduced or absent light-induced pupillary light reflexes. Since 80% of the optic nerve fibers in the horse decussate, the indirect or consensual light pupillary reflex occurs but is usually slower and less complete. When both optic nerves are affected, marked visual impairment or blindness is usually present.

Congenital anomalies

Congenitally blind foals may present with bilateral optic nerve hypoplasia, with or without colobomas and other ocular anomalies (*q.v.*). In either case, the optic nerve can be significantly hypoplastic. Funduscopically the **hypoplastic**

optic disk appears white, reduced in size, and depressed below the surrounding retina. Few or no retinal vessels are present. When **colobomas** (*q.v.*) are present, both the optic disk and ventral non-tapetal fundus may be involved; within these excavations the underlying sclera is visible and pigmented membranes of hyperplastic and dysplastic retina extend forward into the vitreous.

Inflammatory disorders

Inflammation of the optic disk and nerve in the horse has been associated with many diseases including equine recurrent uveitis, systemic leptospirosis, *Onchocerca cervicalis* and toxoplasmosis (*q.v.*). A specific **exudative optic neuritis** occurs in horses in Europe, often with a history of trauma, hemorrhage or colic, and often sudden blindness. Both optic disks may be affected; the disk appears raised with indistinct margins and frequently has hemorrhages on its surface. **Optic atrophy** may occur several months later. The cause or causes for exudative optic neuritis have not been established. Treatment with systemic antibiotics and/or corticosteroids appears ineffective.

Trauma

Optic nerve inflammation and subsequent atrophy may follow skull trauma, usually associated with injury to the head by rearing and hitting overhead objects. Even without obvious orbital and skull fractures and any changes to the optic disk, avulsion and pressure on the optic nerve within the optic nerve canal and the optic chiasm should be suspected. **Orbital hemorrhage and/or edema** may also compress the long optic nerve. The disease is often unilateral. Loss of vision, the direct light-induced pupillary reflex and menace response occurs, as does mydriasis. Early funduscopic findings may include a normal disk or hyperemic disk with peripapillary hemorrhages or edema. Several weeks later, **optic atrophy** can occur with a depressed white optic disk and loss of the peripapillary blood vessels. Other neurologic signs (*q.v.*) such as focal muscle atrophy, proprioceptive deficits and lameness may eventually become apparent. The prognosis for this condition should always be guarded. Treatment with high doses of systemic corticosteroids (10–20 mg dexamethasone daily) and phenylbutazone (1–2 g daily) immediately after the injury may be effective in some cases. Affected optic nerves and even the optic chiasm examined at necropsy may demonstrate focal swelling and constrictions that microscopically are foci of cavitation (liquefactive necrosis), fibrovascular bands, and astrocytic gliosis characteristic of axonal swelling and myelin degeneration.

Ischemic optic neuropathy

Ischemic optic neuropathy occurs in the horse associated with **vessel ligation** of the large arteries (internal and external carotid arteries and palatine artery) for **guttural pouch disease** and the prevention of recurrent hemorrhage. The equine fundus, except for the immediate peripapillary region, is dependent on the underlying choroidal vessels and may be predisposed to hypoxia. The choroidal vessels receive their primary blood supply from the 4–6 short posterior ciliary

arteries that are branches of the external ophthalmic artery. The two long posterior ciliary arteries may also provide some branches laterally and medially to the choroid. In approximately 50% of affected horses the exterior and internal ophthalmic arteries exchange anastomotic branches. Unilateral visual impairment to blindness and mydriasis (*q.v.*) are the usual presenting signs occurring soon after the surgery. Funduscopically the optic disk appears swollen, hyperemic and contains several raised white myelin-like excrescences that extend into the adjacent retina and vitreous. The edema from the optic nerve ischemia may acutely extrude the myelin and ruptured nerve fibers into the peripapillary retina and vitreous. **Unilateral blindness** results from this condition.

Post-hemorrhagic neuropathy

Optic disk and nerve atrophy and retinochoroidopathy occur in the horse following profound hemorrhage postoperatively or occasionally after injury. In many species the retina, optic nerves, and the brain vasculature possess autoregulation. The choroidal vessels have high flow rates, no autoregulation, and are highly permeable, permitting the exchange of metabolites to the neurosensory retina and RPE. With the highest metabolic rate and limited storage of oxygen and glycogen, the equine retina may be **very susceptible to ischemia**.

Clinically the condition most often follows **castration** complicated with extensive postoperative hemorrhage. The horse may become recumbent, and visual impairment or blindness is noted several days post hemorrhage. **Bilateral mydriasis** (*q.v.*) is usually present, with negative light pupillary and menace reflexes. Ophthalmic findings are limited to the ocular fundus and optic disk, and may not be apparent until several weeks to a few months after the initiating event. The blindness appears directly related to the **optic nerve atrophy**; the optic disks appear depressed and white, with absence of the peripapillary vasculature. Numerous tapetal and non-tapetal lesions are concentrated at the posterior pole and consist of clumps of intense pigmentation and reduced pigmentation that mimic the distribution of the underlying choroidal vessels. Focal raised yellow-white exudates may appear on the disk's surface and edge. Microscopic examinations of affected eyes reveal focal full thickness retinal destruction with RPE hyperplasia and migration into the remaining retina. There is also generalized degeneration and loss of the retinal ganglion cells. The optic disk and generalized optic nerve atrophy are characterized by the widespread loss of myelin and axons, and the replacement by gliosis. Treatment with high doses of systemic dexamethasone has been unsuccessful.

Neoplasia

Primary and secondary neoplasms of the optic nerve are very rare in the horse. Medulloepitheliomas have been reported, which presented as space-occupying orbital masses. Benign gliomas, astrocytomas and schwannomas may also occur in the optic nerve head but have not been associated with visual compromise.

Proliferative optic neuropathy

Proliferative optic neuropathy occurs in older and aged horses, usually as a **unilateral** condition **without visual impairment**. It is usually detected during routine ophthalmic examinations. Funduscopically, proliferative optic neuropathy appears as a small single nodule or, rarely, multiple nodules on the edge or surface of the optic disk extending into the vitreous and usually the same color as the adjacent disk. The ocular fundus and peripapillary retinal and optic disk vasculature are usually normal. Microscopically, proliferative optic neuropathy has been classified as astrocytoma, granular (Schwann) cell tumor, and xanthoma. Treatment of the condition has not been attempted.

Miscellaneous

Cupping and excavation of the optic disk occur with glaucoma (*q.v.*). Funduscopically, the optic disk is markedly depressed and gray to white; its surface may be smooth with baring of the lamina cribrosa and loss of the peripapillary blood vessels.

NEOPLASIA OF THE EYE AND ADNEXA

INTRODUCTION

When presented with a horse possessing an ocular and/or periocular mass, signalment, haircoat and skin coloration, husbandry practices, geographic location, rate and location of lesion development, and previous treatment may help in the logical differential diagnosis. Squamous cell carcinoma (SCC), sarcoid, papilloma, melanoma and nerve sheath tumors, in descending order of prevalence, are the most common neoplasms of the equine eye and adnexa. Squamous cell carcinoma, sarcoid, papilloma and melanoma also commonly affect other anatomic regions of the horse; thus, a **complete physical examination** should always be performed in conjunction with the ophthalmologic examination.

If the horse is fractious or in pain, some form of chemical restraint may be required such that a thorough clinical examination and adequate sample collection can be safely obtained in an efficient manner. In addition to systemically administered analgesics and sedatives, topical anesthesia and auriculopalpebral and/or local eyelid nerve blocks may be necessary.

Routine blood tests and conventional skull or thoracic radiography may be indicated if local invasion of the orbit or metastasis is suspected. Special imaging techniques that may yield additional information, especially regarding intraocular or orbital disease, include B-scan, dimensional ultrasonography, dacryocystorhinography and computed tomography.

Biopsy and **histopathologic examination** are required for definitive diagnosis and selection of an appropriate mode of treatment. Excisional biopsy is usually performed on a mass that is readily accessible, localized and relatively small. In contrast, an incisional (wedge) biopsy is generally obtained when a lesion's location impedes easy access (e.g. the orbit) and when lesions are invasive, multiple or large. Fine needle aspiration biopsy (*q.v.*) can be useful as a first step before a more invasive technique is used.

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is the most common tumor of the eye and its adnexa in horses. The globe, adnexa and/or orbit can be affected; however, the nictitating membrane, nasal canthus, limbus and eyelid are most frequently involved. The cause is not known but **non-pigmented adnexa** and exposure to **intense solar radiation** are associated with an increased prevalence. In addition, an increase in age, the breed (draft horses, Appaloosas, American Paints and Pintos), and gender (geldings more than stallions and mares) appear to be associated with a greater likelihood of SCC development. Ocular SCCs usually slowly enlarge, are locally aggressive and rarely metastasize. If metastasis does occur, the regional lymph nodes and salivary glands are generally affected.

Clinical signs and diagnosis

The gross appearance of SCC is dependent upon its anatomic location and stage of development. Early neoplastic change may cause a localized, low grade inflammatory response. A hyperplastic plaque or papilloma-like growth may subsequently develop, undergo further metaplastic change and become an SCC, which can be circumscribed if discovered early in its development. If unhindered growth takes place, the tumor may become invasive, irregular and necrotic in appearance. Histologic confirmation of presumptive ocular/adnexal SCC should always be obtained since its clinical appearance can resemble sarcoid, papilloma, cutaneous habronemiasis, foreign body granuloma, *Onchocerca*-induced keratoconjunctivitis and other less common neoplastic or inflammatory processes (*q.v.*).

Treatment

Treatment of SCC is dependent upon tumor size and anatomic location, the presence or absence of distant metastases, the clinician's expertise, availability of equipment, and the owner's financial limitations. **Routine tetanus prophylaxis** (*q.v.*) should be administered before any invasive procedure.

SCC of the eyelid may be completely removed by **excision** alone. However, if the mass is large, surgical reduction and adjunctive **cryotherapy**, **brachytherapy** or localized hyperthermia are recommended. Cryotherapy is a rapid, inexpensive and repeatable procedure. Two or three rapid freeze (to a tissue temperature of -20 to -25°C) and slow thaw cycles should be performed. A 5–10 mm zone of normal tissue beyond the grossly evident tumor should also be frozen. When eyelids are frozen, depigmentation of the skin is usually transient, whereas whitening of the hair is permanent. Although liquid nitrogen is a stronger cryogen, the use of nitrous oxide may provide better control of freezing cycles when dealing with the relatively delicate ocular adnexa. Excessive cryotherapy of the eyelid can cause marked contracture and subsequent distortion of the eyelid aperture.

Brachytherapy with iridium wires or strontium-90 beta irradiation may be applicable with the former implanted in deeper lesions while the latter can be used after debulking of a more superficial neoplasm.

Localized hyperthermia (50°C for 30 s) is effective when used to treat ocular/adnexal SCCs that are superficial and have a small tumor volume. In contrast, interstitial radiotherapy (e.g. caesium-137 and cobalt-60) has been

successful in the treatment of large, non-resectable eyelid tumors, but the impractical logistics (expense, necessary expertise and potential danger) of this treatment modality limit its availability.

Treatment modalities available for SCC involving the **nictitating membrane** include partial or complete nictitating membrane resection and surgical cytoreduction with adjunctive cryotherapy. Strontium-90 beta irradiation (approximately 90–120 Gray [100 rads]) and carbon dioxide laser ablation may also yield excellent results, but these modalities are not readily available.

Limbal SCC can be effectively treated by superficial keratectomy/conjunctivectomy alone or in combination with localized hyperthermia. Despite the potential for persistent corneal scarring and conjunctival depigmentation, localized hyperthermia is an inexpensive, rational therapeutic modality. **Strontium-90 beta irradiation** and **carbon dioxide laser ablation** are also effective in the treatment of limbal SCC, but expense limits availability.

SCC that goes unnoticed, or recurs despite treatment, may eventually affect the orbit. Orbital SCC should be aggressively treated by **exenteration**. Adjunctive cryotherapy of suspicious, non-resectable orbital tissues has been used in selected cases with success.

Prognosis

Because of slow tumor growth and rare metastasis, ocular/adnexal SCC is associated with a good overall prognosis in horses. However, tumor location may influence the prognosis. Eyelid or orbital involvement is associated with the poorest prognosis, whereas involvement of the nictitating membrane typically has an excellent prognosis. In addition, tumor size is inversely related to survival, and one or more recurrences appear markedly to reduce survival time.

SARCOID

Sarcoid (*q.v.*) is the second most common equine periocular tumor. Two **viruses**, bovine papillomavirus and a C-type retrovirus, have been incriminated as causes of these benign, fibroblastic tumors that affect the skin of horses, donkeys and mules. Although sarcoids in the periocular region are usually less aggressive than those appearing in other anatomic locations, they may be resistant to treatment.

Clinical signs and diagnosis

Sarcoids usually develop in younger horses (<7 yr) and have considerable variation in their clinical appearance. These bizarre dermatologic growths have been divided into three morphologic types: (1) **verrucous** or wart-like sarcoids are generally <6 cm in diameter, dry, hairless and cauliflower-like; (2) **fibroblastic** sarcoids are larger and resemble granulation tissue; (3) **mixed** sarcoids are a combination of the verrucous and fibroblastic types. Reasonable differential diagnoses include SCC, papilloma, nerve sheath tumors, cutaneous habronemiasis, phycomycosis and granulation tissue (*q.v.*). Because no pathognomonic clinical characteristics exist and treatment regimens for these similar diseases differ greatly, histologic confirmation of a presumptive sarcoid should always be made.

Treatment and prognosis

Sarcoids can be extremely difficult to treat. Surgical resection alone often results in recurrence. Small sarcoids may be cured with localized hyperthermia (to 50°C) or cryotherapy (to -20 to -25°C). Radiation therapy, if available, may be extremely efficacious: **iridium wire implantation** is the most effective treatment option. **Cisplatin** (*q.v.*) is effective against most types of sarcoids. However, periocular sarcoids may also be successfully treated by intralesional inoculation of cell walls of **bacillus Calmette–Guérin (BCG)** suspended in oil (*q.v.*). Following surgical cytorreduction, tumor saturation with the BCG vaccine stimulates an active immune response. Treatment must be repeated if the tumor persists after the inflammatory reaction subsides. In general, 1–6 BCG treatments are needed to effect complete regression. Immunotherapy with BCG does not result in excessive scarring or altered function of the treated eyelid tissue and the prognosis is generally good. Complications such as non-healing fistulas can, however, occur even when all tumor has been obliterated by the ensuing inflammatory reaction. See also Chapter 5, page 379.

PAPILLOMA

Papillomas, also called **warts**, are common, benign cutaneous tumors caused by either an equine papillomavirus or non-infectious irritants. The infectious, multicentric variety is referred to as **papillomatosis** (*q.v.*). Once a premise is infected by a papillomavirus, the disease may become a herd problem and recur on a yearly basis affecting new offspring.

Clinical signs and diagnosis

Papillomas frequently affect the muzzle, eyelids and ears of young horses. Papillomas are usually keratinized masses with fronds and may exist in clusters. Diagnosis can generally be inferred from the clinical characteristics.

Treatment and prognosis

Equine infectious papillomatosis is a self-limiting disease but the duration varies considerably, from 1 to 6 mo. Medical or surgical intervention is not necessary unless the lesions are cosmetically objectionable. **Cryotherapy** and **intradermally administered autogenous vaccines** have been effective.

Prevention

Affected foals should be isolated from susceptible foals. In addition, administration of a commercially prepared vaccine to foals 2–3 mo of age may prevent wart development in high-risk environments.

MELANOMA

Horses with gray or white haircoat colors have an increased prevalence of cutaneous (including the eyelid) and intraocular melanoma (*q.v.*). A disturbance in melanin metabolism, and thus an increased likelihood of tumor formation, may be associated with aging and graying in the horse.

Clinical signs and diagnosis

In general, equine **ocular/adnexal melanomas** are slow-growing, pigmented, localized neoplasms that do not metastasize and may affect the eyelid, bulbar conjunctiva and/or sclera, and the anterior uveal tract. Arabian, Lippizaner, Percheron and related breeds have an increased risk for cutaneous melanoma. Epibulbar melanocytomas are rare in horses and should be differentiated from congenital dermoids. Melanomas are the most common equine intraocular tumors. **Intraocular melanomas** are generally locally expansive and destructive, suggesting malignancy, but an absence of metastasis and their histologic appearance imply a benign biologic behavior.

An **anterior uveal melanoma** may present as a slowly or rapidly expanding, darkly pigmented, dense mass with secondary pupil distortion, or possibly obliteration of the anterior chamber. Marked uveal involvement may also cause uveitis and cataract (*q.v.*).

Anterior uveal cysts may resemble an intraocular melanoma. Uveal cysts usually appear as spherical to ellipsoidal, dark brown to black, smooth bodies in older horses. Anterior uveal cysts may become detached and float freely within the globe or they may spontaneously rupture. Heavily pigmented cysts may prevent transillumination by a focal beam of light. In contrast, some uveal cysts may appear thin-walled and translucent.

Hypertrophic and cystic change of the corpora nigra, or granula iridica, may also be difficult to differentiate from melanoma.

Treatment and prognosis

Surgical debulking and adjunctive cryotherapy is an effective treatment scheme for eyelid and epibulbar melanomas. **Complete excision** (sector iridectomy or iridocyclectomy) is the treatment of choice for intraocular melanoma in horses. However, risks inherent in the surgical procedure, tumor size and expense often eliminate the possibility of surgical management for intraocular melanoma. These cases are usually monitored, treated symptomatically and, when painful or secondary complications develop, the affected globe is enucleated. **Exenteration** should be reserved for those cases with extraocular extension. Aggressive surgical management should yield a good prognosis.

NERVE SHEATH TUMORS (NEUROFIBROMA AND SCHWANNOMA)

Nerve sheath tumors arise from perineural fibroblasts and nerve sheath or Schwann cells. The initiating cause of nerve sheath tumors is unknown.

Clinical signs and diagnosis

Neurofibroma of the upper and lower eyelid appears to be a specific entity in the horse. Eyelid neurofibromas occur subcutaneously as single or multiple, small, circumscribed lesions that increase in size up to 1 cm in diameter.

Treatment

Because of local extension, recurrence is common following attempted surgical removal. Cryotherapy, BCG immunotherapy and interstitial radiotherapy

are alternative and possibly more effective treatment modalities for large nerve sheath tumors.

OTHER OCULAR/PERIOcular TUMORS

Many other, less common, ocular, adnexal and orbital tumors have been reported in horses. More information is needed such that natural behavior, preferred treatment modalities and prognosis can be established for these uncommon neoplasms. Some of these rarer tumors involving the equine ocular/periocular tissues are discussed below. Since the first attempt at treatment has the greatest chance of resulting in a cure, an aggressive therapeutic regimen should be utilized when a tumor of which little is known is diagnosed.

Eyelid

Adenocarcinoma, adenoma, basal cell tumor, fibroma, hemangiosarcoma, lymphosarcoma, mast cell tumor and sebaceous adenoma have been documented affecting the equine eyelid. Some eyelid adenocarcinomas have been reported to metastasize following incomplete excision. Equine basal cell tumors are usually solitary, slow-growing, benign lesions that can be successfully removed via surgery. Lymphosarcoma of the eyelids may be primary or secondary. Multicentric lymphosarcoma is presently not treatable via practical means. Equine mast cell tumors do not readily metastasize and may respond to surgery alone or in conjunction with cryotherapy.

Nictitating membrane

Except for SCC, tumors of the nictitating membrane are very rare. The following neoplasms have been reported involving the nictitating membrane of the horse: basal cell tumor, hemangiosarcoma, papilloma, lipoma, lymphangiosarcoma, neurofibroma, primary lymphosarcoma and sebaceous adenocarcinoma. Metastasis has been documented in horses with lymphangiosarcoma and sebaceous adenocarcinoma of the nictitans.

Cornea and sclera

Analogous to neoplasia of the nictitating membrane, except for SCC, tumors of the cornea, bulbar conjunctiva and/or sclera are rare. Histologically confirmed neoplasms include angiosarcoma, hemangioma, hemangiosarcoma, lymphosarcoma, mastocytoma, melanocytoma and papilloma.

Intraocular tumors

Medulloepitheliomas are rare, congenital, neuroepithelial tumors that usually arise from the ciliary body but have been reported to originate from the retina and optic nerve. These tumors are generally non-pigmented, vascularized and slow growing. The characteristic biological behavior of these tumors is unknown; therefore, affected globes should be enucleated once secondary complications or growth are documented. In contrast, a rare, benign proliferation of the optic papilla and adjacent retina has been described in the horse and named

proliferative optic neuropathy. Affected horses are usually aged and asymptomatic. The unique proliferative process affects one globe, protrudes into the vitreous, and is well circumscribed, whitish-gray to pink, and non-progressive. Thus, an affected eye should be retained unless complications are noted upon periodic re-examination.

Orbit

Orbital neoplasia, primary or secondary, is uncommon in horses. Secondary orbital tumors may be the result of metastasis from a distant primary site or local extension from adjacent tissue. Reported equine primary orbital tumors include undifferentiated adenocarcinoma, carcinoma of neuroepithelial origin, lipoma, medulloepithelioma, melanoma, meningioma, multilobular osteoma (chondroma rodens), neuroepithelial tumor of the optic nerve and granulocytic sarcoma.

Orbital tumors are usually slowly progressive and non-painful. The only exception to this is the marked lymphomatous deposit that can cause exceptional chemosis and exophthalmos in cases of leukemia, but such cases are rare. Marked **exophthalmos** may cause lagophthalmos and concomitant exposure keratitis. Orbital tumors may also cause periorbital swelling, shallowing of the supraorbital fossa, protrusion of the nictitating membrane, strabismus, and resistance of the globe to retropulsion. Scleral deformation and retinal detachment, or inflammation and pressure atrophy of the optic nerve may decrease or eliminate vision.

Diagnosis of orbital disease can be difficult because a thorough diagnostic work-up is expensive and may require special techniques, instrumentation or expertise. **Exophthalmos** (*q.v.*) is caused by a space-occupying lesion and must be differentiated from **buphthalmos**, in which the globe is enlarged as a consequence of chronic glaucoma (*q.v.*). Differential considerations for an orbital, space-occupying mass should include tumor, cyst, granuloma, abscess and cellulitis (*q.v.*). Orbital cysts are exceedingly rare. A granuloma, abscess or cellulitis may be caused by a migrating foreign body, guttural pouch mycosis or extension of a suppurative disease from the frontal or maxillary sinuses. Biopsies, and possibly tissue cultures, are necessary to definitively diagnose an orbital disease.

If an orbital tumor is well circumscribed and small, an exploratory orbitotomy may result in complete excision and retention of the eye. Extensive, infiltrative disease usually mandates orbital exenteration. If allowed to progress without some form of intervention, orbital tumors may enter the calvaria, or dome of the skull, and result in neurologic manifestations (*q.v.*). Primary neoplastic disease of the sinuses that has subsequently invaded the orbit is seldom amenable to treatment and the prognosis is poor.

OCULAR TRAUMA

INTRODUCTION

The horse by its nature and lifestyle seems inordinately prone to ocular injuries. Kicks from other horses or sudden head movements in enclosed

spaces can result in considerable force being applied to the orbital area. A closed bony orbit, while protecting against minor blows, may be fractured, entrapping the eye or adnexal structures. The prominence of the eye predisposes itself to both blunt trauma and sharp penetrating injuries. The **prognosis** for saving a traumatized eye and maintaining vision is related to the type of trauma. Sharp penetrating or perforating injuries in general carry a better prognosis than blunt trauma that causes either **contrecoup reactions** (bruising of brain tissue) or ocular rupture. Perforating injuries of the cornea alone tend to have a better prognosis than those that extend into the scleral coat of the globe.

OCULAR EXAMINATION

The most important and urgent question to be answered when examining a horse with ocular trauma is the extent of globe involvement. If the eyeball has been damaged, expeditious medical or surgical treatment is essential. An attempt should be made to assess whether the affected eye has vision using the **menace response** as a guide.

Most horses with eye injuries are in **pain**. Xylazine administered at 0.4 mg/kg IV provides adequate sedation for ocular examination. The direct pupillary light reflex (PLR) should be evaluated if the anterior chamber is clear. A miotic (constricted) pupil most likely indicates iridocyclitis and is a better prognostic sign than mydriasis (reflex pupillary dilation), which suggests damage to the parasympathetic innervation of the iris. If **hyphema** (*q.v.*) is present, the iris and posterior segment may not be seen. If the consensual PLR is present in the normal eye when a bright light is shone into the injured eye, this is an indication that retinal and optic nerve function are still present on the injured side.

To examine the globe, it is essential that **regional motor nerve blocks** (*q.v.*) are used. Failure to do this may result in considerable pressure being exerted on the globe. The auriculopalpebral nerve is blocked with 1–2 mL 1% lidocaine along the dorsal aspect of the zygomatic arch halfway between the lateral canthus of the eye and the base of the ear.

The eyelids, conjunctiva, nictitating membrane, cornea and sclera are examined for contusions, abrasions and lacerations. The anterior chamber is examined for aqueous flare, fibrin, hemorrhage or the presence of a dislocated lens. The posterior segment (vitreous and retina) is examined by ophthalmoscopy for hemorrhage or retinal edema or detachment, and the optic nerve is examined for signs of hemorrhage or optic atrophy.

ORBITAL FRACTURES

Fractures of the ventral orbital wall and zygomatic processes of the orbital bones are relatively common in the horse. Ocular tissues, including extraocular muscles, may be entrapped, and subconjunctival and retrobulbar hemorrhage may occur. Corneoscleral lacerations and uveitis may be present and should be treated independently. Radiography of the orbit can be attempted but positioning and interpretation is often difficult, the lateral oblique view usually giving most information.

Fractures need not be treated immediately, and more attention should be paid to the eyeball initially. If **entrapment** of ocular tissue is considered likely,

however, the fractures should be treated immediately. Initial therapy should consist of cold compresses, dimethyl sulfoxide (DMSO), NSAIDs and systemic corticosteroids to reduce swelling, and systemic antibiotics if fractures are compound. Topical **artificial tears** and petrolatum ointment should be used to avoid corneal exposure if swelling limits eyelid closure. Fractures with minimal displacement may not require surgical treatment. If the cosmetic appearance is affected, displacement is severe or compound fractures occur, surgical repositioning of bones and fragments should be attempted.

EYELID INJURIES

Trauma may result in eyelid contusions or lacerations. Eyelid and conjunctival edema (**chemosis**), conjunctival hemorrhage and reduced eyelid motility are typical signs. Contusions are treated with cold compresses, DMSO applied to the lids, and systemic NSAIDs such as flunixin meglumine 1 mg/kg IV or PO daily. Severe eyelid and conjunctival swelling will result in conjunctival and corneal exposure. **Artificial tears** and **lubricating petrolatum ointment** should be applied to the conjunctiva and cornea to keep these moist until swelling around the eye has subsided.

Lacerations of the eyelids should be repaired surgically. Small lid lacerations involving only the skin can be sutured with 4-0 silk. Complicated, full thickness lacerations of the eyelid should be repaired in two layers. The inner tarsoconjunctival layer of the eyelid is sutured with absorbable 5-0 to 6-0 polyglactin 910, and the skin layer with 4-0 silk. Suturing must begin at the eyelid margin for both layers. A cruciate (figure of eight) suture pattern provides best apposition at the eyelid margin in the outer skin-orbicularis muscle layer. The rest of the laceration is sutured with a simple interrupted pattern. Post-surgical medications should include topical antibiotic ointment, systemic NSAIDs and antibiotics and tetanus prophylaxis.

LACERATIONS OF CONJUNCTIVA AND NICTITATING MEMBRANE

Small conjunctival lacerations will in most cases heal without surgical repair. Extensive lacerations can be repaired with 6-0 polyglactin 910, with a simple continuous suture pattern. Even without surgery these will eventually heal. **Topical antibiotics** should be used. Lacerations of the nictitating membrane may require suturing with 6-0 to 7-0 polyglactin 910 using a simple interrupted or continuous pattern in the conjunctiva. Care should be taken not to leave knots or suture material protruding from the bulbar surface of the nictitating membrane to abrade the cornea. A triple antibiotic solution or ointment should be applied t.i.d. to q.i.d.

CORNEAL AND SCLERAL LACERATIONS

Trauma to the cornea may result in superficial abrasions, or penetrating or perforating lacerations. Lacerations may extend into the sclera. **Corneal abrasions** result in a painful, red eye with a miotic pupil due to reflex iridocyclitis. The area around the laceration is edematous and thickened. The extent of the

corneal abrasion is determined by irrigating the cornea with **sodium fluorescein dye**. Abrasions should be treated with topical antibiotics and atropine 1% q 6 h.

Penetrating corneal and scleral lacerations should be repaired under general anesthesia. The laceration is sutured with 7-0 polyglactin 910 using a simple interrupted pattern. Sutures should penetrate the cornea to two-thirds the depth of the stroma and be placed 1–2 mm apart.

Small perforating **puncture wounds** in the cornea may seal rapidly with fibrin from the aqueous humor, and can be treated medically with topical and systemic antibiotics and atropine for the associated uveitis (*q.v.*) provided leakage of aqueous is not detected.

Perforating injuries to the cornea and sclera may present with a collapsed anterior chamber. The lacerations may be plugged with iris. When the cornea is perforated, the blood–aqueous barrier is disrupted. Fibrinogen enters the anterior chamber and polymerizes to fibrin, forming secondary or plasmoid aqueous and along with the iris helps to seal the laceration. Secondary aqueous that leaks through the laceration forms a gelatinous mass that adheres to the edges of the laceration and prolapsed iris. This may give the appearance that the laceration is larger than is actually the case. The secondary aqueous usually obscures the true extent of the laceration. This may be compounded beyond the limbus where scleral lacerations are obscured by edematous conjunctiva.

These lacerations must be repaired under general anesthesia. **Flunixin meglumine** and **systemic broad-spectrum antibiotics** are given IV **before** surgery. The eye should be medicated immediately before or at the time of inducing anesthesia with a topical broad-spectrum antibiotic and atropine. The extent of the laceration should be explored, paying careful attention to potential extension across the limbus into the sclera. Failure to suture any scleral extension of the laceration will result in phthisis of the globe after surgery.

The iris should be gently freed from any adhesions to the edge of the laceration. In injuries <24 h old, the iris can be replaced into the anterior chamber. The anterior chamber is irrigated with **lactated Ringer's solution** or balanced salt solution to remove as much blood and fibrin as possible. If the anterior chamber is difficult to re-form with irrigating solutions, an air bubble will often push the iris and lens away from the cornea while the laceration is repaired. Alternatively, **viscoelastic materials** including sodium hyaluronate or sodium chondroitin sulfate–sodium hyaluronate can be injected through the laceration to re-form the anterior chamber. Viscoelastics have the added advantage of protecting the posterior endothelial surface of the cornea during surgical manipulations, although the cost of volumes large enough to fill the equine anterior chamber may be prohibitive.

If the laceration has been present >24 h, some of the entrapped iris may be devitalized. The protruding iris may be **trimmed** with scissors until hemorrhage is seen or may be **debrided** with a fine cautery and then the remaining iris can be replaced in the anterior chamber. Extensive debridement of the iris is rarely necessary.

The laceration should be sutured with 7-0 to 8-0 polyglactin placed to two-thirds the corneal depth, spaced 1–2 mm apart in a simple interrupted pattern. An air bubble or viscoelastic material can be replaced by lactated Ringer's solution or balanced salt solution prior to placing the last suture provided that the anterior chamber has re-formed.

It has previously been recommended that a subpalpebral lavage be placed in the upper eyelid at the conclusion of surgery in order to medicate the eye effectively in the postoperative period. More recently a medial lower eyelid lavage system has been suggested which is more readily placed and exceptionally well tolerated by the horse. Clearly, in a trauma situation, the placement of such a system will depend on the areas of lid damaged in the trauma. Medications include systemic NSAIDs and antibiotics, topical antibiotics and atropine q 4–6 h.

CORNEAL FOREIGN BODIES

Superficial foreign bodies in the cornea can be removed using sedation, local motor nerve blocks and topical anesthesia of the cornea with proparacaine hydrochloride. Deep penetrating or perforating foreign bodies should be removed under general anesthesia and the injury site sutured. Gunshot in the eye may be removed if accessible in the anterior chamber. Rarely is gunshot in the vitreous accessible for removal. Gunshot in the orbit should be left in situ.

TRAUMATIC UVEITIS

Anterior uveitis or iridocyclitis (*q.v.*) is a common finding in cases of ocular trauma. It may accompany corneal injuries or occur without any corneal lesion being detected. Signs of uveitis include a hyperemic conjunctiva, corneal edema, aqueous flare or hyphema, miosis and swelling of the iris. The eye is painful due to spasm of the ciliary muscle.

Atropine 1–3% is applied topically q 4–6 h for cycloplegia to reduce pain and dilate the pupil to reduce the incidence of posterior synechiae development. NSAIDs are given systemically to provide analgesia and reduce intraocular inflammation and miosis. Drugs chosen may include **flunixin meglumine** 1 mg/kg administered IV or PO, aspirin 25 mg/kg b.i.d. for 3–5 days and then 30 mg/kg once daily as long as needed, or phenylbutazone 2 g/kg once daily. Topical NSAIDs are also useful. Although not licensed in the horse, topical flurbiprofen (0.03%) can be applied q 6 h while other NSAIDs such as ketorolac can be equally useful. Dexamethasone 0.1% suspension or prednisolone acetate 1.0% should be used q 4–6 h unless corneal ulceration is present or supervenes.

The prognosis should be guarded, especially when the lens cannot be seen. Anterior segment hemorrhage and fibrin will be cleared from the eye via the aqueous outflow pathways and by phagocytosis within a few days of the injury in most cases that receive adequate therapy.

LENS TRAUMA

Trauma to the eye may result in **rupture of the lens**. This is especially likely in cases of sharp perforating injuries through the cornea or sclera. When the lens capsule is disrupted, lens protein released into the eye causes an immunologic reaction with development of severe uveitis. Clinical signs are those of **severe uveitis** (*q.v.*), which shows a poor response to therapy within the first few days. Hazy lens contents may be seen, mixed with fibrin protruding from the

lens surface. Medical therapy alone is not adequate to control the inflammation and in many cases the injury may be of such magnitude that the eye cannot be saved. If the horse still has any vision on the affected side and evidence of a consensual PLR to the other eye the prognosis may be improved. The ruptured lens contents must be removed surgically. This requires referral to an ophthalmologist. The lens material can most easily be removed by phacofragmentation and aspiration. The laceration is repaired at the same time and the eye treated intensively for uveitis.

Lens dislocation can occur in cases of blunt trauma. The zonules that support the lens behind the pupil are quite resistant to breaking in the normal horse, and the magnitude of trauma required to dislocate a normal lens is usually great enough that other signs, including **intraocular hemorrhage** and **retinal detachment**, are also present. The lens may be dislocated into the vitreous or into the anterior chamber. It may often be seen with a focal light source or its position verified if the cornea is opacified by ultrasound. The dislocated lens can be removed by an ophthalmologist, although the prognosis is guarded to poor.

VITREOUS HEMORRHAGE

Hemorrhage into the vitreous may occur with blunt ocular trauma or after rapid decompression of the eye by a perforating injury. Vitreous hemorrhage usually resorbs over several weeks. Therapy is aimed at any coexistent uveitis or retinitis.

RETINAL EDEMA AND DETACHMENT

In cases of blunt trauma, posterior segment inflammation may occur. This is detected by ophthalmoscopy. **Retinal edema** may be seen as gray lines in the tapetal or non-tapetal fundus that may radiate from the optic nerve. The optic nerve may appear edematous, or hemorrhage may be seen in the vitreous. Systemic corticosteroids and NSAIDs should be administered to treat traumatic posterior segment inflammation.

Retinal detachment may occur with ocular trauma. The retina may be detached from the retinal pigment epithelium by edema, or tears may occur, often in the peripheral retina. The affected eye will have visual loss that parallels the extent of the detachment. Total retinal detachment presents with blindness. The PLR may be present initially although this is eventually lost. The retina may be seen with a light source or by ophthalmoscopy as a gray sheet behind the lens in the vitreous. The tapetum may appear more reflective than usual, although this is not a marked finding in this species. Bullous retinal detachments should be treated in the same way as **retinal inflammation** although the prognosis is usually very poor. Surgical repair of rhegmatogenous detachments (where vitreous enters the subretinal space) is not as yet practical in the horse.

RETINAL ATROPHY

Radiating light-colored lines or spots with a pigmented center may be seen several weeks after ocular trauma in the retina. These may be focal or generalized

and be associated with ocular trauma and possibly severe blood loss. The tapetum may undergo color change and appear more reflective than usual.

OPTIC NEUROPATHY

Horses that receive blows to the back of the head when rearing or falling backwards may stretch the optic nerve at the optic foramen as the eye moves forward in the orbit. The affected horse may appear **blind immediately** after the injury or within a few days. Examination of the nerve may show areas of peripapillary edema initially, occasionally with hemorrhage and later signs of optic atrophy. The atrophic nerve is pallid and has a reticulated pattern where the lamina cribrosa of the sclera is seen through the degenerating neurons. Most horses thus affected lose and never regain vision despite therapy. Similar findings have been reported in horses that experienced excessive blood loss. Therapy in the immediate period after the injury should include systemic NSAIDs and corticosteroids.

FACIAL NERVE TRAUMA

Fractures of the zygomatic arch and other bones along the course of the auriculopalpebral branch of the facial nerve may result in **facial paralysis**. Apart from drooping of the lid, the horse is unable to blink and has reduced tear production. Corneal ulceration (*q.v.*) is a common sequel due to exposure of the cornea. Inability to blink can be determined by stimulating the periocular region. Recovery after facial nerve trauma is unusual and the eyelid and lacrimal deficiencies often result in corneal ulceration. Immediate therapy should comprise application of topical **artificial tears** and **petrolatum ointment**. Topical antibiotics should be used if corneal ulceration is present. Permanent lateral and medial tarsorrhaphies will help reduce corneal exposure and drying. **Parotid duct transpositions** can be performed in the horse to increase corneal wetting in the long term.

NEURO-OPHTHALMOLOGY

NEUROANATOMY

Neuro-ophthalmic examination permits evaluation of cranial nerves (CN) II, III, IV, V, VI, VII, and to some extent VIII. The axons of the retinal ganglion cells make up the optic nerve (CN II), and form the afferent pathway of the PLR, and for vision. The optic nerve becomes myelinated after traversing the lamina cribrosa. The nerve crosses the orbit to exit through the optic foramen. The two nerves meet at the optic chiasm, where 10–20% of the nerve fibers remain on the ipsilateral side and 80–90% cross over to the contralateral side. Beyond the chiasm, the nerve fibers serving vision continue via the optic tracts to the lateral geniculate body. Vision fibers project through the optic radiations to the cerebral cortex. Lesions at these levels will cause loss of vision, but not loss of PLR. Pupillomotor fibers project to the pretectal nucleus. From this nucleus, fibers again decussate to the parasympathetic

nucleus of CN III (Edinger–Westphal nucleus). The nerve fibers travel to the ciliary ganglion, where post-ganglionic neurons supply the iris sphincter.

The **menace response** is a cortical blink response to a visual stimulus. The efferent pathway travels via the internal capsule and pons to the nucleus of the facial nerve. Motor innervation to the eyelids is provided by the auriculopalpebral branch of the facial nerve. Cerebellar interaction is required for function, and severe cerebellar lesions may therefore cause loss of the menace response in a visual eye with an intact facial nerve.

Sympathetic upper motor neurons arise in the hypothalamus, midbrain, pons and medulla and descend through the spinal cord to the anterior thoracic segments. Preganglionic fibers run cranially in the cervical sympathetic trunk with the vagus nerve to the cranial cervical ganglion adjacent to the guttural pouch. Post-ganglionic sympathetic fibers supply a number of tissues, including the iris dilator muscle.

In addition to the autonomic component of the oculomotor nerve, it also innervates the dorsal, medial and ventral rectus muscles, as well as the ventral oblique extraocular muscles. Loss of the innervation creates **ptosis** (drooping of the upper eyelid), **lateral strabismus** (abnormal alignment of one or both eyes) and inability to rotate the globe in the direction of the affected muscles.

The trochlear nerve, CN IV, supplies the lateral rectus and retractor bulbi muscles. Paralysis is manifested by a medial strabismus and inability to retract the globe.

REGIONAL NERVE BLOCKS

The **auriculopalpebral nerve** may be blocked at two sites. A depression is palpable caudal to the posterior border of the ramus of the mandible at the level of the temporal position of the zygomatic arch. A 2.5 cm needle is inserted to the hub in the depression, directed slightly dorsally, and 5 mL lidocaine 2% injected. This usually produces a total motor block, although some horses will maintain control of the lower eyelid due to secondary innervation from the buccal nerve. The ipsilateral ear will also droop.

The **palpebral branch** can be blocked as it crosses the zygomatic arch. The accompanying vessels are palpable at the highest point of the dorsal border; 2–3 mL lidocaine are deposited just below the dorsal border.

Sensory innervation to the eyelids is provided by various branches of the trigeminal nerve, CN V. The medial and middle thirds of the upper eyelid and much of the forehead are supplied by the frontal nerve. This nerve travels through the supraorbital foramen, which can be palpated in the supraorbital process at the point where it begins to widen. A 1.5 cm 25 gauge needle is directed perpendicular to the bone, and slightly medially. One to 2 mL lidocaine are injected at this depth, and another 1 mL is injected as the needle is withdrawn through the foramen. Another 1–2 mL is injected SC over the foramen.

The lacrimal nerve supplies the lateral portion of the upper eyelid. The nerve can be blocked by injecting 2–3 mL lidocaine beneath the dorsal rim of the orbit approximately 1 cm medial to the lateral canthus. The infratrochlear nerve supplies the medial canthal area. This nerve can be located by palpating the notch in the dorsal orbital rim, approximately 1–2 cm lateral to the medial canthus, and injecting 2–3 mL lidocaine deep and slightly rostral to the notch.

The zygomatic nerve supplies much of the lower eyelid, and can be blocked by injecting along the ventral orbital rim, approximately 1–2 cm medial to the lateral canthus.

Alternatively, the eyelids may be blocked by **local infiltration**. The cornea and conjunctiva require **topical anesthesia**, unless a retrobulbar block is performed.

NEUROLOGIC DISORDERS

Various neurologic lesions may be localized by identifying the cranial nerves involved in the deficits. Lesions of the retina and optic nerve are discussed in their own section (*q.v.*).

ABNORMAL PUPILLARY RESPONSE

Mydriasis

Pupil size and mobility depend on sympathetic and parasympathetic innervation. A decreased response, or **increased pupil size**, may be due to fright, creating a transient sympathetic overload, pharmacologic blockade (e.g. due to atropine), iris atrophy, synechiae formation, glaucoma, retinal or optic nerve atrophy (*q.v.*), as well as internal ophthalmoplegia, i.e. loss of parasympathetic innervation. Primary neurologic causes are not common and may be located in the pretectal or Edinger–Westphal nuclei, or in the oculomotor nerve. Lesions involving the oculomotor nerve may show an accompanying “down and out” strabismus (*q.v.*) due to loss of innervation to extraocular muscles. Additional neurologic signs are frequently present. Parasympathetic denervation may be confirmed by demonstrating hypersensitivity to pilocarpine instilled into the affected eye compared with the normal eye.

