N/A

PREGNANCY

Changes in hormonal balance, relaxing of the pedal bone suspensory apparatus, changes in diet due to dry cow to lactating rations are predisposing factors for laminitis.

RUMINANT SPECIES AFFECTED

Bovine

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Good cow comfort, especially for springing heifers, is critical to allow cows to spend an adequate amount of time lying.
- Time standing on concrete, whether due to overcrowding, poor stall design or bedding, or long times in the holding area and milking parlor, will increase laminitis.
- Slug-feeding, sorting feed, or overmixing total mixed rations will predispose to subacute rumen acidosis, which, in turn will predispose to laminitis.

SYNONYMS

Coriosis, diffuse pododermatitis aseptica, pododermatitis

LANTANA TOXICOSIS

BASICS

OVERVIEW

- Lantana is thought to have originated in Central America, but today is widely spread throughout the tropics and subtropics of the world. Some 150–160 species and more than 75 named varieties exist.
- Resides in the Verbenaceae, commonly known as the verbena or vervain family.
- An uncommon cause of intoxication, lantana can be a significant cause of poisoning and death losses where it grows wild.
- Mortality is high in severe cases.
- Cattle are most frequently affected.
- It primarily affects the hepatobiliary system and skin. Renal and gastrointestinal systems are often involved as well.
- A squarestemmed perennial herb or shrub ranging between 0.5 and 1.2 m tall, lantana produces flowers in dense spikes from spring to fall.
- The plants are often used as ornamentals because of their showy flowers that come in a wide variety of colors—white, red, yellow, orange, blue, and purple. Different colors may exist on the same plant and colors change as the flowers mature.
- Fruits occur in clusters, initially green then becoming dark purple to black when ripe.
- Simple leaves with serrated margins are ovate to lanceolate in shape and are arranged in opposite or whorled patterns. They emit an aromatic odor when crushed.
- Stems are erect and prickly with yellow, orange, and red petals on *Lantana camara*. Common name—“ham and eggs.”
- Stems on *Lantana montevidensis* are trailing and smooth, with red to purple petals.
- Poisonings are most common in summer and fall, often due to clippings being consumed.
- Frequently planted as an ornamental, lantana has often escaped and become wild.

SIGNALMENT

- Although ruminants tend to be more commonly poisoned, most animal species, including sheep, goats, horses, dogs, wildlife, and children, are susceptible.
- There are no known breed, species, or sex predilections.

SIGNS

- Intoxication and related clinical signs depend upon the amount consumed and the rate of ingestion.
- Signs of acute intoxication may be seen within 24 hours postconsumption.
- Initially depression, weakness, anorexia, depressed ruminal motility, and constipation (often severe) occur.
- Within 2 to 4 days, icterus, bloody diarrhea, skin changes associated with photosensitization, paralysis, and death can be seen.
- Death may be prolonged over several weeks and is due to hepatic disease and renal failure.
- Dehydration and electrolyte imbalances (metabolic acidosis) also play roles in the pathogenesis.
- Chronic poisoning develops over several weeks and primarily involves photosensitization.
- Icterus, oronasal ulcerations, keratitis, and increased sensitivity to light may also be found.

CAUSES AND RISK FACTORS

- Lantadenes are hepatotoxic triterpene acids. Lantadene A is considered the most toxic; lantadene B is less toxic.
- Numerous cultivars and hybrids exist, possessing varying amounts of lantadenes with differing levels of toxicity.
- Leaves are the primary source of lantadene.
- Green fruits may possess other toxins—children have been poisoned with the absence of liver disease after consumption of green fruit. Ripened fruit and seeds are not toxic and reportedly are sometimes sought after by sheep and goats.

- Five to 10 g of dried leaves/kg of body weight will produce severe, often fatal poisoning in sheep and cattle.
- Lantadenes are absorbed primarily from the small intestine, but also the rumen. They are transformed in the liver and excreted in the bile, resulting in an obstructive cholangitis. Conjugated bilirubin and phylloerythrin are retained. Phylloerythrin accumulates in hepatocytes and the skin. When activated by sunlight, it results in tissue damage—photosensitization.
- The effects of lantadenes are cumulative. Subacute poisoning over 1 to 2 days is more common than acute intoxication.
- Lantadenes also have a direct effect on the GI tract, causing severe mucosal irritation. Ruminal stasis, secondary to liver disease, decreases rumen microflora activity. This leads to an increase in pH and ammonia nitrogen.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- The signs of lantana intoxication are nonspecific. A number of hepatotoxic plants are listed.
 - *Helenium* spp.—sneezeweed
 - *Hymenoxys* spp.—rubber weed, bitterweed
 - *Senecia* spp.
 - *Crotalaria* spp.
- Oak poisoning may also produce signs similar to acute lantana intoxication.
- Clinical signs, history of ingestion, finding plants in feed, hay, or rumen contents are supportive of a diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

- Serum bilirubin is elevated; the majority of which is conjugated.
- Serum hepatic enzymes, SDH and AST, are elevated.
- BSP clearance is decreased.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Icteric tissues
- Skin lesions due to photosensitization
- Keratitis
- Gastroenteritis
- Obstructive cholangitis
- Enlarged orange-tinted liver
- Enlarged gall bladder
- Enlarged kidneys with perirenal edema
- Periportal degeneration, portal fibrosis, bile duct hyperplasia, centrilobular necrosis
- Hepatocyte enlargement with multiple nuclei
- Renal tubular necrosis with casts
- Hyperemic and edematous GI mucosa

TREATMENT

- Remove affected animals from sunlight, provide shade.

- Prevent animal access to lantana.
- Removal/destruction of lantana—it is susceptible to 2, 4-D herbicides.
- Support patient, treat symptomatically, maintain hydration and electrolytes.
- Rumenotomy with evacuation of contents may be worthwhile if performed early.

MEDICATIONS

- Control absorption of toxins from the GI tract—activated charcoal—2–5 g/kg in a water slurry given orally (1 g charcoal per 5 ml water).
- Na thiosulfate—0.5 g/kg BW IV may be beneficial.
- Systemic and topical antibiotics

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Providing a proper diet and adequate nutrition to animals will minimize the intake of many toxic plants.
- Protective immunization has been studied and provided limited protection. Results were thought to be promising.

POSSIBLE COMPLICATIONS

None

EXPECTED COURSE AND PROGNOSIS

- Variable, dependent upon the amount and rate of consumption
- High mortality is expected with acute cases.
- Many animals will survive moderate cases of intoxication.

LARYNGEAL OBSTRUCTION

BASICS

DEFINITION

Laryngeal obstruction in ruminants has many causes, including abscesses, granulomas, papillomas, chondritis, trauma, edema, and foreign bodies.

SYSTEMS AFFECTED

Respiratory

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

- All ruminant species are susceptible.
- Abscesses of the arytenoid cartilages tend to occur in calves and sheep.
- Laryngeal granulomas and papillomas tend to occur in feedlot cattle.
- Laryngeal chondritis can occur in sheep.
- Foreign bodies tend to be ingested more readily by cattle.

Breed Predilections

- Laryngeal abscesses in sheep may occur more commonly in Texel and Southdown breeds.
- Laryngeal chondritis in sheep may occur more commonly in the Texel breed.

Mean Age and Range

N/A

Predominant Sex

Laryngeal abscesses in sheep may occur more commonly in rams than in ewes.

SIGNS

HISTORICAL FINDINGS

May be history of recent medication with a balling gun or dosing syringe, or exposure to a feedlot environment, or smoke inhalation, or participation in a roping event.

PHYSICAL EXAMINATION FINDINGS

Dyspnea and/or stertorous breathing exaggerated by palpation of the larynx, extended neck, palpable laryngeal swelling, hypersalivation, cyanosis in severe cases

CAUSES AND RISK FACTORS

- Laryngeal abscesses, chronic laryngitis, laryngeal granulomas and papillomas, edema, chondritis, and foreign bodies may all cause laryngeal obstruction.
- Laryngeal abscesses may be caused by bacterial infection—mainly *Arcanobacterium (Actinomyces) pyogenes*—of the arytenoid cartilages secondary to laryngeal trauma (e.g., from a balling gun or dosing syringe). Chronic laryngitis due to *A. pyogenes* infection in sheep may also cause laryngeal obstruction.
- Laryngeal granulomas may originate from chronic laryngeal contact ulcers (e.g., in feedlot cattle).
- Laryngeal papillomas are caused by a papovavirus, which enters chronic laryngeal contact ulcers.

- Edema of the larynx may be caused by smoke inhalation or anaphylactic reactions, or by laryngeal chondritis in sheep.
- Foreign bodies may lodge in the larynx, although they more commonly lodge in the pharynx.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Necrotic laryngitis
- Actinobacillosis
- Tumors
- Pharyngeal trauma and/or obstruction

CBC/BIOCHEMISTRY/URINALYSIS

Inflammatory profile or stress leukogram

OTHER LABORATORY TESTS

- Biopsy/histopathology of laryngeal mass
- Cytology and culture of aspirated material from a laryngeal abscess

IMAGING

- Endoscopy is useful for direct visualization of the obstruction, and may be used for transendoscopic removal of the obstruction.
- Radiology of upper respiratory system

OTHER DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Laryngeal abscesses—encapsulated abscesses in the arytenoid cartilages near the vocal fold.
- Laryngeal papillomas—sessile to pedunculated yellow frondlike growths over the vocal processes of the arytenoid cartilages.

TREATMENT

- Tracheostomy in severe cases of laryngeal obstruction
- Surgical or transendoscopic removal of obstructing mass or object

ACTIVITY

Restrict activity due to dyspnea

DIET

Softened feed may be less irritating to the laryngeal region following removal of the obstruction.

CLIENT EDUCATION

Proper use of a balling gun and/or dosing syringe so as to minimize trauma.

MEDICATIONS

- Broad-spectrum antibiotics, and NSAIDs
- Epinephrine if obstruction due to anaphylaxis (4–8 ml of 1:1000 solution per 500 kg IV for cattle, 1–3 ml of 1:1000 solution IM or SQ for average adult sheep or goat)

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

Tracheostomy site may need to be surgically closed.

PATIENT MONITORING

Tracheostomy site needs to be regularly monitored and cleaned.

PREVENTION/AVOIDANCE

- See Client Education above.
- Decreasing laryngeal contact ulcers in feedlot cattle by dust control and routine vaccination for respiratory pathogens may reduce the incidence of laryngeal granulomas and papillomas.

POSSIBLE COMPLICATIONS

Tracheostomy can predispose animal to lower respiratory infections since the filtering and humidifying action of the upper respiratory passages is bypassed.

EXPECTED COURSE AND PROGNOSIS

Laryngeal abscesses have a guarded prognosis unless detected and treated early.

LEAD TOXICOSIS

BASICS

OVERVIEW

- Most cases of lead poisoning occur in cattle.
- The vast majority of lead poisoning cases is the result of acute oral exposures; chronic exposures are rare in ruminants.
- Lead sources are many, but most poisonings result from ingesting battery plates.
- The onset of signs is abrupt, and typically includes signs associated with the gastrointestinal tract and central (and to a lesser extent, peripheral) nervous systems.
- Death with few to no premonitory signs may be observed in calves and young animals.
- Death or euthanasia is a common sequelae, due to the severity of neurological signs.
- Antemortem diagnosis relies on elevated blood lead levels and evidence of radiodense objects in the gastrointestinal tract (more common to find in the reticulum). Excessive liver and kidney lead levels; evidence of lead particles in the GIT (reticulum, rumen); and histologic evidence of laminar cortical necrosis provide postmortem evidence for a diagnosis of lead poisoning.
- Treatment, if possible and economically viable, includes administration of oral magnesium sulfate, thiamine, Ca-EDTA, along with supportive care targeted to those signs observed.
- Prognosis is generally poor, and care must be taken in considering home or custom slaughter due to tissue residues.

PATHOPHYSIOLOGY

- Lead salts are absorbed from the gastrointestinal tract.
- The majority of lead is bound to surface proteins of red blood cells.
- Lead has a wide tissue distribution and long half-life (approximately 9 days), and ultimately forms deposits in bone where it resides for years and is considered biologically inert.
- Any bone remodeling can lead to the release of stored lead.
- Lead can cross the placenta and be secreted into the milk.
- Lead affects multiple systems, and the effects are varied depending on whether the exposure is acute or chronic.
- Lead interferes with sulfhydryl and zinc containing enzymes, leading to erythrocyte fragility, bone marrow suppression, and interference with heme synthesis (more common to see these changes with chronic exposures), along with interfering with various neurotransmitters in the CNS.
- Neurological signs may be due to cerebral edema as a result of increased vascular permeability.
- Segmental demyelination of peripheral nerves (e.g., pharyngeal) may be seen.
- Pb will interfere with calcium absorption from the gut, along with displacing calcium in multiple sites.
- Lead, in people, is immunotoxic and carcinogenic.

SYSTEMS AFFECTED

Gastrointestinal and central (and possibly) peripheral nervous systems are the primary targets; other systems affected may include red blood cells, bone marrow, kidney, and liver.

Toxic Dose

- The toxic dose for cattle has been determined experimentally. The acute toxic dose may range from 400–800 mg/kg and the acute dose may range from 1–7 mg/kg/day. These are from experimental exposures and differ from clinical cases where the amount and form of lead ingested is generally not known.
- Cattle—intakes of greater than 6 mg/kg body weight can lead to chronic poisoning, and intakes greater than 10 mg/kg BW may cause acute lead poisoning.
- Sheep—generally occurs only in lambs; symptoms of poisoning appear at intakes greater than 4.5 mg/kg BW.

- Goats—more resistant than sheep or cows. Very minor signs of poisoning occur at intakes of 60 mg/kg BW. This is equal to blood concentrations of 130 micrograms per dl.

Sources

- Lead storage (car) batteries
- Lead shot
- Old lead arsenate
- Lead contamination of soils (smelters)
- Crop production enhancement agents: many crop yields are increased with the use of fertilizers, fungicides, and herbicides that contain lead (e.g., lead arsenate).
- Old lead-based paints
- Mining: strip mining can cause lead to leech into groundwater and soil and into the air as dust particles.

GENETICS

N/A

INCIDENCE/PREVALENCE

Unpredictable, but most cases occur in cattle in the spring, when they are turned out in pastures where they have access to broken batteries.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

- All ruminant species are at risk.
- Young animals are perhaps more susceptible due to their curiosity and greater absorption of lead from the gastrointestinal tract.
- Cattle more likely than other ruminants due to less-discriminating grazing.

Breed Predispositions

N/A

Mean Age and Range

- All ages are susceptible.
- Younger animals are at greater risk of intoxication due to increased capacity to absorb lead from the intestines.

Predominant Sex

N/A

SIGNS

- Signs appear to occur abruptly, though there may be a delay of several days (depending on the lead source) from the time of lead ingestion and the onset of signs.
- Blindness, circling, aimless wandering, head pressing
- Grinding of the teeth
- Rhythmic twitching of the muscles, often involving the face (e.g., eyelids)
- Tucked and painful abdomen; rumen atony, constipation, or diarrhea may be present.
- Salivation, due to pain or pharyngeal paralysis
- Excitement and/or seizures (depression may also be observed)
- Bradycardia and hypertension have both been observed in cattle.

CAUSES AND RISK FACTORS

- Discarded broken batteries are by far the most common source of lead poisoning in ruminants. The interior lead plates often contain > 90% lead.
- Other less common sources of lead include machinery grease, old used motor oil, paint, pesticides, caulk and putty, contamination from mines and smelters, water, and grazing pastures contaminated with lead shot.
- Burning batteries does not destroy lead; this practice only provides animals a more concentrated lead source in the remaining ash.
- Acute oral toxic dose for calves and cattle is approximately 400–800 mg/kg BW.

- Pb can be excreted in the feces, urine and bile. Chelation therapy enhances renal excretion.

DIAGNOSIS

- Based on clinical signs and history of possible exposure
- Definitive diagnosis requires detection of lead in appropriate clinical specimen
- Diagnostic samples:
 - Whole blood
 - Lead concentrations of greater than 0.35 ppm with appropriate clinical signs are diagnostic
 - Kidneys (> 10 ppm Pb wet weight are diagnostic)
 - Liver (> 10 ppm Pb wet weight are diagnostic)

DIFFERENTIAL DIAGNOSIS

- Polioencephalomalacia, salt poisoning, and/or water deprivation, vitamin A deficiency, rabies, listeriosis, abscess, thromboembolic meningoencephalitis, nervous coccidiosis, and hepatic encephalopathy
- There are many differentials for “sudden” death in calves or cows; these could include enterotoxemia, water hemlock (*Cicuta*), botulism, nonprotein nitrogen intoxication, cyanobacteria (blue-green algae), *Delphinium* (larkspur), *Zigadenus* (death camas), *Astragalus* (locoweed), nitrate poisoning

CBC/BIOCHEMISTRY/URINALYSIS

- Basophilic stippling is commonly mentioned as a potential alteration: inconsistent; may be mistaken for other disease processes
- Anemia (subchronic to chronic lead toxicosis)
- Increased RBC fragility

OTHER LABORATORY TESTS

- Whole blood lead, EDTA, or heparin. Levels greater than 0.3 ppm indicate excessive exposure, > 0.6 ppm is compatible with poisoning.
- Even though blood lead levels are diagnostic for confirming exposure, blood Pb levels sometimes do not correlate well with clinical signs. For instance, one might see a blood lead level of 0.30 ppm in a cow that is seizing; and one might see a blood lead level of 0.90 ppm in a cow that is not showing any clinical disease. Because of this, when you diagnose lead poisoning in an individual animal, remaining animals in the “exposed” group should be tested, regardless of whether they are showing signs or not.
- Liver and kidney concentrations greater than 5.0 ppm wet weight are consistent with excessive lead exposure.

IMAGING

Radiography done antemortem or postmortem may show radiographic densities in the GIT, most commonly in the reticulum.

DIAGNOSTIC PROCEDURES

One should find the source (through history, pasture examination, etc.) and remove it from the animal's environment; or remove the animals from the contaminated environment. Sometimes batteries can be so disintegrated and ground into the soil that little visible evidence remains.

PATHOLOGIC FINDINGS

- No findings are pathognomonic for lead poisoning.
- Cerebral edema and mild gastritis and enteritis are sometimes observed grossly.
- Histologically, laminar cortical necrosis, centrilobular degeneration, and proximal renal tubule degeneration and necrosis have been observed. These are uncommon lesions.
- Intranuclear inclusion bodies in the kidney and brain can be seen with chronic exposures or massive acute oral exposures.

Gross Necropsy Findings

- None that is pathognomonic
- CNS
- Flattened or yellow cerebral cortical gyri

HISTOPATHOLOGICAL FINDINGS

- CNS
 - Laminar cortical necrosis with swelling of the capillary endothelium within the brain
- Renal
 - Lead inclusion bodies are often found in the proximal renal tubules.
 - Inclusions are described as intranuclear inclusions in the proximal tubules with periglomerular nephritis.

TREATMENT

- Find and remove the suspect source or remove animals from the contaminated environment.
- Removal of the lead from the multicompartmental ruminant GIT has been shown to be next to impossible.
- Treatment of lead intoxication may not be rewarding and deaths may occur prior to the initiation of antidotal therapy.
- The prolonged retention of lead may be due to continued release and absorption of lead from metal particles in the reticulum or rumen.
- Chelation therapy
 - Ca-EDTA—55–90 mg/kg body weight slowly IV or IM, bid
 - Treat for 3–5 days.
 - Wait for several days and reevaluate neurologic status; another round of chelation may be indicated.
- Symptomatic therapy—thiamine HCL—administer 2 mg/kg IM, bid. Treat for up to 2 weeks.
- Supportive therapy—mineral supplementation may be required if there is prolonged chelation therapy.

MEDICATIONS

- Magnesium sulfate can be added to the diet to help bind lead within the gastrointestinal tract (one recommended dosage: 0.5 g/lb BW daily).
- Thiamine hydrochloride, 250–1000 mg twice daily, IM or SQ, for 5–10 days. This is not a chelator, but many affected animals will improve clinically and when combined with a chelator, it has been shown to enhance the renal excretion of lead.
- Ca-EDTA is an effective chelator, but may not be an economically viable option for many clients. One recommended dosage is 72 mg/kg, slow IV, divided twice to three times daily for 3 to 5 days. This may be repeated after a few days if clinical signs persist. Blood leads should be periodically monitored to evaluate the effectiveness of the chelation therapy.
- Depending on the severity and signs, symptomatic care may include diazepam or barbiturates for seizure control, IV fluid therapy to correct dehydration, monitoring for the development of electrolyte abnormalities, monitoring feed and caloric intake and addressing deficiencies accordingly, zinc supplementation (1.0 mg/kg/day).
- British anti-Lewisite (dimercaprol or BAL) penetrates into the brain, and can be a helpful chelator in animals showing severe neurological signs. One suggested dosage is 3.0 mg/kg IM as a 5% solution in a 10% solution of benzyl benzoate in peanut oil every 4 hours for 2 days, every 6 hours on day 3, then bid for the next 10 days. BAL is potentially nephrotoxic and is painful when injected. It can be difficult to obtain and expensive to use.

CONTRAINDICATIONS

- Ca-EDTA is potentially nephrotoxic, so monitoring renal parameters and maintaining adequate hydration status are recommended.
- Lead may interfere with copper, calcium, zinc, iron, and selenium metabolism.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

- Blood lead levels should be monitored periodically to determine the efficacy of chelation therapy, along with assisting with decision making in regard to slaughter withdrawal times. Normal blood levels should be < 0.10 ppm.
- Lead can be secreted into milk; milk should be tested and discarded if levels are too high.

PATIENT MONITORING

It is common for the neurological signs (e.g., blindness) to persist. Ill thrift may be present in “recovered” young.

PREVENTION/AVOIDANCE

- Knowledge of the common sources of lead should help producers avoid this potentially devastating disease.
- Keep at-risk animals away from junk or “resource” piles located on the property.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- The more severely affected animals have a poor prognosis. It is often impossible to remove the lead from the gastrointestinal tract, and patients showing severe neurological signs often do not respond well to treatment.
- Mild or moderately affected animals may improve if you can remove the lead from the gastrointestinal tract, and enhance renal excretion through chelation therapy.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- The half-life of lead in an intoxicated animal depends on a number of factors including age and physiological status.
- In some references, the half-life of lead is reported to be several weeks to 2 months. This may underestimate the half-life of elimination of lead.
- A study from Michigan examined the half-life of lead in poisoned animals and reports that pregnant or lactating cattle tended to have a shortened half-life as compared to a castrated bull.
- If there is any question of toxicity, a whole blood sample can be collected and analyzed for lead.

AGE-RELATED FACTORS

Younger animals are at greater risk of intoxication due to increased capacity to absorb lead from the intestines.

ZOONOTIC POTENTIAL

- Lead is immunosuppressive and carcinogenic in people. The developing fetus and young children are very susceptible to lead's toxic effect on the nervous system. Care should be taken when using meat or milk from lead contaminated carcasses for human consumption.
- There is potential for lead exposure to animals from milk and meat of poisoned animals.
- In some states, there are restrictions on movement or marketing of cattle poisoned with lead.
- The veterinarian should consult the local diagnostic laboratory or department of public health for questions specific to their practice area.

PREGNANCY

- Lead has been shown to cross the placenta in humans; it is conceivable that lead may exert a deleterious effect on the developing ruminant fetus.
- Pregnant cattle that suffer from lead toxicosis may transfer significant amounts of lead to the developing fetus.
- The amount of lead transferred across the placenta or into the milk is highest when the blood concentrations of lead are greatest.

RUMINANT SPECIES AFFECTED

All ruminant species are susceptible.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Restrict animal access to lead sources (e.g., paint-cribbing, batteries, grease, etc.). Avoid access to junk piles in the pastures.
- Removing nonclinical, exposed animals from the source is very successful in preventing new cases.

LEPTOSPIROSIS

BASICS

OVERVIEW

- Leptospirosis is a zoonotic, acute febrile disease with clinical manifestations depending on the animal species and the serovar (serological variant) involved of a spirochete in the genus *Leptospira*.
- Leptospirosis causes acute and chronic disease (septicemia, agalactia, hepatitis, nephritis, and abortion) in a wide range of domestic livestock and wildlife hosts.
- Vaccination is serovar specific.

PATHOPHYSIOLOGY

- Leptospire enter the body through cutaneous or mucosal abrasions or by direct penetration of moist skin. Rarely transmission can occur by venereal or transplacental routes.
- Septicemia follows for 4–7 days resulting in systemic dispersion of bacterial toxins causing fever, capillary damage (petechia), hepatic necrosis, renal tubular damage, and agalactia. In calves, hemolysin toxin may cause intravascular hemolysis, hemolytic anemia, and hemoglobinuria.
- Humoral response creates rising serum antibody levels resolving the septicemia and fever with the bacteria localizing in the liver and renal parenchyma causing hepatitis, interstitial nephritis, and persistent leptospiruria.
- Animals may succumb acutely to septicemia and hemolytic anemia or later due to interstitial nephritis.
- Animals in the second half of gestation (> 4 months) can have invasion of the placenta and fetus during the septicemic phase resulting in abortion several weeks later.
- Sheep and goats can develop encephalitis due to localization of the leptospire in the nervous system.

SYSTEMS AFFECTED

- Renal and urologic including interstitial nephritis, tubular damage, and chronic renal failure
- Hepatobiliary including hepatitis, necrosis
- Cardiovascular including endothelial cell damage
- Nervous system including meningitis
- Reproductive including abortion, stillbirth, and retention of fetal membranes
- Mammary including agalactia and abnormal milk

GENETICS

N/A

INCIDENCE/PREVALENCE

- A survey of cattle at slaughter in the United States reported 2% of mature cattle were renal carriers of leptospire with serovars *hardjo*, *pomona*, and *grippotyphosa* being isolated.
- *L. hardjo* is host adapted to cattle and has caused epidemiologic or endemic reproductive problems in cattle in the United States.
- *L. pomona* is most common in calves.

GEOGRAPHICAL DISTRIBUTION

- Worldwide distribution favoring warm, wet climates and surviving in standing water for prolonged periods.
- Leptospirosis has been reported in most parts of the globe with different serovars predominant in different regions.

SIGNALMENT

Species

- Cattle, sheep, goats, wild ruminants, water buffalo, deer, and other cervids
- A survey isolating leptospire from kidneys of cattle at slaughter in the United States reported higher isolation rates from

beef cattle than dairy cattle.

- The host-adapted serovars generally cause a mild or unapparent disease developing into a carrier state. For example:
 - *Leptospira borgpetersenii* serovar *hardjo-bovis* is adapted to cattle.
 - *Leptospira interrogans* serovar *hardjo-prajitno* is adapted to sheep.
- Animals infected by a non-host-adapted serovar may develop acute, severe clinical disease, especially young animals; it also may cause abortion in pregnant dams. Examples are *Leptospira interrogans* serovars *pomona*, *grippityphosa*, *canicola*, and *icterohaemorrhagiae* in cattle.

Breed Predilections

N/A

Mean Age and Range

Calves and lambs are more typically affected by the acute form, subacute form in adult cattle, and chronic form in sheep, goats, and occasionally adult cattle.

Predominant Sex

- A survey isolating leptospire from kidneys of cattle at slaughter in the United States reported higher isolation rates from bulls than cows.
- Males are often nonsymptomatic carriers that may excrete *Leptospira* in the urine and semen.

SIGNS

Cattle: Herd Level

- Sudden drop in milk production in 5%–50% of lactating cows
- Increased rate of abortion
- Increase in infertility (lower conception rates) may be seen.

Individual Cow

- Host-adapted serovars
 - Depression, anorexia, transient, slight pyrexia, recumbency ranging from 1 to 7 days
 - Agalactia—sudden sharp drop in milk yield, which lasts from 7 to 14 days. Characterized by a flabby, nonpainful udder, affecting all four quarters. Milk is thick, yellowy, and may contain clots.
 - Abortion, stillbirths, and infertility
- Non-host-adapted serovars: depression, anorexia, pyrexia (40.0°C–41.5°C or 104°F–107°F), hemoglobinuria, jaundice, mucosal surface hemorrhages, mastitis with blood-tinged milk, anemia, lameness (due to synovitis), abortion, death

Sheep and Goats

- Rarely cases of clinical disease
- In young stock: pyrexia, dyspnea, depression, anorexia, may be hemoglobinuria, pale or yellowish mucous membranes; death due to septicemia may occur within 12 hours.

GENERAL COMMENTS

- Presentation will vary dependent on age, pathogenicity of the serovar, and environmental factors affecting the agent's survival.
- Primary reservoir hosts (*L. hardjo* in cattle) may shed leptospire in urine with insidious clinical signs and weak antibody responses.
- Incidental hosts (*L. pomona* in cattle) present with more acute signs and a stronger antibody response.

PHYSICALEXAMINATION FINDINGS

- Calves present with fever, anorexia, depression, (with *L. hardjo*) hemolytic anemia, hemoglobinuria, icterus, and petechia (with *L. pomona*.)
- Hemoglobinuria typically resolves within 72 hours; anemia begins to resolve at 4–5 days and is typically resolved 7–10 days later.
- Mortality rate in calves is higher than in adult cattle.
- Adult cattle present with abnormal milk (thick, yellow, blood tinged) without obvious inflammation of the mammary gland, or later with abortions.
- In endemically affected herds, younger animals may have an increased incidence of sporadic abortions.

CAUSES

- Pathogenic serovars of the *Leptospira* spirochete
- Pathogenic leptospires are classified as a single species, *Leptospira interrogans*, with more than 200 serovars in 23 serogroups. At least 7 serovars are identified in cattle in the United States including *pomona*, *hardjo*, *canicola*, *grippotyphosa*, *ictohaemorrhagiae*, *swaijak*, and *bratislava*.

RISK FACTORS

- Direct transmission through contact with urine, vaginal discharge, postabortion discharge, or the fetus of an infected host.
- Indirect transmission through contact with contaminated environment (water sources)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute to subacute disease (hemoglobinuria and icterus)
- Water toxicosis (young calves)
- Postparturient hemoglobinuria
- Anaplasmosis
- Babesiosis
- Bacillary hemoglobinuria
- Enzootic hematuria
- Snakebite
- Acute hepatitis
- Cholangiohepatitis
- Poisonings: rape, kale, brassica, copper (chronic), acorn, cassia, senna, gossypol (cottonseed), dinitrophenol, mercury, monensin, ionophores, oxalate, ethylene glycol, vetch, pyrrolizidine alkaloids, phosphate fertilizer, solanum
- Copper toxicity

Reproductive Disease

- Anaplasmosis
- Bluetongue
- Bovine viral diarrhea mucosal disease
- Brucellosis
- Campylobacteriosis
- Trichomoniasis
- Infectious bovine rhinotracheitis (IBR)
- Malnutrition
- Mycoplasma
- Mycosis

CBC/BIOCHEMISTRY/URINALYSIS

- CBC may show a hemolytic anemia and leukocytosis; may be leukopenia.
- Urinalysis: may be increased bilirubin, hemoglobin, and albumin. *Note:* urine may be infectious!
- Biochemistry may show increased liver enzymes (AST and ALT), bilirubinemia, and azotemia.

OTHER LABORATORY TESTS

- Serology—microscopic agglutination test (MAT) on acute and convalescent (7–10 days later) sera is a commonly used test for leptospirosis.
- MAT titers are considered diagnostic when greater than 1:800 in an animal with coinciding clinical signs or by a fourfold rise in paired samples.
- In cases of abortion, MAT titers are declining so identification of titers of 300 or greater in several cows would be significant in an unvaccinated herd.
- Results of samples taken in early infection may show cross-reactivity to other serovars.

- As titers drop after several months to low or negative levels, chronic carriers and animals that abort may be seronegative.
- Individual animal serology may not be diagnostic; therefore, leptospirosis should be diagnosed on a herd level. It is important to sample several suspect animals.
- Serological titers due to vaccination cannot be distinguished from those due to infection, although they tend to be lower and more transient.
- Vaccination with a bacterin may produce a low titer on the MAT test; protective immunity can last up to 12 months.
- Chronic carriers or animals with infections isolated in the kidneys may not have diagnostic titers.
- Dark-field microscopic examination of urine, fluorescent antibody staining of urine or tissues, and PCR are other techniques that can be used to diagnose leptospirosis.
- Warthin-Starry silver staining can be attempted on formalin-fixed samples.
- Isolation is not usually performed due to the difficulty in culturing the organism.

Culture

Not generally performed for diagnostic purposes due to high risk of culture contamination and prolonged isolation period ranging from weeks to months

Dark-Field Microscopy

Tentative indication but not specific

Immunofluorescence

- Urine: fast and specific if urine arrives to lab quickly and chilled
- Can add formalin to a final concentration of 0.8% to preserve the bacteria in the sample
- As excretion in cattle is intermittent, a negative result does not preclude the disease.
- FA has also been reported to be used with variable success to detect *Leptospira* in aborted fetal tissues.

IMAGING

N/A

GROSS AND HISTOPATHOLOGICAL FINDINGS

- Anemia, icterus, and hemoglobinuria (young calves)
- Subcutaneous and subserosal hemorrhage
- Autolytic fetus
- Centrilobular hepatic necrosis
- Diffuse interstitial nephritis
- Fetal hepatitis and nephritis

TREATMENT

- Infected animals can be treated with antibiotics to prevent irreversible liver and kidney damage, abortion, establishment of a carrier state, and hemolytic anemia.
- Animals with acute disease may require blood transfusions, oral or intravenous fluid therapy, and other supportive nursing care.
- Treating lactating dairy cattle with agalactia may hasten return to near normal yields, but requires discarding the milk for the withdrawal period. Treatment at this time may also reduce the likelihood of abortion.
- Acute disease in calves should be treated aggressively both symptomatically and with antibiotics.
- No treatment has been proven 100% effective in eliminating the carrier state of a host-adapted serovar.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

Leptospirosis has zoonotic potential through contact with contaminated urine and the environment.

MEDICATIONS

- Antimicrobial therapy
 - Single injection of oxytetracycline, 20 mg/kg of body weight IM
 - Tetracycline, 10–15 mg/kg bid for 3–5 days.
 - Long-acting oxytetracycline, 20 mg/kg twice at 10 day intervals
 - Long-acting amoxicillin, 15 mg/kg, two doses 48 hours apart
 - Tilmicosin, 10 mg/kg SQ
 - Ceftiofur sodium 2.2 or 5 mg/kg IM SID for 5 days or 20 mg/kg IM SID for 3 days
 - Streptomycin or dihydrostreptomycin, 12.5 mg/kg bid for 3 days. A single dose of 25 mg/kg will usually clear the carrier state from *L. pomona* or other non-host-adapted serovars.
- Appropriate meat and milk withdrawal times must be considered.

CONTRAINDICATIONS

N/A

PRECAUTIONS

Previously, streptomycin, dihydrostreptomycin, or dihydrostreptomycin-pencillin G was used for treatment but is no longer available in certain countries for use in food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

- Minimizing access to wildlife, rodents, and contaminated water sources can reduce the exposure in domestic stock.
- Vaccination with bacterins containing multiple serovars generally confers protection to abortion and death and significantly reduces renal colonization.
- Selection of seronegative replacement stock will help prevent introduction into the herd.

MISCELLANEOUS

- Prompt vaccination and antimicrobial therapy for pregnant beef cows early in the epizoonosis can prevent further abortions.
- Leptospirosis is a zoonotic agent so appropriate hygiene and sanitary methods must be followed by practitioners and owners to prevent transmission.

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

The acute form more typically affects calves and lambs, subacute form in adult cattle, and chronic form in sheep, goats, and occasionally adult cattle.

ZOONOTIC POTENTIAL

- Leptospirosis has zoonotic potential through contact with contaminated urine and the environment. All pathogenic *Leptospira* serovars are zoonotic.
- People are generally infected by means of aerosol or direct contact with infected urine or urine-contaminated water, which penetrates through mucous membranes or wet or abraded skin.
- People working with infected cattle should take precautionary measures such as protective clothing, rubber boots, latex gloves, and protective eyeglasses or facemasks.

- All cases of unexplained fever or influenzalike syndromes in contact workers should be reported to the attending general practitioner to determine the possible implication of *Leptospira*.

PREGNANCY

- In endemically affected herds, younger animals may have an increased incidence of sporadic abortions.
- Animals in the second half of gestation (> 4 months) can have invasion of the placenta and fetus during the septicemic phase resulting in abortion several weeks later.

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species are affected.

LEUKOCYTE RESPONSES IN CATTLE

BASICS

OVERVIEW

- Types of leukocytes in cattle:
 - Neutrophils
 - Lymphocytes
 - Monocytes
 - Eosinophils
 - Basophils
- Production of leukocytes:
 - Neutrophils, eosinophils, basophils, and monocytes are produced in the bone marrow.
 - Lymphocytes are produced in lymph nodes, bone marrow, spleen, thymus, and Peyer's patches.

DEFINITION

- Leukocytosis refers to an increase in the numbers of leukocytes in blood. Neutrophilia, lymphocytosis, monocytosis, eosinophilia, and basophilia refer to increased total numbers of the specific cell.
- Leukopenia refers to a decrease in the numbers of leukocytes in blood. Neutropenia, lymphopenia, and monocytopenia refer to decreased total numbers of the specific cell.
- Evaluation of the leukocyte portion of the hemogram is performed on the basis of the absolute numbers of each cell type and not on the percentages of the cell types.
- Left shift indicates that immature neutrophils, which are usually bands but may also include less mature cells such as myelocytes and metamyelocytes, are increased. Regenerative left shift indicates that the total neutrophil count is increased and there is a concomitant left shift. Degenerative left shift indicates that the total neutrophil count is low (or at the low end of normal) and there is a concomitant left shift. Often with a degenerative left shift, the total number of immature neutrophils (band neutrophils, metamyelocytes, etc.) is greater than the total number of mature neutrophils.

PATHOPHYSIOLOGY

General

- Leukocyte counts are higher in calves than in adults. Young adults have higher leukocyte counts than older adults.
- Adult cattle are considered a “small storage pool” species. As such they have fewer neutrophils in reserve in their bone marrow (the storage pool) than do “large storage pool” species such as dogs. “Small storage pool” animals such as adult cattle deplete the storage pool more rapidly when they develop significant inflammation than do large storage pool species.
- Because cattle tend to deplete their storage pool rapidly, they frequently develop neutropenia with inflammation. Increased myelopoiesis occurs in an attempt to produce more neutrophils. Frequently, especially with severe inflammation, immature neutrophils (especially band neutrophils) are released from the marrow, which causes a left shift, which frequently is degenerative.
- With inflammation cattle tend to produce large amounts of fibrinogen. Thus, variable neutrophil counts (neutrophilia, normal neutrophil count, or neutropenia), which may be accompanied by a left shift with hyperfibrinogenemia are often found with inflammation.
- Leukocyte changes with stress are similar in cattle to those of other species. Excitement (epinephrine induced physiologic leukocytosis) results in leukocytosis, which is due to neutrophilia and lymphocytosis. Corticosteroid-induced changes consist of neutrophilia without a left shift and lymphopenia, monocytosis, and eosinopenia.
- Toxic changes in neutrophils indicate the presence of bacterial toxins and inflammatory cytokines. Usually toxic changes indicate bacterial disease. Features of toxicity include Döhle bodies (blue inclusion bodies in the cytoplasm), diffuse

cytoplasmic basophilia, cytoplasmic vacuolation or foaminess, and granulation (these features are listed in order from least to most severe).

- Reactive lymphocytes in blood indicate immune response to antigens. The most obvious feature of reactive lymphocytes is very basophilic cytoplasm. Reactive lymphocytes are generally slightly larger and have a greater amount of cytoplasm than normal lymphocytes. Slight irregularity such as indentations and fissures of their nuclei may be recognized.

Neutrophilia

- Neutrophilia in cattle is usually modest and total neutrophil counts above 15,000/ μ are rare.
- Neutrophilia accompanied by lymphocytosis occurs with physical exertion, excitement and acute stress.
- Neutrophilia accompanied by lymphopenia and occasionally by monocytosis occurs with stress that causes release of corticosteroids and glucocorticoid administration.
- Many infectious diseases of bacterial etiology cause neutrophilia provided that the inflammatory reaction is not of such severity that the bone marrow storage pool is depleted (see neutropenia). Left shift with toxic neutrophils may be found.
- Noninfectious causes of inflammation such as cholangiohepatitis result in moderate neutrophilia.
- Fungal infections, traumatic tissue injury, neoplasia and immune mediated disease may cause neutrophilia.

Lymphocytosis

- Calves have higher lymphocyte counts than adults. Younger adults also have higher lymphocyte counts than older animals.
- Lymphocytosis accompanied by neutrophilia occurs with physical exertion, excitement, and acute stress.
- Lymphocytosis occurs with immune responses. It may be found with infectious diseases, after vaccination, and in young animals reacting to environmental organisms and other antigens.
- Persistent lymphocytosis occurs with many cattle infected with bovine leukemia virus.
- Occasionally, lymphocytosis in which the lymphocytes are bizarre and anaplastic may be seen with lymphoma.

Monocytosis

- Monocytosis may occur with stress that causes release of corticosteroids and glucocorticoid administration.
- Chronic infectious disease may produce monocytosis, particularly if the agent causes granulomatous inflammation.
- Fungal infections may produce monocytosis.

Eosinophilia

- Eosinophilia is rare.
- Migration of multicellular parasites may cause eosinophilia.
- Eosinophilia may be found with emphysema.
- Eosinophilia may be found with allergy.

Neutropenia

- Severe inflammation often depletes the neutrophil storage pool resulting in neutropenia, which is often accompanied by a left shift that includes neutrophilic myelocytes and neutrophilic metamyelocytes as well as band neutrophils.
- Bacteria infections, especially with endotoxin-producing organisms or release of endotoxin through devitalized intestinal barriers, result in toxic cytoplasmic features of neutrophils.
- Bone marrow suppression from toxins such as bracken fern or from myelophthisis such as with rare cases of bone marrow involvement with lymphoma causes marked neutropenia. Nonregenerative anemia and thrombocytopenia are often found as well, which suggests generalized hematopoietic hypo- or aplasia.

Lymphopenia

- Lymphopenia accompanied by neutrophilia occurs with stress that causes release of corticosteroids and with administration of glucocorticoids.
- Viral infectious disease such as bovine virus diarrhea may cause lymphopenia.

Bovine Leukocyte Adhesion Deficiency (BLAD)

- BLAD is a fatal granulocytopeny of Holsteins that is inherited in an autosomal recessive manner.
- It is caused by a defect in CD18 unit of β_2 -integrins, which are expressed primarily on leukocytes. The β_2 -integrins are heterodimers consisting of the β subunit (CD18) and one of several α subunits (CD11a, CD11b, CD11c, and CD11d). Mac-1, the heterodimer of CD11b and C18, mediates tight adherence of neutrophils to postcapillary venule endothelial cells, which is an early activity of neutrophil migration into tissues. The inability of the neutrophils to adhere to

endothelium prevents them from moving into infected tissue. Calves die soon because the neutrophils are unable to extravasate into infected tissues.

- BLAD calves have recurrent soft tissue infections. They do not develop significant inflammation at these sites. Calves may have a history of respiratory disease and diarrhea, periodontal gingivitis, and gingival recession.
- They have marked neutrophilia ($> 40,000/\mu\text{l}$ to well over $100,000/\mu\text{l}$) that persists and continues to increase. The marked and progressive neutrophilia is due to continued stimulation of myelopoiesis, which is a frustrated attempt to provide neutrophils to combat infections. Additionally, the inability of the neutrophils to leave the circulation causes them to remain in blood for a prolonged period of time.
- Presumptive diagnosis of BLAD may be made on the basis of the leukogram findings of persistent and progressive neutrophilia in a young calf. Flow cytometric analysis with fluorescent labeled antiCD18 antibody reveals markedly reduced amounts of CD18. A DNA-polymerase chain reaction (PCR)-restricted technique fragment length polymorphism (RTLP) technique, which unequivocally identifies the genotype of cattle at the CD18 locus, has been developed. It is available through Immgen Inc., College Station, Texas, as well as the Bovine Blood Typing Laboratory of Canada, Saskatoon, Saskatchewan. In the United States, all testing is coordinated and recorded through the Holstein Association of America.

Chédiak-Higashi Syndrome

- Chédiak-Higashi syndrome (CHS) is a rare inherited disease that is transmitted as an autosomal recessive trait that is characterized by hypopigmentation, enlarged or giant granules in granule-containing cells, and a platelet storage pool disease.
- In addition to hypopigmentation (often described as partial albinism) and bleeding diathesis, cattle with CHS have increased susceptibility to bacterial infections. This susceptibility is due to multiple defects of neutrophils and other cells of defense.
- CHS has been described in Hereford, Brangus, and Japanese Black (Wagyu) cattle.
- Diagnosis is based on clinical features coupled with recognition of enlarged granules in phagocytes. In most species, the enlarged granules are best recognized in eosinophils.
- A PCR method for detection of the abnormal CHS gene has been described.

SYSTEMS AFFECTED

- The primary tissues affected are the bone marrow and lymphatic tissue, which are the location for production of the various leukocytes. There may be evidence of increased production such as increased M:E in the marrow or immune reactivity in lymph nodes.
- Any tissue or organ can be affected since leukocytes, especially neutrophils, migrate into them under the influence of a variety of stimuli.
- BLAD calves have numerous soft tissue infections. Very little pus is found in these sites because of the inability of neutrophils to adhere to endothelial cells during the initial stages of inflammation.

GENETICS

- Bovine leukocyte adhesion deficiency (BLAD) occurs in Holstein calves. It is inherited as an autosomal recessive trait.
- Chédiak-Higashi syndrome has been described in Hereford, Brangus, and Japanese Black (Wagyu) cattle. It is inherited as an autosomal recessive trait.

INCIDENCE/PREVALENCE

BLV infection may be as high as 75% in some dairy herds.

GEOGRAPHIC DISTRIBUTION

Since leukocytes are vital for combating infectious and noninfectious causes of diseases, cattle throughout the world may have hemogram features reflecting leukocyte reactions.

SIGNALMENT

- All cattle may have some abnormality in leukocyte parameters or morphology due to a wide variety of diseases and physiological conditions.
- BLAD is a disease of young Holstein calves.
- CHS is a disease of Herefords, Brangus, and Japanese Black (Wagyu) cattle.

Breed Predilections

- BLAD occurs in Holstein cattle.

- CHS has been described in Hereford, Brangus, and Japanese Black (Wagyu) cattle.

Mean Age and Range

- Animals of all ages are susceptible to conditions that cause inflammation and immune reactions.
- Severe, multiple infections are found in young, generally less than 1 month of age, Holstein calves with BLAD.

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

PHYSICAL EXAMINATION FINDINGS

CAUSES AND RISK FACTORS

Bacterial Diseases

- Bacterial infections usually cause suppurative inflammation, which develops through migration of blood neutrophils into tissues. Inflammation often causes neutrophilia if the insult is not markedly severe. Often hyperfibrinogenemia accompanies an inflammatory leukogram.
- However, severe infection with accompanying marked inflammation causes large numbers of neutrophils to migrate from the blood into the inflamed tissue and with subsequent depletion of the neutrophil storage pool resulting in neutropenia with a degenerative left shift. The neutrophils may be toxic, especially with gram-negative infections.
- When the infection and the accompanying inflammatory reaction do not resolve in a few days, myelopoiesis increases to satisfy the demand for neutrophils. Such established inflammation results in neutrophilia without a left shift. Additionally, there may be monocytosis, normal to mildly increased lymphocyte count, and reactive lymphocytes.
- Endotoxin released by bacteria also affects the leukogram. Severe endotoxemia results in marked leukopenia due to neutropenia and lymphopenia. There may also be a degenerative left shift.
- Mastitis, metritis, and other bacterial diseases of tissues and organs that may have multiple etiologies cause similar neutrophil responses as described above.

Viral Diseases

- There are many different viral diseases of cattle which require diagnostic evaluation (see Bovine Blood Chemistry, Diagnostic Techniques—Sampling for Microbiology, and Serologic Testing).
- Lymphopenia is found with many viral infections, particularly during the initial phases. If secondary bacterial infections develop, neutrophilia may occur as a response to inflammation.
- Persistent lymphocytosis occurs in cattle infected with BLV.

Parasitic Diseases

- Leukogram change may be found with many parasite infections. Such changes are nonspecific.
- Occasionally, eosinophilia develops during the migratory phase of multicellular parasites.

Neoplasia

- Neoplasia can cause a variety of leukogram changes. If a neoplasm itself becomes necrotic or if it damages invaded tissue or adjacent organs, neutrophilia and monocytosis may be found.
- Lymphocytosis with large, bizarre mononuclear lymphoblasts is occasionally found in cattle with lymphoma.

DIAGNOSIS

- Leukocyte parameters are evaluated as part of the information used to diagnose many diseases.
- A DNA-polymerase chain reaction (PCR)-restricted technique fragment length polymorphism (RTLTP) technique for diagnosis of BLAD is available through Immgen Inc., College Station, Texas as well as the Bovine Blood Typing Laboratory of Canada, Saskatoon, Saskatchewan (see Diagnostic Techniques—PCR to Detect Microorganisms).

DIFFERENTIAL DIAGNOSIS

CBC/BIOCHEMISTRY/URINALYSIS

See Bovine Blood Chemistry, Bovine Leukemia, Diagnostic Techniques—Sampling for Microbiology, Serologic Testing, Lymphocytosis, and Lymphosarcoma.

OTHER LABORATORY TESTS

Evidence of an inflammatory reaction in the CBC that is suggestive of bacterial infection often suggests culture of the involved tissue or organ should be performed.

IMAGING**OTHER DIAGNOSTIC PROCEDURES****PATHOLOGIC FINDINGS**

Inflammation may be detected in organs and tissues by histopathological evaluation.

**TREATMENT****ACTIVITY****DIET****CLIENT EDUCATION****MEDICATIONS****DRUGS OF CHOICE**

Bacterial infections may be treated with an appropriate antibiotic depending upon the organism's sensitivity and the legality of using a particular antibiotic in food-producing animals.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

LIGHTNING STRIKE—SUDDEN DEATH

BASICS

DEFINITION

- A discharge of electricity occurring in association with thunderstorms.
- Sudden death in groups of animals without signs of struggle is strongly suggestive of lightning strike.

OVERVIEW

Lightning may cause death after

- Direct strike—lightning strikes animals directly
- Contact—electrical charge passing through object such as tree or fence to animals
- Side flash—jumps one path to animals
- Step voltage—lightning strikes object that allows radiation of energy in all directions including where animals are standing thereby killing animals instantly
- Blunt trauma—lightning strike injures animal by knocking it to ground or via falling objects

PATHOPHYSIOLOGY

- The massive electrical current and voltage applied to animals by lightning most commonly results in subacute cardiac and respiratory arrest.
- Neurologic damage in animals can be observed in or around the 4th ventricle leading to cardiac and respiratory arrest.
- Survivors may develop multiple organ system dysfunction including severe burns, vascular injury (subcutaneous hemorrhages to DIC), traumatic injury to limbs (falling, blunt trauma), or nerve excitation resulting in massive muscle contraction and thermal injury to muscle. This may result in myonecrosis, rhabdomyolysis that may lead to renal compromise.
- Renal damage associated with rhabdomyolysis and myoglobinuria can also result in hyperkalemia, hypocalcemia, hyperglycemia, and acidosis.
- Gastrointestinal effects may be due to direct effect of electrical injury on abdominal organs leading to hemorrhage or the result of blunt trauma secondary to falling or objects striking the animal.

SYSTEMS AFFECTED

Any system can potentially be affected; skin lesions on animals struck directly by lightning, others may have minimal or no observable lesions.

GENETICS

N/A

INCIDENCE/PREVALENCE

Commonly observed in specific geographic locations during the spring, summer, and early fall months of the year. Thunderstorms are prevalent in the middle latitudes of the United States and some states have very high incidence of storms (Arizona, Colorado, and Florida).

GEOGRAPHIC DISTRIBUTION

Worldwide distribution

SIGNALMENT

Any animal; more commonly observed in pastured animals

Species

All ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- Animal(s) found dead often after severe weather storms in areas where thunderstorms are frequent. Animals may be found dead where they were standing. Single or multiple animals may be found near large trees, against fences, or near watering holes, dead or unconscious.
- Feed (hay, grass) may be present within the oral cavity. Burn or singe marks on the animal and damage to the environment may be present; however, animals that are electrocuted secondary to charged water or earth or objects (step voltage) may not have visible signs of electrocution (burns).
- Death is usually instantaneous, and therefore little sign of struggle is evident.
- Singe or burn marks on animals are most commonly observed and are commonly present on medial surface of limbs, jaw, neck, and shoulders. Often, singe marks are located at one end of treelike scorch lines.
- Peripheral blood vessels are often distended with blood that clots poorly. There is capillary damage leading to subcutaneous hemorrhage and in some instances subcutaneous gas is noted.
- Ruminal distension may produce venous blood from abdomen to cranial aspect of animal.
- Nasal mucosal and frontal sinus congestion are observed in some cases, and linear mucosal hemorrhages of the larynx, trachea, and bronchi are present in most cases of lightning-induced death. This may lead to blood-tinged frothy fluid or ropes of clotted blood draining from mouth and nares.
- Infrequently, animals rendered unconscious by lightning strike followed by recovery may manifest neurologic signs and evidence of struggling may be present.
- A recent report of ocular disease in dairy cows following lightning strike indicates that electrical or blunt trauma to eyes may occur as is observed in human victims.
- Swine in outdoor pens struck by lightning manifested acute hind-limb paralysis.
- Lesions were limited to fractures of caudal lumbar and sacral vertebrae with dorsal displacement of sacral spine and transection of the spinal cord.
- Bilateral femur fractures were also observed in two calves associated with lightning strike.

DIAGNOSIS

- Careful evaluation of animal(s) and immediate environment (up to 40 meters in diameter), for signs of burns, burnt or damaged trees, or other objects.
- Useful information may include number of animals affected, number in herd, specific management practices (feeding, watering, housing), recent medical history of animals, last observation of animal, and time of death (if known).
- History of recent severe weather, although this may confuse some cases.
- Necropsy of animal(s) is highly recommended. Transport to local state diagnostic laboratory, or a veterinarian should perform field necropsy.

DIFFERENTIAL DIAGNOSIS

- Any cause of acute death in livestock
- Anthrax (*Bacillus anthracis*), clostridial intoxications (*Clostridium hemolyticum*, *Clostridium chauvoei*, *Cl. perfringens*, *Clostridium botulinum*), *Mannheimia hemolytica*, *Haemophilus somnus*, *Listeria monocytogenes* septicemia, organophosphate, carbamate, lead, ionophore, gossypol, toxic gases, blue-green algae intoxication, Japanese yew, nitrates, cyanogenic plants, salt poisoning, and other toxicants

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Samples to collect would include heart, lung, liver, spleen, kidneys, gut, lymph nodes, endocrine glands (thyroid, pancreas, adrenals), rumen content, skin and subcutaneous tissues, muscle (especially from limbs), paying particular

attention to lesions or abnormalities observed.

- Samples should be saved for histopathology (10% buffered formalin), toxicology (frozen organs such as liver, kidney, rumen content, whole eyes, or ocular fluid aspirates), and microbiology (blood, brain, liver spleen, lymph-nodes, kidney and muscle, thoracic or abdominal fluids, CSF, urine).
- Samples for microbiology should be collected in sterile containers and stored on ice but not frozen. Feed or plants consumed may also be evaluated for pesticides, herbicides, and heavy metals.

IMAGING

N/A

TREATMENT

- Treatment of survivors should focus on clinical signs.
- Neurologic sequela are common, and nonsteroidal and steroidal anti-inflammatory agents, hyperosmolar agents (mannitol, 50% dextrose, hypertonic saline) to reduce inflammation and swelling in critical locations (CNS, muscle) are recommended.
- Local wound care for burns and systemic antimicrobial agents
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Euthanasia for more severely affected animals may be appropriate.

LISTERIOSIS

BASICS

OVERVIEW

- The most common clinical presentation of listeriosis in ruminants is a multifocal, assymetrical cranial nerve deficit with varying degrees of cortical involvement. Less common clinical presentations include septicemia, abortion, and mastitis.
- The primary cause of listeriosis is *Listeria monocytogenes*. *Listeria ivanovii* is less pathogenic and a less frequent cause of clinical disease. *Listeria monocytogenes* is common in the environment both as a free-living bacteria and as a contaminant shed by clinically or subclinically infected animals.

SIGNALMENT

The neurologic disease is observed in cattle, sheep, goats, and other ruminants. Septicemic disease may be observed in both ruminants and monogastrics.

SIGNS

- A detailed neurologic examination is the single most important step in determining a diagnosis of listeriosis.
- Affected animals typically have clinical signs suggestive of cortical and multifocal asymmetrical cranial nerve deficits. Referable to the cortical component of the disease, affected animals are usually somnolent and depressed.
- Propulsive walking also may be observed. Occasionally, a primary spinal cord disease is observed in ruminants.
- The most consistent, prominent, and helpful clinical signs are referable to multiple, asymmetrical cranial nerve deficits. Like cattle with otitis, these clinical signs often include drooped or immobile ears, inability to close palpebrae, loss of facial sensation, strabismus, and nystagmus.
- Cranial nerve VIII involvement is common, resulting in head tilt and circling toward the lesion. In contrast to otitis, involvement of additional cranial nerves and cortical involvement are common. Consequently, additional clinical signs including ptosis, inability to swallow, dropped or assymetrical jaw, difficulty ingesting food and water, asymmetry and deviation of the tongue may be observed. Right- and left-sided cranial nerve deficits in the same animal are common.
- Ataxia of varying degree is usually present.
- Dramatic dehydration is common due to loss of saliva and inability to prehend and swallow food and water. Prolonged skin tenting, sunken eyes, and very firm rumen contents confirm dehydration.

CAUSES

- The primary cause of listeriosis is *Listeria monocytogenes*. *Listeria ivanovii* is less pathogenic and a less-frequent cause of clinical disease. *Listeria monocytogenes* is common in the environment both as a free-living bacteria and as a contaminant shed by clinically or subclinically infected animals.
- The bacteria will persist for extended intervals following contamination.
- *Listeria* grows at temperatures ranging from 0°C to 45°C and at a pH as low as 4.5.

RISK FACTORS

- The most common and easily recognized risk factor for listeriosis is the feeding of poorly preserved ensiled forages. These forages will generally have a pH greater than 4.0. Visible spoilage may or may not be present.
- Factors that limit the efficacy of silage fermentation include long fiber length, drier than optimal silage, inadequate packing of forage, use of bunker rather than tower silos, absence of silo covers, and relatively slow feeding, which permits spoilage at the face of a bunker silo or top of a tower silo.
- Baled silage probably increases the risk of listeriosis because the quality of fermentation is generally less adequate.
- Contamination of silage with soil also is a potential risk factor.
- It should be noted that many outbreaks have no history of silage feeding, particularly in the case of small ruminants. In these instances, the presumption is that pasture contamination and persistence of the bacteria create an increased risk for clinical disease.

- Additional risk factors implicated in some outbreaks include abrupt changes in rainfall or temperature, calving, transportation, and poor body condition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Common differential diagnoses include otitis, thromboembolic meningoencephalitis caused by *Hemophilus somnus*, and brain stem abscesses.
- Asymmetrical cortical diseases may be considered initially as differential diagnoses because affected animals often circle; however, these animals will not have the characteristic cranial nerve deficits usually seen in ruminants with listeriosis.
- Diseases that cause diffuse cortical disease like polioencephalomalacia and lead intoxication are sufficiently dissimilar in appearance that they may be discounted by the initial neurologic examination.

CBC/BIOCHEMISTRY/URINALYSIS

- Laboratory tests that may be helpful in the diagnosis and treatment of listeriosis include packed cell volume, serum protein, and serum chemistries.
- Increased hematocrit and serum protein concentrations are often dramatic. Serum chemistries often reveal very low serum bicarbonate or total CO₂, suggesting a metabolic acidosis, low serum urea concentrations, and hypokalemia; however, these results are not pathognomonic. These results will often prove useful during treatment.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Cerebrospinal fluid (CSF) analysis may be helpful in differentiating causes of asymmetrical brain stem disease in feedlot cattle.
- Listeriosis will generally cause mild increases in CSF cell counts and protein concentrations with the predominant cells being mononuclear cells, lymphocytes, and monocytes. In contrast, thromboembolic meningoencephalitis will typically result in a CSF that has a high cell count, a high protein concentration, a visible yellow color, and a preponderance of neutrophils.
- Likewise, culture of the CSF may support specific differential diagnoses; however, negative CSF cultures are expected in most animals with listeriosis.
- Bacterial cultures of CSF or, in the cases of postmortem specimens, brain tissue may permit isolation of *Listeria monocytogenes*. It should be stressed that the sensitivity of this procedure is limited and negative cultures do not rule out listeriosis. Additionally, isolation of *Listeria* spp. typically requires cold enrichment procedures and extended incubation times, which limit the timely diagnosis and preventive intervention.

TREATMENT

- A number of antibiotics have been advocated for the treatment of listeriosis. The two antibiotics most commonly recommended are penicillin (20,000 to 40,000 IU/kg BID) and oxytetracycline (10 mg/kg SID). Various sources strongly advocate one or the other antibiotic; however, no controlled comparative efficacy data are available.
- Drug withdrawal times must be determined and maintained for all drugs utilized in food-producing animals.
- Fluid and electrolyte therapy is critical for optimal patient care. Affected animals are typically profoundly dehydrated with severe metabolic acidosis.
- Additional abnormalities often observed include hypokalemia and hypocalcemia. Efforts to replace fluid and base deficits, meet maintenance requirements, and correct hypokalemia and hypocalcemia should be directed by serum chemistry results because the severity of these abnormalities is highly variable. Fluid therapy is discussed in more detail in a separate chapter.
- Oral fluids are a reasonable, low-cost alternative in most affected animals. Mature cattle readily tolerate administration of 20–40 L of oral fluid several times per day.

DIET

CLIENT EDUCATION

- Parenteral nutrition is costly and probably contraindicated in most cases of listeriosis.
- In expensive animals or pet food animals, the practitioner may consider performing a rumenostomy to facilitate administration of food, water, and electrolytes.

MEDICATIONS

DRUGS OF CHOICE

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

- Prognosis varies between cattle and small ruminants.
- The disease in sheep and goats progresses more rapidly, responds poorly to treatment, and usually is fatal. The prognosis in affected cattle is guarded.
- In cattle, early intervention and appropriate fluid, electrolyte, and nutritional support improve the prognosis.
- Cattle that recover from listeriosis will generally begin to eat and drink within 2 to 3 days after the start of treatment.
- In cattle with severe, progressive clinical signs and no improvement after 2 to 3 days of treatment, euthanasia should be considered.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Affected animals typically have clinical signs suggestive of cortical and multifocal asymmetrical cranial nerve deficits.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- The disease in humans occurs primarily as a food-borne disease affecting the immunosuppressed, fetal, young or old host.
- Contaminated raw milk products pose a particular risk.
- Practitioners and livestock producers should take precautions when handling aborted fetuses or infected tissues because the organism can be spread by direct contact.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species are affected.

BIOSECURITY

LIVER ABSCESSSES

BASICS

DEFINITION

- Hepatic abscesses are common as a sequela to rumen acidosis in cattle fed highly fermentable diets.
- Neonatal calves are susceptible to ascending navel infections, which can occasionally result in hepatic abscesses.
- Foreign bodies can cause abscessation by penetrating the liver parenchyma.
- The most common bacterial species cultured from hepatic abscesses, in cattle and sheep, are *Fusobacterium necrophorum* (predominantly found), *Streptococcus*, *Staphylococcus*, *Bacteroides*, and *Arcanobacterium pyogenes* (formerly known as *Corynebacterium pyogenes*).
- Liver abscesses represent a major economic loss to producers of feedlot cattle.
- Goats that have hepatic abscess are usually older than a year of age and in poor nutritional condition. The abscesses are usually secondary to a primary disorder. The most common bacterial species found in the abscesses are *Corynebacterium pseudotuberculosis*, *Escherichia coli*, and *Corynebacterium* spp.

PATHOPHYSIOLOGY

- Liver abscessation in ruminants is a result of compromise to the integrity of the ruminal wall. The compromise can be a sequela of rumen acidosis and/or objects penetrating the ruminal wall. The objects can range from coarse hay to foreign material.
- The primary organism involved in 85% of liver abscesses cultured is *Fusobacterium necrophorum*. This organism is a commensal microbe of the ruminal flora. Its primary energy substrate is lactate, allowing it to proliferate in an anaerobic environment that is using highly fermentable substrates to produce lactate.
- As bacteria colonize the ruminal wall, they shed bacterial emboli into the vascular drainage of the rumen and enter in the portal circulation. Bacteria and other foreign debris are phagocytized from the blood by Kupffer cells and leukocytes in the liver.
- The liver is a highly vascular and well-oxygenated organ. Since most of the bacteria and primarily *Fusobacterium necrophorum* are anaerobic bacteria, they have special virulence factors that allow them to establish an anaerobic microenvironment in which they can proliferate and produce an abscess.
- *Fusobacterium necrophorum* has leukotoxin and endotoxic lipopolysaccharides that help defend the bacteria from phagocytosis, and also promote intravascular coagulation, which results in infarcts in the parenchyma of the liver.
- As the abscess forms, it becomes encapsulated with connective tissue. In time, fluid reabsorption and connective tissue infiltration result in scar tissue formation in the liver with a net loss of parenchymal tissue.
- Occasionally, the abscess may rupture into the venous circulation resulting in anaphylaxis or showering the lungs with bacterial emboli. Ruptured abscesses can also cause formation of a thrombus in the caudal vena cava, which can result in portal hypertension and lead to ascites. If an abscess continues to increase in size, it may occlude the common bile duct and prevent bile secretion into the gastrointestinal tract.
- Liver abscesses do result from ascending umbilical vein infections in neonates. Neonates that have failure of passive transfer can also form liver abscesses independent of the nidus as they become bacteremic.
- Liver abscesses have also been reported in cattle infected with *Fasciola hepatica*.

SYSTEMS AFFECTED

- Hepatobiliary—loss of parenchymal tissue resulting in a decrease in metabolism of glucose and production of albumin. If the bile duct becomes obstructed, there is a decrease in bilirubin excretion and bile production.
- Musculoskeletal—decrease in weight gain and possible loss in muscle mass. If liver abscesses rupture into the venous circulation, it could result in laminitis.
- Skin—obstruction of the bile duct could prevent the excretion of phyloerythrin, which is a photodynamic agent to the

dermis. The animal's dermis becomes photosensitized to UV light.

- Respiratory—occasionally, liver abscesses rupture into the caudal vena cava resulting in bacterial emboli being carried through the right heart chambers and into the lungs. Once in the lungs, the emboli can form abscesses that may erode through vessels in the lungs and cause hemorrhage into the bronchioles. Bilateral epistaxis and potentially exsanguination may result.
- Nervous—if enough of the liver is compromised, ammonia will not be converted to urea and neurological damage may result.
- Metabolic—destruction of liver parenchyma will prevent proper metabolism of glucose and glucose precursors in the blood. The animals will have poor weight gain and can have weight loss.
- Gastrointestinal—ruminal acidosis is the most consistent finding in animals with abscesses.

GENETICS

N/A

INCIDENCE/PREVALENCE

- In general, the incidence of liver abscesses is increased in ruminants fed diets high in carbohydrates and low in roughage.
- Holsteins are fed a consistently higher energy diet than beef cattle for longer periods; therefore, they have a higher incidence of liver abscesses.
- Feedlot steers have a somewhat higher incidence than heifers, which is believed to be related to higher amounts of feed intake.
- Cattle fed long-stem, dry, coarse hay are more prone to rumen wall penetration and abscess formation.
- Calves born in a dirty environment or that do not receive adequate colostrum are predisposed to ascending umbilical vein infections.
- Cattle in areas where liver flukes are endemic and not provided adequate prophylaxis can have abscesses form along the parasites' migratory tract.

GEOGRAPHIC DISTRIBUTION

None

SIGNALMENT

Species

Liver abscesses have been identified in bovine, ovine, and caprine species. In cattle and in sheep, the appearance of abscesses is primarily associated with animals that are being fed a highly fermentable diet with low roughage, leading to ruminal acidosis. In goats, the animals are usually older than a year and in poor body condition, with an accompanying pathologic disorder.

Breed Predilections

N/A

Mean Age and Range

Caprine, older than one year; beef and dairy cattle old enough to be fed a highly fermentable diet

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

Most cases of hepatic abscesses are subclinical and do not become recognized until the animals are slaughtered.

HISTORICAL FINDINGS

- Loss of weight
- Reduction in feed intake
- Decrease in feed efficiency
- Dairy cows or dairy goats may have a decrease in milk production.

PHYSICAL EXAMINATION FINDINGS

May have fevers, anorexia, exhibit pain when moving, diarrhea, ascites, peritonitis, and septic joints

CAUSES

- Rumen acidosis

- Septicemia and or bacteremia
- Ascending umbilical vein infection
- Liver flukes

RISK FACTORS

- Highly fermentable feeds
- Long-stem, dry coarse hay
- Dirty environment for neonates

DIAGNOSIS

Liver abscesses are usually detected only at the time of slaughter, since two-thirds of the liver must be affected before clinical signs manifest themselves.

DIFFERENTIAL DIAGNOSIS

- Parasitism
- Malnutrition
- Poor-quality feed
- Johne's disease
- Lymphosarcoma
- Traumatic reticuloperitonitis
- Hepatic lipidosis
- Polioencephalomalacia
- Septicemia

CBC/BIOCHEMISTRY/URINALYSIS

- In general, CBC and biochemistry tests are not reliable indicators of hepatic abscesses. If alterations are observed, they usually support the diagnosis but are not specific.
- CBC—can have a leukocytosis characterized by a neutrophilia and may or may not show an increase or decrease in total proteins. Anemia may be present due to chronic inflammation.
- Biochemistry—elevations in liver enzymes such as sorbitol dehydrogenase, gamma-glutamyltransferase, and aspartate aminotransferase may be present. Total bilirubin may not be elevated, but if there is a bile duct obstruction, there could be elevations in direct bilirubin.

OTHER LABORATORY TESTS

Liver function tests are not very informative and usually are cost and time prohibitive in ruminants.

IMAGING

Ultrasound of the liver can be rewarding if the abscess is in an area where it can be visualized.

DIAGNOSTIC PROCEDURES

An ultrasound guided liver aspirate may be useful if the abscess is in an area that can be visualized and aspirated.

PATHOLOGIC FINDINGS

- Abscesses in the liver can appear as large single abscesses or multiple irregular, granular yellow lesions randomly distributed (telangiectasis).
- There are two different types of gross pathologic lesions found in the liver. The first is an abscess with a thin capsule and a central area of necrosis and purulent material. The second is a thick, fibrous capsule with a central cavity and little to no purulent material.
- Some of the lesions with a thickened capsule may have central mineralization.
- Histologically, the abscesses that are a result of bacterial emboli appear as having a central area of coagulative necrosis with numerous phagocytic cells. Depending on the length of time the abscess has been forming, there may be bacteria present in the center, but more likely they are concentrated in the periphery of the necrotic core.
- Abscesses resulting from the migration of hepatic parasites include focal and multifocal coalescence of eosinophils forming granulomatous inflammation.

TREATMENT

- Treatment of animals identified with abscesses is often unrewarding due to the diffuse nature of the abscesses and limited blood supply to the heavy capsular lining. However, high doses of penicillin and oxytetracycline along with supportive therapy may be effective.
- If the abscess is in an area where it can be accessed surgically, it can be drained. This procedure is cost prohibitive in most food-animal cases.
- Anti-inflammatory agents can be administered to reduce damage from inflammatory factors and provide pain management.

APPROPRIATE HEALTH CARE

- There is very little that can be done that is cost effective in production animals. Most of these animals are culled due to poor performance.
- Supportive therapy and high levels of antibiotics can be administered to ruminants that are nonproduction animals.

NURSING CARE

Appropriate supportive care as warranted by the presenting clinical signs

ACTIVITY

- The animal's activity does not need to be restricted if it does not have pulmonary involvement.
- Pulmonary arterial thromboembolism will require that the animal be kept quiet. Activity should be limited to prevent the rupture of abscesses that could lead to hemorrhage.

DIET

- It is important to make sure that highly fermentable feeds are introduced slowly into the diet.
- If an animal is receiving a highly fermentable diet, adequate amounts of roughage need to be added to ensure proper buffering from saliva and ruminal motility.
- Feed additives that contain antibiotics help to decrease the numbers of bacteria responsible for producing acidic agents in the rumen.
- An adequate quantity of high-quality colostrum ingested by neonates will help to prevent septicemia and omphalophlebitis in calves.

CLIENT EDUCATION

- Educating clients on how to introduce highly fermentable feeds into the diet
- Feeding a balanced ration with enough fiber and roughage
- Proper neonatal management to prevent septicemia and failure of passive transfer
- Making sure the client has a proper parasite management program to eliminate the possibility of liver fluke infestation

SURGICAL CONSIDERATIONS

- Abscesses can be drained to the outside of the body if in an anatomic location that will allow for it.
- It is often cost prohibitive and impractical to do surgery on affected animals.

MEDICATIONS

DRUGS OF CHOICE

- Penicillins, ampicillin, and oxytetracycline are the drugs of choice to treat animals diagnosed with liver abscesses. The drugs are usually administered at very high doses for long periods of time, to try to facilitate penetration of the abscess capsular lining. Sometimes these drugs are combined with rifampin and metronidazole.
- Drugs used as feed additives for the prevention of abscess formation are bacitracin, lasalocid, monensin, oxytetracycline, tylosin, tilmicosin, and virginiamycin.

CONTRAINDICATIONS

Since most of the ruminants predisposed to liver abscess are production animals, which will have products that enter the

human food chain, antibiotic residue avoidance needs to be taken into consideration.

PRECAUTIONS

- Any time antibiotics are introduced into a ruminant, they have the potential to alter normal ruminal microflora. Altered ruminal flora populations may either increase or decrease feed efficiency.
- Administering high levels of oxytetracyclines can cause hypocalcemia in cattle.

POSSIBLE INTERACTIONS

Any antibiotics or drugs that require metabolism by the liver should not be used if there is indication that the majority of the liver is affected.

ALTERNATIVE DRUGS

Alternative antibiotics may be used if the ruminant is not an animal that could end up in the food chain.

FOLLOW-UP

N/A

PATIENT MONITORING

There is very little patient monitoring that can be done for ruminants with liver abscesses. Depending on the extent of liver involvement, clinical signs associated with hepatic insufficiency may be evident. However, usually these animals will be “poor doers” and have a decrease in weight gain and increase in the amount of time it takes to achieve production goals.

PREVENTION/AVOIDANCE

- Prevention of ruminal acidosis by feeding adequate amounts of roughage is a key factor in reducing the incidence of liver abscesses in animals being fed highly fermentable feeds.
- The roughage will increase the amount of saliva produced to buffer VFA in the rumen. It will also help to maintain a healthy population distribution of lactobacillus organisms in the rumen.
- Introducing highly fermentable feeds slowly into the diets of ruminants will allow for adaptation of the microflora and absorptive capacity of the rumen to prevent a buildup of acidic agents.
- There are a number of feed additives that are used to decrease the incidence of ruminal acidosis and consequently liver abscesses. These additives can be ionophore antibiotics, which control the growth of gram-positive bacteria in the rumen and reduce the number of lactic acid-producing bacteria present.
- Tylosin is another antibiotic that is added to feeds. It directly decreases the number of *Fusobacterium necrophorum* and *Arcanobacterium pyogenes* bacteria in the rumen, and reduces the incidence of bacterial emboli formed in the ruminal wall that can travel to the liver.
- Regular preventive anthelmintics may reduce the risk of liver flukes producing migratory tracts in the liver that can become infected.
- Proper environmental management, along with navel dipping and assuring adequate colostrums, will help to prevent ascending umbilical vein infections.

POSSIBLE COMPLICATIONS

- The primary problem resulting from liver abscesses is a decrease in feed utilization by the animal. This in turn means a decrease in weight gain and possible weight loss as well as an increase in feed cost.
- Ruminants with liver abscesses also have an increased incidence of other medical complications, resulting in loss of income due to veterinary service and treatment cost.