Miosis

Miosis, or a **failure to dilate**, may be related to the presence of uveitis or ocular pain, posterior synechiae formation, or pharmacologic stimulation of the iris sphincter, e.g. due to pilocarpine or organophosphates, as well as neurologic disease either centrally or associated with Horner’s syndrome (*q.v.*). Bilateral miosis can be a sign of acute, severe central lesions, and may be of little localizing value. Miosis in these cases is a more favorable prognostic sign than mydriasis.

Horner’s syndrome

Lesions causing Horner’s syndrome (*q.v.*) may be central, pre- or post-ganglionic. Etiologies include spinal cord injury, cranial thoracic tumors or trauma, surgery or injections in the neck, including **jugular intravenous injections**, causing interference with the vagosympathetic trunk, as well as guttural pouch disease.

Clinical signs include increased skin temperature and sweating of the ipsilateral face and ear, miosis, ptosis, prolapse of the nictitating membrane and enophthalmos. **Ptosis** (*q.v.*) is most easily assessed from the front of the animal by determining the angle of depression of the eyelashes on the affected side.

The lesion responsible for the syndrome may be localized through pharmacologic tests. Central and preganglionic lesions will allow the affected pupil to respond to **1% hydroxyamfetamine**, causing mydriasis. Post-ganglionic lesions will not respond. However, post-ganglionic lesions will cause the effector cells to be super-sensitized to **phenylephrine**, resulting in rapid mydriasis. Central and preganglionic lesions will not respond to phenylephrine.

Treatment is aimed at the initiating cause, if it can be identified. Palliative therapy consists of topical epinephrine (adrenaline) or phenylephrine, used as required. Clinical signs tend to resolve over time.

Facial nerve paralysis

Damage to the facial nerve is frequently the result of trauma, although polyneuritis, meningitis or middle ear infections (*q.v.*) should be considered. Clinical signs include loss of the blink reflex and lagophthalmos (where the eye cannot close completely), inability to flare the ipsilateral nostril, flaccid lips and facial contracture toward the normal side. Proximal injuries will also show a paralyzed ear. **Keratoconjunctivitis sicca** (*q.v.*) may occur, due to loss of parasympathetic innervation to the lacrimal glands, which travels with the facial nerve. Skull radiographs may be required to determine the cause.

Treatment consists of systemic corticosteroids or NSAIDs in the acute case. Local massage and warm compresses may also be of benefit. Ophthalmic ointments should be used to protect the cornea. The eye should be protected by a temporary tarsorrhaphy if exposure keratitis or KCS is a problem, or a permanent tarsorrhaphy in cases with permanent paralysis. The horse should not wear a halter, to prevent further trauma to the nerve.

Recovery may occur in 3–4 wk, or may be prolonged. The paralysis may be permanent.

Nystagmus

Nystagmus is an involuntary ocular movement that can be induced in the normal horse by moving the head from side to side or up and down. The eye movement has a rapid phase in the direction of the head movement, with a slow phase in the opposite direction, with both eyes moving simultaneously. This system requires function of the vestibular system, the medial longitudinal fasciculus, and CN III, IV and VI.

Abnormal nystagmus may be the result of head trauma, guttural pouch or sinus infections, or CNS inflammatory disease (*q.v.*). In **vestibular disease**, the eyes tend to deviate ventrally on head extension, especially the eye ipsilateral to the lesion. Peripheral lesions are associated with a horizontal or rotary nystagmus, with direction of the rapid phase away from the side of the lesion. Central disorders may show **vertical nystagmus**, or nystagmus that changes with the position of the head. Ataxia and head tilts may also be present.

Skull radiographs may be of benefit in diagnosis, with particular attention paid to the tympanic bullae and the petrosal portion of the temporal bone.

Treatment usually consists of antibiotic and anti-inflammatory therapy. Prognosis is guarded. Initial response may be promising, but complete recovery may be prolonged. A residual deficit may persist.

INTRODUCTION

The **prevalence of tumors in horses is increasing**, partly related to animals living to older ages but also to better preventive and therapeutic medical practices. As a result, veterinarians are called upon more frequently to diagnose and manage horses with tumors. Horse owners are more aware of progress in cancer treatment and are becoming more demanding in seeking care for their horses.

More than 80% of tumors in horses affect the **skin and subcutaneous tissues**. Because lesions involving the skin are easily seen by the owner and so are often rapidly brought to the attention of the veterinarian, the vast majority of equine tumors should be caught early and be highly curable. Unfortunately, mismanagement of equine tumors due to lack of knowledge of the disease process and misuse of conventional treatments may result in euthanasia.

In this chapter the principles of oncology as applied to the equine patient are presented. The intent is to provide equine practitioners an overview of the principles and practices of cancer diagnosis, and treatments. Readers should refer to the Index and the systematic chapters for details of diagnosis and treatments of specific tumor types and locations.

There are five rules for successful tumor management (Box 20.1).

A **correct assessment of the treatment goal** is critical to select the optimal treatment or treatment combination. Overly aggressive treatment plans can expose animals that are not curable to **needless morbidity** or to prolonged

Box 20.1 Rules of tumor management

1. Establish a diagnosis
2. Stage the disease, i.e. to assess tumor size and extent (local invasion and metastasis)
3. Assess the general health status of the patient
4. Discuss treatment goals with the owner
5. Formulate the treatment plan

and expensive treatments. On the other hand, therapeutic decisions that are too pessimistic deprive the animal of a chance for cure.

ASSESSMENT OF THE CANCER PATIENT

THE BASIS OF THE ASSESSMENT

Each affected horse has a **unique set of clinical problems** that should be completely identified by the historical and physical examinations and recorded in the animal's medical record for future reference. In many cases, the **clinical presentation of skin mass** will enable a tentative clinical diagnosis to be made. However, there are occasions when the neoplastic nature of a problem is not obvious. In either case, a **systematic approach** to the case will increase the likelihood of curative management.

HISTORY

The history should establish relevant long-term information about the animal, such as previous disease or illness, and treatments. A complete history should include date of onset of any visible tumor, the rapidity of growth, any change in size, shape and/or color over time and the appearance of new lesions in the same location or at a distance.

Particular attention should be paid to the results of any previous diagnostic tests, diagnoses and attempts at treatment for the presenting problem, and whether any measures have had significant effects on the course of the condition.

PHYSICAL EXAMINATION

Before proceeding to a detailed assessment of a tumor, it is essential to examine the **whole animal**. A **complete physical examination** will alert the clinician to other masses that may not have been noticed by the owner and will also allow an appraisal of any concurrent disease.

Although the incidence of **metastatic disease** for malignant tumors in the horse is only 25%, many tumors (including equine sarcoid [*q.v.*], squamous cell carcinoma [*q.v.*], and melanoma [*q.v.*]) frequently arise in **multiple sites** on the same horse.

For **deep-seated tumors**, the clinician relies upon clinical manifestations of the disease resulting from a mass effect leading to obstruction or compression, bleeding, and effusion or endocrine syndromes associated with **hyperfunctional tumors**. Frequently, indirect systemic effects of cancer, known as **paraneoplastic syndromes**, including cachexia, fever not associated with infection, hypercalcemia, hematologic–hemostatic abnormalities and hypertrophic osteopathy are the first manifestations of an occult tumor.

For superficial or accessible tumors such as cutaneous and endocavitary tumors, the majority of the physical examination can be performed by **direct visual assessment** and **manual palpation**. Cutaneous and subcutaneous tumors such as sarcoid tumors, squamous cell carcinomas, basal cell carcinomas, adenocarcinomas (sweat gland), squamous papillomas, melanomas and dermal melanomatosis, cutaneous lymphomas, soft tissue sarcomas including fibrosarcomas, schwannomas, hemangiosarcomas, liposarcomas, lymphangiosarcomas, hamartomas and mast cell tumors (*q.v.*) should be examined with respect to their appearance (mass or ulcer, symmetry, contour), color, number, size, location, consistency, presence or absence of fixation to underlying tissue, and whether the overlying skin is ulcerated.

The **growth pattern of the lesion**, i.e. any irregular growth and contour, should be carefully assessed. Based on appearance, the biological behavior of the lesion, and risk factors including age, breed/skin pigmentation, exposure to contributing agents such as viruses, sun exposure, chemicals and trauma, a tentative diagnosis of “tumor” can be made.

DIAGNOSIS

Although the clinical manifestations or appearance, location and growth pattern of a lesion may give the veterinarian a high degree of suspicion as to the type of tumor involved, it is imperative that a definitive diagnosis be attained so as to plan treatment properly and discuss prognosis with the owner. The most common diagnostic procedures are **cytology** and **tissue biopsy**.

Aspiration cytology

Aspiration cytology is simple procedure requiring only a 22 G, 25 mm (1 inch) needle and a 6 mL syringe for superficial lesions or 22 G, 65 mm (2.5 inch) spinal needle with stylet for deeper lesions.

The technique can be used for tissues (**fine needle aspirate**) or body cavity fluid. The site is cleaned with a surgical scrub and alcohol if an abdominal cavity is to be entered. Usually there is no need for sedation or local anesthesia. Topical anesthetic (lidocaine 2.5% and prilocaine 2.5%) may be used on a shaved skin but local anesthesia takes approximately 15 min for mucosa and 30 min for intact skin. The sample is obtained by **gentle aspiration**, as the needle is advanced through the tissues in several different locations.

All negative pressure must be released before the needle is withdrawn from the tissue. The syringe is detached and the aspirated cells are then expelled onto a **microscope slide** with a frosted end. A second slide is placed flat on the first and the two are gently slid apart to spread the aspirate. The slide is then allowed to air-dry. If larger volumes of fluid sample are obtained, a small drop

can be smeared in a similar manner. Information regarding patient and aspiration site should be written with a pencil on the frosted end.

Separate needles are used for sampling **multiple sites**. Multiple slide preparation with standard fixative should be made when possible and the cellularity of the specimen should be evaluated prior to submission to a diagnostic laboratory by microscopic examination of a stained slide preparation to ensure sample quality. The air-dried slides are then shipped by courier or mail to a diagnostic laboratory in a polypropylene slide mailer with a snap top lid or Styrofoam container to protect the glass slides.

Fine needle aspirate cytology is a **screening tool** to differentiate neoplastic from inflammatory lesions. Cytology often helps differentiate between epithelial and connective tissue tumors. Several tumors such as melanomas, lymphomas and mast cell tumors (*q.v.*) can be accurately diagnosed cytologically. In most cases a positive cytologic finding can only give a tentative diagnosis and a negative cytologic finding should be treated as inconclusive. Aspiration cytology cannot be a substitute for histopathology because it does not provide any information about the biological behavior of the tumor.

Biopsies

Procurement and interpretation of a biopsy specimen is perhaps **the most important step** in the management of all tumors. Not only will the biopsy provide a definitive diagnosis, it may also be used to predict the biologic behavior of the tumor, which aids in selecting the type and extent of treatment and determining prognosis. It is important to provide the pathologist with a well-fixed (1 part tissue volume to 10 part fixative volume) tissue specimen large enough to represent the **disease process**. Fixative solutions (10% buffered neutral formalin) are provided in containers of different sizes by diagnostic laboratories upon request. Fixed samples are kept at room temperature and shipped to the local veterinary diagnostic laboratory.

As a rule, any active lesion (growth, appearance change, new lesions) **that is not responding or temporarily responding to medical treatment** should be biopsied.

There is no evidence that a biopsy can negatively affect the outcome of a patient as long as it is followed by definitive treatment if the diagnosis is tumor. Moreover, in the human and veterinary literature there is no suggestion of tumor transformation or an increased risk of metastasis after a planned biopsy. The advantages of an accurate diagnosis far outweigh the theoretical risk of enhancing metastasis or the unproven risk of transforming a benign lesion into a malignant one. Thus there is no medical reason for not performing a biopsy, and if a client brings an active lesion to a veterinarian's attention it is worth taking a biopsy. If a veterinarian recommends a biopsy for a suspicious lesion and the client declines the procedure, the reasons for not performing the biopsy should be documented in the medical record for legal purposes and a plan for follow-up established.

The only contraindication for biopsy of an accessible lesion is the lack of commitment of the owner to pursue treatment for financial or emotional reasons because the trauma caused by the biopsy can **trigger tumor proliferation**

of an otherwise slow-growing tumor and precipitate its local evolution. The non-medical reasons for not performing a biopsy should be documented in the medical record and a plan for follow-up established.

An accurate diagnosis should be obtained prior to surgery if the type of treatment or extent of the treatment depends on the tumor type or when the owner's decision to treat depends on prognosis. Large lesions or lesions in unfavorable locations should be biopsied **before any treatment** attempt.

The most common techniques of tissue procurement prior to surgery are needle core biopsy, punch, pinch and incisional biopsies (*q.v.*). All biopsy tracts should be positioned in such a manner that the tracts they create can be excised in continuity with the primary tumor at surgery to prevent tumor seeding. In other words, prior to performing a biopsy, the veterinarian must assume the lesion is a tumor and determine an appropriate surgical approach. Keeping this in mind, the veterinarian must then plan the biopsy sites and tracts within the planned surgical field.

Needle core biopsy

Needle core biopsies of soft tissue tumors may be obtained with **Tru-Cut** or **ABC needles**. Palpable lesions may be fixed in place manually and biopsied blindly. Deep-seated lesions must be biopsied under **ultrasound guidance**. Bone lesions and bone marrow biopsies may be performed with a **Jamshidi needle** or **Michelle trephine**.

After sterile skin preparation with surgical scrub, 3–5 mL of buffered lidocaine (3 mL of 2% Xylocaine plus 1 mL of sodium bicarbonate 8.4% added immediately before injection) is injected using a 25 G needle in and around all of the tissues that extend from the skin to the lesion. A small stab incision is made in the overlying skin, and through the same skin hole several needle cores are removed from **different sites**. Tissue samples recovered from the instrument are **fixed in formalin** solution.

The biopsy procedure is usually done in the conscious animal using sedation, e.g. detomidine 0.01 mg/kg IV plus butorphanol 0.1 mg/kg IV, or xylazine 0.5 mg IV plus butorphanol 0.1 mg/kg IV, if necessary.

In spite of a small sample size, the structural relationship of the tissue and tumor cells can be determined histologically. The technique is relatively atraumatic but care must be exercised to avoid large blood vessels.

Bone marrow aspiration and biopsy

Bone marrow aspiration, and less commonly biopsy, is an essential procedure for determining cytologic abnormalities of the bone marrow caused by a wide variety of neoplastic and myelodysplastic conditions. It is used for the diagnostic and staging of **hematopoietic malignancies** (lymphomas and leukemias [*q.v.*]). A bone marrow biopsy is used when bone marrow aspiration does not yield enough tissue for diagnostic.

The preferred site for bone marrow aspirates is the **sternum** (ventral midline between front legs) because hematopoietic activity persists throughout life, and it provides an easy access. Other sites include tuber coxae or proximal ribs. The hair is clipped, and the bone marrow aspiration site is prepared with a surgical

scrub. Using a 25 G needle, approximately 3–5 mL of buffered lidocaine (3 mL of 2% Xylocaine plus 1 mL of sodium bicarbonate 8.4% added immediately before injection) is injected in and around all of the tissues that extend from the skin where the bone marrow needle is to be introduced to the bone.

The 12 mL collection syringe and bone marrow needle is rinsed with **EDTA** before the procedure to reduce clotting of the bone marrow sample. The biopsy area is scrubbed a final time and, using sterile technique, the skin is stretched between the thumb and index finger and a small stab incision of the blocked skin is made with a no. 11 surgical blade. The bone marrow needle (50 mm/2 inches long, Illinois or Rosenthal bone marrow needle) with the stylet in place is advanced through the stab incision and through the skin and subcutaneous tissue, down to the bone. With the stylet in place, the bone marrow needle is advanced into the bone, using a corkscrew motion (clockwise and counter-clockwise) while applying firm and steady pressure. The instrument should not be allowed to wobble. When the needle is firmly fixed in the bone, the stylet is removed and the syringe is affixed.

The bone marrow sample is **aspirated briskly** into the 12 mL syringe; usually, 1 mL of marrow is adequate. If a sample is not obtained, the stylet is replaced in the bone marrow needle, and the instrument is then advanced further into the bone for a second attempt at aspirating marrow contents. Once marrow has been obtained, marrow can be spread on a glass slide with a frosted end into a monolayer like an ordinary blood smear and air-dried. Sample shipment and identification are the same as for any aspiration cytology sample.

Punch biopsy

Tissue sampling of a relatively flat lesion of skin or mucosa such as an early epithelial or dermal tumor can be done with a **punch biopsy** tool holding a circular blade (2–8 mm in diameter). The tissue specimen is shorter but wider than that obtained with needle biopsy. Preparation of the patient and of the site are the same as for core biopsies (*q.v.*). Once the punch instrument has cut into the tumor, the core is gently lifted and the base of the core is cut off with scissors and fixed in formalin solution.

Incisional biopsy

Incisional biopsy refers to the removal of a small wedge of tissue procured with a surgical blade. It is often used when neither cytology nor core biopsy yields diagnostic material, and the procedure is preferred for the diagnosis of large ulcerated and necrotic masses that require major surgical procedures for excision.

After appropriate sedation, local anesthesia and surgical preparation of the site using the same protocol as for a needle biopsy (*q.v.*), a wedge of viable tumor tissue is procured from the **junction of normal and abnormal tissue**. Care should be taken to choose a location for the biopsy that will not compromise subsequent curative resection. The incisional biopsy tract must be positioned in such a way that it can be removed in continuity with the tumor at subsequent resection because it will have been contaminated by tumor cells. It is important not to open widely any uninvolved tissue planes that could become contaminated with released tumor cells.

The biopsy incision should be orientated to cause the least amount of tension on the skin, which will make the subsequent definitive procedure easier.

Pinch biopsy

Pinch biopsy of lesions affecting natural cavities or a hollow lumen (such as oral and nasal cavities) can be done under direct visualization through endoscopic systems with round-tip biopsy forceps. The technique suffers from limited biopsy sample size and there is a danger of false negative results. This technique is of value for the diagnostic of carcinomas and lymphomas affecting the oropharyngeal, laryngeal and nasal cavities (*q.v.*).

Excisional biopsy

Excisional biopsy is used for small operable lesions for which treatment would not depend on tumor type, and removal may not compromise definitive treatment. The term “excisional biopsy” refers to the removal of the **entire suspected tumor** tissue with little or no margin of surrounding normal tissue. It is more frequently carried out than may necessarily be indicated, but when used on properly selected cases it can be both diagnostic and therapeutic as well as cost effective. A good example would be the removal of a small skin lesion that can be removed with minimal skin tension.

The biopsy site should **never be drained** because the drain tract may be contaminated with tumors if the lesion resected turns out to be a tumor. After an excisional biopsy, the entire tissue should be submitted for histopathologic examination in 10% neutral buffered formalin for diagnosis (and evaluation of surgical margins if it is a neoplastic process) to determine the completeness of the resection.

WORK-UP

After a diagnosis has been reached, a careful physical examination and ancillary diagnostic tests may be undertaken to stage the disease before embarking on treatment. Staging describes the extent of any primary tumor (size, invasion of adjacent tissues, involvement of nerves, blood vessels or lymphatic tissues), site, evidence and sites of metastases (regional, systemic), and the general health status of the patient.

Diagnostic imaging

For tumors surrounded by or attached to critical normal tissues, including bone, blood vessels, nerves, **diagnostic imaging** (*q.v.*) will assist in assessing tumor extent and invasion. This information will help decide whether to pursue treatment or not, and how best to plan surgery and additional treatments. When compared to exploratory surgery, the technique will not have a negative impact on subsequent treatment.

The most common imaging techniques used are plain **radiographs**, **endoscopy**, **ultrasound**, **scintigraphy** and **computed tomography** (CT). **Endoscopy of guttural pouches** (*q.v.*) in horses with melanoma (*q.v.*) allows visualization of the number and size of melanoma masses in the throat area.

Ultrasound images provide information on soft tissue architecture, invasiveness (Doppler) and size that survey radiography can not. For tumors associated with a high risk of metastasis (e.g. lymphomas, carcinomas, melanomas, [q.v.]), quality **thoracic radiographs** and **abdominal ultrasound** examination should always be performed before definitive treatment to rule out widespread metastases.

In addition to ultrasonography, **scintigraphy** is now available at most universities and many private referral hospitals. The procedure requires special gamma cameras and the injection of radioactive materials into the bloodstream. The principle of nuclear scintigraphy then lies in increased uptake of specific radioisotopes in **hyperfunctional tumors**. Scintigraphy using ^{99m}Tc **pertechnetate** (2.6–3.3 MBq/kg) is commonly used for staging of thyroid tumors (benign and malignant) (q.v.). Because of the heavy equipment required and potential radiation hazards, scintigraphy cannot be used in the field.

When available, CT—also known as **computed axial tomography** or “CAT scan”—is ideal for evaluation of tumors of the head and extremities. The procedure requires a dedicated scanner available at most universities and many private referral hospitals with in-house or mobile equipment. The technique allows electronic measurement of the absorption of X-rays by structures within the body and produces images with similar properties to conventional radiographs. It provides images that represent **thin slices** through the body, which eliminates the problem of superimposition of structures that affects conventional radiographs and allows distinction between areas of similar attenuation that would appear the same in conventional radiographs. CT is very accurate for the evaluation of **tumor invasion in bone**. To evaluate soft tissue tumors of the head, **contrast-enhanced CT** (1400–1500 mg of iohalamate/kg, IV) affords sufficient contrast to visualize tumor and normal surrounding tissues, providing information on size and invasiveness.

Clinical laboratory

Routine hematologic, serum biochemical evaluations and urinalysis do not reveal any abnormalities in most horses with cutaneous or subcutaneous tumors that are otherwise healthy. However, laboratory screens are useful to estimate patient tolerance of general anesthesia, extensive surgery or chemotherapy, and to recognize the presence of paraneoplastic syndromes (such as cachexia, anemia, leukocytosis, hyperproteinemia, fever, ectopic hormone production [hypercalcemia] or neurologic abnormalities secondary to endocrine, fluid and electrolyte imbalance). A screen is recommended, particularly for **older horses with concurrent disease (such as chronic renal or gastrointestinal disease, q.v.)** and horses with tumors affecting the endocrine, gastrointestinal and hematopoietic systems.

Careful examination of **peripheral blood** count and cell morphology as well as **bone marrow** cytologic evaluation is of particular importance to rule out systemic or visceral dissemination of **lymphomas** (q.v.). **Bone marrow aspiration** or biopsy is very important in clinical staging of horses with lymphoma to rule out systemic or visceral dissemination and in horses with hematologic abnormalities such as anemia, lymphocytosis, peripheral lymphocyte atypia or other peripheral cytopenias (q.v.).

PRINCIPLES OF TREATMENT

The stage of the disease, treatment cost and availability, and veterinarian's skills must be taken into account before formulating the treatment plan and goals. The clinician should know his or her competence and offer the client a referral to a specialist center if one is within reasonable access. Unless the primary tumor can be removed in toto, it is usually preferable to perform a biopsy of the site (*q.v.*), visualize the extent of the tumor, and then consider the treatment options with the help of a specialist. The clinician should always refrain from undertaking heroic procedures that could compromise the efficacy of other treatments.

Treatments can be broadly grouped into **ablative** (surgery, laser vaporization, cryotherapy), **cytotoxic** (radiation therapy, chemotherapy) and **biologic** (immunotherapy) modalities. Treatments directed at the primary tumor mass include ablative treatments, radiation therapy and local chemotherapy; those directed at the tumor and metastases or multicentric tumors include systemic chemotherapy and immunotherapy.

ABLATIVE TREATMENTS

The goal of ablative treatments is to remove **all tissues** that may contain tumor cells. The treatments are not selective because a cuff of surrounding normal tissue containing microscopic disease is removed with a cold blade or destroyed physically or chemically.

Surgery

Introduction

Surgery has a central role in the diagnosis, treatment and reconstruction of anatomic defects after other treatment modalities. It may be curative, used alone or in combination with other (adjuvant) treatments; it may also be palliative in some cases. Complete surgical removal of localized tumors cures more patients than any other form of treatment. The **first surgery** has the best chance of cure because recurring tumors often appear histologically and biologically more aggressive, and they require wider excision than for the initial tumor.

The surgical technique to be used depends on the tumor volume, histology and location. Surgical failures occur because, despite the most radical procedures, not all microscopic disease is removed or because there is poor surgical technique, i.e. tumor cells may be shed into the operative field from the tumor itself or from the surgeon's gloves or instruments.

Basic principles

The **basic principles** of oncologic surgery include minimal tumor manipulation, en bloc resection of gross tumor mass, early vascular ligation, flushing of the operative wound with warm saline (to wash away exfoliated cells), and frequent changes of gloves and instruments.

Radical operations may eliminate **tumor microextensions** but the price may be **anatomic deformity** and perhaps **physiologic impairment**. It also

must be remembered that there may not be a surgical advantage in excessive removal of surrounding normal tissues that may not contain any tumor. On the other hand, partial removal (**debulking surgery**) of a tumor achieves little because it does not bring residual disease to the microscopic level. It should be remembered that removing 99.9% of a 1 cm tumor (1×10^9) still leaves a large number of tumor cells behind (1×10^6). Grossly **incomplete resections** may actually reduce the efficacy of adjuvant treatments.

Cold blade excision

Standard **cold blade excision** remains the treatment of choice for the majority of equine accessible solid tumors. However, a clinician can never be certain of an incomplete excision and after an **apparent complete resection** it is critical that the surgical margins be submitted for **histopathologic evaluation**. It is best if the surgeon marks the specimen (fine suture on questionable edges) or submits margins in a separate container to help the pathologist identify and evaluate the surgical margins to determine the completeness of the surgical resection. A **detailed history** should always accompany the biopsy specimen and it is useful if the clinician **maps the specimen** if it has been procured from an anatomically complex area.

Adjuvant treatment or re-operation of the entire previous surgical site is warranted when evidence of **microscopic residual disease** (close or positive surgical margins) is present. Adjuvant treatment after histologically complete surgical resection may be recommended when the risk of local recurrence is high after surgery (30% for sarcoids [*q.v.*] and other soft tissue tumors) and when tumor recurrence may be difficult to manage because of tumor location.

Cryotherapy and laser surgery

Alternate modalities including **cryotherapy** and **laser surgery** have **no oncologic benefits** over a well-planned conventional surgery. Cellular death results from the controlled use of cold temperature with cryotherapy while it is induced by heat with laser surgery. Both treatments should not be used in the treatment of tumors because both heat and cold **diffusion is very limited** in living tissue, and target temperatures may not be achieved in tumors and tumor margins without producing significant **normal tissue damage**. These treatments do not allow histopathologic evaluation of surgical margins to assess the quality of the procedure. In addition, **excessive scarring** or healing delay following treatment may delay objective diagnosis until obvious tumor recurrence.

CYTOTOXIC TREATMENTS

Antineoplastic chemotherapy

Introduction

Until recently, the use of antineoplastic agents found limited applications in equine oncology, primarily due to drug cost and potential toxicity. However, access to low cost generic drugs and the development of new routes of administration designed to increase the therapeutic benefit have resulted in new

treatment options. Treatment using antineoplastic drugs can be divided into **local** and **systemic** chemotherapy. Local chemotherapy, including topical and intratumoral chemotherapy, has been developed to improve drug therapeutic index and decrease treatment costs for horses with accessible tumors.

Local chemotherapy

Topical application of ointments containing antineoplastic or caustic drugs has limited applications because of:

1. The **significant biohazard** by contact or inhalation associated with repeated applications by the owner or veterinarian
2. **Poor diffusion and inadequate distribution** of currently available drugs from the surface to the deep margins of a tumor
3. **Poor cosmetic and functional results.**

Because drugs do not diffuse more than 5 mm in normal or tumor tissues before they are reabsorbed in the bloodstream, topical administration of antineoplastic drugs often results in a tumor-free surface, giving the **false sense of efficacy**, which is followed by **tumor recurrence** from the deep margins of the tumor.

Intratumoral treatment

Intratumoral chemotherapy has been developed to improve drug distribution in the tumor and tumor bed and eliminate the risk of biohazard. Treatment is safe to attendants because the drug is administered directly into the tumor, and it is safe for the horse because the doses administered are approximately one fiftieth of the systemic dosage.

Several drugs have shown activity against specific tumor types. A slow-release formulation of *cis*-diaminedichloroplatinum (**cisplatin**) in a viscous-fluid oily formulation (3.3 mg cisplatin per mL of mixture) is the **most effective** against all cutaneous tumor types including **sarcoid of all clinical types, carcinomas, fibrosarcomas** and most **soft tissue sarcomas**, and **solitary melanomas and lymphomas** (B and T cell) (*q.v.*). Medical grade or chemically pure cisplatin is widely available. The treatment consists of four intratumoral administrations at 2 wk intervals. It is most effective when used **in combination with surgery**. It can be used in horses, donkeys and mules, and is safe for use in stallions and pregnant mares. To administer the drug, a 22–25 G needle mounted on a Luer-lock syringe is inserted to the desired length into tissue, and the drug is injected at a **constant flow** while the needle is withdrawn to provide uniform dose distribution in the target volume.

The target volume of tissue to be treated includes **all visible tumor** and a **margin of normal tissue** of 1–2 cm (as a function of tumor type and tumor size). It is critical to treat a margin of normal tissue both laterally and at a depth to kill microscopic deposits of tumor cells extending into apparently normal tissue surrounding the tumor. The volume of tissue to be treated around the gross tumor, i.e. the **biologic margin**, is the same as would have to be resected to obtain a histologically complete surgical resection.

The planning of the pattern of injections (0.6–0.8 cm apart) is **critical** to achieve uniform dose distribution. Depending on the shape and accessibility of the lesion, the target volume is injected via multiple sites using a **parallel-row**

technique or **field-block technique**. Multiple planes of injections may be needed for large tumor volumes using parallel or orthogonal axes of injection. The treatment field size should always remain the same during the course of treatment and the volume of tissue treated should not be decreased if a reduction in tumor size is observed.

Systemic chemotherapy

Most **systemic chemotherapy** protocols in horses rely on the use of a single agent. The benefit of using **combination chemotherapy** protocols has been shown in people and small animals. However, combining drugs at their maximum tolerable dose is still in its infancy in equine oncology. Drugs used as single agents include steroids, doxorubicin, L-asparaginase (400 IU/kg), cyclophosphamide and cytosine arabinoside. Glucocorticoid hormones and synthetic derivatives (prednisolone, dexamethasone) are used at high doses for their immunosuppressive properties (*q.v.*).

Immunosuppression (*q.v.*) is the basis for treatment of various lymphoproliferative diseases (*q.v.*). **Dexamethasone** (starting dose of 50 mg/day, tapering dosage over 2 wk) is used for **multiple cutaneous lymphomas** during an active growth phase (which is often seasonal). **Doxorubicin** (60–80 mg/m², 6 cycles at 3 wk intervals) is used alone for **advanced carcinomas** or in combination with **prednisolone** for **multicentric lymphomas** and **leukemias** (*q.v.*).

The only **combination drug protocol** used commonly for **metastatic lymphoma** and **lymphocytic leukemias** is known as **COAP: cyclophosphamide** (200 mg/m², IV weekly, ×4–6 weeks), **vincristine** (0.75–1 mg/m², IV weekly, ×6 weeks), **cytosine arabinoside** (100 mg/m², slow IV/6–12 h, 3 times a week, ×6 weeks) and **prednisolone** (1 mg/kg, PO every other day, ×2 weeks). Use of these drugs requires appropriate medical training for drug preparation and administration, and management of drug toxicity in horses.

Radiotherapy

Radiation therapy is the use of ionizing radiation in the treatment of **localized tumors**. It was first described for the treatment of equine cutaneous tumors in 1906. Radiotherapy techniques vary considerably based on the tissue involved and adjacent normal structures. Radiation therapy is currently only available at referral practices, e.g. at universities and large referral private practices, because of the cost of equipment, potential radiation hazards and requirements for a radiation use license.

There are two methods of irradiation available for large animals: teletherapy (also called external beam therapy) and brachytherapy.

Teletherapy

Teletherapy is a technique in which the **source of radiation** is at some distance (80–100 cm) from the target tissue. The distance allows the delivery of homogeneous doses of radiation to **large and deep-seated tumors**. However, the technique also results in similar doses being applied to surrounding normal tissues in the path of the radiation beam. The higher the energy of the radiation, the more significant is the sparing of superficial structures (i.e. skin and subcutaneous tissues) and the deeper is the penetration of the beam.

High energy radiation, including X-rays produced by linear accelerators and gamma-rays produced by telecobalt units, is used for treatment of extensive or **deep-seated tumors** and **tumors invading bone**. The total radiation dose is given as a series of small, equally sized doses termed **dose fractions** to spare normal tissue in the radiation path.

All treatments are done while the horse is under **short-term general anesthesia**, which enables accurate positioning and immobilization. Anesthesia protocols are undertaken according to preference and equipment, but a safe protocol for a series of anesthetics (8–12) in an 11 month period might include: premedication with xylazine (0.3–1 mg/kg, IV), induction with ketamine (2.2 mg/kg) plus diazepam (Valium) (0.1 mg/kg) and maintenance with a chemical anesthetic (triple drip, guaifenesin-ketamine-xylazine or GKX) or inhalant anesthetic (isoflurane).

The total dose of radiation (42–48 Gy; 1 Gy = 100 rad) is given in 7–12 dose fractions of 4–6 Gy given two or three times a week over 3–4 wk.

The increased availability of high energy radiation therapy units in veterinary medicine has expanded the use of teletherapy in equine oncology. Teletherapy is very effective for tumors of the **oral and nasal cavity** with bony involvement. Other tumors that can be successfully treated include **inoperable cutaneous and subcutaneous tumors** of the extremities affecting critical tendons, blood vessels or nerves (e.g. squamous cell carcinoma, angiosarcoma, sarcoid [*q.v.*]) and tumors involving large areas or multiple lesions present at the same time in a small area.

Brachytherapy

Brachytherapy is a technique in which **sealed** radioactive sources are **applied directly** to the area to be treated. The short distance between the source of irradiation and the tumor provides a high radiation dose to the tumor-bearing structures while sparing uninvolved adjacent normal tissues because of the rapid decrease in dose as distance from the radiation source increases.

When radioactive sources (usually **iridium-192 in seeds or wire**) are **implanted directly** into the tissues, the treatment technique is called interstitial brachytherapy or **curietherapy**. Remote afterloading of the radiation sources entirely eliminates radiation hazards to personnel and shortens treatment times.

Treatments are performed on an outpatient basis in referral specialist centers, and there is no residual radiation when the horse is discharged. The radiation dose is usually delivered in 2–4 dose fractions at 1 wk intervals while the horse is under general anesthesia.

Brachytherapy is used successfully for any **cutaneous lesion that cannot be completely excised**. Treatment is most suitable for **squamous cell carcinomas**, **sarcoids** and **soft tissue sarcomas** of the head, distal extremities and genitalia.

Plesiotherapy

When radioactive sources are applied onto the tumor surface, the technique is called surface brachytherapy or **plesiotherapy**. Using an ophthalmic applicator, radioactive strontium-90 is mounted on a stainless steel shaft fitted with a Lucite beta shield to emit a high energy beam of electrons (maximum range in

tissue: 3mm). One application (200Gy) while the horse is anesthetized or heavily sedated is usually sufficient.

Treatment is often curative for **superficial lesions of the skin**, including **carcinoma** in situ and early **squamous cell carcinoma**, and tumors of the **eyelid conjunctiva** and **corneoscleral tissues**, including squamous cell carcinomas and melanomas (*q.v.*).

Side effects

Side effects associated with radiotherapy are usually mild and self-limiting and range from **local alopecia** to **erythema** and **minor erosion** of the skin. In horses treated with high radiation doses to the skin or mucous membranes, more severe and **extensive skin reactions** including moist desquamation and necrosis may occur. Management of these reactions is largely symptomatic but should include cleansing the tissue with a 1.5% solution of hydrogen peroxide, systemic antibiotics (trimethoprim–sulfamethoxazole) and flunixin to minimize infection and inflammation.

BIOLOGIC TREATMENT (IMMUNOTHERAPY)

General

Immunotherapy refers to treatments that alter the host–tumor relationship and improve the ability of the host to reject the tumor. Antitumor effects are produced primarily through restoration or **stimulation of immunologic activity**. The only attempt at **restorative immunotherapy** is the use of **cimetidine** for **melanomas** (*q.v.*). Unfortunately, cimetidine treatment has shown modest to no therapeutic benefit and at a dosage of 5 mg/kg t.i.d. has been shown to have little if any effect.

Stimulation of the host's intrinsic immune system can be achieved either through non-specific immunostimulation or through immunization against tumor-associated antigen present on tumor cells. Many **non-specific immunostimulants** have been evaluated in horses including microorganisms (bacillus Calmette–Guérin, *Propionibacter acnes*) and their purified cell wall products (cell wall skeletons and extracts), and plant extracts (acemannan). These products have no direct cytotoxic effects but tumor cells are killed as bystanders at the site of inflammation associated with the delayed type hypersensitivity to the microorganism antigens.

Certainly, convincing results have been shown with the **bacillus Calmette–Guérin (BCG) derivative** (*q.v.*). Treatment consists of **multiple injections into the tumor mass** and tumor bed to ensure complete infiltration of the target volume. The number of treatments ranges from 1 to 6, given at 1–2 wk intervals. Treatment with live freeze-dried BCG is not recommended because side effects from administration of live BCG, including anaphylaxis, fever, diarrhea, laminitis, nodular lymphangitis and death, outweigh the therapeutic benefits and alternative treatments are available. **BCG cell wall extracts** are less toxic and have been shown to be effective against small (<2 cm) **periocular sarcoids** (*q.v.*) in immunocompetent horses. The potential for significant adverse reactions should, however, always be considered before embarking on BCG immunotherapy.

Active tumor-specific immunotherapy

Active tumor-specific immunotherapy consists of immunization with **tumor-specific antigens** or tumor cells carrying these antigens. Partial tumor response to autologous vaccines using antigen-augmented live tumor cells has been documented in horses with **lymphoma** and **melanomas** (*q.v.*). Treatment includes a series of 6–12 intradermal injections of gamma-sterilized autologous tumor cells at 1–2 wk intervals. A polyvalent allogeneic antigen-supplemented vaccine prepared from highly immunogenic melanoma cell lines has shown encouraging results in horses with **multicentric melanomas** (*q.v.*).

INTRODUCTION

When considering anesthesia in domestic animals it is well known that horses, of all of the common species, have by far the **highest morbidity and mortality rates**. While mortality rates appear to have been reduced over the last 30 years, when reasonably accurate records have been kept, from approximately 5% to a current figure of 1.6%, it is unlikely that any further significant reduction will occur in the near future due to a number of factors, which include the conduct of more complex surgery and the associated longer duration of anesthesia. Recent figures show an overall mortality rate of 1.8%, but when colic surgery and emergency obstetric procedures were excluded mortality rate fell to 0.8%. However, the mortality for colic surgery remains in the region of 8%.

Anesthetic risk is increased by a number of factors that include, in addition to colic surgery, extremes of age, increased duration of anesthesia, and those occasions when procedures are performed outside what is considered to be normal working hours. The major causes of death are **cardiac arrest** (*q.v.*) or **postoperative cardiovascular collapse**, and fractures with myopathy. Abdominal conditions, respiratory obstruction and spinal cord malacia (*q.v.*) are lesser causes.

GENERAL CONSIDERATIONS IN ANESTHETIZING HORSES

Horses present **special problems** for general anesthesia due to their weight, breed, temperament and specific anatomy and physiology. Size determines the ease with which horses can be handled both in the conscious and anesthetized states. Breed and temperament are often interrelated. This is well illustrated by a comparison of the nervous young Thoroughbred with the larger and more phlegmatic draft breeds.

Horses are relatively heavy when compared with most of the other domestic species. While the average Thoroughbred weighs approximately 450 kg, it is not uncommon for equines weighing up to 800 kg to be presented for anesthesia. It is very rare for even very large draft horses to weigh >1000 kg. Heavyweight horses are more difficult to position both for surgery and to recover from anesthesia. The greater the **weight**, the greater the predisposition to muscle and/or nerve damage associated with general anesthesia.

Post-anesthetic myopathy (*q.v.*) is produced by **inadequate perfusion** of muscle resulting in ischemia. It is a multifactorial condition and its etiology is not completely understood. However, its incidence can be reduced by:

1. Ensuring that the **duration of anesthesia** is kept to a minimum commensurate with the performance of the procedure
2. Maintaining the **mean arterial pressure** >70 mmHg
3. The choice of suitable material for **padding** of the operating table surface
4. **Careful positioning** of the patient.

Treatment of myopathy is mainly symptomatic with analgesia and sedation plus adequate fluid intake and careful nursing.

Post-anesthetic neuropathy is produced by pressure on the nerve, stretching of the nerve, trauma and ischemia. It occurs in a number of superficial nerves including the facial, femoral and radial. Prevention and treatment are similar to that for myopathy although complete recovery may be prolonged. Euthanasia may be indicated.

In addition to causing musculoskeletal problems, the combination of recumbency and general anesthesia has profound effects on the **cardiovascular** and **respiratory** systems. **Dorsal recumbency** is the most undesirable position but pragmatism dictates that it is often essential to place anesthetized horses in that position for the performance of abdominal surgery.

The **arterial partial pressure of oxygen** is influenced by the size and position of the animal but is relatively uninfluenced by the respiratory depression associated with general anesthesia. Horses are likely to develop **alveolar-arterial (A-a) gradients** during general anesthesia, and these appear to be more marked with inhalational agents. A-a gradients occur when there is a difference between the oxygen tensions (pO_2) in the lung alveoli (**A**) and the arterial circulation (**a**). A-a gradients are the result of a number of factors. The degree of A-a gradient does not appear to differ in those animals that breathe spontaneously compared to those that are subjected to intermittent positive pressure ventilation (IPPV). Factors that may contribute to the development of A-a gradients include pulmonary diffusion defects, progressive atelectasis, right to left intrapulmonary vascular shunts, redistribution of pulmonary blood

flow relative to ventilation and a reduction in cardiac output without a reduction in tissue oxygen consumption.

Pulmonary diffusion impairment is not considered to be a cause of hypoxemia in anesthetized horses but it does develop in the dependent areas of the lungs. Venous admixture is probably due to a mismatching of ventilation and perfusion of the lungs. Normally **cardiac output** is reduced under general anesthesia but oxygen consumption remains relatively unaltered and so it is unlikely to contribute to the A-a gradients.

PREPARATION FOR GENERAL ANESTHESIA

A full and thorough **clinical examination** is essential before administering a general anesthetic to a horse. It should preferably be carried out **at least 24 h** prior to anesthesia to enable any further tests and laboratory examinations to be performed before induction. A full and accurate **history** must be obtained, although this can be difficult, particularly when horses are transported to referral centers, often by a third party.

There are a number of findings that require particular attention. The relatively high incidence of **equine polysaccharide storage disease** (*q.v.*) in the draft breeds increases the risk of postoperative myopathy and this will require further dialogue with the person responsible for the horse. This can, of course, be done during the full discussion of the risks of the procedure and of general anesthesia when obtaining consent. **Informed consent** is crucial before anesthetizing any horse and should only be neglected in an extreme emergency even though it may be necessary to defer a non-urgent procedure.

A thorough investigation of any concurrent or proposed medication is necessary, and any potential drug interactions should be considered. **Oral medication** should never be administered after pre-anesthetic drugs have been given as some medications, particularly of the **paste formulation**, may be retained in the oropharynx or the esophagus. There is then a strong likelihood that they will be regurgitated and/or pushed into the trachea during induction of anesthesia and endotracheal intubation.

Aminoglycoside antibiotics such as gentamicin or neomycin may produce **neuromuscular blockade** and depress pulmonary ventilation and should not be administered immediately prior to or during anesthesia. Particular caution is needed with gentamicin in renally compromised animals. The **IV injection of penicillin** can cause **hypotension** and should also be avoided before or during anesthesia.

While **non-steroidal anti-inflammatory drugs (NSAIDs)** (*q.v.*) have a number of undesirable side effects, particularly when administered over a prolonged period, they are used extensively in equine anesthesia and at other times to provide analgesia (*q.v.*). NSAIDs are best administered by slow IV injection. Side effects can include gastric ulceration, diarrhea and potentiation of protein bound anesthetic drugs by displacement of these agents from their protein binding sites.

General bodily condition should be considered as obesity can influence respiratory movements, and both obesity and extreme thinness may interfere with the disposition of drugs in the body. A history of **recent trauma** should

be thoroughly investigated and during physical examination special attention should be directed to the possible presence of such common conditions as diaphragmatic or bladder rupture and to hemorrhage. **Hemorrhage**, particularly when it is from the nose or associated with trauma and accompanied by tachycardia, will suggest that it is severe and usually will necessitate treatment with **circulatory blood volume expanders** (*q.v.*).

Horses with **chronic lung disease** should have a thorough physical examination of the thorax and any diagnostic aids such as radiography or ultrasound should be utilized when considered appropriate and available. Horses with respiratory infections should be treated with vigorous antibiotic therapy and appropriate ancillary therapy. Anesthesia should be delayed for **not less than 3 weeks** unless emergency surgery is indicated.

Cardiovascular disease (*q.v.*) is an extremely important consideration when assessing anesthetic risk and fitness to undergo general anesthesia. It is of extreme importance when it is severe enough to **restrict exercise tolerance** (*q.v.*) and/or accompanied by **cardiac dysrhythmias** (*q.v.*). All of these animals will require full and further investigation utilizing such diagnostic aids as electrocardiography and echocardiography.

The proposed anesthetic technique may well need to be modified to suit the condition of the patient. In some instances it will be necessary to **defer anesthesia** to initiate suitable therapy in order to improve the patient's condition.

When presented with a horse as an emergency with an **acute gastrointestinal condition**, the relief of pain is often the prime consideration. Analgesia and analgesic drugs are discussed elsewhere (*q.v.*). These animals may also be at risk from **endotoxic shock** (*q.v.*) and from **impaired ventilation** due to the **abdominal distension**.

Pre-anesthetic assessment should include measurement of packed cell volume (PCV) and total protein (TP) plus blood gas analysis.

It is often a matter of fine judgment as to how long anesthesia and surgery should be delayed while an attempt is made to correct any serious abnormality and improve the patient's condition. Except in an emergency it is desirable to **starve** horses of food for 12–18 h before anesthesia, and **water** should be withheld for 2 h. It is still a matter of debate as to whether **horses in training** should be “let down” for a period of 7–10 days before anesthesia. The general consensus is that it should be done wherever possible. The **shoes** should be removed before anesthesia and the **mouth flushed with water** to remove any solid food material. A **padded head collar** should be used to reduce the risk of damage to the poll and the facial nerves.

Horses should be **weighed** wherever possible but formulae and tape measures may be used in the absence of a weigh scales and provide a reasonably accurate estimate of a horse's weight. (See also page 173.)

PREMEDICATION, SEDATION AND CHEMICAL RESTRAINT

DEFINITIONS

A number of drugs are available for the purposes of premedication, sedation and restraint but, as there is some confusion over the terminology used to

Box 21.1 Doses of sedative drugs and their combinations with opioids

Acepromazine	0.03–0.1 mg/kg IV or IM
Detomidine	0.005–0.002 mg/kg IV or IM
Diazepam	0.01–0.02 mg/kg IV only
Romifidine	0.01–0.02 mg/kg IV or IM
Xylazine	0.25–1.1 mg/kg IV or IM

All can be combined with the following opioids:

Butorphanol	0.02–0.03 mg/kg IV or IM
Methadone	0.1 mg/kg IV or IM
Morphine	0.05–0.2 mg/kg IV or IM
Pethidine	1–5 mg/kg IM only

describe the various classes of drugs and their effects in horses, the following definitions are used here. A **hypnotic** depresses the central nervous system and tends to produce sleep; these agents are rarely used in horses. A **sedative** is a drug that relieves anxiety and produces a state of drowsiness. Many drugs appear to be both **hypnotic and sedative** with dose related effects. Chloral hydrate and xylazine are typical examples in the horse. A **tranquilizer** or ataractic drug is one that relieves anxiety and produces a variable degree of sedation. Three categories of tranquilizer are described: **hypnotic/sedatives**, **antipsychotics** and **anxiolytics**. Benzodiazepines are both anxiolytics and sedative/hypnotics. Antipsychotics are also known as neuroleptics and are typified by the butyrophenones and the phenothiazines.

Four main groups of drugs are used to premedicate and sedate horses (Box 21.1). These are phenothiazines, benzodiazepines, α_2 -adrenoceptor agonists and anticholinergics.

PHENOTHIAZINES

There are a number of compounds in this group but only **acepromazine maleate** is generally licensed for use in horses. Acepromazine (ACP) is available as an injectable form (10 mg/mL), as a paste, and tablets (25 mg). It has a wide spectrum of effects in horses.

The response to a given dose of ACP is somewhat **unpredictable** but, in general, a low dose will produce tranquilization or a calming effect while higher doses are required for sedation. It is recognized that sedation only occurs in 60–70% of horses. Larger doses tend not to increase the degree of sedation but to prolong the duration of action. In clinical doses there is very little effect on respiration but **hypotension** does occur. While this may be of minor significance in normal animals, it should be avoided, or the dose reduced significantly, in hypovolemic animals.

ACP produces muscular relaxation, which appears more marked when it is given IV. In males this produces **relaxation of the retractor penis muscle** and hence protrusion of the penis. The penis is normally flaccid but there have

been a few reports of **priapism** (sustained erection) (*q.v.*). **Penile protrusion** is normally of short duration but if it is prolonged it should be treated by massage, compression and lubrication. It is extremely important to avoid damage to the penis, and support should be provided to keep the penis as close to the body wall as possible.

BENZODIAZEPINES

The use of benzodiazepines for sedation in adult horses is limited. However, they do produce sedation in foals and are used at induction of anesthesia, particularly with **ketamine** (*q.v.*). They tend to produce excitement when they are used as sole agents, but have minimal cardiovascular and respiratory effects. The most commonly used agent is **diazepam** (Box 21.1).

α_2 -ADRENOCEPTOR AGONISTS

There are three drugs in this group that are used in horses. They are xylazine, detomidine and romifidine and they all have common properties but different durations of action. For dose rates, see Box 21.1.

One of the most important actions of these drugs is on the cardiovascular system. **Cardiac output** is reduced and a few minutes after IV injection there is a transient rise in arterial blood pressure, which then falls to below the original resting level. The duration of this effect is drug and dose dependent. The response to the hypertension is a **profound bradycardia**, which is accompanied by atrioventricular and sinoatrial block (*q.v.*). Heart block is at its most intense in the first few minutes after IV injection and tends to disappear as the heart rate increases. However, these effects are variable and depend on a number of factors including the drug, its route of administration and the individual animal. Respiratory effects are minimal in normal healthy animals.

The main effects on the central nervous system are analgesia and sedation. They produce an **increase in urine production** mainly due to inhibition of antidiuretic hormone and probably by hyperglycemia.

All three agents produce an increase in **uterine contractions** and in intrauterine pressure although firm evidence on the significance of these actions is lacking. It appears that the degree of these effects varies between agents and possibly between individual animals. As a precaution it is strongly recommended that the drugs should **not** be administered during the last 3 mo of pregnancy.

They produce hypothermia, which is only of significance in **foals**, but they also produce sweating in some animals.

There have been reports that the administration of **detomidine** in conjunction with **potentiated sulfonamides** caused death in horses but precise information on the possible mechanism is not clear. It is therefore advisable not to use any of the drugs in conjunction with potentiated sulfonamides.

Xylazine hydrochloride is the oldest of the drugs in this group. It can be administered either IM or IV, and after IV injection the effects are evident within 2 min. The head is lowered and the eyelids and lips droop. While horses may sway on their feet, cross their legs and knuckle on their forelimbs, they usually remain standing and do not exhibit any signs of panic. Sedation reaches a maximum within 5 min and lasts 30–60 min. Xylazine has good

analgesic properties, which can be particularly useful in horses with colic. The animals remain very **sensitive to touch** and will often respond by kicking even though they appear to be heavily sedated.

Detomidine hydrochloride is a very potent agent and can be administered by both the IM and IV routes. The nature of the sedation is very similar to that produced by xylazine but of longer duration, 90–100 min.

Romifidine has similar properties to the other two agents with a duration of action of up to 2 h. It is suggested that the head does not droop so low and that there is less ataxia with this drug than with the other two.

Drugs in this group have also been administered by the **epidural route** (*q.v.*) to provide analgesia, either alone or in combination with lidocaine or morphine.

A number of α_2 -adrenoceptor antagonists are available but none is licensed for use in horses. The most commonly used agent is **atipamezole hydrochloride**. Reversal is not usually necessary in horses except when adverse reactions occur or excessive ataxia is produced. Atipamezole will antagonize the actions of all of the drugs in the group by displacing them from the receptors. A dose of 50 $\mu\text{g}/\text{kg}$ is administered slowly IV and may need to be repeated. Slow administration is essential as a rapid injection rate may produce a sudden hypotension and reflex bradycardia. The drug is unlikely to be abused in competition horses as the effects are unlikely to affect performance.

Analgesia and the analgesic drugs have been discussed elsewhere (*q.v.*). Analgesic drugs are often used in conjunction with α_2 -adrenoceptor agonists to improve the quality and reliability of sedation. The most commonly used opioids for this purpose are **butorphanol** and **methadone**. Acepromazine is sometimes added to the combination in relatively small doses. The doses and routes of administration are discussed in Box 21.1. The most commonly used combinations are either of the above drugs with the α_2 agent of choice, depending mainly on the duration of action required.

ANTICHOLINERGIC DRUGS

Anticholinergic drugs are not used routinely in equine anesthesia. They may be used occasionally during anesthesia to treat **profound bradycardia** (*q.v.*), and either **atropine** (0.01–0.02 mg/kg IV) or **glycopyrrolate** (0.005–0.01 mg/kg IV) is the drug of choice. Atropine has a prolonged duration of action of many hours in the horse and may produce gastrointestinal problems such as impaction colic, particularly of the cecum. Some reports suggest close monitoring of the patient at a heart rate of 20 bpm and if it falls further atropine is given at 0.001 mg/kg (0.5 mg for a 500 kg horse).

INDUCTION OF ANESTHESIA

GENERAL PRINCIPLES

Following suitable preparation and premedication, a catheter is inserted into the jugular vein. The catheter may also be inserted before the horse is premedicated. It is important to observe strict aseptic precautions when inserting

catheters into veins. A fine gauge needle or a dental syringe is used to place a small “bleb” of local anesthetic solution into the skin over the area of the vein where the catheter is to be inserted. A number of different types and sizes of catheters are available, but it is usual to select a 12 or 14 gauge 10 cm long “over the needle” catheter for the induction of anesthesia and for fluid therapy.

Catheters are introduced into the vein in either an upward or downward direction. The upward direction is usually easier to place, reducing the risks of technical problems such as air embolism. Care must be taken not to introduce the catheter into the **carotid artery**. Catheters are normally fixed in position by sutures or with “superglue”. Once the catheter is in place it should be flushed with **heparinized saline** and the end occluded with either a three-way tap or a cap. It should also be flushed after each injection.

An ideal method of induction of anesthesia has not yet been described and a technique should be selected on the basis of a number of factors including the size of the horse, its temperament, the available facilities and, most importantly, the indication for general anesthesia. It is not advisable to anesthetize any horse without facilities for resuscitation being readily available, with particular emphasis on **oxygen** and a means of administering it, and drugs commonly used for **cardiac resuscitation** such as epinephrine (adrenaline) and lidocaine.

Facilities for induction of anesthesia can vary from the very basic to sophisticated tilting tables. Until relatively recently it was common to anesthetize horses in open fields or paddocks but with the development of more advanced surgical techniques, some of which are of long duration, this is no longer the case. It is still acceptable for simple and short-duration procedures to be performed in the open provided that **adequate facilities** are available for anesthesia, resuscitation and recovery.

When a significant number of horses are being anesthetized, it is appropriate for induction to be performed in a **padded box**, which also serves as a recovery area. The **restraint** applied to a horse at induction of anesthesia will often be governed by the available facilities. When the horse is allowed to fall to the floor or ground at induction, it is normal practice to have one or two people with rope(s) attached to the head collar to control the fall by keeping the head low and gently pushing the horse backwards. In a padded box, the rear end of the horse may be placed against a wall or in a corner, allowing the animal to slide down the wall to the floor. Padded gates are sometimes available in induction boxes and facilitate the restraint of the horse during induction. When **tilting tables** are used, the premedicated horse is stood and restrained against the vertical table; the induction agents are injected IV and the table rotated to the horizontal position.

Normally anesthesia is induced in horses using an IV technique, commonly based on the combination of a sedative followed by a barbiturate or a dissociative agent. In addition, a drug that provides muscular relaxation such as **succinylcholine** or **guaifenesin** may also be used. A variety of drug combinations have been described and the choice is often a matter of personal preference. The various combinations of drugs in common usage, with their dosages, are shown in Box 21.2.

Following the injection of the induction agent it is important to restrain the head, as described above, to prevent it being raised and the horse falling over backwards.

Box 21.2 Doses of some common premedicant and induction agents

Acepromazine 0.05–0.1 mg/kg IM	then	thiopental 10 mg/kg IV
Xylazine 1 mg/kg IV	then	thiopental 10 mg/kg IV
Detomidine 0.01 mg/kg IV <i>or</i> romifidine 0.08–0.1 mg/kg IV	then	ketamine 2.2 mg/kg IV
Xylazine 1 mg/kg IV	then	guaifenesin infused until ataxia
Detomidine 0.01 mg/kg IV	then	thiopental 5 mg/kg IV <i>or</i>
Romifidine 0.08–0.1 mg/kg IV	then	ketamine 1.5 mg/kg IV

THIOPENTAL SODIUM

Thiopental is commonly used to induce anesthesia in horses. The dose depends on the degree of sedation produced by the **premedication** (*q.v.*) and on any adjunctive agents such as guaifenesin that may be used.

Recovery from thiopental anesthesia is more dependent on its redistribution within the body than its elimination from it. Hence, in general, the lower the dose, the better the quality of recovery.

Following **acepromazine premedication**, thiopental will produce recumbency in 25–30 s, and recovery to the standing position will occur in 35–40 min. **α_2 -Adrenoceptor agonists**, such as detomidine or xylazine, will enable a reduced dose of thiopental to be used and will slow the induction time. Recovery time will be similar to that with acepromazine but the quality of the recovery will usually be better.

Thiopental is often administered with the centrally acting muscle relaxant **guaifenesin**. After premedication, guaifenesin is infused IV until the horse becomes ataxic, at which stage a bolus of thiopental is given to induce anesthesia. Under some circumstances a mixture of the drugs can be infused but this provides less control over the induction. For dose rates, see Box 21.2.

KETAMINE HYDROCHLORIDE

Ketamine is a **dissociative agent** that produces profound analgesia combined with a “light sleep” and tends to produce stimulation of the central nervous system and muscle rigidity when it is administered alone. Suitable drugs must be used for **premedication** to offset these latter effects. Drugs of choice are the α_2 -adrenoceptor agonists and/or the benzodiazepines. Ketamine should never be given alone.

Commonly, **xylazine** or one of the other drugs in the group is administered IV and there is a time lag until signs of sedation are obvious, around 5 min. **Diazepam** is then injected, followed immediately by a **ketamine bolus**. Induction of anesthesia and recumbency follow in 2–3 min. The technique normally produces an excellent and well-controlled induction, and while recovery can be **abrupt** it is usually of good quality. Ketamine may also be used with **guaifenesin** in a similar manner to thiopental. For dose rates, see Box 21.2.

INDUCTION IN FOALS

Anesthetic induction in foals is normally performed with a volatile anesthetic agent (*q.v.*). Halothane or isoflurane is vaporized with oxygen or oxygen/nitrous oxide and administered by facemask, by an endotracheal tube introduced nasally, or by nasal insufflation with a narrow bore tube. In the vast majority of animals manual restraint is often sufficient to enable the procedure to be performed. However, small doses of **xylazine** or **pethidine** may be administered IM to produce sedation. In the vast majority of cases the mare should be sedated and kept with the foal until induction of anesthesia is complete.

MAINTENANCE OF ANESTHESIA

INTRODUCTION

Anesthesia in horses is maintained with either **inhalational** or **total intravenous anesthesia (TIVA)**.

In order to maintain a clear airway during anesthesia and to administer oxygen it is essential to **intubate the trachea**. Normally this will be by the oral route and is a relatively straightforward procedure provided anesthesia is deep enough and the mouth can be held open either manually or by a gag placed between the incisor or molar teeth. The lubricated tube is passed blind through the larynx into the trachea. If any difficulties are encountered they can usually be overcome by altering the angulation of the head and neck and using gentle pressure to push the tube into the larynx and on into the trachea.

INHALATIONAL ANESTHESIA

Inhalational anesthetic agents are normally administered with 100% oxygen as a carrier gas. Large circle absorbers and to-and-fro circuits have been developed for use in horses. Ventilators are also used in conjunction with circle systems to deliver IPPV.

Halothane was introduced into equine anesthesia some 40 years ago and can be said to have revolutionized equine anesthesia. It produces a dose dependent reduction in arterial blood pressure and cardiac output in horses. While the facility to measure end-tidal concentrations enables the anesthetist to control the inhaled amount of an agent, this facility is not generally available due mainly to the cost of the equipment. In practice it is usual to maintain anesthesia with delivered concentrations of 2–4% halothane in oxygen. The time from the cessation of the administration of halothane to standing is between 30 and 60 min. It is mainly dependent on which other sedatives and anesthetic drugs have been administered for premedication and induction and on their duration of action.

Isoflurane has been used in horses for approximately 15 years and its properties are similar to halothane, as is the response of animals to its administration. It has a lower blood solubility, which means that the induction of and the recovery from anesthesia can be rapid. Isoflurane produces a lesser fall in cardiac output during anesthesia than halothane but the degree of **respiratory depression** is greater, particularly in the absence of surgical stimulation necessitating the use of IPPV.

Sevoflurane is a recently introduced volatile agent that is currently considered to be too **expensive** for routine clinical use. It has a low blood solubility, which facilitates rapid changes in anesthetic depth and in recovery from anesthesia.

It is well known that horses can exhibit sudden movements during general anesthesia associated with rapid changes in depth of anesthesia, usually in response to a **painful stimulus**. A number of agents are used to provide **additional analgesia**. These include **butorphanol** 0.02 mg/kg and **morphine** 0.1–0.2 mg/kg, although the role of opioids in this situation is still unclear. Small **bolus doses** of thiopental of up to 1 g and ketamine 0.1–0.2 mg/kg are also used. More recently, **infusions** of low doses of ketamine 40 µg/kg/h have been used and this technique merits further investigation.

TOTAL INTRAVENOUS ANESTHESIA

Total intravenous anesthesia (TIVA) has been used in horses for many years, but the results have been variable. Originally, single bolus doses of either thiopental or pentobarbital were used to prolong the duration of anesthesia. Later, combinations of thiamylal or thiopental and guaifenesin or chloral hydrate were used, but they produced prolonged recoveries. More recently a number of other combinations using ketamine, guaifenesin and either xylazine or detomidine have been described. They incorporate 1 g **ketamine** with either 500 mg **xylazine** or 10 mg **detomidine** mixed with 500 mL of 10% **guaifenesin**. When this combination is used for TIVA, guaifenesin should not be used as part of the induction technique to reduce the total dose of this long-acting drug in an attempt to improve the quality of recovery. The combination should be infused at a rate of 1 mL/kg/h but the rate should be based on the **clinical assessment** of anesthetic depth. A more rapid rate may be required during the early part of a procedure and at the time of maximum surgical stimulation and a slower rate toward the end of the procedure.

NEUROLEPTANALGESIA

A technique involving the IV administration of **etorphine** (2.45 mg/mL) and **acepromazine** (10 mg/mL) in combination has been used to produce a state of neuroleptanalgesia for the conduct of short procedures in Equidae. A dose of 0.5 mL/50 kg is recommended and the actions of the etorphine can be reversed by the IV administration of a similar volume of **diprenorphine** (3 mg/mL). In order to reverse the results of any accidental injection in humans, **naloxone** should be available. This combination is no longer available for use in horses or donkeys.

COMPLICATIONS OF GENERAL ANESTHESIA

Complications during general anesthesia in horses generally involve the cardiovascular or respiratory systems.

Hypoxia is very difficult to treat, particularly in animals that are extremely sick with such conditions as endotoxemia associated with colic (*q.v.*). The

administration of **100% oxygen** is not a very effective treatment but it is often used. **Clenbuterol** has been used at a dose of 0.8 mg/kg IV but there is debate regarding its efficacy. **IPPV** may be of some value in the treatment of hypoxia although its effectiveness is still under debate. In order to be effective, a mechanical ventilator is essential, and a rate of **6–10 per minute** and a tidal volume of **10–15 mL/kg** are employed.

Hypercapnia occurs commonly in anesthetized horses. **IPPV** is the rational treatment but it will cause an **increase in intrathoracic pressure** that can have deleterious effects on the cardiovascular system, particularly in the presence of **hypovolemia** (*q.v.*).

Hypotension and hypovolemia are relatively common in horses under general anesthesia. **Hypovolemia** can be prevented and treated by the IV infusion of large volumes (20–30 L) of **balanced electrolyte** solution (Plasmalyte). If this is unsuccessful then **hypertonic saline** solution should be administered at a rate of 4 mL/kg IV. However, its effect may be relatively short lived and **large volumes of electrolyte solution** (20–30 L) should also be infused at the same time or immediately afterwards.

Hypotension, with a mean arterial blood pressure <70 mmHg, is undesirable and should be treated as it is likely to lead to complications such as **myopathy** (*q.v.*) Sympathomimetic drugs such as dobutamine are recommended for the treatment of hypotension but it is often preferable to reduce the depth of anesthesia to a level commensurate with the execution of the surgical procedure and to infuse adequate volumes (up to 10 mL/kg) of electrolyte solution before resorting to drug therapy. The sympathomimetic drug of choice for the treatment of hypotension is **dobutamine**, which should be given IV at a rate of 1–5 µmg/kg/min. In some horses, especially those with **endotoxic shock** (*q.v.*), it will not be effective. Dobutamine does not increase the arterial blood pressure but may produce tachydysrhythmias (*q.v.*). In such situations **phenylephrine** may be administered IV at a rate of 0.2–2 µmg/kg/min, or a single dose of **ephedrine** (0.03–0.06 mg/kg IV) may be given.

RECOVERY

Horses should be allowed to recover from anesthesia in a **padded, dimly lit box** with the minimum of disturbance. If a stormy recovery is anticipated then a small dose of **xylazine** IV (up to 100 mg depending on size, temperament, previous medication etc.; normal sedative dose, 1.1 mg/kg) should be given at the end of anesthesia. Manual assistance at recovery may be justifiable under some circumstances, such as after orthopedic surgery. It is important to emphasize that, while the safety and welfare of the horse is important, the **safety of personnel is paramount** and no unnecessary risks should be taken.

Oxygen (100%) should be administered through the endotracheal tube until the animal begins to swallow and the tube is removed. Nasal insufflation of oxygen is then continued until the animal begins to attempt to stand. After a prolonged period of anesthesia, particularly with the horse in dorsal recumbency, edema of the nasal mucosa may produce **respiratory obstruction**. The passage of a **narrow bore endotracheal tube** up a nostril usually relieves the

problem. The tube should be **well secured** to prevent its aspiration or falling out during recovery. **Phenylephrine** has been used as a nasal spray to reduce nasal edema and facilitate tube entry.

Adequate analgesia should always be provided, either preemptively and/or at the end of anesthesia by the administration of **opioids** such as morphine 0.1–0.2 mg/kg IV and/or **NSAIDs** such as flunixin 1.1 mg/kg IV.

It is essential for animals to be kept under **continuous observation** until they regain their feet and are able to stand and to move in a coordinated manner. Any problems related to the respiratory or locomotor systems should be dealt with rapidly and effectively, hence it is essential to be able to obtain effective assistance should it be required. Normally, under hospital conditions, the animals would be returned to their own box some 20–30 min after regaining their feet. Arrangements should be made for **regular observation** of the patient and the administration of **analgesic drugs** as required.

LOCAL AND REGIONAL ANESTHESIA

LOCAL ANESTHESIA

Three solutions are used commonly to produce **local and regional anesthesia** in the horse. These are bupivacaine, lidocaine and mepivacaine. **Lidocaine** is used most frequently in practice.

Regional anesthesia of the limbs is discussed in Chapter 15 (*q.v.*), where details of forelimb and hindlimb regional and intrasynovial analgesia are provided (see Table 15.1, page 875). A number of regional nerve blocks are also used on the head of the horse. Auriculopalpebral, lacrimal and supraorbital blocks for **ophthalmic procedures** are discussed in Chapter 19 (*q.v.*) (see page 1208).

The rostral part of the infraorbital nerve supplies the upper lips, nostril and related skin of the face. The more caudal part of the nerve, which is situated in the canal, supplies **the teeth** (*q.v.*) to the level of the first molar and the skin of the face. It can be blocked as it leaves the foramen or a needle can be inserted through the foramen into the canal. The mental nerve supplies the skin of the lower lip and can be blocked as it emerges from the foramen. The mandibular nerve supplies the canine and incisor teeth and may be blocked on the medial aspect of the mandible although this is technically very difficult and not used very often.

EPIDURAL ANESTHESIA

Epidural anesthesia has a number of indications in the horse and these include surgery of the anus, perineum and vulva (*q.v.*) plus the prevention of straining during **obstetrical procedures** (*q.v.*). In the horse **posterior anesthesia** is almost invariably used as the interference with locomotion almost totally precludes the use of the anterior technique.

Absolute cleanliness is essential when using the epidural technique. After surgical preparation of the site a **wheel of local anesthetic** solution is placed at the site of the needle insertion using a fine needle. A 20 G, 10 cm needle is most commonly used and it is inserted into the **first inter-coccygeal space**.

One of two techniques is used for insertion of the needle: (1) at right angles to the general contour of the croup until it strikes the floor of the neural canal and is then withdrawn 0.5 cm; (2) at the caudal part of the inter-coccygeal depression, directed at 30 degrees to the horizontal and inserting it to its full length.

Until recently lidocaine was the agent of choice for epidural anesthesia. However, opioids (*q.v.*) and α_2 -adrenoreceptor agonists (*q.v.*) have also been used. It is important to use **preservative-free solutions**. The most common combination is probably lidocaine and xylazine.

EUTHANASIA

INTRODUCTION

Euthanasia is often defined as a quiet and gentle death but it is probably better to refer to it as a quick and painless death. Euthanasia of horses is carried out by veterinarians under three different circumstances:

1. At sporting events when it is not feasible or possible to treat a particular injury such as compound fractures and fractures of the higher long bones of the limbs (*q.v.*)
2. When horses have reached the end of their useful and productive life and are suffering from crippling, debilitating or untreatable conditions (*q.v.*)
3. When incurable conditions are discovered during surgery and the animal is not allowed to recover from anesthesia.

These three situations each require a different approach.

It is important to ascertain whether the animal **is insured** and wherever possible to seek **permission from the insurance company**. If the owner of the horse or a responsible agent is available it is best to secure their agreement to carry out euthanasia. In an emergency and in the absence of the owner or agent it is strongly recommended that a **second veterinary opinion** as to the indications for euthanasia be obtained. Under most circumstances it is preferable to obtain written consent although under certain circumstances verbal agreement, in the presence of a reliable witness, is adequate. **Written records** of the procedure should be kept, and whenever possible a post mortem examination carried out.

TECHNIQUES

Horses can be humanely destroyed using either drugs or physical methods that damage the brain. Irrespective of the technique, the aim is to stop the flow of oxygenated blood to the vital tissues and produce death. The drugs used to produce euthanasia are of two distinct types, i.e. those that produce hypoxia and those that depress the central nervous system.

Hypoxic agents should never be used as sole agents. Muscle relaxants (*q.v.*) may be used in combination with a barbiturate (*q.v.*). They produce **muscle paralysis without anesthesia** and their use as a sole agent is **inhumane**.

Central nervous system depressants that produce cardiac and respiratory arrest are the **agents of choice** for euthanasia in horses. Due to the physical size of horses, the use of a number of agents is impractical. **Barbiturates** (*q.v.*)

are probably the drugs of choice although chloral hydrate, magnesium sulfate and potassium chloride have been used. For doses, see below.

In some countries, shooting with a free bullet has been employed, often with an attached silencer. When using a gun it is important to place the muzzle in the correct position at a site **just above the intersection** of the imaginary lines drawn from the base of the ear to the orbit on the opposite side of the head (Figure 21.1). Captive bolts are not advisable for use in the horse, as if the head moves the bolt may bend and become unusable in the event that a second shot is needed.

Figure 21.1 A front view of the head of a horse showing the two lines joining the base of the ears and the centre of the orbit on the opposite site. The site of entry of the bullet should be just above the point of intersection of these two lines. Reproduced with permission from Jones, R.S. (1992) Euthanasia in horses, *Equine Veterinary Education* 4: 154–157.

Recommended techniques

One technique that has found universal favor is the use of 10 g **thiopental sodium** (*q.v.*) dissolved in 60 mL of water administered IV through a 14 G catheter followed immediately by 100 mg **succinylcholine** (*q.v.*). If death does not occur within 2–3 min then 50 mL of **triple strength pentobarbital** (200 mg/mL) should be administered IV.

The use of α_2 -adrenoceptor agonists (*q.v.*) to produce sedation is not recommended as they slow the circulation and the horse tends to fall over backwards.

An injection of 200 mL of **triple strength pentobarbital** followed by **succinylcholine** administered IV has also been recommended.

In some countries a mixture of **secobarbital** and **cinchocaine hydrochloride** (a local anesthetic) is available (e.g. as Somulose) and widely used for euthanasia in horses. A dose of 5 mL/50 kg is recommended to be administered IV through a catheter over a 12–15 s time period. The use of α_2 -adrenoceptor agonists is not recommended except in a fractious horse or when sedation is essential for assessment prior to euthanasia. This combination solution has the advantage of small volume and a relatively rapid rate of action. In the UK, it is subject to the Misuse of Drugs Act (1971) and is subject to special prescription and record keeping but not to custody requirements. Other restrictions may apply elsewhere.

INTRODUCTION

The pre-purchase examination is a procedure unique to the equine industry and places the veterinarian in a rather peculiar position compared to his or her standard practice of animal husbandry. In no other area are veterinarians consistently called upon to act as objective “consultants” for a buyer before a horse is sold. It would be unusual, for example, for someone to consult with an expert before buying a car, furniture, or other sports equipment. Except in unusual circumstances, pre-purchase examinations are rarely performed in acquiring other species such as companion or food animals. It is also apparent that veterinarians do play a significant role in the outcome of the sale based on their findings during the examination. Beyond the sale, the **reputation of the horse** in the show world and in the next pre-purchase examination can also be affected if the horse did not sell.

Given the competitive nature of equestrian events and the rising costs of maintaining and training these athletes, buyers are pursuing pre-purchase examinations potentially in order to **avert acquiring a problem**. The examinations are an important facet of the equine industry for both owners and veterinarians and can establish new clientele for the veterinarian, provide

significant revenue for the clinician's practice, and provide a beneficial exposure for clients to the veterinary profession.

The veterinarian's examination is critical since many **transfers of ownership** are heavily based on the outcome of the pre-purchase examination, and the decision to buy the animal or not frequently hinges on details revealed during the course of the examination.

While there are many potential benefits to both the client and the veterinarian, the examinations may also pose some **liability concerns** for the veterinarian. This may occur if a lesion is missed during the examination or if a clinical finding such as a radiographic change is misinterpreted. For these reasons, some veterinarians avoid pre-purchase examinations or are extremely conservative in their interpretations of the findings. However, as long as the potential buyer is educated about the objectives and the limitations of the examination, many of these reservations can be reduced or eliminated.

COMMITMENT AND UNDERTAKING

One of the difficulties with pre-purchase examinations is the expectation by the prospective buyer that the veterinarian can **predict and/or guarantee future soundness**. This predicament for the veterinarian becomes even more difficult when the examination is clouded by a mild lameness or mild response to a flexion test in the presence of radiographic changes. Occasionally radiographic changes may also be present in the absence of clinical signs such as degenerative changes at the tarsus or remodeling of the subchondral bone such as the trochlear ridges of the stifle or tarsus. For this reason, practitioners have moved away from declarations of "pass" or "no pass". Instead it is more typical to summarize for the potential buyer the **significant findings** of the examination and the radiographic survey with the understanding that this examination is **simply a snapshot in time and not a prediction of the horse's future athletic career**.

Generally, unless qualified to do so, **veterinarians should not comment on the price** or assist in the negotiation of the purchase price of the horse. It is important for clinicians to inform potential buyers that while they can make an assessment of the horse's overall physical well-being, there are limitations to the pre-purchase examination.

HORSES FOR COURSES

Occasionally, specific details of the pre-purchase examination are dictated by the client's financial ability, expectations, facilities available and the intended use of the animal. In horses intended for a **specific purpose**, such as Western pleasure or endurance, there may be some areas that are more relevant to the prospective buyer than others. For example, the potential endurance prospect may be more likely to receive an upper airway endoscopic examination than a Quarter Horse intended for Western pleasure/show classes. This may also increase the **emphasis of scrutiny in specific areas**. For example, in horses intended for cutting or reining, excessive forces are exerted at the hocks and lower joints so these areas must be especially evaluated to look for any lesion or evidence of an impending problem, most commonly via palpation and radiography.

Given that **navicular degeneration** (*q.v.*) can be common in Quarter Horses, the feet are also examined carefully with special attention to the heel area. It is generally accepted that no horse is “perfect”, especially if it has been competing consistently in some athletic event. Therefore, it becomes a question of what flaws and how many the potential buyer is willing to accept. Again, this question is one that can only be answered by the buyer.

Veterinarians must be aware of their own limitations and refer the horse to specialists if needed. For example, not all veterinarians may be qualified to perform a pre-purchase examination on a **gaited horse** such as a Tennessee Walking Horse. The role of veterinarians in pre-purchase examinations requires examiners to “recognize the seeds of soundness as much as the seeds of disease”.

Pre-purchase examinations are not always strictly confined to determining whether the horse is **currently** sound or not. Many owners may expect veterinarians to provide personal opinions about the horse’s conformation and if it is capable of withstanding its intended use. For example they may question if the musculoskeletal development is appropriate given the horse’s age, whether the horse too small, or fine boned, etc. Generally, **overall balance and conformation** evaluation are important considerations since discrepancies from normal can predispose the horse to future problems. For example, horses with a **toed-in conformation** may be at an increased risk of developing **pastern ringbone** (*q.v.*) or **lateral suspensory branch desmitis** (*q.v.*), and horses with **elongated pastern bones** may develop **flexor tendon sheath effusion** (*q.v.*).

In some cases the pre-purchase examination is highly tailored to the type of horse and its intended use. For example in **polo horses**, palpation of the flexor tendons and suspensory ligaments in addition to fetlock joint flexion can comprise up to 80% of the examination. While attempts have been made over the years to standardize the pre-purchase protocol, it still remains, and likely always will, at the discretion of the veterinarian and the parties involved.

The variables that should be evaluated in a pre-purchase examination should be modified according to the specific parties involved, the clinician’s experience, the intended use of the horse and the owner’s expectations.

HISTORY

It is advantageous for the veterinarian examining the horse to have some information about the horse’s career **prior to the examination**. For example: Have the potential buyers ridden the horse before? How long have they known the horse? What has the horse been used for in the past? Has there been any history of lameness or illness?

Commonly, the buyer will have had only limited exposure to the horse, and information regarding the lameness history or medical problems is scant. Horses that have been retired from one career to start another should have a **good history** and **physical examination**. For example, Thoroughbreds that have been “retired” from racing and are being purchased as prospects for dressage should be evaluated closely for signs of injury **related to the racetrack**. The flexor tendons should be inspected carefully for any sign of **tendinitis** (*q.v.*), and the **joints should be palpated** for any synovitis or effusion that might suggest osteoarthritis or chip fractures (*q.v.*). Horses retired for being too slow and **lacking in “heart”** should also be evaluated for poor performance due to

upper airway conditions such as **laryngeal hemiplegia** or **soft palate displacement** (*q.v.*).

Because of the **potential for litigation** and in an effort to minimize any misunderstandings, it is in the veterinarian's best interest to **document fully the entire examination and conversations with the buyer and the seller**. Some practitioners include a **disclaimer** at the summary of the examination form. In addition, **worksheets** that list the procedures to be performed are routinely used by some clinicians, not as the final report for the buyer, but more as a checklist to ensure that areas are not inadvertently omitted during the course of the examination.

Prior to the examination, it is important to discuss with the owner **the parameters that will be evaluated** to ensure that any diagnostic procedures that the buyer may have expected are not missed and also so that they have an estimate of what the cost of the examination is likely to be. Depending on the intended use of the horse, some buyers will want only a bare examination, while others will expect a very thorough diagnostic evaluation.

PHYSICAL EXAMINATION

BASICS

A **complete physical examination** should be performed as a standard procedure in all cases regardless of the selling price. The basic temperature, pulse and respiration are taken before initiating exercise.

The **perineal** region should be examined while inserting the thermometer for any abnormality such as **melanoma** (*q.v.*) in gray horses or an **excessively sloped conformation** (*q.v.*) in mares. This also allows for a brief assessment of **tail tone**. Other areas of increased incidence of melanoma such as the parotid region and peripheral lymph nodes should also be evaluated.

HEART

Cardiac auscultation (*q.v.*) is important to detect any subclinical abnormality such as atrial fibrillation or heart murmurs. While horses have been known to compete successfully even in strenuous careers with cardiac abnormalities such as low grade murmurs, the heart should be evaluated with ECG and ultrasound if there is a concern about future performance.

Auscultation alone cannot differentiate between **physiologic flow murmurs** (which are common and not usually clinically relevant) due to flow of blood through large vessels and murmurs due to **underlying cardiac disease** (*q.v.*) such as mitral regurgitation.

Depending on the abnormality, **cardiac disease is usually progressive**. In a study to determine the incidence of various heart murmurs and their effect on performance in Thoroughbred racehorses, heart murmurs were detected in 81.1% of horses, with the most common type being the **systolic murmur over the heart base** (43.1%). **Systolic murmurs over the mitral valve** region were detected in only a small percentage of the horses (3.8%). In reviewing the race records of these horses, it was concluded that there was **no significant association between murmurs and performance**.

EYES

It is important to undertake a thorough examination of the eye. This should involve an evaluation of the **menace response**, evaluation of any **corneal defects** (*q.v.*) using a transilluminator where possible, and observing the **retina** using an ophthalmoscope.

If any significant defects or abnormalities are identified, the horse should be referred for a specialist ophthalmic evaluation. It is worth being aware that in some equine disciplines, horses are allowed to compete with only one visual eye. Details of eye problems in horses are given elsewhere in the book. (See Chapter 19, page 1157.)

LUNG FIELDS

The lung fields are evaluated by auscultating the chest with and without the use of a **rebreathing bag**. The procedure is often facilitated by placing a large plastic bag over a muzzle that keeps the bag from being drawn into the nostrils.

The throat latch area should be palpated for any **thickening or sensitivity** and to detect whether a **cough** is easily elicited. Both jugular veins should be palpated for any evidence of **thrombosis** or other swelling that might indicate frequent or recent injections.

The coat is also evaluated for any sign of dermatitis, sarcoids, melanomas (especially in gray horses in the perineal region), old scars and unusual sweat patterns (*q.v.*).

LIMBS

The limbs are also palpated from proximal to distal with special emphasis on the **joints and flexor tendons**.

The **digital pulses** to the feet should be evaluated, preferably **before initiating any exercise**. Hoof testers are applied to all four feet, usually before the horse is exercised. **Bony exostoses** or splints (*q.v.*) may be present and should not be sensitive to palpation. If there is a concern, a radiograph may be indicated to determine if the exostosis is due to a previously fractured splint bone and to ascertain the size of the callus to see whether it is **impinging on the suspensory ligament** as may happen if it extends to the caudal aspect of the limb. If the suspensory ligament is sensitive to palpation near the bony exostosis, then ultrasound is indicated to determine if there is a desmitis associated with proximity to the splint.

Areas of **unusual hair pattern and/or discoloration** should be inspected closely as they may represent an area that has had previous blistering or treatment for a tendon problem.

The **flexibility and range of motion** of the limbs should be evaluated. The fetlock and carpus should easily flex with no restriction. The front limb should be picked up at the carpus and advanced forward and backward with no resistance. The back and lumbar region should be palpated along the entire length for any irregularity or excessive sensitivity to touch. This includes the tuber sacrale, sacrum and pelvis.

In sport horses, particular emphasis should be placed on an examination of the flexor tendons and suspensory ligaments of the front and hind limbs.

Any abnormality such as thickening or sensitivity should be evaluated with **ultrasound** if there is a concern. Healed lesions on the superficial digital flexor tendons can occasionally be seen in sport horses, especially since many Thoroughbreds retired from the racetrack are given a new career in jumping or dressage. Generally these old healed lesions do not flare again in trained well-conditioned horses, especially if the horse has been competing successfully at the desired level. The semimembranosus and semitendinosus muscles should also be evaluated to determine if there is any thickening or scarring as would occur with a **fibrotic myopathy**.

In young and unproven horses, special attention should be paid to the **joints** such as the hocks, stifles and fetlocks to rule out **developmental disease** such as osteochondrosis (*q.v.*). In older horses that have already been in training or competition, less emphasis is placed on subtle radiographic changes that may be present as these may simply be a function of repeated exercise and stresses but **not necessarily** a career-limiting or -ending finding.