EXPECTED COURSE AND PROGNOSIS

Since the vast majority of liver abscesses are undetected until slaughter, this is primarily a subclinical disease with major economic impact in the cattle industry.

LOUPING ILL

BASICS

OVERVIEW

- Louping ill is a term used to describe an acute tick-transmitted encephalomyelitis that affects mainly sheep, but is found in many other vertebrate animals. Louping ill virus is a single-stranded, neurotropic, RNA virus in the genus *Flavivirus* in the family *Flaviviridae*. The virus belongs to a subgroup of related viruses known as the tick-borne encephalitis complex.
- Small mammals and birds such as hares, red grouse, and ptarmigan are believed reservoirs that maintain the virus in the environment.

PATHOPHYSIOLOGY

- Louping ill is transmitted from animal to animal by a tick vector. *Ixodes ricinus* is thought to be the natural vector and other species including *Rhipicephalus appendiculatus*, *Ixodes persulcatus*, and *Haemaphysalis anatolicum* have been found carrying the virus. The larva, nymph, and adult may carry the virus by feeding on a viremic host. Transmission between life cycles of the tick appears to be only transstadially.
- Clinical signs of louping ill occur in two phases. The initial phase may be mild or unapparent with most animals suffering from a mild fever. Infected animals will either recover at this point or the virus will enter the central nervous system leading to associated clinical signs.
- Lactating goats can excrete high numbers of virus in milk, which can lead to a fatal infection in newborn kids. Louping ill virus can also be transmitted to various host species through exposure to aerosols and by parenteral routes.

SYSTEMS AFFECTED

- Nervous—primarily central nervous system
- Respiratory—primarily lungs
- Gastrointestinal

GENETICS

N/A

INCIDENCE/PREVALENCE

- All ages of sheep can be infected with Louping ill virus; however, lambs born to immune dams are passively protected for the first year. Yearlings are most susceptible and may have mortality rates as high as 60%. The prevalence of infection may be as high as 60% in adult sheep, but the incidence of disease is low unless the sheep have been moved from a nonendemic area to an endemic area.
- The disease is most prevalent during April through June and again in September due to the annual periodicity of tick activity.

GEOGRAPHIC DISTRIBUTION

Louping ill can be found strictly in the upland areas of the British Isles and Norway. A similar related disease of sheep has been reported in Bulgaria, Turkey, and the Basque region of Spain.

- Chomping of the jaws
- Hopping “loup ing” gait
- Hypersensitivity to noise and touch

PHYSICAL EXAMINATION FINDINGS

- Fever—42°C, 107.6°F
- Depression
- Muscle tremors
- Incoordination
- Ataxia
- Hyperesthesia
- Louping gait
- Head-pressing
- Paraplegia
- Convulsions
- Opisthotonus
- Coma
- Constipation

CAUSES

A single-stranded, neurotropic RNA virus of the genus *Flavivirus*, family Flaviviridae, causes louping ill.

RISK FACTORS

- Grazing pastures infested with infected ticks is the most common way to acquire infection. The larva, nymph, and adult may carry the virus by feeding on a viremic host.
- Transmission between life cycles of the tick appears to be only transstadially.
- Concurrent infection with *Cytoecetes plagocytophila* or *Toxoplasma gondii* can exert a profound immunosuppressive effect on the immune system.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Sheep

- Scrapie
- Maedi visna
- Pregnancy toxemia
- Hypocalcemia
- Tetanus
- Listeriosis
- Tick pyemia
- Hypocuprosis
- Rabies

- Hydatid disease
- Heavy metal toxicity
- Plant toxicosis

Cattle

- Malignant catarrhal fever
- Listeriosis
- Pseudorabies
- Bovine spongiform encephalopathy
- Rabies
- Hypomagnesemia
- Hypocalcemia
- Acute lead poisoning
- Plant toxicosis

CBC/BIOCHEMISTRY/URINALYSIS

None

OTHER LABORATORY TESTS

- Virus isolation from the blood during the febrile stage
- Hemagglutination inhibition test during febrile stage to detect IgM antibodies
- Fourfold or greater rise in antibody titer after central nervous system signs have developed
- ELISA for tick-borne encephalitis virus

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Virus isolation from necropsy samples of the brain and spinal cord. Sterile unfixed samples should be placed in 50% glycerol and normal saline or frozen on dry ice.

PATHOLOGIC FINDINGS

- Gross lesions: congested meningeal vessels, secondary pneumonia
- Histopathology: nonsuppurative polio- and meningoencephalomyelitis with gliosis, perivascular infiltration, and neuronal degeneration. Lesions are primarily located in the brain stem.

TREATMENT

APPROPRIATE HEALTH CARE

- No specific treatment for individual animals
- Herd preventative care—vaccination with an inactivated, tissue-culture-propagated vaccine, pour-on acaricidal preparations

NURSING CARE

Infected animals should be provided with basic supportive care and sedation to prevent convulsions. Unlike sheep, cattle may fare well with basic nursing care.

ACTIVITY

Animals should be kept in a quiet location to prevent agitation, convulsions, and injury.

DIET

Animals showing clinical signs should be hand-fed to ensure adequate nutrition.

CLIENT EDUCATION

Clients need to be educated in the importance of tick control and vaccination protocols to prevent infection.

SURGICAL CONSIDERATIONS

FOLLOW-UP

PATIENT MONITORING

Affected animals should be monitored frequently for convulsions due to noise or touch.

PREVENTION/AVOIDANCE

- An inactivated, tissue-culture-propagated vaccine is available for sheep, cattle, and goats. One injection will provide protection for > 2 years. All animals kept for breeding should be vaccinated at 6–12 months of age.
- Pour-on insecticides should be used to reduce tick exposure.

POSSIBLE COMPLICATIONS

Animals that survive clinical disease have residual central nervous system deficits of variable severity.

EXPECTED COURSE AND PROGNOSIS

- In most cases, animals that show clinical signs will succumb after a clinical course of 1 to 12 days. Those that survive clinical disease never regain full health.
- Animals infected with louping ill virus are immune for life.

MISCELLANEOUS

ASSOCIATED CONDITIONS

CNS disorders

AGE-RELATED FACTORS

Where the disease is endemic, it is most often confined to animals < 2 years of age because the adults are immune from previous infection and lambs are protected by colostral antibody.

ZOONOTIC POTENTIAL

Louping ill virus may infect humans through tick bites, contamination of skin wounds, and aerosol exposure. Ingestion of contaminated sheep or goat's milk may also result in infection. Infected humans may develop an illness that resembles influenza, polio, biphasic encephalitis, or a hemorrhagic fever.

PREGNANCY

Lambs born to nonimmune ewes that are exposed to the virus may develop a peracute illness with death occurring within 48 hours from the onset of clinical signs.

LOW-FAT MILK SYNDROME

BASICS

OVERVIEW

- Low-fat milk syndrome is characterized by a decrease in milk fat content accompanied by a decrease in milk yield.
- Milk fat content and yield are highly responsive to nutrition; however, fatty acid composition of milk fat is affected to a lesser extent by the biohydrogenation of unsaturated fatty acids by rumen bacteria.
- Fat is the most variable constituent in ruminants' milk and also the major energy component. Triglycerides are the main form of fat secretion into milk, accounting for 97%–98% of the total milk lipids.
- The fatty acids can be either synthesized in the mammary gland from acetate and butyrate or taken up directly from the blood as preformed fatty acids. The mammary gland synthesizes short and medium carbon chain fatty acids (C4:0 to C14:0) and some palmitic acid (C16:0). The long carbon chain fatty acids (>C16:0) incorporated into milk fat arise from dietary lipids and from the mobilization of body fat stores available in the blood.
- Although different milk pricing systems are available worldwide, milk fat is still an important component in most countries and decreased milk fat percentage and yield can have a direct negative effect on dairy farm profitability.

PATHOPHYSIOLOGY

- Many theories exist as to pathophysiology.
- In one theory, biohydrogenation is compromised in animals that are fed diets that do not maintain a favorable rumen environment. Dietary factors that contribute to low rumen pH conditions reduce biohydrogenation of unsaturated fatty acids. Products from the incomplete biohydrogenation of unsaturated fatty acids in the rumen have a negative impact on lipid synthesis in the lactating mammary gland.
- In one study, cows fed low-forage diets (17.5% NDF) had lower milk fat content and yield. In addition, activity of key enzymes involved in de novo fatty acid synthesis in the mammary gland were dramatically reduced, by 62% and 44%, for acetyl-CoA-carboxylase and fatty acid synthase, respectively.
- *Trans*-octadecenoic acid (C18:1, *trans*-10) was shown to be negatively related to milk fat content; however, a direct cause-effect association has not been established.
- In another study, abomasal infusion of 10 g/d of conjugated linoleic acid (CLA; C18:2 *trans*-10, *cis*-12) resulted in 42% and 44% reduction in milk fat percentage and yield, respectively, mimicking the effect of a milk fat-depressing diet.
- Both fatty acids (C18:1, *trans*-10, and C18:2, *trans*-10, *cis*-12) originate in the rumen as intermediates in the biohydrogenation process of polyunsaturated fatty acids ([Figure 1](#)).
- Collectively, these data suggest that milk fat depression is caused by a direct effect of fatty acids originated from incomplete biohydrogenation in the rumen on mammary gland lipid synthesis. The precise role of specific fatty acids and possibly their interactions with mammary gland lipid metabolism is still unknown.

SIGNALMENT

- Holstein cows at or after peak lactation are more predisposed to the disease.
- Early lactating cows are under severe body fat mobilization and down regulation of mammary gland lipid synthesis during this period has little effect on milk fat content.
- Actually, early lactating cows have a higher milk fat content in the first weeks of lactation.

SIGNS

N/A

CAUSES AND RISK FACTORS

Milk fat depression is a consequence of incomplete biohydrogenation of polyunsaturated fatty acids in the rumen and exposure of the mammary gland to the detrimental effect of *trans*-fatty acids, intermediates in the process.

Risk Factors

- The feeding of polyunsaturated fatty acids. Milk fat depression has been shown in diets that contained at least 4%–4.5% crude fat.
- Dietary supplementation of oil is more likely to depress milk fat than oil seed incorporation.
- Low-forage diets (see [Table 1](#) for fiber requirements).
- Excessively processed forages will result in poor particle size, decreased chewing time, and total buffer production.
- Feeding of marine oils
- Feeding corn silage as the only forage source in diets with a high level of NFC

Figure 1. Pathways of rumen biohydrogenation of linoleic acid (adapted from Bauman and Griinari, 2003).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

N/A

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Low-fat milk syndrome is diagnosed comparatively rather than by absolute milk fat percentage or yield. Therefore, knowledge of herd history, nutrition programs, and genetic background can be useful.
- Diagnosis is based on examination of milk production and composition records. In more chronic situations, symptoms related to subclinical ruminal acidosis may also be present. These symptoms include decreased feed intake, higher incidence of laminitis, and increased body condition loss.

TREATMENT

- Adjustment of the diet to maintain rumen health should be the main management goal.
- Low milk fat is frequently associated with dietary fiber (e.g., low forage content, high processed forages, or forages with lower effective fiber). The total NDF requirement in the NRC (2001) varies according to the amount of forage NDF and NFC in the diet. An increase in total diet NDF content for low-particle diets is recommended ([Table 1](#)).

Table 1

Source: Adapted from NRC (2001).

Minimal NDF Requirements for Diets of Lactating Cows Fed TMR with Adequate Particle Size and Ground Corn as the Predominant Starch		
Forage NDF (%)	Total dietary NFC (%)	Maximum dietary NDF (%)
19	25	44
18	27	42
17	29	40
16	31	38
15	33	36

Note: NDF = neutral detergent fiber; NFC = nonfiber carbohydrate; TMR = total mixed ration; NDF requirements should be increased when very processed forages are fed.

- Addition of buffers should be considered.
- Partial replacement of starch in the diet by fibrous by-products (e.g., almond hulls, whole cotton seed, soy hulls, beet or citrus pulp) is a useful tool to minimize decreased rumen pH.
- If marine oils are fed at more than 1% of diet DM, consider substitution of fat source.

MEDICATIONS

N/A

DRUGS OF CHOICE

- Addition of buffers to diet, including sodium bicarbonate and magnesium oxide, has improved rumen pH and diminished the negative effects of low-forage diets on milk fat.
- Sodium bicarbonate added at 0.7%–1.0% of diet DM has been effective in correcting milk fat depression. However, literature results can be inconsistent with respect to the effectiveness of buffers in controlling rumen pH (NRC, 2001).
- Buffer supplementation of high-forage diets or in pasture-based systems has produced poor results.

CONTRAINDICATIONS

N/A

POSSIBLE INTERACTIONS

N/A

PRECAUTIONS

Marine oils seem to directly affect biohydrogenation and cause milk fat depression even in situations of normal rumen pH. In one study, high levels of fish oil (2%–3% of DM) in diets with 50% forage (1:1, alfalfa/corn silage) had a linear negative effect on milk fat content and yield.

FOLLOW-UP

- Careful evaluation of diet composition is important and should account for:
 - NDF content
 - NDF from forage
 - Nonfiber carbohydrate
 - Source of starch in the diet
 - Processing characteristics of grains
 - Total lipid (ether extract) content
 - Type of fat supplement (vegetable oils, marine oils, oil seeds, protected fat, animal fat, etc.), which considers fatty acid composition of the lipid fraction

- Fiber content (NDF) of the diet is a critical issue in maintaining adequate rumen pH, but forage-particle size is also a contributing factor. Regular evaluation of diet particle size and processing characteristics of new forage feeds is recommended.
- Excessive mixing of TMR diets can reduce particle size and is a common mistake observed in the feeding routine.
- Adequate training of farm staff involved in feed activities is warranted in order to keep the feeding procedure as standardized as possible.

LUMPY SKIN DISEASE

BASICS

OVERVIEW

- Lumpy skin disease (LSD) is a viral disease of cattle characterized by deep dermal skin nodules that eventually undergo central necrosis.
- Affected animals also usually have a high fever and a generalized lymphadenitis.
- LSD is caused by a capripoxvirus that is closely related to sheep and goat pox.
- The disease is endemic throughout most of Africa with occasional incursions into the Middle East. The virus primarily affects cattle but has experimentally infected giraffes and impalas.

SIGNALMENT

- Incubation period for the disease varies between 7 and 21 days with most cases being seen 10–12 days after exposure.
- Depending on the susceptibility of the cattle (Channel Island breeds are most susceptible), morbidity may range from 3% to 80% with mortality usually very low (1–3% in most cases).
- Animals with some other debilitating disease (parasitism, nutritional deficiency, or chronic disease) are more likely to die from infections.
- Calves tend to be more susceptible than adult cattle.

SIGNS

- Animals first develop a fever of 104–107°F (40–41.5°C). The fever may persist throughout the disease period and last up to 4 weeks.
- Large (1–5 cm) nodules develop under the skin usually within 2 days after the fever develops. Nodules develop primarily in the skin of the neck, muzzle, nares, eyelids, back, front and back legs, scrotum, perineum, mammary gland, teats, and tail. The oral mucosa may also become involved.
- Nodules become enlarged and involve the epidermis, dermis, and subcutaneous tissues and may involve the superficial muscles. Nodules are often painful to the touch.
- Edematous nodules eventually become necrotic and collapse centrally leaving an umbilicated lesion with a central necrotic core covered by a scab (sitfast). These heal slowly and are often complicated by secondary bacterial infections. Lesions that involve the mammary gland may become severely infected causing a severe mastitis and loss of the affected glands. Necrotic lesions may take up to 5 to 6 weeks to heal. Nodules may remain for some time in the skin until they resolve.
- In severe infections, the animal becomes lame due to the cutaneous nodules causing swelling and inflammation in the joints, tendon sheaths, and coronary band region.
- Large, swollen lymph nodes draining infected regions are often noted.
- Late-term abortions have been noted in infected animals; however, most abortions are believed due to the high fever and not infection of the fetus.
- Bulls may become sterile due to the high temperature or due to mechanical damage to the prepuce and penis from the virus.

CAUSES AND RISK FACTORS

- Transmission is believed to be by biting insect vectors. *Culex mirificus* and *Aedes natronius* are suspected.
- Disease outbreaks tend to occur most commonly during the rainy seasons.
- Contact with virally infected scabs and fomites can also spread the disease but to a lesser extent.
- The movement of contaminated raw hides has been implicated in some outbreaks.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Insect bites and associated urticaria: Lesions are often edematous and usually rise quickly after the animal is exposed. Lesions may itch but are not generally painful. Biopsies identify abundant edema and some eosinophils in the associated dermis.
- *Hypoderma bovis* infections: These are large nodules in the dermis that are usually seen in the skin of the dorsal back. Nodules have a central cavitory hole with fly larva present.
- Photosensitization: Nonpigmented regions are affected. The skin undergoes pronounced swelling and necrosis with flaking of the skin from the affected regions.
- Bovine papular stomatitis: Proliferative pox lesions are seen on the lips, muzzle, and oral and esophageal mucosa. Young animals are usually the only animals affected in the herd. Animals rarely have fever or pain associated with lesions.
- Allerton virus (Bovine herpes mammillitis, bovine herpesvirus type 2): Superficial epidermal lesions are identified primarily on the teats and muzzle but may be generalized. Lesions are small, raised nodules that scab over quickly and resolve leaving a hairless region with no damage to the hide.
- *Dermatophilus congolensis*: Lesions are usually generalized and characterized by some edema of the skin with scabs over affected areas. When the scabs are removed, normal epithelium is present. Characteristic bacteria consisting of numerous rows of coccoid organisms stacking up in the inflammation are present in the scab.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY PROCEDURES

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Biopsies of early lesions that have not developed a scab can be used for virus isolation, histopathology, and electron microscopy.
- Aspirates of swollen lymph nodes should be placed in viral media and shipped on ice for virus isolation.
- Acute and convalescent sera should be obtained for serological testing.

PATHOLOGICAL FINDINGS

GROSS FINDINGS

- Animals develop generalized skin nodules 1–5 cm in diameter. Older nodules have a central area of necrosis with a central scab present (sitfast). Nodules are composed of edema, hemorrhage, and necrotic debris involving the epidermis, dermis, and subcuticular tissues and may extend into adjacent muscles.
- Individual or coalescing pox lesions can be present in the oral cavity, nares, pharynx, esophagus, and trachea. These lesions have coalescing thickening of the mucosa and submucosa with some edema, hemorrhage, and necrosis.
- Lymph nodes are swollen and enlarged.
- Lung lesions can occur with atelectasis and some edema present in affected lobules.
- Fibrin may be present in joints and tendon sheaths.

HISTOPATHOLOGIC FINDINGS

- Early skin lesions consist of swelling of the dermis with edema and some hemorrhage.
- Variable numbers of lymphocytes, neutrophils, and macrophages are present in the dermis with some fibroblastic proliferation present. Older lesions have vasculitis and thrombosis of vessels with necrosis of the associated tissues.
- The epidermis is acanthotic with orthokeratotic and parakeratotic hyperkeratosis, ballooning degeneration of the stratum spinosum, and necrosis of keratinocytes.
- Eosinophilic intracytoplasmic inclusions are present in swollen keratinocytes in the epidermis and in macrophages, fibroblasts, and endothelial cells in the affected dermis and subcutis. In old infarcted lesions, inclusion bodies are usually

absent.

TREATMENT

- In most areas of the world, this is considered a reportable disease. Notification of state and/or federal veterinary authorities is important on suspicion of this disease.
- Treatment is supportive with antipyretic drugs (e.g., aspirin, flunixin meglumine) given to relieve the fever and improve the appetite of the affected animals.
- Antibiotics can be used for secondary bacterial infections that may occur in the skin, mammary gland, joints, or tendon sheaths.

MEDICATIONS

Appropriate antibiotics for treatment of bacterial complications should be made based on sensitivity of the bacterial agent.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

PREVENTION/AVOIDANCE

- In endemic areas of the world, vaccination has been successful in controlling outbreaks.
- Vaccinations with an attenuated LSD vaccine or with a sheep and goat pox vaccine have been successful.
- The control of insects has not proven effective at stopping the spread of the disease.

POSSIBLE COMPLICATIONS

- Secondary bacterial infections of the necrotic lesion are a common finding.
- Secondary bacterial infections of lesions of the mammary gland, joints, and penis can cause serious complications.

EXPECTED COURSE AND PROGNOSIS

- In naïve animals, mortality is usually low with most outbreaks having a mortality of less than 3%.
- Lesions may persist in severely affected animals for up to 6 months.
- Secondary bacterial infections can complicate the outcome of the disease.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Secondary bacterial infections of the necrotic lesion are a common finding.
- Secondary bacterial infections of lesions of the mammary gland, joints, and penis can cause serious complications.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

LUPINE TOXICITY

BASICS

OVERVIEW

- Lupines (*Lupinus* spp.) cause two distinct forms of poisoning in livestock: lupine poisoning and lupinosis. Alkaloid-containing lupines, *Lupinus formosus*, and *L. arbustus*.
- Lupine poisoning is a nervous syndrome caused by alkaloids present in bitter lupines.
- Lupinosis is a mycotic disease.
- The genus *Lupinus* contains a large number of species. In some parts of the world they form a useful fodder crop.
- Lupines are found in climax and grassy habits and are toxic even when dry.
- Many species of lupines contain quinolizidine or piperidine alkaloids known to be toxic or teratogenic to livestock.
- Defects caused by quinolizidine and piperidine teratogens include cleft palate and contracture-type skeletal defects such as arthrogryposis, scoliosis, torticollis, and kyphosis.
- Cleft palate and minor front limb contractures are induced in calves by maternal ingestion of the piperidine alkaloid-containing lupines, *Lupinus formosus* and *L. arbustus*. Crooked-calf disease, which includes an occasional cleft palate, is a congenital condition of widespread occurrence in cattle in the western United States and Canada. It is known to occur after maternal ingestion of certain species of *Lupinus* during specific gestational periods.

PATHOPHYSIOLOGY

- The toxic and teratogenic effects from these plant species have distinct similarities including maternal muscular weakness and ataxia and fetal contracture-type skeletal defects and cleft palate.
- It is believed that the mechanism of action of the piperidine and quinolizidine alkaloid-induced teratogenesis is the same; however, there are some differences in incidence, susceptible gestational periods, and severity between livestock species.
- Although many lupine species contain quinolizidine alkaloids including the teratogenic alkaloid anagyrene, *L. formosus* and *L. arbustus* produce piperidine alkaloids including the reported teratogen ammodendrine. In addition to ammodendrine, *L. formosus* contains both N-acetyl hystrine and N-methyl ammodendrine, whereas *L. arbustus* contains ammodendrine, trace amounts of N-methyl ammodendrine, and no N-acetyl hystrine.

SIGNALMENT

- Sheep, cattle, horses, pigs
- Most common in sheep and cattle

SIGNS

Lupine Poisoning

- Inappetence and dyspnea, usually followed by violent struggles, convulsions, and hyperexcitability
- Death is due to respiratory paralysis.
- There is no icterus.
- Defects caused by quinolizidine and piperidine teratogens include cleft palate and contracture-type skeletal defects such as arthrogryposis, scoliosis, torticollis, and kyphosis.

Lupinosis

- Early signs in sheep and cattle are inappetence and listlessness, complete anorexia and jaundice follows, and ketosis is common.
- Cattle may show lacrimation and salivation.
- Sheep may become photosensitive.
- In acute outbreaks, death occurs in 2–14 days.

CAUSES AND RISK FACTORS

Lupine Poisoning

- Acute poisoning occurs when a considerable amount of the plant is eaten in a short time.
- Lupins contain a number of alkaloids, D-Lupanine is the most toxic and the most widely distributed.
- The concentration of alkaloid is greatest in the seeds, and the plants are most dangerous at the seeding stage.
- The alkaloids are not destroyed by drying.
- Lupine-induced “crooked calf disease”: Crooked calf disease is characterized as skeletal contracture-type malformations and occasional cleft palate in calves after maternal ingestion of lupines containing the quinolizidine alkaloid anagyrine during gestation days 40–100.
- Toxic and teratogenic effects have been linked to structural aspects of these alkaloids, and the mechanism of action is believed to be associated with an alkaloid-induced inhibition of fetal movement during specific gestational periods.

Lupinosis

- The causal fungus is *Phomopsis leptostromiformis*, a phytopathogen causing phomosis stem blight, especially in white and yellow lupines; blue varieties are very resistant.
- The fungus is also a saprophyte and under favorable conditions grows well on dead lupine material.
- The fungus produces hepatotoxic secondary metabolites. The main one is phomopsin A.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Lupinosis

Acute aflatoxicosis

Photosensitization

- Chronic fluke damage
- Congenital porphyria
- Liver disease
- Phenothiazines
- St. John’s wort
- Toxin absorption

Arthrogryposis

- BVD, IBR, bluetongue virus, akabane virus, and Cache Valley virus
- Arthrogryposis-hydranencephaly syndrome (AHS) in lambs may be confused with spider lamb syndrome (SLS), in which there is characteristic hyperflexion of forelimbs, cranial overextension of hind limbs, with a corkscrew deviation of the spine. In lambs with AHS, severe deformities result from primary abnormalities of the CNS and not of the skeleton. Hydranencephaly, micromyelia, hydrocephalus, and cerebellar hypoplasia are also seen with AHS.

CBC/BIOCHEMISTRY/URINALYSIS

Lupine Poisoning

Elevated serum GGT, AST, LDH, and GDH concentrations

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

PATHOLOGIC FINDING

Lupine Poisoning

- No icterus
- No characteristic postmortem lesions

Lupinosis

- In acute disease, icterus is marked. Livers are enlarged, orange-yellow, and fatty.

- Chronic disease shows bronze- or tan-colored livers that are firm, contracted in size and fibrosed, and often likened to a boxing glove.
- Copious transudate may be found in the abdominal and the pericardial sac.

HISTOPATHOLOGICAL FINDINGS

TREATMENT

Lupine Poisoning

Remove animals from the source.

Lupinosis

- Frequent surveillance of sheep or cattle, and of lupine fodder material for characteristic black spot fungal infestation, especially after rain.
- The utilization of lupine cultivars, bred and developed for resistance to *P. leptostromiformis* is advocated.

MEDICATIONS

Lupinosis

Oral doses of zinc (0.5 g of zinc or more, per day) are useful in protection from phomopsis-induced liver injury in sheep.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

POSSIBLE COMPLICATIONS

Lupines have a marked teratogenic effect on cattle and give rise to crooked calf disease, characterized by arthrogryposis, scoliosis, torticollis, and cleft palate.

EXPECTED COURSE AND PROGNOSIS

With acute lupine poisoning, if the animal survives it will likely make a full recovery, because the lupine alkaloid is readily excreted in the urine.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Liver failure, respiratory failure, cleft palate and contracture-type skeletal defects such as arthrogryposis, scoliosis, torticollis, and kyphosis
- Cleft palate and minor front limb contractures are induced in calves by maternal ingestion (crooked calf disease).

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Crooked calf disease is characterized as skeletal contracture-type malformations and occasional cleft palate in calves after maternal ingestion of lupines containing the quinolizidine alkaloid anagrine during gestation days 40–100.

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species are affected.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Producers should be aware of the association between certain toxic plants (e.g., lupines) and angular limb deformities such as CCD.
- To reduce the incidence of crooked calf syndrome, graze lupines during their least hazardous growth period and reduce exposure of pregnant cows. Lupines are most hazardous when either young or in the mature seed stage.
- Fence off heavily infested pasture areas and use intermittent, short-term grazing of lupine pastures.

SYNONYMS

Crooked calf syndrome

Author: Troy Holder

LUXATIONS

BASICS

OVERVIEW

- Luxation is a displacement of the bones in a joint, resulting in abnormal articulation (subluxation) or lack of articulation (complete luxation).
- Luxations seen in cattle include coxofemoral, patellar, tarsal, metacarpophalangeal/metatarsophalangeal, and scapulohumeral
- Coxofemoral luxations are usually craniodorsal, but cranioventral and caudoventral luxations are also seen.
- Patellar luxations are almost always lateral.
- Tarsal luxations usually involve plantarodistal movement of the calcaneus, but lateral and medial luxations in the small tarsal bones can occur secondary to trauma.
- Metacarpophalangeal/metatarsophalangeal luxations are usually lateral or medial.
- Scapulohumeral luxation is rare but usually occurs in a cranioventral direction.
- Luxations can involve any joint, but the most common in ruminants and South American camelids (SACs) are patellar and coxofemoral luxations. Other luxations, such as sacroiliac, metacarpophalangeal, metatarsophalangeal, carpal, tarsal, and scapulohumeral are less common.
- Luxations can occur concurrently with fractures and other musculoskeletal or neurologic injuries.

PATHOPHYSIOLOGY

- Most luxations are caused by falls or trauma
- Falls can be caused by systemic electrolyte disturbances, systemic weakness, poor footing, crowding.
- Luxations can be caused by cows riding each other during heat cycles.

SYSTEMS AFFECTED

Musculoskeletal

INCIDENCE/PREVALENCE

Unknown

SIGNALMENT

- Luxations are most common in bovines, but have been reported in all farm animal species.
- Adult cows are most commonly affected, but young calves can also be affected. Patellar luxations are commonly seen as a congenital condition in young animals. In newborn calves, they often occur in association with femoral neuropathy.

SIGNS

- Findings depend on the joint affected, but in general involve abnormal ambulation or stance.
- Historical findings may include a fall, especially on concrete, recumbency with struggling to stand, recent dystocia, recent estrus, trauma, abnormal stance, or abnormal angle of a limb.
- Physical exam findings
 - Abnormal limb position
 - Abnormal mobility or range of motion of limb distal to luxation
 - Lameness
 - Skeletal asymmetry when viewed from front or back of animal
 - Inability to bear weight on the limb
 - Lack of crepitus
 - Recumbency

Coxofemoral Luxation

- Pelvic asymmetry is present in all cases of coxofemoral luxation. The measured distances between the tuber coxae, greater trochanter, and ischium will be different on the affected and unaffected sides.
- Coxofemoral luxations are most often craniodorsal, with the femoral head and neck resting on the dorsal aspect of the ilium. Consequently, the affected limb appears shorter than the unaffected limb, the greater trochanter is more dorsal and the distance from the greater trochanter to the ischium is greater on the affected limb. The limb also tends to be externally rotated, which makes the stifle appear more prominent.
- Caudoventral luxations occur less commonly, and cranioventral luxations are rare. Ventral luxations in cattle are more often associated with other musculoskeletal injuries, and the animals are often unable to stand. In animals that can stand, pelvic asymmetry is present, the affected limb may appear longer, and the greater trochanter is more ventral than the opposite leg.

Patellar Luxation

- Patellar luxation results in the inability to maintain the stifle in extension, which causes the animal to have a crouched stance on the affected limb because of increased flexion of the femorotibial joint. When unilateral, they may appear to be resting the limb. In some animals, the luxation is intermittent; therefore, the abnormal joint angulation is also intermittent.
- Adult llamas with intermittent luxations may ambulate with the limb locked in extension. On palpation, the patella is palpable in a more lateral or medial location or it can be manually displaced from the trochlear groove in animals with intermittent patellar luxation.

Sacroiliac Luxation

Signs of a sacroiliac luxation include prominence of the wings of the ileum relative to the lumbar spine, and pain on palpation of the sacroiliac region. Animals with sacroiliac luxation may be unable to rise.

CAUSES AND RISK FACTORS

- Falls
- Trauma
- Hypocalcemia/hypophosphatemia/hypokalemia
- Riding during estrus
- Paralysis/paresis causing limb malfunction
- Forced extraction of calf during dystocia
- Dystocia
- Hypocalcemia/hypophosphatemia/hypokalemia
- Slippery floors
- Crowding
- Femoral nerve paralysis (for patellar luxation)

Coxofemoral Luxation

- Coxofemoral luxations in adult animals occur most commonly during falls on hard or slippery surfaces. In cows, these often occur in the postpartum period when ligamentous laxity, weakness, or metabolic derangements, such as hypocalcemia, may be present.
- Coxofemoral luxations also occur in cattle during estrus while being ridden, which is also a cause of sacroiliac luxations.
- Coxofemoral luxations can occur when the rear limb is caught in a gate, fence, or other structure. They occur in neonates, particularly calves, as a result of excessive traction during delivery.
- Excessive traction can also result in sacroiliac luxations or subluxations in cows.

Patellar Luxation

- Patellar luxations in adult cattle are typically traumatic luxations, and lateral luxations occur in calves due either to direct trauma or injury to the femoral nerve during delivery (hip lock).
- Lateral patellar luxations due to trauma have been reported most often in llamas, although congenital and traumatic medial patellar luxations have been reported.
- A genetic predisposition was a likely cause of patellar luxations (predominantly medial) reported in a flock of sheep.
- Congenital skeletal abnormalities involving the angle of the femoral neck and positioning of the tibial tuberosity may result in predisposition of patellar luxation (as described in dogs).
- Hypoplasia of the trochlear ridges, resulting in a shallow trochlear groove, may be present in animals with either lateral or medial patellar luxation. Severe osteochondrosis of the trochlear ridges can result in patellar luxation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

- Fracture
- Paralysis/paresis
- Hypocalcemia/hypophosphatemia/hypokalemia
- Systemic disease causing weakness
- Muscle or tendon trauma or rupture

IMAGING

- Radiographs are often useful for differentiating luxation from fracture.
- The direction of luxation can be determined and coexisting articular fractures or fragments noted.
- Pelvic radiography for diagnosis of coxofemoral luxation may require general anesthesia.
- Ultrasonography is useful in evaluating the depth of the trochlear groove in animals with congenital patellar luxation if surgical repair is being considered. In young animals, the trochlear ridges are incompletely ossified resulting in the appearance of a shallow trochlear groove on radiographs even when the depth of the groove is normal.

OTHER DIAGNOSTIC PROCEDURES

- Clinical examination is generally important and reliable in making a diagnosis of luxation, but concurrent fractures may not be recognized.
- Electromyography (EMG) is useful in confirming the diagnosis of femoral neuropathy in calves with congenital patellar luxation. Since femoral neuropathy can develop because of hip lock during delivery and EMG changes take a week to develop, electromyography is not generally useful before that time.

PATHOLOGIC FINDINGS

- Necropsy will show luxation of the joint affected, associated muscle trauma, concomitant fractures, and bony debris.
- With patellar luxation secondary to femoral nerve paralysis, there may be lack of quadriceps muscle development or histologic degeneration of the femoral nerve.

TREATMENT

Coxofemoral Luxation

- Treatment can be by closed or open reduction.
- Reduction is best performed under general anesthesia, either injectable or inhalant, that provides good muscle relaxation. Sedation (e.g., xylazine) may be adequate if closed reduction is performed within a short time of the luxation; however, the animal will experience more pain and distress.
- Closed reduction should be attempted in calves and other young animals with acute luxations. If unsuccessful, open reduction should be performed if economically feasible.
- To correct a craniodorsal luxation, the animal is placed in lateral recumbency with the affected leg up, and traction is applied to the limb.
- In adult cattle, a calf jack, come-along, or winch is used to apply traction, while the animal is secured with ropes around the chest and abdomen, and the pelvis is held with a rope placed in the inguinal area, to oppose the traction applied to the limb. While traction is applied, the leg is externally rotated and the distal limb is adducted, which will allow the femoral head to externally rotate and “unhook” from the ilium. Once returned to the acetabulum, the limb is abducted and internally rotated. In a ventral luxation, the same manipulation is performed (traction, external rotation, and adduction of the distal limb). Once the femoral head is rotated out of the obturator foramen or other site ventral to the ilium, traction can be released and the femoral head should return to the acetabulum.

Surgical Approach

- Open reduction is performed under general anesthesia at a surgical facility, most often using a craniodorsal approach.

While traction, external rotation, and adduction of the distal limb are performed, a hip skid can be used to facilitate reduction or a large Steinmann pin can be placed in the trochanteric fossa to help lever the proximal femur into position. Clotted blood, fibrin, tissue fragments, and any other material should be removed from the acetabulum. The joint capsule may need to be elevated from the joint space, which also helps reposition the normal fibrocartilaginous rim of the dorsal acetabulum, which is important in preventing reluxation.

- Correction of the luxation should be confirmed radiographically.
- Femoral head and neck excision has been used as a salvage procedure in calves, and extracapsular stabilization with sutures placed between the femoral neck and dorsal acetabulum has been successful in an alpaca.

Patellar Luxation

Correction of lateral patellar luxation requires surgical repair under general anesthesia, although mild intermittent luxations (grade I) can be managed conservatively.

Surgical Approach

- Several procedures are used to correct patellar luxations depending on the underlying cause and the anatomic abnormalities present. These include medial imbrication for lateral luxations (lateral imbrication for medial), with or without lateral release for lateral luxations (medial release for medial luxations), trochleoplasty, and/or transposition of the tibial tuberosity for lateral luxations. Placement of two large sutures between the cartilage on the medial aspect of the patella and the periosteum of the femur at the normal insertion of the medial femoropatellar ligament helps prevent recurrence of lateral luxations.
- Medial luxations more often require transposition of the tibial tuberosity to align the quadriceps, patella, and patellar ligament with the trochlear groove. Trochleoplasty is performed if the trochlear groove is too shallow to prevent reluxation.

Other Luxations

- Correction of other luxations, such as metacarpophalangeal, metatarsophalangeal, carpal, or tarsal luxations generally involves closed reduction under general anesthesia and stabilization in a cast for 4–12 weeks.
- Prolonged casting in young animals results in laxity of soft tissues and possible disuse osteopenia of bone, as well as loss of joint mobility. Surgical arthrodesis can be used in metacarpophalangeal, metatarsophalangeal, carpal, and distal tarsal joint luxations.
- Closed and open reduction with and without internal fixation or arthrodesis has been reported as a treatment for scapulohumeral luxation.

APPROPRIATE HEALTH CARE

- Luxations require emergency medical care.
- Closed reduction of a luxation should occur within 6 hours of the injury for best prognosis.
- Reduction should be performed under heavy sedation or anesthesia, and mechanical pulling devices may be required (e.g., calf jack, come-along, etc.)
- If closed reduction is unsuccessful, surgical reduction can be performed when the patient is stable.
- Following reduction, casts or splints may be used to stabilize the joints of the distal limbs until adequate scar tissue can form to replace disrupted ligaments.

NURSING CARE

- Good footing and bedding should be provided, especially if the animal is recumbent.
- If recumbent, the animal should be rolled from side to side and/or assisted to stand with slings or hip lifters to avoid dependent muscle necrosis and compartmental syndrome.
- Hobbles are useful for providing stability to cows with coxofemoral luxation.
- Feed and water should be easily available.
- Casts and splints must be carefully monitored and replaced if necessary.
- Animals should be confined for at least 4 to 6 weeks after reduction of luxation to reduce stress on the joint. Coxofemoral and scapulohumeral joint luxations should be stall rested for 2 to 3 months following reduction.

SURGICAL CONSIDERATIONS

- Surgical repair by open reduction is possible in most luxations, and can be particularly successful when closed reduction has failed due to debris present in the joint cavity.
- Recumbent animals are less likely to have a favorable outcome after coxofemoral surgery than are animals that were

ambulatory prior to surgery.

- Surgical reduction is more expensive than closed reduction, and therefore may not be elected in many farm animals due to the economics of raising farm animals.
- Careful examination of the animal, consultation of radiographs, and knowledge of anatomy of the region should determine surgical approach. Consultation with or referral to a surgical facility is recommended.
- Surgical repair must be performed under general anesthesia to obtain complete relaxation of opposing muscles around the joint.
- Surgical repair should be performed as soon as possible after diagnosis to avoid contracture of the musculature around the joint with further displacement of the luxation.

MEDICATIONS

DRUGS OF CHOICE

- For closed reductions, NSAIDs/analgesics (flunixin meglumine 1.1–2.2 mg/kg IV q12 to 24 hours) should be administered for 1 to 3 days after reduction of luxation to reduce swelling and make the patient more comfortable.
- Antibiotics should not be required for closed reductions.
- Broad-spectrum antibiotics and analgesics are recommended for 7 to 10 days following open surgical reduction.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids can cause abortions in pregnant females.

PRECAUTIONS

None

POSSIBLE INTERACTIONS

Steroids should not be used for pain relief if the animal is pregnant.

ALTERNATIVE DRUGS

Any analgesics can be used for pain relief as long as they fall within the AMDUCA regulations.

FOLLOW-UP

- Stall confinement is necessary after correction of a luxation. Animals treated by cast fixation should be in a stall while the limb is cast to minimize the risk of pressure sores.
- Neonates and young animals should be kept in a stall for a minimum of 4 weeks after closed reduction of coxofemoral luxation, although some have done well with a shorter period of confinement.
- An Ehmer sling, to keep the limb abducted and internally rotated, can be used in calves in which reduction was difficult or instability remains, but otherwise is not recommended.
- Animals treated for luxations, particularly of the hip and patella, that lie with the affected limb down should be assisted to stand in the early postoperative period. Adult cattle that had ventral luxations may benefit from hobbles applied above the fetlock to prevent abduction of the affected limb.
- Use of a sling after surgery to correct patellar luxation in llamas has been recommended to allow gradual return to weight bearing and exercise.
- Adult cattle with coxofemoral or patellar luxations treated surgically require a minimum of 8 weeks of confinement to a stall with good footing followed by gradual increase in activity level.
- Skin sutures should be removed 10 days to 2 weeks after surgical correction of coxofemoral, patellar, or other luxations.

PATIENT MONITORING

- The animal should be confined after reduction and monitored for any signs of relaxation, for return to weight bearing, and for signs of secondary paresis caused by nerve compression during the luxation.

- Recovery is usually quick following closed reduction.

PREVENTION/AVOIDANCE

- Provision of excellent footing to cattle at all times will reduce the number of spontaneous falls and falls due to riding during estrus.
- Do not crowd or rush cows, especially if not on good footing.
- Avoid dystocia, as both cow and calf are at risk of coxofemoral luxation, and calves are at risk of femoral nerve damage, which could lead to patellar luxation.
- Treat weak cows as soon as possible to restore normal ambulation.

POSSIBLE COMPLICATIONS

- Failure of reduction
- Nerve paresis/paralysis
- Muscle damage
- Arthritis
- Compartmental syndrome (if recumbent)

EXPECTED COURSE AND PROGNOSIS

- Prognosis is good for early closed reduction.
- Prognosis is fair to good for open reduction of coxofemoral luxations.
- Prognosis is good for open reduction of other luxations.
- Prognosis is fair for patella luxation, as the underlying cause often cannot be corrected.

Coxofemoral Luxation

- Untreated coxofemoral luxation results in serious lameness and a very poor prognosis in cattle.
- The prognosis for coxofemoral luxations in young animals is favorable if treated soon after occurrence. The prognosis is fair to poor for correction of chronic luxations, and it is poor for luxations with concurrent fractures of the femoral head, neck, or diaphysis. The prognosis is fair for open reduction of acute coxofemoral luxations in adult animals, but it is poor if they are chronic.
- Some chronic luxations are not reducible even with the animal under general anesthesia. The prognosis is better for cattle with craniodorsal luxations than ventral luxations, most likely because the latter tend to be associated with other musculoskeletal injuries.
- Reluxation has been reported in 17% of calves and 40% of adult cattle after open reduction. In general, smaller species are less likely to develop recurrence of luxation and more likely to have a successful outcome.

Patellar Luxation

- The prognosis for surgical correction of congenital patellar luxation in calves is guarded if femoral neuropathy is also present, since the outcome of the neuropathy is uncertain; however, many do well after the imbrication procedure. Failure to stabilize a luxated patella in an animal with femoral neuropathy ensures a poor outcome.
- In the absence of femoral neuropathy, the prognosis for surgical correction of patellar luxation is fair to good, particularly if done at a young age, if severe anatomic abnormalities are not present, and if the trochlear groove is sufficiently deep to retain the patella without performing a trochleoplasty.
- Correction of medial patellar luxation by imbrication, release, wedge trochleoplasty, and tibial tuberosity transposition has resulted in a good outcome in sheep.
- Correction of patellar luxations in adult cattle has a guarded to poor prognosis because of the size and weight of the animal.

Sacroiliac Luxation

Cases of subluxations generally improve over several days, but generally have reduced pelvic diameter that could result in dystocia. Cows with sacroiliac luxations do not tend to recover.

Other Luxation

- The prognosis for other closed luxations that can be stabilized by cast fixation is favorable with appropriate stabilization, although chronic lameness due to degenerative joint disease is possible.
- Open luxations have a guarded prognosis because of the possibility of joint infection; however, the outcome can be favorable with appropriate treatment.
- The overall results reported for open reduction and stabilization of shoulder luxations are poor. The best success for

correction of scapulohumeral luxation occurs in cases in which the luxation can be corrected by closed reduction.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Hypocalcemia, hypophosphatemia, hypokalemia, laminitis/foot problems, dystocia, femoral nerve paralysis, paralysis/paresis, fractures, hip dysplasia, femoral neuropathy (with patellar luxation), osteochondrosis, congenital limb anomalies

AGE-RELATED FACTORS

- Luxations may be easier to reduce in young animals due to the lack of muscle mass and the pliability of the muscles and tendons.
- Coxofemoral luxations have better prognosis in small and young animals than in large or old animals.

ZOONOTIC POTENTIAL

None

PREGNANCY

- Do not use steroids for pain relief.
- Sedation and anesthesia can cause fetal distress and potentially fetal loss, though the incidence is rare.

LYME BORRELIOSIS

BASICS

OVERVIEW

- Lyme borreliosis is a zoonotic disease caused by *Borrelia burgdorferi*, a bacterium in the order Spirochetes.
- *Borrelia burgdorferi* is transmitted to humans and other animals through the bite of ticks in the *Ixodes* genus. *Ixodes* ticks are most commonly found in moist wooded areas or naturally vegetated habitats with grasses and shrubs.
- Small mammals such as white-footed mice (*Peromyscus leucopus*) serve as the primary reservoir for *B. burgdorferi*.
- Domestic and nondomestic ruminants, except in rare ecologic circumstances, are not likely to serve as reservoirs for *B. burgdorferi*.

PATHOPHYSIOLOGY

- The Lyme borreliosis *Borrelia* complex is divided into *B. burgdorferi* sensu stricto (*B. burgdorferi* ss; those *Borrelia* genetically identical to the type-strain B31, recovered from an *Ixodes scapularis* tick from Long Island, New York) and *B. burgdorferi* sensu lato (*B. burgdorferi* sl; all other closely related *Borrelia*).
- *Borrelia burgdorferi* ss, *B. afzelii*, and *B. garinii* cause Lyme borreliosis in humans and animals in Europe and Japan. Only *B. burgdorferi* ss is recognized as a cause of Lyme borreliosis in the United States.
- Serologic evidence of *B. burgdorferi* infection has been detected in large and small domestic ruminants, but significant clinical disease in these species is not common.
- Clinical Lyme borreliosis in ruminants manifests most commonly as large joint arthritis, but systemic, dermatologic, reproductive, and central nervous system signs can also rarely occur.

SIGNALMENT

- Where infected vector ticks exist and bite cattle.
- Clinical signs often occur as a herd problem with first-calf heifers most severely affected.
- One report of affected lambs

SYSTEMS AFFECTED

- Joint capsules
- Synovial membranes

GENETICS

No evidence of a genetic predisposition to infection has been shown in large animals.

GEOGRAPHIC DISTRIBUTION

Worldwide distribution is possible. Currently, cases in Europe, Japan, and the United States.

SIGNS

- Infection of ruminants with *B. burgdorferi* is most commonly subclinical.
- Joint swelling, usually distal to the carpus or tarsus. May be recurrent.
- Lameness, stiff gait
- Decreased milk production
- Occasionally reported: laminitis, fever, weight loss, abortion
- Rarely reported: erythematous skin rash on udder

CAUSES AND RISK FACTORS

- Exposure to pastures where infected ticks occur may predicate infection.
- *Borrelia burgdorferi* spirochetes commonly establish infection in joints. Some animal models have suggested that the resulting inflammation, which is often disproportionate to the spirochetal load, is possibly an immune-mediated response.
- *Borrelia burgdorferi* has been recovered from tissues in cattle such as synovial fluid, lung, liver, and rarely blood,

colostrum, and aborted fetal tissue.

- Aside from the synovial fluid, disease manifestations do not appear to correlate with tissue location of *Borrelia* isolation.
- Cow-to-cow or cow-to-human transmission via infected blood, urine, or milk has not been shown.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other infectious and noninfectious causes of lameness and joint swelling include trauma, septic arthritis, and spirochete-associated digital dermatitis.
- Infection with *Borrelia theileri*, a tick-borne spirochete reported from Africa, Eastern Europe, Australia, South America, Mexico, and Texas, can cause fever, hemoglobinuria, and anemia.

CBC/BIOCHEMISTRY/URINALYSIS

- Not specific
- Reported abnormalities: leukocytosis with left shift, anemia

OTHER LABORATORY TESTS

Anti-*Borrelia* antibodies may be detected in CSF and synovial fluid.

IMAGING

Radiography of affected joints may help to rule out other causes (e.g., fracture) of inflammation and swelling.

DIAGNOSTIC PROCEDURES

- Definitive diagnosis can be achieved only through detection of *B. burgdorferi* in synovial fluid from affected joints. Polymerase chain reaction (PCR) tests and culture for *B. burgdorferi* by experienced research laboratories are often unrewarding.
- Testing of serum or synovial fluids for antibodies to *B. burgdorferi* using immunofluorescent antibody tests and/or western blots has been used. High titers may be indicative of infection, but cross-reactivity with other ruminant spirochetes or nonclinical infection must also be considered.
- Serologic tests for *B. burgdorferi* must be interpreted carefully in ruminants as there is great potential for cross reactivity with other spirochetal agents that infect ruminants such as treponemes causing digital dermatitis and the tick-borne *Borrelia theileri*.

PATHOLOGIC FINDINGS

GROSS FINDINGS

- Marked thickening of affected joint capsules
- Affected joints may contain excessive amounts of synovial fluid, usually clear.

HISTOPATHOLOGIC FINDINGS

- Affected joint capsules may have layers of granulation tissue and necrotic debris.
- Villus proliferation of the synovial membranes

TREATMENT

MEDICATIONS

- No standard treatment protocol is established for ruminants. Penicillin and tetracycline derivatives have proven effective in other species. Three weeks of antibiotics are recommended to clear the infection, but clinical improvement may be seen with shorter protocols.
- Anti-inflammatory agents may decrease the incidence of postinfectious laminitis.

CONTRAINDICATIONS

- Treatment for Lyme borreliosis with penicillin, oxytetracycline, and ceftiofur has been reported but is off-label usage.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Implement a tick-control program, including regular inspection of resident and introduced animals and pastures for ticks.
- Eliminate the vector tick on cattle through the use of acaricides.
- Elimination of the vector tick from pasture requires an integrated approach targeting hosts (e.g., cattle and deer) and the environment. Contact local extension professionals for appropriate pasture vector control approaches.
- Vaccination against *Leptospira* appears to confer no cross-protection against *Borrelia* spirochetes.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Reports of treatment success range from complete remission in weeks to slow (months) response to treatment.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Joint swelling, usually distal to the carpus or tarsus; may be recurrent
- Lameness, stiff gait
- Decreased milk production
- Occasionally reported: laminitis, fever, weight loss, abortion

AGE-RELATED FACTORS

Heifers seem to be predominantly affected.

ZOONOTIC POTENTIAL

- While it had been postulated that *B. burgdorferi* recovered from milk and urine of cattle could be infective to humans, such transmission has not been conclusively demonstrated. A study in an endemic area demonstrated no significant difference in *B. burgdorferi* titers among dairy farmers and crop farmers.
- Farmers, ranchers, and others working in the same area where ruminants are infected with Lyme borreliosis may themselves be at risk of tick bite and infection with *B. burgdorferi*.

PREGNANCY

While *B. burgdorferi* spirochetes have been recovered from aborted fetal bovine tissues, abortion due to *B. burgdorferi* infection has not been conclusively shown.

LYMPHOCYTOSIS

BASICS

DEFINITION

- Absolute number of lymphocytes greater than the reference range: Bovine > 7500/ μ l; Ovine > 9000/ μ l; Caprine > 9000/ μ l; Camelids > 7000/ μ l
- Absolute lymphocyte counts are greater in juvenile animals than adults.

PATHOPHYSIOLOGY

- Lymphocytes are produced in the bone marrow, lymph nodes, spleen, thymus, and Peyer's patches.
- Lymphocytes retain mitotic capability and can recirculate from the blood to lymphoid tissue. The number of lymphocytes in the blood represents a balance between cells leaving and entering circulation. Therefore, changes in peripheral lymphocyte counts may not necessarily indicate altered lymphopoiesis.
- Blood lymphocytes represent an assorted set of lymphocyte subpopulations including B and T lymphocytes. B cells are involved with humoral immunity and produce antibodies, while T lymphocytes are responsible for cell-mediated immunity and cytokine responses involved in immune system regulation.
- Approximately 95% of all lymphocytes are B and T lymphocytes with T cells predominating. The remaining lymphocytes make up a third group classified as "null" cells. Null cells consist of several subtypes including large granular lymphocytes and natural killer cells.
- In general, most lymphocyte subtypes cannot be identified on a blood film examination. However, large granular lymphocytes are occasionally observed in ruminant blood and can be recognized by the presence of small, red cytoplasmic granules.
- Infrequently, activated B lymphocytes (i.e., immunoblasts) are identified on blood film evaluation by their large size, deep blue cytoplasm, and perinuclear clear zone.
- Ruminant lymphocytes generally have diameters equal to those of neutrophils, but can be quite irregular in size.

SYSTEMS AFFECTED

- Hemic/lymphatic/immune—hepatosplenomegaly may occur as a result of hyperplasia or neoplasia; bone marrow may be hyperplastic; neoplastic populations of lymphocytes may rarely result in anemia and thrombocytopenia due to myelophthisis.
- Lymphosarcoma may affect all organ systems and cause specific problems such as cardiovascular, gastrointestinal, renal, and CNS.

GENETICS

N/A

INCIDENCE/PREVALENCE

- Pathologic lymphocytosis is uncommon in ruminants except cattle infected with BLV.
- Sporadic lymphosarcoma with concurrent lymphocytosis (also known as calf or juvenile form) is extremely rare and multiple cases within the same herd are even less common.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

- Reference values for absolute lymphocyte counts vary with ruminant species. Sheep and goats have higher mean absolute lymphocyte counts than cattle or camelids. However, alpacas and llamas generally have lower lymphocyte counts than camels.
- Sporadic lymphosarcoma (calf or juvenile form) generally affects calves 3–6 months of age, but may be observed in calves as young as 1 month or cattle as old as 3 years.

- Lymphocytic leukemia and BLV-associated lymphosarcoma affect adult ruminants > 4 years of age.

SIGNS

- If cause is physiologic (rare cause in ruminants), excited or fearful
- If cause is pathologic (sporadic lymphosarcoma, lymphosarcoma, or lymphocytic leukemia), lymphadenopathy, anorexia, decreased milk production, poor body condition. Depending on the involvement of other organ systems, melena or diarrhea (intestinal tract), heart failure (myocardium), posterior paralysis (spinal canal), and exophthalmia (retrobulbar tissue) may be observed. Anemia may result in pale mucous membranes, tachypnea, and tachycardia.
- If cause is persistent lymphocytosis associated with subclinical stage of BLV infection, affected cattle rarely exhibit clinical signs.

CAUSES

Physiologic

Epinephrine release due to excitement, pain, fear, restraint. The change occurs within minutes and usually lasts less than 30 minutes. Effect is usually observed in young healthy animals. Physiologic lymphocytosis is uncommon in most ruminants.

Antigenic Stimulation

Uncommon cause, but may occur occasionally with chronic viral or bacterial infections (e.g., caprine arthritis encephalitis virus, bacterial pneumonia) and within 10–14 days of vaccination.

Autoimmune Disease

Rare

Persistent Lymphocytosis

Subclinical BLV infection in cattle results in decreased B cell turnover and an inverted B:T cell ratio. B cells in this condition are non-neoplastic.

Sporadic Lymphosarcoma

Cause is unknown.

Lymphosarcoma or Lymphocytic Leukemia

- Although reported in all ruminant species, lymphosarcoma with lymphocytosis and lymphocytic leukemia are rare except in cattle infected with BLV.
- Approximately 30% of BLV-infected cattle are leukemic. Lymphocytosis is primarily due to decreased cell death of B cells.

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Transient physiologic lymphocytosis typically occurs in young, healthy, and excitable animals.
- Persistent lymphocytosis (3-months duration) in cattle without clinical signs is associated with subclinical BLV infection.
- Ill cattle with absolute lymphocytosis—consider lymphosarcoma or lymphocytic leukemia; may be seropositive for BLV.

CBC/BIOCHEMISTRY/URINALYSIS

Physiologic Lymphocytosis

- CBC
- Mild lymphocytosis
- Rarely, mild increases in RBC, Hgb, and PCV due to epinephrine-mediated splenic contraction
- Mild neutrophilia
- Plasma proteins typically normal

Serum Biochemistry/Urinalysis

No characteristic changes

Persistent Lymphocytosis of Cattle

- CBC
- Mild to moderate lymphocytosis that persists over an interval of at least 3 months
- Morphologically atypical and large lymphocytes may be present on blood film examination, but similar lymphocytes may occasionally be observed in normal cattle or cattle with various non-BLV-associated conditions.

Serum Biochemistry/Urinalysis

No characteristic changes

Lymphocytic Leukemia

- CBC
- Marked to severe lymphocytosis with atypical lymphocytes observed in approximately 50% of the cases. (Approximately 5%–10% of BLV-infected cattle manifest with massive increases in circulating neoplastic lymphoblasts, but <2% develop lymphosarcoma.)
- Anemia (may be regenerative or nonregenerative depending on cause)
- Plasma proteins may be decreased if there is neoplastic involvement of gastrointestinal tract.

Serum Biochemistry/Urinalysis

No characteristic changes.

OTHER LABORATORY TESTS

- For cattle with persistent lymphocytosis: anti-BLV antibody test (anti-GP51 agar gel immunodiffusion (AGID) test is most common)
- Bone marrow evaluation in cases of lymphocytic leukemia often reveals a large population of infiltrating lymphoblasts.

IMAGING

Radiographic or ultrasonographic imaging may reveal evidence of hepatosplenomegaly or internal iliac lymph node enlargement associated with lymphosarcoma.

OTHER DIAGNOSTIC PROCEDURES

- Fine needle aspiration cytology and culture of enlarged lymph nodes is occasionally helpful in differentiating an abscess from lymphosarcoma.
- Histopathologic examination of tumor or lymph node biopsies may be more useful than cytology in confirming lymphosarcoma.

TREATMENT

Physiologic Lymphocytosis

Treatment is not warranted as lymphocyte counts typically return to normal within 30 minutes.

Lymphocytosis Due to Antigenic Stimulation

Treatment should be directed at the primary disease causing the lymphocytosis.

Lymphosarcoma and Lymphocytic Leukemia

No curative treatment for lymphosarcoma or lymphocytic leukemia exists in ruminants. Supportive or palliative therapy may be indicated to reduce discomfort.

ACTIVITY

Restrict

CLIENT EDUCATION

N/A

MEDICATIONS

DRUGS OF CHOICE

Chemotherapeutics

Case report data regarding chemotherapy are rare. A few reports summarizing unsuccessful attempts in treating lymphosarcoma and lymphocytic leukemia with dexamethasone and cyclophosphamide exist. Drug withdrawal periods must be determined and maintained.

Fluid Therapy

Rehydration with IV fluids appropriate for the primary cause (e.g., polyuric renal failure, diarrhea, etc.) and to correct any electrolyte and acid-base imbalances

CONTRAINDICATIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

See Bovine Leukemia, Leukocyte Responses in Cattle and Lymphosarcoma for control suggestions.

POSSIBLE COMPLICATIONS

Chemotherapy-induced bone marrow suppression with subsequent anemia, leukopenia, and thrombocytopenia.

EXPECTED COURSE AND PROGNOSIS

Persistent Lymphocytosis of Cattle

Precedes the onset of lymphosarcoma in approximately 65% of the cases, but less than 5% of cows with persistent lymphocytosis develop lymphosarcoma.

Sporadic Lymphosarcoma

Rapidly progressive and usually fatal within 2 to 8 weeks of onset

Lymphosarcoma or Lymphocytic Leukemia

The prognosis for patients with lymphosarcoma or lymphocytic leukemia is poor with median survival times following diagnosis of < 2–3 months.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Persistent lymphocytosis of cattle is associated with BLV infection.

AGE-RELATED FACTORS

- Young animals—lymphocyte counts generally increase from birth to a maximum at approximately 11–12 months of age. Absolute lymphocyte counts begin to slowly decline in adult animals.
- Physiologic lymphocytosis occurs in young healthy animals.
- Sporadic lymphosarcoma occurs most commonly in 3–6-month-old calves.
- Lymphosarcoma and lymphocytic leukemia generally occur in adult animals > 4 years.

LYMPHOSARCOMA

BASICS

DEFINITION

- Lymphosarcoma is a lymphoid cancer caused by a single stranded RNA retrovirus that integrates into the host cell genome.
- The cause of lymphosarcoma in cattle and sheep is believed to be bovine leukemia virus. Cattle are the natural host for BLV. However, only about 30% of BLV-positive cattle develop persistent lymphocytosis and only 5% of these develop lymphosarcoma.

OVERVIEW

- There are four forms of bovine leukemia: juvenile, thymic, cutaneous, and enzootic. The first three are considered sporadic because the animals are BLV negative for antibodies. The enzootic bovine leukemia animals are positive for BLV antibodies, have persistent lymphocytosis, and can develop lymphosarcoma.
- It can be hard to distinguish between the thymic form of BLV and lymphosarcoma.
- There are no indicators to predict which animals with persistent lymphocytosis will develop lymphosarcoma.
- BLV has not been associated with goats that develop lymphosarcoma.

PATHOPHYSIOLOGY

- In cattle and sheep, seroconversion occurs after exposure to the virus between 14 and 98 days. The wide temporal range of conversion is attributable to dose, route of infection, and immune status of the animal. Concurrent infection with a retro- or herpes virus may make the BLV infection more pathogenic.
- Currently it is believed that the virus is necessary only to initiate tumor development, but after initiation, the tumor self-replicates. The “tat” gene is the only gene identified that appears critical for tumor cell maintenance.
- Tumors can occur in every organ but primarily develop in lymph nodes.

SYSTEMS AFFECTED

Cardiac, musculoskeletal, gastrointestinal, lymphatic, ocular, reproductive, and metabolic

GENETICS

Cattle that have been identified with the BoLA-A allele w8.1 are more resistant to BLV infections and therefore have a lower incidence of lymphosarcoma.

INCIDENCE/PREVALENCE

- In the cattle industry, BLV-positive cattle are estimated to account for more than 44 million dollars in losses a year. These losses are in the form of genetics, carcass condemnation, trade restrictions, and veterinary costs.
- The dairy industry is believed to harbor more BLV-positive cattle because of the increased potential for transmission between cows.
- Male bull calves that have BLV-positive dams are believed to have a higher incidence of utero transmission.

GEOGRAPHIC DISTRIBUTION

Widespread throughout the United States

SIGNALMENT

Species

Cattle are the natural host for BLV. Sheep are highly susceptible to forming lymphosarcoma once exposed to BLV. Goats tend to form tumors but do not seroconvert.

Breed Predispositions

None

Mean Age and Range

Cattle and sheep have the highest incidence of tumor formation between the ages of 2 and 4. Goats older than 2 years of age tend to be identified with tumors.

Predominant Sex

None

SIGNS

GENERAL COMMENTS

Depending on location of the developing tumor, animals will present with a wide variety of clinical signs.

PHYSICALEXAMINATION FINDINGS

- Cattle and sheep: peripheral lymphadenopathy (prescapular, femoral, suprascapular, supramammary), weight loss, anorexia, decreased milk production, ketosis, diarrhea, ataxia, edema on ventral abdomen and udder due to blocked lymphatic drainage, exophthalmia, melena from gastrointestinal ulcers, dyspnea, cardiac dysrhythmia, pounding jugular pulse, masses in the reproductive tract, dog-sitting, and recumbent animals.
- Goats: pyrexia, emaciation, diarrhea, and dyspnea.

CAUSES

- Transmission of BLV occurs both horizontally and vertically.
- Horizontal transmission primarily occurs through fomites during normal cattle processing procedures. These include dehorning, rectal palpation, injections, tattoos, and surgeries. When instruments are not properly sterilized between procedures, contamination of naïve animals with the virus may occur. Body secretions from saliva, nasal discharge, broncho-alveolar fluids and urine have all been demonstrated to seroconvert exposed ruminants. Insects have been hypothesized to be a transmitting vector, but to date, experimental infection has not been demonstrated between animals.
- Experimental vertical transmission of virus can occur through semen, ova, and embryos. It is not believed that these reproductive products are a significant source of infection. None of these products may be sold internationally if the animals are identified as having BLV. In utero, cell-free transmission of virus to offspring occurs through the placenta in 3% to 25% of infected dams after the third month of gestation. Male calves born to an infected dam appear to have a higher incidence of infection than female calves. Colostrum and milk from BLV-positive cows are not believed capable of causing an infection in calves that ingest them if given after gut closure.

RISK FACTORS

- Fomites contaminated with whole blood from an infected cow that are not cleaned properly
- Sheep that are comingled with infected cattle
- Dairy cattle have more intense management and interaction than most beef cattle, which accounts for a higher incidence of transmission.

DIAGNOSIS

- Physical examination revealing peripheral lymphadenopathy
- Rectal palpation revealing large masses
- Virus isolation from the lymphocytes
- PCR testing for viral DNA, although specific and sensitive, is often cost-prohibitive. PCR testing distinguishes between calves that are positive for serology due to passive transfer of antibodies versus animals that have been administered vaccine. Positive results can occur when testing virus-infected lymphocytes within 3 days of exposure. Certain primers have been designed that specifically identify the 3' end of the viral genome that is necessary for lymphosarcoma formation.
- Microscopic identification of viral particle in the lymphocyte. This will not tell you if the animals will develop lymphosarcoma.
- Testing blood samples for tumor specific antigen with monoclonal antibodies
- Serology—all of the serological tests depend on the host immune response to infection. Ruminants must seroconvert prior to detecting antibodies in the serum. The tests are designed to identify antibodies produced to either the gp51 or p24 viral antigen. Lymphosarcoma cattle are usually positive for p24 antibodies. This is not a common test done in labs. Cattle that are preparturient 2 to 3 weeks and postpartum up to 6 weeks may have a false negative test due to antibody compartmentalization in the udder. False positive results may occur in calves up to 6 months of age due to ingestion of

antibodies from the dam in colostrum.

- *Agar gel immunodiffusion (AGID)*—this is the primary test used to screen cattle and the official test for export of cattle. Most labs that run this test are identifying antibodies to gp51 viral antigen, which appears to be more sensitive than testing for p24. Antibodies to gp51 can occur as early as 3 weeks postexposure. A negative test indicates that the animal has not been exposed to BLV for 3 to 12 weeks prior to testing. A strong response to gp51 does not necessarily indicate that the animals will develop lymphosarcoma.
- *Radioimmunoassay (RIA)*—this test is more sensitive than AGID and can detect smaller amounts of antibody within the first 2 weeks of infection. It has been developed for both the detection of p24 and gp51. Both serum and milk can be used for testing.
- *Enzyme-linked immunosorbent assay (ELISA)*—sensitivity and specificity of this test are equal to RIA.

DIFFERENTIAL DIAGNOSIS

- Lymphadenopathy due to systemic infection
- Fat necrosis
- Melanomas
- Carcinomas
- Internal abscesses
- Caseous lymphadenitis in goats and sheep

CBC/BIOCHEMISTRY/URINALYSIS

- Cattle
 - CBC may be normal.
 - May see a lymphocytosis but rare
 - May be anemic, due to gastrointestinal bleeding (microcytic, hypochromic)
 - Can have an increase in liver enzymes if there is hepatic involvement
 - Hyperglobulinemia
 - Hypoalbuminemia
- Sheep and goats
 - Anemia that is nonregenerative
 - Hyperglobulinemia
 - Hypoalbuminemia

OTHER LABORATORY TESTS

A bone marrow aspirate and cytological examination may reveal clonal expansion of lymphoid precursors.

IMAGING

Can see masses on survey radiographs in the cranial thorax in ruminants that could be heart-based tumors

DIAGNOSTIC PROCEDURES

- Fine needle aspirate of the mass and cytological examination. Examination of the aspirate may reveal a large number of lymphoblasts, but it may be hard to distinguish between lymphadenopathy and systemic infections.
- Lymph node biopsy during a laparotomy

PATHOLOGIC FINDINGS

- Grossly, tumors appear to have a heavy fibrous capsular lining with cream-colored, friable inner contents and a necrotic, soft center.
- Tumor masses can occur in one or multiple organs and lymph nodes. The most common sites for development are:
 - Cardiac tumors primarily occur in the myocardium and right atrium. They are very rarely seen in the left side of the heart.
 - Gastrointestinal involvement of the pylorus is common and often will result in ulcers.
 - Ocular masses develop in the retrobulbar region.
 - Lymphatics in the area of the cranial udder
 - Uterine masses diffusely distributed throughout the tissues
 - Ventral spinal cord masses are readily palpable rectally.
 - Liver diffusely

- Lungs diffusely but rare to find
- Spleen diffusely
- Histologically, the masses have a large number of lymphoblast cells.

TREATMENT

None

APPROPRIATE HEALTH CARE

Some affected animals with high genetic value may need supportive care until they can have ova or semen harvested from them. Also, pregnant animals may need nursing care until they have their offspring.

NURSING CARE

Depending on what the animals are presenting as clinical signs, nursing care could range from soft bedding if the animal is recumbent or ataxic to slinging animals to prevent pressure necrosis.

ACTIVITY

Limit activity to prevent further injury if the animal is ataxic or recumbent and struggling.

DIET

Normal diet

CLIENT EDUCATION

It is important to educate your clients on the modes of horizontal transmission to prevent use of contaminated equipment on BLV-negative ruminants. It is important to discuss the economic impact of the disease on the production goals of the farm, to determine if testing and culling of infected animals are reasonable options. There are a number of international shipping restrictions that prevent the sale of breeding stock and their reproductive by-products if they are BLV positive.

SURGICAL CONSIDERATIONS

If the diagnosis is difficult to obtain through noninvasive techniques, an exploratory laparotomy and biopsy of lymph nodes may be warranted.

MEDICATIONS

DRUGS OF CHOICE

None

CONTRAINDICATIONS

None

PRECAUTIONS

None

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUGS

None

FOLLOW-UP

Animals are usually culled from the herd once they present with clinical signs and are diagnosed as having lymphosarcoma.

PATIENT MONITORING

Monitor patients as their health degenerates to ensure they are humanely treated.

PREVENTION/AVOIDANCE

- Identify BLV-positive animals and keep them isolated from BLV-negative animals.
- Properly clean instruments that have whole blood contamination.
- Do not reuse needles.
- Test bulls that are used for natural service for BLV and do not use them if they are positive.
- Vector control—although to date experimental transmission of BLV by vectors has not been shown to be a primary infectious route
- Cull positive animals from the herd and maintain strict testing and biosecurity when introducing new animals to the herd.
- If the owners have BLV-positive cows, they can harvest the ova, rinse them, and implant them into a BLV-negative recipient.

POSSIBLE COMPLICATIONS

None

EXPECTED COURSE AND PROGNOSIS

Ruminants with lymphosarcoma generally deteriorate within a week to 2 months after presenting with clinical signs and eventually need to be humanely euthanized.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Ataxia, anemia, ascites, ventral edema, bloat, choke

AGE-RELATED FACTORS

Lymphosarcoma occurs in mature ruminants, usually over the age of 4 years.

ZOONOTIC POTENTIAL

None

PREGNANCY

There is cell-free transmission of the virus after 3 months of gestation through the placenta to the fetus.

RUMINANT SPECIES AFFECTED

Cattle, sheep, and goats

BIOSECURITY

The optimal biosecurity measures would be to test and cull positive BLV ruminants from the herd. Culling positive animals is cost-prohibitive for most producers, so reducing the rates of transmission is a practical approach to eliminating the disease from the herd. Testing and adding only BLV-negative animals to the herd and eliminating positive animals through natural attrition and preferential selection can accomplish reducing the number of infected ruminants.

PRODUCTION MANAGEMENT

- There are several approaches to eradicating BLV from the herd. The producer is going to have to determine if the cost benefit of eradication is greater or less than having the disease present.
- There is a federally supported voluntary eradication program that has restrictions that vary by state.
- Eradicating or reducing BLV from the herd begins with testing all the animals in the herd. This primarily applies to cattle and sheep. All negative animals need to be retested in 12 weeks, and calves less than 6 months need to be retested at 6 months of age. Once producers have this information, they have three options:
 - Culling all positive animals identified can eliminate BLV from the herd in a few months. However, the economic hardship is extreme if the herd has a high rate of infection. There is also the loss of genetic material from the herd when culling.
 - Segregating infected animals from negative animals and slowly eliminating them from the herd and replacing with negative animals is another option. It takes longer to eliminate BLV from the herd this way, and requires more frequent serologic testing of the herd. Segregating positive from negative animals also requires essentially two separate facilities and equipment.
 - Managerial practices can be altered to prevent the transmission of the disease and allow for natural attrition of infected animals. This takes a long time to eliminate BLV from the herd, and requires frequent serological testing and a long-term

commitment by the producer.

MAEDI-VISNA (VISNA-MAEDI)

BASICS

OVERVIEW

- Visna-maedi (VM), or maedi-visna (MV), is a chronic, multisystemic disease of sheep caused by visna-maedi virus (VMV).
- In the United States, the disease is known as ovine progressive pneumonia (OPP). Other names given to this disease include Graaff-Reinet disease in South Africa, la bouhite in France, and zwoegersiekte in Holland.
- VMV is the prototype species of the ovine/caprine lentivirus group of the genus *Lentivirus* in the family Retroviridae. VMV is closely related to other human and animal lentiviruses, particularly caprine arthritis encephalitis virus (CAEV).
- Like other lentiviruses, the genome of VMV is single-stranded RNA. After infection, the VMV genome is reverse transcribed into a double-stranded DNA copy that integrates into the host cellular DNA. As a result, VMV persists in cells of infected sheep for life, irrespective of the presence of neutralizing antibodies and cell-mediated immunity.
- MV has been reported in most sheep-producing countries of the world.
- In the United States, the average reported prevalence of VMV antibodies in sheep sera is 26%. However, there is a wide range of variation between states and among individual flocks.
- In west Texas, where the majority of U. S. sheep is raised, the VMV seroprevalence is 0.5%. The difference in VM seroprevalence between Texas and other U. S. states is probably due to differences in management between regions. In Texas, most sheep are raised on range conditions in a hot, dry climate and lambing occurs on pasture.
- Transmission of VMV occurs more often during periods when infected and noninfected sheep are housed close together, such as during lambing or in winter.
- During lambing and the postpartum period, transmission occurs by contact of newborns with either contaminated birth products or aerosols from the infected dam. Ingestion of infected colostrum or milk seems to play a less important role. Close contact between infected and noninfected sheep after weaning may also result in transmission.
- Coexistence of other chronic respiratory diseases in the flock, such as ovine pulmonary adenomatosis or lung parasites, seems to increase the risk of transmission.
- Vertical intrauterine transmission from infected ewes to the fetus occurs in 5%–10% of cases.
- Venereal transmission of VMV has not been shown to occur, but sheep experimentally infected with VMV and coinfecting with *Brucella ovis* shed VMV in semen.
- Seroconversion usually occurs between 2 and 8 weeks postinfection (PI). Some sheep may remain seronegative for several months or longer in spite of being infected.