THE VENTRAL MIDLINE

The ventral midline should also be closely palpated for any **evidence of a scar**, which would suggest the horse has had **abdominal surgery**, most likely due to gastrointestinal disease. The history of a horse that has had colic surgery is important, especially if a resection and anastomosis was performed. For example, practitioners may well be concerned about using horses with **large intestinal colopexies** due to displacement or torsion for jumping. The concern is that if these horses are used for rigorous competition, for example challenging high jumps, they may be at greater risk for **tearing the large colon from the body wall** and rupturing the intestine.

Horses with small **ventral midline hernias** have been used in competition with no known deleterious consequences. However because of cosmetic concerns and the potential for incarceration of intestine, most owners elect to repair these defects.

SOUNDNESS EXAMINATION

OBSERVATION

The soundness examination should begin by simply **watching the horse walk** away from and toward the examiner. This allows the clinician to have an assessment of the horse's **demeanor** and look for any **gait abnormalities at a slow speed**, such as interference, landing on the medial or lateral aspect of the foot, and if the horse wings or paddles his limbs.

Certain gait abnormalities, such as **stringhalt** (*q.v.*) and **shivers** (*q.v.*), can also be identified at this time. Horses with these gait abnormalities have been known to compete at high levels of jumping with no apparent difficulty and without an obvious progression of clinical signs.

STRAIGHT LINE TROT, FLEXION TESTS AND LUNGING

The horse is then **trotted in a straight line** and held on a **loose line** so as not to interfere with the movement of the head.

Flexion tests are performed on all limbs in a systematic fashion. The fetlock joints are flexed for 30–45 s followed by the carpus for the same amount of time. On the hindlimbs, the hocks are flexed (**spavin test**) for a minimum of 90 s. Inflammation of the distal intertarsal and tarsometatarsal joints affects a large proportion of jumpers and high level dressage horses, and most will require some treatment to continue competing at these advanced levels. Generally, the clinician can ignore the first several strides as many **sound horses** may be off on the first few steps after flexion. However, if lameness persists beyond that point, it should be considered a positive response. The horse should then be **lunged on a hard surface** in both directions on a loose line. If there is any question or concern, the horse can also be lunged on a softer surface such as a round pen with sand or loose dirt. Generally horses do not need to be ridden, but in some situations it may be advisable for the horse to be observed under saddle and/or performing its intended use such as jumping or dressage.

DIAGNOSTIC PROCEDURES

INTRODUCTION

For the majority of pre-purchase examinations, **radiography** is the most common diagnostic procedure performed. Depending on the owner's wishes, the experience of the veterinarian, and anything else that has come to light during the pre-purchase examination, other procedures may also be performed that are not necessarily routine for every practice. For example these may include radiographs of regions other than the limbs such as the **abdomen** (looking for enteroliths or sand), **nuclear scintigraphy**, **thermography**, **magnetic resonance imaging**, and **ultrasonographic examination of the flexor tendons, heart** or other areas.

Horses intended for international competition may need to be tested for various diseases including **piroplasmosis** (*q.v.*), **equine infectious anemia** (*q.v.*), **glanders** (*q.v.*) and **equine viral arteritis** (*q.v.*) in breeding mares and stallions (if indicated). If the clinician has any questions regarding importation and/or transport regulations, the best source is likely to be someone in the horse transportation business or the US Department of Agriculture (USDA) or the appropriate government's regulatory authority.

Some owners, either through personal experience or on the advice of others, may request **specific tests for diseases** that are common in their area or have received recent publicity or notoriety. Specific examples include testing for **equine protozoal myeloencephalitis** (EPM) (*q.v.*) and **Lyme disease** (*q.v.*). Since EPM is endemic in the USA, serologic testing is not always productive since a positive outcome does not immediately confirm disease, but exposure. Of course, a negative response indicates the horse is free of disease. Because of the inherent risks associated with **cerebrospinal fluid (CSF) sampling**, this procedure is not done routinely, but only if indicated by clinical signs such as **neurologic symptoms**. Newer testing techniques such as the **serum indirect fluorescent antibody test** may have greater accuracy compared with traditional Western blot tests.

RADIOGRAPHY

Radiography has for many years been the primary aid used to diagnose **skeletal lesions** in horses. However, the radiographic diagnosis of a specific lesion is truly more effective when combined with another modality such as a **clinical lameness examination** or **nerve blocks** since it is possible that the radiographic finding may simply be an incidental finding.

Radiographic images generated during a pre-purchase examination remain the **property of the clinician** and are part of the medical record. They do not belong to the person who paid for the examination since the fee charged is for the time, expertise and equipment but not the image produced. If the owner asks for the radiographs to be sent elsewhere for a second opinion, then copies can be made and given to the client, or the images can be sent directly to the consulting veterinarian. In the current age of digital radiography, the transfer of radiographs has been simplified since the images can be sent simply via the Internet or copied onto a CD. The veterinarian needs to remain diligent about exercising good judgment and responsibility with this radiographic information.

A complete radiographic study requires several views to ensure subtle lesions are not missed. For the **feet**, the views taken include the lateral, 65° dorsoproximal–palmarodistal, 45° dorsoproximal–palmarodistal, and the skyline flexor view from palmaroproximal to palmarodistal. For the **joints of the distal limb**, the views required include the lateral, dorsolateral–palmaromedial, dorsomedial–palmarolateral, dorsopalmar and flexed lateral (with the exception of the tarsus unless indicated). For the **stifle joint**, the recommended views include the caudocranial, lateromedial, caudolateral–craniomedial and lateromedial patellar.

ENDOSCOPY

Endoscopy should be offered to all clients, especially those who intend to use the horse for **strenuous athletic exercise** such as endurance or jumping. Horses intended for dressage are also encouraged to have an endoscopic examination of the pharynx and larynx since the roaring sound made by a horse with **laryngeal hemiplegia** (*q.v.*) may lead to faults in the show ring. Further, alterations in head carriage in combination with **laryngeal paralysis** may cause restrictions in performance. Horses used as hunters must not make an abnormal noise during work and therefore may be disqualified for the sound even if performance is not impaired.

Gastric endoscopy is performed occasionally for owners concerned about ulceration in performance horses. It is now known that there is a high prevalence of gastric ulceration (*q.v.*) in most types of racing, competition and show horses, including endurance horses, and gastric endoscopy may therefore be increasingly requested.

ULTRASOUND

Owners may also wish to have ultrasound examinations performed on the **flexor tendons** and **suspensory ligaments** to screen for any existing or preclinical problem. Generally, this type of examination is not routinely performed

unless there is an indication such as swelling and/or lameness in the **metacarpal or metatarsal region**.

Ultrasound examinations should be undertaken only by an **experienced operator** competent in performing the examination and interpreting the results. This will help to ensure that **subtle lesions** are not missed and that normal findings are not construed as abnormal findings.

Ultrasound may also be indicated in cases with **excessive swelling of the joint or associated sheath** such as at the level of the digital tendon sheath. This distension may result from chronic inflammation, adhesions, or tearing of the associated structures in the sheath (e.g. deep and superficial flexor tendons).

REPRODUCTIVE EXAMINATION

In horses intended to be used for breeding, reproductive evaluation is also recommended. The specifics of the examination include semen collection and evaluation (*q.v.*) in stallions, and ultrasound of the uterus and ovaries and uterine culture and/or biopsy in mares.

If a mare is to be sold in foal, **ultrasound evaluation of the uterus** is especially relevant to verify the pregnancy and screen for twins. With the proper technique and training, it may also be possible to determine the sex of the fetus if this information is important to the buyer.

GUIDELINES TO VETERINARIANS CONDUCTING PRE-PURCHASE EXAMINATIONS

THE AMERICAN ASSOCIATION OF EQUINE PRACTITIONERS GUIDE

The American Association of Equine Practitioners (AAEP) provides guidelines for veterinarians in conducting pre-purchase examinations.* Generally, recommendations such as these provide common sense information that most practitioners should already be aware of and practice. Some of the major points mentioned in the AAEP Guide include the necessity to provide a **detailed description of the horse for future identification** with the **time and date of the examination**, all abnormalities noted, and the clinician's opinion on the effects any changes may have on the horse's performance.

One important guideline included in the AAEP Guide states that

The veterinarian should make no determination and express no opinion as to the suitability of the animal for the purpose intended. This issue is a business judgement that is solely the responsibility of the buyer that he or she should make on the basis of a variety of factors, only one of which is the examination and report provided by the veterinarian.

This statement essentially places the burden of making the decision to purchase the horse or not **on the owner** as it should be since he or she will also be assuming the financial, legal and emotional responsibility of owning the

* AAEP (1992) Guidelines for reporting prepurchase examinations approved by the AAEP, *AAEP Report* 6: 3 ISSN 0065-7182.

animal. Maintaining neutrality by the veterinarian minimizes liability should the animal develop a problem after the examination or is found to be unsuitable for the owner's intentions. **Ownership of the horse lies with the buyer**, who should never be in a position to claim that he or she was "talked into the decision to purchase" by the veterinarian.

Another important guideline is that the clinician should qualify any findings to the buyer by **specific reference to tests that were recommended** even if they were not performed, e.g. a **rectal examination** or **blood examination**.

A **drug screen service** can be offered, e.g. for the presence of analgesic and anti-inflammatory agents; such tests are often declined by the buyer. However, the veterinarian should be prepared to provide these types of services, especially in cases where buyers are interested in purchasing a mare primarily as a riding prospect with the option of using her as a broodmare later.

Other national equine veterinary organizations also produce guidelines. Clinicians in the UK, for example, should check the BEVA website for details (www.beva.org.uk).

PREVIOUS INVESTIGATIONS

Studies reporting the results of pre-purchase examinations are sparse. One recent retrospective study of the outcome of 510 examinations over a 10 yr span summarized clinical and radiographic results of pre-purchase examinations and determined whether there was an association between radiographic changes and the lameness outcome. Geldings represented the most common sex. The predominant breed evaluated was Thoroughbreds followed by Quarter-horses. The mean age was 8 years. During the examination, 52.8% of the horses were lame and most of these were valued >\$5000.00. Osteochondrosis lesions were identified radiographically in 5.1% of the horses and the majority of these were sold with no apparent lameness on follow-up (47.4%).

The most commonly requested diagnostic procedure was radiography: in 61.6% at least one radiographic study was requested, most commonly of the front feet or tarsi. The navicular bone, coffin bone and the distal tarsal joints were evaluated, graded (range from 0 to 3, with increasing severity of degenerative changes), and attempts were made to correlate the radiographic findings with the soundness examination. Of horses with grade 0 navicular bones, 85.1% were not lame compared with 22.7% that were not lame with a grade 3. The majority of horses with grades 0 and 1 in the navicular bone and coffin bones were not lame compared to those with more advanced changes. For the tarsus, regardless of the grade (0 to 3), the majority of these horses were sound (78.6–79.2%; respectively). On follow-up with the current owner of the horse, 20 of the 21 horses with a grade 3 change in the distal intertarsal and/or tarsometatarsal joint were in active use. The veterinarian examination was also important since the examination had a direct effect on the outcome of the sale (sold or not sold) and on the final price in 80.9% of the cases.

INFORMATION OWNERSHIP

A question that frequently arises relative to pre-purchase examinations is that of information ownership and, specifically, who is entitled to the results of the

physical/soundness examination and any other diagnostic procedure that was performed such as radiography? Typically, the medical record is established under the name of the person paying for the examination, who is usually the buyer. Therefore, the results of the examination are the exclusive property of that person. This can sometimes lead to conflicts when the horse does not sell and another buyer interested in the horse does not wish to buy another set of radiographs when a recent set already exists. Furthermore, the seller may also wish to disclose the results of the examination to another potential buyer. In these cases, the veterinarian should request permission from the original potential buyer to release the information.

THE NEED FOR GOOD COMMUNICATION

One of the most effective and best ways to avoid misunderstandings associated with pre-purchase examinations is good communication. After recording all the information, time is always well spent in discussing the findings with the potential buyer.

The veterinarian has no obligation to discuss the results of the examination with the seller. In conducting a pre-purchase examination, the clinician is retained by, and represents the interests of, the buyer. It is also in the best interest of the veterinarian to make it clear to the buyer **the limitations of the examination** and/or the veterinarian's experience and knowledge. Statements such as "*I do not know*" and "*in my opinion*" should be used when appropriate so the buyer does not have a false sense of confidence. The clinician should recommend a colleague or other appropriate expert if a second opinion is indicated.

THE WRITTEN REPORT

The format of the written report should be divided into several categories, as in Box 22.1 and as recommended by AAEP (*q.v.*).

Box 22.1 The written report of the pre-purchase examination

1. List the horse's identity (name, age, breed, etc.).
2. State that the buyer (include name) is requesting a physical examination on the horse, the intended use of the horse, the site of the examination, and who is present.
3. State any abnormalities detected during the examination of "those organ systems available for examination" in order to make it clear that there will be some areas that cannot be examined. It is also advisable not to make predictions of the horse's behavior unless it is so unmanageable that there is a substantial risk to people involved in the horse's care.
4. Include a summary of the soundness examination (lunging, flexion tests, etc.) and any other diagnostic procedures that were done.
5. Mention those tests that were not performed as well as the reasons for the omission.
6. Summarize the findings, including any disclaimers, and describe any areas of dispute or question.

In cases where a significant problem is identified, such as a lameness, it is for the buyer to determine if the examination should be aborted or further diagnostics performed. If a diagnostic procedure is considered invasive or carries some risk to the horse, the **owner should be contacted** so that he or she is pre-warned and to minimize problems should a complication arise. For example, if a lameness is detected, **diagnostic nerve blocking** should not be performed unless the owner has been contacted in advance and given approval. The seller should also be contacted if the **shoes are to be removed** for diagnostic purposes or for radiographs. It is critical to ensure the shoe is removed carefully to avoid inadvertent hoof wall defects that may make replacing the shoe difficult.

CONFLICT OF INTEREST

One of the most difficult challenges in any pre-purchase examination arises when there is a conflict of interest between the parties involved. This may occur, for example, if the clinician already is **familiar with the horse** or has **knowledge of the animal's medical history** or the seller is a **client of the veterinarian**.

Generally, the best way to resolve such a problem is for the veterinarian to obtain a **written statement** from the seller that all information pertaining to the horse will be disclosed. If the seller does not wish to disclose this information, the clinician should decline the examination. The more open the communication between all parties involved, the less is the potential for conflict later.

	MANAGEMENT OF ENDOTOXEMIA AND	

INTRODUCTION

Critical care is an exciting area of equine practice that has undergone rapid advancement and increased specialization in recent years. The increasing

pursuit of advanced critical care training and board certification has redefined equine critical care, providing a new focus in the understanding and management of horses requiring intensive care.

The provision of state-of-the-art emergency and critical care is facilitated through the use of an **intensive care unit, or ICU**, with provision of high level monitoring and nursing care, as well as advanced support. Such facilities should have fully trained nursing staff present at all times, with veterinary specialists available 24 h a day.

Critical care medicine is devoted to the comprehensive care of seriously ill horses, which are often suffering from **multiorgan system failure**. A successful outcome requires an **interdisciplinary approach** to the diagnosis, treatment and management of such cases. For example, the horse recovering from colic surgery that develops peritonitis, salmonellosis and renal compromise requires collaborative input from the surgeon, medical internist and critical care specialist. Selection of appropriate antibiotic therapy must address the cause of peritonitis and organisms involved, while balancing the effects of the chosen antimicrobial agents on the *Salmonella* strain, existing gut flora and patient's renal function.

Principles of **infectious disease control** (*q.v.*) must be observed without disrupting primary patient care. The patient must be **isolated** from other susceptible horses, yet maintained in an environment suited to continuous IV fluid administration and frequent monitoring. Additional patient problems to anticipate include electrolyte disturbances associated with **secretory diarrhea**; **catheter-related sepsis** and **venous thrombosis** associated with systemic infection, endotoxemia, prolonged catheterization and rapid fluid administration; **laminitis** due to perfusion deficits and endotoxemia; and negative energy balance resulting from increased energy requirements due to fever, infection, wound healing and decreased feed intake. All aspects of such a case must be addressed **concurrently** and attention focused on monitoring patient trends. Potential complications that could arise while treating existing medical and/or surgical problems must be anticipated.

Excellence of nursing care is the mainstay of any ICU. Critically ill horses are **inherently unstable** and subtle changes in condition must be detected early to allow appropriate changes in therapy. The higher morbidity and mortality rates among critical care patients can become a demoralizing reality. Treatment of seriously ill animals often involves **chronic intensive care**, which is frequently plagued by the development of secondary complications associated with the patient's debilitated state and the need for aggressive and often invasive diagnostic and therapeutic procedures. Nurses working in the ICU must have an understanding of the patient's illness and an appreciation of intensive care therapy to maximize their surveillance capabilities and foster the development of innovative nursing care protocols. Support among co-workers is also vital and helps maintain a positive attitude in the ICU.

Creation of a critical care area within an equine hospital allows trained personnel to monitor and care for a number of seriously ill horses most efficiently. The establishment of a **nursing station** allows for supplies, drugs, delicate instrumentation and monitoring equipment to be centralized. **Recumbency** complicates the care of many horses suffering from neurologic disorders such as rhinopneumonitis and botulism (*q.v.*), or musculoskeletal problems such as

long bone fractures and laminitis (*q.v.*). Stall modifications that facilitate care of critically ill patients include wall-mounted medical gases and suction, padded floors and walls, and ceiling hooks for fluid administration.

Prolonged recumbency is complicated by a variety of secondary problems including decubital sores, self-trauma, gut dysmotility, urine retention and dependent lung atelectasis (*q.v.*). A padded stall equipped with a 2-ton hoist and sling is an invaluable asset when treating such cases.

Deciding which horses to admit to the ICU is termed **triage**, the art of **giving priority to the most critical cases**. Patients should be admitted to the critical care facility based on the intensity of their treatments, the frequency of monitoring required, and the need for special bedding or ICU stall features.

Examples of patient problems that benefit from a critical care setting include the following: **hepatoencephalopathy** (*q.v.*), requiring continuous glucose and fluid infusion, sedation, a padded environment and protective head helmet; **sepsis** (*q.v.*), causing hypotension and organ dysfunction; **renal failure** (*q.v.*), requiring continuous fluid therapy, careful monitoring of fluid administration and urine output, controlled dopamine infusion and diuretic administration; **severe corneal ulcers** (*q.v.*), requiring hourly eye medication via a nasolacrimal or subpalpebral lavage system; **botulism** (*q.v.*), requiring a padded environment to minimize self-trauma associated with recumbency, frequent patient repositioning to prevent dependent lung atelectasis, continuous fluids and enteral nutrition via nasogastric intubation; **severe laminitis** (*q.v.*), requiring padded floors, deep bedding, and supportive care if recumbent; **postoperative colic** (*q.v.*), requiring frequent observation for recurrent pain, gastric decompression via nasogastric intubation, and continuous fluid therapy; **impaction colic** (*q.v.*), requiring continuous IV fluids and frequent administration of oral fluids and laxatives. Monitoring of any critical patient focuses on **frequent evaluation** of standard parameters such as those presented in Table 23.1.

This chapter focuses on guidelines for fluid and electrolyte replacement therapy, critical care protocols with emphasis on monitoring techniques and therapy, pharmacotherapeutics for critically ill patients, management of endotoxemia, and design principles for an intensive care facility. Resuscitation guidelines and principles of ventilatory and nutritional support are reviewed elsewhere, as are specific neonatal disease conditions (*q.v.*).

FLUID THERAPY

INTRODUCTION

Fluid therapy is an integral part of critical care, and is the foundation of hemodynamic support in the ICU. In the emergency setting, horses exhibit a variety of fluid, electrolyte and acid-base disorders. These arise due to a number of factors, including **anorexia** (inadequate intake), **excessive losses** (sequestration, third-space losses) and **hypoperfusion** associated with distributive or cardiogenic shock.

The primary goals of fluid therapy are to replace and correct these imbalances, to restore effective circulating volume and blood pressure, to provide the body's maintenance requirements for water and electrolytes, and to account for

Table 23.1 Physical parameters frequently evaluated in intensive care horses

Parameter	Abnormality	Interpretation
Breathing	Tachypnea	Pulmonary/pleural disease
	Dyspnea	Pain, anxiety
	Upper airway noise	Pulmonary/pleural disease Airway obstruction
Pulse quality	Bounding pulse	Hyperdynamic perfusion
	Weak, thready pulse	Poor peripheral perfusion
Capillary refill time	<1 s	Hyperdynamic state or peripheral vasodilatation
	>2 s	Poor peripheral perfusion, hypovolemia, dehydration
Heart rate	Tachycardia	Pain, anxiety, poor coronary diastolic filling
	Bradycardia	Bradyarrhythmia (AV block), impaired cardiac output
Mucous membrane color	White	Anemia, shock
	Blue	Cyanosis
	Yellow	Liver disease, fasting, hyperbilirubinemia, hemolysis
	Brick red	Hyperdynamic state, toxemia, peripheral vasodilatation
	Petechiation	Thrombocytopenia, disseminated intravascular coagulation
Attitude	Obtunded	CNS disease, hepatoencephalopathy, hypoglycemia
	Depressed	Pain, systemic infection, dehydration, CNS disease
	Maniacal	CNS disease, hepatoencephalopathy
Temperature	Fever	Bacterial or viral infection
Hypothermia	Shock, poor perfusion	
Gastrointestinal borborygmi	Reduced, absent	Ileus, impaction or other obstruction
	Increased	Enterocolitis
Digital pulses, coronary band integrity, foot temperature	Increased pulses, coronary band clefting, warm feet	Laminitis
Musculoskeletal pain	Non-weight bearing	Fracture, joint infection, laminitis

ongoing losses. Rational fluid therapy requires an understanding of the normal homeostatic mechanisms governing body water, electrolyte and acid-base balance, and the pathophysiologic processes that disrupt their homeostasis.

BODY WATER BALANCE

Total body water represents approximately 60–70% of body weight in adult horses and is comprised of the extracellular and intracellular spaces (Table 23.2). The extracellular compartment includes the intravascular (plasma), interstitial and transcellular fluid (gastrointestinal tract water and lymph). The distribution of water between plasma and interstitial fluid is maintained by differences in colloidal osmotic and hydrostatic pressure, and also depends on the integrity of the endothelium.

Table 23.2 Fluid compartments in adult horses

	Proportion of body weight (%)	Approximate volume (450 kg horse) (L)
Total body water	60–70	270–315
Intracellular fluid	35–45	180–203
Extracellular fluid	20–25	90–100
Intravascular fluid	7–8	30–36

Water balance is the difference between input and output. This is determined by the intake of water and fluid contained in food, and by the generation of water due to protein, fat and carbohydrate metabolism, versus water loss through urine and feces, respiratory tract and skin. The **normal water intake** for a 450 kg adult horse is approximately **20–30 L/day**, although this can vary depending on the water content of the diet, ambient temperature and activity level. The largest component of water loss is through the urine.

Dehydration is defined as a reduction in total body water. In the critical care setting, this usually refers to losses in the interstitial fluid compartment. Dehydration occurs with **water deprivation**, either through lack of access to water or through the inability to swallow. It also follows **excessive fluid loss**, most commonly from the gastrointestinal tract, but also sweating or urinary losses. As opposed to hydration status, circulating volume refers to the intravascular fluid compartment. In dehydration, circulating volume may be decreased, but if the onset of dehydration is insidious, it may be maintained despite a reduction in total body water. The effective circulating volume is also reduced when fluid is sequestered in abnormal quantities within one part of the body (third-space accumulation), in **hemorrhage** and in **hypovolemic shock**.

ASSESSMENT OF HYDRATION STATUS AND EFFECTIVE CIRCULATING VOLUME

Clinical examination

Clinical examination is the first, and most important, means of assessment of fluid disorders. The parameters used to evaluate both total body water (**hydration status**) and effective circulating volume are listed in Box 23.1. Clinical evaluation can be used to provide a rough estimate of the fluid deficit (Box 23.1). However, these are only guidelines and replacement fluid therapy is best evaluated by **serial monitoring** of the clinical response. Body weight can be used to determine ongoing fluid losses, however in many clinical situations the initial weight is unknown so it is of little value at the initial evaluation. Fluid deficits will lead to a **decrease in urine** production, and so measurement of urine production in relation to water intake is useful to monitor fluid therapy.

Clinical markers of **hydration status** (interstitial volume) include skin turgor, mucous membrane texture and corneal quality (tear film). Intravascular volume is reflected in capillary refill time, heart rate, pulse quality, mentation, mucous membrane color, extremity temperature, jugular fill and urine production.

Box 23.1 Guidelines for clinical assessment of hydration status and effective circulating volume

Clinical parameters

- Total body water
 - Skin turgor
 - Sunken eyes
 - Mucous membranes
- Effective circulating volume
 - Capillary refill time
 - Pulse quality
 - Heart rate
 - Jugular venous filling time
 - Temperature of the extremities

Interpretation

- Mild fluid deficit (estimated 5–7% of body weight)
 - Slightly decreased skin turgor
 - Dry mucous membranes
 - Prolonged jugular venous filling time
- Moderate fluid deficit (estimated 8–10% of body weight)
 - Decreased skin turgor
 - Dry mucous membranes
 - Prolonged capillary refill time
 - Prolonged jugular venous filling time
- Severe fluid deficit (estimated 11–12% of body weight)
 - Decreased skin turgor
 - Sunken eyes
 - Pale, dry mucous membranes^a
 - Prolonged capillary refill time
 - Weak pulse volume
 - Tachycardia
 - Prolonged jugular venous filling time
 - Cool extremities
 - Obtundation
 - Marked tachycardia

^aIn endotoxic shock, mucous membranes are hyperemic and congested except in the early stages where they are also pale.

MONITORING CIRCULATORY STATUS AND FLUID THERAPY

Packed cell volume and total plasma protein

Packed cell volume (PCV) and total plasma protein (TP) are invaluable for assessing fluid deficits and monitoring the response to fluid therapy. They are quickly performed, using a microhematometer and refractometer, respectively. Guidelines for their interpretation are given in Table 23.3. PCV and TP should always be interpreted **together**. Both rise with simple dehydration.

Table 23.3 Interpretation of packed cell volume and total plasma protein concentrations

	Reference interval	
Packed cell volume (PCV)	32–52% (0.32–0.52 L/L)	
Total plasma protein (TP)	5.9–8.4 g/dL (59–84 g/L)	
	Interpretation	
	PCV	TP
Dehydration	↑	↑
Splenic contraction	↑	N
Dehydration with protein loss	↑	N
Acute blood loss	↓	↓
Chronic blood loss	↓	N
Dehydration with anemia	N	↑

↑, Increased; ↓, decreased; N, within the reference interval.

Table 23.4 Reference intervals for serum urea nitrogen, creatinine and electrolyte concentrations in adult horses

Urea	10–24 mg/dL (3.6–8.6 mmol/L)
Creatinine	0.7–1.8 mg/dL (62–159 μmol/L)
Sodium	132–146 mEq/L (132–146 mmol/L)
Potassium	2.4–4.7 mEq/L (2.4–4.7 mmol/L)
Chloride	99–109 mEq/L (99–109 mmol/L)
Calcium	10.9–12.8 mEq/L (2.7–3.2 mmol/L)
Magnesium	1.3–2.5 mEq/L (0.53–1.02 mmol/L)
Total carbon dioxide	20–36 mEq/L (20–36 mmol/L)
Anion gap	7–15 mEq/L (7–15 mmol/L)

In horses there is a wide reference range for PCV. Splenic contraction, which occurs under the influence of epinephrine/adrenaline, in association with pain, excitement or other stresses, can increase the PCV markedly but generally does not influence TP. An increased PCV with a normal TP, a relative hypoproteinemia, is also seen in animals that are both dehydrated and hypoproteinemic, a common finding in horses with **acute enterocolitis** (*q.v.*).

Despite their usefulness, PCV and TP also have limitations. **Anemia** (*q.v.*) may mask dehydration as a PCV within the normal range. Similarly, a normal total protein concentration suggestive of **euhydration** can be misleading in a hypoproteinemic animal. At the opposite end of the spectrum, hyperproteinemia due to **hyperglobulinemia** (*q.v.*), rather than dehydration, can be misleading in a normally hydrated horse.

Serum urea and creatinine

Serum urea and creatinine concentrations (Table 23.4) are increased in pre-renal, renal and post-renal dysfunctions (*q.v.*). Urea is produced in the liver as a result of breakdown of ammonia. In horses and other large animals, urea concentrations may be influenced greatly by dietary factors, and as a result **creatinine concentration** is considered to be a better guide to renal function.

Creatinine is produced at a relatively constant rate as a by-product of muscle metabolism (creatine phosphate). It is excreted by **glomerular filtration**. Decreases in renal blood flow caused by reduction in effective circulating volume produce an increase in serum creatinine concentrations, yielding **pre-renal azotemia** (*q.v.*). Restoration of circulating volume should produce a rapid response in serum creatinine in these horses, and if serum creatinine concentrations remain persistently increased after rehydration, the presence of primary renal dysfunction or post-renal causes should be evaluated further.

Urine specific gravity

Urine specific gravity is a measure of **urine concentration**, which is made by refractometry. The normal range in adult horses is 1.020–1.050, while foals have more dilute urine. Neonates commonly have **hyposthenuric urine**. In dehydration, urine output decreases and specific gravity increases. The presence of a urine specific gravity of <1.020 in a dehydrated horse suggests that the renal function is impaired and should be evaluated further.

Arterial blood pressure

In many clinical situations, the initial goal of fluid therapy is to increase perfusion pressure by restoration of the effective circulating volume. Measurement of arterial blood pressure provides one objective means of determining and monitoring the **response to fluid therapy**. It is mandatory in cases in which inotrope or pressor support, in the form of pharmacologic agents to increase cardiac output or alter vascular tone, is being considered.

Arterial pressure is measured either directly via a manometer attached to an **intra-arterial catheter**, or indirectly using **Doppler or oscillation techniques**. Direct methods are more accurate and have the advantage that the pulse contour can also be assessed, providing information on the inotropic state and the afterload. Indirect methods are non-invasive, and thus are more readily performed in conscious horses (Table 23.5).

In standing horses, catheters are maintained most easily over prolonged periods in the **transverse facial artery**, to measure direct arterial blood pressure. For indirect arterial blood pressure, cuffs are generally applied to the tail to measure from the **middle coccygeal artery**. The cuff bladder width to tail circumference ratio should be approximately 25% to obtain most accurate results, and measurements should be taken with the horse in the same position for comparison purposes. When using extremities, a ratio of 40–50% should be used.

Table 23.5 Normal blood pressure in adult horses

Direct arterial	
Mean	80–110 mmHg
Systolic	110–160 mmHg
Diastolic	70–90 mmHg
Indirect arterial	
Mean	82–110 mmHg
Systolic	100–135 mmHg
Diastolic	70–97 mmHg
Central venous	0–15 cmH ₂ O

While most indirect means of blood pressure measurement provide only systolic pressures, oscillometric techniques, such as the Dinamap Blood Pressure Monitor (Critikon, Tampa, FL, USA), provide systolic, diastolic and mean blood pressures. Correlation of the displayed pulse rate to the actual heart rate is one means of checking the accuracy of the indirect technique, as is averaging repeated measurements.

Blood lactate concentration

Venous or arterial blood lactate concentration can be utilized as a marker of **peripheral perfusion**. Blood or plasma lactate concentrations represent the balance between production (primarily from glycolysis) and clearance (hepatic, renal). During **reduced oxygen delivery** states glycolysis predominates and results in hyperlactatemia. Other causes of high blood lactate include **proinflammatory states**, catecholamine surges, thiamine deficiency and alkalosis. Patients with liver failure and lymphosarcoma may have reduced clearance of lactate, and fluids devoid of lactate should be used in these groups (e.g. Normosol R, Plasma-Lyte 148). **Lactate concentrations** are <2 mmol/L in healthy adult horses, while they can be as high as 4 mmol/L 1–2 h post partum in neonatal foals. By 24 h of age lactate concentrations should be <2 mmol/L in healthy foals. **Serial measurement** of lactate concentrations is most useful in assessing perfusion responses to fluid volume replacement.

Central venous pressure

Central venous pressure (CVP; see Table 23.5) is dependent on cardiac output and the venous return. It is the pressure within the **intrathoracic vena cava** and approximates right atrial pressure. It is influenced by blood volume, vascular tone, heart rate and ventricular contractility. CVP falls in association with hypovolemia and rises if there is an increase in circulating volume. Measurement of CVP is used to assess cardiac function and to monitor fluid therapy and, in particular, to avoid **overzealous fluid administration**. As such, it can be used as one end point to fluid therapy.

Hypotension (*q.v.*) can be treated with volume support until CVP approaches maximum. Exceeding normal CVP values has the potential to cause pulmonary and tissue edema. CVP is easy to measure, requiring only a simple water manometer, IV catheter and extension tubing. A procedure for the measurement of CVP is described in Box 23.2. It should be noted that the monitoring of trends in CVP over time is crucial, rather than focusing on one value. Pleural and pericardial diseases will also cause increases in CVP (*q.v.*).

Colloid osmotic pressure

Colloid osmotic pressure (COP), or **oncotic pressure**, is the osmotic force within the intravascular compartment exerted by albumin and other macromolecules, which counteract capillary and venule hydrostatic forces in determining net fluid flux across the endothelium. Plasma COP is primarily determined by albumin (65–80%) and is required to maintain proper circulating volume. Patients with hypoalbuminemia are therefore at risk for edema formation and relative hypovolemia, both of which lead to **reduced tissue oxygen delivery**.

Box 23.2 Procedure for the measurement of central venous pressure

1. Advance a saline-filled IV catheter into the right atrium via the jugular vein (adult horses: 46 cm [18 in] or 61 cm [24 in] cm catheter; foals: 20–30 cm [12 in] catheter)
2. Attach a saline-filled extension tube to the IV catheter (patient line)
3. Attach a water manometer to the extension tube via a three-way stopcock
4. Attach a saline-filled syringe to the remaining inlet of the three-way stopcock
5. Suspend the water manometer so that the baseline (0 cm) is at the level of the right atrium, using the point of the shoulder as a landmark
6. Ensure that the horse's head is in a normal position
7. Close the water manometer and flush the patient line with saline
8. Close the patient line and flush the water manometer with saline
9. Turn the three-way stopcock so that the patient line is open to the water manometer
10. The fluid column in the water manometer will fall to the level of the central venous pressure

Although total protein and albumin concentrations provide indirect information about COP, and are crucial in monitoring albumin dynamics, they are not as well correlated with oncotic pressure in the critically ill animal as compared to healthy horses. In ill patients, direct measurement of COP using a **colloid osmometer** (Wescor 4420 colloid osmometer, Wescor, Logan, UT, USA) is important. Additionally, total protein concentrations do not measure the oncotic contribution of synthetic colloids such as hetastarch or Hextend. **Direct measurement** of COP in horses receiving synthetic colloids is the only means of monitoring the oncotic effects of these products. **Normal oncotic pressure** in adult horses is 20–30 mmHg, and in neonatal foals is 15–23 mmHg.

ELECTROLYTE BALANCE

Sodium

Sodium is the most abundant cation in the **extracellular** fluid (ECF; see Table 23.4). Sodium is ingested with feed and water intake, and is lost in urine, feces and sweat. It can be regarded as the “skeleton” of the ECF, as it is the principal determinant of the ECF osmolarity, and consequently its volume. Osmolarity can be measured directly with an osmometer, or alternatively calculated using the following formula:

$$\text{ECF osmolarity} = (\text{Na} \times 2) + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8}$$

where sodium is in mEq/L and glucose and BUN are in mg/dL.

The excretion of sodium via the kidney is controlled by the renin-angiotensin-aldosterone system (*q.v.*). **Hyponatremia** (*q.v.*) occurs if there is a

reduced intake of sodium, however deficits due to excessive losses are more common. These arise if sodium loss from the gastrointestinal or urinary tract is in excess of water loss, and thus hyponatremia indicates a **relative water excess**. Box 23.3 lists clinical conditions associated with hyponatremia.

Hypernatremia (*q.v.*) arises when water is lost in excess of electrolytes (see Box 23.3). Both hyponatremia and hypernatremia should be treated with caution; rapid correction of hyponatremia can result in demyelination and central pontine myelinolysis, while cerebral edema can result from overzealous treatment of hypernatremia. Plasma sodium concentrations should be **altered slowly**, not exceeding 0.5 mEq/h. Hyponatremia can be corrected using sodium-containing fluids such as 0.9% sodium chloride, lactated Ringer's solution, Plasma-Lyte 148, or Normosol R. Varying formulations of hypertonic saline can also be used depending on the rate of rise. Hypernatremia can be treated with the provision of **free water**, as with maintenance fluids. These include Plasma-Lyte 56 or Normosol-M, but 5% dextrose in water can also be used.

Potassium

Potassium is the primary **intracellular** cation. Potassium has a central role in the maintenance of cell membrane electrical potentials, and is important in muscle contraction. The normal intracellular potassium concentration is 145–150 mEq/L, whereas its extracellular concentration is 2.4–4.7 mEq/L. It is present in gastrointestinal secretions, sweat and urine. Its distribution between the intra- and extracellular compartments is influenced by the **acid-base status**; potassium leaves the cell in exchange for hydrogen ions so that in the presence of acidosis serum potassium concentrations increase.

In anorexic horses, potassium can quickly be depleted and diarrhea also frequently results in **hypokalemia** (see Box 23.3). Severe hypokalemia can be accompanied by muscle weakness and ileus. Management of hypokalemia should include supplementation of fluids with potassium chloride or potassium phosphate. The rate of supplementation should not exceed 0.5 mEq/kg/h. Empirical supplementation of fluids with 10–40 mEq/L of KCl is the usual range utilized to treat or prevent hypokalemia. As hypomagnesemia (*q.v.*) can be associated with refractory hypokalemia, magnesium concentrations should be monitored in these patients.

The causes of **hyperkalemia** are also listed in Box 23.3. Hyperkalemia must be regarded as an **emergency** as cardiac arrhythmias (*q.v.*) frequently occur as a result of the electrical instability of the myocardial cell membrane if serum potassium concentrations rise. Electrocardiographic changes associated with hyperkalemia include spiked T waves, prolonged PR interval, disappearance of P waves, prolongation of the QRS complex, shortening of QT or ST intervals and ventricular dysrhythmias (*q.v.*). Management of hyperkalemia includes the use of potassium-free fluids, dextrose, insulin and sodium bicarbonate. Dextrose can be added as a 5% solution. Insulin should be utilized only when plasma glucose concentrations can be monitored frequently and may be given as **regular insulin** (0.01–0.1 U/kg/h).

Sodium bicarbonate should be directed by **blood gas analysis**, but safe amounts can be administered at a dose of 0.5–1 mEq/kg over 30–60 min assuming the patient is not hypoventilating. **Calcium supplementation** can

Box 23.3 Conditions associated with electrolyte and metabolic imbalances in horses**Hyponatremia**

- Esophageal obstruction
- Enterocolitis
- Intestinal obstruction
- Polyuric renal failure
- Urinary tract disruption
- Inappropriate antidiuretic hormone secretion

Hypernatremia

- Enterocolitis
- Excessive sweating
- Water deprivation

Hypokalemia

- Enterocolitis
- Intestinal obstruction
- Anorexia
- Renal tubular acidosis
- Polyuric renal failure
- Diuretic administration
- Bicarbonate administration
- Insulin administration

Hyperkalemia

- Muscle necrosis
- Urinary tract disruption
- Anuric renal failure
- Hyperkalemic periodic paralysis in Quarter-horses
- (in vitro hemolysis)

Hypocalcemia

- Stress
- Lactation and transit tetany
- Synchronous diaphragmatic flutter
- Acute renal failure
- Cantharidin toxicity

Hypercalcemia

- Chronic renal failure
- Hypercalcemia of malignancy
- Vitamin D toxicosis

Metabolic acidosis

- Enterocolitis
- Intestinal obstruction
- Renal tubular acidosis
- Lactic acidosis (shock, grain overload)

Box 23.3 continues on page 1267

Metabolic alkalosis

- Esophageal obstruction
- Nasogastric reflux
- Exertional rhabdomyolysis
- Excessive sweating
- Hyperalimentation
- Diuretic administration

be used to antagonize the membrane effects of potassium, but will not lower potassium concentrations directly. Enhancement of potassium clearance can be accomplished with **exchange resin enemas** (polystyrene sulfonate or Kayexalate) and the use of loop or other potassium-excreting diuretics.

Chloride

Chloride is present in high concentrations in the ECF (see Table 23.4). At most sites within the body, chloride tends to follow sodium passively by diffusion within the cell membrane, so that the regulation of chloride concentration in the ECF is **directly related to the sodium concentration**. In the ECF, chloride concentrations are inversely related to bicarbonate concentrations. Chloride is a strong anion, contributing to **strong ion difference (SID)**.

With increases in chloride concentrations, the SID will decrease, resulting in an acidosis [$SID = (Na + K) - (Cl + lactate)$]. This is the reason that physiologic saline (0.9% NaCl) tends to be mildly acidifying. The chloride content of saline is relatively greater than sodium relative to normal serum concentrations. Chloride is present without sodium in gastric secretions, and there is a specialized transport system for chloride in the loop of Henle. Chloride is excreted in the urine in quantities dependent on the body's need for bicarbonate.

In horses, chloride depletion occurs if there is loss of chloride-rich fluid from the proximal gastrointestinal tract, thus **hypochloremia** may be associated with esophageal obstruction (*q.v.*) or with nasogastric reflux due to ileus or proximal gastrointestinal obstruction (*q.v.*). Hypochloremia is usually accompanied by **metabolic alkalosis** (see Box 23.3) but may be seen in states of **metabolic acidosis** during attempts at metabolic compensation through enhanced excretion of urinary chloride.

Primary hyperchloremia due to excessive salt intake is uncommon, but may accompany renal dysfunction and dehydration due to water loss only. Hyperchloremia accompanies **renal tubular acidosis**.

Calcium

Calcium is an abundant divalent cation throughout the body. Absorption of calcium is via the gastrointestinal tract. It has an integral role in multiple biological processes, including nervous, skeletal, smooth muscle and myocardial

function, and blood clotting. It is excreted by the kidney, and bone represents a large calcium reservoir. Calcium homeostasis is regulated by the hormones **parathormone** and **calcitonin** (*q.v.*).

Hypocalcemia associated with **lactation** may produce signs of tetany, particularly in mares exposed to an additional stressor such as transport (see Box 23.3). Mild hypocalcemia is frequently observed with abdominal crises, and it may contribute to **postoperative ileus** (*q.v.*) and weakness in some of these horses.

Calcium supplementation should be performed **slowly** and diluted in fluids. Supplementation with 0.5–1 mEq/kg of **calcium gluconate** is indicated in horses with hypocalcemia or prolonged anorexia (250–500 mL of 23% calcium gluconate, diluted in fluids). Calcium-containing fluids should not be administered through the same lines as blood products or sodium bicarbonate, due to precipitation problems.

Hypercalcemia (see Box 23.3) is usually due to chronic renal failure (*q.v.*), a biochemical abnormality unique to the horse. Paraneoplastic syndromes (pseudohyperparathyroidism) and vitamin D excess are uncommon causes of hypercalcemia. Hypercalcemia is more difficult to treat, but as a minimum, calcium intake should be reduced by feeding a diet low in calcium; **alfalfa should be avoided**.