SIGNALMENT

- Sheep are the natural host of VMV infection. Goats can be infected experimentally with VMV. Phylogenetic analyses indicate that cross-species transmission of small ruminant lentiviruses (VMV and CAEV) occurs regularly under natural conditions. Feeding VMV-contaminated sheep colostrum or milk to goats can result in infection.
- The percentage of seropositive sheep in a flock increases with age.
- Although VMV transmission may occur at an early age, clinical signs of the disease are rarely shown before 2–3 years of age.
- Some breeds of sheep may be more susceptible to VMV infection than others. Finnish breeds seem to have a greater tendency to infection by VMV than the Ile de France, Rambouillet, or Columbia breeds. Some results may be difficult to interpret because of uncertainty in the exposure histories.
- Breed-related resistance to VMV-induced disease has been described in crosses between Icelandic and Border Leicester, pure Awassi, and Columbia breeds. Texel sheep are considered highly susceptible.
- Individual genetic susceptibility to VMV-induced pulmonary lesions has been demonstrated in artificially created

isogenetic twin lambs.

SIGNS

- Several factors including virus strain, age, breed, and genetics of the animal, route of exposure, secondary infections, and management conditions may influence the clinical outcome of VMV-infection.
- The majority of sheep infected with VMV remains clinically healthy for life.
- In a proportion of infected sheep, VMV infection can lead to a disease complex characterized by cachexia and chronic inflammation in the lungs, lymph nodes, joints, mammary gland, and central nervous system (CNS).
- In North America, the most common manifestation of VM is chronic pneumonia with signs of afebrile, progressive respiratory failure in sheep 2–3 years or older. Affected sheep develop gradual emaciation and loss of body condition despite good appetite. They often remain behind the rest of the flock when driven to pasture and open-mouth breathing and dry cough are common.
- In the latter stages of disease, fever, purulent nasal discharge, cough, and depression are common as a result of secondary bacterial infection. Sheep usually die within 6 to 8 months after clinical signs become apparent.
- In some flocks, more than 60% of infected ewes may present evidence of mammary gland inflammation. In these cases, there is diffuse bilateral enlargement and hardening of the udder (hardbag). Milk may be normal in appearance but scant in quantity.
- Sheep with VMV-associated arthritis become lame and exhibit cachexia despite having a good appetite. There is weight loss and swelling of the carpal and tarsal joints. Clinical signs of arthritis normally appear 2–3 years after infection.
- Neurological manifestations of VM are seldom seen in the United States, but are common in Europe. In this form of the disease, there is aberration of gait affecting primarily the hindquarters. There is gradual weakening, leading first to paraplegia and then quadriplegia up to the point that animals are unable to rise. Affected animals lose weight, and jerking of the lips and facial muscles or blindness may be observed. Spinal taps reveal elevated numbers of mononuclear inflammatory cells in the cerebrospinal fluid.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of chronic weight loss include caseous lymphadenitis, paratuberculosis (Johne's disease), chronic parasite infestations, and malnutrition.
- Other forms of chronic pulmonary disease include *Corynebacterium pseudotuberculosis*–induced mediastinal lymph node and lung abscesses, ovine pulmonary adenomatosis (jaagsiekte), chronic suppurative pneumonia, and parasitic pneumonia.
- Bacterial mastitis (bluebag)
- Arthritis by bacteria (*Chlamydia* and *Mycoplasma*)
- The neurologic form of VM can be confused with other CNS diseases such as scrapie, rabies, brain abscesses, and trauma of the spinal cord or parasitic lesions.

DIAGNOSTIC PROCEDURES

- In the United States, the agar gel immunodiffusion (AGID) test is the most commonly used serological technique to identify infected animals because of its low cost, simplicity, and high specificity. However, the sensitivity of the AGID test generally is considered low.
- Indirect ELISA tests utilizing either whole virus or recombinant OvLV proteins are used widely in Europe.
- The sensitivity of ELISA tests is considered to be better than the AGID test. Some studies have found the effectiveness of indirect ELISA and AGID test to be similar. A major problem is that none of the tests are standardized across laboratories, making comparative evaluations difficult.
- Virus isolation from “buffy coats” is the most definite way to confirm VM. However, this technique is expensive, cumbersome, often unsuccessful, and not recommended as a routine diagnostic test.
- Although PCR is a highly sensitive technique, its usefulness for the detection of VMV in clinical samples from naturally infected goats still requires validation.

PATHOLOGIC FINDINGS

Gross Findings

- The lungs of sheep with VMV-induced chronic interstitial pneumonia do not collapse fully after the thoracic cavity is opened, and they have a white or gray color. Impression lines as a result of rib compression on the costal surface of the lungs can be observed. The lungs are heavier than normal and firm on palpation. Multifocal, discrete, 1 to 2 mm or larger, gray foci may be observed throughout the lung parenchyma. Well-demarcated areas of consolidation without exudate in the airways are sometimes found in the cranioventral lobes. Mediastinal and peribronchial lymph nodes may be five to ten times larger than normal.
- The mammary gland in ewes affected with mastitis is symmetrically enlarged and firm on palpation.
- In sheep with arthritis, there is swelling of the carpal and tarsal joints and bursa. Other joints are less frequently affected. In these sheep, there is increased synovial fluid, discoloration and thickening of the synovial membrane, as well as erosion of the articular cartilage.
- Gross lesions are not observed in the CNS of sheep affected with the neurological form of VM.

Microscopic Findings

- Lymphoid interstitial pneumonia is the characteristic lesion in the lungs of sheep affected by the pulmonary form of VM. There is thickening of the interalveolar septa due to infiltration of mononuclear cells, hyperplasia of smooth muscle, and fibrosis. Numerous lymph follicles with active germinal centers are found adjacent to bronchioles and small vessels. Discrete nodules of lymphocytes are found unrelated to airways and blood vessels. In more severe infections, the alveoli are obliterated due to exudation of macrophages into the lumen.
- Lymphoid hyperplasia of associated lymph nodes is present.
- The mammary gland of ewes with VMV-induced mastitis shows follicular lymphoid hyperplasia around lactiferous ducts, interstitial infiltration of mononuclear cells, and fibrosis.
- Joint swelling is characterized by severe infiltration of lymphocytes, plasma cells, and macrophages as well as villi proliferation of the synovium. Degeneration of the articular cartilage, mineralization of the joint capsule, and periosteal replacement growth can be seen in more advanced cases.
- In the brain of sheep affected by the neurological form of the disease, there is periventricular encephalitis characterized by ependymal necrosis, widespread demyelination, and prominent perivascular lymphocytic cuffing.

TREATMENT

There are no commercial treatments available to control VM.

MEDICATIONS

N/A

CONTRAINDICATIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

N/A

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- There are no commercial vaccines available to prevent VMV infection.
- Serological testing and segregation of positive reactors can achieve eradication of VM from a flock.

- Some VMV-infected sheep may remain seronegative for weeks or months after infection. These sheep may shed virus at irregular intervals, thus representing a major roadblock in VM control.
- Retesting every 3 to 6 months and elimination of new positive reactors is necessary until 3 to 5 consecutive tests result in 100% of the sheep being seronegative. Then, yearly testing and acquisition of replacements from VMV-free flocks are recommended.
- Separation of offspring from their mothers prior to the ingestion of colostrum and the use of heat-inactivated colostrum (56°C for 60 min) and milk substitutes have been used and found ineffective in the past. This method is labor intensive and not always effective.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Clinical signs of VM are seen in animals 2–3 years old and older due to the long incubation period.

ZOONOTIC POTENTIAL

There is no evidence to indicate that VMV is infectious to humans.

PREGNANCY

Vertical transmission from mother to fetus occurs in a small proportion of cases, but there are no clinicopathological changes in infected fetuses.

MAGNESIUM DEFICIENCY/EXCESS

BASICS

DEFINITION

- Hypomagnesemia: measured serum magnesium concentration below established laboratory reference intervals for the species and breed; generally serum concentrations < 1.4 mg/dL considered clinically significant in ruminants.
- Hypermagnesemia: measured serum magnesium concentration above established laboratory reference intervals for the species and breed; generally, serum concentrations > 3.0 mg/dL in ruminants.

PATHOPHYSIOLOGY

- Magnesium (Mg) represents 0.05% of total body weight and is the fourth most prevalent cation in the body following Ca, Na, and K.
- Mg is distributed in bones (60%), soft tissue (38%—mostly muscle), and extracellular fluids (2%—blood, CSF).
- Serum Mg concentration is composed of three fractions: free ionized portion (55%—regulated by hormones), protein-bound portion (30%—albumin, globulins), anion-bound portion (15%—PO₄, citrate).
- Several hormones influence concentration of free ionized Mg fraction.
 - Parathyroid hormone (PTH) increases reabsorption of Mg from the renal tubules, bone, and absorption from the gastrointestinal (GI) tract.
 - Thyroxine increases renal loss of Mg.
 - Aldosterone favors decreased GI absorption of Mg.
 - Activated vitamin D (1,25-DHCC) favors decreased serum Mg concentration via reduced PTH concentrations.
- Total daily body loss of Mg through feces, urine, and lactation can represent total amount of extracellular Mg.
- Limited reserves of mobile Mg in bone and extracellular sources for maintenance of homeostasis of extracellular Mg concentrations (capacity decreases with age).
- Ruminants are dependent upon daily oral intake of Mg (~20 g/day) and its absorption (adults—rumen; neonates—jejunum) to maintain adequate extracellular (CSF, blood) concentrations.
- Mg is an essential element and serves as a catalyst with over 300 different enzymes with particular importance to ATP reactions, bone formation, maintenance of cell membrane potentials, methyl group transfers, protein and fat catabolism, and regulation of RNA and DNA structure.
- Mg regulates CNS excitability by inhibiting Ca-dependant presynaptic excitation-secretion of neurotransmitters.
- Decreased CSF Mg concentrations lead to increased excitation.
- Increased CSF Mg concentrations lead to sedation.
- Mg is important in the production and decomposition of acetylcholine at neuromuscular junctions.
- Decreased Mg concentrations lead to increased acetylcholine at neuromuscular junctions predisposing to tetany.
- Increased Mg concentrations lead to muscle weakness and paralysis.

SYSTEMS AFFECTED

- Skeletal muscle—tetany (Mg decreased)/paralysis (Mg increased)
- CNS—excitement (Mg decreased)/sedation (Mg increased)
- Respiration—increased rate (Mg decreased)/decreased rate (Mg increased)
- Heart—increased rate (Mg decreased)/decreased rate (Mg increased)
- Reproduction—reduced fertility, retained placenta (Mg decreased)
- Renal—urolith formation (Mg increased)

GENETICS

N/A

INCIDENCE/PREVALENCE

- Hypomagnesemia-associated disorders seen in 10% of cattle herds.
- Hypomagnesemia-associated disorders responsible for 1%–3% of cattle, sheep, and goat deaths per year.

GEOGRAPHIC DISTRIBUTION

Worldwide

Species

All ruminants; cattle > sheep > goats.

Breed Predilection

- Adult cattle: beef cattle (Angus > Brahman) > dairy cattle (shorthorn > Holstein)
- Calf: dairy cattle

Mean Age and Range

- Adult cattle—3rd–5th lactation
- Calf—2–4 months
- Sheep—older ewes

Predominate Sex

N/A

SIGNS

Hypomagnesemia, Acute (Adult—Grass Tetany; Juvenile—Milk Tetany)

- Unusual vocalization (bellowing)
- Frenzied running
- Muscle fasciculations
- Erect ears
- Hyperesthesia and hyperexcitability
- Recumbent with seizure activity/nystagmus/limb paddling
- Increased body temperature
- Forceful respiration with tachycardia and loud heart sounds

Hypomagnesemia, Chronic (Adult—Winter Tetany)

- Unthriftiness
- Anorexia
- Frequent urination
- Mild ataxia
- Decreased milk production
- Reduced reproductive rate/retained placenta

Hypermagnesemia (rare)

- Possible hypotension
- Mental sedation
- Cardiac bradycardia, arrest
- Respiration depression, paralysis
- Skeletal muscle weakness

CAUSES

Hypomagnesemia

- Inadequate GI absorption of Mg
 - Anorexia
 - Starvation
- Type of diet: (1) Lush spring pastures (orchard grass, small grain, fescue) that contain high concentrations of potassium (K), PO₄, and nitrogen and low concentrations of Mg and sodium (Na). K interferes with GI absorption of Mg. (2) Whole milk diet for calves is low in Mg concentration and absorptive ability decreases with age.
- Infiltrative rumen disease

- Increased serum aldosterone concentrations—increased GI secretion of K, which interferes with Mg absorption
- Forages with increased concentrations of Ca or aluminum may interfere with Mg absorption.
- Excess urinary loss of Mg—impaired/reduced tubular reabsorption
 - Osmotic, loop diuresis
 - Hypercalciuria
 - Tubular acidosis
 - Aminoglycoside toxicities
 - Ketonuria

Hypermagnesemia

- Decreased urinary excretion
 - Reduced glomerular filtration due to dehydration or glomerular renal disease
 - Reduced renal tubular reabsorption due to renal failure
- Increased intestinal absorption of Mg without including PTH—excess oral administration of Mg
- Other
 - Milk fever/parturient hypocalcemia/paresis—possible mechanism: hypocalcemia \rightarrow \uparrow PTH \rightarrow \uparrow Mg bone, renal, and GI absorption
 - Excess intravenous Mg
 - Possibly hypoaldosteronism and hypothyroidism (both reported only in humans)

RISK FACTORS

All

- Environmental stress
- Poor body condition
- Overbody condition
- Abrupt change of diet

Adult Cattle

- Feeding forage with a ratio defined by $K/(Mg + Ca) > 2.2$
- Grazing forage with a Mg concentration $< 0.2\%$
- Grazing lush nonlegume pastures (*Phalaris Tuerosa*, orchard grass, fescue-bluegrass, small grains) low in Mg and Na—in order of decreasing risk: wheat $>$ oats $>$ barely $>$ rye
- Soils high in K
- Treatment of pastures with fertilizers with high concentrations of nitrogen, potash, and poultry litter
- Beef cattle last 60 days of pregnancy
- Spring calving
- Poor-quality wintering diet
 - Winter diet deficient in Mg and Ca leads to \uparrow PTH \rightarrow depletion of bone Mg
 - Spring grass has \uparrow Ca \rightarrow \downarrow PTH \rightarrow \downarrow Mg bone, renal and GI absorption \rightarrow hypomagnesemia
- Pregnancy
- Lactation
- Third to fifth lactation cycle

Calf

- Diarrhea
- Fast growth rate

Ewe

- Pregnancy with twins
- Older animal
- Dental problems

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hypomagnesemia

Infectious

- Rabies
- Other viral encephalitides
- Enterotoxemia
- Tetanus

Toxicity

- Lead poisoning
- Strychnine poisoning
- Salt poisoning
- *Claviceps paspali* ingestion (ryegrass staggers)

Degenerative

Polioencephalomalacia (thiamin deficiency and other causes)

Metabolic

- Nervous ketosis
- Parturient hypocalcemia/paresis (milk fever)—urine Mg concentration > 10 mg/dL in milk fever, < 1.0–3.0 mg/dL in grass tetany

CBC/BIOCHEMISTRY/URINALYSIS

Hypomagnesemia

CBC—no typical alteration

Blood Chemistry

- Serum preferred over plasma
 - Avoid use of EDTA and citrate collection tubes (chelate Mg)
 - Hemolysis will not elevate Mg concentration in sample (ruminants only)
- Mg < 1.2–1.5 mg/dL
- Often moderate concurrent hypocalcemia (<8 mg/dL)
- Elevation in muscle enzyme activity (CK, AST) if downer-animal or convulsive activity

Urine

- Mg < 2 mg/dL indicator of danger for hypomagnesemia, 2–10 mg/dL marginal, and > 10 mg/dL adequate
- Fractional excretion % of Mg decreased (normally 6.5–8.3% ± 3.7%)— $\frac{[Mg_{Urine}/Mg_{Serum}]}{[Cr_{Serum}/Cr_{Urine}]} \times 100$

Hypermagnesemia

CBC—no typical alteration

Blood Chemistry

- Elevated serum Mg concentration
- Reduced serum Ca concentration

Urine

Fractional excretion % of Mg increased (normally 6.5–8.3% ± 3.7%)— $\frac{[Mg_{Urine}/Mg_{Serum}]}{[Cr_{Serum}/Cr_{Urine}]} \times 100$

OTHER LABORATORY TESTS

Hypomagnesemia

- Cerebrospinal fluid Mg concentration (<1 mg/dL, can be used up to 12 hours postmortem)
- Measurement of Mg concentration in switch hair sample (correlates with serum concentration)

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Hypomagnesemia

- Forage Mg analysis (<0.2% increased risk)
- Calculate forage ratio of $K/(Mg + Ca)$. Values < 2.2 indicate increased risk.
- Monogram for calculating risk factor using serum and forage Mg concentration
- In calves, bone analysis to evaluating the ratio of Ca:Mg, which is 70:1 normally but > 90:1 in hypomagnesemia conditions
- Vitreous fluid (up to 48 hours postmortem) < 1.4 mg/dL (controversial)

PATHOLOGIC FINDINGS

Hypomagnesemia

Gross Pathology

- Muscle and head trauma due to seizure activity
- Petechiation in white matter of the midbrain and brain stem
- Agonal emphysema
- Aspiration of rumen contents

Histopathology

- Tissue mineralization in heart, spleen, and lung arteries
- Diapedesis of red blood cell in periventricular nuclei of the brain

Hypermagnesemia

Gross Pathology

Urinary calculi

TREATMENT

APPROPRIATE HEALTH CARE

Hypomagnesemia

- Cattle: remove from lush pasture, increase dry forage and legume consumption. Reduce stressor elements and environmental stimuli.
- Calf: reduce stressor elements and environmental stimuli.

Hypermagnesemia

Discontinue any dietary Mg supplementation.

ACTIVITY

N/A

CLIENT EDUCATION

- Risk of fatal cardiac arrhythmias or arrest with IV Mg therapy
- Relapse following therapy likely if further prevention steps not taken

SURGICAL CONSIDERATION

N/A

MEDICATIONS

DRUGS OF CHOICE

Hypomagnesemia (Acute)

- Intravenous (IV) Ca borogluconate solution with 5% Mg hypophosphate (preferred medication)
- Sedation with chloral hydrate 50 mg/kg IV (cases of seizure activity)
- 10% magnesium sulfate (100 ml) subcutaneously (supplemental medication)

- Mg-rich enema (optional supplemental medication)
- 2 oz oral Mg oxide/day to prevent relapse

Hypomagnesemia (Chronic)

- 1–2 oz oral Mg oxide/day
- Acute Rx in cases with more severe symptoms

Hypermagnesemia

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Monitor heart during IV Mg therapy for arrhythmias or bradycardia.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Hypomagnesemia

Herd urine concentration of Mg between 3.7 and 9.8 mg/dL indicates adequate herd status.

PREVENTION/AVOIDANCE

Hypomagnesemia

Calf

Offer oral starter ration (beginning at 2 weeks of age)

Cattle

- Forage analysis (see diagnostic procedures)
- Supplement with 1–2 oz Mg oxide/head/day
 - Mix Mg with molasses and water and spray on hay
 - Free choice 1:1:1 ratio of Mg oxide:dicalcium phosphate:ground barley
 - Free choice Mg mineral blocks
 - Apply 2% Mg sulfate dust every 2 weeks to pastures during spring danger period.
- Pasture management
 - Oversow grass with legume.
 - Avoid use of heavy potash and nitrogen fertilizers.
- Transition to a fall calving program
- Maintain adequate nutritional levels in winter months to avoid loss of body condition.

Hypermagnesemia

Avoid rations with Mg concentrations > 1.65%.

POSSIBLE COMPLICATIONS

- Mortality
- Unthriftiness
- Reduced reproduction rates
- Reduced milk production rates

EXPECTED COURSE AND PROGNOSIS

Hypomagnesemia

- Poor prognosis in cases that are comatose or have severe seizure activity

- Fair-good prognosis with IV therapy in less-severe cases
 - Improvement expected in 3–5 hours
 - Additional supplemental therapy and preventive steps vital to prevent relapse

Hypermagnesemia

Poor prognosis with serum Mg concentration > 3.5 mg/dL in association of renal disease

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Hypomagnesemia

- Calves between 2 to 4 months of age
- Older adults

ZOONOTIC POTENTIAL

MALIGNANT CATARRHAL FEVER

BASICS

DEFINITION

- Peracute, acute, subacute, or chronic generalized infectious herpes viral disease characterized by sudden death, severe diarrhea, dyspnea, CNS symptoms, and oral lesions.
- Found in bovidae and cervidae with an extremely high mortality but generally a low morbidity.

PATHOPHYSIOLOGY

- Vasculitis of the endothelium and epithelium disruption characterizes this disease.
- Two or more distinct agents are thought to cause the disease.
- Ovine herpes virus 2 (OHV-2) and alcelaphine herpes virus 1 (AHV-1): OHV-2 is found in sheep and goats while AHV-1 is found in wildebeest.
- Alcelaphine herpes virus 2 (AHV-2) virus, which is similar to AHV-1, has been found in topi, hartebeest, and antelope. Infection of immunoregulatory granular lymphocytes with natural-killer (NK) activity is thought to occur.
- Polyclonal response through T-lymphocyte hyperplasia mediates tissue destruction.
- The disease appears to be an autoimmune phenomenon.

SYSTEMS AFFECTED

Gastrointestinal, CNS, respiratory, musculoskeletal, skin, generalized

GENETICS

N/A

INCIDENCE/PREVALENCE

- Very low morbidity, extremely high mortality in bovidae; high morbidity and extremely high mortality in cervidae
- There is some species variation within cervidae.

GEOGRAPHIC DISTRIBUTION

- Worldwide
- AHV-1 is found in Africa and in zoological and wildlife parks worldwide.
- OHV-2 is found in both wild and domestic sheep and goats worldwide.

Epidemiology

- Fomites are a common method of infection, especially postparturient.
- Nasal, ocular, and fecal contamination is common and the virus is cell associated.
- Serologic evidence supports the theory that deer and cattle may become subclinically infected and precipitate the disease following severe stress or concurrent infection.
- Transmission is primarily vertical; however, in wildebeest, transmission is vertical and horizontal.

SIGNALMENT

Species

- Bovine, caprine, ovine, bison, and wild ruminants
- Wildebeest, sheep, and goats act as asymptomatic carriers.
- Cattle usually experience the acute disease while deer generally exhibit the peracute form of the disease.

Breed Predispositions

- Pere David's deer, Bali cattle, wapiti deer, red deer, Sitka deer, and white-tailed deer are all affected.
- Fallow deer may be resistant.

Mean Age and Range

- MCF usually affects adults (greater than 1 year of age) in the wild and in intensive production systems.
- Juvenile animals also may be affected in zoological and wildlife parks.
- Wildebeest are generally infected by 6 months of age.

Predominant Sex

N/A

SIGNS

- After an incubation period of 3–10 weeks (can be up to 6 months); serous nasal and ocular discharge are common.
- Erosions of the buccal papillae as well as erosive lesions of the mucosa of the upper respiratory tract are evident.
- The acute form is generally considered the “head and eye” form.
- Deer generally exhibit the peracute disease.
- Disseminated intravascular coagulation is usually followed by sudden death in cervidae.
- In all species, ulceration of the coronet, interdigital skin, teats, vulva, and the perineum may occur.
- Behavioral changes, nystagmus, weakness, tremors, paralysis, lameness, vasculitis, thickened skin, profuse mucopurulent nasal and conjunctival discharge, dyspnea, severe dysentery and diarrhea, oral and upper respiratory system ulcers, hypopion, muzzle encrustation, sudden death, generalized lymphadenopathy, fever, epithelial bleeding, and ulcers have all been reported.
- Some animals will progress to CNS signs of hyperesthesia, muscle fasciculation, and aggressive behavior.

GENERAL COMMENTS

Commonly spread from sheep, goats, and wildebeest to cattle, bison, deer, and other wild ruminants through shared grazing contact.

HISTORICAL FINDINGS

Generally found in grazing ruminants associated with sheep, goats, and wildebeest.

PHYSICAL EXAMINATION FINDINGS

- Disseminated intravascular coagulopathy is generally evident in deer.
- Nystagmus, weakness, tremors, paralysis, lameness, vasculitis, thickened skin, profuse mucopurulent nasal and conjunctival discharge, dyspnea, severe dysentery and diarrhea, oral and upper respiratory system ulcers, hypopion, muzzle encrustation, sudden death, generalized lymphadenopathy, fever, epithelial bleeding, and ulcers.
- Mucosal, GI, and respiratory necrosis are associated with lymphoid infiltration.

CAUSES

Generalized infectious herpes viral disease associated with the grazing of sheep, goats, and wildebeest.

RISK FACTORS

- Transmitted horizontally and vertically in wildebeest, vertical transmission in other species
- Nasal, ocular, and fecal contamination is common and is thought to be spread by fomites.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Foot-and-mouth disease, rinderpest, BVD/MD, vesicular stomatitis, IBR, bluetongue, East Coast tick fever (*Theileria parva*) encephalitis, shipping fever, arsenic toxicity, C naphthalene toxicity, rabies, yersiniosis, tick-borne diseases, and any vesicular disease.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC initially will show a lymphocytosis with subsequent lymphopenia.
- When severe tissue damage is evident, neutrophilia occurs.

OTHER LABORATORY TESTS

Buffy coat analysis for virus isolation of AHV-1, AHV-2, and OHV-2.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Virus neutralization and a CIE titer of 1:4 or higher are the most diagnostic tests.
- Polymerase chain reaction (PCR) is highly specific and is the best test for the determination of carriers within a clinically normal population.
- Other tests include immunoperoxidase and indirect immunofluorescence.

GROSS AND HISTOPATHOLOGICAL FINDINGS

- Confirmation is generally through histopathological findings including disseminated vasculitis, multifocal degenerative epithelial lesions, and multisystemic lymphoid tissue infiltration.
- Vascular lesions can vary from mild to fibrinoid necrosis.
- The kidney will generally show gross white raised capsular foci.
- Most lymph nodes are hyperplastic with a prominent paracortex. Multifocal ecchymotic hemorrhage in the colonic serosa occurs.
- In deer, luminal hemorrhage occurs in the colon, ileum, and cecum.
- The carotid rete is the most demonstrative tissue for the evaluation of vascular lesions.
- Other affected organs include: adrenal gland, kidney, liver, heart, meninges, and CNS perivascular spaces.

TREATMENT

- Usually ineffective
- Surviving animals may become disease carriers.

CLIENT EDUCATION

- Physically separate susceptible species from sheep, goats, and wildebeest in known infective areas.
- Wildlife populations may also spread the disease, so ensuring separation is essential to prevent disease introduction.
- Recovery is rare and may lead to a persistent carrier state.

MEDICATIONS

DRUGS OF CHOICE

- Antibiotics can be used as an adjunctive therapy to control secondary infections.
- Fluids and parenteral nutrition may be helpful as supportive measures.

CONTRAINDICATIONS

Survivors may become carriers.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATE DRUGS

None

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- In areas infected with MCF, do not graze sheep, goats, and wildebeest with cattle or deer.

- Elimination of fomites, especially those contaminated with postparturient fluids, is essential. Insect control is also indicated.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Disease course is generally 3–7 days.
- Prognosis is grave.
- Very low morbidity, extremely high mortality in bovine; high morbidity and extremely high mortality in cervidae.
- There is some species variation in cervidae.

MISCELLANEOUS

PREVENTION

- Separate grazing species.
- No vaccine is currently available.

MAMMARY GLAND SURGERIES: TEAT AMPUTATION, MASTECTOMY

BASICS

DEFINITION

Mastectomy is defined as excision of the udder with or without removal of the regional lymph nodes. Teat amputation involves removal of a portion of or the whole teat to allow drainage of the udder in severe cases of mastitis. Supranumery teats are usually removed in dairy heifers at a young age as a management practice.

SYSTEMS AFFECTED

Mammary gland

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Potentially worldwide

SIGNALMENT

Species

Potentially, all lactating ruminant species

Breed Predilections

N/A

Mean Age and Range

Adult lactating animals

Predominant Sex

Female

History

- Adult female cattle, sheep, and goats. It appears that goats may require mastectomy more often than cattle.
- A recent retrospective study showed that 17 of 20 patients presented for mastectomy were goats. Many of the patients (70%) in this study were kept as pets and had never lactated, but had chronic bilateral or unilateral mammary gland enlargement.

SIGNS

With the exception of supranumery teat removal, teat amputation and mastectomy are regarded as salvage procedures when the conditions listed below cannot be resolved with medical therapy.

Teat Amputation

- Removal of supranumery teats
- Drainage of toxins and inflammatory products
 - Peracute coliform mastitis
 - Peracute/acute gangrenous mastitis
- Drainage of a chronic suppurative mastitis
- Prevent milking of a chronically infected mammary quarter

Mastectomy

- Chronic suppurative mastitis

- Mammary gland neoplasia
 - Adenoma
 - Adenocarcinoma
 - Lymphoma
 - Squamous cell carcinoma
- Mammary gland hyperplasia
- Peracute/acute gangrenous mastitis

DIAGNOSIS

- Chronic suppurative mastitis and acute gangrenous mastitis are usually diagnosed based on physical examination.
- Gangrenous mastitis is characterized by avascular necrosis of the udder tissue rendering the udder cool to the touch with blue or dark discoloration of the udder tissue. Crepitation may be present also with gas-forming organisms.
- Systemic clinical signs such as toxemia, acid/base and electrolyte imbalances, and dehydration may be seen in cases of peracute gangrenous mastitis.
- Chronic suppurative mastitis is characterized by purulent material draining from the teat orifice or abscessation of the udder.
- Ancillary testing such as milk culture and ultrasound of the udder may be included in the diagnostic workup.

TREATMENT

The decision of whether to perform a teat amputation or mastectomy will be based on the extent and severity of the mastitis, the degree of pain the animal is suffering, and the desired aesthetic outcome of surgery.

Teat Amputation: Surgical Procedure

- The teat is anesthetized using a 2% lidocaine ring block at the base of the teat.
- In cases of gangrenous mastitis, regional anesthesia is not necessary. The surgery can be performed in a cattle chute or milking parlor.
- The teat can be amputated at the base or midway between the base and tip. The tip of the teat is amputated with scissors by cutting horizontally across the base or middle of the teat. Hemostasis is not needed in cases of gangrenous mastitis.
- In cases of nongangrenous mastitis, hemostasis can be afforded by placing a plastic stent made from a 3ml disposable syringe in the bore of the teat followed by a circumferential ligature placed over the teat and exerting pressure on the stent. The plunger of the syringe is removed and discarded. Two small holes are made in the fingerholds of the syringe case using an 18-gauge needle and the syringe case is circumferentially cut approximately 1 inch (2.5 cm) distal to the fingerholds to remove the tip. The syringe case is inverted and inserted into the bore of the remaining portion of the teat. The holes in the fingerhold portion of the syringe case are used to suture the cases to the end of the teat. A circumferential suture is then placed around the teat applying pressure against the syringe case stent inside the bore of the teat thus facilitating hemostasis. The syringe case stent can be removed in 48–72 hours.

Mastectomy: Surgical Procedure

- There are two techniques for performing a mastectomy.
- Surgical mastectomy involves the removal of the whole or part of the udder.
- An alternative approach is to ligate the external pudendal artery and vein either through a laparotomy incision (the vessels are ligated blindly through a paralumbar fossa incision just proximal to the internal inguinal ring using a sterile cable tie) or inguinal incision.
- The latter methods cause ischemia and gradual sloughing of the mammary tissue on the ligated side. One or both sides can be ligated depending on the distribution of the udder lesions. While the latter methods are less aesthetically pleasing, they may be the best option in cases where the patient is toxemic or severely debilitated, because general anesthesia is not required.

- It may be advantageous to amputate the teats on the ligated side to facilitate drainage and sloughing of the mammary gland parenchyma following ligation.
- Surgical mastectomies are usually performed under general anesthesia with the animal in dorsal recumbency. The udder is clipped and aseptically prepared. An elliptical skin incision is made one-third of the way up the side of the udder from its base. The subcutaneous tissues are bluntly dissected starting laterally and moving cranial and caudal. In cattle, assistance retracting the excised tissue is usually needed. The external pudendal artery and vein, smaller branch of the ventral perineal artery, and subcutaneous abdominal vein are the major vessels that should be ligated.

Note: Investigators recommend ligating the external pudendal artery prior to the external pudendal vein to minimize blood loss. The lateral and medial suspensory apparatus is dissected and the mammary gland removed from the body wall. Small bleeders can be ligated or cauterized using electrocautery. The skin edges are apposed using tension-relieving sutures such as vertical mattress sutures. The skin is then closed with a continuous Ford-interlocking suture pattern using a monofilament nonabsorbable suture material.

- Penrose drains can be placed to reduce seroma formation. Drains should be removed 48 to 72 hours after surgery.
- Skin sutures are usually removed in 10 to 14 days.

MEDICATIONS

- Perioperative antibiotics are warranted given the size and location of the surgery site. Postoperative pain management can be achieved with nonsteroidal anti-inflammatory drugs (NSAIDs) such as flunixin meglumine.
- Epidural administration of opioids via an in-dwelling epidural catheter has been described in goats for postoperative pain management.
- If excessive hemorrhage occurs, blood transfusion may be indicated to normalize the animal's packed cell volume.
- Intravenous fluid therapy during and after surgery will help maintain circulating volume.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Goats are highly sensitive to the effects of lidocaine. Care needs to be implemented in its use.

FOLLOW-UP

POSSIBLE COMPLICATIONS

- The most common postoperative complication is hemorrhage.
- Hemorrhage is reported to be a greater problem in cattle than goats.
- If excessive tension is placed on the skin during closure, wound dehiscence may occur, and given the ventral location of the surgery site, wound infection is always a potential complication.
- Abscesses at the surgery site should be drained.

EXPECTED COURSE AND PROGNOSIS

In a recent study evaluating 20 cases of radical mastectomy in ruminants, 90% of cases were discharged from the hospital and of the animals for which follow-up data were available, the 1-year survival rate was 80%.

MAMMARY GLAND: ULTRASOUND

BASICS

OVERVIEW

- Many bovine practices are now equipped with ultrasound for reproductive cases, and there is a desire to use the machine for other applications.
- Ultrasound is an excellent tool for diagnostic imaging in large animals because it is portable, easy to use in the field, produces results at the time of the examination, and can be used for most soft tissue and some orthopedic problems.
- Ultrasounding is totally noninvasive. Palpation of a gland can detect only certain levels of disease. Ultrasound, in contrast, can give an “insider’s” perception of mammary health, a picture of the inside anatomy and pathology.
- Tumors, growths, scarring, stones, trauma, hematoma formation, and level of mastitic damage can all be evaluated using ultrasound.
- Though culturing or other diagnostic tools are still primary, ultrasounding gives yet another dimension to the hard-to-diagnose case. It will also allow a better estimate of treatment prognosis to aid in deciding whether to cull or treat a cow.
- Ultrasound examination of the mammary gland can confirm diagnoses of tissue destruction, scarring, nonpalpable stones, or tumors. However, it should be emphasized that in many cases ultrasounding is not indicated and other forms of diagnosis are superior. Particularly for cows of low value, an ultrasound diagnosis would not be indicated.
- A limitation of the use of ultrasound in bovine practice is the knowledge and comfort of the practitioner with the technology and the transducer available. Ultrasound transducers intended for rectal examination of the reproductive system are ideal for examination of the mammary gland and teats.

MISCELLANEOUS

Image Production

- Piezoelectric (pressure electric) crystals within the ultrasound transducer are deformed when a pulsed electrical current is

applied to them. The deformations produce a sound beam.

- Ultrasound frequencies range from 20 to 1 MHz. These frequencies are above that which can be detected by the human ear.
- A transducer can produce a single frequency or a range of frequencies. A higher frequency transducer produces an image with better resolution than a lower frequency transducer but the sound beam cannot penetrate as far.
- In selecting a transducer, the transducer with the highest frequency that can provide an adequate depth of penetration for the structure imaged is chosen.

Figure 1. Teat cistern.

- Once emitted from the transducer, the sound wave passes through the tissues and is eventually reflected back to the transducer. The transducer then acts as a receiver for the sound waves. The returning sound wave deforms the piezoelectric crystal producing an electrical signal. The electrical signal is converted into a series of dots on the monitor that form the image. The transducer acts as a receiver 99% of the time and as a transmitter 1% of the time.

Acoustic Impedance

- The number, strength, and time delay of sound waves returning from the tissues determine the ultrasound image.
- The location of the dot corresponds to the anatomic location of the imaged structure. The brightness of the dot is dependent on the difference in acoustic impedance (density and stiffness) of the tissue interfaces.
- Dense tissues such as bone or fibrous tissue produce high intensity (hyperechoic) images, which appear bright white.
- Low-density tissues such as fluid reflect very little sound wave and produce very low intensity (anechoic) images that appear black. See [Figures 2](#) and [3](#).
- Because air has very low acoustic impedance and tissue has relatively high acoustic impedance, the marked difference in acoustic impedance between air and soft tissue causes near complete reflection of the ultrasound beam from the air-filled tissue back to the transducer forming a bright hyperechoic image.
- Because air is a near perfect reflector of the ultrasound beam, no ultrasound waves can penetrate air and any tissues deep to the air cannot be imaged.

Transducer Selection and Patient Preparation

- Appropriate preparation of the site to be imaged will enhance the quality of the image. Clean off any loose hair and dirt. Wet the skin and hair with alcohol. An image can be obtained, in some cases, with just alcohol applied to the skin. Be sure that the probe will not be damaged by the use of alcohol.

- Ultrasound gel can be applied and rubbed in if there is no significant hair growth (i.e., teat) or if the hair has been clipped. Ultrasound gel acts as a coupling agent to prevent air from trapping between the transducer and skin.
- A 7.5 MHz transducer with a stand off pad is ideal for imaging the teats. A 5.0 MHz transducer provides an adequate image. A stand off pad can be purchased separately or can be made from a glove filled with ultrasound gel.
- Many transducers are sold with stand off pads that fit the head of the transducer and these are the easiest to use.
- The mammary gland should be scanned with a 5.0–3.5 MHz transducer to give adequate penetration. All structures should be scanned in cross section and longitudinal planes.

ANATOMY

- The gland is made up of alveoli and alveolar ducts. The alveoli are grouped into lobes and lobules. The collecting ducts open into the gland cistern or lactiferous sinus.
- The gland cistern is separated from the teat cistern by a fibrous annular ring.
- The wall of the teat cistern is composed of 5 layers: the outer stratified squamous epithelium, muscular layer with longitudinal and circular layers, connective tissue which contains the major blood supply, the submucosa, and the inner mucosa.
- The streak canal is closed by a sphincter of smooth muscle and elastic tissue. The junction of the mucosa of the teat cistern and the stratified squamous epithelium of the streak canal is the rosette of Furstenburg.

Ultrasonographic Appearance of the Normal Bovine Mammary Gland

- The glandular parenchyma appears as a mixed trabecular pattern of anechoic (black) areas compartmentalized by hyperechoic (white) partitions. The anechoic areas represent milk within the gland.

Figure 2. Ultrasonographic image of a teat in cross sectional (left) and longitudinal (right) planes. The lumen of the teat is anechoic (black). Note the blood vessels surrounding the lumen.

- Small ducts in the matrix of the gland lead into larger lactiferous ducts that lead into the gland cistern. Blood vessels are seen within the mammary gland, but are difficult to differentiate from lactiferous ducts.
- The pattern formed by the lactiferous ducts and glandular parenchyma may vary among individuals. Nonlactating mammary glands appear as dense hyperechoic tissue with few visible blood vessels and lactiferous ducts.
- Periparturient cows will exhibit subcutaneous edema of the udder several days before and after freshening.
- The gland cistern appears as a large anechoic area. The lining of the gland cistern appears hyperechoic. See [Figure 1](#).
- The annular ring can be detected as a hyperechoic band of tissue separating the gland cistern from the teat cistern.
- The teat cistern has an anechoic lumen surrounded by four layers visible on ultrasonographic examination.

- The outermost layer represents the skin air interface. The next inner layer is intermediate in echogenicity and represents the muscular layer.
- The two layers of longitudinal and circular muscle are difficult to differentiate on ultrasonography. The next inner layer is thin and hypoechoic to anechoic and represents the blood vessels known as the plexus venosus papillaris and the circulus venosus papillae. See [Figures 2 and 3](#).
- The innermost layer is hyperechoic and represents the submucosa and the mucosa. The muscular layer of the streak canal appears hyperechoic.

Mastitis

- Acute purulent mastitis is denoted by marked udder enlargement with engorgement of the lactiferous ducts with fluid.
- If the cell content of the milk is high, the fluid in the ducts may appear hypoechoic as a result of the increased particulate matter. The demarcation between fluid within the lactiferous ducts and the glandular parenchyma may be diminished due to edema within the gland.
- A discrete abscess may be visualized anywhere within the glandular parenchyma. A thick hyperechoic fibrous wall may be present surrounding the abscess. Occasionally, draining tracts can be followed to the abscess. Chronic diffuse mastitis results in an increase in fibrous tissue within the glandular parenchyma and a decrease in the lactiferous ducts, giving the gland an overall hyperechoic appearance.

Obstruction of the Teat

- Obstruction of the teat may occur as a congenital anomaly (membranous shelf) or secondary to a traumatic occurrence. The obstruction may occur anywhere from the teat orifice to the gland cistern.
- Ultrasound can be used to determine the location of the obstruction and its extent. If the teat is completely obstructed, the teat will be filled with milk proximal to the obstruction.
- Distal to the obstruction, the teat will appear collapsed and does not contain milk. To further delineate the thickness, structure, and extent of the obstruction, saline can be infused retrograde into the teat canal. This technique will outline the obstruction and provide information to obtain a treatment plan and prognosis. In the case of a membranous shelf, once filled with saline the teat cistern may have normal anatomy and the proximal obstruction can be defined.
- Obstruction of the teat cistern may also be due to complete fibrosis. No anechoic milk will be visualized within the teat cistern, and instead it will be replaced with hypo- to hyperechoic dense tissue. A teat cannula cannot be passed in this case.
- Trauma or chronic mastitis may form a web within the teat cistern causing teat obstruction. The teat cistern will be filled with anechoic milk but thin hypoechoic strands can be visualized emanating from the walls of the teat cistern. See [Figure 1](#).
- If the streak canal is obstructed, the teat cistern will be filled with anechoic milk. Fibrous clots may form in the lumen of the teat at the streak canal subsequent to trauma preventing milk flow.

Figure 3. Ultrasonographic image of a teat in longitudinal (left) and cross to sectional (right) planes. The lumen of the teat is anechoic (black). Note the obstruction at the streak canal (arrows).

Conclusions

- For the veterinary practitioner currently doing reproductive ultrasounding, it is very simple to make mammary diagnoses with their ultrasound unit.
- Most schools and colleges of veterinary medicine offer ultrasounding short courses if the practitioner needs more specialized training.
- In many cases, ultrasounding is invaluable in determining the prognosis of a case and whether it is economically feasible to treat further.
- Ultrasound diagnosis can provide a more definitive diagnosis on those cases where the veterinarian is just not 100% sure. By no means is it indicated in cows of poor value or lactation performance.

MANAGEMENT OF GUNSHOT WOUNDS

BASICS

OVERVIEW

- The pathology associated with gunshot wounds (GSWs) can vary dramatically with the part of the body affected and the ballistics (shape, weight, stability in flight, and velocity) associated with the bullet.
- Radiographs are indicated to assist in evaluating damage. GSWs may be minor and heal with little or no intervention, may require significant intervention in order to heal, or may be fatal with or without intervention.
- The degree of tissue injury depends on bullet weight, velocity, and the affected tissues' expansile ability.
- Contamination must always be suspected in gunshot injuries.

SIGNS

Variable with anatomical location of GSW

- GSWs may be inapparent during physical examination. Hemorrhage may or may not be visible.
- Hemodynamic instability
- Animal may be asymptomatic.
- Dyspnea
- Hemoptysis
- Epistaxis
- Abdominal tenderness
- Hematuria
- Rectal bleeding
- Infection
- Lameness
- Bony fracture
- Neurologic abnormality

CAUSES AND RISK FACTORS

Wound severity is a function of bullet size, shape, velocity, and tissue characteristics.

- Larger bullets cause more damage simply as a function of size.
- Bullets that fragment or deform (e.g., hollow points) create larger holes.
- Higher velocity bullets cause more damage via shock waves through tissue along bullet path.
- More expansile tissues (e.g., bladder, bowel) struck by a bullet might be perforated only, while less-expansile tissues (e.g., encapsulated organs, kidney) might be severely disrupted.
- Bone can fragment, producing bone shards that act as additional missiles.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Varies with affected system(s)

CBC/BIOCHEMISTRY/URINALYSIS

PCV may be helpful to determine the extent of blood loss and potential anemia/transfusion requirements of valuable animals.

OTHER LABORATORY TESTS

As needed

IMAGING

Radiographs recommended for all GSWs. Anatomical placement of projectile fragments is important in formulating the final prognosis.

DIAGNOSTIC PROCEDURES

History, physical examination (entrance/exit wounds), plus radiographs provide information about bullet path and location.

SEVERITY OF INJURY: DETERMINANT FACTORS

Action of bullet (physical properties):

1. Bullet velocity
 - Velocity is the most important single factor responsible for wound damage.
 - Impact velocity is the speed at which the bullet meets target tissue and is important to the wound characteristics.
 - When impact velocities are low (nonmilitary-civilian bullets) wounds have less tissue damage and do not exhibit explosive effect. High-velocity injuries can exhibit explosive effects.
 - High-impact velocity wounds reflect maximum tissue destruction with remote injury.
2. Bullet mass: Projectile kinetic energy varies directly with the mass of the bullet.
3. Ballistic shape: Bullets of different weights, shapes, and calibers do not pass through the air in similar patterns.
4. Bullet composition
 - Soft-point bullets will mushroom or expand upon impact.
 - Hollow-point bullets behave similar to soft-point jacketed bullets and will mushroom or expand upon impact.
5. Bullet yaw
 - Yaw results from inherent asymmetry of the bullet.
 - Yaw in part explains the aberrant bullet wounds seen in veterinary practice. Because animal tissues are much less dense than air, yaw is magnified.
6. Tissue reaction
 - Tissue retentiveness to the passing bullet contributes to its severity. Wound extent is determined by the projectile's energy upon impact and tissue energy transfer. An entering bullet's kinetic energy is transferred to the surrounding tissue when producing the wound.
 - Tissue elasticity, cohesiveness, and density properties tend to oppose the bullet's inertia and slow it down.
7. Tissue elasticity
 - Tissues of different densities variably alter the kinetic energy transfer.
 - Tissue absorption of the kinetic energy is the determinant of wound severity.

8. Tissue cohesiveness

- Penetrating wounds reflect sufficient tissue resistance to cause dissipation of the bullet's kinetic energy.
- Perforating wounds reflect the difference between energy at wound entry and that remaining at exit.

9. Tissue density

- Damage to bone may result from the bullet striking the long bone directly. Effects depend on the type of bone structure, the physical characteristics of the bullet, and the periosteal supporting structures.
- "Indirect fracture" occurs when a high-velocity bullet passes near a bone but does not strike it directly.

TREATMENT

- Varies with injury; proper management of bullet wounds requires a working knowledge of physical factors involved in the creation of such injuries and the way in which they interact.
- Antibiotics may be indicated as GSWs are contaminated with dirt, hair, and skin fragments.
- Conservative treatment is usually sufficient in limb wounds not associated with fractures. Wounds should be allowed to heal as open wounds, or repaired surgically after infection is controlled.
- Extremity wounds rarely require tissue debridement. Thorough but mild irrigation with physiologic saline to remove surface debris and contaminants is indicated. Excision of devitalized exposed skin, muscle, and fascia may be indicated. Foreign bodies such as shotgun wads must be removed, but probing of the wound is generally avoided if at all possible.
- Fracture treatment varies. Casts or splints may be sufficient in some cases. More serious fractures require bone plating or external fixation. Severe fractures may require amputation or even animal euthanasia.
- GSWs to the abdomen usually require exploratory laparotomy to thoroughly evaluate viscera and repair any damage found.
- Thoracic GSWs are frequently fatal (blood loss). Surgery and blood transfusions can be attempted but may be unsuccessful. Ruminants with thoracic GSWs that are stable, not in shock, and eupyptic generally should not undergo a thoracotomy.
- Euthanasia may be indicated for less-valuable animals.

MEDICATIONS

- Antibiotic choice varies with location of GSW.
- Analgesia as needed
- Fly repellent

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Lead poisoning symptoms may develop if one or more lead slugs are left in the body. Risk depends on body size, size of bullet, and location in body.
- Shotgun pellets decelerate rapidly, resulting in severe damage over a wide area. Devitalization secondary to vascular disruption occurs. Widespread skin and muscular avulsion is noted.
- Contamination must always be suspected in gunshot injuries.

MAST CELL TUMORS

BASICS

OVERVIEW

- Mast cell tumors are a round cell tumor (mesenchymal neoplasm) that may be benign or malignant.
- Tumors arise from cutaneous mast cells.
- Disease may be familial in cattle.
- Mast cell tumors account for approximately 3% of cutaneous and subcutaneous tumors of cattle.

SYSTEMS AFFECTED

GENETICS

May be congenital in calves

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Unknown

SIGNALMENT

Species

Mast cell tumors are uncommon in cattle and unreported in sheep or goats.

Breed Predilections

None reported

Mean Age and Range

- In cattle, tumors occur in animals 6 months to 7 years of age with no breed or sex predilection.
- May occur in calves

Predominant Sex

There does not appear to be a sexual predisposition.

SIGNS

- Lesions are commonly multiple.
- Size varies from 1 to 40 cm in diameter.
- Masses may be firm to fluctuant, dermal or subcutaneous, alopecic or ulcerated.
- Pruritus is common.
- Most commonly seen on the neck and trunk.
- Tumors are usually malignant and metastatic to local lymph nodes, kidney, and other organs.
- Congenital mast cell tumors in calves appear as small, raised skin nodules fixed to the overlying skin with no predilection for pigmented or nonpigmented skin. Lesions have a dry grey-crusts surface and are pruritic.

CAUSES

Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Mast cell tumors may mimic other tumors, abscesses, or granulomatous lesions.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Skin biopsy reveals diffuse to multi-nodular proliferations of mast cells. Tissue eosinophilia and focal areas of collagen necrosis may be seen.
- Biopsy specimens should be stained with toluidine blue to aid in diagnosis.
- Fine needle aspiration may be helpful in diagnosis; many large round mast cells with an eosinophilic infiltrate may be seen; not all mast cells stain with in-house fast Giemsa stains.

PATHOLOGIC FINDINGS

Tumors have been found in skin and dermis and also spleen, skeletal muscle, omentum, abomasums, tongue, uterus, and in a disseminated form.

**TREATMENT**

- Culling affected animals
- Wide surgical excision, if practical
- Radiation and cryosurgery are other treatment options.

**MEDICATIONS**

N/A

**FOLLOW-UP**

- Most tumors in cattle are malignant and metastatic.
- Removal of a cutaneous lesion may give rise to metastasis.

MASTITIS: COLIFORM

BASICS

OVERVIEW

- Acute coliform mastitis (ACM) is the most prevalent cause of mastitis in dairy herds that effectively control contagious mastitis pathogens and has become the most economically important form of mastitis.
- The source of infecting organisms (e.g., *E. coli*, *Klebsiella pneumoniae*, *Enterobacter aerogenes*, *Pasteurella multocida*, *Serratia marcescens*, etc.) is the environment.
- Infections occur primarily at the time of milking, between milking times, or during the dry period.
- Cow-to-cow transmission has minimal impact on disease transmission.
- The severity of disease caused by coliform mastitis can vary from mild to peracute. The majority (60%–80%) of coliform intramammary infections results in clinical disease, whereas only 15%–23% result in acute systemic signs
- The disparate nature of clinical coliform mastitis suggests that a wide range of pathologic events and physiologic responses can occur.
- Bacteremia develops in a substantial proportion of cows with ACM concurrently showing systemic signs.
- Severity classification of cows with ACM based on systemic disease signs is simple and rapid, and may prove useful in determining therapy and outcome of an ACM episode.
- Despite decades of research, no universally accepted control measures or approaches to treatment have been definitively established.

SIGNALMENT

Species

- Coliform mastitis can occur in any species of domestic or wild ruminant.
- Coliform mastitis is most prevalent and clinically relevant in dairy cattle.

Breed Predilection

N/A

Mean Age and Range

Primarily in lactating cows or cows in a dry period

Predominant Sex

Female

SIGNS

- Signs vary in severity from those involving only localized changes of the mammary gland and secretion, to those involving systemic signs of peracute septicemia and even death.
- Varying levels of heat, pain, swelling, and discoloration of the infected gland(s)
- The appearance of the secretion is variable and can range from that which appears to be grossly normal milk to secretions that more closely resemble serum. Additional manifestations can include the presence of flakes, clots, or even blood.
- General systemic signs can include fever, anorexia, rumen stasis, diarrhea, dehydration, and recumbency.
- Signs of septicemia can include petechiation or scleral injection, injected mucous membranes with toxic ring at gingival margins, prolonged capillary refill time, hypothermia, tachycardia, and altered mentation (depression, coma).

CAUSES AND RISK FACTORS

- Poor environmental hygiene
- Poor premilking hygiene (milking wet udders, use of communal towels to dry teats, etc.)
- Poor milking hygiene
- Failure to manage cows properly after milking

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute mastitis characterized by swelling and pain can be caused by numerous organisms in addition to coliforms. A partial list includes *S. agalactiae*, *S. aureus*, *S. dysgalactiae*, *S. uberis*, *Clostridium* spp., and *Bacillus* spp.
- Common conditions that may be manifest by signs of septicemia (in addition to coliform mastitis) include endometritis, peritonitis, and pneumonia.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC is variable and may include hemoconcentration, leukocytosis with neutrophilia, left shift, and leukopenia with neutropenia. Toxic changes to neutrophils may also be observed (Doehle bodies, toxic granulation, cytoplasmic vacuolization, and basophilia)
- Hyperfibrinogenemia
- Nonspecific changes in serum biochemical parameters may include hypocalcemia, hypokalemia, hypergammaglobulinemia, hyperglycemia, or hypoglycemia

OTHER LABORATORY TESTS

- Positive milk bacterial culture
- Positive blood bacterial culture. *Note:* in cows suffering severe ACM, positive blood cultures may isolate coliform organisms originating from the mammary gland or noncoliform organisms (e.g., *Bacillus* spp., *Pasteurella* spp.), which presumably originate from other organ systems (e.g., respiratory, gastrointestinal).

IMAGING

N/A

PATHOLOGIC FINDINGS

Gross and histologic postmortem findings either can be confined to local mammary changes associated with inflammation or may include signs of sepsis.

TREATMENT

- The majority of cases of ACM (>70%) are localized to the udder and exhibit only mild, if any, systemic signs of disease. Affected glands may be warm, firm, and swollen, often with an abnormal secretion. These cases are likely to respond to conservative therapy including frequent stripping of the affected gland, administration of anti-inflammatory agents, and oral fluid therapy (e.g., 16–24 liters of water containing 8 oz NaCl, 2 oz KCl, and 12 oz calcium propionate). Antimicrobial administration, either by systemic or intramammary routes, is unlikely to be warranted.
- Approximately 10%–15% of ACM-affected cows show severe systemic signs of disease. Signs may include significant dehydration, weakness, hypothermia, injected mucous membranes, marked gastrointestinal stasis, and diarrhea. Studies suggest these cows have a high likelihood of bacteremia. The use of systemic antimicrobials should be strongly considered.
- In severely affected cows exhibiting marked systemic signs, fluid therapy is an important consideration. Because oral administration is generally ineffective in cows with marked gastrointestinal stasis, intravenous administration is preferred. The type and volume of fluid for intravenous administration should be based on abnormalities in blood parameters and clinical interpretation. Most cows with ACM are hypoglycemic, hypocalcemic, hypokalemic, and alkalotic.
- Administration of hypertonic saline (7.5% NaCl, 5 ml/kg) is a reasonable alternative to administration of large volume intravenous fluids.

MEDICATIONS

DRUGS OF CHOICE

- Ceftiofur (1.1–2.2 mg/kg, IM, SC, IV, q24h)
- Flunixin meglumine (0.5–1.1 mg/kg, IV, q12h)

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered.

FOLLOW-UP

PATIENT MONITORING

- Monitor local changes to mammary gland and secretion.
- Physical examination
- CBC and biochemistry as clinically indicated

PREVENTION/AVOIDANCE

- Ensure proper environmental hygiene.
- Ensure proper premilking and milking hygiene.
- Provide fresh, palatable feeds and management conditions to help ensure cows remain standing for approximately 30 minutes after milking to allow formation of the keratin plug.

POSSIBLE COMPLICATIONS

Possibility of persistent (chronic) infections

EXPECTED COURSE AND PROGNOSIS

- The majority of cows diagnosed with ACM resolves within 5 days and returns to production.
- Cows with marked systemic signs and prolonged disease have a guarded to poor prognosis.
- Cows with marked systemic signs and concurrent bacteremia have a poor to grave prognosis.

Author: George Barrington

MASTITIS: FUNGAL

BASICS

OVERVIEW

- A variety of yeast and fungi has been found to cause bovine mastitis.
- Yeast and fungi compose part of the normal makeup of the soil and environmental microflora and, if given the opportunity, will colonize the udder resulting in intramammary infection.
- Fungal mastitis is a problem of machine-milked, high-producing dairy animals.
- Etiologic agents are ubiquitous environmental pathogens found worldwide in soil, organic matter, and water.
- Infections are usually sporadic, opportunistic, and limited to affected glands.
- Antimicrobials are suspected to depress host defense mechanisms and stimulate fungal growth.
- The most common etiological agents of fungal mastitis are *Cryptococcus neoformans* and *Candida albicans*.
- Most cases of fungal mastitis are mild and self-limiting; however, cases involving *Cryptococcus neoformans* can result in severe mastitis and permanent damage to the mammary gland.
- Yeast and fungi associated with bovine intramammary infections include:
 - *Candida* spp.
 - *Trichosporon beigelii*
 - *Trichosporon cutaneum*
 - *Rhodotorula* spp.
 - *Hansenula fabianii*
 - *Hansenula holsti*
 - *Hansenula polymorpha*
 - *Hansenula anomala*

PATHOPHYSIOLOGY

Etiologic agents include *Candida* spp. (77% of cases), *Cryptococcus* spp., and *Prototheca* spp. Rare genera include *Trichosporon*, *Aspergillus*, *Torulopsis*, *Saccharomyces*, *Rhodotorula*, *Pichia*, and *Hansenula*.

SYSTEMS AFFECTED

Infections are localized and rarely extend beyond the infected udder with limited spread to supramammary lymph nodes.

GENETICS

There is no evidence of genetic predisposition.

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Worldwide distribution in milking animals

SIGNALMENT

- Fungal mastitis is seen in ruminants but with low frequencies of occurrence. There is no mean age or age range associated with fungal mastitis, and there is no genetic basis associated with fungal mastitis.
- Infections often associated with unsanitary use of intramammary therapeutics.
- Poor milking technique and the buildup of contaminated environmental organic matter are often seen with this disease.
- Infections are more frequent in warm, wet weather.

Species

Potentially, all species used for milk production

Breed Predilections

N/A

Mean Age And Range

Lactating animals

Predominant Sex

Female

SIGNS

HISTORICAL FINDINGS

- Initial localized udder swelling, heat, and hardness are prominent.
- Sharp drop in milk yield with watery secretions containing clots and flakes.
- A 104°F–106°F spiking fever is often seen.
- Affected quarters are positive using the California Mastitis Test (CMT).
- Subclinical cases in herd mates are common.
- The likelihood of infection increases with parity and is most often seen in the second month of lactation.

PHYSICAL EXAMINATION FINDINGS

- Swelling of the affected gland
- Fever
- Reduction in milk production
- Lack of positive response to antibiotic therapy
- Abnormal mammary secretions
- Anorexia

CAUSES AND RISK FACTORS

- Yeast and fungi often gain entrance into the mammary gland through contaminated antibiotics and needles following antibiotic treatment for bacterial mastitis
- Injured or damaged regions of the mammary gland can provide the opportunity for the colonization of environmental yeast and fungi.
- Previous bacterial mastitis increases host susceptibility to fungal mastitis.
- Fungal mastitis is seen with milking machine malfunction and is associated with teat end damage.
- Inadequately sterilized milking units may act as fomites and result in epidemic infections.
- There is increased incidence and severity during warm, wet environmental conditions conducive to pathogen growth.

DIAGNOSIS

Diagnosis of fungal mastitis should be made based upon milk culture.

DIFFERENTIAL DIAGNOSIS

Confusion and misidentification between protothecal mastitis and fungal mastitis is common based on colony morphology. Prototheca is an algae, which produce colonies similar to *Cryptococcus neoformans*.

CBC/BIOCHEMISTRY/URINALYSIS

- Leukocytosis and neutrophilia were found in experimental infections.
- Elevated urine ketones are possible.

OTHER LABORATORY TESTS

Positive California Mastitis Test (CMT)

Microbiologic Laboratory Tests

- *Candida albicans*: fermentation of various sugars
- *Cryptococcus neoformans*: production of the enzyme urease and the assimilation of carbon substrates

Candida albicans

- *Germ tube test*: rapid and reliable. This test utilizes media in which blastospores of *C. albicans* are suspended in serum

and incubated at 37°C for 2–3 hours. The suspension must be examined between 2–3 hours for the presence of hyphal outgrowths.

- *Culture on cornmeal agar at 25°C*: Upon microscopic analysis, *C. albicans* will form chlamydospores, which are morphologically unique.

Cryptococcus neoformans

- *Direct culture*: *C. neoformans* is inhibited by cyclohexamide, but grows well on standard nonselective mycologic media. Identification is made on the presence of a capsule. Direct culture is the definitive test for identifying *C. neoformans*.
- *India ink preparation*: Upon microscopic examination, *C. neoformans* appears as a budding yeast or single cell with a clear halo surrounding it due to the presence of a polysaccharide capsule.

IMAGING

Direct microscopic examination of colonies or mammary secretions reveals yeast and fungi to be morphologically different from bacterial bacilli or cocci.

DIAGNOSTIC PROCEDURES

- The presence of hyphae or spores on direct microscopic examination of defatted milk smears renders a positive diagnosis.
- Predominant cultures on blood and/or Sabouraud's agar at room temperature or 37° F is suggestive of a positive diagnosis.
- Both yeast and *Prototheca* are larger than bacteria with yeast having buds and *Prototheca* being multinucleate.
- In the event of available histologic sections, Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) stains highlight morphology.
- Fluorescent antibody staining can be used with sections and cultures.

TREATMENT

- Antibiotic therapy should be discontinued upon recognizing fungal mastitis.
- Separate milking of infected animals, sterilization of milking units between animals, and CMT screening may reduce spread to herd mates.
- Frequent milking of affected teats increases the chances of a favorable prognosis.
- Hydrotherapy reduces localized inflammation.
- The cow should be culled from the herd.

MEDICATIONS

DRUGS OF CHOICE

- Antimycotic drugs have been used; however, there exists no substantial evidence in regards to the efficacy of antimycotic drug therapy. There are no USDA/FDA approved antimycotic treatments for fungal mastitis in milking animals. Prudent withdrawal times should be utilized.
- Fungal mastitis is usually self limiting; however, clinically recovered cows may shed yeast/fungi for up to 8 months.
- Fungal mastitis is refractory to most drug treatments and there is little evidence to support such therapy modifies the course of disease.
- Antipyretics (flunixin meglumine 1 mg/kg IM/IV q 24 h, aspirin 960 gr p.o. q 12 h) are useful to help reduce high fevers and inflammation. Follow directions and abide by meat and milk withdrawal periods.
- Intravenous sodium iodide (66 mg/kg body weight IV 1x / week) and oil-based intramammary iodine solutions have been reported to be of some value.
- While resistant to most antibiotics, experimental *Prototheca* infections have been treated with limited success using tertamisol hydrochloride or levamisole hydrochloride.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Monitoring temperature and milk secretions in addition to follow-up milk cultures are useful to gauge therapy effectiveness.

PREVENTION/AVOIDANCE

- During the administration of antibiotics, one should use a single-dose sterile treatment tube and use clean or sterile applicators during antibiotic treatments.
- Teat end hygiene is extremely important in preventing fungal contamination.
- Cull persistently infected animals.
- Use aseptic udder infusion techniques.
- Reduce environmental organic matter buildup.
- Practice aseptic milking hygiene.

POSSIBLE COMPLICATIONS

There are rare incidences of systemic mycosis.

EXPECTED COURSE AND PROGNOSIS

- Due to loss of production and persistent shedding, culling is a consideration.
- There is often irreversible tissue damage with near complete agalactia.
- Fungal mastitis does not respond well to antimicrobials.
- Tissue damage and infection are usually confined to the affected udder with rare systemic infections.

Authors: Gabriel J. Rensen and Michael Goedken

MASTITIS: MINOR BACTERIA

BASICS

DEFINITION

- Most cases of mastitis are caused by the major mastitis bacterial pathogens: *Staphylococcus aureus*, *Streptococcus agalactia*, *Mycoplasma* spp. (contagious mastitis pathogens), the coliform group, and *Streptococcus* spp. (environmental pathogens). Mastitis can be caused by many other bacterial and fungal pathogens as well.
- The National Mastitis Council considers the primary minor bacterial mastitis pathogens to be *Corynebacterium bovis*, *Arcanobacterium pyogenes* (formerly *Actinomyces*), and *Nocardia* spp.
- Other uncommon bacterial causes of mastitis to be considered here are coagulase-negative *Staphylococcus* spp., *Pseudomonas aeruginosa*, and *Serratia* spp.
- The classification of mastitis pathogens as common or uncommon causes of mastitis is relative due to the variation of environment, housing, nutrition, management, and diagnostic capability between regions.

PATHOPHYSIOLOGY

- Mastitis is inflammation of the mammary gland, usually as a result of bacterial infection. Pathogens gain entry into the gland either through ascending colonization of the streak canal (*Streptococcus* spp. and *Staphylococcus* spp.), by reverse-impaction during machine milking, or by contaminated intramammary treatments.
- Infection in the gland results in tissue damage either as the direct effect of infection in cells (e.g., *Staphylococcus* spp.) or from the immune response to the pathogen (e.g., gram-negative bacteria).
- Inflammatory responses range from mild to severe, depending on the bacteria, the infectious dose, and the host immune function. Within the gland, the response can range from coagulation of milk or serum proteins (gargut), damage or destruction of secretory tissue, blockage of ductules with necrotic debris and purulent material, endothelial leakage of serum and blood, fibrosis, abscess formation, granulomatous lesions, to gangrene.
- Diapedesis of white blood cells, primarily neutrophils, into the gland results from chemotactic signals by macrophages (the primary leukocyte in healthy glands).
- The leukocyte response, or somatic cell count (SCC), is a useful measure of inflammation in the mammary gland.
- Infections from coagulase-negative *Staphylococcus* and *Corynebacterium* usually result in mild to moderate inflammation, and the gland returns to normal after the infection is cleared.
- Infections from *Nocardia* spp., *Arcanobacterium pyogenes*, *Pseudomonas aeruginosa*, and *Serratia* spp. often cause serious tissue damage and can become chronic with abscesses or granuloma formation (*Nocardia*).

SYSTEMS AFFECTED

Mammary

GENETICS

N/A

INCIDENCE/PREVALENCE

Usually sporadic cases

GEOGRAPHIC DISTRIBUTION

Varies due to regional differences in housing, milking sanitation, intramammary treatments, teat dips, and use of pasture. “Summer mastitis” is seen with *Arcanobacter* infections of cows on pasture in England and Europe.

Epidemiology

- These organisms generally cause sporadic cases of mastitis. They are associated with poor teat hygiene premilking or postmilking, contaminated udder infusions, and teat end damage.
- *Pseudomonas* spp. are found in organic bedding and water and can contaminate water sources, milking equipment, and rubber parts in hoses and the milking system.

- Sources of *Nocardia* spp. are soil, water, and udder skin.
- The reservoir for *Corynebacterium bovis* is normal teat skin and infected udders. Cases of *Corynebacterium bovis* mastitis are often associated with inadequate teat dipping or sanitizing.
- Purulent discharge from wounds, teat injuries, and abscesses are the major sources for *Arcanobacterium pyogenes* infections.
- *Serratia* spp. are saprophytes found in soil and plants. Most of the mastitis-causing coagulase-negative *Staphylococcus* spp. are associated with teat skin.

SIGNALMENT

SIGNS

GENERAL COMMENTS

The primary clinical signs of mastitis are the hallmarks of inflammation: swelling, heat, pain, redness, and firmness. These early palpable signs precede visible changes to the milk.

HISTORICAL FINDINGS

- Postmilking dipping of teats with noniodine products is commonly associated with *Corynebacterium* and *Serratia* mastitis.
- Intramammary infusions with nonsterile products (i.e., other than commercial intramammary treatments).

PHYSICAL EXAMINATION FINDINGS

- Palpation of the mammary gland reveals swelling, heat, firmness, or pain. The milk secretion may have small flakes or large pieces of garget (coagulations of protein and purulent material) and actual pus (in the case of *Arcanobacter*), or may be watery from serum leakage into the gland (with *Serratia*).
- Abscesses or granulomas may be palpable (especially with *Nocardia*). Milk production may be decreased due to damage to secretory cells or fibrosis.
- Fever and tachycardia are usually present in acute infections but not in chronic mastitis.

CAUSES

- Contaminated intramammary infusions, bedding, or water used to sanitize teats or milking machines.
- Not employing postmilking teat dipping, improper teat dipping, or the use of ineffective teat dip preparations are associated with *Corynebacterium* and *Serratia* mastitis.
- Hyperkeratosis or damaged teat ends predispose for coagulase-negative *Staphylococcus* mastitis. Maintaining cows with *Arcanobacter* mastitis or draining abscesses in the herd may also lead to infection.

RISK FACTORS

- Using common medications for intramammary infusion (e.g., bottles of medication rather than individual treatment tubes); warm, moist organic bedding (*Pseudomonas* and *Serratia*); not employing postmilking teat dipping or use of ineffective products (*Corynebacterium*, *Serratia*, and coagulase-negative *Staphylococcus*)
- Maintaining animals with *Arcanobacter* or *Nocardia* abscesses or nodules in the herd.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Subclinical cases must be differentiated from mastitis caused by *Streptococcus agalactia*, *Corynebacterium bovis*, and minor udder pathogens.

- Clinical cases must be differentiated from mastitis caused by coliform bacteria, mycoplasma, and environmental streptococci.
- Gangrenous mastitis with bloody secretion must be differentiated from trauma to the gland.
- Acute mastitis, characterized by swelling, pain, and numerous organisms in addition to coliforms, can cause heat and increased firmness of the gland. A partial list includes *S. agalactiae*, *S. aureus*, *S. dysgalactiae*, *S. uberis*, *Clostridium* spp., and *Bacillus* spp.
- Common conditions that may be manifest by signs of septicemia (in addition to coliform mastitis) include endometritis, peritonitis, and pneumonia.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Indirect tests are available to detect subclinical mastitis.
- Somatic cell count (SCC) or California Mastitis Test (CMT) of milk from quarter or composite samples will indicate if excessive inflammation is present. SCC over 200,000 or CMT score of 2 or 3 indicates mastitis is present. SCC is often reported as the log-linear score, in which case a score over 4 is considered mastitis.
- Other indirect tests include the NAGase test (N-acetyl- β -D-glucosamidase) and electrical conductivity. NAGase increases with somatic cell count and can be used instead of SCC.
- Sodium and chloride in the milk secretion tends to increase with mastitis, thus increasing the electrical conductivity of the secretion. Normal variation of ions in milk makes conductivity less sensitive in detecting subclinical mastitis than other methods.
- Microbiological testing of an aseptically collected milk sample from the affected gland is the only way to determine the causative organism.
- The National Mastitis Council *Laboratory Handbook on Bovine Mastitis* describes acceptable laboratory techniques for differentiating mastitis pathogens.

IMAGING

Ultrasounding the teat canal may be a helpful adjunct to diagnosis.

OTHER DIAGNOSTIC PROCEDURES

- Finding inflammation in the mammary gland during physical exam or seeing abnormal milk secretion (flakes, gargut, discoloration, pus, watery milk, or serum) are usual ways of initially diagnosing mammary gland infection.
- The specific bacteria causing mastitis can be determined only by aseptically collecting a milk sample from the affected quarter and performing appropriate microbiological tests.

GROSS AND HISTOPATHOLOGIC FINDINGS

Gross pathology will show inflamed tissue in the affected glands, ranging from discoloration to fibrosis to severe tissue damage.

TREATMENT

- *Corynebacterium* and coagulase-negative *Staphylococcus* spp. may self-cure but treatment with commercial intramammary antibiotics is advised.
- *Serratia* spp. and *Pseudomonas* mastitis usually respond poorly to antibiotic treatment.
- *Nocardia* and *Arcanobacter* mastitis are often refractory to treatment due to abscessation and purulent material.

Inpatient Versus Outpatient

N/A

CLIENT EDUCATION

Primary concerns are milking hygiene and cattle housing sanitation. Insist on proper postmilking teat dipping with an effective product. Never use medications from common bottles for intramammary infusions; always use separate commercial mastitis tubes.

MEDICATIONS

DRUGS OF CHOICE

Commercial mastitis preparations are advised for cases of *Corynebacterium* and coagulase-negative mastitis.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Author: James P. Reynolds

MASTITIS: MYCOPLASMAL

BASICS

DEFINITION

- Mycoplasmal mastitis is an inflammation of the mammary gland in association with infection by various *Mycoplasma* spp.
- It is a contagious form of mastitis, capable of causing outbreaks of clinical mastitis not responsive to treatment.
- Mycoplasmal mastitis is spread primarily cow to cow at milking.

OVERVIEW

- Mycoplasmas are contagious mastitis pathogens that can cause clinical, subclinical, and chronic intramammary infections (IMI).
- Although *Mycoplasma bovis* is the most important agent of outbreaks of mycoplasmal mastitis in dairy herds, *M. alkalescens*, *M. arginini*, *M. bovis genitalium*, *M. bovirhinis*, *M. californicum*, and *M. canadense* have also been isolated from mastitic milk in the United States.
- Mastitis produced by different *Mycoplasma* is similar but may vary in severity, is unresponsive to antibiotic therapy, and has the potential to cause severe losses in a herd's milk production.

PATHOPHYSIOLOGY

- Mycoplasmas are extremely small self-replicating organisms, with a very small amount of genetic material. The organisms lack a cell wall and, therefore, are not affected by antimicrobials, which act via an effect on the cell wall.
- Because of the organism's limitations, mycoplasmas live in close association with host cells. They tend to produce chronic infections.
- Important in the pathogenesis of mycoplasmal mastitis are the variable surface lipoproteins (Vsps) from the plasma membrane, also referred to as membrane surface proteins. It has been proposed that the Vsps may be involved in attachment to host epithelium, stimulation of the host immune response, and/or in protecting mycoplasmas from destruction by host defenses.
- Changes in Vsps and membrane proteins are important in the pathophysiology of mycoplasmal mastitis.
- Most damage in mycoplasmal mastitis is reportedly from the cow's immune response. However, metabolic by-products and toxins from mycoplasmas also contribute to tissue damage and reduction of milk production.
- Inflammatory cells accumulate in alveoli and ducts, and ductular cells divide and reduce duct lumen space. Cells in alveoli regress and fluid accumulates, with an attendant drop in milk production. In the most severe reactions, fibrous tissue replaces alveoli and ducts, being a permanent loss. In less severe reactions, the cow may regain production, but at a lower level.
- Multiple abscesses, variable in size, can be found in cases of mastitis caused by *M. bovis*. These abscesses may contain *M. bovis*, which can cause long-term shedding.

SYSTEMS AFFECTED

Mammary gland—the primary effect is mastitis, with associated inflammatory changes, increased SCC, abnormal secretions, and loss of milk production.

GENETICS

N/A

INCIDENCE/PREVALENCE

- The disease is reportedly found worldwide.
- The incidence/prevalence is variable among geographic regions and among herds in a region. There is a wide variation in quarter infection rates in herds. The condition is endemic in some areas.
- Based upon culture of a single bulk tank sample, 7.9% of dairies tested positive in a 2002 USDA survey. There was a

higher isolation rate (9.4%) in the West, as compared to the Midwest (2.2%), Northeast (2.8%), or Southeast (6.6%). Larger herds (>500 cows) had higher isolation rates (21.9%) than smaller herds.

SIGNALMENT

Bovine

Breed Predilection

None

Mean Age and Range

All ages of cows are susceptible and at any time during lactation and in the dry period. Cows in early lactation may show more pronounced changes.

Predominant Sex

Female

SIGNS

In lactating cows, signs can include the following:

- Can be cause of subclinical, clinical, and/or chronic mastitis
- Sudden onset swelling of udder
- Swollen, meaty quarters that don't soften normally during milking
- Decrease in milk production, sometimes dramatic
- Lack of systemic signs; maintenance of appetite and thirst (Experimentally infected cows show fever briefly 3–4 days after inoculation; spontaneous cases may also show brief fever, which is usually not detected.)
- Lack of response to therapy
- Agalactia/atrophy
- Increased SCC
- Purulent mastitis (sometimes severe) without systemic signs
- Supramammary lymph nodes may be enlarged.
- Acute arthritis with swollen joints and lameness
- Multiple quarter involvement; sometimes all quarters are involved.
- Variable changes in secretions:
 - Cows can, in some instances, be infected and show no changes in the appearance of secretions.
 - In other cases, secretions in early infections may be normal at first appearance, but with settling may form a sediment and a whey-looking supernatant. With other cases, the secretion may be watery with clots, serous, or thick.
 - The secretion may also appear tan to brown with flakes, or as a colostrum-like secretion, or purulent.
 - It is reported that the majority of milk samples positive for mycoplasmas have normal secretions.
 - A given quarter can be infected with multiple organisms, leading to variable signs.

HISTORICAL FINDINGS

Usually mastitis in multiple quarters without systemic signs; nonresponsive to therapy

PHYSICAL EXAMINATION FINDINGS

See above under Signs.

CAUSES

- Infection of the mammary gland with various species of mycoplasma. As few as 70 colony-forming units of *M. bovis* introduced via the teat canal can initiate mastitis.
- Characteristics of mastitis produced by various *Mycoplasma* spp. are generally similar, but may vary in degree.
- At least 11 species have been reported in milk in natural or experimental cases:
 1. *Mycoplasma bovis* is the most significant and, usually, the most common mycoplasmal agent of bovine mastitis. The NAHMS Dairy Survey 2002 found that *M. bovis* was isolated from 86% of operations that were positive for a mycoplasma.
 2. *M. alkalescens*, *M. arginini*, *M. bovis genitalium*, *M. bovis rhinis*, *M. californicum*, *M. canadense*, *M. dispar*, *M. spp.* Group 7, *M. F-38*, *M. capricolum*
 3. *Acholeplasma laidlawii* (generally considered nonpathogen), *A. axanthum*

Sources of Infection

- The most common source of IMI due to mycoplasmas is the udder of infected cows.
- The purchase of replacement heifers and cows is frequently the origin of mycoplasmal mastitis outbreaks in previously *Mycoplasma*-free herds.
- *Mycoplasma* spp. are commonly spread from infected cows to uninfected cows at milking via milking machines or milkers' hands.
- Mycoplasmal udder infections usually persist through the current lactation and into subsequent lactations.
- Cattle of all ages and at any stage of lactation as well as nonlactating cattle are susceptible to mycoplasmal infections.
- Mycoplasmas present in the respiratory and urogenital tracts of healthy cattle may possibly serve as a source of IMI.
- Herds with and without mycoplasmal mastitis may contain both young and mature asymptomatic carriers.
- Mycoplasmas are sensitive to heat, sunlight, and environmental pressures but can survive on teat skin and in cool, moist, and protein-rich environments for variable periods.
- Contaminated intramammary treatments or improper teat sanitation during or at the end of lactation and airborne transmission in poorly ventilated facilities are also means of new infections.

RISK FACTORS

- Risk factors vary with the particular herd and situation. In California, large herd size is recognized as a risk factor, but this has not been found in New York.
- Herds purchasing outside replacements and expansion herds are at increased risk of infection.
- Four groups of animals at high risk of getting infection or spreading it: (1) first calf heifers, (2) new additions to herds, (3) fresh cows, (4) sick cows leaving/entering treatment herd.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of chronic mastitis unresponsive to therapy
- *Acholeplasma laidlawii*, a nonpathogenic saprophytic contaminant resembling mycoplasmas, may be occasionally found in milk arising from the environment during wet weather or from teat skin.
- Bacterial L-forms, which can be induced by antibiotics used in dairy cows for the treatment of mastitis, also have a fried-egg appearance but have a coarser structure.

CBC/BIOCHEMISTRY/URINALYSIS

- One text reports that a marked leukopenia may be seen early in the disease course.
- Leukocyte numbers markedly increase in the milk. Often, secretions contain over 20 million cells/ml.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A.

DIAGNOSTIC PROCEDURES

- Diagnosis is most commonly made using microbiological procedures on aseptically collected quarter or composite milk samples or on culture of bulk tank milk samples.
- Isolation is most commonly attempted using direct inoculation onto plates containing modified Hayflick medium. Plates are incubated in moist 10% CO₂ at 35–37°C. They are observed for growth with a microscope at intervals after plating. Plates are not called negative for growth until incubated for 7–10 days. Intermittent shedding by carriers not demonstrating symptoms may make diagnosis difficult.
- Results are most favorable when fresh samples of milk kept on ice are plated right after collection. It is also acceptable to refrigerate samples for up to 2–3 days and to freeze samples.
- A variety of methods is used to detect the organisms or their antigens. A variety of serologic/immunologic tests is used. Polymerase chain reaction (PCR) assays are being developed for mycoplasmal diagnostics.
- Serologic methods, most commonly immunofluorescence, are used for species identification. DNA probes have also been

used to identify mycoplasmas to species level.

Other Diagnostic Tests

- Diagnosis of infection at the herd level is usually made by isolation of mycoplasmas from either bulk tank milk (BTM) or samples from cows with clinical and subclinical IMI.
- In large herds, culture of partial BTM samples collected after milking each production group or the use of string sampling or milk-line sampling may be used as a method to locate groups in which cows infected with mycoplasmas exist.
- It is critical that no cows be moved to a different pen until culture results are back from the laboratory.
- Bulk tank milk samples are valuable for screening and surveillance on a herd basis.
- Large numbers of mycoplasmas are usually present in milk samples from cows with clinical disease.
- False-negative diagnosis may occur in BTM because dilution could mask several low-level *Mycoplasma* shedders in the herd.
- Culture of milk samples may be less effective in detecting convalescent carrier cattle that may only shed mycoplasmas intermittently.
- A low level of *Mycoplasma* excretion in milk from latent infections or carrier cattle may also impair diagnosis of IMI.
- Milk samples for culture of *Mycoplasma* must be collected aseptically, kept cool during transportation to the diagnostic laboratory or storage, and plated promptly to maximize isolation.
- If delay of more than 1 day is anticipated from collection to culturing, milk samples should be frozen at -30°C or below to assure viability, or stored in liquid nitrogen.
- Mycoplasmas that cause IMI in cows need a special agar medium for growth in the laboratory, usually modified Hayflick, and plates should be incubated for up to 7–10 days at 35°C to 37°C in a moist 10% carbon dioxide incubator.
- Mycoplasmal colonies have a fried-egg appearance on solid medium because colonies have a dense, central core that grows down into the medium.
- The polymerase chain reaction (PCR) is a highly sensitive, specific, and rapid procedure for laboratory diagnosis, but several practical problems must be solved before full-scale adoption of this diagnostic procedure.
- Mycoplasmal shedding in milk will not impact the standard plate count (SPC), preliminary incubation count (PIC), or the laboratory pasteurized count (LPC).

PATHOLOGIC FINDINGS

- The pathology in mycoplasmal mastitis is most commonly described as a purulent interstitial mastitis. Widespread, scattered fibrosis and granulomatous changes with pus are found in the gland. Teat sinus and ductular linings are seen as thick and rough.
- Evidence of granulomatous mastitis is seen on histopathology.

TREATMENT

APPROPRIATE HEALTH CARE

- In general, the opinion is that there is no known effective treatment.
- Short-term improvement has been reported with parenteral oxytetracycline treatment. Intramammary tylosin and tetracycline have been reported to cure infections.

NURSING CARE

No specific recommendations; provide supportive care similar to that for other cases of mastitis.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

- Even though a dairy is not currently experiencing mycoplasmal mastitis, the organisms are very likely present within the herd and the possibility of a mastitis outbreak exists.
- Mycoplasmal organisms capable of causing mastitis may be present in young and mature animals without disease. Young

animals may acquire mycoplasmal organisms via contact with the urogenital tract and nasal discharges of mothers or in milk.

- At calving, heifers infected earlier in life may produce mycoplasmas in nasal secretions and in the vagina. Infected cows may be brought into a herd.
- The organism can persist long term in animals without showing serious clinical mastitis. Exposure may also occur when animals are brought to livestock shows.
- Transmission has also been proposed to occur between farms, transported by individuals such as veterinarians, milkers, owners, or livestock dealers.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

It is generally held that there is no known effective treatment (see Appropriate Health Care above).

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Mycoplasmas survive for variable, but sometimes extensive, periods of time on teat skin and multiple environmental sites.
- The ability of mycoplasmas to survive is influenced by the site, the ambient temperature, and the presence of light and moisture. In manure at 23–28°C, survival was 236 days in the dark and 145 days in the light, but only 108 days at 37°C. In drinking water, mycoplasmas survived 23 days at 23–28°C in the dark and 1 day in the light, but less than a day at 37°C. *M. bovis* survived at 4°C in sponges for 57 days and 54 days in milk.

PREVENTION/CONTROL

Prevention

Mycoplasmal mastitis may be prevented by the following steps intended to help to keep mycoplasmal mastitis out of a herd:

- Isolate or quarantine new additions
- Culture new additions using procedures described under Diagnostic Procedures above.
- Investigate herd of origin of any animals brought into the herd
- If milk from animals was not cultured at purchase, milks from these animals should be cultured as they calve
- Culture all clinical cases of mastitis and all fresh cows for mycoplasma and screen bulk tank samples for mycoplasmas.
- Workers should practice strict hygienic milking and intramammary treatment procedures.
- Avoid any use of bulk intramammary treatment.
- Practice effective biosecurity.

Control

- There are widely divergent opinions and practices with respect to management and control of mycoplasmal mastitis.
- The epidemiology of the disease is incompletely understood and new knowledge is constantly being acquired. Consult current sources of information and current experts when dealing with cases of mycoplasmal mastitis.
- Provisional identification of a mycoplasmal species from milk sample(s) from a herd should be followed by confirmation of the isolate as a pathogenic mycoplasmal species.
- Depending upon factors such as the experience and capability of the laboratory, this procedure may involve sending the organism to a reference laboratory for species typing. It can take several days to complete this procedure.
- Some factors to consider in the management of the herd in the interim:
 1. Advise the owner that an organism appearing to be a mycoplasma has been isolated from a sample or samples of milk from the herd and is being tested for confirmation. Advise the owner of the potential seriousness of the disease.
 2. Educate the owner about the disease in general, emphasizing epidemiological aspects, focusing on specifics of treatment, control, and prevention. Advise the owner of the specific groups at particular risk.
 3. Advise the owner not to move cows among groups in the herd until results of testing are available.
 4. Assure that intramammary treatment from a bulk source is not being used and that all treatment of mastitis by the intramammary route is done with the strictest hygiene.
 5. Emphasize application of all measures focused on hygiene in milking and at calving.
- Mode of handling will vary from dairy to dairy based on the owner's attitude, facilities, number of infected animals, level of milk production, and reproductive status of carrier animals, and the availability of replacements.
- Control of the disease, when present, is often based upon finding infected cows via culture of all lactating and dry cows in the herd, as well as all clinical cases and all animals at calving.
- An alternative approach is to use culture of bulk tank milk or string/group samples to identify infected groups. Alternative strategies have been proposed to deal with mycoplasmal mastitis.

Types of Approaches to Consider

If mycoplasma is diagnosed in a herd, there are two general types of approaches to be considered:

1. Attempt to eliminate the organism from the herd:
 - Culture all cows, identify infected animals and cull those infected, (particularly if the number is limited)
 - Culture milks from cows at dry-off, freshening and from all clinical cases
 - Culture bulk tank milks at appropriate intervals to monitor new infections
 - Don't move cows between production groups until all cows cultured and classified as infected or not (realizing limitations of a single culture)
2. Limit spread and live animals with the disease:
 - Separate mycoplasma-positive cows, and milk them last or with separate equipment.
 - Cull cows with clinical mastitis or decreased production.
 - Strict milking time hygiene—passed by fomites, such as the milking machine, hands, wash cloths.
 - Culture milk for mycoplasmas—fresh cows, clinical cases, dry cows, bulk tanks.
 - Either don't feed mastitic milk to calves or feed only after pasteurization following current recommendations.
 - Back flushing—variable effects, some question of cost-effectiveness
 - Strict teat dipping, iodine products preferred by some
3. The following apply in all situations:
 - Practice strict milking time hygiene (passed by fomites, such as milking machines, hands, wash cloths).
 - Practice thorough teat dipping, iodine products preferred by some for mycoplasmal herds.
 - Assure milking machine is functioning to standards.
 - Use single-service towels for drying cows.
 - Use gloves, disinfect between cows.
 - Use single-service intramammary treatments.
 - Vaccines to date are generally considered of questionable effectiveness; trials are under way evaluating some products. It is suggested that the practitioner ask manufacturer for evidence of effectiveness of the vaccine prior to consideration of use.

- Either don't feed mastitic milk to calves or feed only after pasteurizing using current recommendations.
- Monitor appropriate milk samples for mycoplasmas: bulk tanks, clinical cases, fresh cows, introduced cows, etc.

4. Further recommendations

- Infected cows should be identified by culture of composite or quarter milk samples from all milking and dry cows in the herd.
- Cows diagnosed with *Mycoplasma* IMI should be considered positive for life.
- Any management plan for mycoplasmal mastitis following a whole herd culture should include segregation and/or removal of infected animals from the herd.
- Removal of infected animals from the herd to slaughter is advised when prevalence of infection is low and segregation is not practical.
- Segregation can be used when prevalence of mycoplasmal mastitis is high in the herd and culling is not economically feasible, but needs adequate facilities and management, and monitoring of the herd by repeated culturing of animals and BTM.
- Segregated cows should be milked last or with a separate milking unit from those used on uninfected cows to minimize the risk of infection for other cows.
- Mycoplasmal mastitis can be controlled with testing and discipline in the management of the disease, including the understanding by dairy personnel of the seriousness of the disease and their role to minimize its spread.
- Culture all replacements entering the herd, cows and heifers at calving, all mammary quarters with signs of clinical mastitis, cows with persistent high somatic cell counts and BTM frequently.
- Use strict milking hygiene, including the wearing of nitrile or latex gloves by milkers, foremilk, pre- and postmilking teat disinfection with a high-quality product that covers almost the entire teat, and single use of paper or cloth towels.
- Clearly identify each infected animal by using a double identification system like leg bands and ear tags.
- Cows with blind quarters harboring mycoplasmas can spread the disease in the herd with uninformed or careless milkers and make isolation inconsistent from BTM.
- Avoid stresses, like the pressure effects of transportation, overcrowding, calving, and milking, particularly for the first calvers because they can be important contributors to the disease.
- A dairy's hospital pen or treatment group is usually a key area for spreading the disease when treatments are administered without following aseptic procedures, including disinfection of gloved hands between treated cows.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- The effect of mycoplasmas on a particular herd is highly variable, depending upon bacterial, host, and management factors. Outcome is also variable, depending upon cow and bacterial factors.
- Some cows may become agalactic and/or develop complications (e.g., arthritis, etc.), may continue in production and produce normal-appearing milk with a high SCC, may be chronically infected with abnormal milk, or may return to production, go through a dry period, and calve again, still shedding mycoplasmas.
- Spontaneous cures may occur, usually after going through a dry period. A "spontaneous and complete recovery" from *M. bovis* has been reported.
- It is generally recommended that cows diagnosed as positively infected be considered positive for life.

MISCELLANEOUS

ASSOCIATED CONDITIONS

See Systems Affected above.

AGE-RELATED FACTORS

Cows susceptible at all ages

ZOONOTIC POTENTIAL

Very limited reports of human infections.

M. bovis reportedly isolated from two human cases with respiratory disease.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

M. bovis is highly adapted to the bovine species, with uncommon isolations reported from buffaloes and small ruminants.

BIOSECURITY

Since many infections are introduced into a herd by bringing replacements on a farm, quarantine of newly introduced animals and milk culturing, as well as careful investigation into the status of the herd of origin of any introduced animals, will help limit this possibility.

PRODUCTION MANAGEMENT

- Many, if not most, new mycoplasmal mastitis infections are introduced when animals are brought into a herd.
- Mastitis has been proposed to occur following hematogenous spread of a respiratory infection to the mammary gland.
- Transmission is primarily at milking by fomites such as milking machines, milkers' hands.
- The organism can also be spread when bulk mastitis treatments are administered from a contaminated vial or via a contaminated syringe or with unsanitary treatment practices.

MASTITIS: NO GROWTH

BASICS

DEFINITION

Mastitis caused by noninfectious reasons or no growth on culture.

PATHOPHYSIOLOGY

Because most cases of no growth clinical mastitis are thought to be caused by bacteria, the pathophysiology would be the same as infectious mastitis.

SYSTEMS AFFECTED

Mammary gland

GENETICS

N/A

INCIDENCE/PREVALENCE

Noninfectious causes of clinical mastitis are relatively rare. Ten percent to 40% of clinical cases of mastitis yield no growth on culture.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Typically seen in lactating ruminants but also can occur during the dry period and in prepartum heifers

SIGNS

- Signs are almost always restricted to changes in the milk, such as clots or flakes.
- Systemic signs in the animal are quite rare in true no growth cases of clinical mastitis.

CAUSES

- Trauma such as bruises or contusions may result in noninfectious clinical mastitis.
- Trauma from environmental hazards that result in perforations into the gland or teat can be expected to eventually result in bacterial mastitis. However, the vast majority of cases of clinical mastitis that result in no growth is largely thought to be due to bacteria.
- Antigen-based studies indicate that gram-negative bacteria may be a more likely cause than gram-positive bacteria; yet there is good evidence for both occurring. There are several other reasons for lack of growth on culture.
- Other reasons: the offending organism has already been eliminated by the cow's immune system, antibiotic inhibition, phagocytized bacteria (within white blood cells but alive), L-forms of *Staphylococcus aureus*, inappropriate culture medium (e.g., *Mycoplasma* does not grow on blood agar), numbers of bacteria are too low to be detected by the quantity of milk cultured, freezer kill (*Escherichia coli* tends to be more susceptible than gram-positive organisms), and in some cases an inaccurate assessment of the significance of culture growth reported as no growth.

RISK FACTORS

Risk factors would be the same as other forms of mastitis. The major risk factor for trauma with subsequent clinical mastitis is a pendulous udder.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bacteria cleared by immune system

- Bacteria alive but phagocytized
- Bacteria numbers too low to detect by standard culture methods
- L-forms (*S. aureus*)
- Viral (sheep and goats)
- Organism does not grow on standard media (*Mycoplasma*, anaerobes)
- Trauma (noninfectious)
- Antibiotic or milk product inhibition
- Storage kill
- Inaccurate interpretation of culture result

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- No additional tests need to be performed routinely on the initial or sporadic case of clinical mastitis that yields no growth, especially in herds with no history of *Mycoplasma* mastitis. However, specialized media should be utilized when multiple cases of clinical mastitis in a single cow or in a group of cows yield no growth.
- Specifically, samples should be cultured for *Mycoplasma*.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

As above

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

- No specific therapy is warranted for cows with clinical mastitis with no growth as the culture result.
- Cases are almost always mild with clots or flakes in the milk with no swelling of the affected quarter(s) and no systemic effects on the cow.

NURSING CARE

ACTIVITY

Normal

DIET

Normal

CLIENT EDUCATION

Clients trained to obtain culture results prior to treatment should be able to reduce drug usage, thereby decreasing the chance of antibiotic residues in bulk tank milk.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- It would be difficult to justify the use of antimicrobial drugs for cases of no growth clinical mastitis.
- If treatment must be given, oxytocin at 1–2 ml to aid milk-out of the affected quarter should do no harm. There are no studies that document the beneficial effects of oxytocin in the treatment of clinical mastitis.

- Intramammary antibiotic therapy (by label) of clinical mastitis will usually occur prior to knowledge of culture results. This treatment does not appear to affect time to cure.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Long-term use of oxytocin may result in cows becoming dependent on oxytocin for milk letdown.

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUGS

None

FOLLOW-UP

PATIENT MONITORING

- Any cow with clinical mastitis, especially those that are not being treated, should be evaluated on a daily basis to assess disease progression. Cows that have truly cleared the infection but are still showing clinical signs (abnormal milk) will show improvement.
- Any cow with repeated episodes of no growth clinical mastitis should be cultured for *Mycoplasma*. Cultures of cows with severe clinical mastitis that are reported as no growth should be held in suspicion.
- In a Virginia Tech study in which cows with clinical mastitis were cultured daily for 8 days, all cases of no growth were mild and did not progress to a more severe condition, whereas all cases of severe clinical mastitis yielded ample growth.

PREVENTION/AVOIDANCE

Standard mastitis control measures should always be utilized.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- In a Virginia Tech study, cows with clinical mastitis were cultured and evaluated once a day for 8 days, then once a week for 1 month, then monthly until completely cured.
- The geometric mean time to clinical cure of 21 no growth cases of clinical mastitis that were not treated with anything was 4.8 days (range 1–26 days) and time until the quarter somatic cell count (SCC) was < 500,000 cells/ml was 10.5 days (range 1–66 days).
- In comparison, the geometric mean time to clinical cure of 19 no growth cases of clinical mastitis that were treated with intramammary cephalixin (by label) was 5.2 days (range 2–26 days) and time until the quarter SCC was < 500,000 cells/ml was 10.7 days (range 1–111). Providing culture results remain negative and no *Mycoplasma* is cultured, the prognosis is good.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Vast majority of cases of clinical mastitis that result in no growth largely thought to be due to bacteria.

AGE-RELATED FACTORS

Author: Jerry Roberson

MASTITIS: SHEEP AND GOATS

BASICS

DEFINITION

Inflammation of the mammary gland due to either infection or trauma, and typified by one or all of the following: loss of milk production, increase in inflammatory cells, abnormal milk, changes in gland size and/or consistency, and occasionally systemic illness or death of the animal.

PATHOPHYSIOLOGY

- Infection is most commonly ascending from the teat sphincter to teat cistern and potentially to the glandular tissue.
- The pathogenicity of the bacteria dictates the potential for severe disease: from subclinical mastitis to peracute toxic mastitis.
- The infectious agent may produce a toxin that is absorbed by the blood stream or the agent may invade the alveoli and interstitial tissues causing inflammation. Some infections may be hematogenous (e.g., retroviruses, some *Mycoplasma*).

SYSTEMS AFFECTED

Mammary gland and, occasionally, systemic illness.

GENETICS

There is a genetic association with logarithmic somatic cell counts (SCC) in some breeds of dairy sheep (e.g., Lacaune). There is also some evidence that selecting for longevity without incidence of mastitis may select against mastitis.

INCIDENCE/PREVALENCE

- Subclinical mastitis is considered to be very common in sheep and goats, dairy and meat.
- The annual flock-level incidence of severe clinical mastitis in which an animal becomes ill or loses a gland, is 3%–15%.
- The prevalence of mastitis in culled sheep is often greater than 30%, indicating that it is an important reason for culling.

GEOGRAPHIC DISTRIBUTION

Found in all sheep- and goat-raising countries, regardless of management

SIGNALMENT

Species

Sheep and goats, both as dairy and meat animals

Breed Predilections

None known

Mean Age and Range

Any lactating animal but prevalence of mastitis increases with age.

Predominant Sex

Female

GENERAL COMMENTS

N/A

HISTORICAL FINDINGS

Peracute Systemic Mastitis

- Highest risk is 2–4 weeks postlambing/kidding (first one-third of lactation) or just after weaning.
- Animal may be found dead or down from effects of toxemia/septicemia.
- If animal is not down, then severely depressed, gaunt/off feed, and may also appear lame.
- Gland or entire udder may appear bluish to black and cold.

Clinical Mastitis

- Animal may go off feed for a day or two. May appear mildly lame from the swollen udder.

- Owner may notice abnormal gland (hard, fibrotic, swollen). In meat animals, abnormal milk/udder may not be noticed until weaning or the subsequent lambing/kidding.

Subclinical Mastitis

- May not be detected in meat animals.
- If routinely screening dairy animals:
 - Dairy sheep: elevated somatic cell count (SCC) or California Mastitis Test (CMT) result.
 - Dairy goats: may only be detected with milk culture unless markedly elevated SCC.

PHYSICAL EXAMINATION FINDINGS

Peracute Systemic Mastitis

- High fever initially ($> 40.5^{\circ}\text{C}$), severe dehydration and depression but temperature may become subnormal terminally. Systemic signs are compatible with toxemia or septicemia.
- The affected gland is swollen, hard, purple in color, and cold to the touch if gangrene is present.
- Serum, occasionally with gas, is expressed from the teat; no milk is present.
- Often the gangrene extends into the groin area and beyond.
- If the animal survives, the gangrenous gland is sloughed.

Clinical Mastitis

- Affected gland is swollen and hard or if more chronic, fibrotic. May contain abscesses.
- Milk is discolored (yellow or tan) and may contain clots. Milk may also appear serum-colored to watery or thickened.

Table 1

Common Bacterial Etiologies for Mastitis in Sheep and Goats	
Acute/Clinical Mastitis	Subclinical Mastitis
<i>Escherichia coli</i>	<i>Arcanobacterium pyogenes</i>
<i>Klebsiella</i> spp.	<i>Bacillus</i> spp.
<i>Mannheimia haemolytica</i>	Coliforms
<i>Pseudomonas</i> spp.	<i>Corynebacterium pseudotuberculosis</i>
<i>Staphylococcus aureus</i>	<i>Pseudomonas</i> spp. <i>Staphylococcus</i> spp. <i>Streptococcus</i> spp.

Subclinical Mastitis

- Milk appears normal but gland may be slightly swollen or slightly hypoplastic, depending on severity and chronicity of mastitis, or may appear normal.
- Scarring and occlusion of the teat canal may occur secondarily to infection with *Staphylococcus chromogenes*.

CAUSES

Peracute Systemic Mastitis

- Most cases are due to *Staphylococcus aureus* and *Mannheimia haemolytica*, and less commonly *Pseudomonas aeruginosa* (from water sources) and coliforms such as *E. coli*, *Salmonella* spp., and *Klebsiella pneumoniae*.
- May be secondarily infected with *Clostridium septicum* (gas gangrene).

Clinical and Subclinical Mastitis

- Bacteria
- See [Table 1](#).
 - Coagulase negative staphylococcus (CNS) are by far the most common isolates. There are many species that have variable pathogenicity (70%–80%). Next in importance is *Staphylococcus aureus* (3%–8%), *Streptococcus uberis* (goats mostly), *Arcanobacterium pyogenes*, *Corynebacterium bovis*, *Listeria monocytogenes*, rarely *Streptococcus agalactiae* (goats).
 - Species of CNS that are considered more pathogenic include *S. epidermidis*, *S. simulans*, *S. chromogenes*, *S. xylosus* (sheep), *S. caprae* (goats). Many of CNS isolates from small ruminants are hemolytic, indicating higher pathogenicity than strains found in cattle.
- Mycoplasma

- *Mycoplasma agalactia* (contagious agalactia) is a common cause of severe mastitis in sheep and goats in the Mediterranean areas but is considered exotic to North America.
- *Mycoplasma mycoides* ssp. *mycoides*, large colony type, occurs in North American goats and causes mastitis and septicemia in adult goats and septicemia, septic arthritis, and pneumonia in kids.
- *Mycoplasma capricolum* and *M. putrifaciens* also cause caprine mastitis.
- Viruses
 - Maedi visna virus (ovine progressive pneumonia virus) causes an interstitial mastitis in sheep.
 - Caprine arthritis encephalitis virus causes an interstitial mastitis in goats.
- Other: occasionally a variety of fungi is isolated from sheep or goat mastitis, most commonly *Aspergillus*. Yeast and *Prototheca* infections may also occur.

RISK FACTORS

- Compromised teat sphincter by one the following:
 - Contagious ecthyma infection (orf, soremouth) of the teat end
 - Over-milking or high teat-end vacuum pressure in dairy sheep and goats
 - Insufficient vacuum reserve so that back-splashing occurs when a milking unit is removed.
 - Possibly trauma from biting or aggressive nursing
- Presence of contagious bacteria, in particular *S. aureus* and CNS or rarely *Streptococcus agalactia* may infect by its presence on the teat end. Occasionally, sheep and goats may have a marked dermatitis from *S. aureus* infection on the udder, which may increase the risk of mastitis.
- Humans may be carriers of *S. aureus* and transmit through poor hygiene.
- *M. mycoides* ssp *mycoides* is highly contagious and can be spread through poor milking hygiene. Does that consume infected milk as kids, may become shedders when they start to lactate.
- A dirty environment (e.g., manure, mud, dirty water) will contaminate the teat end. Water is the most important source of infection due to *P. aeruginosa*. Milking equipment with cracked liners or poorly cleaned after use, may also serve as an important reservoir for environmental bacteria.
- Mastitis due to *M. haemolytica* may be due to the presence of the bacteria in the nasopharynx of the nursing lambs or kids.
- Increased housing density is associated with a higher prevalence of mastitis in dairy and meat sheep.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Gangrene may occur secondary to a wound.
- Swelling of the udder may occur secondary to trauma.

CBC / BIOCHEMISTRY / URINALYSIS

A complete blood count (CBC) may provide evidence of sepsis and/or toxemia. A clinical chemistry profile may be useful in characterizing acid/base and electrolyte abnormalities and organ dysfunction in peracute disease. Serology and viral isolation can be used to diagnose retroviral mastitis.

OTHER LABORATORY TESTS

Detecting Inflammatory Cells

- CMT—there is a good correlation between CMT results and SCC. It has been suggested that all glands with a CMT reaction of 1+ or greater (a reaction associated with $\text{SCC} \geq 0.8 \times 10^6$ cells/mL) on a five-point scale (neg, trace, 1+, 2+, 3+) should be cultured, although up to 30% of infected glands may be missed using this screening test.
- SCC—a more useful screening test for mastitis in sheep than in goats. Sheep have a similar response to infection as cattle and a threshold of 0.5×10^6 cells/mL is a reasonable point above which the gland should be cultured. The SCC in goats is very high at the end of lactation, and is often greater than 1.0×10^6 cells/mL, making it difficult to differentiate between infection and effect of stage of lactation. While it is useful to culture goats with SCC greater than 1.0×10^6 cells/mL, using this cut-point may miss infections due to CNS or even *S. aureus*.

- NAGase—not commonly used but shows good correlation in midlactation with infection.

Detecting Infectious Agents

- A milk sample taken using aseptic technique should reveal a minimum of 5 cfu/mL milk in pure culture, for the organism to be considered significant. Freezing may increase the chances of isolation of some bacteria (e.g., *S. aureus*) but may lower the isolation rate of other bacteria. A high SCC may interfere with isolation of some bacteria, notably *S. aureus*, in which case repeated sampling (e.g., every other day for three samples, frozen and submitted for culture) may increase the rate of diagnosis in cases where infection is strongly suspected but single culture is unrewarding.
- In North America, it is prudent to request culture for *Mycoplasma* when investigating goat mastitis associated with disease in kids.
- Serology for MV-v/CAE-v is alone not diagnostic for interstitial mastitis due to these retroviruses. However, a positive test (ELISA or AGID) would suggest flock infection indicating that control measures are warranted.

IMAGING

Ultrasonography may be useful in the identification of fibrosis and abscesses within the mammary gland parenchyma.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Necropsy of animals dying of peracute systemic mastitis reveals changes associated with severe toxemia or septicemia.
- Histology of glandular tissue affected with MV-v or CAE-v will reveal lymphoid follicles throughout the udder tissue and secondary scarring.

TREATMENT

APPROPRIATE HEALTH CARE

- Peracute systemic mastitis
 - Most cases are noted after gangrene has set in, which can occur within a few hours after becoming ill. Care should focus on supportive therapy (intravenous fluids, nonsteroidal anti-inflammatory drugs), stripping of milk if possible, and administration of broad-spectrum antibiotics.
 - Antibiotics should be selected based on spectrum of activity, ability to be used in dairy animals (if applicable), and the drug's ability to cross into the mammary gland. For meat sheep, tilmicosin (Micotil, Provel) has been shown to be efficacious against *S. aureus* and *M. haemolytica* udder infections, but cannot be used in dairy sheep because of milk withdrawals. Tilmicosin should not be used in goats because of potential toxic effects.
- Treatment of clinical and subclinical mastitis during lactation
 - Cases in which damage has already occurred (e.g., severe fibrosis or abscessation) will not respond to treatment and culling should be considered.
 - Very little work is published on the efficacy of intramammary infusions of antibiotics during lactation in either sheep or goats. Care must be taken not to damage the teat sphincter, and to investigate appropriate withdrawals for milk and meat through FARAD or gFARAD. Parenteral treatment with tilmicosin (Micotil, Provel) has been shown to clear up *S. aureus* dermatitis and mastitis in dairy sheep.
 - Most work has been done on dry period treatment. Cure rates and new infection rates vary between studies, but it appears useful only if a flock or herd has a significant level of mastitis. Again, extreme care must be taken when infusing teats not to cause damage or contaminate the gland. A single injection of tilmicosin (Micotil, Provel) 1 month prior to lambing has been shown to increase lamb weight gains in multiparous ewes at weaning and to reduce the prevalence of abnormal udders regardless of culture results. Routine dry period therapy may be more useful in goats with a shorter dry period although little is published on this. Again, care must be taken to avoid residues with extralabel drug use.
 - CNS infections in particular experience a level of self-cure.
- *Mycoplasma* infections are not considered to be amenable to treatment, and infected animals, once identified, should be culled to slaughter.
- Treatment of fungal mastitis is rarely successful and there are no specific treatments for viral mastitis. Hence, culling the affected animals from the herd is usually recommended.

NURSING CARE

See Appropriate Health Care section above.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

- Cases of *S. aureus* that do not respond to treatment should be culled.
- Milking equipment and technique should be checked semiannually.

SURGICAL CONSIDERATIONS

Chronic suppurative mastitis or severe gangrenous mastitis may require partial (udder half) or total mastectomy to eliminate the source of infection and/or toxemia. Surgery of the mammary gland is covered in a separate chapter (Mammary Gland Surgeries: Teat Amputation, Mastectomy).

MEDICATIONS

DRUGS OF CHOICE

See Appropriate Health Care section above.

CONTRAINDICATIONS

PRECAUTIONS

- Withdrawal periods for milk cannot be extrapolated from those published for dairy cattle.
- Splitting a tube of mastitis ointment is contraindicated because of the risk of contamination.

POSSIBLE INTERACTIONS

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Response to treatment can be monitored most easily by CMT, although SCC is preferable in dairy animals.

PREVENTION / AVOIDANCE

- Cull ewes at weaning that have severe udder damage or that are infected with *S. aureus*.
- Environment should be clean and dry. Use straw and avoid softwood shavings for bedding.
- Dairy sheep and goats:
 - Semiannual check of milking equipment to make sure it is clean, calibrated, and functioning appropriately.
 - Milk primiparous animals first and *S. aureus* carriers last (or cull).
 - Wash water should contain an appropriate sanitizer and udder should be thoroughly dried with a single-use towel before putting on machine. Predipping is optional but udder prep time should be kept to a minimum.
 - Do not overmilk (milk-out time ~2–3 minutes). Use an appropriate registered teat dip.
 - Dry period therapy should be used if infection rates warrant.
 - Dairy sheep SCC values should be monitored several times during their lactation in order to select infected animals for culture.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Course of disease and prognosis will depend on the infectious agent and chronicity and severity of infection. Gangrenous

mastitis generally is associated with a poor to grave prognosis. Subclinical disease, while having a good prognosis for life, may have a poor prognosis for the herd or flock if the inciting agent is a contagious pathogen.

- Chronic infections tend to cause depressed milk production, which ultimately decreases profits from dairy animals and reduces growth rates in lambs and kids.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Decreased milk production and herd/flock profitability.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Many infectious agents found commonly in milk have the capacity to cause illness in humans, which underlines the need to pasteurize all milk prior to consumption.
- The following agents are potentially zoonotic and can either be shed in the milk or contaminate raw milk of sheep and goats: *S. aureus*, *Salmonella* spp., verocytotoxin producing *E. coli* (e.g., H7:O157), *Listeria monocytogenes*, *Brucella* spp., *Yersinia enterocolitica*, *Klebsiella* spp., *Streptococcus faecalis*, and the rickettsia *Coxiella burnetii*, the causative agent of Q fever. Many of these organisms do not cause clinical mastitis but have the capacity to cause illness in humans.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Sheep and goats

BIOSECURITY

- Dairy sheep—limit the number of animals purchased after lactation has begun to reduce risk of purchasing *S. aureus* infected animals.
- Dairy goats—make sure that purchases are from a herd free of *M. mycoides*.

PRODUCTION MANAGEMENT

MASTITIS: STAPHYLOCOCCAL

BASICS

OVERVIEW

- Mastitis is inflammation of the mammary gland caused by microorganisms, usually bacterial, that invade the mammary gland, multiply, and produce toxins harmful to the gland.
- Mastitis compromises the well-being of the patient.
- Mastitis compromises the nutrition available to the offspring.
- All livestock species are affected by mastitis.
- Mastitis in dairy cattle and milk goats produces serious economic losses.
- Mastitis is the single most common disease in adult dairy cows.
- In milk producing animals, losses are due to:
 - Decreased milk production
 - Discarded milk
 - Increased treatment costs
 - Increased replacement costs due to deaths or involuntary culling
- Losses in sheep are associated with acute clinical disease of the ewe or subclinical forms that decrease milk production with resulting poor lamb growth or increased lamb mortality.
- Staphylococci are gram-positive bacteria.
- Staphylococci organisms that cause mastitis are usually identified as *Staphylococcus aureus* and coagulase-negative staphylococci (CNS) or *Staphylococcus* species.

SIGNALMENT

- Mastitis in cattle can occur any time during lactation.
 - No signs are typically noted with subclinical infections.
 - Brood ewes and does usually develop mastitis between parturition and weaning.
- History of acute cases may include anorexia, depression, and loss of milk production.

SIGNS

Signs vary from subclinical to clinical to gangrenous.

Subclinical Mastitis

- Characterized by lack of visible changes to the gland or the milk
- Causes elevation of somatic cell count of the infected gland

Clinical Mastitis

Associated with changes in the gland and the milk. The infected quarter may have signs of swelling, pain, and heat.

Peracute

- Gland has swelling, heat, and pain.
- Secretion is abnormal and may contain clots, flakes, or discolored serum and sometimes blood.
- Signs of systemic illness are present. These include anorexia, depression, increased pulse rate, sunken eyes, and weakness.
- Onset is rapid and mortality may be high.

Acute, Gangrenous

- Gangrenous form is due to staph alpha toxin.
- Acute systemic and local signs are due to toxemia.

- Starts with inflammation of the gland, then development of cold teats and bloody secretions
- The gland has sharply delineated, blue discolorations.
- Mortality may be high.

Acute

- Changes to the gland and secretion are similar to peracute infections.
- Systemic signs are present but less severe than peracute infections.

Subacute

- Mild to moderate alterations to the secretion and mammary gland
- No systemic signs

Clinical Signs in Small Ruminants

- Referred to as “blue bag”
- Fever of 41–42°C (105–107°F)
- Anorexia
- Refusal to lie down or lameness
- Skin of mammary gland is initially red and hot, then becomes cyanotic and cold.
- Milk decreases in volume, becomes watery or bloody, and contains debris.
- Mortality may approach 80% if not treated.

CAUSES AND RISK FACTORS

- Infection of the mammary gland follows introduction of staphylococci bacteria through the teat sphincter
- *Staphylococcus aureus* (*Staph aureus*)
 - In dairy cows, it is usually associated with transfer of infected milk from infected to noninfected quarters during the milking process.
 - Transfer has also been associated with flies and milkers’ hands.
 - Primary source: infected udders
 - Secondary sites include teat skin, udder skin, nose, lips, vagina, and other body sites.
 - Method of spread: via transfer of bacteria-laden milk from infected to noninfected glands. The milking process is a primary means of transfer, but nursing calves, flies, and milkers’ hands can also transfer the organisms.
 - Often introduced into a herd by infected, purchased additions
 - Flies have been associated with infection in prepartum heifers.
- Coagulase-negative staphylococci (CNS)
 - Also referred to as staph species bacteria
 - Are normal inhabitants of bovine teat skin and can be free living in the environment
 - Infections are more common in first lactation cows.
 - Prevalence is high at parturition, then declines through the first month of lactation.
 - Primary source: commonly found on teat skin and in the streak canal
 - Cow-to-cow spread is probably rare.
 - Most infections are transient.
 - May be associated with teat injuries or alteration of teat skin condition

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Subclinical cases must be differentiated from mastitis caused by *Streptococcus agalactia*, *Corynebacterium bovis*, and minor udder pathogens.
- Clinical cases must be differentiated from mastitis caused by coliform bacteria, *Mycoplasma*, environmental streptococci.
- Gangrenous mastitis with bloody secretion must be differentiated from trauma to the gland.

CBC/BIOCHEMISTRY/URINALYSIS

Usually not performed

OTHER LABORATORY TESTS

Microbiological identification of the causative agent is essential in diagnosis.

- Requires plating organisms to evaluate the colonial characteristics and hemolytic patterns on blood agar
- The catalase test is used to differentiate staphylococci from streptococci by mixing the colony with hydrogen peroxide.
 - Staphylococci are catalase positive (produce bubbles).
 - Streptococci are catalase negative (do not produce bubbles).
- Colonies should be gram stained. Staphylococci are gram-positive cocci that appear in clumps.

Staph aureus

- Large colonies that are creamy, grayish-white, or yellowish in color
- Generally produce hemolysis, typically a double zone, around the colony
- Most are coagulase positive.

Coagulase-Negative Staphylococci (Staph Species)

- Large, creamy, grayish-white, or yellowish in color
- Generally have no hemolysis
- Most are coagulase negative.

Coagulase Test

To perform the coagulase test, a *Staphylococcus* colony is mixed with rabbit plasma and incubated. Clotting indicates a positive reaction.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- A strip cup or strip plate is used to identify changes in milk.
- The udder should be palpated for heat, swelling, and induration.
- Perform a physical exam of the animal to assess systemic signs including fever, appetite, and hydration.
- California Mastitis Test: Used to identify infected quarters, especially those with subclinical infections; will not identify the pathogen.
- Culture is the only method to identify the specific pathogen.

TREATMENT

- Both intramammary and systemic therapy have been used.
- Treatment of early cases of *Staph aureus* is often successful; the success of treatment for chronic infections is poor.
- Response to therapy of *Staph aureus* is poorer due to formation of L-forms, penicillinase production, and the formation of microabscesses within the udder parenchyma.
- When possible, treatment should be based on culture and angiobiograms (susceptibility information).
- Goal is to return the gland to production.
- Consider the economics of the treatment.
- Use only products approved for use in food-producing animals.
- Withholding times for milk and meat must be observed.
- Better response to treatment is attained during the dry period.

MEDICATIONS

- Base on culture and sensitivity test results, if possible
- Several commercial products for intramammary administration are available.

- B-lactam antibiotics such as penicillin, hetacillin, and amoxicillin
- Cephapirin
- Novobiocin
- Pirlimycin
- No products are labeled for systemic therapy but injectable ampicillin (3–5 mg/lb) and oxytetracycline (5 mg/lb) have been used in conjunction with intramammary therapy.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) are used to control pain and fever.
- Treatment of small ruminants is the same as for cattle.
- Withholding times for milk and slaughter must be followed.

FOLLOW-UP

Infected quarters should be cultured 21–28 days after treatment to determine cure.

PREVENTION/AVOIDANCE

Control of Staph aureus

- Identify infected cows and isolate or milk last
- Cull chronically infected cows.
- Treat all cows with appropriate dry cow infusion products.
- Apply an effective teat disinfectant to each teat following milking.
- Backflushing systems have been used to reduce the bacterial load in the milking inflations.
- Promote good milking hygiene and proper milking techniques to minimize teat end trauma.
- Vaccines are available but of limited usefulness.

Control of CNS

- Treat all cows with appropriate dry cow infusion products.
- Apply an effective teat disinfectant to each teat following milking.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Mastitis in dairy cattle and milk goats produces serious economic losses.
- In milk-producing animals, losses are due to:
 - Decreased milk production
 - Discarded milk
 - Increased treatment costs
 - Increased replacement costs due to deaths or involuntary culling
- Losses in sheep are associated with acute clinical disease of the ewe or subclinical forms that decrease milk production with resulting poor lamb growth or increased lamb mortality.

MASTITIS: STREPTOCOCCAL

BASICS

OVERVIEW

In many dairy herds with different management approaches, at least one type of streptococcal mastitis is among the most prevalent intramammary infections (IMI), often financially important. These include contagious as well as environmental pathogens.

SYSTEMS AFFECTED

Mammary and production management

GENETICS

N/A

INCIDENCE/PREVALENCE

- Fifteen percent of dairy herds in the northeast United States have *Streptococcus agalactiae* infections present in the herd at any given time, while 85% are free of this eradicable organism.
- Researchers currently suggest prevalence between 11%–47% of herds in various states/regions of North America.
- Within infected herds, prevalence of *Streptococcus agalactia* varies considerably, ranging from 1%–77% of the herd in 2003.
- *Strep ag* is reported as a pathogen in many dairy ruminant species. *Strep ag* in goat milk occurs rarely.
- Of dairy herds in the United States, 96% have *Strep dysgalactiae* or *Strep uberis* infecting at least one cow at any given time.
- Many laboratories and commercial dairy herd mastitis control programs do not speciate between these two types of nonagalactiae streptococci, identifying them as *Strep sp*.
- Among cows, the prevalence of *Strep sp*. is 14%–16% in reports from the United States and other developed countries.

GEOGRAPHIC DISTRIBUTION

Worldwide depending on bacterial species and environment

SIGNALMENT

Species

Dairy cattle

Breed Predilections

Dairy breeds of cattle

Mean Age and Range

N/A

Predominant Sex

Female

Major Pathogens

- *Streptococcus agalactiae* (contagious, usually aggressively spreading pathogen)
- *Streptococcus dysgalactiae* (predominant source is the environment)
- *Streptococcus uberis* (predominant source is the environment)
- The latter two are often diagnosed as a group in mastitis and udder health programs as *Strep sp*.

SIGNS

In herd:

- There is no one classical presentation of these pathogens within dairy herds; however, in most cases, *Strep ag* first becomes evident within months to 1 year following purchase of infected animals.

- Three percent of heifers have infections with *Strep ag* at first calving, and should not be assumed to be risk free as herd additions.
- Ninety-six percent of *Strep ag* cases are subclinical.
- *Strep ag* results in bulk tank SCC usually > 400,000/ml, often > 750,000/ml at least intermittently. SCC often rises steadily once the increase begins.
- Sometimes associated with high bacteria counts in milk, can be > 200,000/ml SPC.
- Often high (> 10%/mo) new infection rate on DHIA (or other test service) monthly reports.
- May be high level (> 10%/mo) of chronic infections as well.
- *Strep sp.* can be major mastitis in any herd, including herd as described above.
- However, *Strep sp.* more likely to be at high level when tank SCC < 400,000/ml, especially when < 200,000/ml.
- *Strep sp.* often are subclinical but many cases can have severe clinical signs, or SCC LS > 5.0.
- Often notice many new infections on DHIA among fresh cows < 60 DIM.
- *Strep sp.* mastitis increases from June through September in many herds in North America.

RISK FACTORS

- Failure to employ standard milking time hygiene measures are risk factors for the spread of *S. agalactiae* IMI. Herds that do not utilize dry cow antibiotic therapy and herds that do not cull chronically high SCC cows would be at increased risk for *S. agalactiae*. There is also a suggestion that teat end hyperkeratosis increases the risk of *S. agalactiae*.
- Historically, the Environmental Streptococci (ES) are considered to be opportunist mastitis pathogens; however, the ES, especially *S. dysgalactiae*, may have some characteristics of contagious pathogens. A few studies have demonstrated a greater risk of ES IMI to cows with advancing age.
- Several studies have documented that straw bedding increases the risk of cows to ES IMI. Likewise, cows bedded on deep bedded straw packs that tend to be urine and feces contaminated are at increased risk. In an Ohio study, increased prevalence of ES was associated with poor sanitation, increased number of days dry, use of tie stalls, and lack of drying teats prior to milking. There is also a suggestion that the increased time associated with correcting liner squawks increases the risk of ES IMI.

DIAGNOSIS

- Bulk tank milk culture is a useful way to screen a herd or group for *Strep ag*.
- Sensitivity for a single bulk tank culture is 77% (across all ranges of prevalence). Three bulk tank milk culture samples collected approximately 3 days apart should be collected and cultured separately; if all 3 samples are negative, the probability the herd is uninfected is 99%.
- Bulk tank milk cultures are frequently positive for *Strep sp.*, and have no practical value in monitoring for these infections.
- Culture of aseptic milk samples is the only definitive way to diagnose either type of mastitis in individual cows at present.
 - Culture should be carried out on blood agar. Incubation overnight at 37°C. Streptococci appear as small, somewhat transparent colonies with or without hemolysis at 18–24 hours.
 - All mastitis associated streptococci are catalase negative (place a small amount of the colonies on a glass slide and add a drop of hydrogen peroxide); there will be no bubbling, which indicates a negative catalase. Gram's stain will typically reveal gram-positive cocci in chains.
 - The three primary mastitis-associated streptococci can then be effectively differentiated from each other by a few simple tests ([Table 1](#)).

TREATMENT

- Culture of entire lactating herd is usually necessary to eradicate *Strep ag*, with resampling of the herd 3 weeks after treatment is complete, repeated until eradication is accomplished.

Table 1

<i>Streptococcus</i>	<i>Esculin</i>	<i>Camp</i>
<i>agalactiae</i>	–	+
<i>dysgalactiae</i>	–	–
<i>uberis</i>	+	+/-

- Intramammary therapy (IMM) cure rates have declined in recent years to approximately 90% of *Strep ag* cases curing following any single course of treatment.
- Individual cows usually warrant two regimens of therapy before being considered nonresponsive; many animals will cure the second time. Cows that are positive on third culture after two rounds of therapy should be strongly considered for culling.
- IMM infusion of beta-lactam antibiotic in all four quarters for three milkings in a row should be done for all infected cows as soon as culture results are available, treating all *Strep ag* –infected cows at the same time.
- Teat dipping and other classical mastitis control measures are weakly associated with control of *Strep sp.*
- The definitive control program for *Strep sp.* has not been developed.
- Environmental sanitation is critical, including dry cow and replacement heifer housing.
- Bedding cultures are often useful. Counts < 100,000 cfu/g are good; some are much lower.
- *Strep sp.* > 1,000,000 cfu/g in bedding (some are billions/g) strongly associated with higher prevalence of the infection in cows.
- Bedding cultures often convince farm management that various types of housing and bedding really are in need of increased cleanliness efforts.
- *Strep sp.* control programs including bedding, housing repair, and milking clean, dry teats must be developed with managers and employees of each farm.

MEDICATIONS

DRUGS OF CHOICE

- Because the spontaneous cure rate for streptococcal mastitis is usually less than 20% and often results in chronically high SCC, timely treatment with an appropriate antibiotic is essential and usually economical.
- Penicillin-based products are the intramammary drugs of choice. Several studies have found that the streptococci are still quite susceptible to the penicillin products.
- The initial therapeutic protocol should be an approved intramammary antibiotic used according to label directions. If this therapy is not successful, there are other alternatives.
- Anecdotal evidence suggests that simply switching to a different class of approved intramammary antibiotic used according to label is often sufficient in obtaining a bacterial cure. Another option is to extend the intramammary antibiotic therapy two to three times the labeled dosage. Studies with pirlmycin and ceftiofur have demonstrated increasing bacterial cures with increasing dosage lengths. However, a study with extended amoxicillin did not demonstrate any benefit over the normal labeled dosage.
- One other option is to treat both intramammary and systemically. In a recent study, increased bacterial cures were obtained by using intramuscular ampicillin with intramammary amoxicillin.
- For herds with a high prevalence of *S. agalactiae*, blitz treatment during lactation should be considered as it is often effective (> 80%) and often proves to be economical. *Enterococcus* species tend to be considerably more resistant to successful treatment than the other streptococci.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Follow-up cultures are recommended on any treated streptococci cases.
- Recommended times to culture are 1–4 days after the milk antibiotic withdrawal (a negative culture at this time is most suggestive of the efficacy of the antibiotic) and at 28–30 days (helps to document that an actual bacterial cure did occur).
- Alternatively, a decrease in individual cow SCC to normal levels would be suggestive of a cure.

PREVENTION/AVOIDANCE

- Although the significance of standard mastitis control procedures varies in importance among the streptococci, a complete mastitis control program is essential in control of the streptococci.
- Milking time hygiene will have the most effect on controlling *S. agalactiae* but will also help with control of the ES.
- Complete teat predipping with an effective germicide, which should be left in place for 15–30 seconds. Avoid water usage in the parlor. Teats should be dried completely with individual udder cloths or paper towels. Milking machines should be properly maintained. Avoid over- or undermilking. Quickly adjust milking units once squawking is heard. One study found increased *S. uberis* IMI associated with delay in correctly liner squawking. In the limited studies performed on backflushing, no benefit was found for the ES. At the end of milking, teats should be dipped up to the base of the udder with an effective germicide. Cows that have been treated and did not cure should be retreated or culled to help remove the intramammary reservoir.
- All quarters of all cows should be treated with an approved intramammary antibiotic at the time of dry off. Studies have shown that around 50% of new streptococci infections occur during the dry period. Proper nutrition, especially in regards to appropriate levels of vitamin E and selenium, is important for mammary immune function.
- Avoid the use of straw bedding when possible, and when not possible, proper maintenance of bedding areas is essential. Inorganic bedding is preferred, however one study found ten times more ES on the teats of cows bedded on sand than on teats of cows bedded on sawdust. Even pasture areas may be heavily contaminated with ES (e.g., common shade area). These prevention measures are less effective against *S. uberis* possibly because of its ubiquitous nature on the dairy farm (shed in the feces). Vaccines are being studied and may be available in the future. However, several studies have found that *S. uberis* strains vary considerably among dairy herds and even within dairy herds, which becomes problematic in regards to an effective vaccine.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Spontaneous cure rate is around 20% for ES. The spontaneous cure rate for *S. agalactiae* is < 10%. Even though the organisms are susceptible, bacterial cures occur only 50–70% of the time.
- Extended intramammary therapy has been shown to increase the bacterial cures up to 100% in some experimental studies.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Loss of milk production and increased culling rates

AGE-RELATED FACTORS

Three percent of heifers have infections with *Strep ag* at first calving, and should not be assumed to be risk free as herd additions.

ZOONOTIC POTENTIAL

Although relatively rare, some streptococci of bovine origin have been identified in human infections. In particular, *S. agalactiae* is one of the leading causes of human neonatal infection. However, most studies have found that the *S. agalactiae* cultured from human infants is of a different type than that found in bovine mastitis.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Dairy cattle

BIOSECURITY

Among cows, the prevalence of *Strep* sp. is 14%–16% in reports from the United States and other developed countries.

PRODUCTION MANAGEMENT

- Intramammary therapy (IMM) cure rates have declined in recent years, to approximately 90% of *Strep ag* cases curing following any single course of treatment.
- Individual cows usually warrant two regimens of therapy before being considered nonresponsive; many animals will cure the second time. Cows that are positive on third culture after two rounds of therapy should be strongly considered for culling.
- Environmental sanitation is critical, including dry cow and replacement heifer housing.

MASTITIS: VIRAL

BASICS

DEFINITION

- Inflammation of the mammary gland due to viral agents
- In cattle, bovine herpes virus (BHV) 1 and 4, foot-and-mouth disease virus (FMDV), and parainfluenza-3 (PI3) have been associated with mastitis but their overall significance is minimal.
- Caprine arthritis-encephalitis (CAE) virus is an agent of caprine mastitis.
- Maedi visna (ovine progressive pneumonia) causes mastitis in sheep.

PATHOPHYSIOLOGY

- The pathophysiology of BHV in bovine mastitis is little understood.
- Bovine herpes virus 4 may influence bacterial intramammary infections but the exact role is not understood. Bovine herpes virus 4 does not appear to be a significant agent of bovine mastitis as experimental inoculation into the mammary gland did not result in clinical mastitis although it did cause an increase in SCC.
- Subclinical mastitis occurred in 50% of inoculated cattle (n = 4).
- Secretory cell necrosis is associated with FMDV.
- In both CAE and MV, the infection is typically spread via virus-infected macrophages, which then enter the reticuloendothelial system where the virus-infected cells spread to target tissues.
- Once the target tissues are reached, the virus replicates and induces a lymphoproliferative response, which eventually leads to scarring and fibrosis of the mammary parenchyma.

SYSTEMS AFFECTED

- Bovine herpes virus 4 may affect the mammary gland and skin, and the reproductive tract.
- Caprine arthritis-encephalitis primarily affects joints in older goats and the central nervous system of young goats but is also commonly associated with the mammary gland and occasionally the lungs.
- Maedi visna (MV) typically affects the lungs and mammary gland of sheep and more rarely the neurologic system and joints.

GENETICS

There appears to be no genetic predisposition to any of the viral mastitis agents.

INCIDENCE/PREVALENCE

- Studies of prevalence and incidence of viral mastitis agents have not been conducted.
- A study conducted in 24 U. S. states in the early 1980s indicated that the ~80% of tested goats were seropositive for CAE. This study was conducted relatively early in the recognition of the disease (1974).
- A recent prevalence study could not be found. Studies among individual herds typically find a within-herd seroprevalence of > 60%. Studies specifically directed toward CAE mastitis could not be found.
- A study conducted in the late 1970s in Idaho found a 58% seroprevalence for MV in three flocks. A more recent study in the United States found a 26% prevalence. Within-flock seroprevalence may reach 100%. Again, prevalence of MV mastitis could not be found.

GEOGRAPHIC DISTRIBUTION

- BHV4 and PI3 likely have a worldwide distribution. The geographic distribution of FMDV is limited.
- Both CAE and MV are found worldwide.

SIGNALMENT

- There is insufficient knowledge regarding a standard signalment for bovine viral mastitis diseases in cattle.
- For both CAE and MV, the typical presentation is an older adult female with a hard udder with scant normal appearing

milk.

SIGNS

- There are no distinguishing signs for the mastitis caused by viral mastitis agents in cattle.
- For both CAE and MV, mastitis typically presents as a hard udder with hypogalactia or agalactiae even at parturition.
- Other clinical signs associated with the mastitis are rare in that there is rarely any pain, swelling, redness, edema, or abnormal milk noted. In fact, the udder looks full and normal and only by palpation is the problem of the extremely firm udder noted. The condition is often bilateral.
- Regional lymph nodes are usually enlarged.
- Given time, the other systems affected by the virus will predispose the ewe or doe to progressive weight loss and eventual death.

CAUSES

- There is only limited and weak evidence to suggest that BHV4 may directly result in mastitis in cattle. Foot-and-mouth disease virus has been shown to result in a clinical mastitis that is often a sequela to a systemic infection. Parainfluenza virus 3 has been isolated from the mammary gland of cattle but its significance is not known.
- Both CAE and MV are retroviruses (slow viruses) that have many similarities but are distinct.

RISK FACTORS

- Too little is known about the epidemiology of bovine viral mastitis agents to elaborate on potential risk factors.
- Major risk factors for both CAE and MV are positive animals in the herd, consumption of milk or colostrum from a positive dam, and close contact with positive individuals.
- Aerosol transmission appears to be especially important in sheep due to MV's predilection for the lungs. The lamb and also herd mates in close proximity to the infected animal are at increased risk. The virus may also be transmitted via milk in the milking parlor.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- For bovine viral mastitis, differentials include any of the more common agents (mostly bacterial) of mastitis.
- For both CAE and MV, there are only a few other viral agents that might be responsible and these are only rarely reported. It is possible that bacterial, fungal, or algal agents could be responsible, but these do not typically result in a completely hard quarter.

CBC/BIOCHEMISTRY/URINALYSIS

These tests are not considered very useful in diagnosing viral mastitis. However, mammary somatic cells may present with more lymphocytes than neutrophils, which may help differentiate bacterial agents from viral agents.

OTHER LABORATORY TESTS

N/A

IMAGING

Imaging is not useful for bovine viral mastitis. Studies have not been conducted for small ruminant viral mastitis.

DIAGNOSTIC PROCEDURES

- Viral isolation and acute/convalescent titers may be used to diagnose bovine viral mastitis.
- For both CAE and MV, definitive diagnosis occurs by histological examination.
- Serology can be conducted and, if negative, suggests that the mastitis is not due to CAE; this is also true for MV. The two most commonly used tests are AGID and ELISA with reported sensitivities of 90% and 98%. A positive serologic test is an excellent indication that the animal is persistently infected.

PATHOLOGIC FINDINGS

- Thorough investigation of bovine viral mastitis pathologic findings has not been conducted.
- For CAE and MV, histopathology reveals foci of inflammatory cells within the interstitium with nodular lymphoid proliferation around the alveolar ducts. In chronic cases, there is increased deposition of connective tissue replacing the parenchyma, which likely results in the firmness of the udder.

TREATMENT

APPROPRIATE HEALTH CARE

- Because bovine viral mastitis is not considered to be very significant and prevalence is low, cattle with clinical mastitis should be treated as if the infection were bacterial in origin. Treatment should be symptomatic.
- There is no known efficacious treatment for CAE or MV mastitis and in production systems affected stock should be culled.

NURSING CARE

N/A

ACTIVITY

Unrestricted

DIET

No special dietary management is known to be helpful.

CLIENT EDUCATION

- The client should be aware that the overall importance of bovine viral mastitis is not known.
- Eradication programs should be discussed with clients when either CAE or MV is diagnosed because antibody-positive stock are considered infected for life.
- Kids and lambs should be fed only colostrum and milk from negative dams or pasteurized colostrum and milk. Kids of dams with “hard bag” may succumb to starvation and should receive supplemental milk and colostrum.

SURGICAL CONSIDERATIONS

MEDICATIONS

DRUGS OF CHOICE

There is no effective treatment for viral mastitis.

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

The patient should be monitored and treated symptomatically.

PREVENTION/AVOIDANCE

- In general, bovine viral mastitis is not common enough nor deemed significant enough to warrant measures of prevention.
- Prevention and eradication programs are essential if small ruminant viral mastitis is to be controlled/eliminated. There are no vaccines.
- Transmission is primarily via milk and colostrum ingestion in neonates but other methods of transmission may occur

(transplacental and sexual).

- Cross infection between sheep and goats is also thought to occur. See Mastitis: Sheep and Goats for detailed eradication programs.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- The duration of naturally occurring IMI is not known, but with the exception of FMDV IMI, mastitis appears to be relatively mild.
- Once the mammary gland is affected with CAE or MV, most cases will not improve.

MELANOMA

BASICS

OVERVIEW

- Melanoma is a neoplastic proliferation of melanocytes that occurs most commonly in the skin and subcutaneous tissues, but can also involve the ophthalmic system.
- Melanomas account for 5–6% of all bovine tumors, and approximately 25% of skin tumors.
- The majority of melanomas in cattle appear benign histopathologically, but local invasion can be seen.
- Metastasis to lymph nodes and distant organs has been reported but appears to be rare.
- Melanomas are rare in sheep and goats.

SIGNALMENT

- Melanomas are most common in cattle less than 2 years of age, but may occur congenitally and have been reported in animals as old as 15 years.
- There is no sex predilection.
- Angus, Angus-crosses, and other dark-skinned cattle appear to be more likely to develop melanomas.

SIGNS

- Most melanomas in cattle are dark in color, and may or may not have hair on the overlying skin.
- Symptoms related to the location of the tumor, for example, intraocular melanoma resulted in a painful eye with buphthalmos, corneal ulceration, and edema.
- Cattle with melanomas may have no clinical signs associated with the tumor (painless soft tissue mass).

CAUSES AND RISK FACTORS

Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other skin/subcutaneous tumors (fibroma, papilloma, lipoma, sebaceous tumors)
 - Requires histopathology for differentiation of tumor type
- Abscess
 - Abscess may be inflamed/painful, where melanomas are not.
 - Melanomas continue to grow over time.
 - Aspiration/cytology will differentiate between an abscess and a melanoma.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Chest radiographs can help determine if there is pulmonary metastasis present prior to attempting surgical excision of the primary mass in a young animal.

DIAGNOSTIC PROCEDURES

- Biopsy of a mass for histopathologic evaluation and culture/sensitivity testing

- Aspiration and cytology of draining lymph nodes to evaluate for the presence of metastasis

PATHOLOGIC FINDINGS

- Often pigmented on cut surface, may exude pigmented fluid.
- Can occur in the dermis or subcutis, may have junctional activity (extension between the epidermis and dermis).
- Melanocyte may be epithelioid or spindloid in appearance and are often highly pigmented.
- Mitotic figures are typically low in number.
- May be positive for vimentin intermediate filaments and S100 protein on immunohistochemistry
- Even though melanomas may appear malignant histologically, recurrence and metastasis is rare.

TREATMENT

- Surgical excision, even when histologically incomplete, often results in long-term local control.
- There are no effective treatments for metastatic melanoma.

MEDICATIONS

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

N/A

FOLLOW-UP

PATIENT MONITORING

Routine postoperative monitoring of the surgical site is recommended.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Scarring or hair loss at surgical site may impact the show quality of an animal.

EXPECTED COURSE AND PROGNOSIS

- Most (> 90%) melanomas have a benign course after excision and do not recur or metastasize.
- If truly malignant, recurrence and metastasis have been reported to occur within a few months.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

MELIOIDOSIS

BASICS

DEFINITION

- Melioidosis is a disease that affects a wide variety of animal species. However, severe disease is most commonly seen in sheep and goats.
- It is caused by the bacterium *Burkholderia pseudomallei*, an opportunistic, aerobic, gram-negative motile bacillus.
- The disease causes caseous abscesses of the lungs and respiratory disease. In disseminated forms, lameness, arthritis or encephalitis may also be seen.
- Goats are also prone to mastitis from this organism.

PATHOPHYSIOLOGY

- Melioidosis is caused by *B. pseudomallei*, an aerobic, gram-negative motile bacterium. It is an opportunistic pathogen that produces exotoxin.
- Disease can develop from the exotoxin produced by the organism (acute disease) or from the survival of the organism within phagocytic cells (latent or chronic form of disease).

SYSTEMS AFFECTED

- Respiratory—caseous lung abscesses, pneumonia, dyspnea
- Musculoskeletal—lameness, arthritis
- Nervous—encephalitis
- Mammary—mastitis (in goats)

GENETICS

N/A

INCIDENCE/PREVALENCE

- Outbreaks and cases typically occur in endemic areas during the wet season or after periods of heavy rainfall in areas with high humidity or temperature.
- The organism is typically ingested or inhaled from contaminated soil or water by animals.
- Limited cases of transuterine transmission have been reported.

GEOGRAPHIC DISTRIBUTION

Melioidosis is endemic in tropical and subtropical regions, particularly southeast Asia, northern and central Australia, the Middle East, India, China, and the Caribbean.

SIGNALMENT

Species

Although melioidosis affects many species of animals, sheep and goats are the most severely affected species. Cattle are rarely affected.

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

Incubation is variable ranging from a few days to many years.

HISTORICAL FINDINGS

N/A

PHYSICAL EXAMINATION FINDINGS

- *Sheep*: Fever, generalized weakness; respiratory distress or dyspnea, severe coughing, mucopurulent nasal discharge; possibly lameness with swollen joints or partial paralysis. Neurological signs may include circling, incoordination, nystagmus, spasms.
- *Goats*: More commonly develop chronic disease and lameness, lymphadenopathy, mastitis, possibly respiratory signs (less severe than in sheep).
- *Cattle*: Rarely affected

CAUSES

Transmission of *Burkholderia pseudomallei* is most commonly through contact with infected soil or water, either by contamination of open wounds or cuts or by inhalation or ingestion. Person-to-person and animal-to-person transmission can occur but is very rare.

RISK FACTORS

The primary risk factor for melioidosis is exposure to the contaminated soil or water in endemic areas during the wet season or after periods of heavy rainfall in areas with high humidity or temperature.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Tuberculosis
- Caseous lymphadenitis
- Actinobacillosis

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Diagnosis of melioidosis is difficult but may be suspected at necropsy (see below).
- Although there are no pathognomonic lesions for the disease, isolation and identification of the organism should be attempted from swabs of nasal discharge and/or abscesses.
- Organisms may also be found in the feces or milk of infected animals.
- Additionally, serological tests (e.g., ELISA, indirect hemagglutination tests, and immunofluorescent tests) may also be used for diagnosis; however, cross-reactions can occur with *B. mallei* (causative agent for glanders).

PATHOLOGIC FINDINGS

- On necropsy, multiple abscesses may be found in any organ, but particularly the lungs, liver, spleen, and lymph nodes.
- Purulent material from the abscesses is thick or caseous and green tinged.
- Polyarthritis may also be seen.

TREATMENT

Treatment is often expensive, prolonged, and unsuccessful. Prevention of the disease is the best method of approach.

APPROPRIATE HEALTH CARE

METABOLIC PROFILING

BASICS

OVERVIEW

- A “metabolic profile” is defined as a series of specific analytical tests run in combination and used as a diagnostic aid. Use of a metabolic profile is the result of technologic improvements in analytical instrumentation, which can complete multiple analyses in a short time period.
- Application of this diagnostic procedure on a herd basis has been questioned relative to its validity and sensitivity in defining a problem as well as its cost.
 - Although diet and metabolic status influence fertility, many other factors confound interpretation.
 - Diet influences nutritional status, but interpretation of metabolic parameters relative to diet must be undertaken under controlled sampling procedures and with an understanding of underlying physiology and metabolism.
 - In spite of past concerns about validity of metabolic profiling, recent advances in our understanding of physiologic and metabolic changes associated with the transition from pregnancy to lactation and improved metabolic tests have increased the diagnostic potential of metabolic profiling.

DIAGNOSIS

CBC/BIOCHEMISTRY/URINALYSIS OTHER LABORATORY TESTS

Rationale for Test Use

- Blood analytes are influenced by nutritional and metabolic state of the animal. Relationship between dietary intake and blood nutrient concentrations have been well documented in experimental research under controlled conditions.
- Metabolic profiling can potentially provide a more direct confirmatory evaluation of metabolic health in relation to nutrition.
- *Assess nutritional status of feeding group or herd.* Ration evaluation is the cornerstone of herd nutritional assessment, but

can be fraught with uncertainty. Metabolic profiling can be used to complement dietary evaluation procedure.

- Evaluate current feeding program adequacy.
- Evaluate response to a change in feeding program.
- *Identify potential risk for disease problems.* Specific blood analytes that are either high or low relative to reference values prior to calving or immediately postpartum can predict potential for increased risk of having periparturient disease problems.
- *Identify disease conditions early.* Metabolic profiling can be used to assess prevalence of subclinical metabolic disease in the absence of obvious clinical disease problems.
- *Survey for potential causes of disease problems.* Metabolic profiling can be used as a screening tool to direct the focus of a herd investigation. Results do not necessarily suggest diet is the problem source, but can help to focus more intensive investigation of potential causes of a current problem.

Application

- Metabolic profiling should not be a stand-alone diagnostic test, but part of an integrated diagnostic system including the following:
 - *Records analysis*—provides a historical and present perspective on the herd including animal inventories, clinical disease prevalence, production, milk composition, dry matter intake, and youngstock.
 - *Animal evaluation*—General appearance and attitude, cud chewing activity, body condition scoring, manure characteristics, and lameness scoring.
 - *Facilities evaluation*—Ventilation, cow comfort assessment (overcrowding, stall usage), stall design (size and bedding type), feed bunk design (space per animal, management), and water (sources, availability and quality).
 - *Dietary evaluation*—for diets on the farm
1. Formulated diet is the one generated as the goal for feeding. To evaluate, compare nutrient composition to NRC recommendations adjusted to environment.
 2. Mixed and delivered diet is the one placed into the feed bunk for consumption. To evaluate, compare nutrient density to formulated diet and particle size to individual ingredients. Also evaluate consistency of mix within feed bunk.
 3. Consumed diet is that portion of the delivered diet consumed by the cows. To evaluate, compare nutrient content and particle size between delivered and refused feed in bunk.
 4. Digested and absorbed diet is the proportion of the consumed diet that is available to the cow to support metabolic functions. To evaluate, compare production response to predictions of dynamic rumen models or use metabolic profiling.

Species Orientation

- Herd-based use of metabolic profiling has predominately been applied to dairy farms
- Larger dairy farms (>150 milking cows) are generally more willing to utilize metabolic profiling as a diagnostic tool as they can distribute the cost over more animals and can gain more opportunity dollars in preventing disease.
- Concepts and principles of metabolic profiling can be applied to other agricultural production systems including beef cattle, sheep flocks and goatherds.

Limitations

- *Costs*—Total costs associated with metabolic profiling may limit the use of this diagnostic testing strategy. Costs will range from \$17 to \$50 per sample depending upon the number of blood analytes measured. One can either reduce the number of tests or number of sampled animals to reduce costs, but this will compromise the quality of information to be derived. Diagnostic laboratories at a subsidized cost of \$200–\$400 offer traditional Compton Metabolic Profiles or some variation thereof.
- *Herd size*—Smaller herds, especially those of less than 100 cows will not have a large enough population of animals to be sampled within a defined physiologic state.
- *Availability*—A limited number of laboratories provide metabolic profiling and interpretation, especially in the United States.
- *Interpretation of results*—Blood analyte concentrations for metabolic profiling must be interpreted differently than for individual animal disease diagnosis. Different reference ranges must be developed.
- *Analyte variability*—A variety of factors can introduce variability into blood analyte concentrations and reduce ability to interpret differences relative to nutritional status. A number of important variability factors can be controlled by careful grouping strategies and sample collection and handling, thus maximizing the observed differences primarily due to

environment, namely nutrition.

- Random biologic variation
- Genetic variation
- Physiologic state (i.e., growth, lactation stage, gestation stage)
- Circadian or seasonal variation
- Health status
- Sampling error or mishandling—especially hemolysis
- Analytical technique—variation in laboratory methods
- Environment—herd-specific nutrition and management

DIAGNOSTIC EVALUATION

Approach

- Although inherently similar relative to the use of automated determinations of blood analytes, metabolic profiling is a different approach compared to diagnostic clinical chemistry analyses (“serum profiles”).
- Blood chemistry profiles are commonly used in all veterinary hospitals as an aid in diagnosis of individual animal health problems.
 - Population selected for blood sampling is sick animals.
 - Results are compared to standard laboratory reference ranges (healthy population mean two standard deviations) to determine those outside the reference range.
 - Identified abnormal blood analytes are used to diagnose disease conditions (i.e., hypocalcemia, ketosis, hypoglycemia).
- Metabolic profiling uses these same blood analytes to assess potential for metabolic disease and nutritional status.
 - Population selected for blood sampling is a large number of healthy animals within specified age and physiologic groups within the herd.
 - Controlled research has shown specific blood analytes to reflect dietary intake
 - Metabolic profiling can be used to assess group/herd nutritional status and potential risk for disease problems.