Monitoring of calcium in the ICU should include daily measurement of total calcium concentration, while ionized calcium concentrations should be checked more often in the patient receiving fluid therapy. Approximately 50% of calcium is bound to plasma proteins, while an additional 5–10% is chelated to plasma anions like phosphate. The remainder is free, ionized calcium, which is the physiologically active form.

Ionized hypocalcemia is the clinically significant form of hypocalcemia, while hypoalbuminemia causes a decrease in the amount of calcium in the protein-bound fraction and is not as physiologically important. Alkalosis causes a shift in calcium fractions and decreased ionized calcium concentration. This should be considered in patients being treated with sodium bicarbonate and in those with respiratory alkalosis. Patients receiving large volumes of blood products should also be monitored for ionized hypocalcemia because of calcium binding by citrate. Magnesium depletion is another risk factor for development of hypocalcemia in the ICU, by inhibiting parathyroid hormone secretion and target tissue responsiveness.

ASSESSMENT OF ELECTROLYTE DISORDERS

The assessment of electrolyte disorders must be based on laboratory evaluation of serum concentrations of electrolytes. Specific electrolyte disorders cannot be predicted simply from the clinical presentation or problem. Serum concentrations of sodium are accurate in assessing sodium deficits or relative excesses, as sodium is an extracellular ion. In contrast, measurement of serum potassium concentration does not reflect the whole body content of potassium, as this is primarily an intracellular ion. Acid-base status further complicates the interpretation of serum potassium concentrations. A decrease in pH of 0.1 units causes an increase in serum potassium concentration of 0.6 mEq/L. Thus, **acidosis can mask potassium depletion** by increasing the

concentration of potassium in the ECF. This is seen commonly with bicarbonate and potassium losses associated with enterocolitis (*q.v.*).

Estimates of sodium and potassium deficits for the purposes of replacement therapy are made by considering the difference between the measured and desired serum concentrations, the horse's body weight and the distribution of the ion within the body, as follows:

$$\begin{aligned} \text{Sodium deficit (mEq)} = & \\ & (\text{sodium concentration desired} - \text{sodium concentration observed}) \\ & \times \text{body weight (kg)} \times 0.6 \text{ (total body water)} \end{aligned}$$

$$\begin{aligned} \text{Potassium deficit (mEq)} = & \\ & (\text{potassium concentration desired} - \text{potassium concentration observed}) \\ & \times \text{body weight (kg)} \times 0.3 \text{ (ICF, intracellular fluid)} \end{aligned}$$

However, repeated **laboratory evaluations** are undoubtedly the most rational means by which to assess the response to replacement of electrolytes. Because potassium is primarily an intracellular ion, serum concentrations are poor indicators of whole body potassium balance. Urinary fractional excretion of potassium may improve understanding of body potassium stores. Fractional excretion is calculated as follows:

$$FE_k = \frac{S_{cr}}{U_{cr}} \times \frac{S_k}{U_k}$$

where S_{cr} is serum creatinine concentration, U_{cr} is urine creatinine, U_k is urine concentration of potassium, and S_k is serum concentration of potassium.

ACID-BASE BALANCE

The **blood pH** is dependent on the respiratory system and the function of a variety of buffering systems. The **carbonic acid/bicarbonate buffer system** is of most interest to the clinician, since it is amenable to clinical intervention. Hydrogen ions, carbon dioxide, water and bicarbonate are produced constantly by cellular metabolism. Carbon dioxide is transported in blood as dissolved or free carbon dioxide; in association with protein and hemoglobin; and as bicarbonate. In the lungs, bicarbonate dissociates to carbon dioxide and water, and carbon dioxide is exhaled. The regulation of serum bicarbonate concentration is achieved in large part by the kidneys.

Acid-base disorders may be classified as respiratory or metabolic in origin (see Box 23.3), and mixed acid-base disorders are common. Failure of ventilation results in the inability to remove carbon dioxide (**respiratory acidosis**), while hyperventilation decreases carbon dioxide and causes **respiratory alkalosis**. It is important to appreciate that acid-base disorders of respiratory origin cannot be alleviated by fluid therapy and require modification of respiratory function.

Metabolic acidosis can be the result of excessive production of organic acids (titration) or of loss of bicarbonate (secretion). The titration form of metabolic acidosis occurs when there is an increase in acid anions and bicarbonate

is required for buffering. In the horse, **lactic acidosis** (*q.v.*) occurs commonly. It is usually associated with hypovolemic, cardiogenic or endotoxic shock (*q.v.*) and inadequate tissue perfusion. The secretion form of metabolic acidosis occurs when bicarbonate ions are actively lost from the body (see Box 23.3). In some conditions, both secretion and titration of bicarbonate will occur.

Mixed metabolic acidosis and alkalosis may be present in horses with gastrointestinal disease (*q.v.*). This occurs, for example, when fluid is sequestered in the proximal gastrointestinal tract leading to chloride and hydrogen ion loss and metabolic alkalosis, with a concurrent reduction in effective circulating volume, producing shock, poor tissue perfusion and lactic acidosis.

Assessment of acid–base balance

An **arterial blood gas analysis** is required for full evaluation of both the respiratory and metabolic components of acid–base balance. Normal values for arterial and venous blood gas analysis are given in Table 23.6. Interpretation of the respiratory component is based on the partial pressure of carbon dioxide in arterial blood (Table 23.7). Metabolic disorders are manifested by alterations in bicarbonate concentrations and the base deficit. Both arterial and

Table 23.6 Reference intervals for blood gas analysis in horses

	Arterial	Venous
pH	7.347–7.475	7.345–7.433
PO ₂ (torr or mmHg)	80–112	37–56
PCO ₂ (torr or mmHg)	36–46	38–48
HCO ₃ [–] (mEq/L or mmol/L)	22–29	22–29
Base excess (mEq/L or mmol/L)	–1.7 to +3.9	–2.7 to +4.1

Table 23.7 Interpretation of blood gas analysis and acid–base status

	pH	PCO ₂	[HCO ₃ [–]]	Anion gap ^a
Respiratory acidosis	↓	↑	N	N
Respiratory alkalosis	↑	↓	N	N
Metabolic acidosis				
Secretion	↓	N	↓	N
Titration	↓	N	↓	↑
Metabolic alkalosis	↑	N	↑	N
Mixed metabolic acidosis and alkalosis	N	N	N	↑

↑, Increased; ↓, decreased; N, normal.
^a Anion gap = ([sodium] + [potassium]) – ([bicarbonate] + [chloride]).
NB: In acid–base disorders, compensation may result in the following changes:
Respiratory acidosis: acute: [HCO₃[–]] increases 1 mEq/L for every 10 mmHg increase in PCO₂;
 chronic: [HCO₃[–]] increases 3.5 mEq/L for every 10 mmHg increase in PCO₂.
Metabolic acidosis: PCO₂ decreases 1.2 mmHg for every 1 mEq/L decrease in [HCO₃[–]].
Metabolic alkalosis: PCO₂ increases 0.6–1 mmHg for every 1 mEq/L increase in [HCO₃[–]].
Respiratory alkalosis: acute: [HCO₃[–]] decreases 2 mEq/L for every 10 mmHg decrease in PCO₂;
 chronic: [HCO₃[–]] decreases 5 mEq/L for every 10 mmHg decrease in PCO₂.

venous blood gas analysis are equally suitable for assessment of the metabolic component of acid–base disorders (see Table 23.6).

Respiratory and metabolic components of acid–base balance are interdependent so that a respiratory disorder may lead to compensation and concurrent alterations in bicarbonate concentrations. Equally, a metabolic disorder may induce changes in respiration pattern and alteration in the PCO_2 .

The anion gap (the difference between cations and measured anions) is used to distinguish titration and secretion forms of metabolic acidosis (see Table 23.7). The **anion gap** is a reflection of those ions that are not measured, organic acids, phosphates, sulfate and protein. **Lactic acidosis** increases the anion gap, whereas the anion gap is unchanged when the primary problem is loss of bicarbonate. In that situation, chloride concentrations increase as bicarbonate concentrations fall to maintain electrical equilibrium. An increase in the anion gap with a normal pH and bicarbonate are the hallmarks of **mixed metabolic acidosis and alkalosis** (see Table 23.6). Without assessment of the anion gap, this abnormality might otherwise go unnoticed as alterations in both pH and bicarbonate are counteracted by the conflicting processes.

Blood samples for blood gas analysis are collected in **heparinized syringes**, and tightly capped prior to analysis to prevent air contamination. Ideally, the sample should be processed as quickly as possible, but samples may be stored on ice for up to 4 h if necessary. **Total carbon dioxide (TCO_2) concentration** can be used as an alternative to measurement of bicarbonate concentration for the assessment of metabolic acid–base disorders. Total carbon dioxide is slightly less accurate, but is usually adequate for clinical purposes. Various pieces of equipment are available for rapid “in practice” total carbon dioxide assays and this test is included in chemistry panels on many autoanalyzers. Base deficit can be estimated using the total carbon dioxide as well. Subtracting the TCO_2 from the median normal bicarbonate (24 mmol/L) will provide an estimate of the base deficit.

PRINCIPLES OF FLUID THERAPY

In most clinical situations, the plan for fluid therapy includes three components: replacement of existing deficits; supplying of maintenance requirements; and matching ongoing losses.

Over-hydration, the administration of fluid in excess of the body’s requirements, is occasionally indicated. Colonic impactions (*q.v.*) represent clinical conditions that are treated with over-hydration. The selection of type of fluid and the rate of administration are dependent on the clinical problem and the specific deficits. The clinical and laboratory assessments described above are used to estimate deficits and evaluate ongoing losses.

In horses, fluids are administered either by oral or IV routes. In most clinical conditions in which replacement of fluid deficits or restoration of effective circulating volume is required, the IV route is mandatory because of the volumes required, and because many gastrointestinal diseases preclude oral administration. However, the **oral route should be used whenever possible**. It has the advantages that it is more physiological, it is considerably less expensive and the risk of iatrogenic or nosocomial infections is negligible.

REPLACEMENT THERAPY

Cardiovascular collapse

Replacement of fluid and effective circulating volume is the first priority in horses presenting with signs of cardiovascular collapse. IV administration is required to provide sufficient volumes. **Crystalloid solutions** are most widely used for replacement therapy. Effective circulating replacement can be achieved using crystalloid or colloidal solutions.

Crystalloids

The ideal crystalloid solution for **volume replacement** has a composition similar to that of plasma. These include lactated Ringer's (Hartman's) solution or similar balanced polyionic solutions such as Plasma-Lyte (Baxter Health Care Corp., Deerfield, IL, USA [available in 5 L bags]), Multisol-R (Normosol-R, CEVA) and Isolec (IVEX Ltd, Larne, Northern Ireland, UK [available in 5 L bags]) (Table 23.8). **Lactated Ringer's solution (LRS)** contains calcium, whereas Plasma-Lyte and Normosol contain magnesium.

Since blood products should not be administered through the same lines as calcium-containing fluids, the latter fluids should be used during blood or plasma transfusions. Another difference between LRS and Plasma-Lyte/Normosol is the type of alkalinizing agent present. LRS contains lactate and Plasma-Lyte/Normosol products contain acetate and gluconate. Lactate is cleared primarily by the liver, acetate is cleared primarily by muscle, and gluconate is metabolized by most cells.

Colloids

Colloid solutions contain glycerin, glucose polymers, or dextrans of high molecular weight. They are effective because they remain in the intravascular compartment longer than crystalloid solutions, assuming normal vascular integrity. **Anaphylactic or anaphylactoid reactions** (*q.v.*) have been associated with the use of dextrans in horses, and **hetastarch** appears to be safer.

Plasma is a suitable alternative for rapid replacement of circulating volume (see Table 23.8). However, in the volumes required it is often prohibitively expensive to be used for colloid support alone. Under these circumstances, plasma should be used in combination with synthetic colloids such as hetastarch.

The **rate of administration** of replacement fluid depends on the severity of the clinical signs and the ongoing losses. There is no one correct way to replace volume; one half of the deficit may be given in the first 2–6 h, with the remainder being given over the following 6–12 h. However, in adult horses with cardiovascular collapse, fluids may be administered safely at rates of **up to 30 L/h** if necessary to restore perfusion. Such boluses are often required in horses with **hypovolemic shock** (*q.v.*). The **clinical response** is often the best guide to rate of fluid administration.

Fluid overload produces **pulmonary edema**, thus the respiratory rate and effort and the quality of the lung sounds should be evaluated frequently

Table 23.8 Composition and indications for use of intravenous fluids

	pH	Tonicity	Na (mEq/L)	K (mEq/L)	Ca (mEq/L)	Mg (mEq/L)	Cl (mEq/L)
Lactated Ringer's (Hartmann's)	6.2–6.7	Iso	130	4	3	—	109

7% saline	—	Hyper	1200	—	—	—	1200
Plasma	7.0	Iso	142	5	5	3	103
5% sodium bicarbonate	7.8	Hyper	595	—	—	—	—
Isotonic sodium bicarbonate	—	Iso	150	—	—	—	—

	Buffer (mEq/L)	Calories/L	Indications
Lactated Ringer's (Hartmann's)	Lactate, 29	9	Volume replacement maintenance ^a
Plasma-Lyte R (Baxter)	Acetate, 47	11	Volume replacement maintenance ^a
Plasma-Lyte 148	Gluconate, 8		
	Acetate, 27	18	Volume replacement
	Gluconate, 23		
Plasma-Lyte 56	Acetate, 16	—	Maintenance
Multisol R/ Normosol R (CEVA)	Acetate, 27	18	Volume replacement
	Gluconate, 23		
Normosol M	Acetate, 16	—	Maintenance
2.5% dextrose in 0.45% saline	—	85	Maintenance
5% dextrose	—	170	Provision of water for maintenance
Normal saline	—	9	Sodium or chloride replacement
			Acidification ^b
7% saline	—	—	Expansion of circulating volume ^c
Plasma	Bicarbonate, 27	3	Expansion of circulating volume, hypoproteinemia
5% sodium bicarbonate	Bicarbonate	—	Replacement ^d of bicarbonate in metabolic acidosis due to bicarbonate secretion
Isotonic sodium bicarbonate	Bicarbonate, 150	—	Replacement ^{d,e} of bicarbonate in metabolic acidosis due to bicarbonate secretion

Iso, isotonic; Hyper, hypertonic.

^a These solutions are not designed for maintenance as their sodium concentration is excessive. However, they are commonly used for this purpose, largely for convenience, and are safe provided renal function is normal. Consideration should be given to simultaneous administration of 5% dextrose if they are to be used for maintenance purposes for extensive periods.

^b Normal saline should not be used for volume replacement, but only to correct specific sodium or chloride deficits, and as an acidifying solution.

^c Hypertonic saline is contraindicated in renal failure and must always be followed with isotonic solutions. Seven per cent sodium chloride is made by dissolving 175 g sodium chloride in 2.5 L of water.

^d Serum potassium concentration must be monitored carefully.

^e Isotonic bicarbonate is made by adding 250 mL of 5% sodium bicarbonate (150 mEq Na: 150 mEq HCO₃⁻) to 750 mL of sterile water.

during the rapid IV administration of large volumes. CVP is the most objective guide to the rate of fluid administration, but examination of the height of the **jugular pulse** also gives a crude estimation of rising CVP. CVP can be easily measured in both horses and foals, through the use of central lines and a water manometer as described in Box 23.2. Optimization of the CVP can be used as a fluid administration end-point goal. Once near maximum CVP (10 cmH₂O in a neonate; 12–15 cmH₂O in an adult) is achieved using fluid loading, rates of administration should be decreased to avoid risks of edema formation.

Hypertonic saline (7%) is a valuable alternative for the **emergency resuscitation** of horses with hemorrhagic, hypovolemic or endotoxic shock (see Table 23.8). Administration of hypertonic solutions increases the effective circulating volume, cardiac output and blood pressure. The precise mechanisms by which it is effective are still unclear. A number of processes may be involved, including a vagally mediated reflex, redistribution of blood from peripheral to central vascular beds, increasing cardiac contractility, and relocation of fluid from the interstitium and ICF to the intravascular space.

Urine output is increased following administration of hypertonic solutions and this leads to a decrease in total body water. For that reason, it is imperative that hypertonic solutions are followed with isotonic solutions to maintain total body water. Hypertonic saline is administered at 4 mL/kg and is given as quickly as possible (in approximately 10 min). It is **contraindicated** in horses with **renal failure**. Some authors have expressed reservations about its use in hemorrhagic shock, as increasing the blood pressure may promote further bleeding. It should not be used in horses with uncontrolled bleeding.

Hyperosmolarity is another consideration. Because hypertonic solutions borrow water from the interstitium and intracellular spaces, they should not be utilized in maximally dehydrated horses. In these cases, concurrent or prior administration of isotonic crystalloid should be performed.

METABOLIC ACIDOSIS

The approach to the correction of **metabolic acidosis** depends on the underlying cause. Acidosis due to depletion of bicarbonate by buffering acid anions in lactic acidosis (titration) is best addressed by the correction of the underlying cause. Hypoperfusion should be improved by volume replacement with a **balanced polyionic solution**. These solutions contain bicarbonate precursors such as lactate, acetate or gluconate. For horses with fluid-refractory hypotension, inotrope and vasopressor therapy should be considered. **Hypoxemia** or reduced oxygen carrying capacity should be addressed through oxygen supplementation or blood transfusions, respectively.

In horses with **enterocolitis** (*q.v.*) that are actively losing bicarbonate or sodium ions (secretion), administration of sodium bicarbonate may be warranted. **Hyperchloremic metabolic acidosis** may also benefit from sodium bicarbonate administration. Bicarbonate should only be supplemented when the serum base deficit is >6–8 mEq/L. The bicarbonate deficit may be estimated as follows:

$$\text{Bicarbonate estimate (mEq)} = 0.3 \times \text{body weight (kg)} \times \text{base deficit (mEq/L)}$$

or, if total carbon dioxide (TCO₂) is measured, as on a serum biochemistry profile:

$$\text{Bicarbonate deficit (mEq)} = 0.3 \times \text{body weight (kg)} \times (\text{total carbon dioxide desired} - \text{total carbon dioxide measured})$$

It is often suggested that one half of the calculated deficit be given over 1 h, the blood gas analysis then repeated, and the remainder of the deficit replaced over the next 6 h. However, in horses with **diarrhea**, considerable quantities of sodium bicarbonate may be required simply to meet **ongoing losses**, and more than the initial calculated deficit may be needed. Repeated blood gas or total carbon dioxide measurements are the most reliable guides to the administration of bicarbonate.

Sodium bicarbonate administration may have a number of adverse effects. It can constitute an **excessive sodium load**. Potentially, a **paradoxical central nervous acidosis** may develop because carbon dioxide is formed following bicarbonate administration, and this diffuses through the blood–brain barrier, decreasing pH in the cerebrospinal fluid, while bicarbonate cannot pass the blood–brain barrier to buffer the carbon dioxide. Intracellular acidosis may also be potentiated through the rapid administration of sodium bicarbonate for similar reasons. Bicarbonate should not be administered to horses with impaired ventilation as carbon dioxide excretion is limited, and bicarbonate administration can potentiate carbon dioxide production.

Bicarbonate administration may induce **hypokalemia** as potassium ions enter the cells in exchange for hydrogen ions. Potassium concentrations should be monitored and potassium chloride (20 mEq/L) should be added to bicarbonate solutions to avoid this. Sodium bicarbonate can also produce decreases in plasma ionized calcium.

Sodium bicarbonate is available as 5% and 8.4% solutions, both of which are hypertonic and should be **diluted** before use. An isotonic solution of bicarbonate can be made by dilution with sterile water to a concentration of 150 mEq/L of sodium and of bicarbonate (1.3% sodium bicarbonate) (see Table 23.8). Bicarbonate should not be added to calcium-containing solutions as **precipitates** are formed.

METABOLIC ALKALOSIS

Metabolic alkalosis is uncommon in horses. It is seen as a result of loss of hydrogen and chloride ions in **nasogastric reflux** (*q.v.*), often accompanied by hypochloremia and hypokalemia. Horses with **heavy sweating**, such as those in **endurance rides**, can also develop alkalosis. Therapy is aimed at replacement of chloride, and promotion of excretion of bicarbonate via the kidney by restoration of body water. Normal saline, supplemented with potassium, is the fluid of choice for the treatment of metabolic alkalosis (see Table 23.8). Circulating volume deficits should be addressed. Supplementation with magnesium can also aid in treating refractory alkaloses.

Sodium

Hyponatremia rarely requires specific therapy, however **normal saline** can be used to increase serum concentrations of sodium. Hyponatremia should

be corrected slowly to prevent rapid dehydration of the central nervous system (CNS) thereby leading to central pontine dysmyelinolysis and demyelination (*q.v.*).

Hypernatremia indicates a water deficit. Replacement of water can be achieved using **5% dextrose**, as at this concentration dextrose is metabolized to carbon dioxide and water. Once glucose is metabolized, 5% dextrose is essentially free water. Alternatively, an infusion of 0.45% saline in 2.5% dextrose may be used for delivery of lower rates of free water.

Extreme caution should be exercised in the treatment of hypernatremia as **cerebral edema** (*q.v.*) may develop if the plasma osmolality is reduced too rapidly. A safe rule of thumb is that both hyponatremia and hypernatremia should be corrected slowly, without exceeding 0.5 mEq/h.

Potassium

IV replacement of potassium deficits is difficult to achieve as **cardiac arrhythmias** can develop when excessive quantities of potassium are administered. No more than 0.5 mEq/kg/h should be given IV in horses with normal renal function, with lower amounts for those with **kidney disease**. Oral replacement of potassium is much safer, and larger quantities (up to 60 g at a time) can be administered. Potassium supplementation should be performed with extreme caution in horses with **hyperkalemic periodic paralysis (HYPP)** (*q.v.*) and those with acute anuria or oliguria.

Hyperkalemia is regarded as a medical emergency because of the risk of cardiac arrhythmias or dysrhythmias (*q.v.*), including diminished P wave amplitude, loss of P waves, spiked or tented T waves, increasing duration of the QRS complex and a variety of ventricular dysrhythmias.

The concentration of potassium in the ECF can be reduced by promoting cellular uptake by the administration of sodium bicarbonate, or insulin (0.1–0.5 units/kg), or enhancement of the secretion of insulin by dextrose infusion (4–6 mL/kg of 5% dextrose). Potassium-wasting **diuretics, such as furosemide or carbon anhydrase inhibitors**, may be used to remove potassium from the body. Calcium has been recommended for its cardioprotective effects in hyperkalemia because it raises threshold potential (0.2–0.4 mL/kg of a 23% calcium gluconate solution, administered very slowly and diluted, i.e. over no less than 20 min and preferably longer).

Calcium

Replacement of calcium in horses requires **extreme caution** in order to avoid development of **bradycardia** or dysrhythmias (*q.v.*). Calcium gluconate solutions designed for the treatment of hypocalcemia in ruminants can be administered to horses. However, they must be given considerably **more slowly** in horses than in ruminant species. Unless calcium is being administered for its life-saving cardioprotective effects, e.g. in HYPP, it is wise to supplement calcium slowly over a period of 12–24 h.

Accurate estimation of calcium deficits is impossible, and calcium is given to effect, ideally based on serum ionized calcium concentrations. Calcium supplementation should be performed diluted in fluids, and it should not be administered along with sodium bicarbonate or blood/plasma products. Average-sized

and adult horses require 10 g of calcium per day (20 g orally), which can be supplied through 1 mEq/kg/day calcium as 23% calcium gluconate.

MAINTENANCE FLUID THERAPY

The maintenance requirements may be divided into those required by normal body losses, and additional losses that are incurred as a result of the animal's clinical problem (ongoing losses). It is estimated that **maintenance requirement** for fluid in adult horses is 40 mL/kg/day or more, thus a 500 kg horse needs at least 20 L/day. Based on water intake studies, a rate of 2–3 mL/kg/h is a reasonable maintenance rate to be utilized in most horses. Diarrhea or nasogastric reflux can considerably increase this figure.

In horses with **nasogastric reflux** (*q.v.*) it is easy and helpful to quantitate fluid losses, however with diarrhea this is generally difficult. Regardless, clinical parameters, biochemical markers such as lactate, and the **PCV and TP** should be serially evaluated to determine the adequacy of fluid administration. If **over-hydration** (*q.v.*) is a concern (e.g. in horses with renal failure) CVP should be measured and fluid administration tailored to ensure that CVP remains below 15 cmH₂O. Serial monitoring of CVP is more important than single measurements in order to follow trends.

IV maintenance

Fluids **specifically designed** for IV maintenance therapy are isotonic to hypotonic. To avoid an excessive sodium load, these solutions generally contain dextrose and water in addition to saline, e.g. 2.5% dextrose in 0.45% saline (see Table 23.8) or free water, e.g. Plasma-Lyte 56 or Normosol M (osmolality 110 mOsm/L).

Some free water is needed for hydration of the intracellular fluid compartment. However, balanced polyionic replacement fluids such as lactated Ringer's (LRS) or equivalent balanced polyionic solutions can be, and frequently are, used for short-term maintenance (see Table 23.8). Although these solutions contain more sodium than is necessary, the excess sodium load can readily be excreted if renal function is normal. In addition, replacement fluids such as LRS can be utilized as maintenance fluids for horses that are allowed access to oral water. True "maintenance fluids" will be necessary for long-term fluid management of horses not allowed oral water, and for those with **renal failure**.

The horse has a high requirement for potassium (approximately 3000 mEq/day for a 450 kg horse). It is therefore standard practice to add 20 mEq of potassium chloride per liter of prepared balanced polyionic solutions. However, this will provide only approximately 1250 mEq of potassium per day, and further supplementation may be required in some cases. Potassium should be administered IV at rates of 0.3–0.5 mEq/kg/h or less.

Ideally, maintenance fluids should be administered as a **constant infusion**. Automated digital fluid pumps can accurately deliver fluids as a constant rate infusion (CRI). However, if necessary, the daily requirement can be divided into 4–6 doses and administered as boluses. This is an inefficient method, as some fluid is lost by urination following rapid boluses. In addition, CVP may

increase after boluses, which may promote edema in hypo-oncotic horses, horses with increased vascular permeability, or those with high venous pressures (e.g. cardiac failure).

Oral maintenance

The **oral route** should always be used for fluid administration whenever possible. In addition to a financial advantage, oral fluid therapy is more physiological and carries little risk of over-hydration. Potassium, which can be dangerous when administered in large doses IV, can be administered orally in larger quantities. Horses unwilling or unable to drink and those with mild dehydration associated with chronic diarrhea or other fluid losses may be managed very successfully with fluids given by **nasogastric tube**. Some horses will drink electrolyte solutions voluntarily, but **fresh water** should also be offered.

The horse has a small stomach relative to its size (12 L capacity). In horses with normal gastrointestinal function, **up to 7 L isotonic solution** can be administered safely by nasogastric tube and this can be repeated within 1 h if necessary. Fluids should not be administered by nasogastric tube to recumbent horses. The presence of nasogastric reflux should be evaluated carefully prior to administration of fluids by nasogastric tube.

For repeated administration, indwelling nasogastric tubes are fairly well tolerated for a short time but may cause **pharyngitis** (*q.v.*). Equally, repeated stomach tubing can be traumatic, and even the quietest horse will become frustrated by repeated tubing. If fluids are to be administered for more than a few days, an indwelling soft and small diameter nasogastric or esophageal tube should be considered. Complications associated with esophagostomies and esophageal tubes include **cellulitis** and **stricture formation**. A number of commercially available soft and small diameter feeding tubes allow for longer duration maintenance of nasogastric tubes, with fewer side effects.

Oral fluid therapy requires adequate gastrointestinal absorption to be successful. In **bacterial enterocolitis**, such as salmonellosis (*q.v.*), diarrhea is secretory in origin and fluid absorptive function should not be impaired to a great extent. However, in **viral diarrhea**, villus atrophy can reduce the absorptive capacity and limit the effectiveness of oral fluid therapy. Many commercially available oral hydration solutions contain glucose or glucose and glycine. These are included to promote water absorption through the coupled transport of sodium and glucose. A potential disadvantage is that they can induce **bacterial fermentation** of glucose in the large colon if it is not absorbed in the small intestine.

OVER-HYDRATION

The main indication for over-hydration as a therapeutic goal in horses is the treatment of pelvic flexure, cecal or small colon **impactions** (*q.v.*). The goal of over-hydration is to hydrate the gastrointestinal contents as part of the extracellular fluid compartment, to increase the plasma hydrostatic pressure, and to reduce plasma oncotic pressure, thereby allowing the secretion of fluid into the intestinal lumen. It has been proposed that, in the presence of an

impaction, the interstitial pressure in the surrounding gut wall may be increased, enhancing fluid secretion into the intestine. However, this remains speculative. Over-hydration is performed using a combination of oral and IV fluid administration. Rates of twice the daily maintenance fluid requirement have been suggested for increasing gastrointestinal water content.

TECHNICAL CONSIDERATIONS IN FLUID THERAPY

IV catheterization

The **jugular vein** is most commonly used for venous access in horses. It is large, has high flow and is easily accessible, making jugular catheters easiest to maintain. The lateral thoracic and cephalic veins can be used as alternatives. The most common complication of IV catheterization is **thrombophlebitis** (*q.v.*). Others include septic phlebitis, local cellulitis, and dislodgement of injection ports with subsequent hemorrhage. Attempts should be made to minimize complications by ensuring **sterile insertion** techniques and a rigorous catheter care protocol.

The composition of the catheter influences thrombogenicity: polyethylene catheters are most thrombogenic, and they should be removed within a maximum of 72 h after insertion. Teflon (tetrafluoroethylene) is intermediate in reactivity. Siliconized rubber and polyurethane (Mila International, Florence, KY, USA and Arrow International, Reading, PA, USA) catheters are least thrombogenic and can be left in place for extensive periods.

The maximum rate of fluid delivery through IV administration sets is influenced by both the bore and the length of the catheter, an important consideration in replacement therapy in adult horses. Size 14 G catheters are most popular for routine use in adult horses. Size 10 or 12 G catheters can be used to provide larger volumes of fluid quickly. The diameter and length of IV administration tubing also affect rates of delivery. Fluid pumps and pressure bags can be utilized to hasten fluid delivery.

Fluid delivery systems

The ideal fluid delivery system is sterile and resistant to contamination, allows the horse to move around freely without obstructing flow, and can achieve a wide range and accuracy in flow rates. In most cases, sufficient volumes of fluid can be delivered by **gravity flow** using a large bore, disposable coiled administration set, e.g. the Large Animal Stat IV Set (Win International Ltd., Kennett Square, PA, USA), particularly if a 10 G catheter or two catheters are used for initial replacement therapy. However, in some instances when extremely large volumes of fluid are necessary, **pressurized fluid pumps** may be advantageous. Homemade fluid delivery systems can be manufactured using large (20 L) carboys and coiled tubing. However, their major disadvantages are difficulty in the maintenance of sterility and limited ranges in flow rate.

In veterinary medicine, guidelines for use of IV administration sets and equipment have been extrapolated from human medicine. Ideally, administration sets should be changed on a daily basis. Particular care should be

employed when solutions containing dextrose are used. Handling of the administration set should be minimized, and injection ports swabbed with alcohol before use and changed daily.

Formulation, handling and storage of IV fluids

The **maintenance of sterility** is the overriding priority in the handling of IV fluids. A sterile technique, and ideally a flow hood, should be used during the insertion of additives to fluids for IV use. Commercially prepared solutions are undoubtedly the most convenient. Sterility of the product is assured and appropriate quality control of pH and osmolarity can be expected.

The manufacturer's instructions for storage of fluids should be carefully adhered to. Homemade fluids are considerably less expensive (estimated at half price), and in horses, where the volumes required are often extremely large, this may be an important factor. However, if homemade fluids are to be used, careful consideration should be given to the ability to maintain sterility and to ensure consistent composition. Such homemade fluids are associated with thrombophlebitis and endotoxemia in horses, and are not ideally suited for use in the ICU.

INOTROPES AND VASOPRESSORS

Indications for use of inotropes and pressors include **fluid-refractory hypotensive states**. Before administration of inopressors, fluid balance must be optimized. Preload and stroke volume should be maximized without compromising CVP. Once maximum fluid loading has occurred, inotropes should be utilized to treat persistent hypotension.

Inotropes act primarily by increasing cardiac output through enhancement of stroke volume. It is safest to start with inotropes, because use of vasopressors increases cardiac afterload and can therefore decrease cardiac output. **β_1 -Agonists** are the mainstay of inotrope therapy. **Dobutamine** and **β -dose dopamine** are most commonly employed. Suggested doses of dobutamine include 1–10 $\mu\text{g}/\text{kg}/\text{min}$ as a constant rate infusion.

Vasopressors should be utilized only after cardiac output has been maximized through the administration of fluid boluses and inotrope infusions. The most commonly utilized pressor is **norepinephrine/noradrenaline**, because of its primarily **α_1 -agonist** activity. If norepinephrine/noradrenaline is utilized, it should be used with **low dose dobutamine** (1–5 $\mu\text{g}/\text{kg}/\text{min}$) in order to preserve splanchnic circulation. Suggested dosages for norepinephrine/noradrenaline infusions include 0.01–0.1 $\mu\text{g}/\text{kg}/\text{min}$ diluted in 5% dextrose in water, whereas individual animals may require higher doses.

Vasopressin is a newer pressor receiving attention in human and veterinary critical care. Vasopressin acts on V1 receptors present on the vasculature smooth muscle. Animals treated with pressors should be monitored for paradoxically reduced perfusion, because pressors can increase afterload and peripheral resistance excessively. Increases in blood lactate concentrations, reductions in mixed venous oxygen tension, or decreasing urine output warrant reconsideration of pressor therapy.

Horses being treated with inotropes and vasopressors should be monitored for dysrhythmias and tachycardia (*q.v.*) with serial or continuous electrocardiography.

PHARMACOTHERAPY OF THE CRITICALLY ILL NEONATE AND HORSE (Table 23.9)

INTRODUCTION

For the foal, any number of conditions that present pre partum, at birth or develop shortly post partum may necessitate hospitalization and intensive care. (See also Chapter 14, page 765.) Once in intensive care, the **immunologically immature** foal is at risk from serious focal infection (pneumonia, septic arthritis or osteomyelitis) (*q.v.*) and septicemia, particularly if access to the mother's **colostrum** has been limited or curtailed. The incidence of infection among critically ill equine neonates is not known, but may be as high as 40% with an additional 30% unconfirmed but suspected cases. Over 70% of critically ill premature foals may be infected, often in utero.

Diagnosis of infection in neonates is quite problematic. Physical signs can be vague and non-specific. **Sepsis** often develops and is well established before any clinical signs are observed. For this reason, any newborn foal that appears weak, depressed or lethargic, or exhibits behavioral changes or decreased suckling should be presumed to be septicemic and treated accordingly. Since the course of infection in newborns is quite rapid, therapy should not await the results of blood cultures, but **must be instituted at once**. While **blood cultures** are indicated in all critically ill foals, results are sometimes misleading. A false negative rate that has been estimated at 25% or higher should not be relied upon for defining sepsis.

Infections in neonatal and young foals are predominantly **Gram negative**. When streptococci or staphylococci are cultured, Gram-negative species are also usually present in **mixed infections**. One retrospective study reported 108 positive cultures in 27% of a total of 251 foals admitted to an ICU over a 6 yr period. Among these foals, Gram-negative organisms accounted for 76% of total organisms cultured, of which 42.5% were *Escherichia coli*, 9% were *Klebsiella pneumoniae*, 7% were *Actinobacillus equuli*; the rest of the foals showed multiple other organisms as the infectious agents.

Another retrospective study of septicemic foals ≤ 8 days old reported that Gram-negative organisms were cultured from 100% of 72 foals. *E. coli* was isolated from over 50% of septicemic and pneumonic neonates and 30% of foals with septic arthritis. *Actinobacillus* spp. (36%) and *Klebsiella pneumoniae* (24%) were the second and third most common isolates. Entirely Gram-positive pathogens—most frequently β -hemolytic streptococci—were isolated in 12 of 46 foals with septic arthritis (*q.v.*). Among septicemic and pneumonic foals, **Gram-positive bacteria** occurred only in **mixed infections** alongside Gram-negative organisms.

The selection of an antimicrobial and a dosing regimen is complicated by the **physiologic immaturity** of the newborn foal, in which the absorption, distribution, metabolism and elimination of drugs differ markedly from the

Table 23.9 Pharmaceutical preparations for the critically ill equine patient

Agent	Route of administration	Spectrum of activity
Antimicrobial agents		
<i>Aminoglycosides</i>		
Amikacin	IV, IM	Gram-negative aerobic bacilli
Tobramycin	IV, IM	Gram-negative aerobic bacilli
Gentamicin	IV, IM	Gram-negative aerobic bacilli
Kanamycin	IV, IM	Gram-negative aerobic bacilli
<i>Cephalosporins</i>		
Cefazolin	IV, IM	Penicillinase-producing <i>Staphylococcus</i> , streptococci, <i>Escherichia coli</i> , <i>Klebsiella</i> and <i>Proteus mirabilis</i>
Cefoperazone	IV, IM	Expanded Gram-negative aerobes, anaerobes
Ceftiofur	IV, IM	Expanded Gram-negative aerobes, anaerobes
Moxalactam	IV, IM	Expanded Gram-negative aerobes, anaerobes
<i>Penicillins</i>		
Aqueous benzylpenicillin	IV	Streptococci, non-penicillinase-producing staphylococci, <i>Pasteurella</i>
Procaine benzylpenicillin	IM	Streptococci, non-penicillinase-producing staphylococci
Benzathine benzylpenicillin	IM	Streptococci
Oxacillin	IV, IM	Penicillinase-producing staphylococci
Ampicillin	IV, IM	Greater activity against Gram-negative bacilli
Ticarcillin	IV, IM	Anti-pseudomonal activity
Ticarcillin–clavulanic acid	IV, IM	Broad Gram-negative activity—aerobes and anaerobes
<i>Tetracyclines</i>		
Oxytetracycline	IV	Broad-spectrum antimicrobial activity
<i>Sulfonamides</i>		
Trimethoprim–sulfamethoxazole	IV	Gram-positive and Gram-negative aerobes
<i>Macrolides</i>		
Erythromycin lactobionate	IV	Gram-positive cocci
<i>Miscellaneous antibiotic agents</i>		
Vancomycin	IV	Methicillin-resistant staphylococci, group D streptococci, enterococcus
Metronidazole	IV PO	<i>Bacteroides fragilis</i> plus other Gram-positive and Gram-negative anaerobes
Chloramphenicol	IV	Gram-negative aerobes and anaerobes
Agent	Dosage	Comments
<i>Aminoglycosides</i>		
Amikacin	21–25 mg/kg q 24 h	Potential nephrotoxicity/ototoxicity
Tobramycin	3–7 mg/kg/day	Potential nephrotoxicity/ototoxicity
Gentamicin	6.6 mg/kg q 24 h	Potential nephrotoxicity/ototoxicity
Kanamycin	5 mg/kg q 8 h	Potential nephrotoxicity/ototoxicity
<i>Cephalosporins</i>		
Cefazolin	12–22 mg/kg q 6–8 h	Synergistic with aminoglycoside
Cefoperazone	No dosage reported for horses	Expensive
Ceftiofur	2.2 mg/kg q 12–24 h Up to 10 mg/kg q 6–12 h	Third generation, use cefotaxime susceptibility disk in neonates
Moxalactam	50 mg/kg q 6–12 h	Expensive

Table 23.9 (Continued)

Agent	Dosage	Comments
<i>Penicillins</i>		
Aqueous benzylpenicillin	22 000 IU/kg q 6 h	Na ⁺ K ⁺ salt form available
Procaine benzylpenicillin	22 000 IU/kg q 12 h	Synergistic with aminoglycosides
Benzathine benzylpenicillin	40 000 IU/kg q 2–3 day	Repository form
Oxacillin	16–50 mg/kg q 8–12 h	Synergistic with aminoglycosides
Ampicillin	22–100 mg/kg q 6–8 h	Inactivated by β -lactamases
Ticarcillin	50–100 mg/kg q 6 h	Synergistic with aminoglycosides
Ticarcillin–clavulanic acid	50–100 mg/kg q 6 h	Clavulanic acid inhibitor of β -lactamases
<i>Tetracyclines</i>		
Oxytetracycline	4.4–5 mg/kg q 12–24 h	Gastrointestinal irritation
<i>Sulfonamides</i>		
Trimethoprim–sulfamethoxazole	15–30 mg/kg q 12 h	Gastrointestinal irritation
<i>Macrolides</i>		
Erythromycin lactobionate	15–20 mg/kg q 6–8 h	May be given in combination with rifampicin
<i>Miscellaneous antibiotic agents</i>		
Vancomycin	5–7 mg/kg q 8 h	Potential nephrotoxicity
Metronidazole	7.5 mg/kg q 6 h	IV preparation expensive in ready-to-use-form
	15 mg/kg q 8 h	Active when given orally, relatively inexpensive
Chloramphenicol	50 mg/kg q 8 h	Blood dyscrasias in humans
Agent	Route of administration	Dosage
Gastrointestinal drugs		
Metoclopramide	IV, PO	0.1–0.2 mg/kg q 12 h
Loperamide	PO	8.0 mg/40–70 kg
Bismuth subsalicylate	PO	0.5–1.0 mg/kg
Ranitidine	IV	1.5–2 mg/kg q 8 h
	PO	6.6 mg/kg q 8–12 h
Cimetidine	IV	6.6 mg/kg q 6 h
	PO	6.6–20 mg/kg q 6–8 h
Sucralfate	PO	20–40 mg/kg q 6 h
Prostaglandin E ₂ analogues	PO	2–5 μ g/kg q 8–12 h
Anticonvulsants		
Diazepam	IV	5–10 mg/45 kg
Phenobarbital	IV	3–5 mg/kg diluted in 30 mL saline
Phenytoin	IV	5–10 mg/kg first 12 h
	IM	1–5 mg/kg q 2–4 h
	PO	1–5 mg/kg q 2–4 h
		1–5 mg/kg q 6–12 h
Pentobarbital	IV	2–4 mg/kg to effect
Anti-inflammatories/analgesics		
Xylazine	IV	0.1–0.5 mg/kg
	IM	0.25–1.0 mg/kg
Butorphanol	IV	0.01–0.04 mg/kg
	IM	0.02–0.08 mg/kg
Detomidine	IV	10–40 μ g/kg
	IM	Start at 1–5 μ g/kg initially
Dimethyl sulfoxide (DMSO)	IV	1.0 g/kg diluted to 10–20% saline
		5% dextrose
Phenylbutazone	IV	Up to 2 mg/kg q 12 h
Flunixin meglumine	IV	0.25 mg/kg q 8–12 h

(Continued)

Table 23.9 (Continued)

Agent	Uses
Gastrointestinal drugs	
Metoclopramide	Promotes gastric emptying
Loperamide	Slows gastrointestinal motility
Bismuth subsalicylate	Intestinal protectant
Ranitidine	H ₂ antagonist
Cimetidine	H ₂ antagonist
Sucralfate	Gastric protectant
Prostaglandin E ₂ analogues	Increases gastric mucosal blood flow, bicarbonate secretion, gastric mucous viscosity
Anticonvulsants	
Diazepam	Stops recurring and refractory seizures
Phenobarbital	Stops recurring seizures if diazepam ineffective
Phenytoin	Controls seizures if phenobarbital ineffective
Pentobarbital	Controls seizures as a direct result of anesthetic effects
Anti-inflammatories/analgesics	
Xylazine	Potent sedative-hypnotic drug
Butorphanol	Narcotic agonist-antagonist
Detomidine	Very potent sedative-hypnotic drug
Dimethyl sulfoxide (DMSO)	Diuretic, anti-inflammatory effects in CNS
Phenylbutazone	NSAID
Flunixin meglumine	Anti-endotoxic effect

adult horse. Moreover, there are significant physiologic differences between the premature foal, the full-term newborn, and the 1-wk-old neonate (*q.v.*), all of which will respond differently in terms of pharmacokinetics and pharmacodynamics. The pharmacokinetics of antimicrobials and other drugs have been little studied in the foal. Many of the available guidelines and dosages rest on surmise, extrapolation and clinical experience rather than hard data.

PHYSIOLOGIC AND PHARMACOKINETIC DIFFERENCES IN THE NEWBORN

Drug elimination is slower in the newborn (*q.v.*). Both the hepatic metabolic pathways and the renal excretion mechanisms are immature at birth. Non-polar drugs, such as chloramphenicol, theophylline, phenobarbital and phenytoin, must be metabolized in the liver prior to excretion. They can, therefore, be presumed to have a **longer half-life** in the newborn. Studies in other species have demonstrated that the liver’s enzyme systems and smooth endoplasmic reticulum achieve mature functioning around the third to fourth week of life. Some reported determinations of non-polar drug half-lives suggest that these drug-metabolizing mechanisms may develop somewhat more rapidly in the foal.

The more water-soluble polar drugs (e.g. penicillins, cephalosporins and aminoglycosides) do not require hepatic metabolism, but are eliminated by renal excretion. The excretory mechanisms of glomerular filtration and tubular secretion appear to mature rapidly over the first month, based on studies

of non-polar drug half-lives. The mean elimination half-life for amikacin has been determined to be 3 h in 2–11-day-old foals, compared with 2.3 h in the adult. Glomerular filtration may develop more rapidly than tubular secretion. In general, then, a longer half-life can be anticipated for many drugs, particularly the non-polar agents, and, thus, **less frequent dosing** is advisable in the newborn. Dosing rates and intervals should be determined by **therapeutic drug monitoring**.

Total body water in the foal may equal 75% of total body weight, compared with 60–70% in the adult animal. Extracellular fluid volume in the 2-day-old foal is approximately 39% of total body weight, decreasing to 36% by 2 weeks. In contrast, the full-grown horse has an extracellular fluid volume of 22% of total body weight.

The **greater fluid compartment** in the foal would suggest that increased doses are required to reach the desired bactericidal concentration. However, some oral drugs are expected to have higher blood concentrations in the newborn compared with the adult receiving the same mg/kg oral dose. The ability of the foal to absorb antibodies, which are macromolecules, from the mother's colostrum suggests that the intestinal epithelium may be **more permeable** to drugs, and drugs that are normally poorly absorbed from the gastrointestinal tract, such as the aminoglycosides, may be better absorbed in the newborn. However, the high calcium content of the milk diet of the suckling foal may reduce or retard absorption of orally administered drugs that form calcium chelate complexes, such as the tetracyclines.

Other differences in gastrointestinal function and maturity can be presumed to have an impact on the rate and extent of gastrointestinal drug absorption. At birth, the pH of the stomach and upper intestine is relatively high, decreasing with milk intake and the development of pepsin activity over the first few weeks. During the same time period, venous blood flow, gastrointestinal surface area and mucosal enzyme activity all increase and the intestinal microflora establish their presence. Gastric emptying time, ingesta and intestinal transit time all differ substantially from the adult horse. The overall impact of these rapidly changing variables is not known.

Drug binding to plasma albumin directly affects drug distribution since only the free, unbound fraction will penetrate target tissues. The relative hypoalbuminemia observed in many species at birth is much less marked in the foal, however, and so this factor is thought to require little dosage adjustment.

The "blood—brain barrier" is more permeable in the newborn for about the first 7–10 days, a potential advantage in treating conditions such as **meningitis** (*q.v.*), but also a complicating factor when selecting the proper dosage for a CNS depressant such as xylazine and the barbiturates. The latter agents may also achieve somewhat higher plasma concentrations in the young foal, because the lower body fat proportion of the neonate (2–3% compared with 5% in the adult) limits the sequestration of lipid-soluble drugs, including barbiturates.

It is relatively straightforward to enumerate the physiologic differences of the neonate, and quite another matter to apply them to working out an appropriate drug regimen. Because developmental pharmacokinetics in the foal have been little studied, the following section will draw on clinical experience and set out basic principles to provide guidelines for administering antimicrobial agents in the equine neonate.

Antimicrobials

Because of the rapid progress and severe consequences of infection and the high susceptibility of the neonate, all at-risk foals should be started on antimicrobials early. Foals with **pre partum** risk factors, such as **placentitis** (*q.v.*) or premature placental separation, should be treated with antimicrobials **shortly after birth**. **Intra partum** considerations include dystocia and asphyxia (*q.v.*), while **post partum** risk factors for sepsis include failure of passive transfer, contaminated birthing environment or concurrent disease (meconium impaction, enteritis, uroabdomen) (*q.v.*).

Broad-spectrum combinations of antimicrobials that provide good coverage of the common Gram-negative organisms are optimal. **Bactericidal** agents are preferred to bacteriostatic drugs because of the neonate's relatively immature humoral and cell-mediated immune responses. Antibiotics that do not require extensive hepatic metabolism prior to excretion (e.g. penicillins, aminoglycosides and cephalosporins) are preferred in the management of premature and newborn foals. A combination of an aminoglycoside (gentamicin or amikacin) with a penicillin or cephalosporin provides broad, relatively safe coverage pending culture results. If use of an aminoglycoside is contraindicated by the presence of renal disease, a third generation cephalosporin, including ceftiofur, will provide Gram-negative coverage.

β -Lactam antimicrobials

The penicillins are bactericidal agents that act by interfering with cell wall formation. They are generally more effective against Gram-positive organisms than Gram-negative bacteria, which have a more complex cell wall. **Benzylpenicillin**, the most commonly employed antimicrobial in the horse, is particularly effective against **β -hemolytic streptococci**, the most commonly isolated bacteria in sepsis in the adult, although not in the neonate. Most **corynebacteria**, with the exception of *Rhodococcus equi*, are quite susceptible to benzylpenicillin. A high percentage of anaerobes are also susceptible to penicillin (up to 80–90% of isolates). Very high doses of benzylpenicillin may put the newborn at risk for **central nervous system toxicity** and **platelet-associated hemorrhaging**, although these are rare. The recommended dose is 25 000–50 000 IU/kg IV q 6 h or q 8 h for sodium or potassium benzylpenicillin, or q 12 h for procaine benzylpenicillin.

The broad-spectrum penicillins, such as ampicillin and amoxicillin, were developed to provide coverage against a range of Gram-negative species. Over time, however, most Gram-negative enterics, such as *Escherichia coli* and *Klebsiella* spp., have become **resistant** to these agents. Thus, these compounds should not be used as single therapy for broad-spectrum effect against unidentified pathogens in the foal. Suggested dosage for amoxicillin, which is more rapidly bactericidal than ampicillin, is 22 mg/kg IM q 6 h.

The extended spectrum penicillins, which include ticarcillin and carbenicillin, have increased activity against Gram-negative organisms, including many isolates of *E. coli*. Resistance is still a problem, particularly in the treatment of *Pseudomonas* infections. These agents are best used in combination with another antimicrobial, such as an aminoglycoside. The suggested dose regimen for carbenicillin is 100 mg/kg IV q 6 h or q 8 h, and for ticarcillin

50 mg/kg IV q 6 h or q 8 h, extrapolated from pharmacokinetic studies in adult horses.

Third generation cephalosporins, such as cefotaxime or ceftazidime (20–50 mg/kg, IV q 6 h), and higher class penicillin drugs, such as imipenem (15 mg/kg IV q 6 h), can be utilized in foals with isolates that are resistant to ceftiofur or aminoglycosides, or in foals with compromised renal function. However, these drugs should be used judiciously in order to minimize microbial selection pressure. Recently, a fourth generation cephalosporin, cefepime, has been studied in healthy neonatal foals. The suggested dose is 11 mg/kg IV q 8 h. This drug should also be reserved for use in refractory cases.

Aminoglycosides

This group of bactericidal agents includes streptomycin, kanamycin, gentamicin, tobramycin, netilmicin and amikacin. The aminoglycosides are primarily active against aerobic, Gram-negative bacteria; some of the aminoglycosides are also active against staphylococci. **Potential nephrotoxicity** and **ototoxicity** are the major limitations in using aminoglycosides. It has been suggested that foals are more susceptible than adult horses to the nephrotoxic effects of the aminoglycosides, particularly gentamicin, because of their slower rate of elimination, but there is little evidence to support or refute this supposition.

Streptomycin has been so widely used that many microorganisms are now quite resistant to it. Kanamycin, which has been previously active against most Gram-negative enteric organisms except *Pseudomonas aeruginosa*, has become less effective due to plasmid-mediated resistance among Enterobacteriaceae in many veterinary settings.

Gentamicin, tobramycin, netilmicin and amikacin are active against *Proteus*, *Klebsiella*, *Enterobacter*, *Serratia*, *Salmonella* and *Shigella* species, *E. coli*, and *Pseudomonas aeruginosa*. However, resistance to gentamicin and tobramycin has occurred in many areas and therapy should be guided by antimicrobial susceptibility testing once available.

Optimal peak and trough levels in the foal may be attained with 6.6 mg/kg **gentamicin** IV or IM q 24 h or with 21–25 mg/kg **amikacin** IV or IM q 24 h. However, because of the high degree of **interindividual variability** in the pharmacokinetic disposition of aminoglycosides in neonatal foals, therapeutic drug monitoring should be performed on all foals in the ICU. Peak plasma concentrations for aminoglycosides should be 10 times the minimum inhibitory concentration (MIC) of the offending microorganism. The MIC of common equine pathogens for amikacin is 4–8 µg/kg, and therefore peak concentrations should be at least 40 µg/kg. Trough concentrations should be <2 and <1 µg/kg for amikacin and gentamicin, respectively.

Cephalosporins

The cephalosporins, being β-lactam drugs, are similar to the penicillins both functionally and structurally. These bactericidal agents are classified into three generations according to their in vitro spectrum of activity. Cefalotin, cefapirin, cefazolin, cefadroxil and cefalexin are all first generation cephalosporins and are active against most aerobic Gram-positive cocci, many anaerobic cocci and bacilli, and some aerobic Gram-negative bacteria. Some Gram-negative

bacteria are resistant, but the relative safety of the cephalosporins makes them commonly used agents in human neonates with septicemia and meningitis caused by Enterobacteriaceae.

Second generation cephalosporins include cefamandole, cefoxitin, cefuroxime, cefonicid and cefaclor. These agents retain the Gram-positive and anaerobic activity of the first generation agents and are more effective against specific Gram-negative bacteria. The latter, nonetheless, frequently exhibit resistance.

The **third generation agents** are moxalactam, cefotaxime, cefoperazone, ceftizoxime, ceftriaxone, ceftazidime and ceftiofur. These cephalosporins penetrate the "blood-brain barrier" well in humans and are largely reserved for the treatment of meningitis (*q.v.*). They are expensive, and resistance to them can develop.

A suggested regimen for **sodium cefazolin** is 11 mg/kg IM or IV q 6 h. Cefalotin can be administered IM or IV in doses of 18 mg/kg q 6 h. Dosage recommendations for the other cephalosporins are based on data in humans and other species and so require careful monitoring and adjustment. The suggested dosage for ceftizoxime and ceftazidime is 20–50 mg/kg IV q 6–8 h. The recommended dosing protocol for ceftriaxone is 20–50 mg/kg IV q 12 h.

Other antimicrobials

Combinations of trimethoprim and sulfonamides (the potentiated sulfonamides) are believed to be bactericidal against a broad spectrum of Gram-positive and Gram-negative organisms, although resistance is developing among Enterobacteriaceae in response to their widespread use in the horse. Theoretically, the oxidative effects of the sulfonamide on the newborn's erythrocytes may lead to hemolysis and methemoglobinemia. In the adult horse, this combination has rarely been associated with neutropenia, acute enteritis and transient ataxia. Sulfonamides bind competitively with albumin, resulting in higher serum concentrations of other administered drugs and endogenous substances such as bilirubin. The elimination of trimethoprim is delayed in the newborn due to the immaturity of the hepatic metabolic pathways in the first weeks of life. The recommended dosage in the neonate, based on data obtained from adult horses, is 15–25 mg/kg IV or PO q 12 h, depending on the problem being treated.

Chloramphenicol is a broad-spectrum bacteriostatic agent that acts by inhibiting ribosomal protein synthesis. Toxic bone marrow depression and bone marrow aplasia have occurred rarely in humans, and the neonates of some species are more susceptible to **toxicity** due to a deficiency of the enzymes required for its metabolism. This does not appear to be the case in the foal, however, and the pharmacokinetics of chloramphenicol in the older foal are similar to those of the adult horse. Elimination is delayed in 1–3-day-old foals. Chloramphenicol can **potentiate** hexobarbital, pentobarbital, aminopyrine, dicumarol (dicoumarol) and phenytoin in impeding their biotransformation. The recommended dosage has been reliably set at 50 mg/kg IV q 4 h for chloramphenicol succinate, and 40–50 mg/kg q 6–8 h for oral chloramphenicol base or chloramphenicol palmitate.

Other antimicrobials commonly used in the horse, such as erythromycin, oxytetracycline and rifampicin, have specific indications in the neonate. **Erythromycin** is administered at 10–15 mg/kg IV or 20–25 mg/kg PO q 4–6 h for peracute and **acute respiratory infections**, such as *Rhodococcus equi* (*q.v.*) in foals 3 weeks and older. Rifampicin is dosed at 5.0 mg/kg PO q 12 h.

Anticonvulsants

Foals may exhibit **seizures** (*q.v.*) associated with septicemia and bacterial meningitis, electrolyte imbalances, asphyxial injury or hypoglycemia. Seizures are caused by aberrant electrical activity in the brain. Phenothiazines, such as acepromazine, may decrease the seizure threshold and induce seizures in foals. They should not be used as anticonvulsants at any time. Neonatal foals appear to have a **low seizure threshold**, believed to be due to cortical immaturity.

The signs of seizures are often subtle and difficult to recognize but include oral and buccal movements, referred to as “**chewing-gum fits**”, jaw chomping, drooling, facial grimacing and twitching. Other clinical signs include repetitive eye blinking and rapid eye movements, tachypnea and apneustic breathing, as well as paddling or tonic posturing of a limb. Differentiation of the subtle signs of seizure activity from the foal in deep sleep (REM) may be achieved by the response to noxious stimuli and easy arousal in the normal foal. Additionally, there is a marked difference in **pupillary light response** in the normal and abnormal foal. Current or continuous seizure activity may cause **brain injury**, resulting from increased cerebral metabolic needs, altered cerebral blood flow, respiratory depression with hypoxia, secondary metabolic derangements and increased intracranial pressure.

Therapy for generalized seizures is focused on controlling the seizure using appropriate anticonvulsant therapy.

Diazepam has a rapid effect, but may require several doses to stop recurring and refractory seizures. The duration of action is short, and the IV form should not be used for maintenance purposes, as it may cause respiratory depression. Suggested doses include 5–10 mg/45 kg administered by slow IV administration or the drug can be used as needed. Diazepam in prolonged contact with plastic (e.g. a syringe) is inactivated, therefore **the drug should not be stored in plastic syringes**. **Midazolam** is a newer benzodiazepine that can be utilized for anticonvulsant therapy. It has a very rapid onset of action that may be advantageous in treating seizures. Doses suggested for horses include 0.011–0.044 mg/kg IV.

Phenobarbital is used if several doses of diazepam do not control the convulsions. An IV loading dose of 3–5 mg/kg IV diluted in 30 mL of saline is administered over a 25–30 min period. Higher loading doses may be needed for neonates, although premature foals may have prolonged elimination half-lives. Therapeutic drug monitoring is therefore crucial in this signalment. Once the convulsions are controlled, a maintenance dose of 5–9 mg/kg IV (diluted and infused over 25–30 min) or PO q 8–12 h can be given. Peak and trough blood levels of the drug should be monitored to titrate the dose to the minimum effective dose to control seizures. Adequate levels appear to range

from 10 to 30 $\mu\text{g}/\text{mL}$. The dose of phenobarbital should be tapered over 7–10 days before discontinuation, to prevent precipitation of seizures.

Bromide (sodium or potassium) is another drug available for controlling convulsions. Suggested oral doses include 44 mg/kg q 24 h for sodium bromide and 50 mg/kg q 24 h for potassium bromide in adult horses. Bromide is renally excreted. Because of its long half-life (5.2 days), bromide should not be utilized to treat active seizures in the acute stages. Bromide administration has few complications and the drug is considered an **effective anticonvulsant** for long-term management of horses with seizure disorders.

Phenytoin is an alternative drug to control seizures, if others are ineffective. A loading dose of 5–10 mg/kg IV is used, followed by a maintenance dose of 1–5 mg/kg q 2–4 h IM or PO. Thereafter (≥ 12 h), a q 8–12 h schedule may be used with a dose of 2.83–16.43 mg/kg. The major side effect is **prolonged depression** in the foal.

Sodium pentobarbital is an inexpensive drug and has profound depressant effects on respiration with repeated doses. Its ability to control seizures is a direct result of its anesthetic effects, rather than it being a true anticonvulsant. Doses of 2–4 mg/kg IV to effect are used.

MANAGEMENT OF ENDOTOXEMIA AND SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

INTRODUCTION

Acute toxic enteritis, strangulating obstruction of the intestine and overwhelming Gram-negative infections such as those seen with acute pleuropneumonia (*q.v.*) are associated with a high degree of morbidity and mortality. Many times, the complications associated with these diseases, such as hypovolemia and dehydration, coagulopathies, ileus, intra-abdominal adhesions and laminitis (*q.v.*), can be traced back to an endotoxic insult.

PATHOPHYSIOLOGY

The outer membrane of Gram-negative bacteria is composed of a lipid bilayer, of which the characteristic component is **lipopolysaccharide (LPS)** or **endotoxin**. LPS is a major factor in the pathogenicity of these bacteria, a receptor site for bacteriophages, and a permeation barrier for the intact bacterium. The LPS molecule is composed of three portions: (1) phospholipid A; (2) a core oligosaccharide; and (3) an “O-specific antigenic” polysaccharide side chain.

Lipid A is the most well conserved portion of the LPS molecule and has the same basic structure for all Gram-negative bacteria. Most importantly, it is the portion of the molecule primarily responsible for the pathophysiologic effects of endotoxin in mammals. The core is the next most well preserved, with only six different varieties identified. In contrast, the O side chains are a very diverse group, of which the structure and composition are different for each bacterial species.

Bacteria do not actively excrete endotoxin; rather, it is released during bacteriolysis and the **rapid growth phase of bacterial multiplication**. The largest

source of **equine endotoxin** is contained within the gastrointestinal tract lumen and is a result of the normal turnover of enteric bacteria. In health, the mucosal layer acts as an efficient barrier to the transmural movement of endotoxin. However, damage from ischemia, inflammation or parasites can result in mucosal compromise, alteration of intestinal motility and a decrease in intraluminal pH. This may result in loss of mucosal integrity, with subsequent **leakage** of endotoxin into the portal circulation and peritoneal cavity.

If endotoxin escapes neutralization by the hepatic reticuloendothelial system or by antibodies in the systemic circulation, it can initiate a variety of hemodynamic, hematologic and metabolic disturbances. Endotoxin is a potent stimulator of a **systemic inflammatory response syndrome (SIRS)**. SIRS (*q.v.*) is a clinical state of exuberant inflammatory and/or anti-inflammatory responses to a number of septic and non-septic triggers. It is defined clinically by the presence of two or more of the following: tachycardia, tachypnea or hyperventilation, hyperthermia or hypothermia, and leukocytosis or leukopenia.

The underlying features of endotoxemia are **inadequate perfusion** of vital tissues and **multisystemic organ dysfunction** and failure. Early on, vasodilation yields red mucous membranes with rapid capillary refill time. Next, vasoconstriction results in pale mucous membranes with prolonged capillary refill. With time, pooling of blood in the capillaries and increased permeability result in dark, muddy membranes with prolonged capillary refill. Hypoxemia, and decreases in arterial pressure and cardiac output accompany increases in heart and respiratory rates. Ileus, abdominal pain and/or diarrhea may occur as a result of blood pooling in the mesenteric vasculature.

One of the most **sensitive indicators** of endotoxemia is the rapid margination of neutrophils and release of immature cells causing leukopenia with a left shift. Dehydration and hypovolemia with loss of intravascular volume and splenic contraction (increased sympathetic tone) lead to **hemoconcentration**. Intravascular platelet aggregation and endothelial adhesion result in thrombocytopenia while coagulopathies such as disseminated intravascular coagulation (DIC) occur secondary to release of tissue factor and other procoagulants.

Metabolic alterations include **hyperglycemia** (increased glycogenolysis, sympathoadrenal activation), soon followed by **hypoglycemia** (glycogen depletion and inhibition of gluconeogenesis). Pyrexia occurs as a result of direct stimulation of the thermoregulatory center and release of pyrogens, such as interleukins 1 and 6 and tumor necrosis factor (TNF- α). Free radical release occurs subsequent to tissue ischemia. Circulatory failure, free radicals, edema formation, damage from inflammatory mediators, and coagulopathies result in tissue and subsequent organ dysfunction and failure. Mitochondrial dysfunction is another sequel to SIRS and the secondary derangements that follow.

ANTIBIOTICS AND HYPERIMMUNE PLASMA

Endotoxin plays a significant role in the morbidity and mortality of many Gram-negative bacterial diseases and is often the reason for failure despite the use of appropriate broad-spectrum antibiotics. Even when endotoxin is present in undetectable amounts, the position of the LPS molecule on the bacterial surface allows for activation of many biological mediators of SIRS and circulatory

or distributive shock. The clinical features of **Gram-negative sepsis** (bacteremia with subsequent SIRS) are identical to the effects of IV administered endotoxin. Therefore, **antimicrobials cannot be expected to reverse the clinical signs attributed to circulating endotoxin**. This does not preclude the use of antibiotics in the treatment of Gram-negative infections, since it is often difficult to differentiate between bacteremia and endotoxemia. Rather, they should be used judiciously and directed at the invading Gram-negative organisms involved.

Blood, transtracheal aspirations and pleural or peritoneal fluids should be sampled for **culture** when appropriate. Perioperative antimicrobials in the management of patients with strangulating intestinal lesions should be broad spectrum in coverage, used only as long as necessary, and used with caution to minimize the risks of potential side effects (e.g. nephrotoxicity, drug-induced diarrhea).

Recently, **passive immunotherapy** directed against the common structural and immunogenic properties of the LPS molecule has shown promising results. Mortality was substantially reduced in human patients with Gram-negative bacteremia when treated with human antiserum to the common core structures of LPS. Clinical trials have been performed comparing the use of hyperimmune plasma with control plasma in horses suffering from a variety of gastrointestinal crises and demonstrating signs of endotoxic shock. In one study, horses receiving hyperimmune plasma experienced reduced mortality rate, improved clinical score and shorter recovery times. It is recommended that horses suffering from endotoxemia that weigh ≥ 250 kg receive 2 L **hyperimmune plasma**.

Occasionally, individuals that do not respond may require additional plasma. Other advantages of plasma transfusions include the presence of immunoglobulins, clotting factors, antithrombin, activated protein C, fibronectin, albumin and other proteins.

In other studies, administration of hyperimmune plasma failed to alter the course of experimentally induced endotoxemia in horses. A variety of causes for these divergent results have been proposed. For example, LPS in clinical situations exists in various forms. During an infection, bacteria rapidly multiply; if they come in contact with core antibody during early cell wall synthesis, before side chain attachment is complete, the antibody could easily bind to the naked core. Host defense mechanisms and antimicrobial agents can also alter the structure of the LPS molecule and enhance antibody binding.

FLUNIXIN MEGLUMINE

Endotoxin interacts with a variety of inflammatory cells and **induces the synthesis** and/or secretion of numerous humoral mediators. Mediators produced as a result of the arachidonic acid cascade have been the focus of recent endotoxin research in horses. Arachidonic acid is incorporated in the phospholipids of all plasma membranes of mammals. Once liberated during endotoxin-induced cell activation, it is further metabolized by two major enzyme systems—the cyclo-oxygenase and lipoxygenase cascades.

Prostaglandin (PG) reductase results in the formation of the stable prostaglandins PGE₂ (a vasodilator) and PGF_{2 α} (a vasoconstrictor). Thromboxane (TX) synthetase activity, which is found primarily in platelets and mononuclear cells, produces TXA₂, a potent vasoconstrictor and promoter of platelet

aggregation. Prostacyclin synthetase, contained in endothelial cells, produces prostacyclin PGI_2 , a potent vasodilator and inhibitor of platelet aggregation. In health, this system keeps a “**check and balance**” on vasoactivity and maintains homeostasis.

During endotoxemia, **endothelial damage** initially allows TX activity to prevail, resulting in widespread vasoconstriction, platelet aggregation, microthrombosis and tissue ischemia. The beneficial effects of non-steroidal anti-inflammatory drugs such as **flunixin meglumine**, a cyclo-oxygenase inhibitor, support the role of these mediators in equine endotoxemia.

The role of the products of the lipoxygenase pathway during equine endotoxemia has not been clearly elucidated. In other species, these mediators produce vasoconstriction and bronchoconstriction, elicit plasma exudation and are involved in microthrombi formation and leukocyte chemotaxis.

It has been demonstrated that NSAIDs, most specifically flunixin meglumine, are not only useful as analgesics but are potent mediators of the arachidonic acid cascade during equine endotoxemia. Because of the popular use of NSAIDs and their potential for gastrointestinal and renal toxicity (*q.v.*), investigations of minimal dosages required to manipulate the arachidonic cascade were undertaken. Horses experimentally challenged with endotoxin were treated with doses of 1.1, 0.25 and 0.1 mg/kg flunixin IV. Clinical parameters, although altered by flunixin, remained useful for evaluating the horses' status during the endotoxemia challenge. Horses receiving the 0.25 mg/kg dose showed milder signs of colic and regained their appetite and drank water earlier than those receiving 0.1 mg/kg. Endotoxin-induced lactic acidosis was reduced comparably in the groups receiving 1.1 and 0.25 mg/kg flunixin. The reduction in lactic acidosis may be attributed to inhibition of TXA_2 , a potent vasoconstrictor, thus allowing better tissue perfusion. Data from this study suggest that flunixin meglumine, in doses ≤ 1.0 mg/kg, follows relatively linear pharmacokinetics, even in the face of endotoxin challenge. It should be expected that 0.25 mg/kg flunixin q 8 h would reduce eicosanoid generation in response to endotoxin challenge.

The potential toxic side effects associated with the use of NSAIDs in the hypovolemic patient necessitate that **flunixin meglumine be used with caution when treating horses with colic**. In health, prostaglandins help protect the gastrointestinal mucosal barrier by enhancing mucosal microcirculatory blood flow, improving re-epithelialization and restitution following mucosal injury, promoting mucus and bicarbonate release at the mucosal surface, and moderating acid secretion. Interference with their production can lead to intestinal ulceration. Prostaglandin precursors shunted down the alternate lipoxygenase pathway may form other biologically active eicosanoids. Prostaglandins are also important mediators of renal blood flow during hypovolemia. Disruption of that balance can lead to **renal tubular damage**.

Flunixin meglumine at the manufacturer's recommended dose of 1.1 mg/kg can be used judiciously in cases that are not hypovolemic, and such horses should be monitored for signs of deterioration in condition. **Repeated doses are not recommended without thorough patient re-evaluation**. Alternatively, 0.25 mg/kg can be used in order to minimize side effects of NSAID use and still provide for reductions in eicosanoid production.

POLYMYXIN B

Polymyxin B is a cationic polypeptide antimicrobial drug that binds to circulating endotoxin (lipid A portion) and thereby prevents its binding to cellular receptors. This agent has shown promise in horses experimentally, but it needs further evaluation clinically. Side effects of polymyxin B include neurologic signs and nephrotoxicity. Renal function should be evaluated serially in horses receiving polymyxin B. Doses range from 1000 to 6000 IU/kg q 12 h, and each dose of polymyxin B should be diluted in 1 L saline and infused over 30–60 min.

LOW MOLECULAR WEIGHT HEPARIN

Horses experiencing endotoxemia and SIRS are at risk for development of **coagulopathies** and subsequent **thromboses** (*q.v.*). **Heparin** is indicated to minimize the complications of **intravascular coagulation**. Low molecular weight heparin has constant anticoagulant properties, greater bioavailability and longer half-life than unfractionated heparin. Low molecular weight heparin (LMWH), such as **dalteparin** or enoxaparin, has been recently studied in both experimental horses and clinical cases.

A randomized double-blind clinical trial compared unfractionated heparin (UFH) with LMWH in horses with colic. The authors concluded that LMWH has markedly fewer side effects than UFH in horses. Packed cell volume decreased in horses treated with UFH, but did not change significantly in horses administered LMWH. The activated partial thromboplastin time (APTT) and thrombin time (TT) were prolonged in horses administered UFH, but not in those treated with LMWH. Horses receiving LMWH had fewer injection site skin reactions than those receiving UFH. In addition, horses given UFH had significantly more subclinical jugular vein changes or partial thromboses than those treated with LMWH. Suggested dosages for dalteparin in horses include 50 IU/kg q 24 h SC.

IV FLUID THERAPY

Correction of the cardiac collapse and decreased peripheral perfusion associated with endotoxemia requires aggressive IV fluid management. **Prognosis** is often directly related to the rapidity with which homeostasis is re-established.

IV fluid therapy starts with an evaluation of the patient's circulating volume status and hydration, electrolyte and acid-base status. Mucous membrane color and refill, skin turgor, PCV and TP concentration are useful in determining the degree of hypovolemia and dehydration (Tables 23.10 and 23.11).

Markers of volume status include capillary refill time (CRT), heart rate, extremity temperature, jugular refill time, mentation, mucous membrane color and pulse quality. Blood or plasma lactate concentration, urine output and specific gravity, acid-base status (anion gap, base excess) and mixed venous oxygen tension are biochemical and hematologic markers of circulating volume status. **Hydration** can be assessed by using skin turgor, mucous membrane texture and corneal quality. Once the degree of hypovolemia and dehydration has been

Table 23.10 Clinical signs of dehydration and estimated fluid lost in a 400 kg horse

%	Signs	Fluid loss (L)
0–5	Not detectable	0–24
5	Delay in return of skin to normal position, sunken eyes, slightly prolonged capillary refill time (CRT), dry mucous membranes	24
8–10	Tented skin stands in place, prolonged CRT, may see signs of shock (increased heart rate, weak pulse, delayed jugular filling [flat veins])	32–40
12–15	Shock, decompensation, may be moribund, death imminent	48–60

Table 23.11 Evaluation of packed cell volume (PCV) and total plasma protein (TPP)

PCV (%)	TPP (g/dL)	Possible interpretation
↑	↑	Dehydration
↑	N or ↓	Splenic contraction Erythrocytosis Hypoproteinemia with dehydration
N	↑	Hyperproteinemia Anemia with dehydration
↓	↑	Anemia with dehydration Anemia with pre-existing hyperproteinemia
↓	N	Non-blood loss anemia, normal hydration
N	N	Normal hydration
		Dehydration, after secondary compartment shift Dehydration, with pre-existing anemia and hypoproteinemia
		Acute hemorrhage
↓	↓	Blood loss anemia Over-hydration

↑, Increase; ↓, decrease; N, normal.

established, the volume needed to replace the patient's fluid deficit can be calculated:

$$\% \text{ dehydration} \times \text{body weight (kg)} = \text{fluid deficit (L)}$$

The **calculated fluid deficit** can be given quite rapidly to an adult horse (10–20 L isotonic fluids/h) with frequent reassessment. The response to therapy should be monitored closely, especially in patients that may be **hypoproteine-mic** or experiencing **capillary leak syndrome** and leaking plasma proteins into interstitial spaces. Improved mucous membrane color and refill, decreased skin tenting (increased turgor), decreased heart rate, urination, and warming of cool extremities indicate a response to therapy. Serial PCV and TP evaluations should be obtained and the rate of fluid administration adjusted accordingly. If the total protein approaches 4.0 g/dL, the patient should be monitored closely for signs of pulmonary and upper airway edema that can result in acute respiratory distress and death.

Fluid administration is best achieved using a 14 gauge or larger catheter aseptically placed in the jugular vein. Size 10 gauge catheters are especially

useful for rapid fluid administration. A variety of types are available, but “over the wire” models with minimally thrombogenic material such as polyurethane have proved most useful. The catheter should be **securely sutured** to the skin to minimize its movement and the tension on the administration set. “Superglue” sparingly used at the venepuncture site is also helpful. Fluid administration is most commonly achieved with gravity flow using 5 L bags of commercial, sterile IV fluids. Mechanical pumps that can increase flow rates are available.

When available, **arterial blood gas analyses** provide the most accurate determination of acid-base status. Most equine patients suffering from endotoxemia experience some degree of **metabolic acidosis** (*q.v.*). Because the acidosis is primarily a result of decreased tissue perfusion and impaired lactate metabolism, rapid restoration of circulating blood volume in most cases of mild to moderate endotoxemia will produce dramatic improvements without buffer supplementation. Many commercial fluid preparations contain bicarbonate precursors such as acetate or lactate that also help to counter the effects of metabolic acidosis. **Sodium bicarbonate** is often chosen as a supplemental buffer because of its practicality, availability and compatibility when mixed with other fluids. However, it is **not compatible** with fluids containing large volumes of calcium. If sodium bicarbonate supplementation is necessary, the amount required can be estimated by:

$$\text{base excess (mEq/L)} \times \text{body weight (kg)} \times 0.3 = \text{base deficit}$$

Sodium bicarbonate administration is necessary when the base deficit is 10 mEq or greater and only after organic acidoses (lactate) are corrected by addressing perfusion with volume replacement and inotropes and pressors (*q.v.*). Over-administration of bicarbonate can cause hypernatremia and hyperosmolality as well as paradoxical intracellular acidosis and should be avoided. One gram of sodium bicarbonate provides 12 mEq of bicarbonate and 12 mEq of sodium. An isotonic solution can be obtained by mixing 50 g (600 mEq) of sodium bicarbonate in 4 L sterile water. Bicarbonate can also be administered safely with other isotonic fluids if the combined tonicity remains near normal (i.e. $<2 \times$ isotonic).

Alternatively, small amounts (1–2 L) of 5% sodium bicarbonate can be administered concurrently with large volumes of isotonic replacement fluids. Specific guidelines for fluid and electrolyte replacement are presented in the section on fluid therapy (*q.v.*).

Hypertonic saline

Based on their relative safety and beneficial effect, **isotonic replacement solutions** have been considered the fluid of choice for volume resuscitation of adult horses in hypovolemic shock for many years. However, there are certain disadvantages. In many instances, it is often necessary to administer **large volumes** (20–60 L) of isotonic fluids to achieve a desirable effect. Under field conditions, these volumes may not be readily available for many practitioners. In addition, maximum benefit is achieved from continuous rather than

bolus administration, which is time consuming for the practitioner and may not be safely undertaken by an unsupervised owner or trainer.

The time required to administer such large volumes of fluids safely can delay referral and pre-anesthetic time by hours. This time can mean the difference between success and failure for many critically ill patients, especially those suffering from **strangulating intestinal obstructions** (*q.v.*). If large volumes of isotonic fluids are administered too rapidly, complications (e.g. pulmonary edema, hypoproteinemia, anemia, phlebitis) can occur. Large volumes of sterile preparations are also expensive.

Hypertonic saline has been studied in a variety of endotoxemia models and shows promise as an inexpensive and rapid resuscitative fluid with administration of small volumes. In horses previously challenged with endotoxin, administration of **hypertonic saline** was associated with increased cardiac output, increased heart rate, and decreased pulmonary artery pressure. Plasma volume increased, as indicated by decreased PCV and TP concentrations, to a greater extent than can be explained by the small volume of fluid administered. Other benefits include improved arterial pressure and reductions in pulmonary and peripheral vascular resistance. Hypertonic saline also attenuated the effects of endotoxin on PCV, lactate production and arterial blood temperature and resulted in the development of less concentrated urine, natruresis, chloruresis and kaluresis.

The mechanism of action of hypertonic saline is believed to be due to increased plasma osmolality resulting in increased plasma volume expansion. A reflex arc involving the pulmonary osmoreceptors, efferent and afferent pathways and vagus nerve has been described, but its importance is not well known.

Little information is available on the use of hypertonic saline in clinical cases of equine endotoxemia. Although no clinical trials have been published, small volumes (4–6 mL/kg) of approximately 7% hypertonic saline have been used in patients needing rapid circulatory restoration or as part of pre-anesthetic stabilization. It should be administered over approximately 15 min and followed by 15–20 L (or greater amounts as needed) of isotonic fluids within 1–2 h. Serial re-evaluation of the patient's clinical parameters including lactate concentration, PCV and TP should be undertaken.

Until further studies on its mechanism of action and clinical application are completed, hypertonic saline is contraindicated in horses with **hyperosmotic states** (salt intoxication, water deprivation, heat prostration, certain renal diseases), exhaustion and electrolyte depletion, and hyperkalemic periodic paralysis. In addition, horses with maximal interstitial dehydration should be administered isotonic crystalloid prior or concurrent to hypertonic saline, in order to allow for fluid shifting from the interstitium to the plasma compartment and to prevent significant hyperosmolality.

PATIENT CARE PROTOCOLS FOR THE CRITICALLY ILL HORSE

INTRODUCTION

In recent years, large animal adult intensive care has made numerous advances. A better understanding of disease processes, expansion of the field

of veterinary emergency and critical care into equine medicine, improved medical and surgical techniques, and a commitment on the part of veterinarians and owners regarding the care of critically ill horses have been important to this progress. This section focuses on patient care protocols in the critically ill **adult** equine patient.

INITIAL PATIENT EVALUATION

Equine clinicians commonly encounter emergencies. In most instances, the presenting complaint will guide initial therapeutic and diagnostic efforts. In life-threatening situations, the “**ABC**” of **acute care** (**A**irway, **B**leeding, **C**ardiovascular) is attended to concurrently. First a patent airway is established and cardiopulmonary cerebral resuscitation performed as needed. Bleeding should be controlled by application of pressure and lacerated vessels ligated. Heart rate and rhythm, pulse character and peripheral perfusion must be assessed.

The physical examination and diagnosis of a critically ill adult equine patient must sometimes be performed simultaneously with life-saving treatment. Once the patient is stabilized, a more thorough physical examination can be performed to assess the degree of injury or illness with attention refocused on the primary problem. The examination should include evaluation of abnormalities in **attitude or mentation** (pain, anxiety, depression), **body conformation** (distended abdomen, obvious lameness/fracture) and evidence of **nasal discharge** (regurgitant food, blood, purulent exudate). **Colic** is the most common form of pain. However, encephalopathies, botulism, exertional rhabdomyolysis, hyperkalemic periodic paralysis and severe lameness (*q.v.*) can be confused with colic. Depression can result from a variety of disorders including neurologic, renal, hepatic and cardiac failure, enteritis and respiratory disease.

Abdominal distension with abdominal pain is usually due to large colon obstruction, but less commonly can be due to severe colitis or extensive small intestine distension (*q.v.*). Abdominal distension without pain can be due to ascites, peritonitis and pregnancy. **Regurgitant food** or gastric reflux at the nares may indicate dysphagia or excessive gastric fluid accumulation requiring immediate nasogastric decompression (*q.v.*). **Epistaxis** may signify a variety of respiratory disorders including guttural pouch mycosis, coagulopathies, ethmoid hematoma or pulmonary hemorrhage (*q.v.*).

Once the initial examination is completed and the patient is out of immediate, life-threatening danger, a thorough history can be obtained, problem list and rule outs considered, a diagnosis made and appropriate medical and/or surgical therapy initiated.

ACUTE RESPIRATORY DISTRESS

Etiology

Respiratory distress exists when the effort to breathe, as assessed by respiratory rate or effort, rhythm and auscultation, is disproportionate to the level of ventilation actually achieved. In most cases, a lesion of the upper and/or lower airways is the problem. In some cases, other underlying systemic

diseases such as cardiac and renal failure should be considered. Major categories of **differential diagnoses** for acute respiratory distress syndrome in horses include the following:

1. Upper airway obstruction, e.g. laryngeal paralysis (*q.v.*). Clinical hallmarks include stertor or stridor.
2. Lower airway obstruction, e.g. recurrent airway obstruction (*q.v.*). Clinical hallmarks include expiratory wheezing on auscultation and double expiratory efforts.
3. Parenchymal disease, e.g. pneumonia (*q.v.*).
4. Pulmonary vascular disease, e.g. pulmonary thromboembolism or infarctive pneumonia (*q.v.*).
5. Pleural disorders, e.g. pneumothorax and pleural effusion (*q.v.*).
6. Chest wall or diaphragm disorders, e.g. botulism or trauma (*q.v.*).
7. Abdominal distension, e.g. ascites or colonic torsion (*q.v.*).
8. “Look alike” disorders. These are non-respiratory origin causes of tachypnea or increased effort. Examples include hyperthermia, anxiety, hypotension, anemia and neurologic disease (*q.v.*).

Clinical signs

Evaluation begins with a history of the duration and progression of clinical signs as related to the respiratory tract. Concurrent or recent systemic illness should be investigated. Any history of recent trauma, such as a collision, fall or administration of oral medications with a balling gun, may be important to the diagnosis.

Physical examination includes rectal temperature, pulse and respiratory rate. Anxiety associated with respiration, flared nostrils, expiratory grunting, increased intercostal or abdominal effort and the presence of a “**heave line**” characterize respiratory distress. Upper airway obstruction may be associated with respiratory stridor, asymmetry of airflow from the nostrils, halitosis, abnormal sinus resonance and the presence of unilateral nasal discharge.

Thoracic auscultation at rest and with a **rebreathing bag** helps identify lung parenchymal disease. Mucous membrane color is assessed for cyanosis, hemorrhage, congestion and injection. If pleural fluid, pneumothorax, lung consolidation or a space-occupying mass is suspected, thoracic percussion should be performed. Serial arterial blood gas analysis and pulse oximetry help to monitor progression of disease and response to therapy.

A **thorough physical examination** helps localize the problem to the upper or lower airway. If an upper airway lesion is suspected, endoscopic examination should be performed immediately to evaluate the nasal passages, nasal septum, ethmoid turbinates, pharynx, larynx, guttural pouches and trachea. Radiography allows further evaluation of the upper airways. Abnormalities include increased soft tissue density, bony lysis or proliferation, fluid lines and distortion of the normal architecture of the head or larynx.