Methods Used

- Metabolic profiling should not be a random sample collection process followed by measurements of various blood analytes. One should have a plan in mind in approaching a problem.
 - Define a problem by asking a specific question relative to a problem. This is akin to defining a scientific hypothesis and then setting up an experimental design to test the hypothesis.
 - Consider pertinent comparisons of interest relative to the defined problem and identify which populations of animals are of concern.
- Survey evaluation—Use of metabolic profiling as a broad-based diagnostic tool to identify potential problem areas or assess overall nutritional status.
 - Individual sampling
 1. Randomly select an appropriate number (7–10) of “healthy” cows within defined parity and physiologic stage-based groups for evaluation.
 2. Measured analytes can be interpreted relative to calculated mean value compared to reference value or percentage of individuals above or below a defined threshold value.
 3. Due to cost constraints, either number of groups tested or analyte numbers are reduced, thus limiting the scope of the metabolic profile.
 - Pooled sample technique
 1. Individual samples can be pooled by defined groupings and a “mean” value determined by analysis.
 2. By pooling samples, you are obtaining information from a greater number of animals for much less cost.
 3. Limitations to this methodology are loss of statistical evaluation (i.e., population variance) and issues of interpretation.
- Targeted diagnostics—Use of specific individual tests to identify potential disease problems.
- Threshold criteria—measured analyte has a defined value in which samples either above or below this value suggest increased risk for a disease process. Collect 12 samples and if 3 or more samples are beyond the threshold value, then the sampled population is at risk for a given disease process.

1. NEFA—values greater than 0.4 mEq/L in prefresh cows are suggestive of potential risk for a variety of postpartum metabolic diseases.
2. BHB—values greater than 14.4 mg/dl (1.4 mmol/L) in fresh cows are suggestive of subclinical ketosis problems in the herd.
3. Rumen pH—values less than 5.5 pH units in any cow are suggestive of subacute ruminal acidosis problems.

Table 1

Description of Blood Collection Tubes Used for Metabolic Profiles			
Stopper Color	Additive	Sample Obtained	Intended Use/Disadvantages
Red	None	Serum	Routine use for all tests. Prolonged clot exposure results in increased glucose, Ca and decreased phosphorus. Hemolysis problems in poorly handled samples.
Gray	Na fluoride or K oxalate	Serum	Glycolytic Inhibitor for sensitive glucose analysis
Royal blue	Plastic stopper Na heparin	Serum, plasma or whole blood	Trace mineral analysis, especially Zn
Lavender	EDTA	Whole blood, plasma	Routine use for Complete Blood Count/EDTA chelates Ca, Mg, and increased enzyme activities.
Green	Na heparin	Plasma, whole blood	Routine analyses for either plasma or whole blood / no effect on metabolites

- Mean analysis—measured analyte can be interpreted as a mean for a defined group of animals relative to a predefined reference range. Group means can both be above or below the reference range and be associated with problems.

1. Urea nitrogen—mean values below 10 mg/dl and above 16 mg/dl are of concern.

2. Urine pH—mean values should be between 6.5 and 7.0 or 6.0 and 6.5 pH units for prefresh Holstein or Jersey cows, respectively.

Animal Selection

- For metabolic profiling, the selected population of cows to be sampled should be apparently “healthy” cows. Cows without clinical disease signs may have metabolic measures consistent with subclinical disease, which may be masked when combined with results from clinical disease cows.
- To address a fresh cow problem, samples are collected from:
 - Early dry cows: defined as > 10 days following dry-off and < 30 days prior to expected calving
 - Close-up dry cows: defined as 3 to 21 days prior to expected calving
 - Fresh cows: defined as 3 to 30 days in milk
- To address a specific disease problem: clinically affected cows can be sampled and compared to normal cows that are matched according to parity and stage of lactation.

Sample Collection Procedures

- Blood samples should be taken from either jugular or coccygeal veins with a minimal amount of stress. Lower concentrations of P and K have been documented in jugular compared to coccygeal blood samples as a result of salivary gland uptake. Blood samples from the mammary veins are not appropriate given the loss of nutrients into the mammary gland.
- Time of sampling relative to feeding and feeding management may also influence metabolite concentrations and should be considered in the decision process of when to sample.
 - NEFA, glucose are best sampled prior to first feeding.
 - BHB, UN are best sampled 3 to 5 hours following a feeding.
- If herds are being repeatedly sampled as a monitoring tool, samples should be taken at approximately the same time of day to minimize diurnal and prandial variation.
- Vacuum tubes are colored coded for specific diagnostic test procedures based on the specific anticoagulant or additive present in the tube ([Table 1](#)). Plasma from green-top tubes is generally preferred, but red-top (serum) tubes can be used. It is best to ask the laboratory which sample is preferred.

- Extreme efforts should be taken to prevent hemolysis of the sample. All samples should be iced, but not frozen, immediately after collection and kept refrigerated until processed. For serum samples, the clot should be removed as quickly as possible (within hours of collection).
- All samples should be properly identified with animal and group identification and date of collection.
- Other pertinent information for interpretation of the metabolic profile would include animal age, lactation number, milk production level, milk composition, days in milk, pregnancy status, and body condition score.

METALDEHYDE TOXICOSIS

BASICS

OVERVIEW

- Metaldehyde poisoning is characterized by the abrupt onset of severe neurologic signs.
- Metaldehyde is widely used for the control of slugs and snails. In some countries (outside the United States), metaldehyde is also used as a solid fuel in camping stoves and lamps.
- Available formulations include pellets, granules, liquids, or wettable powder. Baits may also contain other pesticides such as insecticides. The concentration of metaldehyde in baits sold in the United States is generally between 1.5% and 5%.
- Metaldehyde poisoning in ruminants is reported infrequently but has occurred in cattle, sheep, and goats.
- The onset of clinical effects may occur as soon as 30 to 60 minutes after ingestion and death may be seen as soon as 1 hour.
- The poisoning is commonly referred to as the “shake and bake syndrome” because of the development of tremors and hyperthermia in affected animals.
- Metaldehyde toxicosis results in the disruption of the GABA-ergic system and may also involve other neurotransmitters.
- The oral lethal dose of metaldehyde in sheep is estimated to be 300 mg/kg body weight and 200 mg/kg body weight in cattle.

SIGNALMENT

- All ruminant species are susceptible to metaldehyde.
- Cases in cattle, sheep, and goats are reported infrequently. Most reported cases involve dogs.

SIGNS

- Signs of poisoning generally begin within 30 to 60 minutes of exposure.
- Initial clinical signs include salivation, tremors of the fore and hind legs, staggering, and respiratory distress.
- This is quickly followed by weakness, ataxia, hyperventilation, hyperthermia, and convulsions. In severe cases, the animals become recumbent, unconscious, and show continuous convulsions with leg paddling.
- Disseminated intravascular coagulation may occur as a result of severe hyperthermia (body temperature may reach 110°F).
- Death may occur within 60 minutes of exposure as a result of respiratory failure.

CAUSES AND RISK FACTORS

- Geographic areas with a high slug and snail population present a greater risk due to the increased use of metaldehyde baits.
- Bran or molasses is commonly added to the bait to increase its palatability. However, some baits have chemicals added to make them less likely to be ingested by species other than slugs and snails.
- Wild ruminants with access to metaldehyde baits are at risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cyanide toxicosis—initially bright cherry-red blood, history of exposure to cyanide-containing plants
- Nitrate toxicosis—chocolate-brown discoloration of blood, history of exposure to nitrate-containing plants
- Lead poisoning—determination of blood lead concentration

- Organophosphorus or carbamate insecticide exposure—commonly associated with gastrointestinal upset and neurological signs, evaluation of cholinesterase activity, detection of pesticides in gastrointestinal contents
- Exposure to neurotoxic plants, such as poison hemlock, water hemlock, tree tobacco, lupine—history of presence of plants in the environment and identification of plant parts in gastrointestinal contents, chemical analysis for plant toxins in gastrointestinal contents
- Exposure to cardiotoxic plants, such as oleander, milkweed, and azalea—chemical analysis for plant toxins in gastrointestinal contents, history of presence of plants in the environment
- Nonprotein nitrogen toxicosis—history of NPN supplements in the feed ration, detection of toxic levels of ammonia in rumen content and blood
- Strychnine toxicosis—history of exposure to strychnine-containing bait, detection of strychnine in gastrointestinal contents or liver
- 4-Aminopyridine—history of exposure to the avicide, detection of 4-aminopyridine in gastrointestinal contents
- Neurotoxic blue-green algae toxins—peracute onset, access to pond water, detection of anatoxin-A in gastrointestinal contents
- Seizures—nontoxic etiologies (e.g., trauma, neoplasia, infection, metabolic disorder)

CBC/BIOCHEMISTRY/URINALYSIS

- No specific clinical pathologic changes occur.
- Metabolic acidosis may be present.

OTHER LABORATORY TESTS

Detection of metaldehyde in serum, urine, rumen content, or liver. Confirmation of metaldehyde in suspect material.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- There are no clearly distinctive changes due to the rapidity of death.
- Generalized renal, hepatic, and pulmonary congestion.
- Petechial and ecchymotic hemorrhages in the heart, lung, and gastrointestinal tract.
- Metaldehyde has a characteristic odor of formaldehyde that may be present in the rumen contents along with bait material.

TREATMENT

- Metaldehyde poisoning progresses so rapidly that immediate treatment is necessary.
- Control of CNS signs and hyperthermia is essential. Decontamination with activated charcoal should be considered after initial stabilization of the poisoned animal.
- Fluid therapy should be instituted to control acidosis and dehydration.
- Any possible stress should be avoided.

MEDICATIONS

DRUGS OF CHOICE

- No antidote available
- Pentobarbital at 20–30 mg/kg IV or diazepam at 0.5–1.5 mg/kg IV for control of seizures
- Lactated Ringer's or sodium bicarbonate solutions IV
- Activated charcoal at 2 g/kg orally

CONTRAINDICATIONS

- Pentobarbital can cause respiratory depression.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

Monitor progression of clinical signs

PREVENTION/AVOIDANCE

- Avoid metaldehyde-containing baits in areas accessible to livestock.
- Use bait according to label instructions.
- Consider the use of less-toxic alternatives to control slugs and snails.

POSSIBLE COMPLICATIONS

Renal and hepatic disease may develop if poisoned animal survives the initial convulsive phase.

EXPECTED COURSE AND PROGNOSIS

- Animals poisoned with metaldehyde may be found dead.
- Metaldehyde poisoning progresses so rapidly that treatment is often too late. In most cases, the affected animals have a poor-to-grave prognosis.
- If treatment is initiated promptly after the onset of clinical signs, the prognosis is fair.

METRITIS

BASICS

OVERVIEW

- Metritis is an inflammation of all layers (endometrium, myometrium, and serosa) of the uterus during the postpartum period.
- This condition is more commonly seen in dairy cattle.
- Economic losses from metritis are associated with systemic diseases that occur during the first few weeks postpartum.
- Affected cows become pyretic, have a fetid purulent discharge from the uterus, and in some cases the condition can become septic and life threatening. In addition, cows with metritis are more likely to develop other postpartum disorders such as ketosis, displacement of the abomasum, endometritis, and pyometra.
- Cows with metritis usually go off feed, produce less milk, and experience a delay in days to first service, lower conception rates, and increased days open.

PATHOPHYSIOLOGY

- The vulva, vulvar sphincter, and cervix are mechanical barriers that protect the uterus from bacterial contamination. However, during parturition and shortly thereafter, these barriers break down and allow pathogenic and nonpathogenic bacteria to contaminate the uterus. Most of these bacteria are transient residents and are eliminated by the defense mechanisms of the uterus.
- The bacterial population is mixed and consists of both aerobic and anaerobic gram-negative and gram-positive organisms.
- The most common organisms associated with metritis are *Arcanobacterium (Actinomyces) pyogenes*, *Fusobacterium necrophorum*, *Bacteroides melanogenicus*, *Escherichia coli*, and *Staphylococcus aureus*. *Bacteroides* decreases chemotaxis-inhibiting phagocytosis by neutrophils allowing *A. pyogenes* to persist. Occasionally, *Clostridium* spp. infects the uterus and causes a gangrenous metritis.
- In cows with a normal parturition, the uterus resolves the bacterial infection by 4 weeks postpartum. However, in cows affected with dystocia, retained fetal membranes, and delivery of twins, the bacterial contamination may become more severe and persistent.
- Unsanitary calving conditions and traumatic obstetrical manipulation can also predispose the cow to uterine infections.
- Because of differences in husbandry practices and stress from lactation, postpartum metritis is more commonly seen in dairy cows than beef cows.

SYSTEMS AFFECTED

- Endocrine/metabolic
- Herd health
- Reproductive

GENETICS

Due to differences in calving environment and stress from lactation, metritis is more commonly seen in dairy than in beef cattle or other ruminant species.

INCIDENCE/PREVALENCE

- The postpartum incidence of metritis varies among reports and with the definition criteria used for diagnosis.
- A mean of 17% with a range of 8.8% to 24% has been reported. About one-half of the cows with an abnormal parturition (dystocia, retained fetal membranes, twins) can be expected to develop metritis.

GEOGRAPHIC DISTRIBUTION

Worldwide; in hot, warmer climates the incidence of metritis may be higher due to the effect of heat stress.

SIGNALMENT

Species

More commonly seen in bovine than in caprine or ovine species.

Breed Predilection

Dairy cattle

Mean Age and Range

Reports are conflicting as to the effect of parity on incidence. However, most agree that the incidence is higher in primiparous than multiparous animals.

SIGNS

GENERAL COMMENTS

- Clinical signs of metritis are influenced by the virulence of the bacteria and predisposing risk factors.
- During the first few weeks postpartum, lochia is normally expelled from the reproductive tract. Lochia is red to brown in color and should not be considered abnormal.
- Discharges from the reproductive tract should only be considered abnormal when they are fetid, serous, or purulent with accompanying systemic signs.

HISTORICAL FINDINGS

Metritis occurs more commonly in those cows that experienced an abnormal parturition and they should be monitored carefully during the first 2 weeks postpartum. Affected cows are usually off feed, have low milk production, and appear depressed.

PHYSICAL EXAMINATION FINDINGS

- Fever ($> 103.0^{\circ}\text{F}$ or 39.4°C)
- Partial or complete anorexia
- Low milk production
- Lethargy or depression
- Fetid serosanguineous discharge from the reproductive tract
- Ketosis
- Displaced abomasum
- Mastitis

RISK FACTORS

- Fat or overconditioned animals
- Retained fetal membranes
- Dystocia
- Twins
- Abortion
- Weather

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Normal discharge from the uterus or lochia
- Endometritis

CBC/BIOCHEMISTRY/URINALYSIS

- In cows with a septic metritis, a degenerative left shift accompanied with a neutropenia
- Hypocalcemia
- Hypoglycemia
- Ketonemia

OTHER LABORATORY TESTS

Bacterial culture and sensitivity

IMAGING

Real-time ultrasonography can be used to illustrate postpartum uterine changes related to infection.

- Uterine lumen fluid associated with infection contains echogenic particles.
- Uterine wall appears more thickened.

DIAGNOSTIC PROCEDURES

A vaginal examination with a speculum can be used to characterize the type of exudates from the uterus.

PATHOLOGIC FINDINGS

Necropsy findings in cows that die from toxic or septic metritis: peritonitis; friable, gangrenous uterus

TREATMENT

APPROPRIATE HEALTH CARE

- Because of the differences in diagnostic criteria and the lack of controlled studies, treatment of this condition remains controversial among clinicians.
- Most cases of metritis do not require inpatient medical management and can be successfully treated and managed medically on the farm.
- Therapy generally includes antibiotics (systemic and or intrauterine) and hormonal and supportive treatment for hypocalcemia or ketosis.

NURSING CARE

Fluid and electrolyte replacement therapy may be indicated in cows with septic or toxic metritis.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

Clients should be educated on management strategies to help reduce risk factors in parturient animals.

SURGICAL CONSIDERATION

N/A

MEDICATIONS

DRUGS OF CHOICE

- A variety of broad-spectrum antibiotics is recommended for systemic administration in cows with metritis, particularly those that are pyretic. Label recommendations to avoid antibiotic residues in salable milk should be followed when systemic antibiotics are used.
 - Penicillin or a synthetic analog: 20,000 to 30,000 IU/kg bid
 - Ceftiofur: 1–2.2 mg/kg bid
- Intrauterine antibiotic administrations with penicillin or oxytetracycline are used by some clinicians with questionable efficacy. The author is not aware of any antibiotic that is approved for intrauterine use in the United States.

CONTRAINDICATIONS

- Systemic oxytetracycline is not recommended because of difficulty in reaching the minimal inhibitory concentration required for *A. pyogenes* in the uterine lumen.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Sanitary conditions and prevention of genital tract trauma must be carefully considered when intrauterine antibiotics are used.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

Hormones such as estrogens and oxytocin have been used to increase uterine contractions and help evacuate uterine contents.

- Research is lacking that supports the use of these hormones for the treatment of metritis.
- Estrogenic compounds have been used to improve uterine contractions. Contractions induced by estrogen have been associated with flushing septic uterine contents into the uterine tubes.
- Oxytocin causes contraction of the postpartum uterus if it is used within 48 hours after calving. Doses of 20–40 IU repeated every 3 to 6 hours are generally used.

FOLLOW-UP

PATIENT MONITORING

Metritis patients should be monitored for development of ketosis, displaced abomasum, and mastitis. In addition, if the condition does not improve by 3 days of antibiotic treatment, an alternative antibiotic should be considered.

PREVENTION/AVOIDANCE

- To prevent the incidence of risk factors, producers should follow routine monitoring of prepartum cow management strategies.
- Postpartum health monitoring during the first 2 weeks postpartum should include rectal temperature, milk production monitoring, and attitude to help diagnose and treat the condition early.

POSSIBLE COMPLICATIONS

- Septicemia
- Ketosis
- Displaced abomasum
- Mastitis

EXPECTED COURSE AND PROGNOSIS

Cows treated promptly can be expected to recover fully from metritis. However, milk production and reproductive performance are affected in the current lactation. In some cases, cows can develop uterine abscesses and pyometra.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Ketosis, displaced abomasum

AGE-RELATED FACTORS

In general, incidence of metritis is greater in primiparous than multiparous animals.

MICROPTHALMIA

BASICS

OVERVIEW

- The term “microphthalmia” encompasses all conditions where the globe, palpebral fissure, eyelids, and intraocular structures are abnormally small.
- This condition occurs occasionally and can be unilateral or bilateral.
- In severe cases, the microphthalmic eye may be represented only by a tiny, melanotic cyst, which is embedded in the orbit with a permanently closed eyelid. In less-severe forms, there may be a small, but well developed eye with normal vision; this is called nanophthalmia.
- Varying degrees of severity and functional deficits exist, and may be associated with one or multiple ocular structures affected.
- It may be associated with other body system anomalies, such as with posterior vertebral column disease in dairy and beef cattle.

PATHOPHYSIOLOGY

- Microphthalmia in Texel sheep has its lesional morphogenesis during embryonal development.
- In one study, the microphthalmic eyes showed an anteriorly located conus-shaped mass composed of connective tissue with cartilage, smooth muscle, and fat tissue, particularly in the posterior part of the conus, and often islets of lacrimal glands and cystic structures lined with squamous epithelium in the anterior part.
- The iris, ciliary body, and ciliary processes were incorporated in the periphery of the broad base of the conus. The study showed an abnormal development of the lens vesicle. In a later stage (45 days), a conus-shaped mass was seen in the anterior part of the eyes, which at 56 days consisted of mesenchymal tissue with focal differentiation to cartilage and epithelial structures in the anterior part of the conus. The primary event proved to be abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 and in the newborn lambs seemed to be remnants of the epithelial lens vesicle.

SYSTEMS AFFECTED

Ophthalmic

GENETICS

- Congenital microphthalmia has occurred in Texel sheep in New Zealand, and is likely inherited as an autosomal recessive trait.
- May be heritable in shorthorn cattle
- Often associated in Hereford cattle with congenital hydrocephalus and appears to be a simple autosomal recessive trait

INCIDENCE/PREVALENCE

- In one study, 10% of Texel sheep were found to carry the recessive gene defect.
- One or both eyes may be affected.

GEOGRAPHIC DISTRIBUTION

Microphthalmia occurs in all ruminants and has a worldwide distribution. It is one of the most frequently encountered ocular anomalies of ruminants.

SIGNALMENT

Species

Has been reported in sheep, goats, cattle, and white-tailed deer.

Breed Predilections

- Texel sheep and shorthorn cattle

- Often associated in Hereford cattle with congenital hydrocephalus and appears to be a simple autosomal recessive trait.

Mean Age and Range

N/A

Predominant Sex

N/A

CAUSES AND RISK FACTORS

- Multiple etiologies are suspected, including a genetic inherited defect in white shorthorn cattle and as a possible sequelae to teratogenic agent exposure.
- Often associated in Hereford cattle with congenital hydrocephalus and appears to be a simple autosomal recessive trait.
- May be a sequelae of calves born from cows with in utero infections of bovine viral diarrhea.
- *Veratrum californicum*, skunk cabbage, western hellebore, false hellebore, and wild corn may also predispose to microphthalmia. Alkaloids in the plant roots seem to affect globe development. Sheep are considered more susceptible than goats and goats more than cattle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Veratrum californicum*—skunk cabbage, western hellebore, false hellebore, wild corn
 - Sheep > goats > cattle
 - Alkaloids found in plant and concentrated in root (jervine, pseudojervine, veratrosine)
 - Globe abnormalities include anophthalmia, cyclopia, and synophthalmos
 - Highly susceptible on gestational day 14
 - On days 11,12,13,15, and 16, normally developed fetuses or embryos that die between 18th and 23rd day of development
- Selenium “blind staggers” in sheep
 - Microphthalmia, multiple cysts, colobomas, cornea, lens, iris defects; felt to be sulfur-related polioencephalomalacia (PEM)
- Maternal vitamin A deficiency: found in pigs; primarily microphthalmia; anophthalmos, macrophthalmia, retinal dysplasia may also occur.
- Other conditions
 - Bluetongue virus—sheep; ocular lesions induced by modified- live vaccine use in pregnant sheep
 - Bovine viral diarrhea—cataracts, retinal degeneration and dysplasia, optic nerve gliosis and neuritis, microphthalmia
 - Congenital cataracts reported in cattle, sheep, rare in goats. Autosomal recessive in several breeds: Jersey, Hereford, Holstein-Friesian. Can be associated with microphthalmia and retinal lesions from in utero exposure to BVD, 76–150 days of gestation
 - May be secondary to inflammation, toxins, metabolic disease
 - Cattle—secondary to IBK, malignant catarrhal fever, IBR

MIDDLE UTERINE ARTERY RUPTURE

BASICS

OVERVIEW

- Middle uterine artery rupture is a rare, acute, life-threatening hemorrhagic event encountered in ruminants associated with parturition.
- Rupture is more commonly seen in association with forced fetal extraction or fetotomy compared to simple uncomplicated delivery.
- Rarely, it may accompany correction of uterine torsion using the “plank in the flank” technique.

SYSTEMS AFFECTED

Hemolymphatic

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Dairy cattle; potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

Female

SIGNS

- Sudden death during or soon after parturition may be the only signs noted.
- Severe blood loss anemia may give rise to tachycardia, tachypnea, and signs of anxiety immediately preceding death.
- Occasional cases may occur subsequent to uterine prolapse, particularly in multiparous cows; in these animals death may occur soon after, or during, repositioning of the everted uterus.

DIAGNOSIS

- Usually a postmortem diagnosis, demonstrating the location of the rupture within the uterine artery
- Antemortem it may be presumptive based upon severe pallor of mucous membranes and corroborative clinical evidence of anemia (elevated heart and respiratory rates) immediately following dystocia.
- Rectal palpation may reveal large soft tissue swelling (hematoma) within the broad ligament on the affected side.
- In cases of arterial rupture coincident with uterine rupture, hemorrhage may be evident at the vulva, but otherwise external evidence of hemorrhage is absent.
- Some less-severe cases are diagnosed days to weeks after parturition by incidental rectal findings of a soft tissue mass within the broad ligament and/or a corresponding defect or aneurysm in the miduterine artery.

DIFFERENTIAL DIAGNOSIS

- Acute blood loss anemia from other internal site (large abdominal, pelvic, or thoracic vessel hemorrhage)
- Acute septic peritonitis due to uterine rupture.

CBC/BIOCHEMISTRY/URINALYSIS

- Affected cattle may die so peracutely that diagnostic procedures are redundant.
- If the animal survives the first few hours, routine blood work may show evidence of blood loss anemia.

OTHER LABORATORY TESTS

N/A

IMAGING

Rectal ultrasound will show a variably sized heterogeneous soft tissue mass within the broad ligament on the affected side. Ultrasound may also demonstrate a defect in the affected miduterine artery.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Grossly, the miduterine artery will be ruptured on the affected side with accompanying massive hemorrhage into the broad ligament.
- Hemoabdomen may also be noted grossly.
- Extreme pallor of mucous membranes

TREATMENT

- Whole blood transfusion (6–12 liters)
- Hypertonic saline given intravenously (2–4 ml/kg of 7% sodium chloride) may be of acute resuscitative value.
- Intravenous oxytocin (20–100 IU) to promote uterine contraction and involution—may be given repeatedly.
- Intravenous formalin—500 ml of normal saline to which 10 ml of formalin has been added; questionable value; contamination of meat and milk issues, no determined withhold time.
- Aminocaproic acid (10–20 mg/kg, diluted in 1 liter of normal saline and given slowly intravenously)
- Vessel ligation may be tried but will be possible only if a full thickness uterine tear accompanies miduterine artery rupture.
- Keep affected individuals in close confinement with box stall rest to promote clot formation and stabilization.

MEDICATIONS

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

MILK VEIN RUPTURE

BASICS

DEFINITION

Hemorrhage from the caudal superficial epigastric vein (milk vein).

PATHOPHYSIOLOGY

- The milk vein is a common site for veinapuncture by laypeople because it is very superficial cranial to the mammary gland on the ventral abdomen. It is an especially convenient vein for farmers and workers treating down cattle for conditions such as milk fever (hypocalcemia). The vessel is only thinly covered by skin and subcutaneous tissue.
- Perivascular hemorrhage or leakage of irritating products such as calcium, dextrose, or antimicrobials can cause small abscesses or fibrous tissues that weaken the covering over the milk vein, sometimes resulting in rupture.

SYSTEMS AFFECTED

Cardiovascular

SIGNALMENT

Species Affected

Bovine

Breed Predilections

N/A

Mean Age and Range

Usually adults after IV treatment

Predominant Sex

Females secondary to the propensity for hypocalcemia treatment

SIGNS

Bleeding from either of the caudal superficial epigastric veins

GENERAL COMMENTS

N/A

HISTORICAL FINDINGS

IV treatment in the milk vein some time prior to hemorrhage. May see an increased incidence during times of biting flies and other insect activity due to bunching of cattle and increased leg kicking for fly avoidance.

PHYSICAL EXAMINATION FINDINGS

Hemorrhage from milk vein

CAUSES

Weakened tissue superficial to the milk vein

RISK FACTORS

Conditions requiring IV treatments, such as hypocalcemia, ketosis, or some mastitis treatments. Farmers treating cattle IV in milking parlors without adequate restraint tend to favor the milk vein.

MILKWEED (ASCLEPIAS SPP.) TOXICOSIS

BASICS

OVERVIEW

- Toxicity associated with ingestion of one of many *Asclepias* spp. (milkweed)
- There are over 100 species of *Asclepias* spp. growing naturally in North America and all are potentially toxic.
- Two mechanisms of toxicity (1) cardiovascular and gastrointestinal toxicity associated with cardenolides (cardiac glycosides) and (2) neuromuscular toxicity associated with neurotoxic pregnane glycosides.
- Milkweed is considered to be one of the most toxic plants in North America and has been associated with mortality rates of greater than 50% in sheep grazing milkweed for 24 hours or less.
- Distribution of plants varies by species, however there is at least one species present over most of the continent.
- Two leaf types are present and vary in their expression of the relative amounts of toxins:
 - Wide leaf varieties (i.e., *A. speciosa* and *A. syriaca*) are more commonly associated with cardiac and gastrointestinal toxicity. Toxicity is less common as they are only eaten when no other feed choices are available.
 - Thin leaf (< 1 cm wide) varieties (i.e., *A. fascicularis* and *A. subverticillata*), which contain higher levels of the neurotoxin and are consumed more commonly due to their more palatable nature and the animal's difficulty in selectively not consuming them in hay.
- Plants are most toxic during rapid growth but retain their toxicity even when dried in hay. Toxicity tends to decrease with maturity.
- Clinical signs develop with consumption of 0.05%–2% of body weight depending on the species and toxin concentration of the plant
- The cardenolides produced by the wide leaf varieties inhibit the function of the Na^+/K^+ -ATPase pump and allow accumulation of Na and Ca inside the cell and depletion of intracellular K. This leads to abnormal membrane potentials and irregular action potential initiation.
- The mechanism of action of the neurotoxin is not known.

SIGNALMENT

- Sheep are most commonly affected.
- Can occur in any ruminant species
- Cattle require ingestion of twice as much toxin as sheep.
- Animals are consuming toxin-producing forages either in the field green or in hay.

SIGNS

- Vary with the species of plant consumed (i.e., neurotoxin-producing thin leaf or cardiotoxin-producing wide leaf), amount consumed, and duration of toxicity.
- Acute death may be the only clinical sign.
- Signs generally develop within 12 to 18 hours of ingestion of cardiac glycosides and may be immediate or delayed (i.e., 12 hours) with ingestion of neurotoxic compounds.
- Cardiac glycoside (cardiac and gastrointestinal toxin) symptoms include depression, weakness, reluctance to stand, enteritis, bloat, labored respiration with grunt, and possibly cardiac arrhythmias.
- Neurotoxic symptoms include depression, mydriasis, ataxia, weakness, pelvic limb paresis, humped-up appearance, rabbitlike gait, seizures, opisthotonus, and death due to respiratory failure.

CAUSES AND RISK FACTORS

- Ingestion of toxin-containing *Asclepias* spp. in pastures or hay
- Ingestion of neurotoxic compounds may be cumulative.

- Cattle on ionophore-containing diets may have an increased risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other sources of cardiac glycosides, including dogbane, Indian hemp, lily of the valley, foxglove, and oleander
- Other cardiotoxic plants including yew, rhododendron, and laurels
- Other neurologic diseases including heavy metal toxicosis, buckeye toxicity, dallis grass toxicity, traumatic nerve damage (calving paralysis), spinal column lymphosarcoma, and rabies
- Other causes of recumbency including fractures, hypocalcemia, hypomagnesemia, hypophosphatemia, and hypokalemia.
- Other causes of cardiac arrhythmias including traumatic reticulopericarditis, electrolyte disorder associated atrial fibrillation, cardiac neoplasia

CBC/BIOCHEMISTRY/URINALYSIS

There may be an increase in serum creatinine kinase activity. However, this is not a specific indicator for milkweed toxicity.

OTHER LABORATORY TESTS

- Evaluation of the pasture or hay for evidence of milkweed contamination. Careful examination for the narrow leaf varieties must be done, as they are often hard to identify due to their similarity to grasses even when contained in large quantities in hay.
- Analysis of urine, serum, tissue, and stomach contents for cardiac glycosides is available using high-performance liquid chromatography.

IMAGING

Echocardiography would be helpful in excluding other differential diagnosis. However, it is technically challenging and requires expensive equipment and thus is not routinely done.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Depends on the toxin consumed
- Cardiac glycoside toxicity is associated with a hyperemia with or without hemorrhage of the abomasum and small intestine, pulmonary congestion, acute ischemia associated glomerulopathy and tubular necrosis, and in some cases mild nonsuppurative myocardial cellular degeneration. Hemorrhage may be present on the surface of the lung, kidney, and heart.
- Ingestion of the neurotoxic compound is more difficult to determine on necropsy, but there may be evidence of external trauma; hemorrhages in the trachea, heart, and lungs; and often an empty urinary bladder.

TREATMENT

- If acute ingestion of large amounts of toxin are suspected, a rumenotomy to evacuate the ingesta may be beneficial.
- Other herd mates should be isolated from the source of the toxin (i.e., pasture or hay).

MEDICATIONS

DRUGS

- Orogastric intubation with activated charcoal, cathartics, or mineral oil may decrease intestinal absorption of the toxins and increase rate of excretion in feces.
- Administering balanced polyionic fluids as needed to maintain hydration and for renal diuresis may minimize effects of ischemic-induced kidney damage.
- Sedative and or anesthesia may be helpful in patients with severe convulsions associated with neurotoxin ingestion.

- Antiarrhythmic drugs such as procainamide, lidocaine, or atropine sulfate may be used in rare cases exhibiting arrhythmias. (Appropriate records for extralabel drug use must be maintained.)
- Appropriate drug withdrawal periods must be determined and maintained.

CONTRAINDICATIONS

Use of calcium-containing fluids is contraindicated as it may potentiate the affects of cardiac glycosides.

FOLLOW-UP

PATIENT MONITORING

- Evaluation of neurologic status and monitoring for seizure activity should be done frequently.
- Frequent auscultation of the heart should be performed to access for development of cardiac arrhythmias.
- Monitoring of urinalysis and serum chemistry for azotemia is indicated in patients that survive the acute toxicosis.

PREVENTION/AVOIDANCE

Prevent animals from grazing on pasture or eating hay containing milkweed.

POSSIBLE COMPLICATIONS

If the animals survive, they may develop acute to chronic renal failure.

EXPECTED COURSE AND PROGNOSIS

- Varies with amount of toxin ingested, duration of exposure, and response to treatment
- Most animals will start developing signs within 12 to 18 hours of ingesting toxin.
- If symptoms are severe, animals will often die within 24 hours.
- If animal develops seizures and convulsions, the prognosis is grave.
- If animals survive the first 24–36 hours, they often will remain weak for a period of time before improving.

MISCELLANEOUS CONDITIONS OF THE HOOF WALL

BASICS

OVERVIEW

- There are some conditions that may affect the hoof wall of cattle that may result in severe lameness; however, most of the lesions are cosmetic with little significance for the animal, but because the lesions are so obvious to the producer they may be regarded as a serious problem.
- There are essentially three conditions of importance: (1) vertical fissures (sandcracks), (2) horizontal grooves (hardship lines), and (3) axial cracks.

SYSTEMS AFFECTED

Skin and musculoskeletal systems

GENETICS

Mean Age and Range

The prevalence of the lesions appears to be related to increasing age of the animal and increased weight.

Predominant Sex

N/A

SIGNS

Vertical Fissures

- Vertical fissures are a vertically orientated defect in the hoof wall of variable length. They are generally found on the cranio-abaxial aspect of the hoof and are most common on that lateral foreclaw.
- A classification of vertical fissures has been proposed:
 1. Fissure starts at the coronary band and extends a short way down the hoof wall.
 2. Fissure starts at the coronary band and extends more than half way down the hoof wall.
 3. Fissure starts at the coronary band and extends the entire length of the hoof wall.
 4. Fissure may start at any point on the hoof wall and extends all the way down to the toe.
 5. Fissure is found in the center of the hoof wall and extends neither to the coronary band or the toe.
- Vertical fissures are extremely common affecting more than 20% of adult beef cattle in some areas; however, they rarely result in lameness. The fissure in the hoof wall typically results in a marked thickening of the hoof capsule that prevents debris from reaching the sensitive corium.
- The thickening of the hoof wall may be so marked that dorsal surface of the pedal bone becomes remodeled. On occasion, debris may reach the corium and an abscess may develop resulting in severe lameness.
- The presence of an abscess may be confirmed based upon the fact that the hoof feels warm and there is a marked

response to focal pressure in the region of the sandcrack when “hoof testers” are applied.

Horizontal Grooves

- A horizontal groove is a groove found running around the circumference of the hoof capsule parallel to the coronary band. It may be found at any point on the hoof wall and be of variable depth. In extreme cases, the hoof capsule may fracture along the horizontal groove.
- In those affected, the distal portion of the hoof becomes a “thimble.”
- The distal portion typically remains attached to the underlying corium in the region of the toe and any movement of the “thimble” causes great pain.
- This condition is also occasionally referred to as a “hangnail.”

Axial Cracks

An axial crack is a full thickness vertical crack in the hoof wall found on the axial aspect of the hoof. The fact that the crack extends through the full thickness of the hoof wall is apparent, as there is typically a small amount of granulation tissue protruding from the fissure. Animals typically exhibit signs of great pain when the lesion is handled.

HISTORICAL FINDINGS

- Vertical fissures are seen almost exclusively in beef cattle, especially those on the western prairies of Canada. The prevalence of the lesions appears to be related to increasing age of the animal and increased weight.
- Horizontal grooves may be seen in cattle of almost any age and production type.
- Axial cracks are only seen in mature dairy cattle.

CAUSES AND RISK FACTORS

Vertical Fissures

- The cause of vertical fissures has been hotly debated for hundreds of years. The high incidence of this lesion has been explained by theories about nutritional deficiencies and horizontal grooves as a risk factor. Recent research has demonstrated that vertical fissure formation may be due simply to environmental effects. During long dry winters the hoof horn dehydrates.
- Biomechanical studies of equine hoof horn have shown that the fracture toughness of the horn decreases when the horn is dehydrated resulting in easier cracking. Consequently, vertical fissures may simply be a result of the environment in which we keep beef cattle.

Horizontal Grooves

- The wall horn of the hoof grows from the coronary band toward the toe at a rate of approximately 3 mm/month in beef cattle and 5 mm/month in dairy cows.
- Any metabolic insult (change in diet, illness, etc.) may result in a change in horn formation. As the wall horn grows out toward the toe, the changes in horn formation appear as grooves. The depth of the groove is dependent on the severity of the insult.
- In beef cattle, a common cause of horizontal grooves is spring turn out, when the diet changes from old hay and grain to lush spring pasture. It is thought that the ingestion of large amounts of freely fermentable carbohydrate may result in ruminal acidosis and the release of compounds from the rumen that results in alterations in horn formation.
- In dairy cows, horizontal grooves are typically related to calving when there is again a sudden change in diet and there may also be concurrent problems such as a mastitis or metritis. If a horizontal groove is deep enough, it may act as an area of weakness in the hoof wall and eventually crack all the way around allowing debris to impact between the hoof wall and the underlying corium. The corium responds by forming a thin layer of horn tissue to protect it itself. However, the attachment between the corium and the hoof wall typically remains vascular and intact in the region of the toe, where the movement of the distal portion of the hoof wall results in great pain.

Axial Cracks

- The cause of axial cracks is not known. However, since axial cracks are commonly seen in dairy herds that also have a high incidence of digital dermatitis, a theory has developed to explain their formation. It is assumed that atypical cases of digital dermatitis may develop on the coronary band at the cranial extremity of the interdigital cleft and that as a result of this lesion there is irreversible damage to the tissue resulting in a failure of normal horn formation.
- New horn is laid down on either side of the lesion. A full thickness defect occurs in the hoof wall exposing the underlying corium resulting in great pain.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other than a traumatic injury to the hoof, there are no real differentials for these lesions.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Radiographs may be helpful in diagnosing the specific condition and prognosis.

DIAGNOSTIC PROCEDURES

- All the above-described lesions are diagnosed on the basis of the characteristic clinical signs.
- Diagnosis is based on a necessary close examination of the foot.

TREATMENT

Vertical Fissures

- The majority of vertical fissures does not require treatment.
- If the lesion is associated with abscess formation, the fissure should be debrided using either the end of a hoof knife or a small rotary grinding tool (Dremel). This allows lesion identity while draining the abscess is indicated.
- Experience has shown that many abscesses are found at the tip of the pedal bone and commonly extend caudally below the sole. These require resection of a large portion of the sole.
- The application of an orthopedic block (Technovit or similar) to the opposite claw may be necessary to provide pain relief to the animal.

Horizontal Grooves

- Simple horizontal grooves do not require treatment. If the groove fissures result in a thimble, the distal portion of the hoof should be removed. This is best done with the distal limb anesthetized with an intravenous regional anesthetic. The horn should be slowly resected with hoof cutters and a hoof knife.
- A light bandage may need to be applied to the extremity of the pedal bone for control of hemorrhage.
- An orthopedic block should be applied to the opposite claw.

Axial Cracks

- Axial cracks are extremely painful and an intravenous regional anesthetic should be performed before attempting any examination of the area. The horn on either side of the lesion may be resected and granulation tissue trimmed back to the corium. A bandage will be necessary to control hemorrhage.
- It is the author's experience that it is not possible to permanently resolve such lesions due to the damage to the coronary band. An alternative is to amputate the affected digit.

MEDICATIONS

- Antibiotics are not indicated in the treatment of any of the above conditions.
- Depending on the severity of the lesion, some clinicians may elect to use a short course of NSAIDs for pain relief.
- Proper drug withdrawal periods for meat and milk must be maintained.

FOLLOW-UP

PATIENT MONITORING

Orthopedic blocks should always be removed within 7 weeks of application.

PREVENTION/AVOIDANCE

- There is some evidence to suggest that supplementing diets with biotin may help to reduce the incidence of vertical fissures.
- Biotin supplementation may not be cost effective when one considers the low likelihood of vertical fissures resulting in lameness.
- Avoiding sudden diet changes should help reduce the incidence of severe horizontal grooves.
- Maintaining an effective control program for digital dermatitis may also help reduce the incidence of axial cracks.

EXPECTED COURSE AND PROGNOSIS

- Vertical fissure: after adequate drainage of the abscess, the prognosis is extremely good. Complications such as spread of infection to the distal interphalangeal joint are extremely rare. It is not clear whether suitably debriding the vertical fissure will allow the formation of new horn at the coronary band that will in time grow without the formation of a new fissure. After removal of a thimble, the prognosis for such animals is excellent. The animal should be completely pain free in approximately 2–4 weeks. Complete resolution of the lesion requires that new horn grow down and cover the lesion. This may take several months depending on the rate of horn wall growth and the position of the lesion.
- The prognosis for axial cracks is poor.
- Debriding the lesion can typically make the animal pain free for several months; however, the lesion typically becomes extremely painful soon after.

MITES OF SHEEP AND GOATS

BASICS

OVERVIEW

- Mange is caused by parasitic arthropods of the subclass Acari in the class Arachnida.
- The mites affecting sheep and goats are obligate parasites.
- The entire life cycle is completed on the host.
- Mite species are either burrowing or nonburrowing.
- Heavy mite infestations cause dermatitis.
- Transmission is by direct skin-to-skin contact.

SYSTEMS AFFECTED

Production management, skin, reproductive, and hemopoietic

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on species and environment

SIGNALMENT

- Sheep and goats are affected by species-specific or species-adapted strains of mites.
- Different mite species have predilections for different body regions.

Species

Sheep and goats

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

CAUSES AND RISK FACTORS

Psoroptidae

Sheep

- *Psoroptes ovis* (sheep scab/psoroptic mange)
- Infestation is biphasic: a quiescent phase in the axillae, groin, and face during warmer months, alternating with an active multiplying phase affecting the whole body in winter
- The mites are nonburrowing but bite through the skin resulting in an exudative, scabby lesion that is severely pruritic.
- Psoroptic mange is highly contagious and occurs worldwide, except in Australia and New Zealand, which eradicated sheep scab in the 1890s.

Sheep and Goats

- *Chorioptes bovis* (scrotal mange/chorioptic mange)
- Haired skin, particularly of the lower body, is colonized. Most infestations are light and clinical signs are easily overlooked.

- The mites are nonburrowing and feed on the skin surface. Lesions range from mild epidermal hyperplasia, to severe exudative dermatitis with marked epidermal hyperplasia, and hyperkeratosis with encrusted dried serous exudate.
- Affected rams have impaired fertility secondary to increased intrascrotal temperature.
- Although infection is common, lesions are rarely seen on goats. Chorioptic mange has worldwide distribution.

Goats

- *Psoroptes cuniculi* (ear mange).
- Mites inhabit the external ear, feed on whole blood, and cause epidermitis with scab formation.

Cheyletidae

Sheep

- *Psorergates ovis* (itch mite) mostly affects fine-wooled sheep.
- The preferred site of infestation is the fleece-covered areas along the sides of the body.
- The mites live on the skin surface. Infestation spreads through flocks slowly; the population increases on host animals slowly and peaks in winter.
- Affected sheep are irritated by the mites; they rub and bite at their sides, and the fleece contains excessive debris.
- Itch mite occurs sporadically in the fine wool growing areas of Australia, South Africa, New Zealand, and North and South America.

Sarcoptidae

Sheep

- *Sarcoptes scabiei* (ovine-adapted strains)
- Haired areas of the skin are affected. The female mites burrow into the skin.
- There is intense pruritis and an exudative dermatitis consequent to both the direct action of the mites and to self-trauma.
- Sarcoptic mange of sheep is rare and no longer occurs in nations with advanced sheep industries.

Goats

- *Sarcoptes scabiei* (caprine-adapted strains)
- Female mites burrow into the skin.
- Initially, there is traumatic alopecia, excoriations, and encrustations.
- Chronic cases have marked epidermal hyperplasia.
- Caprine sarcoptic mange is of greatest importance in areas where goats are the primary domestic ruminant.

Demodicidae

Sheep and Goats

- *Demodex* species ordinarily live in the hair follicles and sebaceous glands as commensal organisms.
- Demodectic mange, with heavy infestation and seborrheic dermatitis, is rare and of little economic importance.

DIAGNOSIS

- Behavior and lesions of self-trauma consistent with pruritis
- Locally extensive exudative dermatitis and epidermal hyperplasia with crusting
- Demonstrate the mite in skin scrapings.

MOLYBDENUM TOXICITY

BASICS

OVERVIEW

- Molybdenum (Mb) is an essential micronutrient, which forms molybdenoenzymes. Dietary intake of excess Mb causes, in part, secondary hypocuprosis.
- The metabolism of copper, molybdenum, and inorganic sulfate is a complex interrelationship. Mb toxicity is directly associated with copper deficiency and has similar signs.
- Ruminants are especially susceptible to dietary molybdenum excess, leading to depressed growth, diarrhea, neurologic defects, and eventually death, if untreated.
- The ruminal interaction of molybdates and sulfides gives rise to thiomolybdates. At high levels, these compounds decrease the availability of dietary copper and, when absorbed, slow the metabolism of tissue copper and inhibit copper enzymes. This leads to signs of copper deficiency.
- Increased levels in the east and west coasts, increased in acidic, wet soil (peat bogs)
- Forage plants can accumulate Mb. Concentration is lowest in winter, increased in summer and fall.
- Seen in contamination of soils, industrial contamination, fertilizers, feeding of forages and grain. When Cu levels of feed or forages in the normal range of 8–11 ppm, cattle can be poisoned with Mb levels above 5–6 ppm and sheep on levels above 10–12 ppm.
- If Cu level is below 8–11 ppm, or sulfate level is high, even 1–2 ppm Mb may be toxic in cattle.
- High level of Cu in diet to 13–16 ppm can protect Mb poisoning up to 150 ppm dietary Mb.

Species Affected

Ruminants tend to be more susceptible than nonruminants; cattle are more susceptible than sheep.

PATHOPHYSIOLOGY

Causes cytochrome oxidase deficiency and limits heme synthesis.

SIGNALMENT

- Young animals have increased susceptibility.
- Calves can be poisoned by milk from cows on increased Mb.
- Lambs under 1 month of age, severely uncoordinated, ataxic, and usually blind

SIGNS

- Defects in pigmentation, keratinization, bone formation, myelination of the spinal cord, connective tissue formation, and pica
- With chronic ingestion, get osteoporosis, bone fractures, beaded ribs, and overgrowth of long bone ends
- Emaciation, depressed growth
- Liquid diarrhea full of gas bubbles, called peat scours, or teart
- Swollen genitalia impaired reproductive performance
- Anemia from decreased hematopoiesis
- Achromotrichia (depigmentation) of the hair coat especially around the eyes, giving a “spectacled” appearance
- In sheep, depigmentation of dark wool, loss of crimp and quality of the fine wool
- In Australia, enzootic ataxia, in the UK “sway back” seen in the lysis of CNS white matter
- Death is the result of starvation, exposure, or pneumonia.

CAUSES AND RISK FACTORS

The susceptibility of ruminants to a high intake of molybdenum depends on a number of factors:

- The copper contents and intake of the animal: the tolerance to molybdenum decreases as the content and intake of

copper fall.

- The inorganic sulfate content of the diet: high dietary sulfate with low copper levels exacerbates the condition; low dietary sulfate causes high blood molybdenum levels due to decreased excretion.
- The chemical form of the molybdenum: water soluble in growing herbage is the most toxic, and curing decreases toxicity.
- The presence of certain sulfur-containing amino acids
- The species of the animal: cattle are less tolerant than sheep.
- The age: young animals are more susceptible.
- The season of the year: plants concentrate molybdenum beginning in the spring with the maximum level in the fall.
- The botanic composition of the pasture: legumes take up more of the element than other plant species.
- In cattle forage as safe ratio of Cu:Mb > 2:1; when the ratio is less than 2:1, Mb poisoning occurs.

DIAGNOSIS

Made by clinical appearance, response to Cu treatment

DIFFERENTIAL DIAGNOSIS

- Ca/phos/vit D metabolic imbalance
- Massive parasitism, GI parasites
- Johne's disease
- Demyelinating diseases of brain and spinal cord

CBC/BIOCHEMISTRY/URINALYSIS

- Decreased PCV, microcytic, hypochromic anemia
- Cu and Mb levels in forage and tissues
- Liver levels of Cu < 10–30 ppm, Mb > 5 ppm significant
- Whole blood Cu < 0.6 ppm, Mb > 0.1 ppm, significant
- Milk Mb up to 300 ppm significant

PATHOLOGIC FINDINGS

GROSS FINDINGS

Cardiovascular hemorrhage

HISTOPATHOLOGICAL FINDINGS

- Lysis of white matter and degeneration of motor tracts of spinal cord
- Microscopic to massive subcortical destruction
- Neuronal degeneration and demyelination

TREATMENT

- Remove animal from feed source.
- Where Mb content of forage is < 5 ppm, Cu sulfate in salt mineral mixture 1%. With higher Mb, use 2%.
- Repository Cu glycinate SQ and 60 mg for calves, 120 mg for mature cattle. May need to be repeated for a good response.
- Can use as top dressing in pasture, trace mineral mix free choice in feed.

MEDICATIONS

DRUGS OF CHOICE

Copper sulfate oral drench

CONTRAINDICATIONS

- Sheep are highly susceptible to copper drench.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

MISCELLANEOUS

MONENSIN TOXICITY

BASICS

DEFINITION

- Monensin is a carboxylic ionophore antibiotic produced by the fungus *Streptomyces cinnamonensis*.
- Monensin is commercially available as Rumensin and Coban. It is commonly added in feed to treat ruminant coccidiosis and to improve feed efficiency and growth by increasing the propionic acid in the rumen, therefore providing more energy for metabolism. It also spares dietary proteins in the rumen and prevents bloating and acidosis.
- Poisonings have been reported in cattle, sheep, and goats. Ingestion of toxic amounts of ionophores in these animals affects the cardiovascular, musculoskeletal, neuromuscular, hepatic, and renal systems.
- Toxicosis can result from overdosage and misuse. Mixing errors and ingestion of premix concentrates are the leading causes of such presentations.
- Clinical signs in affected animals may be evident within a day, or take several weeks, depending on the concentration of monensin in the diet. Some effects may persist for months and lead to permanent damages. In one incidence, signs persisted in sheep for months after removal of the high-monensin (160–550 ppm) feed.
- The following lethal doses have been reported for various ruminants on a body weight basis:
 - Cattle LD₁ = 5.5 mg/kg; LD₁₀ = 11 mg/kg; LD₅₀ = 21.9–80 mg/kg
 - Sheep LD₀ = 4 mg/kg; LD₅₀ = 10.7–13.1 mg/kg
 - Goat LD₅₀ = 22.4–30.4 mg/kg
- The FDA recommends 5.5–33 ppm monensin in the total diet of cattle and 22 ppm for goats.
 - 100 ppm, for about 1 year, had no effect on circulatory or reproductive functions of cattle.
 - 200–400 ppm monensin in feed for some days may lead to chronic toxicosis in cattle.
 - Goats consuming feed with 55 ppm monensin for 3 weeks may manifest hepatotoxicity. However, no such effect is seen in goats at 11 ppm for 3 weeks, or at 8 mg/kg BW × 5 days.
- Although not approved for sheep, monensin has been purposefully added to ovine feed at levels similar to that of cattle. In lambs < 1 month of age, diffuse gastrointestinal hemorrhage has been reported. Single dose of monensin at 12 mg/kg resulted in no muscular abnormality. At 2–4 mg/kg × 4 days, listlessness and feed refusal were observed; and at concentrations ≥ 8 mg/kg × 2 days, toxicity was observed.

PATHOPHYSIOLOGY

- Monensin is well absorbed from GIT, and undergoes hepatic metabolism by P-450s and glutathione. O-demethylation and hydroxylation are the primary pathways. Urinary excretion is very low, < 1%.
- Ionophores form dynamically reversible Ca²⁺/Mg²⁺/Na⁺/K⁺-lipid soluble complexes that are easily transported across membranes, following the gradient. This causes increased intracellular sodium, and loss of potassium from the cells, discharges the potential gradient, and hence leads to reduction in ATP. An increased ATP utilization is required to maintain the cation concentrations across the membranes. These responses lead to reduction in cellular function and cell death. Increased intracellular sodium also results in mitochondrial swelling and changes in osmotic pressure and thus causes cellular swelling, in addition to the defects in oxidative phosphorylation.
- Increased intracellular sodium also triggers the Ca²⁺-Na⁺ exchange cycle, resulting in an increased intracellular calcium concentration in order to maintain the osmotic balance. This increase in intracellular calcium increases catecholamine production and leads to a positive inotropic effect. This is then followed by a negative inotropic effect.

SYSTEMS AFFECTED

Cardiovascular

- The loss of potential gradient across the myocardial cells results in abnormal impulse transmission and therefore cardiac arrhythmias and congestive heart failure in some cases.

- In more chronic cases, the lack of ATP availability causes cell death or necrosis, and such areas are then replaced by nonfunctional connective tissues such as fibroblasts. Thus, monensin toxicosis results in permanent myocardial damage that appears as pale areas/streaks.

Musculoskeletal

- Effects on skeletal muscles are similar to those seen in the cardiac muscles. Cattle have about equal predilection to develop heart and skeletal muscle lesions.
- In animals surviving the acute exposure, scarring and pallor of certain muscle groups may be noted.

Neuromuscular

The alteration in the normal conduction of impulse can result in altered reflexes and muscular incoordination.

Renal/Urologic

Myoglobinuria and urinary bladder distension have been reported in some ruminants.

Hepatobiliary

Mottling of liver along with hepatocellular necrosis have been reported also.

Respiratory

Pulmonary edema and congestion have been reported in acute cases.

GENETICS

N/A

INCIDENCE/PREVALENCE

The incidences are sporadic, but not very prevalent because of the awareness of monensin toxicity among farmers.

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

- Based on the LD₅₀ values, among ruminants, sheep are more susceptible to monensin toxicosis than cattle or goats.
- No differentiation of toxicity on the basis of age, sex, or breed has been reported.

SIGNS

Acute Effects

- Death
- Recumbency
- Arrhythmias
- Dyspnea
- Stiffness
- Ataxia
- Tremors
- Anorexia
- Edema of abdomen and legs
- Weakness
- Myoglobinuria
- Diarrhea

Chronic Effects

- Anorexia
- Diarrhea
- Depression
- Dyspnea
- Arrhythmias
- Unthriftiness
- Poor exercise tolerance
- Death

CAUSES

Monensin toxicosis is generally a result of feeding of premix ration or other mixing errors.

RISK FACTORS

Presence of other natural cardiotoxins and absence of adequate amounts of selenium and vitamin E can result in aggravation of the ionophore toxicosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Selenium deficiency—evaluated by measuring selenium concentrations in blood, serum, or liver.
- Vitamin E deficiency—evaluated by measuring vitamin E in serum or liver.
- Cardiotoxic plants—identification of plant in feed, testing of rumen content for plant alkaloids.

CBC/BIOCHEMISTRY/URINALYSIS

Goats

- Increased phenobarbital-induced sleeping time
- Increased SDH

Cattle

- Muscle damage causing—increased AST, increased CPK.
- Diarrhea/ruinitis causing—hypokalemia, hyponatremia, and hypocalcemia.
- Also seen is leukocytosis with increased PMN cells and decrease in lymphocytes.
- Myoglobinuria in severely affected animals

OTHER LABORATORY TESTS

- Analyze feed, GI contents, and molasses for identification and quantification of monensin. The analysis can be done using TLC, colorimetric, or the LC-MS method.
- Tissue samples are not diagnostic because of the rapid elimination and low concentrations in tissues.

IMAGING

Echocardiography may be used to determine the myocardial damage in live, chronic cases. However, animals with acute exposure cannot be diagnosed with this method, as the fibrosis is not present.

DIAGNOSTIC PROCEDURES

- Prolongation of Q-T interval and the QRS complex. Absence of P wave and increased amplitude of S and T waves have been observed.
- Atrial/ventricular fibrillation, ventricular tachycardia, and intermittent and premature ventricular contractions may be evident.
- ECG abnormalities are not consistent with severity of exposure or the amount of myocardial damage.

PATHOLOGICAL FINDINGS

Findings similar to congestive heart failure

GROSS FINDINGS

- Enlarged heart with hydropericardium, epicardial hemorrhages, and a tigroid appearance
- Diffusely pale and yellow myocardium with pale and ventricular dilatation
- Pulmonary congestion and edema.
- Hepatic congestion
- Abomassal and SI mucosal congestion
- Ecchymotic hemorrhages around subcutaneous layer and fascia of the neck and forelimbs
- Yellow-to-grey necrotic streaks in skeletal muscles

HISTOPATHOLOGICAL FINDINGS

- Cattle—mitochondrial swelling and vacuolar degeneration of cardiac myositis. Pallor/pale streaking in ventricular walls and the septum was also seen, in addition to the centrilobular hepatic necrosis with vacuolar degeneration. Focal degeneration of active skeletal muscles may be evident.

- Sheep—fibrosis and hyalinization with sarcoplasmic mineralization were reported in ewes consuming 160-ppm monensin over a period of 70 days. Mononuclear infiltration was also observed. Unlike in cattle, the skeletal-muscle lesions in sheep were more severe than cardiac lesions.

TREATMENT

APPROPRIATE HEALTH CARE

- Intense medical management is generally not required, however it is recommended to monitor and correct the blood electrolyte imbalances, if any. There is no effective medical management procedure.
- Apart from isolation, GIT decontamination, and general supportive care, consider surgical evacuation of rumen contents in case of substantial exposure.
- Fluids can be administered to maintain hydration and enhance elimination or prevent renal casting by myoglobin.

NURSING CARE

- A couple of months of stall rest and a quiet environment are essential to reduce stress and limit the cardiac damage.
- A good management and plane of nutrition

ACTIVITY

Restricted exercise and excitement

DIET

N/A

CLIENT EDUCATION

Animals surviving a toxic exposure can have permanent cardiac damage that may make the animal susceptible to sudden death following stress.

SURGICAL CONSIDERATIONS

Rumenotomy may be considered in acute cases to evacuate the rumen, followed by activated charcoal or mineral oil.

MEDICATIONS

DRUGS OF CHOICE

- No antidote
- AC/mineral oil/saline cathartics
- Vitamin E/Se to minimize secondary oxidative tissue damage

CONTRAINDICATIONS

IV fluids should not be administered in animals with cardiovascular problems.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

Monensin toxicity may be potentiated by the concurrent use of tiamulin, oleandomycin, chloramphenicol, erythromycin, sulfonamides, furazolidone, and other cardiac glycosides.

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Serum chemistry, ECGs, and echocardiography are helpful to monitor progress, however, they cannot predict the prognosis.

PREVENTION/AVOIDANCE

- Proper storage of the premixes and concentrates
- Maintain a proper feed-management protocol to avoid mixing errors and possible miscalculations.
- Test feed to ensure monensin concentrations within the FDA recommended ranges (see Definition above).
- Keep animals at a good nutritional level, especially selenium and vitamin E.

POSSIBLE COMPLICATIONS

The myocardial damage may persist for a long period of time without clinically affecting the animal. This may predispose the animal to succumb to factors resulting in an elevated heart rate or requiring an increase in cardiac output.

EXPECTED COURSE AND PROGNOSIS

- Suspected animals may exhibit clinical signs within a few hours of exposure or, in some cases, may take months for the precipitation. Depending on the amount of exposure, the animals may manifest the acute or chronic effects (please see Signs listed above).
- The prognosis is guarded to poor for any animal with suspected myocardial damage. The animals can be maintained, but their performance may be decreased.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Ionophores have not been directly associated with reproductive problems. However, the compromised cardiovascular function may result in abortion.

RUMINANT SPECIES AFFECTED

Cattle, sheep, and goat have reportedly been affected. However, all ruminant species should be considered susceptible.

BIOSECURITY

The tolerance level of monensin in edible tissues of cattle is 0.05 ppm.

PRODUCTION MANAGEMENT

- Do not feed to lactating dairy cows.
- Ensure proper mixing and final concentration within the FDA-recommended range of 5.5–33 ppm.

SYNONYMS

N/A

MUCOSAL DISEASE

BASICS

OVERVIEW

- Mucosal disease in nature is rare because of the special circumstances that are required for it to occur.
- Mucosal disease is invariably fatal.
- Mucosal disease occurs only in cattle immunotolerant to and persistently infected with bovine viral diarrhea virus (BVDV).
- This persistent infection occurs when a fetus becomes infected in utero between 1 and 4 months of gestation with noncytopathic bovine viral diarrhea virus.
- Mucosal disease occurs when cattle persistently infected with BVDV become superinfected with an antigenically homologous cytopathic BVDV virus.
- The most common source of the cytopathic BVDV is for a mutation to occur at specific sites in the noncytopathic virus genome of the persistent virus, converting it from a noncytopathic to cytopathic virus.
- The mutation does not change the antigenic makeup of the virus, therefore the cytopathic virus is not recognized by the host's immune system and is allowed to replicate without challenge.
- Other sources of cytopathic viruses would include modified live vaccines or other cattle with mucosal disease. Antigenic homology between the cytopathic and noncytopathic virus must be maintained for mucosal disease to occur.
- A form of mucosal disease, called chronic mucosal disease, has been described. However, instead of being antigenically identical to the original virus, slight differences exist in the antigenic makeup of the new cytopathic virus. This allows the persistently infected cow to mount an immune response against the cytopathic virus. However, the immune response is often incomplete and pathology slowly evolves leading to the eventual death of the animal.

SIGNALMENT

- Mucosal disease occurs only in cattle persistently infected with BVDV.
- Mucosal disease can occur in any age animal. However, the vast majority of cases occurs in younger animals, generally less than 2 years of age.

SIGNS

- Mucosal disease is inevitably fatal.
- The clinical course of mucosal disease ranges from days to weeks.
- Onset of mucosal disease is characterized by fever (103–105°F), depression, weakness, and anorexia.
- Erosive lesions of the lips, gingival margins, dental pad, tongue, and hard palate are generally present. Erosive lesions may also be present on the external nares, teats, and vulva.
- Profuse foul smelling watery diarrhea is common and may include clotted blood and intestinal casts.
- Similar signs may be observed in cattle with chronic mucosal disease, but less severe in nature.

CAUSES AND RISK FACTORS

Mucosal disease occurs only in cattle that are persistently infected with BVDV.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Any vesicular disease needs to be considered including vesicular stomatitis, papular stomatitis, foot-and-mouth disease, and malignant catarrhal fever.

- Diseases that may induce hemorrhagic diarrhea include salmonellosis and hemorrhagic enteritis.

CBC/BIOCHEMISTRY/URINALYSIS

A severe leukopenia is common with total leukocyte counts ranging from 1000 to 4000 cells/ μ l.

OTHER LABORATORY TESTS

Isolation of both a cytopathic and noncytopathic BVDV from serum, whole blood, nasal swabs, or lymphoid tissue in clinically affected cattle.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

NA

GROSS FINDINGS

- Erosive lesions of the lips, gingival margins, dental pad, tongue, and hard palate are generally present. Lesions may coalesce leading to large areas of mucosal sloughing.
- Linear erosions in the esophagus are common.
- Erosions of the rumen papillae and omasal leaves may be present.
- The abomasum is usually severely congested and erosions may be present.
- Erosions of the mucosal surface covering the Peyer's patch area located in the small intestine are very common.
- Erosions in the cecum and colon may also be present.

HISTOPATHOLOGICAL FINDINGS

- Severe lymphoid depletion of the Peyer's patch areas is common.
- A lack of inflammatory cells around erosive lesions is often appreciated.

TREATMENT

- Mucosal disease is invariably fatal.
- Animals suspected or confirmed with having mucosal disease antemortem should be humanely euthanized.

MEDICATIONS

N/A

CONTRAINDICATIONS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Prevention of mucosal disease revolves around a comprehensive BVDV control program with the goal of preventing the birth of cattle persistently infected with BVDV.
- Preventing persistent infections requires reducing exposure to BVDV, especially during the first trimester of gestation, and developing solid immunity through a BVDV immunization program.
- If cattle persistently infected with BVDV are identified, they should be removed from the herd immediately to reduce the risk of their serving as a source of virus spread to naïve cohorts.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Mucosal disease is invariably fatal.
- Cattle affected with classic mucosal disease usually die within 5–10 days.
- Cattle affected with chronic mucosal disease may live for months.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Most cases of mucosal disease occur in cattle less than 2 years of age.

ZOONOTIC POTENTIAL

BVDV is not considered a zoonotic agent.

Author: Daniel L. Grooms

MYCOPLASMA INFECTIONS IN CATTLE

BASICS

DEFINITION

- The genus *Mycoplasma* has been associated with a wide range of clinical presentations in cattle.
- In North America, common clinical presentations include pneumonia, polyarthritis, otitis media/interna, mastitis, and ocular disease.
- Outside of North America, contagious pleuropneumonia is a critically important production-limiting disease of cattle.

SIGNALMENT VARIES WITH MYCOPLASMA SPP. AND SPECIFIC SYNDROME

Clinical Syndromes

- Clinical syndromes commonly associated with *Mycoplasma* spp. include pneumonia, polyarthritis, mastitis, otitis, reproductive disease, and ocular disease.
- Recently weaned beef calves and stockers often have respiratory and/or ocular disease.
- Dairy calves, particularly group housed, raw milk fed dairy calves with inadequate passive transfer, will often have pneumonia and otitis.
- Mastitis affects primarily adult dairy cattle.
- Although the disease may shift its clinical presentation and jump between age groups of cattle housed on the same farm, this is not a common or consistent observation.
- *Mycoplasma* spp. infections rarely cause acute death losses. Rather, these infections tend to cause chronic persistent infections, which are refractory to treatment.
- The reader is referred to those chapters discussing specific clinical syndromes for more detailed descriptions.

Pneumonia

- *Mycoplasma bovis* and *M. disbar* have been isolated from cattle with pneumonia. In general, *Mycoplasma* spp. appears to require several predisposing factors before the bacteria can cause clinical pneumonic disease.
- Predisposing management and host factors include weaning and shipping stresses, mixing cattle from multiple sources, and inadequate preconditioning programs.
- Preceding infections with respiratory viruses and *Mannheimia haemolytica* are commonly recognized as predisposing factors and may be obligatory stressors for the onset of pneumonic mycoplasmosis.
- In contrast to clinical signs observed with other pneumonia syndromes, the onset of clinical signs occurs longer after exposure (feedlot arrival or mixing of groups), has less dramatic clinical signs, has a more persistent clinical course, and often resists therapeutic intervention.

Polyarthritis

- *Mycoplasma polyarthritis* is observed most commonly in young dairy calves. In dairy herds, the syndrome may be associated with previous pneumonia and polyarthritis outbreaks.
- Feeding raw milk from cows with mycoplasma mastitis has been implicated as an important risk factor. In beef cattle, the syndrome is most often seen in recently weaned calves mixed and assembled from multiple sources.
- Preexisting pneumonic disease is a common part of the history.
- Affected calves are moderately lame. The joints most commonly affected include the carpus, hock, and stifle.

Otitis Media/Interna

- Otitis caused by *Mycoplasma* spp. is observed most commonly in dairy calves fed raw milk.
- Clinical signs usually include head tilt, loss of facial sensation, and loss of motor activity in the muscles of facial expression.
- Purulent drainage from the ear also is common. Preexisting or concurrent respiratory disease is common.

Mastitis

- *Mycoplasma bovis*, *M. californicum*, *M. bovis genitalium*, and others have been associated with clinical and subclinical mastitis in dairy cattle. *Mycoplasma* spp. tend to behave as contagious intramammary pathogens.
- Both acute clinical mastitis and chronic subclinical mastitis are common with *Mycoplasma* spp.
- Introduction of the pathogen into a dairy herd may result in fulminate outbreaks of clinical mastitis if poor milking and intramammary treatment hygiene potentiates the spread of the organism.
- The presence of clinical mastitis in multiple quarters is a common observation in cattle infected with *Mycoplasma* spp.
- Death losses caused by mycoplasma mastitis are rare. The most common clinical presentation is one of persistent high milk somatic cell counts and decreased milk production.
- Mycoplasma mastitis resists intramammary or systemic antibiotic therapy during either the lactating or dry-cow period.

Keratitis

- The predominant clinical sign is that of keratitis and conjunctivitis. This disease is not readily distinguished from infectious bovine keratoconjunctivitis (IBK). *Mycoplasma* spp. have been isolated from outbreaks of infectious bovine keratoconjunctivitis.
- A mycoplasma component should be suspected when outbreaks occur outside the accepted vector seasons or in the face of rigorous implementation of accepted control measures for *Moraxella bovis*.
- Herds in which cattle are frequently added to existing groups appear to be at greatly increased for *Mycoplasma* spp. ocular disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Varies with *Mycoplasma* sp. and specific syndrome.

DIAGNOSTIC PROCEDURES

- Definitive diagnostic testing is based upon identification of the organism. Culture of *Mycoplasma* spp. is often problematic. The organisms have strict and complex growth requirements, generally require a high CO₂ atmosphere and are very slow growing. Furthermore, species and isolates often vary with regard to their growth requirements.
- The advent of polymerase chain reaction (PCR) assays has greatly expedited the diagnosis of mycoplasmosis. Both species- and genus-specific assay systems have been described for use on host tissues and samples.
- Most *Mycoplasma* spp. infections produce an inflammatory response in which the predominant cellular infiltrate is mononuclear. The relatively paucity of neutrophils in an inflammatory response strongly supports the potential for *Mycoplasma* spp.

TREATMENT

- Varies with *Mycoplasma* sp. and specific syndrome
- *Mycoplasma* spp. have been reported to be sensitive to a broad range of antibiotics including tetracyclines, florfenicol, enrofloxacin, tylosin, and tilmicosin. It should be emphasized that methods to determine in vitro sensitivity are currently under development and have not been standardized. Furthermore, in vitro sensitivity has not been demonstrated to accurately predict response to treatment.
- Vaccines have been approved and marketed for *M. bovis* respiratory disease in the United States. However, at this time the efficacy and performance of these vaccines has yet not been demonstrated in controlled clinical trials.
- No data are available to demonstrate the efficacy of prophylactic antibiotics.
- In general, preventive management strategies including optimal passive transfer, maintaining closed herds, or all-in all-out processing and standard preconditioning programs will decrease the prevalence and severity of clinical signs attributable to mycoplasmosis.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

MISCELLANEOUS

ASSOCIATED CONDITIONS

Otitis media/interna, pneumonia, polyarthritis, mastitis, keratitis

AGE-RELATED FACTORS

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Bovine

BIOSECURITY

- Introduction of the pathogen into a dairy herd may result in fulminate outbreaks of clinical mastitis if poor milking and intramammary treatment hygiene potentiates the spread of the organism.
- Herds in which cattle are frequently added to existing groups appear to be at greater risk for *Mycoplasma* spp. ocular disease.

PRODUCTION MANAGEMENT

- Vaccines have been approved and marketed for *M. bovis* respiratory disease in the United States. However, at this time the efficacy and performance of these vaccines has yet not been demonstrated in controlled clinical trials.
- *Mycoplasma* mastitis resists intramammary or systemic antibiotic therapy during either the lactating or dry-cow period.
- Predisposing management and host factors include weaning and shipping stresses, mixing cattle from multiple sources, and inadequate preconditioning programs.
- Feeding raw milk from cows with mycoplasma mastitis has been implicated as an important risk factor. In beef cattle, the syndrome is most often seen in recently weaned calves mixed and assembled from multiple sources.

MYCOTOXINS

BASICS

DEFINITION

- Mycotoxins are secondary metabolites that have no biochemical significance in fungal growth and development.
- They are produced mainly by the mycelial structure of filamentous fungi (molds).
- Toxicogenic molds are known to produce one or more of these secondary metabolites. It is well established that not all molds are toxigenic and not all secondary metabolites from molds are toxic.
- Some molds are capable of producing more than one mycotoxin and some mycotoxins are produced by more than one fungal species. For example, aflatoxins (AF) are produced by several fungal species, have numerous structural variations, and have different modes of action depending on the target animal. Additionally it is common to find more than one mycotoxin in a contaminated feed.
- Despite isolation and chemical characterization of more than 300 mycotoxins, research has focused on those toxins that are known to cause significant damage to humans, livestock, and companion animals.
- Examples of mycotoxins of greatest public health and agroeconomic significance include AF, ochratoxins (OT), trichothecenes, zearalenone (ZEN), fumonisins, tremorgenic toxins, and ergot alkaloids.
- Mycotoxicosis are characterized as feed related, noncontagious, nontransferable, noninfectious, and nontraceable to microorganisms other than fungi. Clinical symptoms usually subside upon removal of contaminated feed.
- Mycotoxins that adversely affect ruminant health or production are found mainly in postharvest crops such as cereal grains or forages. These toxins are produced by saprophytic fungi during storage or by endophytic fungi during plant growth.
- Except for fumonisins, mycotoxins are lipophilic and therefore tend to accumulate in the lipid fraction of plants and animals.

OVERVIEW

- Worldwide contamination of foods and feeds with mycotoxins is increasingly becoming a significant problem.
- In general, mycotoxins have various acute and chronic effects on humans and nonruminant animals.
- Depending on the target species, mycotoxins are known for their immunosuppressive, mutagenic, and carcinogenic effects. Additionally, they are well known for causing life-threatening injuries to critical organs such as the liver and kidney.
- The economic impact of mycotoxins includes loss of human and animal life, increased health and veterinary care costs, reduced livestock production, disposal of contaminated foods and feeds, economic investment in research and applications to reduce severity of the mycotoxin problem.

MISCELLANEOUS

Types and Fungal Origin of Mycotoxins Aflatoxins

- Over 20 AF are produced by different *Aspergillus* species (e.g., *A. flavus* produces AFB₁ and AFB₂; *A. parasiticus* produces AFB₁, AFB₂, AFG₁, and AFG₂).
- Variations in the magnitude of toxicity exist among AF (e.g., AFB₁ is the most toxic in both acute and chronic aflatoxicoses, whereas AFM₁ is as hepatotoxic as AFB₁ but not as carcinogenic).

Ochratoxins

- OT are produced by both *Aspergillus* and *Fusarium* species.
- They are nephrotoxic in poultry, acutely toxic in rats and mice; they can promote tumors in humans.
- The most toxic OT is OTA, produced by *A. ochraceus* and selected *Penicillium* species such as *P. cyclopium* and *P. viridicatum*.

Trichothecenes

- Trichothecenes are mainly produced by several *Fusarium* species such as *F. sporotrichioides*, *F. graminearum*, *F. poae*, and *F. culmorum*. They are also produced by members of other genera such as *Myrothecium* and *Trichothecium*.
- Trichothecenes include T-2 toxin, diacetoxyscirpenol (DAS), and deoxynivalenol (DON—also known as vomitoxin and nivalenol).
- Both T-2 toxin and DAS are considered the most toxic.

Zearalenone

- Zearalenone is a phytoestrogenic compound that is a metabolite primarily associated with several *Fusarium* species such as *F. culmorum*, *F. graminearum*, and *F. sporotrichioides*.
- *F. graminearum* is considered the fungal species most responsible for the estrogenic effects commonly found in farm animals. Fumonisin
- Fumonisin (B₁ and B₂) are cancer-promoting metabolites of *F. proliferatum* and *F. verticillioides*.
- Fumonisin B₁ is the most toxic and has been shown to promote tumors in rats and to cause equine leukoencephalomalacia and porcine pulmonary edema.

Moniliformin

- Moniliformin is produced by several *Fusarium* species (mainly *F. proliferatum*) and is usually found on the corn kernel. It can be transferred to next generation crops and survives for years in the soil.
- Although both fumonisin B₁ and moniliformin are produced by the same fungal species (*F. proliferatum*), no structural resemblance is found between the two toxins. Both toxins are shown in several FDA studies to be ubiquitous in U.S. corn.