Abnormalities of the lungs, pleura and pericardium that can be demonstrated with radiographs and ultrasonography include obstructive space-occupying masses such as tumors, abscesses or hematoma, and diffuse disease such as lung consolidation, pleural effusion, hemothorax or pneumothorax (*q.v.*) resulting in reduced lung capacity.

The clinical signs and therapeutic approaches for common problems resulting in respiratory distress are described in Table 23.12.

Treatment

A **tracheotomy** should be performed in cases of obvious or potentially life-threatening upper airway obstruction. Although the procedure is usually performed at the junction of the proximal and middle thirds of the neck, it is important that the tracheotomy is distal to the upper airway obstruction.

Once the site is determined and aseptically prepared, local anesthetic is infiltrated into the skin and underlying cutaneous muscle in a linear fashion. The horse's head is then stabilized, the skin tensed, and a 6–8 cm longitudinal incision is made through the skin and cutaneous colli muscle, exposing the paired sternothyroid muscles. These deeper muscles are then separated along their median raphe with a scalpel or scissors to expose the trachea. The tracheotomy is performed by **transverse incision of the annular ligament** between two centrally located cartilaginous rings. The incision should be just slightly wider than the tracheotomy tube for ease of placement and be limited to one third of the tracheal circumference to maintain tracheal stability and minimize complications of wound healing. The tube is secured in place and, if the site of obstruction has been bypassed, air should flow easily through the tube and the horse's respiration return toward normal. It is important to confirm or have strong suspicion of an upper airway obstruction before performing a tracheotomy. Critically ill horses suffering from lower airway obstruction or endotoxemia can have very little airflow at the nares, mimicking an upper airway obstruction. In these cases a tracheotomy will not help.

Thoracocentesis should be performed if the horse is in respiratory distress due to accumulation of effusion, blood or air within the pleural space. The preferred site is the **sixth or seventh intercostal space** just dorsal to the costal-chondral junction for fluid accumulation, but the caudodorsal region for pneumothorax. Ultrasonography should be utilized to select an appropriate site whenever possible. Free blood within the pleural space should not be tapped unless it is the source of hypoventilation or respiratory distress. Any fluid obtained should be submitted for cytologic examination and microbiologic culture (aerobic and anaerobic culture and antimicrobial susceptibility testing). Repeated thoracocentesis or placement of a chest drain may be warranted if fluid or air reaccumulates rapidly.

If blood loss is severe, IV fluid therapy and replacement with whole blood may be necessary. In the case of **hemothorax**, the cause of the hemorrhage should be treated if possible. For example, **fractured ribs** (*q.v.*) are common in foals and should be stabilized. Cases of uncomplicated trauma usually respond quite well, although secondary infection and pleural pneumonia may affect the outcome. Broad-spectrum antimicrobial therapy is indicated in cases of **bacterial pleuropneumonia** (*q.v.*).

Intranasal oxygen insufflation or mechanical ventilation may be needed in severe cases of pulmonary edema, regardless of the underlying etiology. IV fluids, if required, should be administered cautiously in order to avoid potentiation of edema. **Diuretics** such as furosemide may be helpful, although the effects of furosemide on pulmonary hemodynamics in the presence of

Table 23.12 Characteristics and treatment of acute respiratory distress

Disease	Clinical signs	Other diagnostics
Upper airway obstruction, e.g. laryngeal paralysis, arytenoid chondrosis, tracheal stenosis, foreign body, neoplasia, abscessation	Anxiety with increased respiratory effort, decreased or absent airflow at nares; no or limited thoracic airflow auscultated: cyanotic mucous membranes	Obstruction observed endoscopically and/or radiographically
Pulmonary disease, pleuropneumonia	Fever, anorexia, depression, cough, weight loss, respiratory distress, pleural pain; airflow auscultated dorsally, minimal to none ventrally; pleural friction rubs	Thoracic percussion—dull resonance ventrally; ultrasound—hypoechoic and anechoic fluid in pleural space, increased density ventrally with horizontal fluid line. Leukocytosis, hyperfibrinogenemia
Hemothorax (may occur in conjunction with pneumothorax)	History of trauma, signs of coagulopathy, erosion of vessel by abscessation, neoplasia; lung sounds are normal dorsally, muffled ventrally; heart sounds may radiate widely; may be unilateral or bilateral	Thoracic percussion—normal dorsally, dull ventrally; radiographs—increased density ventrally, normal lung dorsally; ultrasound—blood in pleural space
Pneumothorax	History of trauma or disease with airway or parenchymal erosion, i.e. neoplasia or abscessation, difficult to auscultate air sounds especially dorsally	Thoracic percussion—abnormal resonance dorsally; radiographs—evidence of air in pleural space or mediastinum; ultrasound
Pulmonary edema	Often a life-threatening complication of other disease (renal failure, cardiac failure, sepsis, DIC, hypoxic acidosis) or over-zealous fluid administration. Auscultation—shallow rapid respirations with crackles, \pm clear or frothy fluid at nares	Radiographs—peribronchial and perivascular cuffing, increased prominence of vessels, hazy reticular pattern
Disease	Treatment	
Upper airway obstruction, e.g. laryngeal paralysis, arytenoid chondrosis, tracheal stenosis, foreign body, neoplasia, abscessation	Relief of obstruction Tracheotomy distal to the site of obstruction	
Pulmonary disease, pleuropneumonia	Thoracocentesis for culture and sensitivity and cytologic examination, to remove large volumes of fluid; may repeat or leave indwelling catheter in place Antibiotics	
Hemothorax (may occur in conjunction with pneumothorax)	Thoracocentesis to remove blood May need to repeat if reaccumulates Broad-spectrum antibiotics. Treat the source of hemorrhage if possible, e.g. fractured ribs	
Pneumothorax	Thoracocentesis to remove air. Repeat as necessary or indwelling catheter. Treat source	
Pulmonary edema	Treat underlying disease. Intranasal/tracheal oxygen; decrease rate or stop IV fluids. Diuretics—furosemide (1–2 mg/kg IV), NSAID (flunixin meglumine 0.1 mg/kg), corticosteroids (50–100 mg adult horse)	

DIC, disseminated intravascular coagulation.

pulmonary edema have not been studied. Plasma products may help to increase oncotic pressure, but these should also be administered cautiously since colloids increase vascular pressure. In addition, colloids may extravasate into pulmonary edema fluid in capillary leak states such as acute respiratory distress syndromes.

NSAIDs, antihistamines and corticosteroids may also be useful in treating some forms of pulmonary edema, particularly those caused by inflammatory or allergic states.

EXERTIONAL RHABDOMYOLYSIS

Exertional rhabdomyolysis (*q.v.*), otherwise referred to as azoturia, Monday morning disease, tying up and paralytic myoglobinuria, can be a severe, life-threatening condition. It is of particular importance in draft breeds, but can occur in light breeds as well.

Etiology

Classically, the disease has been described in draft horses following Sunday's day of rest, hence the name Monday morning disease. In the light breeds, exertional rhabdomyolysis often occurs in fit horses in **rigorous training** programs that are rested for a period of time while being maintained on the same **high concentrate diet** required while in work. The disease occurs once the horse returns to work, even after light exercise. Sudden increases in exercise level may also be associated with sporadic forms of the disease. Exertional myopathies may also be observed in horses that are **inadequately fit** for competition and over-exerted. Disease pathogenesis is poorly defined. A variety of factors that result in metabolic alterations of the muscle, mitochondrial function and electrolyte and fluid balance are involved.

Two specific heritable syndromes have been recently described: **polysaccharide storage myopathy (PSSM)** and **recurrent exertional rhabdomyolysis (RER)**. PSSM mostly affects **Quarter-horses** and Quarter-horse crosses (Appaloosas, Paints). It is a glycogen storage disorder with accumulation of glycogen and abnormal polysaccharide with enhanced insulin sensitivity. Another similar syndrome occurs in draft breeds. RER primarily affects **Thoroughbreds**. It is due to a defect in intracellular calcium regulation, with subsequent muscle hypercontraction and necrosis. Nervous animals are most commonly affected, with young race fillies being over-represented.

Clinical signs

Clinical signs are variable. During **acute episodes** of rhabdomyolysis, horses walk with a stiff, stilted gait and may have muscle fasciculations. Severe cramping results in reluctance or inability to move. In extreme cases, animals are recumbent and unable to rise. Typically, muscles of the back and hindlimbs are tight and painful to palpation. These horses are often anxious, sweat profusely and have elevated vital signs. Exacerbation of the condition may occur during attempts to move the affected horse. Myoglobinuria occurs in severely affected animals.

Creatinine phosphokinase (CPK) and aspartate aminotransferase (AST) levels rise markedly with rhabdomyolysis. CPK levels increase rapidly, peaking at 4–6 h after muscle damage has occurred and returning to normal levels in 36–72 h. Levels of AST rise more slowly, peaking at 24–48 h and declining by 2–3 wk after the insult. The **degree of elevation** often reflects the extent of myonecrosis. Therefore, serial evaluation of both enzymes to monitor the progression of the disease and rate of recovery is suggested.

Treatment

Treatment of the severely affected horse involves **preventing further muscle damage**, correcting metabolic abnormalities and dehydration, and providing analgesia in animals that are in extreme pain and reluctant to move. In severe cases, even walking back to the barn is contraindicated. In those cases, transport to a stall should be arranged. In mild cases with minimal muscle damage, hand-walking has proven to be beneficial. Experienced clinical judgment is necessary to ascertain which cases benefit from additional exercise.

In cases with **severe dehydration** or hypovolemia and electrolyte imbalances a balanced polyionic electrolyte solution should be administered IV or through a nasogastric tube. Many **endurance horses** suffering from this disease will be alkalotic with hypochloremia and hypocalcemia, and therefore bicarbonate therapy should be avoided. **Myoglobin can be nephrotoxic**, especially in the dehydrated animal. Myoglobin possesses vasoactive properties that in the dehydrated horse may encourage the development of **renal ischemia** (*q.v.*) and tubule damage, and its presence warrants IV fluid diuresis. Serial monitoring of the PCV, TP, serum electrolytes and creatinine should be performed.

NSAIDs, such as phenylbutazone or flunixin meglumine, help relieve muscle pain and spasm. Acepromazine reduces anxiety and improves peripheral blood flow through α -adrenergic blockade. In extremely anxious horses, small doses of xylazine, butorphanol or detomidine may be indicated.

Good nursing care is essential. A warm, comfortably bedded stall in an environment that encourages the horse to rest is important. The horse should not be forced to stand if it wishes to remain recumbent. However, **prolonged recumbency** in one position can be detrimental, and frequent repositioning may be necessary. If the patient remains recumbent for a long period, a **padded helmet** helps protect the head and eyes, and **ocular lubricant** and antibiotic ointments help prevent corneal ulcers.

Intermittent slinging of recumbent horses for short periods is beneficial in some cases. The distal limbs should be bandaged to prevent self-trauma. Massage and warm blankets may also encourage muscle relaxation and blood flow. A variety of hand-held electric, pulsating massagers or therapeutic ultrasound units are commercially available. Using light pressure, the massager is directed in a circular motion over the large muscle groups for 10–15 min 2–4 times daily. Severely affected horses with painful muscles may object to this technique.

Prevention of rhabdomyolysis episodes in horses with RER or PSSM includes **dietary and exercise management**. These horses should be fed diets low in simple carbohydrates, meaning no grain for horses with PSSM and less

than 2–2.5 kg per day for horses with RER. Additional calories should be provided in the form of fat. Exercise management includes regular exercise and turnout rather than stall confinement.

ACUTE RENAL FAILURE

Etiology

Nephrotoxicity and ischemia are the most common causes of acute renal failure (ARF) (*q.v.*), which is associated with **acute tubular necrosis**. Clinical signs and progression of the disease are dependent upon the severity of the insult and therapeutic aggressiveness.

Box 23.4 includes a list of common causes of acute renal failure in the horse.

Clinical signs

The clinical signs of ARF are similar regardless of the etiology and are often overshadowed by signs of the primary disease. **Azotemia** (*q.v.*), as indicated by increases in creatinine and BUN, can be caused by pre-renal, primary renal or post-renal problems. Initially, oliguria will be present; only rarely will anuria occur in the adult horse. Pre-renal azotemia, due to hypovolemia, is associated with decreased urine production and highly concentrated urine. Renal azotemia results in isosthenuria despite dehydration.

If oliguria and isosthenuria persist after rehydration, tubular damage has occurred, signifying renal disease. Following this acute oliguric phase, diuresis accompanied by polydipsia and polyuria can persist for many weeks while tubular cell regeneration occurs.

In ARF, the **left kidney** may be swollen and painful to palpation per rectum. In severe cases, the right kidney may also be palpated. Ultrasonographic evaluation can reveal renal enlargement and changes in parenchymal architecture due to inflammation, hemorrhage, edema or infiltrative disease.

Box 23.4 Common causes of acute renal failure in the horse

Nephrotoxicities

- Aminoglycosides
- NSAIDs
- Vitamin D
- Mercury

Hemodynamic causes

- Hemorrhagic shock
- Endotoxic/septic shock
- Heart failure
- Coagulopathies

Immunologic causes

- Drug-induced interstitial nephritis
- Glomerulopathy

Ultrasound-guided **percutaneous renal biopsy** can confirm the diagnosis and aid in provision of a prognosis. Ischemia often damages tubular epithelial cells and basement membrane while toxicities may damage only the epithelial cells, leaving the basement membrane intact. **Urinalysis** (*q.v.*) is important in the differentiation of pre-renal and primary renal disease. Table 23.13 outlines common abnormalities of urinalysis and their causes.

Serum electrolyte concentrations vary depending on the degree of renal failure, water loss and concurrent disease processes. Severe tubular disease may cause total body sodium depletion but, because of accompanying water loss, plasma sodium concentration may remain normal. **Hyponatremia** may also occur with acute renal failure. **Hypernatremia** can occur with acute oliguria or anuria, but is most commonly associated with hypovolemia due to gastrointestinal obstruction or diarrhea. Increased sodium conservation by the kidney is counterbalanced by electrolyte loss into the gut lumen and feces. Chloride loss tends to follow sodium concentrations.

Because the kidney is the main site of potassium excretion, **hyperkalemia** may occur with acute oliguria or anuria. Unlike other species, the horse's major site of calcium regulation is the kidney. During chronic renal failure (*q.v.*), hypercalcemia and hypophosphatemia can occur, while hypocalcemia and hyperphosphatemia are often present with acute disease. Acid-base balance may also be disturbed if there is a failure to conserve bicarbonate and/or excrete hydrogen ions (renal tubular acidosis).

Treatment

Treatment of ARF is initially directed at **replacing fluid volume deficits** and **correcting electrolyte and acid-base abnormalities**. IV administration of a **balanced polyionic solution** is sufficient in most cases. During polyuria, additional sodium and chloride replacement may be necessary in order to match fluid input with output. However, excessive administration of sodium can result in sodium retention and edema formation. During oliguric renal failure, the volume of fluid administered and electrolyte balance should be monitored very carefully. Changes in daily body weight, PCV and central venous pressure (CVP) help assess plasma volume expansion.

Table 23.13 Common abnormalities of urinalysis and their causes

Abnormality	Cause
Small volume, highly concentrated urine	Hypovolemia, dehydration
High volume, dilute urine or isosthenuria	Polyuric phase of failure
Blood	Polydipsia or fluid administration
Hemoglobin	Intravascular hemolysis
Erythrocytes	Acute glomerular damage, hemorrhage into the urethra, bladder or ureters
Protein	Glomerular damage. Tubular failure to absorb
Glucose	Renal threshold exceeded, renal tubular damage and failure to absorb
Sediment	
Hyaline casts	Seen in a variety of systemic diseases; not necessarily indicative of renal disease
Granular and epithelial casts	Formed from diseased tubules

Attempts should be made to determine **daily fluid intake and urine output**. Urine collection in the male can be accomplished by strapping a urine collection device around the abdomen. In mares, an indwelling Foley catheter attached to a closed collection system can be used.

During oliguric renal failure, an IV solution of 20% mannitol (0.25–1 g/kg) and furosemide (1 mg/kg q 2h) may help improve urine production. Failure to respond to **furosemide** may indicate severe tubular disease. Low doses of **dopamine** (1–5 µg/kg/min) can be used in conjunction with furosemide during oliguria or anuria in an attempt to improve renal blood flow through vasodilation. Recent evidence in human critical care suggests that low dose dopamine therapy may not be indicated in patients with oliguric/anuric renal failure despite successful urine production, due to an increase in oxygen consumption by the renal tubular epithelium. However, because hemodialysis is currently not readily available for adult horses, dopamine is still indicated for use in anuric/oliguric renal failure by promoting urine flow, thereby providing time for regeneration of the renal epithelium.

High doses of dopamine produce α -adrenergic vasoconstriction with possible systemic hypertension. Therefore, **blood pressure** must be monitored during the dopamine infusion. Hypotension should be treated aggressively in ARF patients with the use of crystalloids, colloids, and inotrope and pressor agents (*q.v.*).

Most cases of ARF in adult horses are **non-oliguric** and do not require mannitol, furosemide or dopamine. Plasma-Lyte 148, lactated Ringer's solution, Hartman's solution, sodium chloride (0.9%) or other **balanced polyionic solution** can be administered at 48–100 mL/kg/day until a significant decrease in serum creatinine is observed. It is not uncommon for creatinine to stay high without decreasing for up to 72h of fluid therapy. IV fluid therapy should be continued at 10–20 mL/kg/day until the serum creatinine is normal. Once a steady state has been achieved, and the patient is eating and drinking adequately, IV fluids may be gradually discontinued over the next several days. Renal function should be re-evaluated after discontinuing therapy to assure against relapse of the condition.

Prognosis

Generally, ARF due to **toxicity** (except with heavy metals) has a reasonable prognosis and will respond to therapy unless persistent oliguria develops. **Hemodynamic causes** of renal failure have a more variable prognosis, but often respond to therapy if the underlying disease (such as colitis) can be corrected. If renal histopathology reveals an intact basement membrane, and appropriate therapy corrects the underlying cause, the prognosis is good. Patients with perirenal edema and marked renal enlargement have a poorer prognosis, as do horses with chronic disease.

ACUTE CRANIAL AND SPINAL CORD TRAUMA

Etiology

Acute trauma to the CNS (*q.v.*) is relatively common in the horse. Unfortunately, regardless of the location of the lesion, it can be one of the most debilitating

injuries. Falls at high speeds, collisions and penetrating wounds can result in fractures or **subluxation of the vertebral column** (*q.v.*). Falling over backwards with concussion to the poll is common in young horses and may result in **basilar fractures** of the basioccipital or basisphenoid bones. In most cases, the fracture or subluxation is not the primary problem; rather, the underlying neural damage results in the greatest morbidity and mortality.

With acute disruption of neural tissue the degree of clinical dysfunction is proportional to the degree of compression, traction or crushing involved. Progressive changes following the initial injury are common and are often due to vascular damage. **Ischemic injury** to the brain or spinal cord results in secondary injury, including release of free radicals, prostaglandins and other vasoactive compounds that in turn cause further inflammation. As neural tissue becomes more edematous within the confines of the cranium or vertebral canal, vascular occlusion and tissue compression increase. Hemorrhage causes further vascular compromise and exacerbates edema formation.

Clinical signs

Thorough physical examination to assess involvement of other organs and stabilization of life-threatening lesions are the first steps. Respiratory rate and character, hydration and volume status, and the presence of other fractures or severe injury should be addressed first. Hypoxemia, hypercapnia, and hypovolemia or hypotension can significantly worsen secondary injury and subsequent prognosis for recovery. These should be avoided or treated immediately when found on initial examination or clinicopathologic assessment.

An accurate description of how the injury occurred and the horse's condition at the time of injury are important for rapid localization of the CNS lesion(s) and for comparison with the present condition. **Neurologic examination** (*q.v.*) includes evaluation of the patient's mentation, ocular response and position, vestibular system, posture and motor function. Additional diagnostics that may be necessary include radiography and myelography. **Cerebrospinal fluid** is commonly xanthochromic with an increased protein, but can be normal. In cases of severe trauma, frank hemorrhage may be observed. Hemorrhage noted in the external ear canal can be due to cranial fractures. **Bilateral epistaxis** may be associated with basilar fractures of the cranial vault, although it may also be seen with guttural pouch or other bleeding.

Treatment

Treatment of acute, traumatic neurologic injuries is aimed at control and prevention of cerebral edema and/or hemorrhage. Supportive care to maintain hydration and prevent infection and self-trauma should be instituted early. Patients should be **routinely re-evaluated** during therapy to assess progress. Oxygen insufflation and ventilation may be required in patients with severe hypoventilation.

Many horses that are involuntarily recumbent can be quite violent and may require **sedation** to prevent self-inflicted trauma. Phenothiazine derivatives may lower the seizure threshold and should be **avoided** in horses with intracranial disease. Ketamine and xylazine are **contraindicated** in horses with cranial trauma because of their hypertensive effects, especially in cases

of known cerebral hemorrhage. Chloral hydrate (15–60 g IV, to effect) can be used in the adult horse for sedation and to control seizures. If this fails, IV anesthesia with **pentobarbital** is usually successful. **Diazepam** (0.1 mg/kg IV) may be administered four to five times at 3–4 min intervals to the recumbent patient for sedation and seizure control.

The patient should be monitored closely while sedated or anesthetized for changes in heart and respiratory rates and rhythms, and response to external stimuli. Indirect blood pressure measurements should be made to avoid hypotension and reduced perfusion.

When possible, **arterial blood gases** should be monitored, especially in patients with abnormal breathing patterns or rates. Increases in arterial CO₂ can cause cerebral vasodilation and encourage **intracranial hemorrhage**. If hypercapnia is present, increasing the minute ventilation will help decrease the CO₂. This is best accomplished in the ICU using a mechanical ventilator that can blend oxygen and compressed air and provide a large enough tidal volume to ventilate an adult horse. Although most clinical information on the ventilatory management of acute head trauma comes from small animals and humans, the principles can be applied to the care of large animals if the equipment is available. Current recommendations from human critical care include mild hyperventilation to normoventilation, with a goal of 32–40 mmHg for PaCO₂.

Corticosteroids have been recommended for the control of CNS pressure caused by edema of the spinal cord and are most beneficial when administered early in the course (within 8 h of spinal cord injury). The use of corticosteroids for head trauma is controversial in human medicine and may be contraindicated. Dexamethasone (0.1–0.2 mg/kg) can be administered q 12–24 h for 1–2 days to reduce edema formation and inflammation associated with spinal cord injuries.

Mannitol (0.25–2 g/kg IV) in a 20% solution generally works rapidly and can be useful in reducing cerebral edema. It is a hypertonic solution and should be used with caution in the presence of ongoing intracranial hemorrhage. If the hemorrhage is not under control, decreasing the edema may increase available space for hemorrhage. Over-hydration with supportive maintenance fluids should be avoided.

Hypertonic saline (1232 mmol Na/L) has recently been advocated in human critical care. Doses suggested include 2 mL/kg every 4 h for 5 infusions. The hyperosmolar infusions aid in reducing extravascular volume of the brain.

Dimethyl sulfoxide (DMSO) has been used to treat acute neurologic trauma. The recommended dose of 1 g/kg in no greater than a 20% solution is administered IV q 24 h for 3 days. The use of DMSO in CNS trauma remains controversial.

Antimicrobial therapy should be instituted in cases with suspected basilar skull fractures and blood in the nasal passage or ear canal. Antibiotics should be considered in recumbent patients who are more susceptible to respiratory infection. Trimethoprim–sulfadiazine (5 mg/kg of trimethoprim portion, IV or PO, b.i.d.) is a good choice although other broad-spectrum drugs should achieve adequate levels in the CNS with blood–brain barrier disruption. Tetanus prophylaxis is also important.

Good nursing care for the recumbent horse is essential. If possible, the patient should be attended by a trained assistant who can recognize changes in condition, help prevent self-trauma and manage the necessary support equipment. Patients that are able to sit sternally can be propped up using pads or bales of straw. **Ventilatory and circulatory problems will be minimized if the patient can maintain sternal rather than lateral recumbency.** In lateral recumbency, large foam mats or deep bedding should be used and repositioning performed q 2–6 h to help prevent compartmental syndrome and to maintain adequate respiratory function. Large mats, designed to pad the walls of the stall, help prevent self-trauma in violent patients. Sharp, hard or immobile objects such as buckets, feed tubs, salt lick holders, and hay racks should be removed or be padded. Helmets can be used to protect the head from self-trauma, and the head should be elevated by 10° in head trauma cases to minimize intracranial pressure.

A sling may help support patients that can bear some weight or are weak and cannot get up without assistance. It can also facilitate the repositioning of large patients. Those patients that tolerate the sling require **constant observation** to prevent self-trauma by entanglement or asphyxia. They should be allowed to lie down and rest intermittently. Some horses must be assisted to lie down.

Decubitus is a serious problem in the recumbent horse and usually develops over pressure points such as the tuber coxae, tuber ischii, point of the shoulder, zygomaticotemporal protuberance, lateral malleolus and greater trochanter. Prevention focuses on minimizing pressure over these points by applying **extra padding** or redistributing the pressure by **frequent patient repositioning**. Deep, dry bedding that is highly absorbent and provides good footing should be used. Non-abrasive thick mats are helpful. Wet skin should be towel dried. Grooming and massage can also stimulate circulation and encourage the development of healthy skin. If decubitus develops, infrared laser therapy can be employed once to twice daily for a period of time proportional to the size of the wound. The beam should be set at medium and used with constant motion over the wound to prevent blistering.

The eyes should be protected from **corneal abrasion** with an ophthalmic **lubricant** applied every 4–6 h. Products containing corticosteroids should be avoided. Ophthalmic antimicrobial products should be utilized if a corneal ulcer is present. Rubber helmets are available that not only protect the eye but the head as well. If the patient is unable to blink, care should be taken to assure the down eyelid is closed and that the bedding is non-abrasive or covered with soft padding. If a corneal ulcer is suspected, **fluorescein staining** (*q.v.*) should be performed and appropriate therapy instituted.

Prolonged recumbency and the associated lack of normal exercise, interruption in feeding schedule, and decreased water intake may result in the development of **colic**, most commonly from **impactions of the large intestine** (*q.v.*). Animals that can eat and drink should be offered fresh water frequently (q 2–4 h) and highly digestible feeds. In animals unable or unwilling to drink or eat, nasogastric intubation with water may be necessary unless IV fluids are provided. **Hypotension** must be avoided at all costs in horses with neurologic injury.

Table 23.14 Recipe for hyperalimentation diet

Maintenance electrolyte mixture (daily requirement for 450 kg horse)							
Sodium chloride (NaCl)	10 g						
Sodium bicarbonate (NaHCO ₃)	15 g						
Potassium chloride (KCl)	75 g						
Potassium phosphate (dibasic anhydrous) (K ₂ HPO ₄)	60 g						
Calcium chloride (CaCl ₂ 2H ₂ O)	45 g						
Magnesium oxide (MgO)	24 g						
Recommended tube feeding schedule (for 450 kg horse)	Day						
	1	2	3	4	5	6	7
Electrolyte mixture (g)	210	210	210	210	210	210	210
Water (L)	21	21	21	21	21	21	21
Dextrose (g)	300	400	500	600	700	800	900
Dehydrated cottage cheese (g)	300	450	600	750	900	900	900
ME (Megacalories/day)	2.4	3.8	4.4	5.4	6.4	6.8	7.2

The above allowances should be divided up and fed in three feeds daily. Alfalfa meal is added to make a slurry.

Hyperalimentation can be initiated using alfalfa meal gruel or other liquid diets administered by **nasogastric tube** (Table 23.14). Alternatively, a complete pelleted diet, such as Equine Senior (Purina) or other product, can be blended to a slurry and easily administered via nasogastric tube. Impactions (*q.v.*) can be treated with laxatives, mineral oil and IV fluids. Ileus (*q.v.*), not uncommon in the recumbent patient, precludes oral intake and necessitates IV fluid support when present. **Manual evacuation of the rectum** several times a day may be necessary since many recumbent patients are unable to exert sufficient abdominal pressure for defecation.

Recumbent patients that are reluctant or unable to urinate require continuous or intermittent **urethral catheterization**. Long-term catheterization is best accomplished by using an aseptic, closed system. Complications of catheterization include cystitis and ascending pyelonephritis. Antimicrobial therapy should be directed by urine culture and sensitivity.

LAMINITIS

Etiology

The development of laminitis (*q.v.*) is not clearly understood. Possible causes include carbohydrate overload, endotoxemia, sepsis, excessive unilateral weight bearing and administration of corticosteroids. Laminitis often occurs as a complication of serious systemic disease and frequently has a **fatal outcome**. Due to the numerous predisposing factors and systemic pathologic events associated with laminitis, therapy is often complicated and controversial.

Clinical signs

Acute laminitis may affect one or more feet. Usually both front feet are affected, and the horse will stand with the hind legs well under the body and

front legs extended with weight on the front heels. If all four feet are affected, the horse will stand with the legs tucked under the body to form a narrow base stance. In either case, the horse will often lie down for extended periods of time.

Classically, the laminitic horse is in pain and reluctant to move, with tachycardia, tachypnea and muscle trembling. The affected feet have increased warmth and digital pulses. **Pain** can be elicited from the sensitized sole, usually in the toe region, with or even without hoof testers. In severe cases, the coronary band becomes edematous with clefting, and may ooze serum and blood. **Penetration of the sole** after rotation and/or sinking of the third phalanx can also occur. Lateral radiographs of the foot help evaluate the degree of rotation and/or sinking of the third phalanx.

Treatment

The goals of therapy are outlined in Box 23.5.

Box 23.5 Goals of therapy in laminitis

1. Treat the primary illness if one exists

Treatment will vary with the systemic disease associated with laminitis. However, a few principles should be kept in mind. Dehydrated animals require fluids to replace volume deficits. Broad-spectrum antimicrobials, flunixin meglumine (0.25 mg/kg IV q 8 h) and endotoxin antisera should be considered in suspected cases of septicemia and endotoxemia (*q.v.*). In cases of **grain overload** (*q.v.*), mineral oil administered by nasogastric tube may slow the absorption of endotoxin, and adsorbents such as activated charcoal or smectite (ditrioctahedral smectite: Bio-sponge, Platinum Performance, Buellton CA, USA) may reduce the extent of endotoxin absorption.

2. Provide analgesia

NSAIDs, especially phenylbutazone, have been useful in the treatment of laminitis, and act by decreasing inflammation, edema and pain in the digit. Dosage of phenylbutazone is dependent upon the degree of discomfort and ranges widely, but is most commonly 2.2 mg/kg IV/PO q 12–24 h. A maximum of 4 mg/kg q 12 h should not be exceeded, and the dosage should be reduced within 4–5 days in order to minimize NSAID toxicity. To avoid drug toxicity (e.g. gastrointestinal ulceration, diarrhea, azotemia, renal papillary necrosis) the minimum dose that provides adequate analgesia should be used. Some clinicians consider that the degree of analgesia provided should not be complete, but rather a **balance** between providing some relief and not providing enough to encourage standing or increased ambulation with increasing risk of **damage to laminae**.

Padded floors and deeply bedded stalls improve phalangeal support and digital comfort and provide protection for recumbent animals. Straw mixed with wood shavings, sand and peat moss are good choices, although if the patient is frequently recumbent, sand can be abrasive and contribute to

Box 23.5 continues on page 1312

Box 23.5 Goals of therapy in laminitis [continued]

decubitus. With increasing comfort, mild exercise encourages a return of normal digital circulation.

Local anesthesia with **digital nerve blocks** (*q.v.*) has been advocated in the early phase to relieve pain transiently, to promote digital vascular dilatation and to encourage weight bearing. However, this is controversial as it can promote increased **laminar damage** by encouraging ambulation and shearing.

Although **some exercise** may be warranted in the early phase to encourage normal circulation in the foot, too much exercise may increase the mechanical forces producing third phalanx rotation. Therefore, nerve blocks should be used judiciously. Slinging in a pool has been used successfully to provide pain relief and exercise with reduced weight bearing in some recumbent patients.

3. Promote normal circulation of the digit

Laminitis is thought to occur as a result of two interrelated mechanisms: a **vasoactive process** and a **coagulopathy**. More recent work indicates involvement of zinc metalloproteases. Although there is an overall increase in blood flow to the foot, ischemia develops from decreased capillary perfusion in the laminae due to bypass of blood through arteriovenous shunts regulated by vasoactive hormones and toxins. Pain and subsequent catecholamine release contribute to vasoconstriction by activation of α -adrenergic receptors within the dermal vasculature. Alterations in the intrinsic coagulation system have also been identified.

Acepromazine (0.04 mg/kg IV/IM 3–6 times a day) and phenoxybenzamine (2 mg/kg PO *b.i.d.*) have been used to **reduce vasoconstriction** by non-competitive α -adrenergic blockade. Hypotension can occur with these drugs and they should be used cautiously in hypovolemic patients. The **sedative effects** of acepromazine are also beneficial and may encourage the horse to lie down.

Heparin has been used to prevent coagulation within the microcirculation in the foot. Unfortunately its efficacy in the treatment of laminitis is unknown, and the use of unfractionated heparin is associated with erythrocyte agglutination. Unfractionated heparin has been used at a variety of dosages, most commonly 40–70 IU/kg SC or IV *q* 8–12 h. Low molecular weight heparin (dalteparin, 50 IU/kg SC *q* 24 h) is associated with fewer side effects in humans and horses, and may be more effective in preventing thrombosis, although further study is required. **Aspirin** (10–20 mg/kg PO every other day) is a potent inhibitor of platelet aggregation and thromboxane synthesis, and may help minimize coagulation within the microvasculature of the foot.

DMSO, an anti-inflammatory agent and free radical scavenger, has been used to prevent reperfusion injury of the laminae although its efficacy in the treatment of laminitis is unproven. The recommended DMSO dose is 1 g/kg IV diluted to a 10% or less solution daily for 3 days.

Box 23.5 continues on page 1313

Corticosteroids are **contraindicated** in treatment of laminitis because they enhance the vasoconstrictive effects of catecholamines and may contribute to the development of laminitis.

The use of hot and/or cold soaking of the foot remains controversial. Since the foot is ischemic, decreased temperatures may decrease the metabolic demands for oxygen. However, increasing the temperature may promote vasodilatation and increase capillary perfusion. **Icing of the feet** has recently been advocated.

4. Prevent further rotation/sinking of the third phalanx

Sand stalls provide good sole support, reduce the mechanical forces required to flex and extend the digit and allow the horse to stand in a comfortable position. Cushioning the sole with supportive material, such as foam, cast material, Orthoplast, soft rubber and silicon, has been advocated but care must be taken to distribute the weight **evenly** to avoid point pressure and sole necrosis. Support of the frog with pads or shoes is useful in some cases, but may complicate compression of the vasculature between the third phalanx and the sole and subject the horse to more pain.

In advanced cases, **hoof wall resection** may be necessary to remove necrotic debris and relieve the pressure from fluid accumulation between the third phalanx and hoof wall. Resection should only be considered when there is serous or purulent drainage from the coronary band or when the hoof wall is completely separated from the skin and gas lucencies are visualized radiographically between the hoof and the third phalanx.

Pain that is refractory to other shoeing techniques may be relieved with hoof wall resection. If complete separation is evident, the entire toe is usually resected and may extend to the coronary band—hoof wall junction. A power rotary burr is commonly used although hoof nippers, rasp and cast cutters can be substituted. The cuts are made to the level of the stratum medium, where a texture change should be felt. The affected wall can be gently peeled away from the laminae and necrotic debris removed. Care must be taken to avoid damaging the coronary band.

After hoof wall resection, the foot must be aseptically bandaged and cleansed daily until healthy horn covers the exposed wound. Healing proceeds by granulation. Once the corium covers the granulation tissue, new horn is produced, accompanied by growth from the coronary band. During the growth period strict attention to asepsis must be maintained and areas of infection adequately drained. Exercise should be limited to stall confinement. Depending on the amount resected, 6 mo to 1 yr should be allowed for hoof regrowth.

Prognosis

The prognosis for laminitis is always **guarded**, particularly if rotation or distal displacement of the third phalanx is evident. The prognosis is good for horses with mild laminitis that respond to anti-inflammatory/analgesics and rest almost immediately. If the duration is short and the symptoms mild,

lameness can be controlled with proper shoeing and low doses of analgesics. If the third phalanx is severely rotated or sunken with sole penetration, euthanasia is often recommended due to the poor prognosis and extensive care required for further treatment.

ACUTE ABDOMINAL CRISIS (COLIC)

Etiology

Despite significant advances in prevention and treatment, colic (*q.v.*) remains a relatively common problem associated with a high degree of morbidity and mortality. A wide variety of intestinal and non-intestinal causes can result in colic (Table 23.15), of which most respond to analgesic therapy alone. In more serious cases, early detection and referral for intensive therapy or surgical intervention can dramatically improve prognosis and outcome.

Physical examination and diagnosis

A thorough history with emphasis on the husbandry, previous episodes of illness, and duration and severity of present condition should be completed. General questions that should be asked are listed in Box 23.6.

The **physical examination** starts with observation of the horse's general appearance and attitude. Horses with abdominal pain that is unrelenting or minimally responsive to analgesics more often have a lesion requiring surgery. Horses that are depressed or only intermittently painful have a better chance of responding to medical therapy. Evidence of **sweating** and **self-inflicted trauma** is consistent with previous uncontrolled pain.

Temperature, pulse and respiration rate are evaluated on initial examination and should be assessed intermittently to evaluate the progression of the disease. The **temperature** is usually normal, although it may be elevated from overexertion in the violently painful horse or in cases of enteritis or colitis (*q.v.*).

Patients in hypovolemic or endotoxic shock (*q.v.*) may have subnormal temperatures. **Pulse** rate and character, **mucous membrane** color, moistness and capillary refill time, skin turgor and temperature of extremities should be assessed as markers of circulating volume and hydration status. Direct or indirect blood pressure should be measured when available. Tachycardia (pulse greater than 52bpm), poor pulse pressure, cool extremities and dry mucous membranes with a prolonged capillary refill time reflect significant volume contraction and the need for IV fluid therapy.

Evaluation of the gastrointestinal tract includes auscultation and percussion of the abdomen, nasogastric decompression, rectal examination, abdominal radiography, abdominal ultrasonography and abdominocentesis. Although not inclusive, Table 23.16 includes a list of general findings when evaluating the intestinal tract of a colic patient.

Abdominocentesis should be performed in most cases of colic, particularly referral cases and those that are persistent or recurrent. Although the peritoneal fluid responds quite rapidly to inflammation of the peritoneum or intestine, the sample obtained may not accurately reflect the general health of the abdomen. Fluid can pool between layers of mesentery and it may take time for the fluid to mix at the sample site. **Intussusceptions and entrapment**

Table 23.15 General description of common colic etiologies and their treatment

Disease	Treatment
Large colon impaction	
Alert with intermittent mild to moderate pain Pain may be severe, but responsive to analgesics Heart rate—normal to mild elevation Mucous membranes—pink with mild to moderate dehydration Borborygmi—normal to slight decrease Cecal tympany— \pm Rectal exam—ingesta filled large colon; colon in normal orientation; \pm cecal distension Peritoneal fluid—normal Gastric reflux—unusual, but possible if generalized ileus	Aggressive medical therapy with oral fluids and laxatives; IV fluids may be necessary; no feed until problem resolved; surgery may be necessary in refractive cases—enterotomy and evacuation of colon with postoperative supportive care
Large colon displacement/volvulus	
Pain—moderate to severe; often unresponsive to analgesics (volvulus) Heart rate—moderate to marked increase Mucous membranes can be toxic with prolonged capillary refill time; dehydration Borborygmi—decreased to absent Cecal tympany—common Rectal exam—gas-distended large colon with abnormally taut and oriented teniae Peritoneal fluid—normal to moderate increase in protein and white blood cells Reflux—unusual, but possible if generalized ileus	Surgery —correction of displacement or volvulus; enterotomy in selected cases; resection or colopexy in selected cases; postoperative supportive care (IV fluids, antibiotics, NSAIDs); some cases of left dorsal displacement may respond to phenylephrine administration
Small colon impaction	
Pain—moderate to severe, usually with marked abdominal distension (large colon and cecum) Heart rate—moderate increase Mucous membranes—mild toxicity and dehydration Borborygmi—normal to decreased Cecal tympany—common Rectal exam—loops of ingesta-filled small colon, usually do not have distinct fecal balls; cecum and large colon may be gas filled Peritoneal fluid—usually normal, but may have increased protein and/or white blood cells if bowel is necrotic	Aggressive medical therapy —oral and IV fluids, laxatives; may require cecal decompression; if unresponsive, surgery—relieve impaction with high enema, \pm enterotomy; large colon may need to be evacuated as well; fecolith or enterolith may be present
Small intestinal strangulation	
Pain—moderate to severe, often unresponsive to analgesics Heart rate—marked increase that does not improve with gastric decompression Mucous membranes—often toxic and very dehydrated Borborygmi—near absent Rectal exam—distended loops of small intestine, usually gas filled and non-compressible, often painful to palpation Peritoneal fluid—serosanguineous with increased protein and white blood cells Reflux—large volume; may be only small amount if the obstruction is in the distal small intestine and early on in course of disease	Immediate surgical intervention once patient's cardiovascular system is stable; resection of diseased intestine and anastomosis; postoperative supportive care

(Continued)

Table 23.15 (Continued)

Disease	Treatment
Duodenitis/proximal jejunitis	
Pain—moderate which responds to gastric decompression of fluid	Supportive care: IV fluids; nothing per os; frequent gastric decompression to prevent rupture; NSAIDs; ± antibiotic; attempt to prevent laminitis
Heart rate—increased when stomach full of fluid; improves once decompressed	
Mucous membranes—often toxic with marked dehydration; often pre-renal azotemia marked	
Borborygmi—decreased but present; generally more than with a small intestinal strangulation	
Rectal exam—fluid/gas-distended loops of small intestine, easily compressible, non-painful to palpation	
Reflux—large volume often blood tinged and fetid	

This table is not inclusive and should serve only as a guide when making a diagnosis and establishing a treatment plan. Clinical signs of many of these diseases can overlap, making diagnosis more difficult.

Box 23.6 Basic questions regarding the history of a colic patient

Husbandry

- What kind of parasite control program is in place and when was the horse last wormed?
- What kind of diet is the horse on—type of hay, grain, pasture?
- Is the horse housed inside, outside or a combination of both? If inside, what type of bedding is used?
- What kind of exercise program is the horse on?
- Have there been any recent changes or injuries requiring rest?
- Has the horse recently been shipped a long distance or exposed to a new environment or different horses?
- Are any other horses on the farm sick, and if so, with what?

Previous illness

- What, if any, previous illness and/or bouts of colic has the horse had?
- How long ago?
- What was the therapy and how did the horse respond?