Endophytic Tremorgens and Ergot Alkaloids

- Several colonizing toxigenic fungal species (e.g., *Acremonium lolii*, *A. coenophialum*, *Claviceps purpurea*, and *Penicillium* spp.) may thrive exclusively on live forages, especially grasses such as tall fescue.
- *A. lolii* is an endophytic fungus that thrives on perennial ryegrass and produces indole-terpene neurotoxins called tremorgens such as lolitrem B toxin.
- Perennial ryegrass staggers in livestock have been linked to lolitrem B toxin from *A. lolii* and to other tremorgens (e.g., penetrem B and verruculogen) produced by several *Penicillium* species (e.g., *P. crustosum* and *P. verruculosum*, respectively).
- Fescue foot, summer fescue toxicosis, and fat necrosis in cattle have been linked to tall fescue with growth of *A. coenophialum*.
- Other *Acremonium* species and *C. purpurea* are also responsible for sleepygrass toxicosis in livestock. This is a result of

the ergot alkaloids (e.g., ergotamine, ergostine, and ergocristine) produced by these fungal species.

- Ergotamine and other lysergic acid amide derivatives in the perennial grass *Stipa robusta* are commonly associated with toxicoses in sheep.
- The two types of ergotism known in humans and animals are convulsive and gangrenous.

Mycotoxins in Ruminant Feed

- There are physical, chemical, and biological factors that operate interdependently and affect fungal colonization and/or mycotoxin production in ruminant feeds.
- The physical factors include the environmental conditions (e.g., temperature, relative humidity, and insect infestation) conducive to fungal colonization and mycotoxin production.
- The chemical factors include the use of fungicides and/or fertilizers.
- The biological factors include fungal strain specificity, strain variation, and instability of toxigenic properties.
- In general, the environmental conditions related to storage can be controlled, whereas those extrinsic factors (e.g., climate) or intrinsic factors (e.g., fungus-related factors) are more difficult to control.
- Unseasonable conditions have been suggested to render crops and forages susceptible to mycotoxin production (e.g., cool and damp springtime weather favors germination of the sclerotia and thus ergot alkaloid formation in fescue and ryegrass).

Negative Effects of Mycotoxins on Ruminants

- Ruminants are less known to exhibit the life-threatening effects that mycotoxins usually demonstrate in humans and other animals.
- Growth, production (milk, meat, or wool), and reproduction can be altered when ruminants consume mycotoxin-contaminated feed for extended periods of time (e.g., decreased productivity in cattle by AF and ZEN in sheep).

Cattle

- The role of AFB₁ in inducing bovine immunosuppression has been attributed to suppressing mitogen-induced stimulation peripheral lymphocytes and inhibiting bovine lymphocyte blastogenesis. Rumen motility can be reduced in a dose-dependent manner by feeding graded levels of AF (200–800 µg/kg of feed). Increasing AFB₁ level (up to 108.5 µg/kg of feed) decreases feed intake and a higher level (600 µg/kg of feed) also may decrease feed efficiency and body weight gain. These effects can be attributed to compromised rumen function (i.e., decreased cellulose digestion, volatile fatty acid production, and rumen motility). Milk yield and quality decreases with the feeding of AFB₁ (13 mg per cow/day) and the carryover rate of AFM₁ in milk is higher in early lactation than late lactation.
- Ochratoxins have not been shown to cause toxicity when fed alone or in combination with AFB₁ in naturally occurring doses (up to 540 and 13 µg/kg of feed, respectively).
- Except for T-2 toxin, trichothecenes have not been shown to affect cattle. T-2 toxin can induce immunosuppression by lowering serum concentrations of IgM, IgG, and IgA; by decreasing neutrophil functions, lymphocyte blastogenesis, and lymphocyte response to phytohemagglutinin; and finally by inducing necrosis of lymphoid tissues. Infertility and abortion in the final trimester of gestation have been also caused by T-2 toxin. Other effects of T-2 toxin included hemorrhagic syndrome in dairy cattle and abomasal ulcers and the sloughing of rumen papillae in calves.
- Zearalenone has been suggested to cause infertility and to decrease milk production.
- Consumption of tall fescue infected with *A. coenophialum* may cause fescue foot, hyperthermia, and fat necrosis. Fescue foot (vasoconstriction and gangrene in the hooves and tail) is attributed to the relaxation of smooth muscles caused by ergot alkaloids. Hyperthermia (summer fescue toxicosis) is characterized by weight loss, salivation, and heat stress, whereas fat necrosis is characterized by hardening of body fat and constricting internal organs, reducing serum cholesterol levels, and elevating serum amylase levels. Consumption of tall fescue infected with *A. lolii* also causes staggers, excitability, increased rectal temperature, increased respiration rate, and loss of body weight.

Sheep

- Feeding diets contaminated with AF (2.5 or 5.0 mg/kg of feed) caused hepatotoxicity in ewes. Symptoms such as hepatic and nephritic lesions, altered mineral metabolism, and increased size and weight of the liver and kidney were reported for lambs consuming AF at 2.5 mg/kg of feed. This AF dose also lowered plasma concentrations of several minerals (Ca, P, Mg, K, and Zn) in response to decreased feed intake and to malfunctions of the liver and kidney in lambs. The same AF dose also decreased lamb weight gain, suppressed cellular immunity, and induced changes in extrinsic coagulation factors as illustrated in increased fibrinogen concentration.
- Effects of trichothecenes on sheep appear to vary greatly even when high levels are consumed. For example, exposing lambs to DON (15.6 mg/kg of feed) had no effect on body weight gain, hemacytology parameters, or liver function.

Exposing lambs to DAS (5 mg/kg of feed), however, induced weight loss. Further weight loss was also reported when lambs were fed the same level of DAS in combination with AF (2.5 mg/kg of feed) suggesting a synergistic effect of these toxins.

- Zearalenone has been shown to affect reproductive performance of sheep negatively by reducing fertility and ovulation rates when the dietary levels approached 12 mg/kg of feed.
- Fumonisin at high doses (11.1–45.5 mg/kg of body weight) have been demonstrated as acutely and fatally nephrotoxic and hepatotoxic in lambs. These high levels, however, have not been found in fumonisin-contaminated feeds.
- Sheep have been affected by ryegrass toxicosis as shown in the resulting tremors, decreased productivity, and occasional death. Perennial ryegrass staggers have been observed in sheep consuming ryegrass contaminated with *A. lolii* and the symptoms included shaking with loss of coordination and inability to walk. Staggers have been demonstrated when *A. lolii*-contaminated ryegrass had lolitrem B toxin at levels ranging from 2.0 to 2.5 mg/kg.

Other Ruminants

- Ruminants other than cattle and sheep have shown variable resistance to mycotoxins.
- Exposing white-tailed deer to AF (800 mg/kg of feed) caused acute injuries in the liver as illustrated in the increased serum bile acid concentrations and hepatic lesions.
- Offering weaned goats fumonisin-containing feed (95 mg/kg) had no effect on body weight gain and did not show any toxicity-related symptoms.

Ruminal Degradation of Mycotoxins

- The great resistance of ruminants to the negative effects of several mycotoxins is due to degradation and detoxification of these compounds in the rumen environment.
- Ruminal microbial degradation of mycotoxins has been demonstrated in isolated cultures of rumen contents.
- The rumen function, however, is negatively affected by the presence of mycotoxins. The negative effects include decreased cellulose fermentation, volatile fatty acid production, ammonia production, and proteolysis.
- Degradation of AF, OT, ZEN, T-2 toxin, DON, and DAS was demonstrated by using rumen protozoa and (or) rumen bacteria. Contribution of protozoa to ruminal degradation of mycotoxins, however, appears to be more significant than that of bacteria.

MYIASIS

BASICS

DEFINITION

Invasion of living or dead tissue by larvae of dipteran flies causes myiasis in livestock. Myiasis can be facultative or obligatory. The condition is of economic importance especially in Africa, Asia, and Australia.

OVERVIEW

- Myiasis, also known as fly-strike, is the infestation of the body by fly larvae.
 - Obligator myiasis: fly larvae are completely parasitic and will die without a host.
 - Facultative myiasis: fly larvae are free-living but can adapt themselves to a parasitic dependence on a host under the right circumstances.
- There are eight major flies affecting cattle: face flies (*Musca autumnalis*), houseflies (*Musca domestica*), horn flies (*Haematobia irritans*), horseflies (*Hybontia* spp. and *Tabanus* spp.), deerflies (*Chrysops* spp.), heel flies (*Hypoderma lineatum* and *H. bovis*), screwworms or blowflies (*Cochliomyia hominivorax*).
- Blackflies (family Simuliidae) produce a salivary toxin.
- Can be vectors for other diseases

SIGNS

- Animals show signs of restlessness and may bite at affected areas. Affected areas produce a foul-smelling odor with exudates, and the mature larvae are usually observed on the lesions.
- Signs can be broken into general categories based on action of the flies.
- Annoyance/irritation (all flies)
 - Weight loss
 - Reduced performance (decreased feed intake due to constant avoidance behavior)
 - Decreased milk production
 - “Gadding”—stampeding, wild running
- Blood-sucking flies (horn flies, stable flies, horseflies, deerflies, black blackflies)

- Dermal lesions, wounds
- Anemia
- Transmission of infectious diseases (anaplasmosis, bovine leukemia virus, anthrax, tularemia)
- Hide damage (heel flies, screwworms)
 - Warbles (cysts)—heel flies
 - Ventral midline lesions—horn flies
 - Liquefactive necrosis and cavernous lesions filled with larvae—screwworms
- Toxin production (blackflies): secrete a salivary toxin that increases capillary permeability and allows fluid to escape into extravascular tissues.

Other

Heel flies, if killed in the fall before migrating: anaphylaxis, weakness, ataxia, dyspnea, bloat

CAUSES

- Larvae of the flies *Cochliomyia hominivorax* (North America) and *Chrysomia bezziana* (Africa, Asia, and Persian Gulf) cause screwworm myiasis. They are obligatory myiasis-producing flies, and they depend on the host to complete their life cycles. They invade living tissues.
- Larvae from other dipteran flies including *Musca domestica* (the housefly) and flies from the genera *Phornia*, *Lucilia*, and *Calliphora* (blowflies) are facultative myiasis-producing flies. They invade cutaneous dead tissues and cause cutaneous myiasis.
- Understanding the life cycle of the flies allows a better opportunity to break the cycle and control the flies.
 - Face flies: overwinter in buildings. Females feed on facial secretions (tears, saliva, nasal secretions, milk on calves' faces).
 - Horn flies: reproduce only in bovine feces, but feed on horses, sheep, and goats as well as cattle. Flies can travel 7–10 miles in search of a host.
 - Horseflies: intermittent blood feeders. Females must have a blood meal to lay eggs. Larvae are aquatic or semiaquatic.
 - Stable flies: require a blood meal one to two times daily. Larvae develop in decaying organic matter, such as grass clippings.
 - Houseflies: breed in manure
 - Screwworms: blowfly lays eggs on a preexisting wound. Obligate myiasis requires live tissue. Disease is self-perpetuating and more common in hot, humid weather.
 - Heel flies: 9–12-month life cycle. Eggs are attached to hairs on the lower limbs. Eggs hatch, enter skin, and migrate. *H. bovis* migrates to the epidural fat in the spinal cord region. *H. lineatum* migrates to the esophagus. Larvae migrate a second time to the back in January and February. Third-stage larvae emerge from warbles and drop to ground. In 1–3 months, flies emerge and live < 1 week.

RISK FACTORS

- Obligatory myiasis-causing flies lay their eggs only on fresh wounds. These include wounds created by procedures such as castration, dehorning, and docking. Sites such as the navel of newborns, perineum, vagina, and wounds from tick bites also are susceptible to invasion.
- The exudates and odor from these flies attract more flies including flies causing cutaneous myiasis.
- Cutaneous myiasis is of major economic importance in sheep. Flies are attracted to wet fleece, areas affected by fleece rot, foot rot, and perineum soiled by feces or urine staining. The most common area affected in sheep is the breech.
- Lush pastures and parasitic gastroenteritis predispose to cutaneous myiasis because of perineal soiling. In addition, dense thick pastures with wet plants keep the fleece wet.
- Fly numbers with screwworm myiasis or cutaneous myiasis are affected by ambient temperatures. Hot, humid weather favors development of the flies.

Life Cycles

Screwworm Myiasis

- Adult females lay eggs on fresh wounds. Larvae hatch in 12–24 hours, feed on tissue, and complete growth in 5–7 days. Larvae exit the wound, fall to the ground, and pupate in the soil.
- Pupal period depends on environmental conditions and varies from a few days to 2 months. Emerging adults mate and females can lay eggs as early 6 days of age.

- Adult flies can breed only once in life.

Cutaneous Myiasis

- Larvae hatch from eggs deposited by adult females that are attracted to sites with excessive moisture or exudates within 12–24 hours. After feeding on tissues, the larvae fall to the ground and pupate in the soil.
- Life cycle is shorter in hot, humid conditions.

DIAGNOSIS

- Larvae from dipteran flies can be differentiated based on morphology. Formalin-fixed samples must be submitted for identification.
- Predisposing factors such as foot rot, fleece rot, tick bites, and diarrhea can be easily differentiated from cutaneous myiasis.

GROSS FINDINGS

- Heel flies: summer months; yellow exudate on the distal limbs
- Spring warbles (cysts) on back with breathing hole
- Screwworms: cavernous lesions filled with larvae that look like wood screws. Lesions are commonly found around the head (i.e., dehorning lesions)
- Horn flies: ventral midline lesions

TREATMENT

- *Cochliomyia hominivorax* has been eradicated in the United States by an ongoing sterile male release eradication program and this condition is considered a reportable disease.
- Ivermectin is effective in killing *Chrysomia bezziana* larvae. Ivermectin and organophosphates can be used in cutaneous myiasis. Ivermectin also kills adult flies.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Sanitation: Remove decaying vegetation and bedding, rotting silage. Remove manure at least twice weekly
- Topical: ear tags, back rubbers and dust bags, pour-ons
- Feed additives (to kill eggs and larvae in feces): diflubenzuron (chitin inhibitor), tetrachlorvinphos
- Surgical: surgical removal of warbles

MEDICATIONS

CONTRAINDICATIONS

- Steroids should not be used in pregnant animals.
- Pour-ons and ivermectin/moxidectin must be given before October 15 (Northern Hemisphere) if used for treating heel flies. If treated after migration to epidural fat or esophagus, an inflammatory response can occur and a granuloma can form around the dead parasite.
- Always follow label recommendations for meat and milk withdrawal times, as well as mixing directions.

FOLLOW-UP

PREVENTION/AVOIDANCE

Treatment of wounds, ear tags with larvicide can be used. Sterile male release eradication has been successful.

EXPECTED COURSE AND PROGNOSIS

- Prognosis depends on the number and type of flies, as well as success of preventive measures. In general, animals should make a full recovery. However, severe screwworm infestations can cause death.
- Large numbers of blood-sucking flies can cause death from anemia. Massive infestations of blackflies can cause death due to capillary permeability.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Secondary wound infections and subsequent septicemia
- Face flies transmit *Moraxella bovis* (pink eye). They are vectors for *Thelazia* spp. and *Parafilaria bovicola*.
- Horn flies are the intermediate host for *Stephanofilaria stilesi* (filarial dermatosis of cattle)
- Horseflies can transmit anthrax, anaplasmosis, and tularemia.
- Stable flies are vectors of anthrax and surra.
- Screwworms can cause secondary bacterial infections and toxemia.

AGE-RELATED FACTORS

MYOCARDITIS

BASICS

DEFINITION

Myocarditis is an inflammation of the myocardium due to various organisms (bacterial, viral, parasitic) or due to a thromboembolism from a vegetative endocarditis caused by these organisms.

PATHOPHYSIOLOGY

Damage to the endocardium due to unknown causes (possibly secondary to monensin toxicity) may lead to penetration of various organisms (bacterial, viral, parasitic) into the myocardium causing inflammation of the myocardium.

SYSTEMS AFFECTED

Cardiovascular system

GENETICS

N/A

INCIDENCE/PREVALENCE

Difficult to assess due to the disease often being subclinical

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Mainly cattle

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

May be history of sudden death following stress, or failure to thrive, or recurrent fevers, or monensin toxicosis

PHYSICAL EXAMINATION FINDINGS

- Tachycardia, cardiac arrhythmias, dyspnea, fever
- May have pronounced gallop rhythm or cardiac murmur over mitral valve or tricuspid valve in acute myocarditis

CAUSES AND RISK FACTORS

- Bacterial causes include *Staphylococcus*, *Streptococcus*, *Clostridium*, *Hemophilus*, and *Mycobacterium*.
- Viral causes include foot-and-mouth disease virus, bovine lymphosarcoma virus or BLV, bluetongue virus in sheep.
- Parasitic causes include toxoplasmosis, cysticercosis, sarcocystis, and *Neospora caninum* in neonatal calves.
- May also be associated with monensin or gossypol ingestion, nutritional myodegeneration (vitamin E/selenium deficiency or white muscle disease), and copper and cobalt deficiency in lambs

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Endocarditis
- Cardiomyopathy
- Cardiac neoplasia
- Congestive heart failure
- Monensin or gossypol intoxication
- Nutritional myodegeneration

CBC/BIOCHEMISTRY/URINALYSIS

- Leukocytosis due to neutrophilia, decreased serum albumin. If congestive heart failure occurs, may have liver damage with serum albumin and increased SDH, GGT, and bilirubin.
- Hemoglobinuria may suggest monensin or gossypol intoxication or nutritional myodegeneration as a cause of the myocarditis.

OTHER LABORATORY TESTS

- Blood culture
- Elevated myocardial enzymes of creatine kinase (myocardial bound) and lactic dehydrogenase, or LDH (LDH₁), may be present, interpretation uncertain in large animals.
- Whole blood selenium to rule out nutritional myodegeneration

IMAGING

Ultrasound/echocardiography to check for increased ventricular size, decreased interventricular septum size, and decreased myocardial function

OTHER DIAGNOSTIC PROCEDURES

- Pericardiocentesis with culture and sensitivity to check for bacterial agents
- Electrocardiogram, or ECG, to assess tachycardia and arrhythmia

PATHOLOGIC FINDINGS

- May be coronary thrombi and infarctions, and pale streaking of cardiac muscle, or may be no gross lesions
- Microscopically, may see increased interstitial fibrous tissue, foci of inflammatory mononuclear cells, and degeneration, necrosis, and fibrosis of myocardial cells

TREATMENT

ACTIVITY

Animal must be rested.

DIET

More forage and additional protein sources and limited cottonseed meal feeding to reduce gossypol ingestion to less than 1–2 g/kg for adult cattle and less than 0.5–1 g/kg for immature cattle.

CLIENT EDUCATION

- Good general husbandry (nutrition, vaccination, deworming) to boost immunity and limit exposure to disease agents
- Proper mixing of feed containing monensin; limited feeding of cottonseed meal to control gossypol toxicity
- Adequate supplementation of selenium and vitamin E to prevent nutritional myodegeneration

MEDICATIONS

- Control cardiac arrhythmias using quinidine
- Broad-spectrum antibiotics

DRUGS OF CHOICE

Quinidine 48 mg/kg IV over a 4-hour period

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals

PRECAUTIONS

Concurrent IV administration of a balanced electrolyte at 3–4 ml/kg/h along with quinidine can help maintain adequate electrolyte and acid-base balance and blood pressure.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

**FOLLOW-UP**

N/A

PATIENT MONITORING

Monitor carefully during quinidine administration for adverse side effects (e.g., sweating, weakness, restlessness, cardiac arrhythmias).

PREVENTION/AVOIDANCE

See Client Education above.

POSSIBLE COMPLICATIONS

May develop idiopathic dilated cardiomyopathy

EXPECTED COURSE AND PROGNOSIS

Prognosis is fair to good if no signs of congestive heart failure, guarded to poor if signs of congestive heart failure are present.

NAIROBI SHEEP DISEASE

BASICS

DEFINITION

Nairobi sheep disease (NSD) is a highly pathogenic, tick-borne, viral disease of sheep and goats. It is a reportable disease in the United States and on List B of the International Office of Epizootics.

PATHOPHYSIOLOGY

- NSD is transmitted by the bite of the brown tick, *Rhipicephalus appendiculatus*.
- The tick maintains the virus through transovarial and transstadial transmission. Unfed adult ticks can remain infectious for up to 2 years.
- The African bont tick (*Amblyomma variegatum*) in Kenya and a population of *R. pulchellus* in Somalia also transmit the NSD virus.
- Under normal field conditions, the virus is not transmitted by contact with infected animals. Experimentally, animals have been infected through inoculations of infectious blood, serum, and organ suspension and through large oral doses (50 ml) of infected blood or serum.
- Sheep tend to be more susceptible to NSD than goats.

SYSTEMS AFFECTED

- Gastrointestinal—abomasum, cecum, rectum, and ileocecal valve
- Hemic/Lymphatic/Immune—spleen, lymph nodes
- Respiratory
- Reproductive
- All organs and tissues will be affected with nonspecific changes.

GENETICS

N/A

INCIDENCE/PREVALANCE

- Sheep and goats in endemic regions are generally immune to NSD as are most lambs exposed while still protected by colostral antibodies.
- Naïve animals entering endemic regions often develop severe infections with mortality rates ranging from 40% to 90%.

GEOGRAPHIC DISTRIBUTION

- NSD is found primarily in east Africa. Infected animals have been found in Kenya, Uganda, Tanzania, Somalia, Ethiopia, and Zaire.
- One report has suggested the presence of the virus in India and Sri Lanka.

SIGNALMENT

Species

Sheep, goats

Breed Predilections

Masai sheep are more susceptible to NSD than other breeds.

Mean Age and Range

All ages

Predominant Sex

None

SIGNS

HISTORICAL FINDINGS

- Depression
- Diarrhea
- Straining
- Anorexia
- Nasal discharge
- Recumbency
- Abortions

PHYSICAL EXAMINATION FINDINGS

- Depression
- Fever—104–106°F (40–41°C)
- Diarrhea—initially thin and watery then progressing to contain frank blood and mucus
- Straining
- Mucopurulent nasal discharge
- Dyspnea
- Conjunctivitis

CAUSES

NSD is caused by virus in the genus *Nairovirus* of the family Bunyaviridae.

RISK FACTORS

- Outbreaks occur when naïve animals are moved into endemic regions.
- Sporadic outbreaks in nonendemic regions may occur after excessive amounts of rainfall and subsequent expansion of the tick vector's range.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Heartwater
- Rift Valley fever
- Anthrax
- Peste des petits ruminants
- Coccidiosis
- Plant and heavy metal poisonings

CBC/BIOCHEMISTRY/URINALYSIS

Leukopenia during febrile stage

OTHER LABORATORY TESTS

- Virus isolation from the noncoagulated blood during febrile stage
- Paired sera samples showing a fourfold or greater rise in antibody titer
- ELISA of serum for neutralizing antibodies
- AGID of serum for neutralizing antibodies
- ID of serum
- HA of serum

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Virus isolation from mesenteric lymph nodes and spleen using cell cultures or by inoculating laboratory animals
- Virus identification from mesenteric lymph nodes and spleen using AGID
- IFA of cell cultures or from inoculated laboratory animal brain material
- CF of cell cultures or from inoculated laboratory animal brain material

PATHOLOGIC FINDINGS

GROSS FINDINGS

- Generalized lymphadenitis; ecchymotic and petechial hemorrhages on serosa on thoracic and abdominal organs; bloodstained intestinal contents; hyperemia and petechial hemorrhages on mucosa of abomasums, cecum, rectum and ileocecal valve; “zebra striping” of rectum; hyperemia of genital tract; congested spleen
- Aborted fetuses will have hemorrhages throughout internal organs, fetal membranes may be swollen, edematous, and hemorrhagic

HISTOPATHOLOGY FINDINGS

Nonspecific congestion and petechial and ecchymotic hemorrhages in most organs and tissues, mucosal hemorrhages from the abomasum to the rectum, severe glomerulotubular nephritis, lymphoid hyperplasia, myocardial necrosis

TREATMENT

APPROPRIATE HEALTH CARE

- No specific individual treatment
- Herd preventative care—vaccination of susceptible animals moving to an endemic area with an attenuated, tissue-culture-propagated vaccine, pour-on acaricidal preparations

NURSING CARE

Infected animals should be provided with basic supportive care by replacement of lost fluids and restoration of electrolytes.

ACTIVITY

Animals should be protected from climatic conditions and stress.

DIET

Infected animals should be fed good-quality feed, avoiding rough feeds with low nutrient values.

CLIENT EDUCATION

- Clients need to be educated in the importance of tick control and vaccination protocols to prevent infection.
- Strict quarantine is not necessary because NSDV is not transmitted through direct contact.
- Dead animals should be disposed of by incineration or burial.

SURGICAL CONSIDERATIONS

MEDICATIONS

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Patients should be monitored frequently for signs of dehydration.

PREVENTION/AVOIDANCE

- Owners should avoid taking naïve animals into endemic areas. If this is impossible, animals should be vaccinated with an attenuated, tissue-culture-propagated vaccine.
- Susceptible sheep and goats may also be protected from the vector by weekly application of acaricides, but this is often not feasible.

POSSIBLE COMPLICATIONS

Exposure of naïve herds of sheep or goats to NSD may result in 90% mortality.

EXPECTED COURSE AND PROGNOSIS

- Prognosis is poor unless animals were exposed when young while still protected by colostral antibody.
- Goats have a better prognosis than sheep.
- All animals who recover are immune for life.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Colostral antibodies protect young in endemic areas.

ZOONOTIC POTENTIAL

- NSD appears to cause rare, mild, influenza-like symptoms in humans. One naturally acquired infection has been reported in Uganda.
- Precaution should be taken against aerosol exposure when working with this virus.

PREGNANCY

Pregnant animals will abort when infected with NSD.

RUMINANT SPECIES AFFECTED

NASAL ANOMALIES

BASICS

OVERVIEW

- Several nasal anomalies can affect the ruminant respiratory system.
- These include rhinitis (inflammation of the nasal passages), mycotic nasal granuloma (fungal infection of the nasal passages leading to granuloma formation), nasal tumors, allergic rhinitis (allergic reactions due to exposure to plant or fungal allergens), foreign body, trauma, and paranasal sinusitis (bacterial inflammation of the paranasal sinuses, mainly the frontal sinus and maxillary sinus).

PATHOPHYSIOLOGY

Rhinitis

Viruses, bacteria, fungi, and exposure to allergens can all lead to inflammation of the nasal passages. *Oestrus ovis* larvae or bots can also cause inflammation. The female fly deposits eggs around nostrils during summer and fall. Eggs hatch, and larvae crawl up nasal passage to dorsal turbinates and frontal sinuses, remain for weeks to months, and eventually migrate back to nostrils. They are sneezed out, and pupate on the ground.

Mycotic Nasal Granuloma

Eroded nasal mucosa becomes inoculated with fungal spores, causing a delayed (type IV) hypersensitivity and eventual granuloma formation.

Nasal Tumor

Growth of tumors leads to progressive airway obstruction.

Allergic Rhinitis

Exposure to allergens results in development of antibodies (e.g., IgE). Subsequent exposure results in an immediate (type I) hypersensitivity reaction. Chronic exposure may lead to chronic tissue damage from mast cell enzymes, causing hyperplasia and granulomatous inflammation (enzootic nasal granuloma).

Foreign Body

The presence of the foreign object leads to irritation and decreased airflow.

Trauma

Trauma and fractures of the facial bones, sinuses, and turbinates can lead to swelling, airflow obstruction, and epistaxis.

Paranasal Sinusitis

Bacterial inflammation of the sinuses may lead to anorexia, fever, and nasal discharge, and cause a head tilt probably due to inflammation of the peripheral portion of the vestibulocochlear nerve (cranial nerve or CN VIII).

SYSTEMS AFFECTED

Respiratory

GENETICS

Allergic rhinitis may be a familial predisposition.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

- Rhinitis—all ruminant species
- Mycotic nasal granuloma—all ruminant species, mainly cattle

- Nasal tumor—all ruminant species, but rare
- Allergic rhinitis—mainly cattle
- Foreign body—all ruminant species, mainly cattle probably due to more aggressive eating habits
- Trauma—all ruminant species
- Paranasal sinusitis—most common in cattle, infrequent in sheep and goats

Breed Predilections

- Rhinitis, mycotic nasal granuloma, nasal tumor, foreign body, trauma, paranasal sinusitis—N/A
- Allergic rhinitis—Jersey, Guernsey, Holstein cattle

Mean Age and Range

- Rhinitis, foreign body, paranasal sinusitis—any age
- Mycotic nasal granuloma, nasal tumor, trauma—mainly adult animals
- Allergic rhinitis—usually 6 months to 2 years old

Predominant Sex

N/A

SIGNS

N/A

HISTORICAL FINDINGS

- Rhinitis—history of previous *Oestrus ovis* infection
- Mycotic nasal granuloma—previous signs of nasal irritation
- Nasal tumor—progressive signs of airway obstruction
- Allergic rhinitis—usually seasonal (warm, moist conditions) onset of signs
- Foreign body—signs of allergic rhinitis, with frequent attempts to scratch nose by rubbing against objects
- Trauma—fighting, roping, improper restraint, and passage of excessively large nasogastric tubes
- Paranasal sinusitis—dehorning or injury to the horns, or infected cheek teeth

PHYSICAL EXAMINATION FINDINGS

- Rhinitis—mucoid to purulent nasal discharge, stertorous breathing, sneezing, and inspiratory dyspnea if due to *Oestrus ovis* in sheep with milder signs in goats
- Mycotic nasal granuloma—stridor, dyspnea, mucopurulent nasal discharge, epistaxis, granulomas appear as yellow to red nodules or polyps up to 5 cm in diameter
- Nasal tumor—dyspnea, stridor, head shaking, nasal discharge, sneezing, epistaxis, foul breath odor, distorted facial bones
- Allergic rhinitis—sneezing, intense nasal pruritus, profuse bilateral mucoid nasal discharge, may develop enzootic nasal granulomas seen as multiple firm white nodules or flat pink plaques scattered throughout nasal cavity
- Foreign body—head shaking, sneezing, snorting, frequent nose licking, unilateral nasal discharge, foul breath odor, decreased airflow
- Trauma—facial swelling, subcutaneous emphysema, airflow obstruction, stertorous breathing, epistaxis. Secondary bacterial infection may cause foul breath odor and mucopurulent nasal discharge.
- Paranasal sinusitis—anorexia and fever initially, then nasal discharge, stridor, foul breath odor, purulent discharge from dehorning site, head tilt

CAUSES AND RISK FACTORS

- Rhinitis—bacteria, viruses (e.g., IBR, fungi, allergens). In sheep and goats, mainly caused by parasites (e.g., *Oestrus ovis* larvae or bots)
- Mycotic nasal granuloma—*Rhinosporidium*, *Aspergillus*, *Phycomyces*, other fungal species, more common in warm, wet climates
- Nasal tumor—squamous cell carcinoma, osteosarcoma, adenocarcinoma in cattle (e.g., ethmoid adenocarcinoma, which tends to be unilateral in cattle and metastasize to lymph nodes and lungs in cattle 6–9 years old); adenocarcinoma in sheep and occasionally goats (e.g., nasal adenocarcinoma in yearling to adult sheep)
- Allergic rhinitis—plant pollen or fungal spores
- Foreign body—aggressive eating habits (mainly cattle) or attempts to scratch nose in animals with allergic rhinitis
- Trauma—fighting, improper restraint, and passage of excessively large nasogastric tubes

- Paranasal sinusitis—dehorning or injury to the horns can cause frontal sinusitis, infected cheek teeth (molars, premolars) can cause maxillary sinusitis. *Actinomyces pyogenes* and *Pasteurella multocida* are the most common bacterial causes. Respiratory viruses (e.g., IBR/BHV-1 and PI-3, and *Oestrus ovis* larvae or bots in sheep) can also cause sinusitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rhinitis—allergic rhinitis, *Oestrus ovis* infection in sheep
- Mycotic nasal granuloma—allergic rhinitis, foreign body, tumor, nasal actinobacillosis or actinomycosis
- Nasal tumor—fungal granuloma, foreign body, sinusitis, fracture, nasal actinobacillosis or actinomycosis, *Oestrus ovis* bots in sheep
- Allergic rhinitis—fungal granuloma, tumor, foreign body, respiratory virus, nasal actinobacillosis or actinomycosis
- Foreign body—allergic rhinitis, tumors, fungal granuloma, nasal actinobacillosis or actinomycosis, *Oestrus ovis* bots in sheep
- Trauma—snakebite, actinobacillosis, actinomycosis, cellulitis from *Clostridium* or *Fusobacterium*
- Paranasal sinusitis—facial fracture, nasal tumors, actinobacillosis, actinomycosis

CBC/BIOCHEMISTRY/URINALYSIS

- Rhinitis, trauma, paranasal sinusitis—nonspecific inflammatory profile
- Mycotic nasal granuloma, nasal tumors, foreign body—N/A
- Allergic rhinitis—nonspecific inflammatory profile, eosinophilia

OTHER LABORATORY TESTS

- Rhinitis—nasal swabs for cytology and culture (numerous eosinophils and mast cells if *Oestrus ovis* infection is present)
- Mycotic nasal granuloma—biopsy/histopathology
- Nasal tumor—biopsy/histopathology
- Allergic rhinitis—biopsy/histopathology, cultures (bacterial, viral, fungal)
- Foreign body, trauma, paranasal sinusitis—N/A

IMAGING

- Rhinitis, mycotic nasal granuloma, allergic rhinitis, foreign body—endoscopy
- Nasal tumors—endoscopy, radiography
- Trauma, paranasal sinusitis—radiography

OTHER DIAGNOSTIC PROCEDURES

- Rhinitis, mycotic nasal granuloma, nasal tumor, allergic rhinitis, foreign body, trauma—N/A
- Paranasal sinusitis—oral/dental examination, percussion, sinus centesis, and cytology and culture

PATHOLOGIC FINDINGS

- Rhinitis—inflamed mucous membranes
- Mycotic nasal granuloma—granulation tissue containing eosinophils, mononuclear cells, sporangia, occasional hyphae
- Nasal tumors are commonly noted on necropsy
- Allergic rhinitis—inflamed mucous membranes, granulation tissue if enzootic nasal granulomas present
- Foreign body—inflamed mucous membranes
- Trauma—inflamed mucous membranes, traumatized soft tissue
- Paranasal sinusitis—purulent debris in frontal or maxillary sinuses

TREATMENT

- Rhinitis—see Medications below.
- Mycotic nasal granuloma—difficult to treat; salvage is often the most practical option. Can try surgical removal with

long-term sodium iodide 66 mg/kg IV as 20% solution repeated at 14-day intervals until remission or iodism occurs

- Nasal tumor—surgical removal
- Allergic rhinitis—remove allergen (i.e., remove animal from pasture, anti-inflammatory drugs) and treat with anti-inflammatory drugs (e.g., dexamethasone 0.04–0.22 mg/kg IM or IV sid, or an antihistamine—tripelennamine hydrochloride 1.1 mg/kg IV or IM bid to qid as needed).
- Foreign body—manual or transendoscopic removal
- Trauma—surgery not usually needed unless injury very severe or breathing compromised
- Paranasal sinusitis—sinusotomy by trephining, flush daily with dilute antiseptic solution (e.g., 0.1% povidone iodine or 0.1% chlorhexidine); however, the frontal sinus of sheep and goats is very compartmentalized making flushing difficult. Antibiotics may be indicated (e.g., procaine penicillin G) and NSAIDs (e.g., flunixin meglumine) if systemic signs present.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

See Prevention/Avoidance below.

MEDICATIONS

- Rhinitis—anti-inflammatory drugs (e.g., flunixin meglumine); ivermectin 0.2 mg/kg PO if due to *Oestrus ovis*. Treat in late summer to prevent heavy infestation and treat again in winter to kill overwintering larvae.
- Mycotic nasal granuloma—sodium iodide 66 mg/kg IV as 20% solution
- Allergic rhinitis—dexamethasone 0.04–0.22 mg/kg IM or IV sid, prednisolone 1–2.2 mg/kg IM or IV sid, topical corticosteroids in severe cases
- Trauma—prophylactic antibiotics (e.g., procaine penicillin G 22,000 U/kg IM or SQ bid) to prevent infection or sinusitis, NSAIDs (e.g., flunixin meglumine)
- Paranasal sinusitis—procaine penicillin G

DRUGS OF CHOICE

- Flunixin meglumine 0.5–1.1 mg/kg IV or IM sid to tid
- Procaine penicillin G 22,000 U/kg IM or SQ bid

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroidal agents are contraindicated in pregnant animals.

PRECAUTIONS

Allergic rhinitis—corticosteroid treatment may decrease milk production.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

N/A

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Rhinitis—if due to *Oestrus ovis*, ivermectin 0.2 mg/kg PO in late summer to prevent heavy infestation, and treat again in winter to kill overwintering larvae
- Paranasal sinusitis—dehorn at early age, avoid dehorning during rainy or dusty conditions; fly control; bandage if necessary

POSSIBLE COMPLICATIONS

Nasal tumor—surgical removal may be accompanied by significant blood loss; should have blood donor animal available for blood transfusion.

EXPECTED COURSE AND PROGNOSIS

- Rhinitis—usually good prognosis
- Mycotic nasal granuloma—guarded to poor prognosis
- Nasal tumor—poor prognosis
- Allergic rhinitis—fair to guarded prognosis
- Foreign body—usually good prognosis
- Trauma—usually good prognosis
- Paranasal sinusitis—guarded to fair prognosis

NECROTIC STOMATITIS

BASICS

DEFINITION

- Necrobacillosis is a term used to describe any lesion associated with the gram-negative, strictly anaerobic bacterium *Fusobacterium necrophorum*.
- Oral necrobacillosis is a term used to describe infections of the mouth and larynx with *F. necrophorum*.
- This syndrome includes “necrotic stomatitis” in which the lesions are restricted to the oral cavity and “calf diphtheria” in which the lesions are largely confined to the larynx, buccal, and pharyngeal mucosa.
- *F. necrophorum* is a ubiquitous bacterial organism commonly found in the environment (soil) and is considered part of the normal flora of the oral cavity, respiratory tract, gastrointestinal tract, and urogenital tract of many omnivores and herbivores. The organism is commonly isolated from the soil of feedlots.

PATHOPHYSIOLOGY

- The organisms gain access to the body through traumatic injuries to mucous membranes and are considered to be infectious but noncontagious.
- It is generally thought that *F. necrophorum* is unable to penetrate and invade intact mucous membranes. Underlying mucosal defects (such as mucositis and laryngeal contact ulcers caused by repeated closure of the larynx associated with reflex coughing and swallowing) and laryngeal ulcers associated with mixed upper respiratory tract infections likely serve as portals of entry for bacterial organisms.
- *F. necrophorum* is thought to be a secondary bacterial invader and is often found in mixed infections. The ability of *F. necrophorum* to cause disease is enhanced by concurrent bacterial infections (e.g., *Arcanobacterium pyogenes*) and this synergy may play an important role in mixed infections.
- The organism produces a number of toxins associated with virulence, including necrotizing exotoxin, leukotoxin, hemolysins, hemagglutinin, adhesins, platelet-aggregating factor, extracellular enzymes, and endotoxins. The leukotoxin is known to be cytotoxic and causes vascular thrombosis.
- Infection leads to localized inflammation and edema of the laryngeal mucosa and cartilage; however, bacteremia and dissemination of organisms to the liver and other organs can occur in some cases.

SYSTEMS AFFECTED

- Gastrointestinal—primary (oral cavity, tongue, pharynx) and secondary (liver)
- Respiratory—primary (larynx/lungs)

GENETICS

N/A

INCIDENCE/PREVALENCE

The incidence of necrotic stomatitis is considered to be sporadic, with only a few calves in a herd becoming infected (low group morbidity rate). Outbreaks can occur in areas with poor hygiene or in areas with high concentrations of animals. Clusters of cases may occur when predisposing factors are present in large groups of animals over a short period of time. The disease occurs year-round, but there tends to be a higher incidence in the fall and winter.

GEOGRAPHIC DISTRIBUTION

- Worldwide distribution
- More common in countries where animals are housed indoors in the winter (confined quarters), maintained in feedlots, or housed in unsanitary environments

SIGNALMENT

Species

Cattle (bovine), sheep (ovine), goats (caprine), pronghorn antelope (*Antilocapra americana*), white-tailed deer (*Odocoileus*)

virginianus), mule deer (*Odocoileus hemionus*), elk (*Cervus elaphus*), caribou (*Rangifer tarandus*), and wild/exotic ruminant species (e.g., gazelles, impalas).

Breed Predilections

There are no breed predilections.

Mean Age and Range

- The oral infection (necrotic stomatitis) tends to occur in calves < 3 months of age, most commonly between 2 weeks and 3 months of age.
- Involvement of the larynx (necrotic laryngitis) is more common in older calves (yearlings up to 18 months of age).

Predominant Sex

There is no sex predilection.

SIGNS

HISTORICAL FINDINGS

Swollen, distended cheeks, tongue, and throat region; acute onset of a moist painful cough; lethargy, anorexia, and depression; inspiratory stridor, tachypnea, loud wheezing respiratory sounds;ptyalism, frequent and painful swallowing, dysphagia; fetid/rancid odor to the breath/halitosis; acute cases may remain active and bright without a fever initially; purulent nasal discharge (often bilateral); difficulty and reluctance to nurse; affected animals often stand and sip water continually.

PHYSICAL EXAMINATION FINDINGS

- Fever: temperature tends to be higher for calf diphtheria: 106° F (41°C); body temperature is moderately elevated for necrotic stomatitis: 103–104°F (39.5–40°C).
- Swollen (edematous) and hyperemic oral, pharyngeal, or laryngeal mucous membranes.
- The pharyngeal region may be painful on external palpation.
- Laryngeal opening is often reduced by edema and inflammation.
- Inspiratory dyspnea progressing to open-mouth breathing with extended head and neck.
- Necrotic erosions and ulcers (with diphtheritic membranes) are usually visible in the larynx/pharynx.

CAUSES

- The etiologic agent is thought to be *Fusobacterium necrophorum*, a gram-negative, strictly anaerobic bacterium, although many of these cases involve mixed infections.
- *F. necrophorum* is an opportunistic pathogen that gains entry either through lesions of viral infections (IBR or papular stomatitis) or after traumatic injury to mucous membranes.
- Many predisposing factors to infection have been suggested, including:
 - Contact ulcers of the laryngeal mucosa
 - Debilitating diseases
 - Erupting teeth
 - Generalized mucositis
 - Inhaled irritants/allergens
 - Nutritional deficiencies (e.g., vitamin A)
 - Other upper respiratory infections (IBR, PI3, bacterial, mycoplasmas, etc.)
 - Poor hygiene
 - Teeth grinding (bruxism)
 - Traumatic injuries to the oral mucosa

RISK FACTORS

- The incidence of disease tends to be highest in groups of animals that are kept in confined quarters under unsanitary conditions.
- Coarse, abrasive feeds may increase the risk of disease.
- General debilitating diseases may also predispose animals to developing disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious bovine rhinotracheitis (IBR)
- Bovine viral diarrhea virus (BVD)
- Pharyngeal trauma (including iatrogenic)
- Dental abscess; maxillary or mandibular fracture
- Nasal granuloma
- Severe viral laryngitis/tracheitis
- Actinobacillosis
- Laryngeal edema; laryngeal abscess
- Foreign body
- Mycotic stomatitis
- Tumor (neoplasm)

CBC/BIOCHEMISTRY/URINALYSIS

Acute cases show changes in the CBC consistent with acute septic conditions:

- Leukopenia
- Neutropenia with a left shift
- Nonregenerative anemia
- Absolute neutropenia
- Granulocytopenia
- Hypoproteinemia
- Increased fibrinogen levels

OTHER LABORATORY TESTS

Anaerobic bacterial cultures can be obtained from deep within the oral and laryngeal lesions.

IMAGING

- Direct examination can be aided with use of an oral speculum with a good light source.
- Laryngoscopy to examine the lesions and the extent of laryngeal immobility
- Endoscopy (via nasal passage)
- Radiographs of larynx and oral cavity

DIAGNOSTIC PROCEDURES

- Clinical signs are often sufficient in establishing a diagnosis.
- Thorough visual examination of the oral cavity and larynx with an oral speculum or the above-mentioned imaging techniques are recommended to confirm the diagnosis.
- Bacteriology may be useful in identifying bacterial organism(s); however, *F. necrophorum* is strictly anaerobic and is relatively difficult to cultivate. Smears taken from the margins of the lesions may assist in confirming the diagnosis.
- Postmortem examination of affected animals is recommended to confirm diagnosis and to rule out other diseases.

PATHOLOGIC FINDINGS

- The gross lesions are most commonly located in the vocal processes and/or the medial angles of the arytenoid cartilages.
- Acute lesions include edema and hyperemia surrounding large, central, well-demarcated, yellowish-gray necrotic ulcers in the mucosa of the mouth, pharynx, and/or larynx.
- The lesions may extend along the vocal folds and processes and can involve the cricoarytenoideus dorsalis muscle. The tongue, buccal mucosa, pharynx, cheeks, gums, palate, and trachea may also be involved.
- The necrotic tissue projects slightly above the normal surface and is friable and adherent. In time, this tissue may slough, leaving erosions and ulcers.
- Chronic cases contain necrotic cartilage often associated with draining tracts and granulation tissue. In severe cases, you may see occlusion of the airway.
- The regional lymph nodes may be swollen and/or hyperemic; may see necrosis of the palatine and pharyngeal tonsils.
- On histopathology, areas of coagulation necrosis are surrounded by a zone of vascular reaction, leukocytes, and granulation tissue.

- The bacteria are typically arranged in long filaments (sometimes as rods or cocci), but are relatively difficult to demonstrate in tissue sections.

TREATMENT

APPROPRIATE HEALTH CARE

- Mild cases can be treated with outpatient medical management.
- Severe cases with respiratory dyspnea may require immediate attention and possibly surgical intervention to maintain a patent airway.

NURSING CARE

- Good nursing and supportive care are critical in treatment of necrotic stomatitis and calf diphtheria.
- Easy access to food and fresh water, adequate ventilation, shelter, and oral electrolytes or intravenous fluids, if necessary.

ACTIVITY

- The activity level of these animals may likely be reduced due to respiratory dyspnea.
- High activity levels may exacerbate the condition and compromise the animal's respiration.
- Attempts should be made to keep affected animals calm and quiet to minimize stress.

DIET

- Avoidance of rough feed may minimize oral/pharyngeal abrasions.
- Affected animals may be reluctant to feed due to pain and swelling of the oral cavity and pharyngeal region.

CLIENT EDUCATION

- Care must be taken in examining affected animals not to compromise the respiratory tract. Visual examination and laryngeal imaging can be stressful and may result in additional insult to the animal's respiration.
- This condition is commonly associated with dry and dirty environmental conditions. Steps to minimize stressors and to clean up the environment may reduce the occurrence of this condition.

SURGICAL CONSIDERATIONS

- In severe cases, a tracheotomy can be performed if necessary to obtain a patent airway.
- Severe, chronic cases may require surgical debridement to remove necrotic and/or granulation tissue and to drain laryngeal abscesses.
- Subtotal arytenoidectomy may be indicated in severe cases involving chronic chondritis (inflammation of the cartilage).

MEDICATIONS

DRUGS OF CHOICE

Antibiotics:

- Sulfonamides such as sulfamethazine (initial/loading dose of 140 mg/kg IV, followed by 70 mg/kg IV SID/daily OR 150 mg/kg PO daily for 3–5 days). Treatment not to exceed 5 days.
- Initial parenteral administration of antibiotics followed by oral administration is recommended.
- Procaine penicillin (22,000 units/kg IM or SQ BID).
- Penicillin G procaine—15,000 units per pound IM or SQ SID for a minimum of 1 week. Withdrawal time = 10 days for cattle.
- Recommendations for antibiotic therapy should take into consideration that there may be multiple bacterial agents involved.

CONTRAINDICATIONS

- Oral medications should be avoided initially if possible to prevent additional damage to the irritated oropharynx and larynx and because affected animals have reduced ability to swallow.
- Crystalluria and renal disease have been reported in association with long-term administration of certain sulfonamides.
- Do not give oxytetracycline and penicillin at the same time.

- Drug withdrawal times must be determined and maintained for food-producing animals.

POSSIBLE INTERACTIONS

Please refer to the manufacturer's recommendations for specific drug dosages, timing, routes of administration, and withdrawal times.

ALTERNATIVE DRUGS

- Streptomycin, oxytetracycline, and tylosin are also effective antibiotics and have been used to treat calves with this syndrome.
- Nonsteroidal anti-inflammatory agents (NSAIDs) such as aspirin, phenylbutazone, or flunixin (0.5 mg/pound IM SID) can be used as adjunct therapy to reduce fever, swelling, inflammation, and edema.
- Corticosteroids and/or antihistamines may be used as supportive treatment to reduce laryngeal swelling and to prevent asphyxia.
- The use of mild topical disinfectants and antiseptics (e.g. Lugol's or povidone iodine) has been described.

FOLLOW-UP

PATIENT MONITORING

Affected animals should be monitored frequently, including body temperature, respiratory rate, oral and laryngeal examination. Identify infected animals early to prevent the spread of calf diphtheria.

PREVENTION/AVOIDANCE

- There are no specific control measures to prevent necrotic stomatitis.
- Minimizing predisposing factors, instituting good hygiene practices, avoiding rough feed, and minimizing exposure to dust and inhaled irritants may reduce the incidence of disease.
- In high incidence areas, prophylactic antibiotic feeding may minimize the impact of the disease.

POSSIBLE COMPLICATIONS

- Pneumonia, either from aspiration or hematogenous spread, is the most common complication.
- Septicemia/Fusobacteremia, toxemia. If the bacterial organisms gain access to the portal circulation, sequelae such as liver abscesses and ulcerative rumenitis may be seen.
- Necrosis of laryngeal cartilage can lead to laryngeal chondritis, resulting in a "chronic roarer." Permanent distortion of the larynx can lead to a harsh dry cough and inspiratory stridor.
- Extensive necrosis may lead to laryngeal paralysis (involvement of the cricoarytenoideus dorsalis muscle) and restriction of the laryngeal orifice. This results in increased efforts to breathe and this forced inhalation may lead to pneumonia.
- Venous drainage from the face into vascular sinuses of the meninges may lead to abscessation of the brain and pituitary gland.
- Severely affected animals that survive are often chronic "poor-doers."

EXPECTED COURSE AND PROGNOSIS

- If the condition is detected early and treated aggressively, the prognosis is guarded to good. Case mortality has been reported as approximately 15–20%.
- The disease course for acute cases ranges from 7–10 days, but may be as long as 2–3 months for chronic cases.
- Severe complications as listed above can occur, especially if the diagnosis is delayed. Several reports suggest that approximately 20% of affected animals progress to chronic cases. The prognosis for chronic cases (especially cases with bilateral involvement) is guarded to poor.
- Untreated calves tend to die from toxemia, upper airway obstruction/asphyxia, and pneumonia, usually within 2 to 7 days.
- A 60% success rate for surgical intervention in severe and chronic cases has been reported.
- Involvement of the laryngeal cartilage (ulcers and necrosis) often leads to a delay in healing or a failure to recover.
- It is recommended that chronic, unresponsive cases be culled.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Aspiration pneumonia
- Laryngeal chondritis

AGE-RELATED FACTORS

- Most calves affected are between 3 and 18 months of age; however, calves as young as 5 weeks and as old as 24 months have been affected.
- The oral form (necrotic stomatitis) is more common in younger calves less than 3 months of age.
- The laryngeal form (necrotic laryngitis/calf diphtheria) is most common in older calves up to 18 months of age.

ZOONOTIC POTENTIAL

- There have been case reports of *F. necrophorum* septicemia in humans; however, this syndrome is not commonly considered to be zoonotic. General precautions (e.g., wearing gloves) should be taken when working with infected animals.
- Oropharyngeal infection with anaerobic bacteria and subsequent thrombophlebitis and septic embolization in human patients is termed Lemierre's syndrome.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

- Bovine, ovine, caprine, cervids, wild/exotic ruminant species
- There is a similar syndrome observed in housed lambs as a complication of contagious ecthyma (parapox infection).

BIOSECURITY

- Although the organism is fairly ubiquitous, measures taken to control other respiratory diseases may reduce the incidence of necrotic laryngitis.
- Proper hygiene precautions and disinfection of potential fomites in calf pens and feeding/drinking places

PRODUCTION MANAGEMENT

- Observation and early diagnosis of cases are critical to minimize the impact on a feedlot.
- Preventive measures and early treatment can reduce the total number of animals affected.
- This disease is usually sporadic in nature and the economic losses are primarily due to reduced live weights, inefficient feed conversion, expensive treatments, and deaths.

SYNONYMS

- Necrotic/necrotizing stomatitis, necrobacillary stomatitis, oral necrobacillosis
- Calf diphtheria, necrotic/necrotizing laryngitis, laryngeal necrobacillosis
- The organism *Fusobacterium necrophorum* was previously named: *Sphaerophorus necrophorus*, *Actinomyces necrophorus*, *Corynebacterium necrophorum*, and *Fusiformis necrophorus*.

NEMATODIRUS

BASICS

DEFINITION

Infestation with the intestinal roundworm *Nematodirus* spp.

PATHOPHYSIOLOGY

- Adult *Nematodirus* spp. reside in the anterior third of the small intestine of ruminants. Eggs are shed in the feces and, in the case of *N. spathiger* and *N. helvetianus*, development into the third stage larvae happens within the egg in 2 to 4 weeks. *N. battus* and *N. filicollis* have a delayed development and require conditioning by cold over winter. These infectious larvae remain within the egg until they are stimulated to hatch with rain and they can remain viable in the soil or on vegetation for many months. They are then ingested by the host during grazing and develop into mature adults in about 3 weeks.
- If the animal survives the effects of the parasite infestation, resistance to reinfection can develop.

SYSTEMS AFFECTED

Production management, gastrointestinal

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

- Worldwide depending on species and environment
- Varies with geographic location.
- UK, Europe, New Zealand, Australia, South Africa, North America

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Pasturing in an enzootic area
- Previous year's lambs, calves, or kids were infected and were on the premises.
- Asymptomatic in resistant animals to acute illness within 3 weeks of exposure in susceptible animals
- Most severe in young animals but older nonresistant animals can also be affected.
- Lack of adequate anthelmintic program

PHYSICAL EXAMINATION FINDINGS

- Diarrhea, anorexia, dehydration
- Poor body condition
- In severe cases, sudden onset and death

CAUSES AND RISK FACTORS

- *Nematodirus* spp.
- Cattle—*N. helvetianus* primarily, also *N. spathiger*, *N. filicollis*, and *N. battus*
- Sheep and goats—*N. battus*, *N. spathiger*, *N. helvetianus*, *N. abnormalis*, *N. davitiani*, *N. filicollis*, and *N. lanceolatus*
- Bighorn sheep, deer, gemsbok—*N. spathiger*
- Moufflon—*N. filicollis*
- Bison—*Nematodirus* spp.
- Feeding on infested pasture, usually early in the grazing period
- Inadequate use of anthelmintics and preventive pasturing practices

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The epidemiology of *N. spathiger* and *N. helvetianus* can resemble that of *Trichostrongylus* spp.

CBC/BIOCHEMISTRY/URINALYSIS

CBC and biochemistry are indicated in severely affected animals.

OTHER LABORATORY TESTS

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Identification of eggs in feces during the patent period; however, clinical signs start during the late prepatent period making diagnosis more difficult early in the outbreak.
- Eggs are distinctive and easily identified. They are large (180–230 microns by 90–170 microns), smooth and elongate, tapering at both ends. They are segmented (8 cells inside) when initially passed in the feces.

PATHOLOGIC FINDINGS

- Severe dark green diarrhea staining the escutcheon or breech
- Dehydration and possibly cachexia.
- Fluid mucoid content of upper small intestine and soft or fluid feces in the colon. Duodenal mucosa might show hyperemia with excess mucus, but is usually normal in appearance. Third-stage larvae reside in the deeper layers of the mucosa and crypts. Fourth- or fifth-stage larvae reside coiled among the villi, and if in high enough numbers, result in villous atrophy.
- Worm counts reveal tangled cottony masses of elongate, lightly coiled nematodes in heavy infestations.

TREATMENT

- With clinical disease, adequate high-quality nutrition and water are essential.
- All animals in the group should be treated with anthelmintics to reduce exposure level.
- If possible, prevent reinfestation by moving to premises free of the parasite.

MEDICATIONS

- Anthelmintics should be given initially when first animals are put to pasture in spring, then again in 3–5 weeks.
- Repeated treatments may be needed depending on environmental conditions and the species of *Nematodirus* in the area. Single treatments can be used with a delayed spring turnout or if transfer to noninfested premises is done.
- Protocols will vary with location making the experience of local veterinarians essential.

- Ivermectin or doramectin at 200 micrograms per kilogram body weight given subcutaneously
- Do not treat animals that produce milk for human consumption with ivermectin or doramectin.
- U.S. meat withdrawal times are: ivermectin and doramectin, 35 days.
- Other anthelmintics that may be effective include (use as directed and observe withdrawal times): levamisole—5 mg per kg body weight; morantel—numerous preparations available; benzimidazoles (fenbendazole, oxfendazole, and albendazole)—numerous preparations available.

POSSIBLE INTERACTIONS

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Anthelmintics as above
- Avoid infested premises/pastures
- Without reinfestation, premises should be relatively free of infective larvae or eggs after two seasons, so pasture rotation at that interval will decrease potential of exposure.
- Potential pasturing of different, not susceptible livestock species in the off years.
- If calves, lambs, or kids are put on the pasture, follow them with adults who are likely resistant.

POSSIBLE COMPLICATIONS

In UK, New Zealand, and Australia, high mortality rates have been experienced.

EXPECTED COURSE AND PROGNOSIS

Full recovery with resistance to reinfestation if clinical disease is mild and treated early

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Other intestinal parasites
- Diarrhea, anorexia, dehydration

AGE-RELATED FACTORS

- Clinical disease seen primarily in calves, lambs, and kids
- Most severe in young animals, but older nonresistant animals can be affected also.
- If calves, lambs, or kids are put on the pasture, follow them with adults who are likely resistant.

ZOONOTIC POTENTIAL

None

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected.

BIOSECURITY

- Isolation and quarantine of new stock entering the herd/flock
- Treat and or cull new animals for disease conditions prior to herd introduction.
- If possible, prevent reinfestation by moving to premises free of the parasite.

PRODUCTION MANAGEMENT

- Avoid infested premises/pastures.

- Without reinfestation, premises should be relatively free of infective larvae or eggs after two seasons, so pasture rotation at that interval will decrease potential of exposure.
- Potential pasturing of different, not susceptible livestock species in the off years.

NEONATAL DIARRHEA

BASICS

OVERVIEW

- Neonatal diarrhea is the most prevalent illness in ruminants during the first 28 days of life.
- The development of diarrhea in neonates occurs because of a lack of adequate immunoglobulin transfer, an overwhelming exposure to enteric pathogens, or a combination of the two.
- Although diarrheas are discussed as being caused by a single disease entity, most cases of diarrhea are a result of mixed infections.
- Treatment centers on the correction of electrolyte imbalances and hydration status.
- Death occurs due to dehydration, metabolic derangements, and electrolyte imbalances.
- Prevention focuses on vaccination of the dams with appropriate antigens prepartum, ensuring adequate colostrum intakes, and providing a clean birthing and housing environment.

PATHOPHYSIOLOGY

Secretory Diarrhea

- Results from the stimulation of intestinal cells to secrete fluid into the lumen of the intestine. Although the absorptive capacity of the intestine remains intact, the amount of fluid secreted overcomes the absorptive capacity resulting in diarrhea.
- *E. coli* and *Salmonella* secrete entero- or exotoxins, which stimulate intestinal epithelium to secrete sodium, chloride, and potassium along with fluid.
- The production of prostaglandins, as a result of inflammatory processes, will stimulate cellular secretions as well as cytokines which are commonly seen in salmonellosis infections.

Malabsorptive Diarrhea

Results from injury to the absorptive epithelium of the intestinal tract. Viral agents—coronavirus and rotavirus—and parasitic agents—cryptosporidia and coccidia—are the main agents involved in this type of diarrhea.

Injury to the Intestinal Epithelium

- Results not only in the loss of absorptive capacity but also the loss of the enzyme systems needed for the digestion of nutrients such as lactose.
- Osmotically active solutes result from improper digestion and subsequent bacterial fermentation of nondigested nutrients. These osmotically active solutes draw fluid into the intestine, overcoming the absorptive capacity of the gut.
- Because diarrhea is usually the result of the interaction of multiple disease agents, various mechanisms are involved in the development of diarrhea.

SYSTEMS AFFECTED

Gastrointestinal, cardiovascular, musculoskeletal

GENETICS

NA

INCIDENCE/PREVALENCE

Incidence is higher in neonates born to primiparous dams due to ingestion of poor-quality colostrum and limited volume. Incidence is variable depending on the neonate's colostrum intake and the environment in which it is born and housed.

SIGNALMENT

Species

Bovine, caprine and ovine

Breed Predispositions

NA

Mean Age and Range

- Enterotoxigenic *E. coli*—usually within the first 4 days of life, may extend to 2 weeks if the animal is infected with viral or parasitic agents
- Enteroinvasive *E. coli*—first week of life for septicemia, joint infections may develop during the first two weeks of life.
- Enteropathogenic and Enterohemorrhagic *E. coli*—usually in the second and third weeks of life, range 4–28 days
- Salmonella—14 days to 2 months
- Coronavirus—7–14 days of age
- Rotavirus—4 days to 2 weeks of age
- Cryptosporidiosis—7 days to 3 weeks of age
- Coccidiosis—16 days of age and older

Predominant Sex

NA

SIGNS

GENERAL COMMENTS

- The severity of the diarrhea is dependent on agent virulence factors as well as host factors. Some animals may remain bright and alert and only exhibit mild signs of diarrhea, while others may have a profuse watery diarrhea and exhibit systemic involvement resulting in death.
- Most of the clinical signs observed are related to hypovolemia as a result of dehydration.
- The characteristics of the diarrhea are not diagnostic, although the presence of blood and mucus indicates large-intestine involvement.
- The presence of milk curds in the feces indicates a malabsorptive and or maldigestive type condition often associated with viral agents.
- Clinical signs of septicemia are associated with animals that are agammaglobulinemic or infected with enteroinvasive *E. coli* or *Salmonella*.

HISTORICAL FINDINGS

In a herd or flock situation, the number of cases increases with the duration of calving, lambing, or kidding season as the pathogen load builds over time.

PHYSICAL EXAMINATION FINDINGS

- Animals will have soiled perineums and tails. Animals will have varying degrees of dehydration exhibited by increased skin tent, sunken eyes, and tacky mucous membranes.
- Animals may or may not be febrile. Heart rate is increased due to dehydration but some animals may be bradycardic due to hyperkalemia. Respiratory rate will be elevated depending on the animal's acid-base status.
- The abdomen may appear slab sided if the animal is not eating or may appear bloated, especially on the right side, due to ileus and collection of fluid in the intestines.
- The umbilicus may be enlarged indicating omphalitis often associated with failure of passive transfer.
- Scleral injection as well as hypopion may be observed in calves that are septicemic.
- Animals may be recumbent and unable to rise indicating severe dehydration and acidosis.

CAUSES

- Rotavirus
- Enterotoxigenic *E. coli*
- *Cryptosporidium parvum* and *muris*
- Coronavirus
- Enteropathogenic and enterohemorrhagic *E. coli*
- Enteroinvasive *E. coli*
- *Salmonella* spp.
- *Clostridium perfringens* type C
- *Eimeria* spp.
- Bovine viral diarrhea virus

- Breda virus
- Calici virus
- Astro virus
- Parvovirus
- *Campylobacter coli* and *jejuni*

RISK FACTORS

- Inadequate colostral transfer of immunoglobulins resulting in agammaglobulinemia or hypogammaglobulinemia
- Birthing areas contaminated with fecal material containing pathogenic agents
- Inadequate or improper nutrition
- Neonatal housing in which the buildup of fecal material occurs. Environments that are cold, wet, and drafty.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- If diarrhea contains blood, *Salmonella*, coronavirus, enterohemorrhagic *E. coli*, BVDV, and coccidia should be considered.
- If diarrhea contains mucus, *Salmonella*, coronavirus, enteropathogenic *E. coli*, enterohemorrhagic *E. coli*, and coccidia should be considered.
- If the animal is febrile, *Salmonella*, enteropathogenic and enterohemorrhagic *E. coli*, and coccidia should be considered.
- Although infectious agents are often associated with neonatal diarrhea, poor-quality milk replacers may cause diarrhea in neonates as well as sudden changes in the diet.

CBC/BIOCHEMISTRY/URINALYSIS

CBC

- Hemoconcentration, increased plasma proteins
- A left shift may be observed in animals in which the infectious agent invades the mucosa, produces endotoxins, or causes mucosal damage to an extent that allows invasion of intestinal bacteria.

Serum Chemistry

- Hypoglycemia, metabolic acidosis, and prerenal azotemia are commonly observed.
- Serum Na and Cl may appear normal due to hemoconcentration but are low.
- Hyperkalemia may be present due to acidosis but a whole body potassium deficit exists.

OTHER LABORATORY TESTS

Determination of immunoglobulin status during the first week of life:

- Plasma protein, determined by refractometer, < 5 mg/dL indicates failure of passive transfer.
- Zinc sulfate or sodium sulfite turbidity tests can be performed to estimate immunoglobulin status.
- Fecal floatation for observation of coccidia and cryptosporidia oocysts.

PATHOLOGIC FINDINGS

Gross Findings

- The intestines are filled with fluid. The mucosa may be congested. Gross lesions are not observed with most of the common causes of neonatal diarrhea.
- Hemorrhagic enteritis is associated with *Clostridium perfringens* type C infections.
- Mucosal ulceration is associated with BVDV infections.
- Disruption of the mucosa and petechial hemorrhages may be observed in animals infected with *Salmonella* or coccidia.
- Congestion of the lungs, liver, and spleen along with petechial hemorrhages of the epicardium and serosal surfaces of organs are often observed in animals with septicemia due to *Salmonella* or enteroinvasive *E. coli*.

HISTOPATHOLOGY

- Colonization of intestinal epithelium by enterotoxigenic *E. coli*.
- Adherence and effacement of epithelial cells by enteropathogenic and enterohemorrhagic *E. coli*. Stages of cryptosporidia and coccidia development are observed.

- A desquamation of epithelial cells, shortening and possible fusion of villi are observed with viral infections.

TREATMENT

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

- Fluid therapy is needed to correct dehydration, circulatory impairment and electrolyte and metabolic imbalances. Fluid may be administered orally or intravenously. Commercial oral electrolyte solutions containing glucose and an alkalinizing agent are recommended if the neonate is still nursing. Neonates without a suckle response need IV fluids. IV administration of lactated Ringer solution is adequate.
- With severe acidosis, isotonic sodium bicarbonate solution (1.3%, 13 of sodium bicarbonate to 11 of distilled water) may be used. Dextrose solutions (2.5–5%) are indicated in cases of hypoglycemia.
- With hypoglycemia and an unknown electrolyte and acid-base status, a 2.5% dextrose and 0.45% saline solution has been recommended.

ACTIVITY

N/A

DIET

- Neonates with a suckle response should be left with the dam and allowed to nurse. Animals being reared artificially should remain on their diet or switch to whole milk or colostrum. If the diarrhea becomes worse or the calf becomes depressed, removal from the dam or milk is warranted. In case of hand-fed neonates that are depressed and not interested in sucking, or neonates not nursing the dam, neonates should receive a high-energy electrolyte solution at a rate of 10% of body weight divided into a minimum of four feedings. Once neonates are suckling, feed milk 5% of body weight in four feedings a day increasing amount per feeding gradually so calf is back on full feed within 2 to 3 days.
- Oral electrolytes containing an alkalinizing agent, other than acetate, should not be fed when calves are receiving milk as milk digestion may be disrupted.

CLIENT EDUCATION

- Neonates should be kept dry and in a draft-free environment.
- Equipment used to treat neonates should be cleaned between animals.
- Diarrheic animals should be isolated from healthy animals as they are sources for large numbers of pathogens.
- Caregivers should wash hands between animals and keep clothing free of fecal material.

MEDICATIONS

Many causes of diarrhea in neonates are self-limiting and antibiotics are not indicated. However, approximately 30% of neonates with diarrhea will have a bacteremia in which antimicrobial therapy may be beneficial.

DRUGS OF CHOICE

Broad-Spectrum Antibiotics

- Oral amoxicillin trihydrate 10 mg/kg PO q 12 h for nonruminating calves, 20-day slaughter withdraw (extralabel in small ruminants); amoxicillin trihydrate-clavulanate potassium 12.5 mg combined drug/kg PO q 12 h for 3 days (extralabel usage)
- Parenteral ceftiofur 2.2 mg/kg IM/SC q 24 h for 3 days (extralabel usage)

NSAIDs

Flunixin meglumine (1.1 mg/kg IV or 2.2 mg/kg IM) has been shown to decrease secretion induced by *E. coli* enterotoxins and reduce morbid days in calves with fecal blood (extralabel usage).

Plasma Transfusion

In cases of failure of passive transfer and depending on value of the animal, plasma transfusion may be warranted.

CONTRAINDICATIONS

- Do not use kaolin and pectin as they may increase electrolyte loss.
- Drug withdrawal times must be determined and maintained for food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Monitor attitude, suckling response and appetite, fecal color and consistency, and hydration status.
- Monitor age cohorts for signs of diarrhea.

POSSIBLE COMPLICATIONS

- Sepsis
- Hypovolemic shock
- Septic arthritis

PREVENTION/AVOIDANCE

- Ensure adequate colostrum quality and intake.
- Birthing area should be clean.
- Remove dam and neonate after birth from birthing area and place in a clean environment.
- Dip navels in an antiseptic.
- Eliminate areas of fecal buildup.
- Vaccines containing enterotoxigenic *E. coli*, rotavirus, and coronavirus antigens and autogenous *Salmonella* vaccines given to dams prepartum may be beneficial.

EXPECTED COURSE AND PROGNOSIS

- Most cases of neonatal diarrhea resolve over a 2- to 3-day period. Recovery is dependent on the cause of the diarrhea.
- Diarrhea is more severe in animals in which multiple disease agents are present, for example, a virus-induced diarrhea with secondary bacterial infection.
- The length of time to recover is proportional to the amount of mucosal damage the animal experiences.
- Prognosis is directly related to the ability of the animal to maintain hydration and its immunoglobulin status.
- Animals that are hypogammaglobulinemic or are septicemic are at increased risk of dying.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Septic arthritis
- Omphalitis
- Meningitis

AGE-RELATED FACTORS

Neonatal disease

ZOONOTIC POTENTIAL

- All diarrheic animals should be handled as having a zoonotic potential.
- *Salmonella*, cryptosporidia, *Campylobacter*, and some *E. coli* are potentially pathogenic to humans.

NEONATAL SEPTIC ARTHRITIS

BASICS

DEFINITION

- An inflammatory disease confined to the synovial membrane and articular surfaces as a result of sequestered bacteria.
- Route of infection is hematogenous as a result of bacteremia, which often originates from umbilical infection.
- Often occurs in multiple joints

PATHOPHYSIOLOGY

- Bacterial infections of newborn ruminants occur largely as a result of hypogammaglobulinemia.
- Neonates become bacteremic or septicemic from an infection that often originates from the umbilical cord or via oral ingestion.
- Bacteria then sequester in the joint and cause inflammation of the synovial membrane.
- Multiple joints are often affected
- Synovitis causes distension of joint capsule with fluid.
- Arthritis may be suppurative or serofibrinous.
- Erosion of articular cartilage, infection of subchondral bone, and osteomyelitis can be sequelae.

SYSTEMS AFFECTED

Musculoskeletal

GENETICS

N/A

INCIDENCE/PREVALENCE

- Incidence is not well described.
- Usually sporadic
- Can cluster in herds where calving occurs in unhygienic conditions

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Cattle, sheep, goats, camelids

Breed Predilections

More common in dairy calves than beef calves

Mean Age and Range

- Neonatal ruminants < 4 weeks of age
- Usually evident within 2–3 days after birth

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Unhygienic calving environment
- History of inadequate colostrum intake in the first few hours of life
- Small weak calves that remain recumbent for some hours
- Beef cows that reject their calves

PHYSICAL EXAMINATION FINDINGS

- Lameness is sudden and severe
- Multiple joints may be involved
- Joint effusion
- Pain
- Fever
- Inappetence
- Recumbency
- Palpation and flexion of joints reveal heat and pain.
- Tachycardia and dehydration may be evident.
- Umbilical abscessation may be evident on palpation.
- Nervous symptoms associated with meningitis may be present.

CAUSES

- *Arcanobacterium pyogenes*
- *Escherichia coli*
- *Streptococcus* spp.
- *Salmonella* spp.
- *Mycoplasma bovis*
- *Histophilus somnus*
- *Chlamydia psittaci* (lambs)
- *Erysipelothrix rhusiopathiae* (lambs)

RISK FACTORS

- Hypogammaglobulinemia as a result of inadequate colostrum intake
- Dystocia
- Mismothering or abandonment
- Hypothermia
- Poor-quality colostrum
- Unhygienic calving area
- Overcrowded calving area

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious arthritis can occur from primary causes such as penetration of joint by foreign body.
- Infectious arthritis can also occur from extension from surrounding tissues such as decubital lesions.
- Myositis
- Degenerative myopathy
- Trauma
- Diseases of the nervous system that may cause recumbency or lameness
- Osteomyelitis

CBC/BIOCHEMISTRY/URINALYSIS

Elevated white blood cell counts

OTHER LABORATORY TESTS

- Assessment of passive transfer can be evaluated at 8–12 hours after birth.
- Serum total protein less than 4.2 g/L is indicative of failure of passive transfer (FPT).
- Sodium sulfite precipitation test: rapid and accurate field test to assess FPT
- Serum GGT correlates moderately well with serum IgG concentrations.

- Radial immunodiffusion is the gold standard test for FPT but is expensive and takes longer to perform.

IMAGING

- Radiology may only reveal soft tissue swelling in early stages.
- Destruction of articular cartilage and bone may be evident in advanced cases.
- Occasionally, new bone may be deposited at periphery of joint.

DIAGNOSTIC PROCEDURES

- Joint aspiration may reveal purulent synovial fluid.
- Total leukocyte counts range from 50,000–100,000 cells/uL.
- Leukocytes are usually > 90% neutrophils.
- Synovial fluid has elevated protein content (> 4 g/dL).
- Joint culture is often unrewarding.

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

- Systemic antibiotic therapy should be initiated and maintained for 5 to 10 days.
- Treatment of failure of passive transfer should be considered if possible.
- Short-term analgesic therapy (24–48 hours) in the form of nonsteroidal anti-inflammatories (flunixin meglumine or ketoprofen) may be used to reduce pain.
- Drug withdrawal times must be determined and maintained in treated animals

NURSING CARE

- Calf may need to be assisted to stand and nurse if appropriate (beef cattle).
- Physiotherapy by gentle flexion and extension or regular exercise may improve return to function.

ACTIVITY

Restricted until resolution of symptoms

DIET

N/A

CLIENT EDUCATION

- Predisposing causes should be discussed and eliminated if possible.
- Colostral management should be evaluated.
- Calving area hygiene should be evaluated.
- Warn client of need for long-term antibiotics and guarded prognosis.

SURGICAL CONSIDERATIONS

- Joint lavage using a “through and through” technique with two 14-gauge needles placed on either side of the joint.
- Warmed lactated Ringer’s should be flushed through joint to remove debris.
- A light dressing should be applied to joint for 24–48 hours after joint lavage.
- Arthroscopy may be considered if joint lavage is unsuccessful in valuable animals. Allows high-volume lavage and is quite effective.
- Arthrotomy can be attempted in advanced cases.

MEDICATIONS

DRUGS OF CHOICE

- Selection of antibiotic may be determined by results of joint culture and sensitivity.

- Procaine penicillin G
- Ampicillin
- Ceftiofur
- Oxytetracycline
- Potentiated sulphonamides

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

Ketoprofen or flunixin meglumine may be used for short-term pain relief (24–48 hours).

FOLLOW-UP

PATIENT MONITORING

Duration of antibiotic therapy should continue despite resolution of symptoms for up to 10 days.

PREVENTION/AVOIDANCE

- Ensure adequate colostrum intake.
- Utilize tincture of iodine.

POSSIBLE COMPLICATIONS

- Chronic arthritis may result in severe degenerative joint disease.
- Recurrence of infection may occur if source of infection is not eliminated.
- Osteomyelitis
- Meningitis may occur in neonates with septicemia.

EXPECTED COURSE AND PROGNOSIS

- Prognosis is dependent on level of failure of passive transfer.
- Prognosis is poor if multiple joints or meningitis is evident.
- Delay in initial treatment will also cause prognosis to be poor.
- Cases involving a single joint that are treated early have a reasonably good prognosis (up to 80% of calves may recover).

MISCELLANEOUS

ASSOCIATED CONDITIONS

NEONATOLOGY: BEEF

BASICS

DEFINITION

- Common diseases found in beef calves within the first few weeks of life
- Neonatal mortality in beef calves ranges from 4%–10%, with approximately 50%–70% of neonatal mortality occurring during the first 3 days after birth.

PATHOPHYSIOLOGY

Various, depending on disease condition

SYSTEMS AFFECTED

- Hemo/immune—Failure of passive transfer of immunity is the most common predetermining factor for disease development in neonates. In cases of septicemia, the umbilicus is frequently the site of bacterial entrance to the body.
- Gastrointestinal—Diarrhea is the most common disease manifestation in neonates.
- Respiratory—Aspiration of meconium may occur during dystocia. Premature calves may have immature lungs and lack sufficient pulmonary surfactant production. Pneumonia usually affects older calves; however, neonates can be affected during disease outbreaks and due to septicemic spread of bacteria.
- Endocrine/metabolic—Hypovolemia leading to reduced perfusion and hypoxia can result in hypoglycemia, hyponatremia, and acidosis (respiratory or metabolic).
- Cardiovascular—Congenital cardiac defects such as PDA, ventricular septal defects, and Tetralogy of Fallot; hypovolemia leading to circulatory shock
- Musculoskeletal—Many musculoskeletal defects are due to congenital abnormalities. Dystocia may result in trauma to the calf. Lameness may result from septic arthritis.
- Renal/urologic—Umbilical abscess or infection; reduced renal perfusion due to hypovolemia

GENETICS

Some neonatal conditions are genetic (e.g., epitheliogenesis imperfecta in shorthorn and Angus; cerebellar hypoplasia in Hereford, Angus, and shorthorn).

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Beef breed calves < 2 weeks of age

SIGNS

HISTORICAL FINDINGS

- Dystocia
- Premature delivery
- Weakness
- Anorexia
- Failure of passive transfer
- Diarrhea

PHYSICAL EXAMINATION FINDINGS

- Weakness/depression
- Dehydration

- Hypothermia
- Fever (may or may not be present)
- Congenital abnormalities (e.g., cleft palate, contracted tendons)

CAUSES

Congenital

Although rare in occurrence, there are numerous congenital defects that may affect calves.

Metabolic

- Hypoglycemia
- Hypoxia
- Acidosis
- Dehydration
- Hyponatremia

Nutritional

- Maternal malnutrition can greatly affect neonatal calf livability.
- Starvation due to weak calf, inability to stand, poor mothering ability, etc.

Immune

Failure of passive transfer is a leading cause of neonatal morbidity and mortality.

Infectious

- Bacterial, viral, and fungal agents can all cause infections in the neonate.
- Rotavirus, cryptosporidia, coronavirus, *Escherichia coli*, and *Salmonella* spp. are the most common causes of infectious diarrhea.

Traumatic

Fractured ribs or other bones due to dystocia

RISK FACTORS

- Failure of passive transfer
- Dystocia
- Pathogen buildup due to crowded calving area
- Maternal malnutrition

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diarrhea: *E. coli*, *Salmonella* spp., rotavirus, cryptosporidia, coronavirus, *Clostridium perfringens* type C
- Septicemia: *E. coli*, *Actinomyces pyogenes*, *Staphylococcus aureus*, *Streptococcus* spp.
- Umbilical infection: *Actinomyces pyogenes*, *E. coli*, *Proteus*, *Enterococcus* spp.
- Pneumonia (usually seen in older animals but can occur in neonates)
 - Aspiration pneumonia
 - Septicemic spread of bacteria
 - Bovine respiratory syncytial virus
 - Infectious bovine rhinotracheitis
 - Bovine viral diarrhea virus
- Congenital defects
- Lameness: Septic arthritis, trauma
- Hypothermia
- Abomasal bloat
- Cardiac abnormality (PDA, VSD, etc.)

CBC/BIOCHEMISTRY/URINALYSIS

- Hypoglycemia
- Acidosis (metabolic or respiratory)
- Hyponatremia
- Hyperkalemia
- Leukocytosis with left shift

OTHER LABORATORY TESTS

- Failure of passive transfer—IgG < 10 g/L or TP < 5.5 g/dL
- Positive blood culture for bacteria
- Positive fecal culture

IMAGING

- Thoracic radiographs
- Ultrasonography of umbilical structures

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

Varies based on disease condition

TREATMENT

APPROPRIATE HEALTH CARE

Varies based on disease diagnosis.

NURSING CARE

- Fluid therapy to correct dehydration and acidosis
 - Oral solutions should contain 50–80 mmol/L of alkalinizing agent (acetate, lactate, citrate, gluconate, and bicarbonate are most common). Acetate solutions provide best results for calves still drinking milk.
 - IV fluids can be provided to recumbent calves that are unable to suckle.
- Provide heat source to correct hypothermia
- Supplemental oxygen
- Meet nutritional needs
- Keep recumbent neonates in sternal recumbency, if possible

ACTIVITY

- Restrict contact with other animals
- Minimize physical activity
- Minimize stress

DIET

- Maintain proper nutrition of pregnant cows
- Ensure adequate colostrum intake in calves
- Weak, recumbent calves with severe diarrhea may benefit from being held off milk. Malabsorption of milk can increase osmotic diarrhea and promote bacterial overgrowth.
 - Provide fluid therapy.
 - Withholding milk for extended periods will result in weight loss and can lead to severe cachexia. Most calves will respond to fluid therapy within 2 days.
 - Calves that are alert and interested in nursing should be allowed to do so.

CLIENT EDUCATION

- Discuss importance of colostrum.
- Discuss calving and environmental management protocols to minimize disease transmission.

SURGICAL CONSIDERATIONS

- Congenital defects and/or traumatic injuries may require surgery.
- Stabilize calf before anesthesia.

MEDICATIONS

DRUGS OF CHOICE

Varies based on disease condition and antimicrobial susceptibility

CONTRAINDICATIONS

- Drugs prohibited for use in food animals.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

- Prolonged use of some drugs may result in cartilage damage.
- Prolonged use of oral antibiotics can lead to diarrhea.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

- Oral IgG supplements
- Probiotics

FOLLOW-UP

PATIENT MONITORING

Watch neonates closely; they can go downhill very quickly.

PREVENTION/AVOIDANCE

- Calving area hygiene and colostrum management are important aspects of preventing neonatal disease.
- Monitor newborn calves closely for signs of disease and begin proper treatment as soon as a problem is recognized.
- Ensure proper vaccination of cows.
- Avoid genetic lines known to produce defects.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Varies depending on disease condition

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

NEONATOLOGY: DAIRY

BASICS

OVERVIEW

At birth, a calf is transferred from a nearly sterile environment to an environment containing a multitude of pathogenic and nonpathogenic organisms. The calf is born with a naïve immune system. Therefore, any alterations in the animal's physiological state may depress the already delicate protective responses. This means an increase in disease susceptibility in the newborn, often with a negative impact on growth and development. The health of the neonate depends on many factors occurring before, during, and after parturition.

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on breed and environment

MISCELLANEOUS

Prenatal Care (Conception to Parturition)

Proper care of the cow during gestation is essential to producing a healthy calf. Two areas of most importance are

- (1) providing protection for the dam and calf through appropriate maternal vaccination and
- (2) ensuring optimal maternal body condition and sufficient nutrition.

Table 1

Source: Adapted from LDHM, American Dairy Science Association, 1999, p. 399.

Vaccines That May Be Used During the Dry Period
Leptospirosis, multivalent
Bovine respiratory syncytial virus, BRSV (modified live or killed virus)
Infectious bovine rhinotracheitis, IBR (altered or killed virus only)
Clostridium, multivalent bacterin/toxoid
Parainfluenza type 3, PI3 (modified live or killed virus)
<i>E. coli</i> (K99) vaccine
Bovine virus diarrhea, BVD (killed virus only)
<i>E. coli</i> J5 vaccine
Rotavirus
Coronavirus

Maternal Vaccination

- Maternal vaccination strategies to protect the neonate should be targeted at enhancing disease-specific colostral immunity and early protection against organisms causing diarrhea and respiratory diseases in the neonate (see [Table 1](#)).
- Calves should not be vaccinated (actively immunized) during the period immediately after birth, as colostrum-derived antibodies passively immunize them. The priority for vaccinating against infectious agents will vary from herd to herd, and should be based on the incidence of disease in the herd.
- When after birth a calf can be successfully vaccinated depends on (1) the ecology of the host-parasite interaction for the agent, (2) quantity of antibody transferred from the dam at birth, (3) the quality and timing of colostrum ingested, and (4) absorption efficiency of colostral antibodies.

Table 2

Source: Adapted from Gearhart et al., 1990.

Suggested Body Condition Score (BCS) for Various Stages of Lactation	
Stage of lactation	BCS Range ¹
Calving	3.00–3.75
Peak milk production	2.25–2.75
150–200 days in milk	3.00–3.50
Dry off	3.00–3.75

¹ Range: 1 (emaciated) to 5 (fat).

Maternal Body Condition Score

- It is essential that the cow be maintained in good condition throughout the dry period and the lactation cycle to provide energy and building blocks for calf development and growth (see [Table 2](#)).
- Dry cows should be managed to allow for transition from a period of relatively low metabolic demands during the dry period to extremely high metabolic demands during parturition and the onset of lactation.
- Dietary manipulations for sustaining the cow's body condition require appropriate planning. Late lactation cows are more efficient at utilizing metabolizable energy than cows in the dry period.
- Body condition is based on scale of 1 (emaciated) to 5 (fat).

Perinatal Care

Initial Management of the Neonate

- Initiation of respiration is critical in the neonatal calf. An extended period without gas exchange leads to acidosis and accumulation of mucus in respiratory passages.
- Fluid in the lungs may be removed by lifting the calf by the hind legs until the muzzle is off the ground.
- A prolonged period of calving may result in fetal hypoxia. Consequently, cows should receive assistance during calving, when necessary. Mild to moderate hypoxemia in calves will produce metabolic acidosis.
- Normal calves have a venous pH of 7.34, bicarbonate of 30 mmol/L, and base excess of 5 mmol/L. Acidotic calves have been observed with a pH as low as 7.03 and a base deficit of 18 mmol/L. This is crucial, since a significant negative correlation exists between the severity of metabolic acidosis and efficiency of colostrum ingestion.
- The most frequent causes of mortality in the neonatal calf are dehydration and acidosis. Consequently, the highest priority in treating a diarrheic calf is to return the calf to metabolic homeostasis (venous pH 7.25–7.45).
- A variety of alkalinizing agents have been used (lactate, acetate, gluconate), but bicarbonate is consistently effective in severely acidotic calves. Bicarbonate requirements can be calculated from base deficit values (based on blood gas measurements or estimated from physical examination findings):

$$\text{bicarbonate} = \frac{\text{mmol}}{\text{body weight (kg)} \times \text{base deficit (mmol/L)} \times 0.5}$$

- An estimate of the severity of acidosis in the neonatal calves before 8 days of age can be ascertained by physical examination using indicators of body position, strength of suck reflex, and age. A standing calf with a strong suck reflex will not likely have any base deficit. In contrast, a calf that is in sternal or lateral recumbency will likely have a base deficit of 10 mmol/L or greater.

- Severely depressed calves are best treated with intravenous fluids. Moderately depressed calves should be treated with intravenous fluids, if the condition is progressing in severity rapidly. A no. 15 scalpel blade can be used to make catheterization easier. A calf can be suspended upside down to allow blood to pool and distend the jugular vein. Before inversion, the calf's neck should be clipped and prepared. The calf should be placed flat after catheter is placed.

Navel Dipping

Disinfecting the calf's navel can minimize the threat of navel infection and subsequent development of septicemia. The navel must be thoroughly saturated with 7% iodine solution. The navel cord should be filled and an area approximately 2 inches around the base of the navel saturated with iodine. This should be conducted within 2 hours of birth, when the calf is put in the hutch, and 12–18 hours later.

Neonatal Period (0–14 d)

- Adequate colostrum ingestion and neonatal nutrition will help the calf combat infection, such as septicemia and neonatal diarrhea, during the early neonatal period.
- Colostrum performs a crucial role in protecting the newborn against gastrointestinal and respiratory infections. A brief description of the components in colostrum (see below) will aid in an understanding of how colostrum provides protection for the neonate.

Immune Function

A brief explanation of the neonatal immune system is warranted here. However, this explanation should not be considered to be all inclusive. The author strongly suggests other reviews of bovine neonatal immunology.

General Parameters

Immunoglobulins

- Susceptibility of the neonate to contagious and opportunistic infections is a consequence of the immaturity of the immune system. Bovine colostrum contains a high concentration of IgG (45 mg/dL).
- Passively acquired immunoglobulins are essential to the neonatal calf, as most calves are born agammaglobulinemic. The function of colostral immunoglobulins in the protection of neonatal calves has been extensively studied.

Colostral Leukocytes

- Bovine colostrum contains about 106 leukocytes/mL. Colostral leukocytes appear to contribute to regulation of the cellular aspect of the neonate's immune responses.
- Newborn calves are able to absorb colostral leukocytes through the intestinal barrier, and the preferential route is through the follicle-associated epithelium of the Peyer's patches.
- The common practice of freezing colostrum may destroy essential colostral leukocytes and diminish the protection delivered to the neonate.
- Mammary secretions contain four types of cells: epithelial cells, macrophages (50% of leukocytes), lymphocytes (20% of leukocytes), and neutrophils (30% of leukocytes) at 1 to 2 days after parturition.

Colostral Components

Several components of colostrum, other than immunoglobulin, may help to protect the neonatal calf from infection. These components include lactoferrin, CD14, and cytokines that enhance both innate and adaptive immune responses.

Lactoferrin

- Lactoferrin is an iron-binding protein product of the transferrin gene family.
- Lactoferrin is a major constituent of the secondary granules of polymorphonuclear neutrophils (PMN) and is found in high concentrations in colostrum and milk during mastitis.
- Higher concentrations of this protein are found in bovine colostrums than milk (1–5 mg/dL). Oral lactoferrin is absorbed in calves, but does not alter PMN superoxide production or IgG absorption. Lactoferrin has direct activity against at least two pathogens, *Escherichia coli* and rotavirus.

CD14

- CD14 enhances and regulates the inflammatory response to the bacterial cell wall. CD14 is a glycosyl-phosphatidyl-inositol anchored membrane protein expressed on mature monocytes and macrophages. Lipopolysaccharide binding proteins help mediate lipopolysaccharide complexation with soluble CD14.
- A soluble form of CD14 is found in colostrum. In addition, postsuckling calves show evidence of transfer of maternal CD14 to the circulation. Soluble CD14 induces B cell development, and increases antibody secretions by the neonate.

Cytokine

- Limited data are available concerning the activity of cytokines present in bovine mammary secretions. The activity of IL-2 is detected in the mammary gland 2 weeks before parturition, but diminishes by the last week of gestation.
- Antiviral activity demonstrated in mammary secretions is assumed to result from tumor necrosis factor- α present in the secretion. Insulinlike growth factor is found in colostrum at high concentrations and may promote both growth and immune system development of the neonate.
- The level of transforming growth factor decreases rapidly in the milk. It is almost undetectable by 30 days postpartum.

Neonatal Diseases

Septicemia

Septicemia often affects multiple organ systems, especially respiratory and gastrointestinal. Calves may be lethargic with poor suckle reflex, weakness, tachycardia, tachypnea, and recumbency.

Neonatal Diarrhea

- *Escherichia coli* is an important pathogen in the domestic livestock industry. This organism causes enteric colibacillosis, characterized by severe diarrhea, and septicemia, an acutely fatal systemic infection.
- Neonatal diarrhea may be caused by viral, bacterial, parasitic, or dietary insult. The diarrhea caused by specific organisms is usually observed at specific ages of the neonate, but does not always occur at these ages.
- The viruses most commonly associated with neonatal calf diarrhea are rotavirus (4–14 days of age), coronavirus (4–30 days of age), and bovine viral diarrhea virus (any age). Bacterial infections are common in the neonate: *Clostridium perfringens* (less than 10 days of age), enterotoxigenic *Escherichia coli* (1–4 days of age), and *Salmonella typhimurium* (any age).
- Parasitic infections in calves are common caused by *Cryptosporidium parvum* (7–28 days, possibly older), *Eimeria bovis* (clinical signs, older than 3–4 weeks) and *Giardia* spp. (are thought not be major pathogens in calves).
- Neonatal diarrhea may be caused by a combination of dietary and infectious agents. Calves with diarrhea usually have a partially compensated metabolic acidosis with decreased pCO₂, negative base excess, a decreased buffer base, and a lowered blood pH.
- Nutritional aspects include overfeeding, inadequate sanitation of equipment, feeding of waste milk, or poor-quality milk replacers. Restricting intake of milk replacers may be beneficial in calves with diarrhea, but the deliberate underfeeding of healthy calves predisposes them to diarrhea.

Neonatal Nutrition Requirements

- Proper nutrition in the neonatal period may help the neonate survive disease challenges.
- Neonatal calves must have a good source of energy; milk replacers should contain a minimum of 15% fat on a dry matter basis, but may contain more than 20% (see [Table 3](#)). High levels of fat often are included in milk replacers to provide extra energy for growth, and inclusion of fat may tend to reduce severity of diarrhea.

Table 3

Recommended Nutrient Content of Milk Replacers	
Nutrient	Amount
Metabolizable energy (Mcal/lb)	1.71
Crude protein (%)	22
Ether extract, fat (% minimum)	15 ^a
Vitamin A, K (IU/lb)	3.682 ^b
Vitamin D (IU/lb)	245 ^b
Vitamin E (IU/lb)	20.4 ^{b,c}

^aNational Research Council, 1989.

^bNational Research Council, 2001

^cReddy, 1987.

- Milk replacers should contain 22% protein, all derived from animal sources, since plant proteins are less digestible. However, the use of animal proteins in milk replacers may not be feasible with the outlawing of feeding animal proteins to animals due to bovine spongiform encephalopathy (BSE).

- Although vitamins A, D, and E are necessary components of the calf's diet, some milk replacers supply excessive amounts of these fat-soluble vitamins. In addition, vitamin E appears to be immunostimulatory at levels of 125 IU/day.

Additional Considerations

- Proper rearing of replacement heifers for today's dairy herds is filled with pitfalls for the producer and the veterinarian alike. When raising calves, producers should consider the threats of disease occurrence including general hygiene, pathogen density in the local environment of calves, pathogen virulence, physical environment (temperature, humidity, and wind chill), and nutritional status of calves.
- Knowing the level of antibody transferred may not be enough. Total circulating immunoglobulin is not necessarily indicative of the specific trafficking antibody.
- A high level of serum immunoglobulin does not guarantee that the immunoglobulins will reach the site of infection and neutralize the organism. A better understanding of the herd and maternal vaccination limitation will make quantitative immunoglobulin measurement more useful.

TREATMENT

APPROPRIATE HEALTH CARE

Varies based on disease condition and the environment

NURSING CARE

- Warming neonate
- Oxygen supplementation
- Oral or intravenous fluids (correct electrolyte and acid-base disturbances)
- Meet caloric needs via PO or IV nutrition

(i.e., oral sugar/syrup or IV dextrose for hypoglycemia)

- Enema for meconium impaction

ACTIVITY

- Passive range of motion
- Rolling from side to side
- Maintain sternal recumbency

DIET

- Proper nutrition of the prepartum doe
- Important to feed the kids a balanced diet that meets their caloric and nutritional requirements. This may help prevent starvation, hypoglycemia, and nutrient deficiencies.

CLIENT EDUCATION

Correct any deficiencies in husbandry or breeding selection.

SURGICAL CONSIDERATIONS

- Stabilize patient before beginning any surgical procedures.
- Congenital defects and/or traumatic injuries may need surgical correction.
- Neonates in many instances are not good surgical candidates.

MEDICATIONS

DRUGS OF CHOICE

- Antibiotics based on suspected problem and/or culture and sensitivity
- NSAIDs may be indicated. Care should be used in selection and hydration status of the neonate. Some NSAIDs are contraindicated in the neonate.
- Intravenous plasma, oral plasma, or oral colostrum
- Antidiarrhea medications

CONTRAINDICATIONS

Avoid using drugs prohibited or not labeled for use in food-producing animals (e.g., aminoglycosides, metronidazole). Follow drug withdrawal periods for meat and milk.

PRECAUTIONS

Beware of drugs that may affect growing tissues.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

Probiotics may be indicated.

**FOLLOW-UP****PATIENT MONITORING**

- Keep in contact with farm owner/manager.
- May recheck blood work results for changes in values

PREVENTION/AVOIDANCE

- Correct management deficiencies.
- Avoid poor husbandry and/or breeding selection.
- Ensure colostrum quality.
- Ensure adequate amount of colostrum is administered within the first 24 hours after birth.
- Adequate nutrition and vaccination of parturient does.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Varies based on disease(s) encountered

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

Some diseases of small ruminants may have zoonotic potential (e.g., *Salmonella* spp., *E. coli*, *Campylobacter* spp., *Cryptosporidium* spp., *Giardia* spp.)

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

N/A

BIOSECURITY

- Biosecurity measures may help to decrease the severity and course of neonatal diseases and may improve the prognosis.
- Can decrease transmission among other neonates, adult goats, and humans
- Isolation and quarantine of new stock entering the herd/flock
- Treat and or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT

- A good environment is vital to neonatal health.
- Management of pregnant does is important to neonatal health and viability.
- Proper husbandry and breeding practices are crucial in selecting for healthy neonates.

NEONATOLOGY: LAMBS

BASICS

OVERVIEW

- Prewearing lamb mortality typically consumes 10%–35% of the lamb crop each year. The majority of loss occurs shortly after parturition and often goes unrecognized by producers.
- As is the case with neonates of other species, disease involving newborn lambs occurs with little warning. Consequences to the newborn lamb are usually severe and treatment is often unrewarding. Thus, from an economic perspective, prevention is more important than individual animal treatment.

PATHOPHYSIOLOGY

- In most flocks, the causes of lamb mortality can be divided into several basic categories that can be used to catalog 75%–85% of all preweaning mortality (See chapter on abortion in sheep and goats).
- Typically these basic categories include (1) starvation/hypothermia, (2) stillbirth/dystocia, (3) pneumonia, and (4) abortion (see [Table 1](#)). However, the relative importance of each category is generally defined by production system and management decisions. While these basic categories are useful for defining mortality patterns within a given flock, it is important to remember that the significance of each category will vary between flocks and from year to year (see [Figure 3](#)).
- Furthermore, it should also be obvious that production system design (producer decisions) often impacts lamb mortality to a greater extent than do infectious diseases (see [Figures 1](#) and [2](#)).
- Prevention programs need to address environment, weather, forage resources, available markets, disease prevention, nutrition, genetic selection, maternal behavior, labor, and facility resources.
- Due to the complex intertwined character of management factors affecting prevention programs, it is often difficult to affect a change in mortality patterns during the same lambing season.

[Table 1](#) Common Lamb Mortality Issues, Flock and Individual Assessment and Treatment

Hypothermia/Starvation Complex
Individual Assessment and Treatment

1. Simple Hypothermia
• Age: 6–8 hr following birth
• Clinical signs
• Weak, lethargic, often comatose
• Cold mouth, weak to no suckle reflex
• Gaunt, empty abdomen
• Mild hypothermia: 99°–102° F
• Severe hypothermia: below 99° F
• Normal temp: 101°–102° F
• Adequate tan fat and blood sugar
• Tan fat not depleted
• Problem: Excessive heat loss
• Cold environmental temperature
• Wet birth coat, evaporation
• Wind chill
• Small body mass (low birth weight)
1. Large surface area to weight ratio increases susceptibility to heat loss when adverse conditions
2. Poor mothering ability
3. Lack of movement (no heat generated)
• Hypoxia during delivery (due to dystocia): Can't regulate body temperature for several days.
• Treatment: Provide warmth!!
• Producers fail to recognize the importance of thermal management
• Remove from ewe and dry
• Supplement with warm dry heat @ 100°–103° F maximum temp.
• Tube feed with 120–200 ml of colostrum (dose at 20 ml/lb body weight)
• Return to ewe when rectal temp. normal (1–3 hours)
• Assure future nutrition (i.e., check ewe)
2. Hypothermia 2° to Starvation
• Age: over 6–8 hr old
• Clinical signs same as Simple Hypothermia above
• Problem: Inadequate heat production due to starvation
• Depleted tan fat
• Low blood sugar
• Compounded by limited intake of colostrum
• Treatment: Aimed at elevating blood sugar and providing warmth
• If able to stand or in sternal recumbency and can support head: treat as for Simple Hypothermia above.
• If comatose: also inject 40 cc of 20% warm dextrose solution intraperitoneally.
<i>Flock Prevention Issues (and Contributing Factors) Simple Hypothermia and Hypothermia 2° to Starvation</i>
• Gestational nutrition: Smaller lambs chill more rapidly.
• Less tan fat—less resistant to H/S
• Energy levels during early and late gestation influence birth weight.
• Failure to address increased energy demands associated with late gestation and/or increased fetal numbers (twins/triplets)
• Available shelter and fleece status impact nutritional requirements (more energy needed).
• Poor quality/quantity of colostrum
• Weigh first lambs—document size, then correct nutrition: commercial lambs should weigh 9–11 lb at birth.

• Underfeeding the ewe may also affect maternal bond.
• Replacement selection pressure
• Breed variations in wool cover and tan fat deposition at term
• Prolificacy: how much is too much°
• Mothering instinct and lamb vigor
• Lactational nutrition: an issue if starvation occurring in older lambs
• Vitamin E–selenium: routinely add to feeds/salt in deficient areas.
• Protection from environmental conditions
• Important in winter-lambing systems if housing suspect: <i>Weather issues</i> (temperature, wind chill, rain, snow and ice storms), especially if pasture lambing
• Schedule lambing for weather conducive to lamb survival
• Utilize: Historical weather data; ground temperature data (start lambing when > 50 °F); natural protection—rough areas, clump grasses, pine and artificial wind breaks
• Quantity and quality of help
• Lambing pen and group pen availability and use: need one lambing pen per 5–10 ewes
• Dam/lamb identification
• Unshorn ewes: prone to expose lambs to poor weather
• Lack of milk: due to secondary diseases
• On pasture: forced movement of lambs contributes to mismothering
Pneumonia
Individual Assessment and Treatment
• Confinement related—common in barn-reared lambs especially when lambing occurs during periods of transitional weather
• Uncommon in pasture operations
• Clinical signs typical of acute bacterial (<i>Pasteurella spp.</i>) pneumonia in other species
• Elevated temp.—above 103.5 °F
• Moist, harsh lung sounds
• Elevated respiratory rate
• Depressed, lethargic; (+/–) nasal discharge or cough
• In problem flocks, sudden death may be only sign (<i>Pasteurella septicemia</i>)
• Severe lesions develop shortly after birth (first week)—difficult to treat
• Treated lambs that survive may relapse when stressed (weaning, weather, and transport)
• Common antibiotics used in treatment
• SQ procaine penicillin or procaine penicillin/benzathine penicillin combination @ 10,000 to 20,000 IU/lb body weight SID (dose NA)
• SQ long-acting tetracycline injectable products @ 5 mg/lb SID or 9 mg/lb every 48 hours (NA)
• SQ ceftiofur @ 0.5–1.0 mg/lb SID (A)
• SQ florfenicol @ 9 mg/lb every 48 hrs (NA)
• SQ tilmicosin @ 4.5 mg/lb given once (NA). CAUTION: FATAL TO HUMANS, HORSES, AND PIGS
• Oral and injectable sulfonamide or trimethoprim/sulfam combination products common
• Anti-inflammatory: SQ flunixin meglumine @ 0.5 mg–1.0 mg/lb
Flock Prevention Issues (<i>and Contributing Factors</i>)
• Inadequate ventilation is a primary issue
• Facility overcrowding @ 12 sq ft/ewe common in problem flocks
• Difficult for nonmechanical ventilation @ less than 20 sq ft/ewe
• Transitional weather compounds ventilation problems
• Temperature fluctuations and increased humidity
• Facilities—difficult to exchange enough air

• Addressing inadequate ventilation
• Remove solid sidewalls
• Replace sidewalls with (1) side-wall curtains; (2) greenhouse shade cloth (80/20 fabric); (3) hinged/sliding panels.
• Open ridge vent and square for “chimney” drafting effect.
• Place shade cloth over sliding doors.
• Cover open-sided barns with shade cloth to prevent draft and weather stress, yet allow ventilation.
• Ventilate “dead spaces” with fans.
• Prolonged lambing season—increases crowding, contamination, and stress and extends into transitional weather.
• Pneumonia secondary to starvation or selenium/tocopherol deficiency
• Excessive moisture in bedding at lamb level
• Bedding quantity insufficient
• Unshorn ewes “drag” moisture into barn.
• Drop-lot or “flow through/no mix” lambing systems helpful
• Advantages
1. Decreases crowding—fed outside
2. Decreases pregnant ewe/newborn lamb contact (scours, pneumonia)
3. Facilitates proper group feeding
4. Facilitates observation
5. Facilitates bulk feeding of round bales and silage
6. Maximizes facilities
7. Encourages routine procedures in lambing/group pens
• Disadvantages
1. Occasional ewe lambs outside.
2. Producer comfort
3. Wool frosting
4. Feeder cost and mobility
• Pneumonia issues reduced by drop-lot lambing system (lambs and ewes go directly to grass by 5–7 days old) or with pasture lambing system (unless poor weather)
• Problem pneumonia flocks
• Routine SQ long-acting antibiotics on days 1 and 3 after birth
1. Benzathine/procaine penicillin-G combination (NA) or
2. Slow release tetracycline (NA)
Stillbirth/Dystocia
Individual Assessment and Treatment
• Stillbirth—treatment not applicable
• Common presentations associated with dystocia
• 26.4% anterior presentation with head back
• 25.0% anterior presentation with one leg back
• 16.7% anterior presentation with elbow lock
• 11.1% anterior presentation with both legs back
• 12.5% posterior presentation with true breech
• 8.3% others (multiple tangles and deformities)
• Posterior presentation normal in lamb
Flock Prevention Issues (<i>and Contributing Factors</i>)
• Stillbirth/dystocia mortality rate—constant in most flocks at 2%–3% of lambs born each year

• Difficult to reduce further
• Stillbirth/dystocia—Problem Flock Issues
• Nutrition
1. Overfeeding—increased birth weight with dystocia
2. Underfeeding—weak and stillborn lambs
3. Triplet/twins/single size related to nutrition
• Lambing supervision—delayed assistance
• Breed differences—especially in bred ewe lambs
• Skeletal deformities
• Secondary to abortion outbreaks
• Typical 4%–5% dystocia rate
Abortion
Individual Assessment and Treatment Individual lamb treatment not applicable
<i>Abortion Outbreak (Practical Response Until Diagnosis)</i>
• 400 mg oral tetracycline/hd/day immediately (first 2–3 days)
• Then reduce to 200 mg/hd/day after 2 or 3 days
• Small flocks: SQ long-acting tetracycline @ 5 mg/lb as switched to oral
• Continue oral tetracycline through lambing—unless diagnosis or response dictates otherwise
• When possible, feed in bunks—not on ground.
• Clean up abortions and placentas
• Isolate aborted ewes until discharge ceases (3 wk).
• Vaccinate late-lambing groups.
• Treat retained placentas as needed.
<i>Flock Prevention Issues (and Contributing Factors)</i>
• Fairly constant at about 1%–2% of the ewe flock
• Greater than 2% in one flock is action level.
• Sheep abortions—transmission via ingesting contaminated material
• Infected fetal fluid
• Infected manure or urine from carrier ewes
• Licking aborted fetuses
• Infected hay or grain—especially if fed on ground
• Campylobacter and Chlamydia often follow new ewe additions to the flock.
• Carrier ewes (in gallbladder to manure)
• Bird vectors
• Closed flock important for prevention
• Toxoplasmosis—cat feces contamination of hay and grain
• No vaccine in United States
• No treatment
• Monensin added to gestation feed may help prevent (NA)
• Vaccination Campylobacter and/or Chlamydia
• Effectiveness variable
• Often unavailable
• Use only ovine strain vaccines
• If open flock or problem flock
1. Two doses, to new arrivals or replacements, before breeding and midpregnancy
2. Booster yearly before breeding

• Closed flock with no problems: no vaccine
Scours
Individual Assessment and Treatment
1. E. coli Scours
• Difficult to treat once signs appear; work at prevention in remaining lambs
• Predisposing factors
• Insufficient colostrum
• Hypomotile intestine—not eating
• Contaminated environment
• Signs related to
• Rapid multiplication of E. coli in intestine
• Endotoxin release
• Scours, dehydration, and death in 12–36 hours
• Treatment suggestions
• Standing/depressed
1. 5%–10% dehydrated
2. Oral fluids and antibiotics
• Sternal/depressed
1. 10%–15% dehydrated
2. SQ and IV fluids and antibiotics
• Comatose
1. 15%–20% dehydrated
2. Death
• Antibiotics for treatment
• Spectinomycin: common piglet scour medication in oral pump formulation—dose @ 5 mg/lb SID or BID (NA)
• Trimethoprim/sulfamethoxazole oral syrup or tablets @ 15–20 mg/lb SID or BID (NA)
2. Coccidia Scours
• Common cause of scours in 3–8-week-old lambs born in confinement
• Clinical scours may occur 4–5 days before oocysts appear in fecal material—often treat by history
• Nursing lambs require individual treatment with oral sulfa or amprolium drench for five consecutive days
• Labor intensive/impractical with larger groups of lambs
• Prevention better option
<i>Flock Prevention Issues (and Contributing Factors)</i>
1. E. coli Scours (Contributing Factors)
• Prolonged lambing season: Environmental E. coli conc. increased
• Environmental conditions conducive to E. coli survival and transmission
• Humidity and warmth associated with transitional weather
• Unshorn ewes increase moisture in facility.
• Facilities concentrate organism: lambing pen and common entry areas
• Poor sanitation
• Lack of colostrum
• Flock outbreak
• Change location of lambing pens
• Increase bedding
• Prophylactic antibiotic at birth

1. Spectinomycin oral syrup or trimethoprim/sulfamethoxazole oral syrup or tablet (NA)
2. Time antibiotic before clinical signs occur; usually dose on days 1, 2, and 3 following birth.
3. If annual problem, vaccinate ewes prior to lambing.
2. Coccidia Scours (Contributing Factors)
• Environmental and sanitation factors similar to those listed for <i>E. coli</i>
• Ewes are asymptomatic carriers—oocysts in manure
• Prevention aimed at decreasing oocysts shed into lambing barn environment from the ewe flock
• Ewes treated 30 days prior to entering lambing area with:
1. Lasalocid in feed @ 30 grams/ton of feed or
2. Monensin in feed @ 15 grams/ton of feed (NA) or
3. Decoquinate in feed or free-choice salt mix (NA) or
4. Amprolium or sulfonamide compounds in drinking water or feed (NA)
• Weaned lambs: treat as a group in drinking water with oral sulfamethoxazole or amprolium medications.
• Unweaned lambs: treat as individuals or decide to not treat and let immunity develop (3–6 weeks).
Omphalophlebitis
Individual Assessment and Treatment
• Difficult to treat as infection localized in liver and joints
• Aim at prevention
• Clinical signs
• 10-day to 3-week-old lamb
• Lame, gaunt, depressed, weak
• Elevated temperature 103.5°–106°F
• Swollen, hot, fluid-filled joints
• Systemic treatment with antibiotics similar to those presented above in Pneumonia section
Flock Prevention Issues (and Contributing Factors)
• Commonly a flock problem when transitional weather, crowding, and lack of bedding cause poor environmental conditions in lambing area
• Same contributing factors and management suggestions as with Pneumonia and <i>E. coli</i> Scours above
• Often associated with failure/improper iodine application to navel
• Use 7% strong tincture of iodine as a dip.
• Use fresh solution to prevent contamination.
• In problem flocks, prevention using SQ long-acting penicillin or tetracycline in newborn lambs; see Pneumonia Prevention above
Enterotoxemia
Individual Assessment and Treatment
• Commonly referred to as “overeating disease”
• Difficult to treat as signs are acute
• May exhibit convulsions shortly before death
• Prevention is key issue.
• Oral antibiotics and antitoxin can be given, but are usually unsuccessful.
Flock Prevention Issues (and Contributing Factors)
• Commonly associated with feed changes to high-concentrate rations
• Also common in “orphan lambs” fed milk replacer
• Exercise caution when introducing lambs to grain rations
• Vaccinate ewes 4–6 weeks prior to lambing to encourage passive protection in the colostrums
• Vaccinate their lambs at 3–4 weeks and again at 6–8 weeks of age.
• If ewes are not vaccinated prior to lambing, vaccinate lambs during first few days of life and again at about 4 weeks of age.

NEOSPORA

BASICS

DEFINITION

Neospora caninum is a protozoa that is associated with abortion as well as the birth of congenitally infected, weak, and unthrifty calves in cattle. It is a very rare cause of reproductive failure in sheep and goats.

PATHOPHYSIOLOGY

- *Neospora caninum* is a protozoan; the dog is the definitive host.
- Cattle are dead-end hosts.
- Vertical transmission (transplacental) during pregnancy is the most common means of spread, but cattle may also become infected from consuming feed contaminated with dog feces.
- Most abortions occur at 5–6 months of gestation.
- Infected mature cattle usually develop an asymptomatic persistent infection that can undergo recrudescence during pregnancy with subsequent parasitemia to the fetus and placenta.
- *Neospora* may also be found in the semen of infected bulls.
- Transplacental infection and subsequent abortion are documented in sheep and goats due to *Neospora caninum* but appear to be less common than in cattle.

SYSTEMS AFFECTED

- Infection of the reproductive organs during pregnancy, specifically the fetus and placenta are the most pathologically significant targets for *Neospora* infection.
- Within the fetus, nervous, neuromuscular, and musculoskeletal systems can be affected.

GENETICS

There is no known genetic basis to the disease in cattle.

INCIDENCE/PREVALENCE

- Neosporosis in cattle has a widely variable prevalence on both a regional and individual herd basis.
- It can be associated with both endemic and epidemic abortion outbreaks.
- In some dairies in the United States, up to 90% of cows are seropositive.
- Abortion storms of up to one-third of all pregnant cows over a 2–3-month period have been documented.
- Quantitative studies have documented that between 12% and 42% of aborted fetuses from dairy cattle in the United States, Europe, and New Zealand are infected with *Neospora caninum*.

GEOGRAPHIC DISTRIBUTION

- Neosporosis can be found across the United States and has been documented in other countries, which include Australia, New Zealand, Argentina, United Kingdom, Italy, Portugal, Japan, and Korea.
- It is more commonly identified in higher density dairy areas of the United States.

SIGNALMENT

- Both dairy and beef cattle can be affected, but *Neospora* abortion is more common in dairy cattle.
- Clinical disease is not documented in males but infected bulls can shed the organism in semen.
- Abortions can occur year-round.
- No breed predilection is evident.
- Both multiparous and first-calf heifers can be affected by abortions.
- Both endemic and epidemic disease is reported.

SIGNS

- Abortion, usually between 5 and 6 months of gestation

- A small proportion (<5%) of cows will abort repeatedly in subsequent pregnancies.
- Fetuses may die in utero and be resorbed or become mummified.
- Following in utero exposure, calves may be born congenitally infected.
- Up to 95% of congenitally infected calves appear clinically normal at birth.
- Clinical signs due to *Neospora* infection are documented only in neonates (<2 months old).
- Neurologic signs include ataxia, weakness, and varying degrees of tetraparesis predominate in neonates, but congenitally infected calves may also be clinically normal.
- Congenital birth defects such as exophthalmia, hydrocephalus, torticollis, and arthrogryposis are reported but are rare.

CAUSES

Neospora caninum

RISK FACTORS

Self-rearing of heifer replacements, high stocking density, limited pasture access, and the presence of farm dogs have been documented to be risk factors for higher herd seropositivity rates.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other protozoal causes of abortion—*Toxoplasma gondii* and *Sarcocystis cruzi* infection in cattle
- Viral causes of abortion—bovine viral diarrhea virus, infectious bovine rhinotracheitis, and bluetongue virus.
- Bacterial causes of abortion—*Salmonella* spp., *Leptospira interrogans*, *Haemophilus somnus*, *Arcanobacterium pyogenes*
- Miscellaneous causes of abortion—foothills abortion (Western United States), mycotic abortion
- Causes of weak and unthrifty neonatal calves—selenium deficiency (white muscle disease), iodine deficiency, persistent infection with BVDV, congenital infection with bluetongue virus, neonatal septicemia/failure of passive transfer

CBC/BIOCHEMISTRY/URINALYSIS

- Clinicopathologic data from cows that have aborted or congenitally affected calves is generally unremarkable and nondiagnostic.
- Congenitally infected calves may demonstrate elevations in muscle enzymes CK and AST due to recumbency.

OTHER LABORATORY TESTS

- CSF obtained from neurologically abnormal, congenitally infected calves may demonstrate a mild pleocytosis.
- Congenitally infected calves are at high risk for failure of passive transfer with hypogammaglobulinemia and septicemia if they demonstrate a weak suckle response.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Serologic tests—ELISAs, IFAT, and NAT are all available and offer serologic confirmation of the presence of antibodies to *Neospora caninum* in blood obtained from a suspect animal.
- Due to widespread seropositivity in cattle populations, a positive antibody test does not incriminate *Neospora caninum* as the cause of an abortion.
- Refer to testing laboratory for arbitrary cutoffs in titer values that are considered more suggestive of disease.
- Consider serologic testing of comparably sized groups of cows with reproductive failure and those with normal reproductive histories when investigating putative problem herd, so as to gain data on background seropositivity in herd.
- Positive serologic tests on blood samples obtained from an aborted fetus or a presuckle blood sample from a newborn calf is diagnostic for congenital infection.
- Peritoneal fluid from an aborted fetus is a useful sample to submit for serology if heart blood is not available.
- Fetal tissues/placenta can also be examined by immunohistochemistry and/or PCR.

PATHOLOGIC FINDINGS

- Fetal brain, heart, liver, and placenta are best submitted for routine histopathology and immunohistochemistry.

- Fetal brain is the most consistently affected organ and shows signs of nonsuppurative focal encephalitis.
- Hepatitis, myocarditis, and myositis may also be present histologically in an aborted fetus.
- Placental lesions are also those of focal, nonsuppurative encephalitis.
- Protozoa are very rarely identified in histosections from aborted feti or placenta.
- Congenitally infected calves may be normal or may be born weak, unable to stand, and demonstrating a weak suckle reflex and diminished spinal reflexes.
- Some calves may appear comparatively normal at birth but develop progressive neurologic deterioration over the subsequent days to weeks.

TREATMENT

APPROPRIATE HEALTH CARE

- Health care of dams that have aborted can be managed on farm.
- Health issues of importance relate to complications of abortion—retained fetal membranes, metritis, delayed involution, and protracted return to service and conception.

NURSING CARE

N/A

ACTIVITY

Normal

DIET

Normal

CLIENT EDUCATION

Education of clients with respect to mode of transmission and preventative measures is highly relevant to the control of neosporosis.

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUGS OF CHOICE

- There is no treatment for clearance of the infection in serologically positive individuals.
- Treatment of congenitally infected calves with weakness or neurologic signs is unrewarding.

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

A commercial vaccine is available in the United States—vaccines may inspire a serologic response but the strength and duration of protection are uncertain.

POSSIBLE COMPLICATIONS

- Poor individual animal and herd reproductive performance can be a feature of both epidemic and endemic neosporosis.
- Milk production losses as the result of midpregnancy abortion

EXPECTED COURSE AND PROGNOSIS

Infected cows will often have a return to normal health and conceive again, but there is an increased chance of repeated abortion in subsequent pregnancies.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

The age of the dam, lactation number, and history of prior abortion do not appear to influence the rate of congenital infection.

ZOONOTIC POTENTIAL

None

PREGNANCY

Neosporosis is a prominent cause of abortion and fetal loss.

RUMINANT SPECIES AFFECTED

- Cattle, sheep, and goats
- Not reported in camelids

BIOSECURITY

- Embryo transfer appears to prevent vertical transmission of *Neospora* from seropositive donors to offspring provided the recipient is seronegative.
- Seropositive cows are more likely than seronegative cows to abort in subsequent pregnancies.
- Direct cow-to-cow transmission does not occur.
- Avoid contamination of cattle feedstuffs with dog feces.

PRODUCTION MANAGEMENT

- Serologic screening of new purchases may be considered, particularly for known negative herds.
- Consider presuckle serology of calves born to seropositive dams when attempting to reduce prevalence rate.
- Colostrum from seropositive dams does not appear to be a clinically significant means of vertical transmission

SYNONYMS

None

SEE ALSO

Bacterial causes of abortion—*Salmonella* spp., *Leptospira interrogans*, *Hemophilus somnus*, *Arcanobacterium pyogenes*

Causes of weak and unthrifty neonatal calves—selenium deficiency (white muscle disease), iodine deficiency, persistent infection with BVDV, congenital infection with bluetongue virus, neonatal septicemia/failure of passive transfer

Miscellaneous causes of abortion—foothills abortion (western United States), mycotic abortion

Protozoal causes of abortion—*Toxoplasma gondii* and *Sarcocystis cruzi* infection in cattle

Viral causes of abortion—bovine viral diarrhea virus, infectious bovine rhinotracheitis, and bluetongue virus.

ABBREVIATIONS

AST = aspartate aminotransferase

BVDV = bovine viral diarrhea virus

CK = creatine kinase

CSF = cerebrospinal fluid

ELISA = enzyme-linked immunosorbent assay

IFAT = indirect fluorescent antibody test

NAT = neospora agglutination test

PCR = polymerase chain reaction

NIGHTSHADE (*SOLANUM SPP.*) TOXICOSIS

BASICS

OVERVIEW

- Solanaceae family consists of many genera of which *Solanum* spp. (nightshade) has the largest number of species:> 1500 species worldwide
- Plants exist as herbs, shrubs, even small trees, annuals or perennials, some with thorns; fruits are fleshy berries.
- Plants may live in a wide range of habitats—pastures, gardens, waste areas, and in cultivated crops.
- Common species of *Solanum* in North America include *S. nigrum* (black nightshade), *S. carolinense* (horse nettle), *S. elaeagnifolium* (silverleaf nightshade), *S. rostratum* (buffalo bur), *S. tuberosum* (Irish potato), *S. ptychanthum* (eastern black nightshade).
- Gastrointestinal irritation, nervous system dysfunction, and terata are possible.

SIGNALMENT

All species affected (ruminants, swine, equine, humans, etc.)

SIGNS

- Salivation, vomiting, abdominal pain, diarrhea, or constipation may result from GI irritation.
- Decreased salivation, pupillary dilatation, decreased GI motility, and increased heart rate may result from anticholinergic effects.
- Neurologic signs reported in cattle, sheep, and goats: depression, incoordination, tremors, weakness, paralysis, seizures
- Rarely teratogenic effects

CAUSES AND RISK FACTORS

- Toxins primarily consist of steroidal alkaloids including solanidine and solanine. Numerous others exist.
- Toxins are found throughout the plant but are concentrated in the green (unripe) fruits and leaves.
- Activity of anticholinesterase is blocked, allowing accumulation of acetylcholine with resultant decreases in GI motility and salivation.
- Seasonality—most likely consumed in summer/fall. Could be fed throughout the year in hay or silage.
- Lack of available food sources increase likelihood of consumption.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Numerous other plants and chemicals may produce similar signs of gastroenteritis or nervous dysfunction.
- Clinical signs, history of ingestion, finding plants in feed/hay, identifying plants in stomach/rumen contents are keys to diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Gastroenteritis, possibly severe with hemorrhage and necrosis
- Hyperemia of intestinal mucosa
- Increased peritoneal fluid, especially in calves
- Purkinje cell swelling and/or loss
- Evidence of plant material/berries in rumen contents

TREATMENT

- Support patient, treat symptomatically.
- Rumenotomy and evacuation of contents may be useful early in the course of intoxication.
- Prevent further access to toxins.
- Maintain good source of nutrition.

MEDICATIONS

DRUGS OF CHOICE

- Dependent on clinical signs
- Atropine sulfate—if cholinergic signs predominate (salivation, diarrhea)—0.1–1.0 mg/kg IV, IM, or SQ. Give 1/4 IV and remainder SQ or IM. May repeat every 3–4 hours for 1–2 days.
- Physostigmine—if anticholinergic signs predominate (dilated pupils, GI stasis)—30–45 mg SQ cattle
- Activated charcoal—2–5g/kg in a water slurry given orally (1 g charcoal per 5 ml water)

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Providing a proper diet/adequate nutrition to animals will minimize intake of many poisonous plants.
- Do not allow access to areas or feeds that contain nightshades.

POSSIBLE COMPLICATIONS

None

EXPECTED COURSE AND PROGNOSIS

- Variable, dependent on amount consumed and time period of consumption.
- Prognosis often good with symptomatic treatment.

NITRATE AND NITRITE TOXICOSIS

BASICS

OVERVIEW

- Most cases of nitrate (NO_3)/nitrite (NO_2) poisoning in ruminants occur as the result of consumption of nitrate-contaminated hay.
- Forages capable of accumulating toxic concentrations of nitrate include oat hay, *Sorghum* spp. and alfalfa. Pigweed (*Amaranthus* spp.), lambs quarter (*Chenopodium* spp.), Canada thistle (*Cirsium arvense*), and fireweed (*Kochia scoparia*) are several of many well-recognized nitrate-accumulating weeds, and can easily invade hay fields.
- Toxicities are acute, and animals suffer from hypoxia/anoxia secondary to methemoglobin formation.
- The onset of signs is rapid, and death can occur within a few hours of ingestion.
- Slow IV 1% methylene blue, 5–15 mg/kg, is the current drug of choice for treatment of clinically affected animals.
- Abortions due to fetal hypoxia may follow the initial outbreak.
- Many factors affect nitrate uptake by plants, and it is impossible to predict when problems may arise.
- Careful examination of pasture and hay for weed infestation and multiple random nitrate tests of the feed can be used to prevent losses.
- Nitrate/nitrite analysis of feed, water, and biological samples is readily available at many laboratories.

PATHOPHYSIOLOGY

- Nitrite is ten times more toxic than nitrate.
- Nitrate is converted to nitrite by rumen microorganisms.
- Nitrite, once absorbed systemically, oxidizes the ferrous iron to ferric in hemoglobin, converting it to methemoglobin.
- Lack of oxygen to the tissues is the ultimate cause of the signs observed.

SYSTEMS AFFECTED

Cardiovascular, leading to multiple organ failure

GENETICS

N/A

INCIDENCE/PREVALENCE

Generally unpredictable, but more likely to occur in times of drought and during the winter months.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Potentially all ruminant species; adults appear to be more susceptible.

Species

All ruminant species at risk

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- Abrupt onset of dyspnea and weakness

- Recumbency
- Salivation
- Pale, cyanotic, or muddy mucous membranes
- Muscle tremors and seizures terminally
- Methemoglobin formation imparts a chocolate brown color to the blood. This color will disappear postmortem.
- Animals may appear to drop dead in their tracks, some with no signs of significant struggling.

CAUSES AND RISK FACTORS

- Animals that are more glutinous and higher on the pecking order, in an energy deficit or debilitated with a preexisting disease, may be more susceptible.
- Developing fetus in pregnant animal is susceptible to nitrate's anoxic effect.
- Clinical signs in animals and death can occur abruptly, despite history of feeding the same diet for days or weeks. This is not a cumulative or chronic problem. The sporadic nature of illness is directly related to the nonhomogenous distribution of nitrate in the feed and lack of rumen adaptation.
- An acute oral lethal dose is approximately 0.5 g nitrate/kg BW.
- Nitrate levels in the diet > 0.6% (equivalent to 6000 ppm nitrate [NO₃] or 1363 ppm nitrate-nitrogen [NO₃-N] are potentially toxic to animals. Divide ppm by 10,000 to convert to% (move decimal four to the left). To convert nitrate-nitrogen (NO₃-N) to nitrate (NO₃), multiply by 4.40.
- Many plants have been associated with nitrate accumulation: sorghums, alfalfa, oat hay, corn stalks, barley straw, *Amaranthus*, *Chenopodium*, *Kochia scoparia*, *Cirsium arvense*.
- Water can be the source of poisoning, but this is uncommon. Gross contamination of the water source and/or environment with nitrogen-containing fertilizers or use of tanks that once transported nitrogen-containing fertilizers as water troughs can be a risk. Nitrate levels < 200 ppm are generally considered safe, and most animals can tolerate much higher levels (1000–1500 ppm).
- Once the animal's rumen has become "acclimated" to nitrate, the animal can tolerate much higher dietary levels.
- Clinical signs generally occur within a few hours of ingesting a toxic dose, so often animals, particularly ones out on pasture or range, are showing signs of illness, or death occurs in large numbers of animals, when no one is around.
- Chronic exposures have been reported in clinical case reports, but this has been hard to experimentally reproduce and verify. Reported problems associated with chronic exposures include abortion, infertility, and hypovitaminosis A.
- Frost can stunt the growth of the plant in the field, but allows the plant to continue to accumulate nitrogen and nitrate from the soil.

DIAGNOSIS

Antemortem

- Muddy-colored mucous membranes, "chocolate brown" blood, and clinical signs suggestive of oxygen deprivation are consistent with nitrate/nitrite toxicosis.
- Nitrite is either converted to nitrate or excreted within 2 hours in cattle.
- Nitrate concentrations can be measured in refrigerated blood, serum or plasma, or urine using ion chromatography, for up to 24 hours after exposure.
- In blood, serum, or plasma, nitrate concentrations > 15 ppm are suggestive, and nitrate concentrations > 30 ppm are diagnostic of excessive exposure to nitrates.
- Suspect forages can be tested using diphenylamine to semiquantitatively estimate the nitrate concentration.
- Ion chromatography can be used to quantitatively analyze for nitrate and nitrite in suspect forages and water.
- Due to the instability of MHb and the need for phosphate buffers for storage of blood samples, determination of MHb concentrations is rarely performed.

Postmortem

- Muddy-colored mucous membranes, "chocolate brown" blood, and postmortem changes suggestive of oxygen deprivation are consistent with nitrate/nitrite toxicosis.

- Ocular fluid (aqueous humor) nitrate concentrations can be determined, using diphenylamine (semiquantitative) or ion chromatography (quantitative) for up to a week after death in refrigerated samples.
- Ocular fluid nitrate concentrations > 10 ppm nitrate are suggestive, and ocular fluid nitrate concentrations > 20 ppm are diagnostic of exposure of nonneonates to excessive nitrates.
- Since neonatal calves normally have ocular fluid nitrate concentrations approximating 20 ppm during the first day of life, nitrate concentrations > 30 ppm are generally more consistent with nitrate/nitrite toxicosis in these animals.
- Nitrate concentrations can also be determined in urine, peritoneal, and pericardial fluids.
- Suspect forages can be tested using diphenylamine to semiquantitatively estimate the nitrate concentration, and ion chromatography can be used to quantitatively analyze for nitrate and nitrite in suspect forages and water.
- Rumen contents are not useful diagnostically because of postmortem instability associated with the activity of microorganisms.

DIFFERENTIAL DIAGNOSIS

- Chlorate, found in some fertilizers, is capable of causing methemoglobinemia.
- Other causes of “abrupt” onset of similar signs and death include *Cicuta* (water hemlock), cyanobacteria (blue-green algae), botulism, *Taxus* (yew), *Zigadenus* (death camas), *Delphinium* (larkspur), lightning strike, anthrax, organophosphate and carbamate insecticides, ionophores, and nonprotein nitrogen.

CBC/BIOCHEMISTRY/URINALYSIS

No remarkable abnormalities are observed, other than the blood appearing “chocolate” brown.

OTHER LABORATORY TESTS

- Methemoglobin levels can be run at select laboratories. Special sample preservation may be required.
- Diphenylamine kits or nitrate/nitrite qualitative or semiquantitative strip tests can be used on feed and water to confirm high nitrate levels.
- Nitrate/nitrite levels can be quantitatively assessed in serum, plasma, whole blood, feed, water, and ocular fluid. Eyes should be removed intact and sent to the laboratory for analysis. Levels in serum, plasma, whole blood, and ocular fluid > 20 ppm nitrate are generally indicative of excessive exposure and possible poisoning if accompanied by compatible history and signs; levels > 50 ppm nitrate are consistent with nitrate poisoning. Nitrate levels in ocular fluid may remain stable for up to 72 hours postmortem.
- Caution should be used when interpreting nitrate/nitrite levels of ocular fluid or gastrointestinal contents collected from aborted fetuses. This does not appear to be a very sensitive or specific diagnostic tool.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

Nonspecific—congestion of major organs. Signs of a terminal struggle or seizure may be apparent.

TREATMENT

- Stress associated with handling must be minimized in severely hypoxic animals.
- Exposure to the identified source of the excessive nitrates should be discontinued.
- Rumen lavage with cold water and oral penicillin may slow the continuous reduction of nitrate to nitrite in the rumen.
- Methylene blue is a specific antidote for nitrate/nitrite toxicosis, but its commercial availability has become somewhat limited in the last several years.
- Methylene blue can be administered intravenously (5–15 mg/kg body weight) in a 1% solution in physiological saline.
- Since methylene blue is rapidly cleared from the circulation (serum half-life of 1.5 hours) and has a relatively wide margin of safety, additional, lower doses of the antidote can be administered to animals still exhibiting signs.
- Mild to moderately affected animals, if left untreated, can recover because of erythrocytic NADPH-dependent reduction of Fe^{3+} in MHb to functional Fe^{2+} in hemoglobin.

MEDICATIONS

- 1% Methylene blue, 5–15 mg/kg IV, slow. Response should be immediate.
- Ascorbic acid is thought to be less effective at reversing the methemoglobinemia.

CONTRAINDICATIONS

- The use of methylene blue is off-label. A recommended withdrawal period is 6 months.
- Methylene blue may not be available for much longer.

FOLLOW-UP

Pregnant animals may abort several days to a few weeks after the toxic insult, due to fetal anoxia.

PATIENT MONITORING

No long-term problems have been documented other than abortions. Animals can completely recover, with or without treatment (depending on exposure dose), within a few hours.

PREVENTION/AVOIDANCE

- Knowledge of the high-risk nitrate-accumulating plants and ability to recognize in the field or hay will hopefully minimize the risk.
- Knowledge of the risk factors predisposing high nitrates in the feed (e.g., fertilization, irrigation, soil conditions, environmental conditions) can lead one to be proactive in testing forages during the growing season and pre- and postharvest.
- Suspect forages or crops known to accumulate nitrate should be tested for nitrate concentrations prior to inclusion in the diet of ruminants, especially cattle.
- Forages containing < 5000 ppm nitrate are generally safe for consumption by ruminants.
- High nitrate-containing forages can be diluted with low-nitrate-containing forages prior to feeding to ruminants, or suspect forages can be divided into two feedings to prevent rapid intake.
- High nitrate-containing forages can be ensiled for at least 30 days to reduce the nitrate content prior to feeding to ruminants.
- Sorghums may contain toxic concentrations of cyanide. Lathrogenic compounds present has been associated with neuroaxonal degeneration in sheep. Chlorate, found in some fertilizers can also be toxic.
- The harvest of forages or crops grown under conditions conducive to nitrate accumulation should be delayed until conditions improve to allow nitrate levels in stalks to drop.
- If the harvest of forages or crops grown under conditions conducive to nitrate accumulation cannot be delayed, then the harvesting cutter-bar should be raised to 18 inches to leave the lower portions of the stems or stalks in the field.
- Gradual adaptation of ruminants to high-nitrate-containing forages can be performed over a period of 7 to 10 days.
- Feeding readily fermentable carbohydrate sources in conjunction with high-nitrate-containing forages will promote a denitrifying environment within the rumen.
- Feeding a supplement containing *Propionibacterium* spp. (Bova-Pro, Pro Brands LLC, Columbia, IL) for 10 days prior to anticipated exposure to high-nitrate-containing diets or administering a ruminal inoculum of the same product 10 days prior to nitrate exposure can reduce concentrations of nitrite in the rumen by enhancing denitrification.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Nitrate poisoning can have a high morbidity and mortality rate; or only individuals may be affected.
- The course of the disease is relatively short, generally lasting within one feeding period.
- The prognosis is heavily dependent on the exposure dose within a short time frame, and levels of methemoglobinemia (blood levels > 80% are typically fatal).

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Younger animals with nonfunctional, nondenitrifying rumens are resistant to nitrate/nitrite toxicosis.
- The fetus has higher oxygen demands and is reported to be more susceptible to the adverse effects of methemoglobinemia.
- The influence of age-related factors in nitrate-nitrite toxicosis is somewhat dependent on the quality of the forage. If hay is primarily nitrate-containing stems, older, more dominant ruminants, especially cattle, will consume greater quantities of nitrate. If hay contains some leafy portions, which are consumed primarily by older, dominant animals, younger, less-dominant ruminants, especially cattle, will be forced to consume less-palatable portions of the hay dominated by nitrate-containing stems.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

- Abortions may occur several days to a few weeks after the initial toxic insult in those animals that survive.
- Abortion is a common sequela in pregnant cattle consuming forages containing excessive nitrates (> 0.5% or 5000 ppm).

RUMINANT SPECIES AFFECTED

All ruminant species are susceptible.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Avoid feeding exceptionally weedy feeds, particularly avoiding those weeds that are well-recognized nitrate accumulators.
- Oral products (Bova-Pro) are sold as rumen adaptors; these products are marketed as altering the microflora population, allowing the animal the ability to tolerate high dietary nitrate levels.

OAK (QUERCUS SPP.) POISONING

BASICS

OVERVIEW

- Oak or acorn poisoning has been reported worldwide in different animal species for more than 300 years.
- Poisoning is associated with ingestion of oak buds, stems, leaves, or acorns. More than 60 species of oak are found in North America and many are reported to be toxic.
- Oak poisoning is most commonly seen in cattle and sheep, while the phenomenon is infrequently reported in horses. Pigs and deer are resistant, while goats are less susceptible than other ruminants.
- The toxic principles, tannins, are hydrolyzed in the rumen to gallic acid, pyrogallol, and other phenolic metabolites that induce gastrointestinal and renal dysfunction.
- Hydrolyzed tannins are absorbed and become bound to plasma proteins and endothelial proteins, which leads to GI ulceration, and hemorrhage and fluid loss from blood vessels resulting in edema.
- The main lesion associated with oak poisoning is renal tubular necrosis.
- Gallic acid and pyrogallols are extremely toxic to renal tubules causing acute renal tubular necrosis (ATN). ATN often leads to anuria, electrolyte imbalances, and uremia. Chronic poisoning results in chronic renal failure.
- Animals that survive acute renal insults often develop chronic renal disease and demonstrate poor weight gains compared with their cohorts.

SYSTEMS AFFECTED

Renal, gastrointestinal

SIGNALMENT

- Oak poisoning has been reported in cattle, sheep, goats, rabbits, and horses. Young buds and leaves are palatable to cattle, especially weaned calves.
- A history of ingestion for 2–14 days (average of 1 week) usually precedes clinical signs.

SIGNS

- Clinical signs include anorexia, depression, ruminal stasis, and constipation, which are often followed by hemorrhagic diarrhea. Polyuria and hematuria are often seen. A mucoid nasal discharge and/or epistaxis may also be seen in addition to dehydration, weakness, recumbency, ascites, hydrothorax, and ventral edema. In peracute poisoning, cattle may be found dead.
- Secondary complications such as bronchopneumonia, GI ulceration, perforation, and abscessation may also occur.

RISK FACTORS

- Immature leaves, stems, acorns, and buds are the most toxic and the most palatable.
- Oak poisoning associated with ingestion of leaves and buds is seen in the spring. Oak poisoning occurs in the autumn with ingestion of acorns.
- An increase in oak poisoning is often seen during droughts or other circumstances that lead to poor grazing.
- Cases may also be seen following wind or rain storms that drop leaves, acorns, or branches into pastures where cattle are grazing.
- Affected animals often develop a craving for acorns, occasionally to the exclusion of other available forage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diagnosis of oak poisoning is made on history of exposure and characteristic clinical signs or necropsy findings.
- Primary differentials include diseases that cause acute or chronic renal failure in ruminants.
- Pigweed (*Amaranthus retroflexus*) poisoning, obstructive urolithiasis, clostridial diseases, heavy metal poisoning, leptospirosis, and renal injury due to nephrotoxic antibacterial drugs should be considered.
- Other differentials include diseases that cause gastrointestinal ulceration: infectious bovine rhinotracheitis, bovine viral diarrhea, foot-and-mouth disease, and bluetongue.

CBC/BIOCHEMISTRY/URINALYSIS

- Chemistry profiles of animals in peracute and acute disease states indicate elevated serum urea nitrogen and creatinine, hyponatremia, hyperkalemia, hypochloremia, hyperphosphatemia, and/or hypocalcemia.
- Mild metabolic acidosis with a high anion gap may also be seen. The animal may be anuric or urine may be isosthenuric with proteinuria, hematuria, and/or glucosuria.
- Granular or proteinaceous casts are often found on urinalysis.
- In chronic cases, elevated serum urea nitrogen, creatinine, and anion gap in addition to variable electrolyte imbalances may be seen.
- Some animals show chronic oral, esophageal, or gastrointestinal ulceration or perforation with abscessation.
- Elevated white blood cell counts usually indicate chronic GI ulceration or abscessation.
- Chronic inflammation may lead to a normocytic normochromic anemia. Serum protein levels may be abnormally low due to gastrointestinal and renal losses.

OTHER LABORATORY TESTS

Urinary phenolic content can be used to confirm diagnosis.

PATHOLOGIC FINDINGS

- Tubular necrosis and perirenal edema are prominent in ruminants. Grossly, the kidneys are pale and enlarged.
- Multifocal ulcerative lesions are found in the mouth and esophagus, and throughout the gastrointestinal tract. Ascites and hydrothorax are often present.
- Histopathologic examination reveals coagulation necrosis of the cortical tubular epithelium. Tubules are dilated and devoid of epithelium but with intact basement membranes. Many tubules contain granular, hyaline or cellular casts. Necropsy findings after 3–6 weeks of disease may show GI abscessation associated with perforated ulcers, and secondary bacterial pneumonia. Some tubular regeneration may also be seen.

TREATMENT

- There is no specific antidote for oak poisoning.
- The goal of therapy is to restore adequate renal perfusion and urine production. Intravenous fluid therapy is recommended to promote diuresis and correct acid-base and electrolyte abnormalities. Oral fluid therapy can be used in some cases, but is less effective.
- Antibiotic therapy should be initiated to treat secondary pneumonia and GI abscessation. Nephrotoxic antibiotics should be avoided.
- Transfaunation may be necessary to restore rumen motility. Remove affected animals from oak trees and provide fresh hay and water.
- Adding calcium hydroxide into feed as a 10% concentration has been shown to be effective in decreasing the incidence of intoxication and mortality rates.
- The mechanism of action is currently unknown.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

OBSTRUCTIVE UROLITHIASIS

BASICS

DEFINITION

Obstructive urolithiasis is the formation of calculi in the urinary system with obstruction and is almost exclusively a male-dominated condition.

PATHOPHYSIOLOGY

- Obstructive urolithiasis occurs when uroliths lodge in the excretory tract, most commonly in the urethra, traumatize the surrounding tissue, and either partially or completely obstruct urine outflow. Uroliths may form in both males and females (see Causes/Risk Factors below for urolith formation); however, the female outflow tract is short and distensible compared to the long, tortuous, and inelastic outflow tract of the male. This anatomic difference allows females to more easily excrete calculi.
- Although calculi may become lodged at any point along the urinary tract including the kidneys, ureters, and trigone area of the bladder, the locations along the urethra that have the smallest diameter are the most common sites for the obstructions to occur.
- In small ruminants, calculi most often are found in the urethral process and tip of the penis. In cattle, the most common site is the sigmoid flexure. In camelids, stones will lodge in the urethra at the level of the ischial arch to the glans penis.

SYSTEMS AFFECTED

Renal/urologic

GENETICS

There may be a genetic predisposition, which has not yet been proved.

GEOGRAPHICAL DISTRIBUTION

None

SIGNALMENT

Species

Cattle, camelids, goats, sheep

Breed Predilection

Texel sheep are predisposed to excreting increased amounts of phosphorus than other breeds of sheep. This may put them at greater risk to develop phosphatic calculi.

Mean Age and Range

Affected animals are 6 months of age or greater.

Predominant Sex

- The condition occurs almost exclusively in males.
- In small ruminants and cattle, the condition is more frequent in animals that have been castrated. In particular, those animals that were castrated before the onset of sexual maturity are more commonly affected.
- In camelids, obstructive urolithiasis occurs more often in intact males.

SIGNS

Clinical signs vary depending upon whether the condition is acute or chronic, with partial or complete obstruction, and whether or not the urinary tract is intact.

Acute or Partial Obstruction

- Dysuria, stranguria, dribbling urine
- Vocalization during episodes of straining
- Flagging of the tail

- Forceful contractions of the abdominal muscles while straining, accompanied by arching of the back and elevation of the head
- Abdominal discomfort may be demonstrated by stretching, kicking at the abdomen, and bruxism.
- Mild distension of the abdomen may be noted.
- Animal may appear normal between episodes.

+/- Anorexia

Chronic or Complete Obstruction

- More pronounced clinical signs as outlined above
- Anorexia and depression
- No dribbling of urine and the preputial area is dry when obstruction is complete

If a rupture of the urethra or bladder occurs, the animal may temporarily appear comfortable since the pressure on the tract has been relieved. This comfort will be short-lived as urine accumulates in the abdomen (uoperitoneum) or in the subcutaneous tissues surrounding the penis and prepuce at the ventral abdomen.

Ruptured Bladder

- Bilaterally symmetrical distention of the abdomen; may not be noted in camelids
- A fluid wave may be noted in the opposite paralumbar fossa when the abdomen is balloted.
- Dribbling of urine may still be observed with a ruptured bladder.

Ruptured Urethra

- Plaquelike swelling surrounding the prepuce and penis on the ventral abdomen
- Swollen tissue gradually becomes cool and moist, and epilation may occur.
- Dribbling of urine may still be observed with a ruptured urethra.

CAUSES/RISK FACTORS

- There are multiple causes/risk factors for urolithiasis. Dietary factors play a major role.
- Chemical analysis of the stones (see urolith analysis laboratories below) and review of the ration to identify imbalances are crucial steps to the control and prevention of urolithiasis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- With early or partial obstruction, animals with obstructive urolithiasis will display forceful abdominal contractions during their bouts of stranguria. Otherwise they will appear bright and alert. These signs are suggestive for urinary tract obstruction especially if accompanied by tail flagging, vocalization, dribbling of urine, or having a dry prepuce. It is common for owners to describe these signs and indicate that the animal may be constipated; however, constipation in male ruminants is much less common than obstructive urolithiasis.
- Chronic or complete obstruction accompanied by anorexia, depression, and/or colic, abdominal distension, and tachycardia are signs that are also associated with gastrointestinal disorders, such as rumen acidosis, abomasal emptying defect, abomasal impaction intestinal obstruction. However, with abdominal disorders, the animal's ability to urinate should be intact. Placing an animal in a stall with no bedding so that the presence or absence of pools of urine may be observed is useful to assess urination function.
- Rupture of the urinary bladder will create uoperitoneum, which will show as a progressive, bilaterally symmetrical distention of the abdomen. Many abdominal disorders that result in abdominal distension do not produce symmetrical distension. For example, the abdominal distension associated with rumen acidosis/atonny is usually confined to the left abdomen, whereas abomasal emptying defect and abomasal impaction usually cause distension on the lower right side, with some involvement of the dorsal left paralumbar fossa.
- Rupture of the urethra is associated with ventral abdominal swelling surrounding the preputial area. Differentials for swelling in this area include umbilical hernia, abscess, or hematoma.

CBC/BIOCHEMISTRY/URINALYSIS

Early/Partial Obstruction

- CBC: usually within normal limits
- Serum biochemistry: possible increase in BUN, creatinine

Chronic/Complete Obstruction

- CBC: hemoconcentration, stress leukogram
- Serum biochemistry: increased BUN and creatinine, hypochloremia, normal or low potassium and sodium; potassium and phosphorus may be elevated in animals with uroperitoneum, and to a lesser extent in animals with rupture of the urethra

Commercial Laboratories That Perform Analysis on Uroliths

- Urinary Stone Analysis Laboratory, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California at Davis, Davis, CA 95616; 1-530-752-3228
- Dr. Carl Osborne, Department of Small Animal Clinical Medicine, 1352 Boyd Ave., St. Paul, MN 55108; 1-616-625-7744
- Urolithiasis Laboratory, P.O. Box 25375, Houston, TX 77265-5375; 1-800-235-4846

IMAGING

- History and physical examination findings in cases of obstructive urolithiasis are usually straightforward; however, abdominal ultrasonography of the bladder and kidneys may be useful for further diagnostic confirmation and prognostic/therapeutic approach purposes.
- In small ruminants and camelids, a 3.5–5.0 MHz probe placed in the right inguinal area and directed toward the pelvic inlet should provide good visualization of the bladder. If this structure is not ruptured, its distended outline will be readily apparent.
- If rupture has occurred, free fluid in the abdomen will be seen. In cattle, transrectal ultrasonography using a 7.5 MHz probe can be used to visualize the pelvic urethra, bladder, and left kidney.
- If obstruction has been present for 48 hours or longer, it is likely that hydronephrosis has developed, which also can be seen using ultrasound imaging of the kidneys. Observation of this abnormality is associated with a poor prognosis.
- Abdominal radiography for survey and/or contrast studies of the urinary tract in cattle to ascertain the location of uroliths and abnormalities (bladder rupture, hydronephrosis) probably has limited availability in large cattle for most private practices. The equipment that is required is prohibitive.
- In small ruminants (including calves), lateral abdominal views may be useful in detecting radiodense uroliths on survey films, or radiolucent stones using contrast material. However, in animals where the penis cannot be extended (prepubertal males, males castrated before puberty) and the urethral process removed (sheep and goats), catheterization of the urethra to introduce contrast material is generally precluded.

DIAGNOSTIC PROCEDURES

- Abdominocentesis and chemical analysis of the retrieved sample for creatinine is useful to document uroperitoneum. Peritoneal fluid is most easily obtained from the right side of the abdomen, right of midline in the inguinal area.
- Abdominocentesis performed in an animal with a bladder rupture will yield a moderate to large amount of free flowing, clear, colorless to yellow-tinged, usually nonodiferous fluid. Comparison of peritoneal fluid creatinine to serum creatinine usually shows a 2:1 ratio.

PATHOLOGIC FINDINGS

- At the site(s) of the obstruction and proximal to this, the urethral mucosa will appear discolored from hemorrhage and necrosis. Discrete calculi may be found, or in the case of struvite crystals, sandlike granules may be compressed along the obstructed area. If the urethra has ruptured, subcutaneous accumulation of urine will be found surrounding the site of rupture.
- The bladder may be distended and thin or it may be thickened. The mucosa may appear hemorrhagic and/or necrotic.
- If the bladder has ruptured, uroperitoneum will be present and there may be blood clots in the abdomen. Hydroureters and hydronephrosis may also be noted.