Present illness

- How long has the horse been in pain and to what degree?
- What are the temperature, pulse and respiratory rates and how have they progressed through the course of illness?
- Are gastrointestinal sounds present?
- Is the abdomen distended?
- Results of the rectal examination?
- Results of nasogastric intubation?
- What drugs have been administered? How much and when? What was the response to the medication?

Table 23.16 Abnormalities of the gastrointestinal tract in the colic patient

Procedure	Finding	Cause/comment
Abdominal auscultation	Borborygmi absent ^a	Ileus; strangulating lesion
	Normal	Medical colic; resolving colic; enteritis
	Hyperactive, fluidy	Enteritis
Percussion	Large tympanic region—right flank	Cecal distension secondary to large colon obstruction (volvulus, displacement, impaction)
	Tympanic region—left flank	Large colon tympany associated with displacement or volvulus
Nasogastric intubation ^b	Gastric fluid obtained after intubation or siphoning	Small intestinal obstruction—mechanical or functional
Rectal examination	Large amount of firm ingesta in large colon	Large colon impaction; enterolith—right dorsal or transverse colon
	Large colon distension—gas with abnormal orientation of teniae	Large colon volvulus or displacement
	Large colon distension—fluid	Colitis
	Small colon distended with heavy ingesta, often formed fecal balls	Small colon impaction; feco- or enterolith
	Cecal distension	
	Gas	Colonic obstruction
	Ingesta	Cecal impaction
	Small intestinal distension—gas, taut, ±pain on palpation	Strangulating obstruction
Abdominocentesis ^c	Compressible, non—painful small intestinal distension	Ileus; duodenitis—proximal jejunitis
	Increased protein	Initial response to inflammation
	Serosanguineous fluid	Diapedesis of RBC with progressive vascular leakage
	Increased WBC	Migration of cells into fluid in response to progressive intestinal vascular compromise
	Mixed population of bacteria and plant material ^d	Intestinal rupture

^a The presence of borborygmi does not necessarily correlate with motility.

^b Nasogastric reflux usually indicates a small intestinal obstruction. Strangulating obstructions (e.g. volvulus, lipomas, epiploic foramen entrapment, internal or inguinal hernia, etc.) and mechanical obstructions (e.g. adhesion, intussusceptions, etc.) must be differentiated from functional obstructions (ileus); the former two require surgical intervention for correction. Impingement of a distended large colon on the small intestine can result in gastric reflux. pH should be evaluated along with color, content and odor.

^c Normal peritoneal fluid will be clear yellow and contain less than 5000 white blood cells/ μ L and less than 2.0 g protein/dL.

^d Peritoneal fluid with an intestinal rupture can be distinguished from intestinal contents by the presence of phagocytized bacteria within neutrophils. Intestinal contents will contain very few neutrophils.

of intestine in the epiploic foramen are examples in which the exudate from severely compromised bowel may not be reflected in the fluid sample.

The risk of **intestinal laceration** is real, and extreme caution should be used when sampling largely distended abdomens, particularly when small intestinal distension is evident. **Fractious horses** pose not only a threat to the sampler, but to themselves as well, and should be properly restrained or sedated with short-acting α_2 -agonists, such as xylazine, before the procedure.

Aside from cytologic evaluation, **biochemistry tests** can also assist in evaluating abdominal fluid. These include pH, glucose, LDH and lactate

Table 23.17 Clinicopathologic evaluation of the colic patient

Laboratory findings	Problem	Comments
Increased PCV and TP	Dehydration and shock	PCV is somewhat dependent upon splenic contraction; PCV >60% indicates a poor prognosis
Increasing PCV with decreasing TP	Ongoing dehydration with protein loss into the bowel or peritoneal cavity	Often secondary to intestinal compromise or severe enteritis/colitis
Increased creatinine	Volume contraction and pre-renal azotemia	Renal dysfunction may be present and caution should be used when administering NSAIDs and aminoglycosides
Electrolytes (sodium, potassium, chloride calcium)	Concentrations depend on nature of problem and duration of disorder	Hypokalemia and hypocalcemia may induce intestinal stasis and should be replaced if low
Acid–base balance		
Metabolic alkalosis	Sequestration of hydrogen and chloride ions in stomach	May be seen early on, but with progressive dehydration metabolic acidosis is usually observed
Metabolic acidosis	Occurs with progressive dehydration	Bicarbonate replacement is usually not necessary unless base deficit is greater than 10 mEq. Most imbalance is corrected with fluid replacement
Leukogram	Normal with most obstructive disorders	Leukopenia seen with endotoxemia or enteritis (e.g. salmonellosis)

concentrations. With **sepsis** the pH and glucose concentration decrease, while lactate and LDH increase. A gradient between serum and abdominal glucose concentrations >50 mg/dL is consistent with a septic process. A peritoneal pH <7.3, absolute glucose concentration <30 mg/dL, and peritoneal fibrinogen concentration >200 mg/dL are also indicative of **septic peritonitis** (*q.v.*). Aerobic and anaerobic culture and susceptibility testing should be performed if peritonitis is present. Clinicopathologic evaluation of the colic patient focuses on assessment of hydration, electrolyte imbalance and acid–base status. Table 23.17 lists some common abnormalities.

Treatment

Analgesia

Often the most immediate problem is control of **abdominal pain**. During small intestinal ileus or obstruction (*q.v.*), a great deal of the pain results from gastric distension. Decompression of the stomach by **nasogastric intubation** (*q.v.*) relieves pain and helps prevent gastric rupture. Even in cases with severe gastric distension with fluid and gas, the pressure in the stomach may not force the fluid/gas freely out of the tube, and suction or siphoning is required. To avoid trauma associated with repeated intubation the tube may be secured in place at the halter. However, **prolonged intubation** should be avoided to prevent pharyngitis and esophageal ulceration/trauma.

Cecal tympany (*q.v.*) due to obstruction of the large and/or small colon can be relieved by **cecal decompression**. The horse is sedated with a short-acting analgesic such as xylazine or butorphanol and the right flank is aseptically prepared between the last rib and tuber coxae at the level of the ventral aspect of the tuber coxae. Percussion of the abdomen with localization of pinging will aid in placement of the catheter. After a small bleb of local anesthetic is placed in the skin, a 14 G 13.4 cm over-the-needle catheter is placed through the abdominal wall into the cecum. Gas is allowed to escape freely or can be drawn off with suction. Once the gas is removed, the catheter can be flushed with an antimicrobial while it is being withdrawn to minimize contamination of the body wall.

Walking can increase motility and decrease pain, but is best used in conjunction with other therapy. **Excessive walking can exhaust the horse** and prevent ongoing treatment with other therapeutics.

Prostaglandins and thromboxane play a role in the development of pain associated with gastrointestinal distension and ischemia. NSAIDs limit the production of these mediators via the arachidonic acid cascade and have been useful as analgesics in the treatment of equine colic. **Flunixin meglumine** is most commonly used for its analgesic and anti-endotoxin properties. However, it should be used judiciously to prevent **masking** of clinical signs of diseases requiring surgical intervention. Failure to relieve abdominal pain with flunixin meglumine suggests a more serious disease requiring surgery. Phenylbutazone and dipyrone are also used as analgesics but in general are less effective than flunixin meglumine in treating colic. Because of the potential toxic side effects, NSAIDs should be used cautiously in the **hypovolemic patient** that may already be experiencing gastrointestinal and renal hypoperfusion.

Xylazine and detomidine are the most commonly used α_2 agonists in the treatment of colic. They are potent analgesics and sedatives and are very effective at relieving colic pain. If repeated doses are required to control pain, serious abdominal disease should be suspected and prompt referral for surgical evaluation is indicated. Because the duration of effect from xylazine is shorter than that of detomidine, it is less likely to **mask signs of a strangulating obstruction** for an extended period of time. Xylazine and detomidine will cause bradycardia, transient vasoconstriction and increased urine production, and their use may adversely affect horses with hypovolemic shock. In addition, intestinal motility can be decreased, which may not be desirable in the treatment of impaction colic. Because of its longer duration of effect, **detomidine should not be used in cases that are surgical candidates**.

Butorphanol is a very effective analgesic with minimal side effects. It is a partial opioid agonist and antagonist that causes some reduction in intestinal motility, but has minimal cardiovascular effects except at higher doses. Although morphine is a potent analgesic, its use for treatment of colic remains limited because of its **excitatory effects** and tendency to reduce intestinal motility. Pentazocine and pethidine have less predictable analgesic effects than other opioids.

Common analgesics and their dosages are listed in Table 23.18. The degree of pain, specific diagnosis and the veterinarian's clinical experience will all determine the ideal analgesic drug regimen. Once the diagnosis of a surgical problem has been made, more potent analgesics can be used to control pain

Table 23.18 Analgesics for abdominal pain

Analgesic	Dosage	Effectiveness
Flunixin meglumine	0.25–1.1 mg/kg IV or IM	Excellent
Phenylbutazone	2.2–4.4 mg/kg IV	Fair
Dipyrone	10 mg/kg IV or IM	Fair
Xylazine	0.2–1.1 mg/kg IV or IM	Good
Detomidine	10–40 µg/kg IV	Excellent
Butorphanol	0.02–0.08 mg/kg IV	Good
Pentazocine	0.3–0.6 mg/kg IV	Fair
Pethidine	1.1–2.2 mg/kg IV or IM	Fair

Reproduced with permission from White N. A. (1990) *The Equine Acute Abdomen*. Lea & Febiger, Philadelphia.

during the preoperative preparation, provided the patient has adequate cardiovascular status.

Fluid therapy

Severely dehydrated horses, especially those requiring surgical intervention, require **rapid volume replacement** with a **balanced polyionic IV solution**. It is not unusual for a colic case to require 40–60 L of IV fluid for preoperative stabilization. Even marginal dehydration and hypovolemia, in combination with the cardiovascular depressant effects of the anesthetic agents and endotoxemia, and compromised venous return due to abdominal distension, can severely complicate the anesthetic procedure and outcome. **Colloids**, particularly in the form of plasma products, have several advantages for use in colic patients. Synthetic colloids, such as hetastarch, are best administered postoperatively in surgical cases due to potential concerns over coagulation disorders.

Rapid fluid administration may be achieved after aseptic insertion of a size 9 French introducer catheter in the jugular vein (Deilets-Hoffman Introducer Set, Cook Critical Care, Bloomington, IN, USA). Four 5 L bags of commercially prepared sterile fluids can be administered at one time by gravity flow with a large bore coiled administration set and hanger system (Stat IV 1000 International WIN Inc., Kennett Square, PA, USA). In some cases of severe dehydration, hypertonic saline may be indicated.

If dehydration is not severe and gastrointestinal function is not impaired, oral fluids can be used for rehydration and continued maintenance therapy. Oral fluids are contraindicated in the presence of gastrointestinal reflux and small intestinal disease. **Enteral fluid therapy** is particularly effective in the treatment of large colon impactions (*q.v.*) due to its ability to **stimulate gastric motility** and to penetrate the impaction. Six to eight liters of fluid can be administered safely to an adult horse, 3–4 times daily or more often. Fluid composition varies and is dictated by the disease being treated and the clinician’s personal preference. Water alone, or with an electrolyte solution, may be used. Some commercially available products contain glucose and/or glycine to promote sodium and water reabsorption.

Stimulation of motility

Increasing the water content of the ingesta often improves intestinal motility, decreases transit time and encourages resolution of the impaction. **Lubrication**

Table 23.19 Common cathartic drugs used for treatment of equine abdominal diseases

Name	Action
Bulk cathartics (fiber)	
Bran	Cause retention of water via hydrophilic action; increased bulk and water transit speeds
Psyllium	
Methylcellulose	
Saline cathartics	
Magnesium sulfate	Cause osmotic retention of intestinal water with possible stimulation of the small intestine and decreased transit time
Sodium sulfate	
Surfactants	
Dioctyl sodium sulfosuccinate	Increase penetration of ingesta with water and cause reduction of net absorption of water
Dioctyl calcium sulfosuccinate	
Emollient	
Mineral oil	Lubricates and softens ingesta

Reproduced with permission from White N. A. (1990) The Equine Acute Abdomen. Lea & Febiger, Philadelphia.

of the tract eases transport. Table 23.19 lists **common cathartics and hydrophilic substances** and their mechanism of action.

Mineral oil has been used for years as an intestinal lubricant for impaction colic. Commonly, 2–4 L of mineral oil is administered to a 450 kg horse. If intestinal transit is normal, oil-covered feces should be passed within 12–24 h. Mineral oil is not good at penetration of firmly impacted material such as sand and can be passed around the impaction. Its use is contraindicated in horses with gastrointestinal reflux and those requiring abdominal surgery, especially if an enterotomy or anastomosis is anticipated, because the serosal surface of the intestine may become contaminated with oil.

Parasympathomimetics can be used judiciously to increase intestinal motility. **Neostigmine** (1–2 mg SC q 30–60 min to effect in an average sized horse) is an anticholinesterase that increases progressive motility of the large intestine with minimal effect on small intestinal activity. It has been helpful in treating large colon impactions (*q.v.*) that are soft and easily indented but are not moving. Stimulating motility with a firm impaction could initiate pain and predispose to bowel rupture, and should therefore be used with caution. Neostigmine is contraindicated in cases of strangulation, obstruction or large colon displacement (*q.v.*) and should be used only after aggressive oral and IV fluid therapy has proven unsuccessful. **Metoclopramide** has been shown in other species to coordinate gastric emptying and improve small intestinal activity. However, in the horse, the dose–response curve has been varied and extrapyramidal neurologic side effects have been observed. Its mechanism of action is not clear, but probably involves direct cholinergic stimulation and dopamine antagonism. **Erythromycin** has been used as a prokinetic drug in humans with reasonable success and has been used in horses with unresponsive ileus (*q.v.*).

Calcium may also help stimulate intestinal motility, especially if hypocalcemia is present. IV administration of 500 mL 23% calcium gluconate solution diluted to 5–10% is relatively safe, but it should be done slowly while monitoring heart rhythm and rate.

Nutrition

Horses with colic of undetermined origin should be held off feed until the primary problem is corrected. Horses with large colon or cecal impactions (*q.v.*) may be allowed oral fluids but should not be fed until the impaction is passed. Gastrointestinal reflux indicates small intestinal ileus (*q.v.*) and addition of food or water will only add to the gastric distension and discomfort. Post-operative nutritional management is dependent upon the primary problem, what was done to correct it, and gastrointestinal function.

Enteral support should be started as soon as gastrointestinal function resumes. **High quality, highly digestible feeds** should be fed in small quantities. Examples include complete pelleted feeds, fresh grass and alfalfa leaves. Hand-walking and grazing small amounts of grass is a safe way to begin. Small quantities of high quality alfalfa hay and bran mashes can be used as well. If function exists but the horse refuses to eat, enteral support can be achieved by administering a hyperalimentation diet via stomach tube.

Parenteral nutrition (total or partial) may be necessary in critically ill patients with prolonged gastrointestinal dysfunction, increased metabolic needs (e.g. sepsis, peritonitis, pleuritis) or those that are unable to eat or need to be force fed (oropharyngeal surgery, pharyngeal trauma).

Prognosis and referral

Horses with progressive, non-responsive abdominal pain, cardiovascular deterioration (dehydration, tachycardia, poor perfusion), distended small intestine or significant volumes of gastric reflux (*q.v.*) should be referred to a surgical facility for further evaluation. Because simple medical colics usually resolve in 2–4 h, referral should also be considered in patients whose pain persists beyond this time interval. The **travel time** to a referral center should also be considered.

Early surgical intervention in cases with strangulation obstruction improves prognosis. Overall, the current survival rate with surgery exceeds 50% and is highly variable with the underlying problem. Individuals with a systolic blood pressure <100 mmHg, weak pulses, heart rate >80 bpm, PCV >60% and evidence of a coagulopathy should be given a guarded to poor prognosis.

DESIGN OF AN INTENSIVE CARE UNIT

INTRODUCTION

The design of a large-animal ICU should not be left to hospital administrators, architects and engineers, but requires the input of all the veterinary medicine specialists who will be caring for critically ill patients in the unit. A **planning team** should be formed at the outset that includes administrators, veterinarians and architects who will be able to communicate easily and exchange information vital to basic design decisions. The veterinary members of the

planning team must educate the architects about necessary instrumentation and patient management practices that will affect unit design. The architect, in turn, will need to provide the ICU veterinarians with relevant information about building materials and architectural and engineering issues involved in ICU design and construction.

An essential part of the design process is planning for the future. The veterinarian members of the planning team must make intelligent predictions about the ways in which ICU medicine will change over the next decade, both in technology and in the kinds of conditions treated and their treatment. Trends in human medicine often are useful harbingers of new developments in veterinary medicine.

LOCATION

The placement of the ICU relative to other departments is a necessary consideration, except where existing space limitations have forced selection of a particular site. Traditionally, of course, the ICU is located near surgery and medicine services. Intensive care is being provided for diverse medical conditions, not just surgical sequelae, and there may be equally valid reasons for locating the ICU adjacent to the emergency room or near vital support services, particularly given the difficulties of transporting bulky equipment and/or immobilized or unconscious animals.

CAPACITY

The greatest difficulty in planning an ICU is in calculating the optimal capacity, given the fluctuations in ICU patient population. A unit that is always near capacity may be too small, or the criteria for admission may be too broad. However, a unit with overall low occupancy will have an unnecessarily high operating cost per animal.

The most important factors involved in determining the appropriate capacity for the unit are the admission and discharge criteria (in particular, the presence or absence of a step-down unit) and the total patient capacity of the hospital. A criterion suggested for human hospitals calculates the optimal ICU capacity as 15% of adult medical beds or 20% of adult surgical beds.

PHYSICAL DESIGN

After the location and capacity of the ICU have been decided, the planning team can move on to considering the physical design of the facility. The physical plan should balance considerations of convenience and efficiency of operation for the nursing staff with the goal of **minimizing stress** to the animals. Thus, noise and harsh lighting should be avoided, along with excessive traffic of attendants, trolleys and equipment.

The overall dimensions of the ICU can be calculated as a ratio of total unit square meterage (footage) per patient area. In human hospitals, this ratio ranges from approximately 137 to 182 m² (450–600 ft²) per bed and has been increasing steadily as ICUs treat more gravely ill patients with a greater array of medical technology. In determining the total area for ICUs treating human

patients, this calculation is sometimes made by factoring the total bed space by 2.5–3.0.

The **stall dimensions** in the ICU should vary to accommodate the mix of cases that will be admitted to the unit. The standard 3×3 m (ca. 10×10 ft) or 3.0×3.6 m (ca. 10×12 ft) stall is acceptable for most patients; however, if the ICU is to be fully utilized, it should have flexibility in the design and stall configuration to allow for different size and species patients, plus monitoring equipment (Figure 23.1). Mare and foal pairs require larger stalls, as do larger breeds of horses.

The design and location of electrical and gas outlets in the stalls is another important consideration. Gas and electric outlets can be suspended from the ceiling on a recoil mechanical system, reducing problems of patient interference during delivery of care or, typically, these devices can be built into the head wall, with the essential concern being the simultaneous access to the patient and damage to the lines if they are on the stall floor. The overhead arrangement seems ideal. Whether the gas or electrical outlets are in the ceiling or in a wall chase, they should be of high quality materials, waterproof, and grounded, to reduce the hazard to the patient and withstand frequent cleaning. Generally, **oxygen** and **suction** are minimum requirements in each stall; the addition of compressed air is useful for the blending of gases in respiratory therapy. This combination of gases should meet all the needs in the ICU. Furthermore, oxygen delivery in each stall should be of sufficiently high flow rates to operate several ventilators simultaneously in the unit.

Facilities for **feeding** and **waste removal** are equally as important as the stall dimensions. The goals are to minimize traffic in the unit, ease cleaning and maintenance, improve labor efficiency and provide minimal risk to the critically ill patient within the unit. Several ideas that have proven useful in the Connelly Intensive Care Unit/Graham French Neonatal Section of New Bolton Center include manure removal using a chute for dumping and a holding

Figure 23.1 Main level plan of the intensive care/neonatal unit at New Bolton Center.

container on a lower level to minimize handling and rapid and easy disposal. This system limits the steps in handling equipment and the need for more than a single individual to work in the unit. The chute and utility room should be easily disinfected and maintained; this will limit nosocomial infections.

The **equipment needs** in the ICU will depend on the level of care provided for the critically ill patient. This may range from basic cardiovascular and respiratory monitoring to total parenteral nutrition and kidney dialysis. The equipment should be portable and permit upgrading to meet the changing technological developments and training of the ICU personnel. As a minimum, blood pressure monitors (direct and indirect), ECG, fluid infusion pumps and respiratory monitoring (expired gases, pulse oximetry) should be readily available. Other equipment considerations include portable radiographic and ultrasound units. The equipment should be stored in a clean, climate-controlled environment. This will prolong the life of equipment and minimize malfunction when used.

A central nursing station (see Figure 23.1) is an ideal arrangement for maintenance and storage of equipment, and ICU personnel use. The nursing station allows for centralizing supplies, pharmaceutical preparation and patient monitoring. Additionally, the nursing station serves as a staging area for equipment, a basic clinical laboratory and pharmaceutical preparation. The nursing station should be maintained as the cleanest part of the ICU. The design of the station should envision flexibility, labor efficiency, and ease of flow for people in the unit. A sterile hood in the nursing station is important in preparing hyperalimentation fluids and other admixtures.

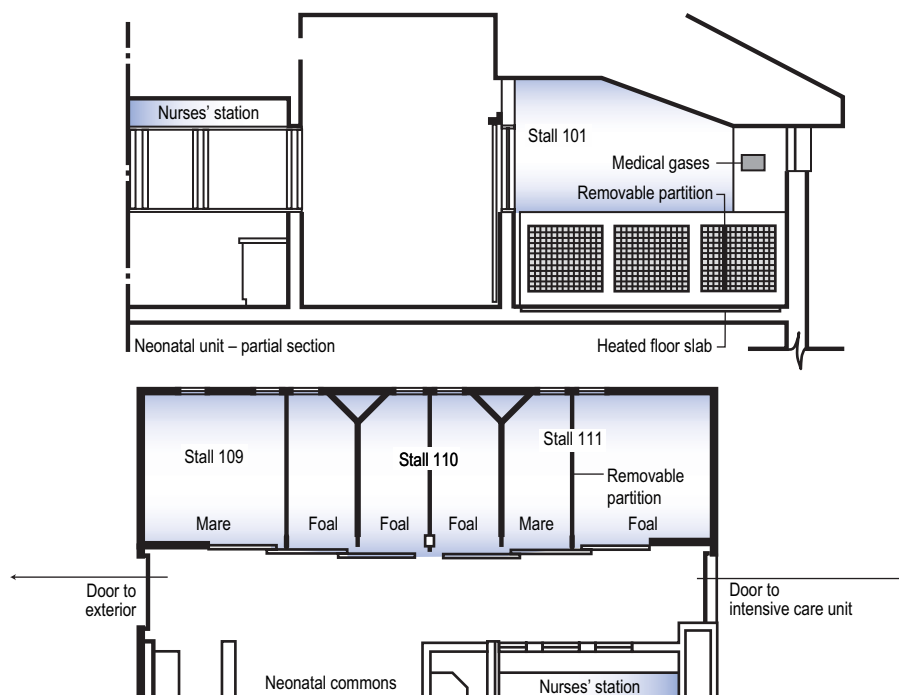

Figure 23.2 Partial plan of the neonatal unit at New Bolton Center.

Sinks used in the ICU should be strategically placed to stress cleanliness and encourage frequent hand washings. They should be designed to be operated with foot pedals or knee controls to minimize hand contact. Additional design considerations in the unit are concerned with the high risk of cross-infection in an open ICU, thus the justification for solid partitions. Studies on the relationship between ICU and nosocomial infections have been inconclusive to date. However, it seems prudent to physically separate the neonate from the adult patients, because of concerns with increased risk of septicemia in the younger animals. The mare/foal stalls should allow controlled separation of dam and neonate in such a way as to prevent the mare from interfering with care of the foal, while still allowing her to see, smell and touch the foal to foster normal bonding (Figure 23.2).

Rapid advances in veterinary medicine, combined with the limits imposed by budgetary constraints and available space in a given institution, will probably conspire to create a situation with some design limitations and some requirements that are not adequately foreseen or accommodated. Nonetheless, careful and creative planning will result in a well-designed facility that will respond well to the present and future developments in critical care medicine for large animals.

Abbreviations list

5-LO	5-lipoxygenase	AT	antithrombin
α	alpha	ATN	acute tubular necrosis
AAEP	American Association of Equine Practitioners	ATP	adenosine triphosphate
ABC (of acute care)	Airway Bleeding Cardiovascular	AUC	area under the curve
ACD	acid citrate dextrose solution	AUIC	area under the inhibitory curve
ACE	angiotensin-converting enzyme	AV	atrioventricular
ACP	acepromazine	AVP	arginine vasopressin
ACTH	adrenocorticotrophic hormone	AVT	atrioventricular tachycardia
ADF	acid detergent fiber	β	beta
ADG	average daily gain	BAL	bronchoalveolar lavage
ADH	antidiuretic hormone	BALF	bronchoalveolar lavage fluid
ADP	adenosine diphosphate	BBB	blood–brain barrier
AELRU	Australian Equine Laminitis Research Unit	BCG	bacillus Calmette–Guérin
AF	amniotic fluid	β-END	β-endorphin
AF	atrial fibrillation	BEVA	British Equine Veterinary Association
AFP	alpha-fetoprotein	b.i.d.	bis in die (twice a day)
AFV	amniotic fluid volume	BMC	bone mineral content
AHS	African horse sickness	BMD	bone mineral density
AHSV	African horse sickness virus	BP	blood pressure
AI	artificial insemination	bpm	beats per minute
AID	anemia of inflammatory disease	BPP	biophysical profile
AIHA	autoimmune hemolytic anemia	BSP	sulfobromophthalein (clearance test)
ALP	alkaline phosphatase	BUN	blood urea nitrogen
AMP	adenosine monophosphate	BW	body weight
ANS	autonomic nervous system	ca.	circa (about)
AP	antiplasmin	Ca	Calcium
APC	activated protein C	CAH	chronic active hepatitis
APT	activated partial thromboplastin time	CAT	computed axial tomography
ARF	acute renal failure	CBC	complete blood count
AST	aspartate aminotransferase	CD	cluster of differentiation
		CEM	contagious equine metritis
		CF	complement fixation; crude fiber
		CFT	complement fixation test
		CFU	colony-forming units

CID	combined immune deficiency	DIC	disseminated intravascular coagulation
CIN	chronic interstitial nephritis	DIP	distal interphalangeal (joint)
CINOD	cyclooxygenase inhibiting nitric oxide donor	DJD	degenerative joint disease
CK	creatinine kinase	dL	deciliter(s)
Cl	chloride	DLE	discoid lupus erythematosus
Cl_B	systemic clearance	DM	dry matter
CLIP	corticotropin-like intermediate lobe peptide	DMSO	dimethyl sulfoxide
cm	centimeter(s)	DNA-PK	DNA-dependent protein kinase
C_{max}	peak plasma concentration	DOD	developmental orthopedic disease
CN	cranial nerve	DST	dexamethasone suppression test
CNA	colistin–nalidixic acid	DYP	dyschondroplasia
CNS	central nervous system	EAV	equine arteritis virus
CO	cardiac output	ECD	equine Cushing's disease
CO₂	carbon dioxide	ECF	extracellular fluid
COP	colloid osmotic pressure	eCG	equine chorionic gonadotropin
COPD	chronic obstructive pulmonary disease	ECG	electrocardiogram/electrocardiography
COX	cyclo-oxygenase	EDDI	ethylenediamine dihydroiodide
CP	creatine phosphate	EDM	equine degenerative myeloen- cephalopathy
CP	crude protein	EDSS	Equine Digital Support System
CPAP	continuous positive airway pressure	EDTA	ethylenediaminetetraacetic acid
CPE	cytopathic effect	EE	Eastern encephalitis
CPK	creatine phosphokinase	EEDS	eosinophilic exfoliative dermatitis and stomatitis
CPR	cardiopulmonary resuscitation	EEV	eastern encephalitis virus; equine encephalosis virus
CRF	chronic renal failure	EFD	early fetal death
CRI	constant rate infusion	EFP	equine fetal protein
CRT	capillary refill time	EHSCL	European Horserace Scientific Liaison Committee
CS	condition score	EHV	equine herpesvirus
CSF	cerebrospinal fluid	EIA	equine infectious anemia
CT	computed tomography	EIPH	exercise-induced pulmonary hemorrhage
CTL	cytotoxic T cells	ELISA	enzyme-linked immunosorbent assay
CVID	common variable immunodeficiency	EMG	electromyography
CVM	cervical vertebral malformation	EMND	equine motor neuron disease
CVP	central venous pressure	EPC	effective plasma concentration
CVS	cardiovascular system	EPF	early pregnancy failure
δ	delta	EPG	eggs per gram
Da	Dalton(s)	EPH	equine purpura hemorrhagica
DCAB	dietary cation–anion balance	EPM	equine protozoal myeloencephalitis
DCP	digestible crude protein	EPSM	equine polysaccharide storage myopathy
DDAVP	1-deamino-8-D-arginine-vasopressin	ERAV	equine rhinitis A virus
DDFT	deep digital flexor tendon	ERBV	equine rhinitis B virus
DE	digestible energy	ERDC	equine respiratory disease complex
Defra	Department of Environment, Food and Rural Affairs	ERS	equine rhabdomyolysis syndrome
DFA	Directigen Flu A (test)		
DHA	dihydroepiandrosterone		
DI	diabetes insipidus		

ESKD	end-stage kidney disease	HBHA	Heinz body hemolytic anemia
EU	European Union	HBLB	Horseace Betting Levy Board
EVA	equine viral arteritis	hCG	human chorionic gonadotropin
F	systemic availability of a drug	HCO₃	bicarbonate
FAB	French–American–British (classification of non-lymphoid leukemias)	HDCV	human diploid cell vaccine
FAD	flavin adenine dinucleotide	HETE	monohydroxyeicosatetraenoic acid
FAST	fluorescent allergosorbent test	Hg	mercury
FAT	fluorescent antibody test(ing)	HI	hemagglutination inhibition (test)
FDA	Food and Drug Administration	HIE	hypoxic–ischemic encephalopathy
FDP	fibrinogen degradation products	HMWK	high molecular weight kininogen
FEE	fractional electrolyte excretion	HPA	hypothalamus–pituitary–adrenal
FFA	free fatty acids	HPLC	high performance liquid chromatography
FE	fractional excretion (of electrolyte)	HR	heart rate
FEI	Fédération Equestre Internationale	HR_{max}	maximum heart rate
fL	femtoliter(s)	HV	Hendra virus
FMDV	foot-and-mouth disease virus	HYPP	hyperkalemic periodic paralysis
FPT	failure of passive transfer	Hz	Hertz
FSH	follicle-stimulating hormone	IA	intra-articular(ly)
ft	foot/feet	IAD	inflammatory airway disease
γ	gamma	ICF	intracellular fluid
g	gram(s)	ICU	intensive care unit
G	gauge	IFAT	indirect fluorescent antibody test
GABA	γ-aminobutyric acid	IFN	interferon
GAD	glutamic acid decarboxylase	Ig	immunoglobulin
GC	gas chromatography	IH	inhibiting hormone
GC-MS	gas chromatography-mass spectrometry	IL	interleukin
GFR	glomerular filtration rate	IM	intramuscular(ly)
GGD	generalized granulomatous disease	in	inch(es)
GGT	gamma glutamyltransferase	iNOS	inducible nitric oxide synthase
GH	growth hormone	IOP	intraocular pressure
GIT	gastrointestinal tract	IPC	irrelevant plasma concentration
GKX	guaifenesin-ketamine-xylazine combination	IPPV	intermittent positive pressure ventilation
GM-CSF	granulocyte–monocyte colony-stimulating factor	ISCOMs	immune stimulating complexes
GOT	glutamic oxalacetic transaminase	IT	intratracheal(ly)
GnRH	gonadotropin-releasing hormone	ITP	idiopathic thrombocytopenia
GPT	glutamic pyruvate transaminase	IU	international unit
GSH-px	glutathione peroxidase	IU	intrauterine
GUS	gastric ulcer syndrome	IUC	irrelevant urinary concentration
Gy	gray (unit of absorbed dose of radiation)	IUGR	intrauterine growth retardation
h	hour(s)	IV	intravenous(ly)
H	hemagglutinin	J	joule(s)
ha	hectare	JE	Japanese encephalitis
HA	hyaluronic acid	JEV	Japanese encephalitis virus
		JFA	jaundiced foal agglutination (test)
		κ	kappa
		K	potassium
		kcal	kilocalorie

KCl	potassium chloride	mL	milliliter(s)
KCS	keratoconjunctivitis sicca	mm	millimeter(s)
kDa	kilodalton(s)	mmHg	millimetres of mercury
keV	kilo electric volt	mmol	millimole(s)
kg	kilogram(s)	MMP	matrix metalloproteinase
kJ	kilojoule(s)	mo	month(s)
km	kilometer(s)	MPa	megapascal(s)
λ	lambda	MPK	multiple punctate keratotomies
L	liter(s)	MPS	mononuclear phagocyte system
LAK	lymphokine-activated killer (cell)	MRI	magnetic resonance imaging
LC	larval cyathostomiasis	MRLS	mare reproductive loss syndrome
LC-MS	liquid chromatography-mass spectrometry	MRSA	methicillin-resistant <i>Staphylococcus aureus</i>
LD₅₀	lethal dose that kills 50% of a test population	MSH	melanocyte-stimulating hormone
LDH	lactic dehydrogenase	MT3	third metatarsus
LEM	leukoencephalomalacia	MW	molecular weight
LH	lutinizing hormone	N	neuramidase
LMWH	low molecular weight heparin	N₂	nitrogen
LPS	lipopolysaccharide	Na	sodium
LRS	lactated Ringer's solution	NAD	nicotinamide adenine dinucleotide
LRT	lower respiratory tract	NADH	reduced NAD
LT	leukotriene	NAIT	neonatal alloimmune thrombocytopenia
μ	mu	NB	nota bene (note well)
μg	microgram(s)	NaCl	sodium chloride
μL	microliter(s)	NaHCO₃	sodium bicarbonate
μm	micron(s)	NDF	neutral detergent fiber
m	meter(s)	NE	net energy
MAD	modified acid fiber detergent	NEC	necrotizing enterocolitis
MAFF	Ministry of Agriculture, Fisheries and Food	NEFA	non-esterified fatty acids
MBq	megabecquerel(s)	NfE	nitrogen free extract
MC3	third metacarpus	ng	nanogram(s)
MCH	mean corpuscular hemoglobin	NGT	nasogastric tube
MCHC	mean corpuscular hemoglobin concentration	NH₃	ammonia
ME	metabolizable energy	NI	neonatal isoerythrolysis
mEq	milliequivalent(s)	NMDA	N-methyl-D-aspartate
min	minute(s)	NMS	neonatal maladjustment syndrome
mg	milligram(s)	NO	nitric oxide
MgO	magnesium oxide	NOS	nitric oxide synthase
MHC	major histocompatibility complex	NRC	National Research Council
MHz	megahertz	ns	nanosecond
MJ	megajoule(s)	NSAID	non-steroidal anti-inflammatory drug
MLV	modified live vaccine	NSP	non-starch polysaccharide
MAD	modified acid detergent	NST	non-stress test
MDI	metered dose inhaler	NV	Nipah virus
MES	minimum effective strain	O₂	oxygen
MIC	minimum inhibitory concentration	OA	osteoarthritis
		OBLA	onset of blood lactate accumulation

OC	organochloride; osteochondrosis	PT	prothrombin time
OCD	osteochondritis dissecans	PTH	parathyroid hormone
OIE	Office International des Épizooties	PU/PD	polyuria–polydipsia
OLWFS	Overo lethal white foal syndrome	q	quaque (every)
OP	organophosphate	q.i.d.	quater in die (4 times a day)
P	probability	QUS	quantitative ultrasound
Pa	pascal(s)	qs ad	quantum sufficiat ad (a sufficient quantity of)
PAF	platelet-activating factor	q.v.	quod vide ("which see") – see elsewhere in this book for further information
PAGE	polyacrylamide gel electrophoresis	rad	radiation absorbed dose
PAI	plasminogen activator inhibitor	RAO	recurrent airway obstruction
PAS	periodic acid–Schiff (stain)	RAST	radioactive allergosorbent test
PaCO₂	partial pressure of arterial carbon dioxide	RBC	red blood cell
PaO₂	partial pressure of arterial oxygen	RBF	renal blood flow
PCA	procoagulant activity	RCV	red cell volume
PCO₂	carbon dioxide tension	REM	rapid eye movement (sleep)
PCR	polymerase chain reaction	RER	recurrent exertional rhabdomyolysis
PCV	packed cell volume	RH	releasing hormone
PDA	patent ductus arteriosus	RID	radioimmunoassay (test)
PDGF	platelet-derived growth factor	RIG	rabies immune globulin
PEEP	positive end expiratory pressure	ROS	reactive oxygen species
pg	picogram(s)	RPE	retinal pigment epithelium
PG	prostaglandin	RQ	respiratory quotient
PGE	prostaglandin E	RS	respiratory secretions
PGF_{2α}	prostaglandin F _{2α}	RT-PCR	reverse transcriptase–polymerase chain reaction
PGFM	13,14-dihydro-15-keto-prostaglandin-F _{2α}	RVV	recombinant vector vaccine
PGI₂	prostacyclin	s	second(s)
PHF	Potomac horse fever	SBC	subchondral cystic lesions
PHMB	polyhexamethylene biguanide	SC	subcutaneous(ly)
P_i	inorganic phosphate	SCC	squamous cell carcinoma
PK–PD	pharmacokinetic–pharmacodynamic (modelling)	SCID	severe combined immunodeficiency
PL	phospholipid	S_{cr}	serum creatinine
PLGE	protein-losing gastroenteropathy	SD	standard deviation
PLR	pupillary light reflex	SDFT	superficial digital flexor tendon
PMMA	polymethyl methacrylate	SDH	sorbitol dehydrogenase
PMSG	pregnant mare serum gonadotropin (eCG)	SE	standard error (of the mean)
PN	parenteral nutrition	SG	specific gravity
PO	per os (orally)	SGA	small for gestational age
POMC	pro-opiomelanocortin	SGOT	serum glutamic oxalacetic transaminase
ppb	parts per billion	SGPT	serum glutamic pyruvate transaminase
ppm	parts per million	s.i.d.	semel in die (once a day)
PPM	persistent pupillary membranes	SID	strong ion difference
PPSC	pluripotent stem cells	SIMV	synchronized intermittent mandatory ventilation
PPV	positive pressure ventilation		
PSGAG	polysulfated glycosaminoglycan		
PSSM	polysaccharide storage myopathy		

SIRS	systemic inflammatory response syndrome	TTA	transtracheal aspiration
SLE	systemic lupus erythematosus	TX	thromboxane
S_k	serum potassium	U	unit(s)
SN	serum neutralizing	U_{cr}, uCr	urine creatinine
SNT	serum neutralization test	UFH	unfractionated heparin
SPA	staphylococcal protein A	U_K	urine potassium
SPAOPD	summer pasture associated obstructive pulmonary disease	UK	United Kingdom
SPF	specific-pathogen free	URT	upper respiratory tract
spp.	species	US	ultrasound
SRH	single radial hemolysis	USA	United States of America
STDV	standard deviation of data (over time range)	USDA	United States Department of Agriculture
SVPD	supraventricular premature depolarization	UTI	urinary tract infection
SVT	supraventricular tachycardia	UV	ultraviolet
T₃	tri-iodothyronine	V₂₀₀	treadmill velocity that results in a heart rate of 200 bpm
T₄	thyroxine	V_d	volume of distribution
t_{1/2}	half-life	VE	Venezuelan encephalitis
TB	Thoroughbred	VEV	Venezuelan encephalitis virus
Tc	technetium	VFA	volatile fatty acids
TCA	tricarboxylic acid	VLa4	see OBLA
TCO₂	total carbon dioxide (concentration)	VLDL	very low density lipoprotein
TF	tissue factor	VN	virus neutralization
TGF	tissue growth factor	VO₂max	the maximal rate of oxygen consumption
t.i.d.	ter in die (3 times a day)	VPC	ventricular premature contractions
TIMPS	tissue inhibitors of matrix metalloproteinases	VPD	ventricular premature depolarization
TIVA	total intravenous anesthesia	VS	vesicular stomatitis
TLC	thin layer chromatography	VSD	ventricular septal defect
TMP/S	trimethoprim and sulfonamide	VSV	vesicular stomatitis virus
TNF	tumor necrosis factor	VT	ventricular tachycardia
TP	total protein	vWF	von Willebrand factor
TPP	total plasma protein	WBC	white blood cell
tPA	tissue plasminogen activator	WE	Western encephalitis
TRH	thyrotropin-releasing hormone	WEV	Western encephalitis virus
TSH	thyroid-stimulating hormone	wk	week(s)
TT	thrombin time	WNV	West Nile virus (<i>q.v.</i>)
		XLA	X-linked agammaglobulinemia
		yr	year(s)

Index

A

Aa antigen

- donor selection and, 494, 525
- neonatal hemolytic disease and, 128, 494, 495, 834, 835

ABC of acute care, 850, 1298

see also airway; breathing; circulation

abdomen

- abscessation, **227**, 592–5
- adhesions within, 548–9
- auscultation *see* auscultation
- herniation of small bowel through wall of *see* hernia

pain

- abdominal distension with/without, 1298
- analgesics, **545**
- colicky *see* colic
- in large bowel intussusception, 577, 578
- in large bowel tympany, 580
- in small intestinal obstruction, 544, 546

surgery *see* surgery

see also peritoneal cavity

abdominal cryptorchidism, 715

abdominocentesis (incl. peritoneal fluid analysis)

- abscessation, 594
- bladder rupture/patency, 680
- colic, 1314–17
- epiploic foramen hernia, 554
- inguinal hernia, 557
- intussusception of small bowel, 559
- left dorsal displacement of colon, 573
- peritonitis, 625

salmonellosis, 598

volvulus, 550

abortion, 745–52

- causes, 735–7
 - diagnosis, 748–51
 - infective *see* infections
 - non-infective, 746–7
- clinical signs, 748, 753
- incidence, 745
- pathogenesis, 747–8
- prevention, 752
- treatment, 752

abscesses, 323

- abdominal, **227**, 592–5
- in actinobacillosis, 49
- brain, 1111–12
- corneal stroma, 1178
- cutaneous, 323
 - C. pseudotuberculosis*, 81, 82, 82–3
 - with wounds, minimizing formation, 360

foot, 974–7

- in laminitis, recurrent formation, 1004

hepatic, **227**, 623

periapical, 407–8

- sinusitis due to, 400

pharyngeal, 409, 413

pulmonary/lower respiratory tract

- R. equi* infection, 59, 241
- syndrome associated with, 430, 431

renal, multifocal, 684

retroperitoneal, 761

absorption

carbohydrate, tests of, 588–9

drug

- antibiotic, 231, 232, 234, 235
- neonate vs adult, 1285
- NSAIDs, feeds affecting, 270

- absorption (*contd*)
 - nutrient, 153, 166–7
 - defective *see* malabsorption