TREATMENT

- Once a diagnosis of obstructive urolithiasis is made, decisions concerning the affected animal should be made without

delay and with consideration for the animal's utility and health status.

- The prognosis for recovery for an animal that is found early in the disease process with an intact bladder and urethra is considered good if supportive therapy (fluids, antibiotics, and frequent monitoring) and surgical intervention are provided.
- The prognosis declines somewhat if the urinary tract has ruptured. In cases where the obstruction is either partial or complete and chronic with or without rupture within the urinary tract, the prognosis is very poor to guarded even with supportive care and surgical intervention. Oftentimes these cases have sufficient urinary tract trauma including hydronephrosis that is irreversible.

APPROPRIATE HEALTH CARE

- Medical management consists of extension of the penis for examination and/or removal of the urethral process in those animals whose penis can be extended (sexually mature males and males castrated after the onset of puberty).
- A urinary catheter is placed in the urethra. The author prefers a semirigid type, 22-inch catheter for small ruminants and camelids. The 5–8 French size works well for animals that are less than 45 kg, whereas the 10–20+ French is used in larger animals. Use of epidural anesthesia and setting the small ruminant on its hindquarters aids in performing this procedure.
- Surgical management consists of performing a perineal urethrostomy (PU) or abdominal exploratory surgery combined with tube cystotomy.
- Perineal urethrostomy is an economical option as a salvage procedure since its prognosis as a long-term solution is fair to poor. It is an excellent option for an animal destined for slaughter. Abdominal exploratory surgery allows for repair of the bladder if a rupture has occurred and for placement of a urinary bladder catheter that exits through the body wall to provide a temporary outflow of urine directly from the bladder. This allows time for the traumatized urethra to heal. It is the recommended procedure for breeding animals and pets.

NURSING CARE

This consists of providing fluid therapy (usually intravenous) to correct electrolyte abnormalities. Assessing and addressing azotemia, maintaining good hydration and glomerular filtration rate are important components to adequate nursing care. Abdominal bandaging and urinary bladder catheter maintenance may also be required for those animals that have had abdominal surgery.

ACTIVITY

Animals that have intravenous and/or bladder catheters should be restricted to a small pen and housed alone so that other animals do not interfere with catheter lines.

DIET

Please see [Table 1](#).

CLIENT EDUCATION

Clients should be informed of the possibility of condition recurrence. Even with surgical intervention and dietary management, the urethra may heal with a stricture/adhesion that may predispose an animal to future obstruction.

SURGICAL CONSIDERATIONS

See Appropriate Health Care above.

MEDICATIONS

DRUGS OF CHOICE

Antimicrobial Therapy

Considerations should include drugs that achieve a high concentration in the urine, have a low potential for nephrotoxicity, have a broad spectrum of activity, and, if possible, are approved for use in the target species. Examples include ampicillin, sulfonamides, and third-generation cephalosporins such as ceftiofur. Additional considerations may include withdrawal times for food-producing animals, urine culture, and sensitivity. In general, tube cystotomy patients will require a more prolonged course of antimicrobial treatment (at least for several days past the removal of the indwelling bladder catheter) than those animals that undergo a perineal urethrostomy.

Anti-inflammatory Therapy

Nonsteroidal anti-inflammatory drugs such as flunixin meglumine (1–2 mg/kg, IV or SQ, q 12 hours for 1–3 days) and aspirin (100 mg/kg, PO, q 8 to 12 hours for 1–3 days) may be useful to decrease tissue irritation and inflammation. These drugs

should be used with caution because of their nephrotoxic potential.

Sedatives/Analgesics

Sedation or epidural anesthesia is useful to aid in extension and examination of the penis. Diazepam (0.1 mg/kg IV) or acepromazine (0.05–0.1 mg/kg IV or IM) are recommended sedatives. Because xylazine has a diuretic effect, it may contribute to bladder distension and is not recommended unless immediate resolution of the obstruction is anticipated. Caudal epidural anesthesia (1 ml of 2% lidocaine/100 kg not to exceed 10 ml/450 kg in cattle or 3 ml in a 60 kg small ruminant for standing anesthesia) provides excellent relaxation of the retractor penis muscles, relief from urethral pain, and minimal side effects, and greatly facilitates examination of the penis and distal urethra.

Table 1

Urolithiasis Analysis and Associated Risk Factors.			
Type of calculi	Risk factors	Radiodense	Prevention
<i>Phosphatic:</i> Magnesium ammonium phosphate (struvite) Calcium phosphate	High concentrate (↑ P+):low roughage (↓ Ca++) ration High magnesium (> 6%) Pelleted rations Alkaline urine (pH > 7.0)	No	Balance ration for calcium, magnesium, and phosphorus Adjust Ca:P ratio to 2:1 Add sodium chloride ¹ or ammonium chloride ² to ration Maximize water intake
Silicates	Western U.S. plants grown in sandy soils accumulate silicates. Hi silica-containing water Hi Ca: Low P ration	No	Adjust Ca:P ratio to 1:1 rather than 2:1 Maximize water intake
<i>Oxalates:</i> Calcium oxalate Calcium carbonate	Oxalate-containing plants Alfalfa diets (High in cations Ca++ and K+) Alkaline urine	Yes Yes	Maximize water intake Feed grass hay (better cation to anion balance) Add sodium chloride ¹ or ammonium chloride ² to ration Maximize water intake
Any of the above types	Castration, especially before the onset of puberty Inaccessible (distant location, frozen) or unpalatable water	See above	<i>Water management:</i> Fresh, clean, palatable, and accessible source Encourage water intake with addition of salts (sodium chloride ¹ or ammonium chloride ²) to the ration

¹The addition of sodium chloride to a ration at a level of 2%–5%, or an individual dose of 1 tsp/45 kg, will encourage water intake, thus producing a greater volume of dilute urine (flushing action).

²The addition of ammonium chloride at 1%–2% (2–4 pounds/ton) of the ration, or an individual dose of 0.05–0.1 g/kg (1 tsp/45 kg), will encourage water intake with the same results as described for sodium chloride. Additionally, ammonium chloride may aid in decreasing urine pH, which is useful since some calculi, such as struvite, more readily precipitate in alkaline urine, which is the normal pH for ruminants.

CONTRAINDICATIONS

- Avoid drugs that are nephrotoxic. Stabilizing a patient with fluids and establishing urine flow may be necessary to accomplish first or concurrent with usage of drugs that have nephrotoxic potential, such as nonsteroidal anti-inflammatory agents.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Following medical or surgical treatment, an animal should be housed in an area that allows for observation of urination, either directly, or indirectly (removal of bedding and noting wet areas on the floor).

PREVENTION/AVOIDANCE

See [Table 1](#).

POSSIBLE COMPLICATIONS

A range of complications may occur in an individual animal or group of animals in the case of a herd or flock outbreak. These may include: death, renal failure, reobstruction, peritonitis (postoperative and/or secondary to bladder rupture), and cellulitis

(secondary to urethral rupture).

EXPECTED COURSE AND PROGNOSIS

See Treatment above.

OCULAR TREATMENTS

BASICS

OVERVIEW

- Ectropion is uncommon in farm animals, except when secondary to scar tissue formation.
- Entropion is seen as a congenital form, a traumatic form, which results from scarring, and secondary to other ocular disease, which causes squinting.
- Numerous other masses, growths, or lacerations can occur on the cornea, conjunctiva, eyelids, or nictitating membrane, which require surgery.
- The presence of ocular tumors on or around the eye may indicate the presence of tumors elsewhere in the body.

SIGNALMENT

- Entropion, ectropion, and other ocular lesions can occur in all ages and species of food animals.
- Entropion is more common in young animals, especially lambs, as a congenital defect.
- Cattle with nonpigmented periocular skin are more predisposed to squamous cell carcinoma (SCC).

SIGNS

- Anatomical abnormality can be directly observed.
- Epiphora
- Squinting
- Corneal edema
- Periocular masses
- Lacerations with associated hemorrhage
- Corneal defects

CAUSES

- Congenital
- Trauma
- Corneal ulcer/laceration
- Palpebral laceration
- Infectious conjunctivitis/keratitis
- Neoplastic

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Corneal ulcer
- Corneal laceration
- Conjunctivitis
- Keratitis
- Periorbital tumor
- Dermoid
- Ocular tumor
- Orbital fracture

TREATMENT

CONDITION

Congenital Entropion

- Repeated manual eversion of the lids
- Subconjunctival injection of saline or antibiotic
- Superglue can be used to plicate the lid to evert the margin.
- Skin staples or mattress sutures can be placed to plicate and evert the lid.
- Holtz-Celsus procedure to resect a wedge of skin in severe or recalcitrant cases

Traumatic Entropion

Surgical correction of laceration is required. Consultation with an ophthalmologist may be necessary to determine the best method of reconstructing the lid margins.

Secondary Entropion

- Diagnosis and treatment of the primary disease is essential.
- Pain relief usually results in resolution of the entropion.

Third Eyelid Masses

- Very small masses can be resected with scissors and topical or local anesthesia while leaving the rest of the nictitans intact.
- Larger masses or traumatized third eyelids can be resected entirely. Following topical and/or local anesthesia, hemostats are placed across the base of the nictitating membrane, and it is resected with scissors or scalpel. No suturing is required. Topical antibiotics are recommended to prevent infection.

Corneal Dermoids and Small SCC Lesions

- Superficial keratectomy can remove small lesions from the corneal surface with local and/or topical anesthesia.
- Hyperthermy can be used to remove small lesions or spreading thin lesions (< 10 mm thick). Repeated treatment and debulking may be required.
- Laser ablation can be used to remove some superficial lesions.

Corneal Lacerations and Ulcers

- Most ulcers and lacerations will heal with medical treatment.
- Severe lesions and lesions that could cause corneal rupture may benefit from protection.
- Conjunctival flaps can be performed, but may require consultation with an ophthalmologist.
- Tarsorrhaphy can be performed by suturing the outer eyelid margins closed. Absorbable suture can be used so that the sutures do not have to be removed, or nonabsorbable sutures can be used, but must be removed.
- A third eyelid flap can be performed to cover and protect the eye, and can be performed so that it can be raised and lowered for medicating the eye. A suture is placed through the lateral aspect of the upper eyelid, passed through the third eyelid around the cartilage to provide strength, and passed again through the upper eyelid. The suture is then drawn tight, pulling the third eyelid over the cornea to protect it. Avoid dragging or rubbing the suture on the cornea.

Eyelid Masses

- Wedge resection
- H-blepharoplasty
- Hyperthermy
- Cryotherapy
- Radiotherapy

Eyelid Lacerations

Careful surgical reconstruction in multiple layers

DRUGS OF CHOICE CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Careful monitoring of corneal damage is essential to avoid further damage or corneal rupture.
- Concurrent infections must be treated.
- Animals with ocular or periocular tumors should be monitored for new growths or recurrence of treated growths.

POSSIBLE COMPLICATIONS

- Corneal damage or rupture
- Ectropion, if entropion is overcorrected
- Recurrence of tumors

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Squamous cell carcinoma (SCC)
- Infectious bovine keratoconjunctivitis

SEE ALSO

Anesthesia and analgesia

Enucleation/exenteration

OESTRUS OVIS INFESTATION

BASICS

DEFINITION

- Infestation of the nasal cavity and/or sinuses with larval stages (bots or maggots) of *Oestrus ovis*.
- Infestation can produce a chronic rhinitis and sinusitis, most commonly associated with a mucopurulent nasal discharge.

PATHOPHYSIOLOGY

- *Oestrus ovis* is a dipteran fly in the same family as the warble fly of cattle.
- The adult fly is dark gray and is approximately 1 cm long.
- The adult fly has rudimentary or vestigial mouthparts and cannot feed.
- After mating, female flies deposit larvae (larviposit or oviposit) in and around the nostrils of the ruminant host. The fly does not land on the host in the process.
- Adult *Oestrus ovis* live 2–28 days and each female produces up to several hundred larvae.
- The parasite can “overwinter” as first-stage larvae in the nasal cavities of hosts and/or as pupae in the ground.
- The first-stage larvae, or instars, initially less than 2 mm long, enter the nasal cavity and feed upon mucus and exfoliated epithelial cells.
- The first-stage instars migrate in the nasal passages and undergo maturation to second-stage larvae or instars, which reside in the frontal and maxillary sinuses. Further maturation leads to third-stage instars. After a total larval period of weeks to several months, the fully developed third-stage larvae migrate back to the nostrils, are sneezed out, and pupate in the ground.
- The pupal period is 3–9 weeks.
- Adult flies arise after a period of approximately 4 weeks in summer but require much longer in cooler weather climates.
- Mechanical damage and trauma occur to the nasal mucosa due in part to attachment by the oral hooks and cuticular spines of the larvae.
- Hypersensitivity has been proposed to play a role in the pathophysiology; an increase in numbers of eosinophils and mast cells has been found in the mucosa. In the sinuses, dead larvae may produce an allergic and inflammatory response.
- Larvae and/or their products may produce inflammatory reactions in the lung.

SYSTEMS AFFECTED

Respiratory

- Rhinitis with nasal discharge, sneezing, and difficult, snoring respiration. The rhinitis is associated with a chronic catarrhal discharge, which may become purulent and which can contain many eosinophils.
- Chronic sinusitis and secondary pneumonia may be observed.

Nervous

- Rarely, the brain may be involved. Larvae enter the brain from the sinuses, or there is extension of purulent inflammation from the sinusoids.
- In “false gid,” signs of incoordination and a high-stepping gait may simulate signs of gid, a parasitic invasion of the CNS due to larval stages of a canine tapeworm (*Coenurus cerebralis*) and related species (*Taenia multiceps*).

General

Heavy adult fly activity and/or larval burdens may cause sufficient annoyance to hosts to interfere with feeding and lead to loss of condition and/or reduced weight gains.

GENETICS

N/A

INCIDENCE/PREVALENCE

- The incidence/prevalence is variable among geographic regions and within flocks in a given region. The condition is endemic in some areas.
- The parasite is found worldwide. Various sources report it as widely distributed in Africa, Australia, Europe, countries of the Mediterranean basin, South Africa, some countries in South America, countries of the former USSR and the United States.

SIGNALMENT

Species

- Most common in sheep, reported less commonly in goats
- Has been reported in bighorn sheep (*Ovis canadensis*) and the European ibex (*Capra ibex*), some deer, elk, camels and camelids, dogs, and people

Breed Predilections

- Affects all breeds of sheep
- Larval burdens have been reported as lighter in goats than in sheep.

Mean Age and Range

- All ages are apparently affected.
- Larval burdens have been reported by some sources as being higher in younger animals.

Predominant Sex

Occurs in sheep of all sexes, breeds, and ages

SIGNS

GENERAL COMMENTS

Production effects may occur from larger parasite burdens when feeding is interfered with. Both the adult fly and larvae can affect the host. The effects include interference with feeding, complications of nasal infestations, and the results of aberrant larval migration.

HISTORICAL FINDINGS

The female adult flies bother sheep, causing one or more of the following signs: head shaking, sneezing, rubbing the nose on the ground or on other sheep, foot stamping, circling with nose to the ground, stamping feet and shaking heads, blowing, and interference with grazing.

PHYSICAL EXAMINATION FINDINGS

- Major findings include: rhinitis with nasal discharge (initially clear and mucoid; later mucopurulent and often with blood), sneezing, and difficult, snoring respiration.
- Chronic sinusitis, secondary bacterial pneumonia is possible in some cases.
- Very uncommonly, larvae may enter the brain from the sinuses or there can be the spread of purulent inflammation from the sinuses to the brain.

CAUSES

Infestation of the nasal cavity/sinuses with larvae or bots of *O. ovis*.

RISK FACTORS

- Environmental factors may play a major role in influencing the frequency of infestation.
- In North America, the adult fly is seen from spring to summer or autumn.
- The fly is particularly active in warm weather. In warm climates, the fly can be active over a greater portion of the year.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Foreign bodies (visualization of foreign body in nasal cavity), nasal adenocarcinoma (visualization of tissue and/or biopsy), pneumonia (characteristic clinical signs, evidence of pulmonary pathology), sinusitis (clinical signs, lack of evidence of oestrosis), trauma (history), and others depending upon specific symptoms.

CBC/BIOCHEMISTRY/URINALYSIS

N/A.

OTHER LABORATORY TESTS

Serologic techniques such as an enzyme-linked immunosorbent assay (ELISA) test have been developed.

IMAGING

Techniques such as endoscopy may be used to visualize the parasite in the nasal cavity.

DIAGNOSTIC PROCEDURES

- Diagnosis is usually based upon clinical signs; it can be confirmed by necropsy postmortem or visualization of the larvae in the sinuses (e.g., endoscopy) antemortem.
- Diagnosis can also be based upon clinical signs and inferred from response to appropriate treatment.
- Diagnosis of problems associated with adult flies is based upon behavior of sheep. Larval identification may facilitate diagnosis also.

PATHOLOGIC FINDINGS

- Up to 20 or more larvae at different developmental stages may be found in the sinuses.
- Sinuses with live larvae may be seen as normal; sinuses with dead larvae may demonstrate edematous and thickened membranes and cavities with exudates.

TREATMENT

APPROPRIATE HEALTH CARE

- Treatment may be administered at various times during the year, based upon climatic factors and occurrence of infestations.
- In temperate climates, treatment in autumn has been recommended. The majority of larvae are small during this time period.

NURSING CARE

No specific recommendations

ACTIVITY

N/A.

DIET

N/A.

CLIENT EDUCATION

Strategic treatment may interrupt life cycle before the parasite becomes widely established.

SURGICAL CONSIDERATIONS

N/A.

MEDICATIONS

DRUGS OF CHOICE

- These recommendations refer to treatment of the disease in the United States in sheep, the most commonly affected species.
- Obtain specific information for drug approvals by country and for other species.
- Some anthelmintics used in control/treatment programs for GI parasites may be effective in maintaining control of *O. ovis*.
- Ivermectin at 0.2 mg/kg (200 ug/kg) PO kills all instars and is reported as highly effective. A controlled-release form of ivermectin is available in some countries and has been shown to be effective over an extended period of time.
- Obtain country-specific meat and milk withdrawal times following drug use.
- It has been recommended in temperate zones to treat in autumn when the majority of larvae are small.

CONTRAINDICATIONS

- Ivermectin is not recommended for use in lactating animals due to its extended milk withdrawal time.
- Obtain current and complete information on any drugs used.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A.

POSSIBLE INTERACTIONS

Check drug label and follow all regulations within individual country.

ALTERNATIVE DRUGS

- A variety of drugs has been used for treatment.
- Closantel, moxidectin, ruelene, rafoxanide, trichlorfon, and other systemic products have been reported in the literature.
- Some authors have recommended various treatments applied directly into the nostrils.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Treating at appropriate cycle stages can reduce the incidence of infection.
- Prevention is difficult. Attempts to minimize the effects of adult flies have been made by utilizing insecticides and by providing shelter or access to cool areas.
- Shelter or cool areas may decrease exposure to the adult flies, which are active in sunlight and warmth.
- The fly has a fairly narrow preferred temperature range.

POSSIBLE COMPLICATIONS

- Larvae may be unable to exit the sinuses and may die; calcified or septic sinusitis may result.
- Purulent inflammation in the sinuses may spread to the brain with the presence of dead larvae.
- Interstitial pneumonia and lung abscesses have been reported.
- Killing mature larvae may result in marked reactions in the membranes of the sinuses.

EXPECTED COURSE AND PROGNOSIS

Treatment at the appropriate life cycle with an effective drug should produce high cure rates.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Chronic sinusitis, secondary bacterial pneumonia are possible in some cases.

AGE-RELATED FACTORS

Young animals may experience greater larval burdens.

ZOONOTIC POTENTIAL

- *Oestrus ovis* is a zoonosis.
- It most commonly causes ocular myiasis or ophthalmomyiasis, primarily among individuals with close contact to sheep or infested animals (e.g., shepherds).
- Affected individuals most commonly report the sensation of being struck in the eye by an insect or foreign body, followed by pain and inflammation in the ocular conjunctiva.
- Cases of conjunctival ophthalmomyiasis have been reported as caused by *O. ovis* larvae in locations such as Africa, the Middle East, countries of the former USSR, Europe, and the United States. The larvae are usually visualized and removed.

PREGNANCY

N/A.

RUMINANT SPECIES AFFECTED

Sheep (most commonly affected), goats, bighorn sheep (*Ovis canadensis*), blesbock (*Damaliscus albifrons*), camels and camelids, European ibex (*Capra ibex*), elk, and some species of deer

BIOSECURITY

Spread of the parasite may be promoted by importation of infested animals.

PRODUCTION MANAGEMENT

- Moderate numbers of larvae cause little harm; heavy infestations may produce effects such as decreased grazing and feeding times.
- Infestations may cause a significant decline in production of milk or a decrease in weight gains.

Author: Kevin L. Anderson

OLEANDER AND FOXGLOVE

BASICS

OVERVIEW

- A member of the dogbane (Apocynum) family, oleander (*Nerium oleander*) is an evergreen ornamental shrub 15–25 feet tall.
- It has smooth, green bark and dark green leathery leaves, which are opposite at bottom, but appear whorled at the top.
- Multiple colors of flowers may bloom year round.
- The fruit is a hanging long slender pod and the seeds have tufts of hair.
- Foxglove (*Digitalis purpurea*) is tall with lanceolate dark green, hairy leaves that are low on the flowering stalk.
- Flowers are trumpet shaped, multiple colored, and profuse on the upper stalk.
- Additional plants include dogbane (*Apocynum cannabinum*), lily of the valley (*Convallaria majalis*), yellow oleander (*Thevetia peruviana*), squill (*Scilla maritima*), Ouabain (*Strophanthus* spp.), silkvine (*Periploca graeca*), and milkweed (*Asclepias*).
- Worldwide distribution due to cultivation as ornamentals
- Oleander is generally nonpalatable as a green plant, but most poisonings are associated with dried leaves from trimming.
- All parts of the oleander plant are toxic and only a small amount (0.005%–0.015% BW) must be ingested for toxicity

PATHOPHYSIOLOGY

- Foxglove is the natural source for digitalis.
- All parts of the plant are toxic.
- Toxicity due to oleander and foxglove ingestion is the same as digitalis toxicity.
- Na/K/ATP pump is affected leading to bradycardia, heart block, and asystole.
- Inhibition of pump leads to elevated intracellular Na and Ca and extracellular K.
- Cardiovascular compromise is predominant sign.
- Gastrointestinal and neurologic signs may also occur.
- Death usually occurs within 36 hours, but may take up to 14 days.
- Toxin is widely distributed in body, including milk, fetal fluids.
- Urinary excretion is primary route.

SIGNALMENT

All animals of all ages ingesting plants are at risk.

SIGNS

- Sudden death
- Neurologic
- Hyperexcitable nervous function
- Seizures
- Gastrointestinal
 - Vomiting and abdominal pain leading to severe diarrhea
 - Rumen atony
 - Increased salivation
 - Cardiovascular
- Present later in the course of intoxication

- Bradycardia progressing to arrhythmia, paradoxical tachycardia, heart block, and then asystole
- Weakness, depression, and coma occur secondary to cardiac insufficiency.

CAUSES AND RISK FACTORS

Any animal ingesting the plant is at risk of developing toxicity

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Any cause of severe diarrhea
- Other plant toxicities

CBC/BIOCHEMISTRY/URINALYSIS

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Serum digitalis assay may cross-react with toxin.
- Presence of plant in intestinal content
- Evidence of plant consumption
- Laboratory assays have been developed for detection of oleander in ingesta.
- ECG alteration includes widening of the QRS complex, ST segment depression, enlarged P waves, and ventricular arrhythmias.

PATHOLOGIC FINDINGS

- Nonspecific
- Gastrointestinal irritation
- Pale mottling of heart with congestion
- Histological evidence of myocardial degeneration and necrosis

TREATMENT

- Treatment is supportive and symptomatic.
- Rumenotomy to prevent further intoxication
- Prevent additional exposure.

MEDICATIONS

DRUGS OF CHOICE

- Activated charcoal (AC) (2–5 g/kg PO in a water slurry)
- Evidence in other species of recycling through gastrointestinal system; repeat doses of AC may be beneficial.
- Atropine for heart block (1 mg/kg to effect)
- Anti-arrhythmics
- Treatment for hyperkalemia
- Cathartics

CONTRAINDICATIONS

- Calcium-containing solutions are contraindicated.
- Potassium-containing solutions may be contraindicated with severe hyperkalemia and must be titrated.
- Drug withdrawal time must be determined and maintained.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

- Monitoring of serum potassium
- Monitoring of ECG

PREVENTION/AVOIDANCE

- Remove toxic plants from property
- Discard clippings appropriately

POSSIBLE COMPLICATIONS EXPECTED COURSE AND PROGNOSIS

- Death is likely in severely affected animals.
- Treatment is often not cost effective.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Ischemia secondary to hypoperfusion
- Respiratory failure

ONCHOCERCIASIS

BASICS

OVERVIEW

- Filarioid of genus *Onchocerca*, superfamily Filarioidea
- Filamentous, threadlike nematode parasite
- May parasitize horse, cattle, sheep, goats, buffalo, pigs, humans, and others
- Filarial infection is an important cause of skin diseases of horses and cattle throughout the world.
- Three *Onchocerca* spp. associated with cutaneous lesions in cattle
 - *Onchocerca gibsoni* infests cattle in Africa, Asia, and Australia.
 - *Onchocerca gutturosa* infests cattle and horses in North America, Africa, Australia, and Europe.
 - *Onchocerca ochengi* infests African cattle.
- Other *Onchocerca* species in cattle
 - *Onchocerca lienalis* (synonym *O. bovis*) found in North America and worldwide in cattle; relatively nonpathogenic
 - There is debate about the speciation of these organisms that will most likely be decided via PCR testing. Some consider *O. lienalis* and *O. gutturosa* separate species but others consider them to be the same species.
 - *Onchocerca armillata* live in the aorta of cattle, buffalo, and goats of India and Iran.
- Prevalence of infection is very high (20%–100%) in a given population of animals.

PATHOPHYSIOLOGY

Life Cycle

- Indirect life cycle with arthropod intermediate host that serves as vector.
- Transmitted by intermediate hosts (bloodsucking insects, biting fly)
 - Each *Onchocerca* species has a particular intermediate host.
 - Intermediate hosts are primarily species of *Culicoides* (midge), *Simulium* (blackfly), or sandflies.
- Adults worms are tightly coiled and woven into deep connective tissues in “nodules” or “subcutaneous cysts.”
 - *O. gibsoni* adult in nodules in fibrous tissue
 - *O. gutturosa* adults in connective tissue around nuchal ligament
 - *O. lienalis* found in gastrosplenic ligament, other ligaments, ligamentum nuchae, stifle, omentum, splenic capsule
 - *O. armillata* in the aorta
- Fertilized females produces vermiform embryos (microfilariae) into subcutaneous tissues and lymph spaces.
 - Microfilariae found in the skin and subcutaneous tissues at the feeding site of their intermediate host
 - Microfilaria of *O. gutturosa*, *O. lienalis*, and *O. ochengi* are found in the dermis.
 - *O. ochengi* hosts an endosymbiotic bacterium (genus *Wolbachia*) that is transovarially passed from female to offspring.
- Intermediate host, midge (*Culicoides* spp.), sandfly, or blackfly (*Simulium* spp.), ingests microfilaria from lymph spaces and subcutaneous tissue when it feeds.
 - *Culicoides* spp. gnats are intermediate host for *O. gibsoni*.
 - Numerous *Simulium* spp. and *Culicoides* spp. gnats serve as intermediate hosts for *O. gutturosa*.
 - *Simulium* spp. gnats serve as intermediate hosts for *O. ochengi*, *O. lienalis*.
- Ingested microfilariae develop to the infective larval (juvenile) stage in the vector.
- Transmission takes place when infective larvae that develop in the vector are deposited on the skin of their definitive host at a subsequent feed.

- The larvae develop to adult at site of vector bite or after migrating to predilection site depending on species.
- Adults become surrounded by fibrotic tissue (“nodule”) or encapsulated in connective tissue cyst as result of host’s response to parasite.
- In bovine, cutaneous onchocerciasis
 - Necrosis, abscess formation, mineralization, and granulomatous to pyogranulomatous inflammation occur around adult worms.
 - Adult worms of some species may also affect muscle.
 - Microfilariae reside in the surrounding connective tissue and lymphatics.
- In some other species, cutaneous onchocerciasis is thought to represent a hypersensitivity reaction to microfilarial antigen(s) but the pathophysiology of the condition is not fully defined in cattle.
 - In humans, cutaneous reaction to *O. volvulus* microfilariae is thought to represent type I and type III hypersensitivity reactions.
 - In horses and humans, microfilarial therapy may provoke an intense inflammatory reaction. Exacerbation of cutaneous signs associated with dead and dying microfilariae (Mazzotti reaction).

SIGNALMENT

- No sex, or breed predilection
- Infestation prevalence tends to increase with age
- Onchocerciasis is seen worldwide but is more common in the tropics and subtropics.
- Putatively immune adult cattle exist in endemically exposed populations.

SIGNS

- Adult worm infestation is often symptomless but response varies with species.
- Several species, most notably *O. gibsoni*, cause subcutaneous nodules or “worm nests.”
- *O. gutturosa*, *O. lienalis* are relatively nonpathogenic.
- *O. gutturosa*
 - Adult worms inhabit the ligamentum nuchae and connective tissue of scapula, stifle, and hip areas.
 - Few clinical signs
 - Firm, subcutaneous nodules or fibrous cyst under the (up to 3 cm diameter) skin over hip, stifle, and shoulder regions
 - Microfilariae are most numerous in the dermis of the face, neck, back, and ventral midline.
- *O. lienalis*
 - Few signs when found in ligamentum nuchae or gastrosplenic ligament
 - Occasional swelling over stifle joint
 - +–Disability if supporting ligaments are affected
- *O. gibsoni*
 - Causes unsightly firm subcutaneous nodules most notably over the brisket but also over hip, lateral stifle area, and lower limbs
 - Nodules are freely moveable.
 - Consist of worms encased in fibrous tissue
 - May cause rejection of beef carcasses
- *O. ochengi*
 - Adults produce asymptomatic, firm subcutaneous and dermal papules and nodules in scrotum and udder primarily, also on flanks, sides, and head.
 - Microfilariae are numerous in dermis of scrotum, udder, and ventral midline; cause mild to severe dermatitis resembling demodectic mange and pox.
- *O. armillata*—induces corrugation and swelling of inner aortic wall
- *Onchocerca* spp.
 - Sheep and goat may be parasitized.
 - Adults cause nodules in connective tissues.
 - Microfilariae migrate into dermis of ventral abdomen and thorax.
 - Host’s response to dying larvae results in alopecia, erythema, and thickening of skin in area ± depigmentation.

CAUSES AND RISK FACTORS

- Three *Onchocerca* associated with cutaneous lesions in cattle are
 - *Onchocerca gibsoni* in Africa, Asia, and Australia
 - *Onchocerca gutturosa* in North America, Africa, Australia, and Europe.
 - *Onchocerca ochengi* infests African cattle
- Other *Onchocerca* species that infect cattle are
 - *Onchocerca linealis* (synonym *O. bovis*) found in North America and worldwide; relatively nonpathogenic
 - *Onchocerca armillata* affect cattle, water buffalo, and goats of India and Iran.
- Diseases are most common when seasonal insect populations are highest.
- Although all intermediate hosts are not fully defined, transmission is primarily by arthropod (*Culicoides* spp., *Simulium* spp.) vectors.
- It is not known how long the adults and microfilariae of the various *Onchocerca* spp. survive in the host. In humans, *O. volvulus* adults may live up to 16 years and the microfilariae up to 5 years.

DIAGNOSIS

- Diagnosis is based upon history, clinical signs, presence of vectors, and skin biopsy.
- Identification of microfilariae from excised piece of skin or skin punch biopsy near nodules
- Skin biopsy—minced preparation to identify microfilariae
 - Punch biopsy (≥ 6 mm)
 - Mince specimen with a razor or scalpel blade
 - Place minced skin sample on a glass slide or in a Petri dish and cover it with room temperature physiologic saline.
- Allow preparation to incubate at room temperature for 30 minutes.
- Examine specimen under a microscope for the rapid motion of the microfilariae in the saline.
- Do not use saline-containing preservatives (e.g., alcohol); they may kill microfilariae and not allow their migration from the minced skin.
- Technique only confirms the presence of *Onchocerca* spp, microfilariae but alone does not confirm diagnosis of cutaneous onchocerciasis.
- Must differentiate *Onchocerca* spp. microfilaria from those of other species (e.g., *Setaria* spp., *Stephanofilaria* spp., *Pelodera*, *Strongyloides*): *Setaria* are sheathed. *Onchocerca* spp. are nonsheathed; have short sharply pointed tails
- Skin biopsy: histologic section—distinguishing structural traits of adult female *Onchocerca* organisms
 - Thin and very long, threadlike worms
 - Found coiled in dense connective tissue, or some species form distinctive fibrous nodules
 - Cuticle has distinctive external circular ridges and striae in inner layer. Number of striae per ridge helps distinguish various species of *Onchocerca*.
 - Poorly developed muscle cells
 - Prominent hypodermal tissue
- \pm Hoepli-Splendore material seen on the worm cuticle.
- Species: Size of adult worms and microfilaria
 - *O. gibsoni*: adult up to 20 cm long; microfilariae 240–280 μ m long
 - *O. gutturosa*: adult up to 60 cm long; microfilariae 200–230 μ m long
 - *O. ochengi*: adult up to 25 cm; microfilariae 256–207 μ m long
- Skin scrapings and direct smears are unreliable for the demonstration of microfilariae.
- Microfilariae are rarely found in the peripheral blood.

Postmortem Findings (Gross Findings)

- Single or clusters of firm fibrous nodules (0.5–5 cm in diameter)
- Nodules contain tightly coiled worms.

- Parasite tunnels
 - Worms may be dead or calcified.
 - Affected ligaments (e.g., nuchal, rumenosplenic, etc.) may appear gelatinous and brown with nodules.
- ±Roughening or calcification of aortic walls

Postmortem (or Biopsy) (Histologic Findings)

- Edema
- Cellular infiltrations predominantly eosinophilic
- Hemorrhage
- Necrosis
- Chronic granulomatous to pyogranulomatous inflammation with macrophages, lymphocytes, plasma cells, giant cells, calcification, and fibrosis around degenerate or dead parasites
- Some have parasites with no tissue reaction.

DIFFERENTIAL DIAGNOSIS

- Skin tuberculosis
- Demodectic mange
- Bacterial and fungal granulomas
- Abscesses
- Parafilariasis, cysticercosis
- Eosinophilic myositis
- Viral nodules
- Neoplasia, neurofibromatosis

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTING

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Skin biopsy
- Minced skin preparation to identify microfilariae

TREATMENT

- Success of treatment of bovine onchocerciasis is doubtful.
- No currently available drug effectively kills adults or all developmental stages of *Onchocerca* spp. in cattle.
- Long-term oxytetracycline is macrofilaricidal in cattle with adult *O. ochengi* infection; possibly due to its action on the endobacteria *Wolbachia*.
- Avermectins/milbemycins have little effect on adults but induce sustained abrogation of embryogenesis. Repeated dosing may enhance the adulticide effect of drugs.
- In humans, ivermectin (Mectizan) is the only drug currently recommended for the treatment and control of onchocerciasis.
- All agents used for treatment of microfilariae/adults in ruminants must be evaluated for
 - Approval in species in which they are to be used
 - Appropriate dosage for species and age group in question
 - Particular side effects noted in species and age group in question.
 - Withdrawal times for lactating animals and for slaughter time
- Diethylcarbamazine citrate 4 mg/kg in feed may be helpful.

- Experimentally, prophylactic treatments with ivermectin or moxidectin prevented adult worm infection following field exposure of naïve calves.
- Ivermectin treatment at times of maximal transmission may help prevent infection and may have some therapeutic value against *O. ochengi* in cattle.
- Combinations of ivermectin with suramin, mebendazole, melfoquine, flubendazole, albendazole, levamisole on adult *O. gutturosa* and *O. volvulus*, in vitro, only showed a marginally increased effect on motility compared to ivermectin alone.

MEDICATIONS

N/A

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Control of arthropod intermediate host(s) is difficult to impossible.
- Avoid grazing areas with high insect population.
- Housing of animals during prime activity time of intermediate host
- Insect repellents, dusting bags

MISCELLANEOUS

ASSOCIATED CONDITIONS

Secondary bacterial or mycotic infections

ZOONOTIC POTENTIAL

Onchocerca volvulus causes human onchocerciasis and “river blindness.”

ON-FARM PASTEURIZATION OF WASTE MILK

BASICS

OVERVIEW

- The use of waste or hospital milk to feed young stock is a very common practice among dairy farms. Although cost-effective, increased calf morbidity and mortality due to ingestion of pathogenic agents can be seen. Dairy producers are implementing on-farm pasteurization of their waste milk as a disease control procedure before feeding the milk to calves.
- Diarrhea, respiratory problems, pneumonia, arthritis, otitis media, and mastitis are diseases that have been associated with feeding nonpasteurized waste milk to calves.
- Proper pasteurization can reduce most pathogens in milk, providing a safe and nutritious feed.
- Calves fed pasteurized waste milk have higher mean body weight gain, lower mortality rates, and fewer days with diarrhea and pneumonia than calves fed with nonpasteurized waste milk.
- Pasteurization of waste milk decreases illnesses in calves compared with no pasteurization. If handled properly, waste milk is an economical and nutritious source of liquid feed for young dairy calves.
- Shedding of viable *M. paratuberculosis* has been documented in the colostrum and milk of infected dams.

SYSTEMS AFFECTED

Gastrointestinal, respiratory, central nervous system, mammary

GENETICS

N/A

INCIDENCE/PREVALENCE

- The 2002 NAHMS Dairy Survey indicated that 87.2% of dairy farms in the United States fed waste milk to their neonatal calves.
- National Animal Health Monitoring System (NAHMS) suggests between 20% and 40% of dairy herds in the United States have some level of Johne's disease.
- In one study, pasteurization of colostrum was found effective in the destruction of *M. paratuberculosis* but resulted in an average 25% reduction in colostral immunoglobulin.
- Discarded milk losses range from 48 to 136 pounds of milk per cow per year.

GEOGRAPHIC DISTRIBUTION

Worldwide depending on species and environment

SIGNALMENT

Species

Lactating bovine, ovine, and caprine species

Breed Predilections

Dairy breeds

Mean Age and Range

Calves, lambs, and kids

Predominant Sex

N/A

TREATMENT

- Two types of on-farm pasteurization are commonly utilized: (1) batch, where milk is heated to 63°C/145°F for 30

minutes and (2) HTST (high-temperature short-time) or flash pasteurization, where temperature reaches 72°C/162°F for 15 seconds.

- Waste milk has a much higher bacteria count than regular milk and therefore requires more than a 90% reduction in bacterial load.
- Farms that have problems with *Mycoplasma* spp. are especially problematic. *Mycoplasma canadense* is more heat resistant than other bacteria; it requires 5 min at 67.5°C or 2 min at 70°C to be eliminated.
- *M. paratuberculosis* may not be controlled by pasteurization and therefore on-farm pasteurization should not be considered as a way to control Johne's disease.
- There is no effect of pasteurization on antibiotics present in milk.
- Flash pasteurization of milk at 162°F (72°C) for 15 seconds kills most *Mycoplasma* spp. To effectively destroy *Mycoplasma* spp. in waste milk, a continuous-flow pasteurizer is necessary and must be monitored closely.
- Bacterial organisms in milk may bind together and not be effectively pasteurized with a batch-type pasteurization system.
- The need to handle large quantities of waste milk requires dairy operators to have the proper equipment. A small, used, bulk tank can store the daily production of waste milk.

CLIENT EDUCATION

- On-farm pasteurization has to be closely monitored to be efficient. Management and workers involved in the process must receive specific training in maintaining and operating the equipment, recording the data, cleaning the equipment, and general hygiene procedures.
- Maintain standard operating procedures (SOPs) for all the steps in the operation.
- Although it is recommended that waste milk be pasteurized, pasteurization of colostrum is not recommended. The elevated temperatures associated with pasteurization can destroy immunoglobulins.

PRECAUTIONS

- Refrigerate waste milk until pasteurization. Storage at room temperature will increase the microbial load and lower quality.
- Use milk immediately after pasteurization, but assure that the temperature is adequate to feed calves (around 38°C, 100.4°F).
- Do not pasteurize any milk that is acidic, bloody, or abnormal.
- Heat treatment can decrease the level of immunoglobulins (IgG).
- If high-quality colostrum (>60 mg/ml) is pasteurized, there is a higher chance the postpasteurized product will exceed 50 mg/ml.
- Several bacterial organisms, including *E. coli*, bovine viral diarrhea (BVD), *Salmonella* spp., *Streptococcus* spp., and *Staphylococcus* spp., have been identified in waste milk.
- Pasteurization destroys bovine leukemia virus (BLV), so the pasteurized milk from BLV-positive cows can be fed to calves when BLV-free milk is not available.
- Pasteurization is not sterilization. A heavy bacterial load in waste milk will not be completely eliminated by pasteurization.
- Pasteurization does not remove antibiotics from waste milk.

FOLLOW-UP

- Randomly check records, time, and temperature during pasteurization procedure.
- Regularly culture samples of pasteurized milk for pathogen load.

POSSIBLE COMPLICATIONS

- Complications originate from a failure in training and cleaning or equipment maintenance.
- If colostrum is pasteurized, the fluid characteristic of the liquid may become altered. This can cause problems in calf feeding and subsequent equipment cleaning.
- Do not feed waste milk to newborn calves on the first day of life. Bacteria can potentially penetrate the intestinal wall

and cause illness.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Diarrhea, respiratory problems, pneumonia, arthritis, otitis media, and mastitis are diseases that have been associated with feeding nonpasteurized waste milk to calves.

AGE-RELATED FACTORS

- Calves fed pasteurized waste milk have higher mean body weight gain, lower mortality rates, and fewer days with diarrhea and pneumonia than calves fed with nonpasteurized waste milk.
- House calves and feed waste milk individually to prevent them from suckling one another. This should reduce possible transmission of infectious microorganisms that cause mastitis.

ZOONOTIC POTENTIAL

Brucellosis, Q-fever, and tuberculosis are zoonotic diseases that can be transmitted in waste milk if it is not pasteurized properly.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Lactating bovine, ovine, and caprine species

BIOSECURITY

- Maintain standard operating procedures (SOPs) for all the steps in the operation.
- HACCP (hazard analysis critical control points) and quality control programs can help manage the process and assure standardization.
- Do not feed waste milk from antibiotic-treated cows to calves intended for meat production. Antibiotic residues from the milk could be deposited in the tissues of the calves.

PRODUCTION MANAGEMENT

- On-farm pasteurization is indicated for calf ranches that receive waste milk from different sources.
- Before using as a calf feed, pasteurize waste milk to reduce microbial load.
- Do not feed waste milk to newborn calves.
- Use caution when feeding waste milk that may contain antibiotics to calves that are potentially to be used for beef production.
- House heifer calves individually (i.e., hutches) when feeding waste milk.
- Know the health status of the cows from which waste milk is obtained. Unless milk is pasteurized, do not feed milk from cows with BVD or Johne's, or from cows infected with *E. coli*, *Mannheimia*, or BLV.
- Refrigerate milk at all times until use.
- Discard waste milk that is excessively bloody, watery, or unusual in appearance.

ORCHITIS AND EPIDIDYMITIS

BASICS

OVERVIEW

- Inflammation of the testicle and epididymis may occur separately but often occur concurrently and frequently have the same etiology. The inflammation may be the result of infection or trauma.
- Hematogenous spread from systemic infections is the most common route of infection. Retrograde extension from other parts of the urinary tract or secondary sex organs, particularly the epididymis, is also an important route of infection.
- Periorchitis of the tunica vaginalis testis within scrotum may be directly related to orchitis or an extension of severe peritonitis.

SIGNALMENT

- These conditions can occur in males of any breed and age but are most commonly seen in adults. The exceptions to this are several ram lamb diseases indicated below.
- Orchitis/epididymitis usually occurs unilaterally but both testicles/epididymi may be involved simultaneously.

SIGNS

- Warm, painful swelling of the entire testicle or one or more segments of the epididymis is the most common sign of acute disease.
- Epididymitis most frequently involves the tail segment.
- Some cases of *Brucella ovis* epididymitis in rams are subclinical and cannot be detected by palpation alone.
- Painful animals may refuse to mate or may be reluctant to move. Frequently they walk with a stilted gait.
- Chronic disease of these organs may not be accompanied by either heat or pain. Swelling of the head, body, or tail of the epididymis may be the only clinical sign of chronic epididymitis.
- Transient testicular degeneration usually occurs subsequent to inflammation of either the testicle or epididymitis. Severe inflammation of one or both testicles may lead to permanent testicular atrophy.
- Blood and/or pus in the semen may be seen in the ejaculate. In some cases, abscessation and liquefaction of the testicular parenchyma may occur with subsequent eruption and drainage through the scrotum. This is especially evident with cases of brucellosis in bulls and caseous lymphadenitis in goats.

CAUSES AND RISK FACTORS

Infectious

- *Brucella abortus* (bulls)—endemic areas
- *Brucella abortus* vaccine (bulls)
- *Brucella melitensis* (bucks) rare
- *Brucella ovis* epididymitis (mature rams)
- Epi-Vag virus (bulls) Africa
- Caseous lymphadenitis (CLA) (*Corynebacterium pseudotuberculosis*) (bucks, rams)
- Tuberculosis (*Mycobacterium tuberculosis*) (bulls) rare

Microbial

- *Actinomyces pyogenes* (*Corynebacterium*) (bulls and rams)
- *Actinomyces bovis* (bulls)
- *E. coli*
- *Hemophilus* spp. (bulls, young rams)
- *Salmonella*
- *Chlamydia psittaci*

- *Corynebacterium ovis* (young rams)
- *Actinobacillus seminis* (bulls, bucks, young rams)
- *Actinobacillus* spp. (young rams)
- *Histophilus ovis* (young rams)
- *Nocardia farcinica*
- *Pseudomonas* (bucks)
- *Salmonella abortus ovis* in Germany
- *Streptococcus* spp.
- *Staphylococcus* spp.
- *Yersinia (Pasteurella)pseudotuberculosis* in the United Kingdom

Nonspecific Bacteria

- *Mycoplasma* spp. (ram)
- Herpesvirus III (IBR-IPV) (bulls)

Parasitic

- Trypanosomiasis (bucks) Africa
- Besnoitosis (bucks) Africa

Traumatic

- Kick
- Butting
- Fighting
- Stepped on
- Barbed wire entanglement
- Penetrating wounds

Risk Factors for Trauma

- Overcrowding of males
- Mixing young males with older males
- Introducing new males into the herd with an established dominance order
- Poor pasture/range management

Sadistic Behavior

- Shotgun pellets
- “BB” shot

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Inguinal hernia
- Hydrocele
- Hematocele
- Spermatocoele
- Varicocele
- Metastatic mesothelioma

CBC/BIOCHEMISTRY/URINALYSIS

Blood, pus, or increased WBCs in urine

OTHER LABORATORY TESTS

Blood, pus, or large numbers of WBCs in ejaculate

IMAGING

- Radiographs may reveal radiodense foreign bodies (BBs, buckshot, etc.)

- Ultrasonography may help differentiate hernia, hydrocele, varicocele, etc.
- Thermography may localize inflammation.

DIAGNOSTIC PROCEDURES

- Scrotal palpation
- Semen evaluation
- Semen culture
- Aseptic aspiration of peritesticular fluid for culture/cytology
- Testicular aspiration for culture—last resort, may lead to adhesions or abscessation and atrophy
- *Brucellosis ovis* serological test—complement fixation test

PATHOLOGIC FINDINGS

- Transient testicular degeneration
- Permanent testicular degeneration (atrophy)
- Occluded seminiferous tubules, rete testes, vas deferens, or epididymis

TREATMENT

- Unilateral castration if acute and the disease is limited to one testes
- Systemic antibiotic therapy for 7–14 days after the acute inflammatory stage subsides. Culture and sensitivity of the organism is indicated.
- Cool water hydrotherapy 30 minutes twice daily for 7–10 days
- Sexual rest

MEDICATIONS

DRUGS OF CHOICE

- Antibiotic selection based on culture and sensitivity results
- Systemic doses of procaine penicillin G or oxytetracycline
- Oxytetracycline 10 mg/kg plus dihydrostreptomycin 25 mg/kg twice daily for 7 days stopped shedding of *Brucella ovis* but is not recommended except for valuable rams that won't enter the food chain.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Reevaluate scrotum and testes for adhesions or atrophy 1 month after the end of therapy.
- Reevaluate semen quality a minimum of 60 days after the end of the insult to the testicle(s) or removal of the affected testicle.

PREVENTION/AVOIDANCE

- *Brucella ovis* vaccination (rams)
- *Corynebacterium pseudotuberculosis* vaccination (caseous lymphadenitis)

POSSIBLE COMPLICATIONS

Reduced fertility and or sterility

EXPECTED COURSE AND PROGNOSIS

- Poor fertility prognosis for affected testicle/epididymis

- Guarded prognosis for normal fertility in adjacent testicle in cases of severe inflammation

ORF/CONTAGIOUS ECTHYMA

BASICS

OVERVIEW

- Orf, often referred to as contagious ecthyma, cutaneous pustular dermatitis, sore mouth, or scabby mouth, is a communicable disease characterized by the development of ulcero-pustulo-proliferative lesions in the skin of sheep, goats, wild ruminants, and humans.
- Orf is caused by orf virus (ORFV), the prototype species of the *Parapoxvirus* genus in the subfamily Chordopoxvirinae of the Poxviridae family.
- The precise geographic distribution of orf is not known, but it is thought to be present in most parts of the world where sheep and goats are raised.
- ORFV can be transmitted by close contact between infected and susceptible animals. Indirect transmission through contact with contaminated objects has been suspected, but it is difficult to demonstrate.
- ORFV does not cause latent infections in animals that recover from clinical disease, but clinically healthy animals that are moved from infected to noninfected premises or transported in contaminated vehicles can act as mechanical carriers.
- Before the eradication of screwworm flies (*Cochliomyia hominivorax*) from North America, orf was a major problem for the livestock industry. The fly larvae invade skin lesions, leading to secondary infections and high mortality among sheep and goats.
- Since the eradication of the screwworm fly from this region, mortality due to orf has decreased significantly. Still, outbreaks of orf continue to occur on a yearly basis. Although rarely fatal, orf is considered an economically important disease, particularly on premises where sanitary conditions are poor.
- Orf can lead to growth retardation, loss of body condition in young lambs and kids, and predisposition to secondary infections. The disease can also result in economic losses as a result of international trade barriers imposed on animal shipments.

SIGNALMENT

- Sheep, goats, and humans are the species most commonly affected by orf. The infection also has been reported in musk ox, takin, mule deer, camels, bighorn sheep, mountain goat, and the dog.
- With the exception of musk ox and takin, reports of orf in wild ruminants and other species have been limited to descriptions of the clinical and pathologic findings and to the identification of the virus by electron microscopy (EM). Therefore, the possibility of the etiological agent being a closely related parapoxvirus cannot be ruled out in those cases.
- Clinical orf is more common among lambs or goat kids after weaning. Animals that have recovered from orf, or that have been vaccinated, are potentially susceptible to reinfection. In reinfected animals, lesions usually are of less severity and the clinical course is shorter.
- Adult animals less often present clinically with orf with exception of does and ewes that may develop orf lesions in the teats while nursing affected kids/lambs.

SIGNS

- Orf is recognized by the appearance of macules in the skin that rapidly progress to form papules, vesicles, and pustules.
- Within a few days, the pustules rupture leaving an ulcerated area where a thick overlying crust is deposited giving rise to rapidly growing scabs. Papillomatous growths, resulting from continued epidermal proliferation, do occur.
- The lesions usually start at the commissures of the lips and spread around the lip margins to the muzzle. In more severe cases, the skin of other areas, such as the eyes, feet, vulva, or udder, may be affected.
- Occasionally, lesions may develop in the gingiva, dental pad, palate, tongue, and in the skin of the interdigital space. These lesions are painful, and affected animals may be reluctant to suckle, eat, or walk depending on the location of the lesions.

- In the majority of cases, the lesions are self-contained and heal spontaneously within 3 to 4 weeks after they first appear.
- A generalized, persistent form of orf, characterized by severe, multifocal, proliferative dermatitis, occurs in sheep and goats. Some individuals of the Boer goat breed seem to be more susceptible to this form of the disease. In these cases, secondary bacterial infections or maggot infestation of affected areas may occur.
- Morbidity often reaches 60 to 80% in susceptible animals. Occasionally, mortalities as high as 10% have been reported.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Orf lesions may be confused with other ulcerative, vesicular or proliferative dermatitis, such as the ones caused by capri or sheep poxviruses, bluetongue virus, foot-and-mouth disease, or pearmouth, the latter a dermatitis of lips and muzzle caused by ingestion of prickly pear cactus.

DIAGNOSTIC PROCEDURES

- In the majority of cases, the diagnosis of orf is made by observation of clinical signs and lesions.
- The most common laboratory confirmatory test is the identification of parapoxvirus virions by negative staining EM in scab material. Several pieces of scab from various animals that are in the early phases of the infection should be submitted for diagnosis. Dry, late-stage scabs tend to contain smaller numbers of virus particles and larger numbers of bacteria reducing the possibilities of getting an accurate diagnosis.
- Gloves should be worn during the clinical exam and collection of samples from affected animals. Samples for diagnosis can be submitted at room temperature or refrigerated in a double-container to prevent infection of people handling the samples.
- The EM technique relies on the identification of typical ovoid-shaped parapoxvirus virions. A limitation of this technique is that all parapoxviruses, including bovine papular stomatitis virus (BPSV) and pseudocowpox virus (PCPV), are morphologically identical; and therefore, indistinguishable by EM.
- PCR has been used successfully to corroborate the clinical diagnosis. Most likely, this method will replace EM as the method of choice for confirmation of orf.
- Virus isolation is often unsuccessful. However, it can be attempted using a variety of primary cell cultures, including ovine and bovine kidney cells, ovine and bovine testis cells, and others. Typical cytopathic effect consists of cell rounding, clumping, and detachment. Intracytoplasmic eosinophilic inclusion bodies can be observed in stained cell culture.
- Serological tests such as serum neutralization, agar gel immunodiffusion (AGID) test, complement fixation, or agglutination, for the detection of anti-ORFV antibodies, are occasionally used, but have limited diagnostic value.

PATHOLOGIC FINDINGS

Gross Findings

- The predominant macroscopic lesions consist of ulcers, crusting, and papillomatous growths in the skin of lips and muzzle. These lesions range in size from a few millimeters to several centimeters. Macules, papules, vesicles, and pustules also can be observed, but in the majority of cases, these changes are transitory and rapidly progress to crusting lesions.
- Lymph nodes draining the affected areas of the skin are often enlarged.
- Secondary bacterial pneumonia and suppurative arthritis are common in animals with disseminated persistent orf.

Microscopic Findings

- Histologically, orf lesions in the skin are characterized by papillated, hyperplastic dermatitis with a mixture of epidermal and dermal proliferation.
- Hyperkeratosis, parakeratosis, and elongation of the rete pegs are evident, the latter particularly at the borders of the epidermis between areas of papillomatous proliferation and normal skin.
- Clusters of epidermal cells with vacuolated cytoplasm or cells with eosinophilic intracytoplasmic viral inclusions may be found in the stratum spongiosum. Subcorneal vesicles and pustules may be present throughout the epidermis. Ulcers covered by serocellular crust containing bacterial colonies or vegetable debris may be observed in the epidermis.
- The dermal component consists of proliferating connective tissue with various degrees of lymphocyte and plasma cell infiltration. Infiltration by neutrophils is more common in ulcerated areas. Capillary proliferation and edema of the dermis

are also common.

TREATMENT

- There are no specific treatments for ORFV.
- Affected animals should be placed in shaded pens protected from the environment and provided with clean water and good quality hay or feed.
- Wide-spectrum antibiotics and topical insecticide should be used in animals with secondary bacterial infections or maggot infestations, respectively.
- Meat and milk withdrawal periods must be maintained for drug use.

MEDICATIONS

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION AND CONTROL

- The use of live ORFV vaccines, prepared by sheep skin passage or in cell culture, is a common practice.
- The vaccine should not be used in locations where the disease has never been diagnosed, but when used for the first time, all susceptible animals in the premises should be vaccinated.
- On premises where orf is endemic, all lambs and goat kids should be vaccinated at 6 to 8 weeks of age.
- In subsequent years, only the new lamb/kid crop and newly acquired animals should be vaccinated.
- Vaccines contain nonattenuated live virus and can induce disease in orf-naïve animals that share pens with vaccinated animals. Vaccine orf virus also can cause disease in humans and should be used with caution.
- First, scarify an area of the skin of animals at risk, most commonly in the medial aspect of the thigh, and then rub the vaccine in to apply the vaccine. The appearance of a localized lesion 2 to 3 days later indicates a successful vaccination.
- Although vaccinated animals or those that recover from natural infection are susceptible to reinfection, subsequent orf infections tend to be milder and of shorter duration. In practice, most vaccinated animals remain protected for several years after a primary infection.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Most cases of orf occur in lambs and kid goats after weaning.

ZOO NOTIC POTENTIAL

- In humans, orf is considered primarily an occupational hazard. The disease is common among farmers, sheep shearers, veterinarians, and producers that handle small ruminants. Slaughterhouse workers, butchers, and meat handlers are sometimes infected from carcasses.

- Orf in humans is manifested by the appearance of one or several localized pustules and scabby lesions on the hands and sometimes face or ears. The lesions progress to form large painful nodules that eventually regress and disappear in 4 to 6 weeks.
- Multifocal, widespread skin lesions in humans have been reported in immunocompromised people.
- Erythema multiforme may be a sequella in human orf.

PREGNANCY

- In ruminants, there are no indications that ORFV affects the fetus.
- In two cases of orf in pregnant women, the deliveries were uncomplicated, and the patients gave birth at term to normal babies.

OSTEOCHONDROSIS

BASICS

DEFINITION

- Osteochondrosis (OCD) is a disease that results from defective endochondral ossification. This defect may cause dissection cartilage flaps (osteochondrosis dessicans), subchondral bone cysts, or physitis.
- “Dyschondroplasia” and “chondrodysplasia” are other terms used for osteochondrosis.
- These conditions often progress to degenerative joint disease and chronic arthritis.

PATHOPHYSIOLOGY

- In osteochondrosis, cartilage cells fail to differentiate normally and calcification fails to occur; however, the cartilage cells continue to grow resulting in a zone of hypertrophied cartilage cells.
- Synovial fluid provides nutrition to the immature joint cartilage. A thicker zone of cartilage results in decreased nutrition to the basal layer of the cartilage cells. This results in degeneration and necrosis of the cartilage cells. The necrotic area can form the basis of a fissure that can lead to dissecting flaps, which present as osteochondrosis dessicans.
- Direct trauma has also been cited as a source of necrosis and eventual fragmentation.
- Subchondral bone cysts may result from thickened cartilage that infolds into subchondral bone of weight-bearing surfaces. Other studies suggest that subchondral bone cysts may develop from defective connective tissue or cartilage rather than endochondral ossification. This theory suggests that the cartilage cracks following mechanical trauma creates an opening and synovial fluid pumps through the defect into subchondral bone during weight bearing.
- Physitis is associated with thickening and weakening of the growth plate cartilage.

SYSTEMS AFFECTED

Musculoskeletal

GENETICS

May reflect the effects of genetic selection for rapid growth

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on species and environment

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

- There is no specific breed predilection in cattle, pigs, and goats.
- Hereditary dyschondroplasia, known as “spider lamb syndrome” in Suffolk and Suffolk crossbred lambs, has been recognized.

Mean Age and Range

Osteochondrosis has been reported in animals as young as 5 to 7 months, but overt clinical signs usually are observed in cattle between 12 and 24 months of age.

Predominant Sex

Osteochondrosis is more common in males than females. Among males, the disease is more common in bulls than steers.

SIGNS HISTORICAL FINDINGS

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- The primary clinical sign in cattle with osteochondrosis is lameness and joint effusion. Joint effusion is believed to be associated with joint capsule proliferation and synovial fluid production due to inflammation.
- The most commonly affected joints are the stifle, tarsus, carpus, and shoulder and multiple joint involvement is common and expected.
- Affected cattle are usually reluctant to move and typically walk with a short strided gait that entails minimal flexion of the stifle and hock. Animals often have a postlegged conformation with abnormally straight stifle and tarsus joints.
- Localization of lameness to a specific limb may be difficult.

CAUSES AND RISK FACTORS

The exact cause of osteochondrosis is unknown, but predisposing factors have been implicated.

Risk Factors

- The most important risk factor for OCD appears to be rapid weight gain during a young animal's period of cartilage maturation (prior to 2 years of age). More cases are reported in males than females, and among males the disease is more common in bulls than steers.
- High-energy and protein diets producing rapid growth have been implicated.
- The disease is more common among registered or valuable animals; however, this apparent predisposition probably reflects superimposed effects of genetic selection for rapid growth, diets composed to support maximum growth, and the increased likelihood of more definitive diagnostics in valuable animals.
- Among commercial beef and dairy replacements, the condition is rare because these animals are fed to support relatively slow growth.
- Although lesions are common in feedlot cattle, these animals rarely show clinical disease because they attain market weight before clinical signs become severe.
- This condition appears most common among registered beef bulls and male and female show cattle of both beef and, to a lesser extent, dairy breeds because these animals are fed diets supporting maximum growth for extended periods of time.
- Mineral imbalances including calcium, phosphorus, copper, and zinc are believed to contribute to the development of osteochondrosis.
- Cattle raised on concrete floors with limited exercise are thought to be more predisposed to the development of osteochondrosis. These surfaces are thought to increase loading of the joints leading to mechanical trauma to the articular surface, increasing incidence of osteochondrosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differential diagnoses include those diseases and conditions causing either polyarthritis or multiple limb lameness. Consequently, diseases such as mycoplasmosis, *Hemophilus somnus* infections, and bacterial endocarditis should be considered as differentials. Mycoplasmosis and *Hemophilus* infection are usually associated with respiratory signs. Mycoplasmosis can occur in neonates and may also be associated with otitis and feeding of dump milk. *Hemophilus* can also result in brain stem and cortical signs. Joint fluid analysis with both mycoplasmosis and *Hemophilus somnus* infections are associated with marked increase in white cell count and protein. PCR on joint fluid can be used to identify *Mycoplasma*. Signs of right-sided heart failure (distended jugular veins, increased jugular pulses, tachycardia, and submandibular edema) and presence of a systolic murmur are characteristic in endocarditis.
- Septic physisitis, a common sequela to salmonellosis, may appear as a lameness involving multiple limbs and multiple swollen joints; however, joint distention is usually absent in this condition and close physical examination will generally reveal that swelling is localized to the physis, rather than joints.
- Both acute and chronic laminitis should be considered as likely differentials. The signalment, dietary composition, and

management factors predisposing the two conditions are very similar and the two conditions often are present concurrently. Cattle with chronic laminitis will have altered hoof growth. Both acute and chronic laminitis will be confirmed by close examination and trimming of the hooves. Joint distention will be absent in cattle with laminitis.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Joint fluid analysis reveals a nonseptic inflammation with mild to moderate increase in leukocyte count and protein.

IMAGING

Radiology

- Definitive diagnosis of osteochondrosis is confirmed by radiographic findings.
- Lesions are either the appearance of subchondral bone irregularity with bone fragmentation referred to as osteochondrosis dissecans or subchondral bone cysts characterized by periarticular focal areas of subchondral bone lucency.
- The stifle joint is the most commonly affected joint followed by the tarsal joint.
- Other joints reported as sites for osteochondrosis include the shoulder joint, distal radius, and phalanges.
- Osteochondrosis is radiographically apparent bilateral. Consequently, bilateral radiographs should be considered although clinical signs of bilateral disease might not occur.
- Radiographs of the shoulder and stifle are difficult (if not impossible) in most awake standing cattle.
- Osteochondrosis can lead to degenerative joint disease.

Arthroscopy

- Arthroscopy can be an effective technique for the diagnosis and treatment of osteochondrosis in cattle.
- Equipment costs and subsequent surgery may be prohibitive for most individuals.
- Arthroscopic techniques are also useful in the evaluation and treatment of osteochondrosis in sheep, goats, and camelids.

OTHER DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- Conservative therapy includes stall rest for 1 to 3 months.
- Deep bedding and dirt-floored or pasture housing are recommended.
- Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be dramatically decreased and the patient's rate of gain limited.
- Nonsteroidal anti-inflammatory drugs may be considered for short-term palliative therapy.
- Surgical treatment involving removal of the osteochondral fragment and debridement of the fragment bed or debridement of the cyst in cases of subchondral bone cyst may be considered in valuable animals; however, no controlled clinical trials have examined the efficacy of these procedures in cattle.
- In feedlots, therapy should not be attempted and affected cattle should be marketed immediately.

ACTIVITY

Decrease activity

DIET

Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be dramatically decreased and the patient's rate of gain limited.

CLIENT EDUCATION

- Conservative therapy includes stall rest for 1 to 3 months. Deep bedding and dirt-floored or pasture housing are recommended. Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be dramatically decreased and the patient's rate of gain limited.
- Breeding stock with clinical disease will likely have a shortened productive lifespan due to the anticipated development of degenerative joint disease and culling should be considered.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

Monitor animal for appetite and pain response.

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- The diet and housing of herd mates in the same group as the affected animal should be examined.
- Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be decreased to the level needed to support economically relevant rates of gain.
- In feedlot animals, the energy density of the diet is not decreased.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Most cases with signs of lameness and secondary degenerative joint disease have poor prognosis.
- Refractory lameness has been associated with medical management.
- Breeding stock with clinical disease will likely have a shortened productive lifespan due to the anticipated development of degenerative joint disease; culling should be considered.

OSTERTAGIOSIS

BASICS

OVERVIEW

- *Ostertagia* are nematode parasites of the gastric glands and lumen of the abomasum of ruminants.
- The subfamily ostertaginae has been divided into several morphologically distinguishable but biologically similar genera that are usually host specific but may be found in other ruminants.
- *Teladorsagia* of sheep and goats, *Mazamastrongylus* of American cervids, and *Spiculopteragia* of old world cervids plus other genera in cameloids and antelope appear to be able to cause similar syndromes in their respective hosts.
- The disease is associated with the emergence of larvae from the gastric glands causing increased abomasal pH, lowered serum protein, and anorexia.
- *Ostertagia ostertagi* is the most economically important nematode parasite of cattle in temperate regions and *Teladorsagia (Ostertagia) circumcincta* one of the most important parasites of sheep and goats in cool moist climates.

SIGNALMENT

- All ages may become infected but the young of the year are more at risk for disease.
- Stressed animals and those that have not been repeatedly exposed to the parasite are more likely to have signs of disease.
- Breeds that evolved in cool, moist environments are more likely to have genetic traits making them resistant to infection.

SIGNS

- Weight loss and diarrhea are the most common clinical signs.
- Hypoalbuminemia and dehydration may be seen in individual animals.
- The disease is seasonal and manifests in different ways depending on the epidemiology in a geographic region.

Type I Ostertagiosis

- Occurs in young animals during the early phases of exposure to larvae on pasture.
- Larvae enter the gastric glands a few days postinfection then emerge 2 to 3 weeks later.
- Most of the animals in a population will have some disease from anorexia to diarrhea and weight loss.

Pretype II Infection

- Occurs later in the grazing season as larvae acquired on pasture are programmed to enter hypobiosis.
- These larvae enter the gastric glands and cease development at the early fourth stage.
- They do not feed or develop and no disease is seen.

Type II Ostertagiosis

- Occurs when the previously arrested (hypobiotic) larvae resume development.
- The larvae tend to emerge from the gastric glands more or less en masse; those acquired over several months may emerge in weeks.
- The number of animals showing signs may be less but the disease is usually more serious from the numbers of gastric glands being destroyed.
- Watery diarrhea with type I—the forage is rapidly growing and a greenish diarrhea is seen. Type II varies with the forage—a brownish diarrhea if hay or silage is consumed or green if lush grass from autumn rains.
- Submandibular edema (bottle jaw), anemia, and dehydration with a dull hair coat are often seen.

Host Immunity

- Livestock develop resistance to infection following repeated exposure to larvae. However, the resistance is not complete and parasites can occur in any age animal.
- Cattle that have been treated with anthelmintics aimed at the transmission patterns of *Ostertagia* have increased milk production even though they are not showing signs of disease.

- A high-protein diet may mask some signs of disease but also may aid in the immune response of the host against the parasite.
- Apparently multiple exposures to the parasite are required to stimulate a protective response.
- Zebu cattle and zebu crosses are more likely to exhibit signs of disease than European breeds of cattle.
- *Ostertagia* cause a nonspecific suppression of immunity.
- Hypersensitivity reactions occur with infections, which may be deleterious to both host and parasite.

Parasite Survival Strategies

- Heat and desiccation are deleterious to larvae in pastures but survival under snow is common.
- Larvae can survive in pastures for up to a year during periods of drought if entrapped in dung pats.
- Arrested development of early fourth-stage larvae in the gastric glands enables the parasite to evade unfavorable conditions in the environment (extremes of hot, dry or cold) or immune response by host.
- Emergence from the arrested state often coincides with reproduction and the periparturient relaxation of resistance by the host allows the survival of worms for a sufficient period to ensure the next generation of worms is present in the pastures for acquisition by the offspring.

HISTORICAL FINDINGS

- Grazing history
- Age of animals with clinical signs
- History of anthelmintic use and evaluation of anthelmintics on the premises
- Weight loss, diarrhea, and no fever
- Season

CAUSES AND RISK FACTORS

- Ostertagids do well in most cool climates or during that portion of the year when those conditions are present.
- Young animals and those in early lactation are at greatest risk.
- Heavily stocked and overgrazed pastures
- Animals on low-protein diets
- Breeds that evolved in arid or tropical conditions are at greater risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diarrhea due to intestinal parasitism
- Hypoproteinemia due to haemonchosis or fascioliasis
- Enteric viral or bacterial diseases
- Malnutrition

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia low packed cell volume but not clinically apparent
- Hypoproteinemia, especially low serum albumen levels
- Elevated serum pepsinogen levels > 3.0 IU tyrosine, cattle or > 2.0 sheep

OTHER LABORATORY TESTS

- Fecal flotation egg counts are usually elevated but the level may not be high, as individual ostertagids do not produce as many eggs as some other nematodes and there may be dilution due to diarrhea.
- Eggs are not diagnostic, as other genera of gastrointestinal nematodes produce identical eggs.
- Culturing larval nematodes to the infective L3 stage will enable a differential identification of worms at the generic level.

PATHOLOGICAL FINDINGS

GROSS FINDINGS

- Edematous roughened (Morocco leather) abomasal folds
- Enlarged regional lymph nodes

- Raised umbilicated nodules on surface of abomasum
- May be sloughing of mucosa
- Elevated abomasal pH
- Adult worms (ca. 1 cm) may be seen on surface of abomasum, easily overlooked if not fresh and moving.

HISTOPATHOLOGICAL FINDINGS

- Distended gastric glands may contain developing worms.
- Cells lining glands are undifferentiated with a scarcity of acid-producing cells.
- Reactive regional lymph nodes
- Edema and inflammatory cells in submucosa

TREATMENT

- Broad-spectrum safe anthelmintics are the primary means of treatment and control.
- Anthelmintic resistance by *Teladorsagia* is commonly seen in some geographic regions.
- Virtually all of the available anthelmintics are effective against adult and metabolically active larvae.
- Some benzimidazoles and all macrolides are effective against arrested larvae.
- Macrolides have a residual effect against incoming larvae that will kill them before they can establish. This residual period (several weeks) varies with the chemical and may be a powerful selection mechanism for resistance.
- Dose and move young, susceptible animals to a pasture with few parasite larvae in the summer in cool climates; summer dosing with a product effective against arrested larvae in the warm climates when the pasture larvae die out.
- Ruminal boluses containing anthelmintics may be used to clear pastures of infective larvae over periods of several months.
- Drug withdrawal times must be maintained.

Anthelmintic Resistance

- Treating to kill every worm will, if not 100% successful, select resistant worms. Those survivors will only have other survivors to mate with.
- Strategic deworming will select for anthelmintic-resistant worms but will also have a greater impact on total worm populations lowering numbers below the economic threshold for a longer time than will other approaches.
- Levamisole may appear to have resistant worms because it is only effective against adult worms. When the adults are removed, arrested larvae will rapidly mature, thereby causing clinical signs, and begin producing eggs. The drug may be effective but against the wrong stage of the life cycle.
- Resistance is usually seen in the geographic region where the ostertagids are the predominant worm and control programs have targeted them.
- Resistance must be evaluated at the farm level.
- Rotation of anthelmintics does not seem to slow the onset of resistance and may in fact result in resistance to all of the drugs in the rotation faster than if a product is used until it fails and another product in a different drug family is utilized.

Preventive Management

- Management systems that lower the exposure of hosts to parasites can be devised. These systems may not optimize the value of forages but they result in healthier livestock.
- Rapid pasture rotation systems, where pastures are vacated for as few as 30 days before returning animals, may be of value in warm humid climates during the hottest time of the year in high rainfall areas or on irrigated pastures.
- Rapid pasture rotation otherwise will insure that the worms are waiting for the hosts when they return to the pasture.
- Utilizing pastures that have been used for cropping, especially in the last half of the grazing season, is grazing parasite-free pastures and, by the following year, any larvae deposited on the cropland will not survive until the next grazing.
- Alternate or cografing with other species or classes of livestock may harvest larvae from the pasture. In general, the *Ostertagia* species in sheep and goats do not do well in cattle. Horses do not share *Ostertagia* and can be safely grazed in areas dangerous to ruminants.
- Older cattle may become infected but are highly resistant to effects of the worms and can be used to clear larvae from a

pasture.

- Providing sufficient protein is vital with ostertagiosis as that is what is being lost.
- During the periparturient period, increased protein, not energy, levels will lessen egg production by gastrointestinal nematodes.
- To be sure, you cannot feed animals through the disease, but it is vital in recovery especially for those whose immune response is compromised.
- Summer treat and move young animals to pastures with low numbers of parasitic larvae.

Natural Biological Control

- Pastures containing plants high in condensed tannins are safer grazing for hosts as the incoming larvae are adversely affected.
- The physical structure of some plants is also a challenge for larvae to ascend the vegetation.
- If animals browse, their chances of acquiring larvae diminish as the distance from the ground increases. Most infective larvae are found within 2 inches (50 mm) of the soil surface.
- Predaceous fungi have been evaluated as agents that kill larvae in pastures. One species, *Duddingtonia flagrans*, is able to traverse the digestive tract and is present in the fecal pat when the larvae hatch. Feeding spores or incorporating them in ruminal boluses has the capacity to lower pasture contamination.

Vaccination

- Vaccination is an approach deemed likely to be successful because animals naturally develop resistance to gastrointestinal nematodes.
- The requirement for multiple exposure and maturation of the host immune system appears to be important in natural immunity and also appears to be the case with whole-worm antigens, selected antigens, or irradiated larval vaccines.

Genetics

- The selection of individual animals with a level of resistance to the parasite or those that have the capacity to rebound from the effects of parasitism seems to be a logical approach. The offspring of resistant hosts are likely to be resistant also. Therefore, resistance to *Ostertagia* could be a selection criterion used in a flock or herd.
- The genetic aspect of resistance to gastrointestinal parasites is not well understood. It appears that multiple genes are involved in aspects of the protective response and that different genes may be more important at different times in the course of infection.
- Some breeds have more individual animals with sufficient factors, and they are more likely to survive exposure levels that would kill other animals.
- Even in resistant breeds, all animals are not equal, and factors such as lactation, age, or nutritional status may influence the course of disease.
- When animals are producing at their genetic maximum, they are at greater risk of parasitic disease because they are immunologically and nutritionally challenged.
- Other phenotypic characteristics such as production of milk, fiber, multiple births, and resistance to other agents may be at odds with resistance to helminths. Research does not indicate that the traits, which lead to increased production, are linked to those of increased susceptibility.
- To determine if genetic resistance is the answer to the problem of ostertagiosis, as currently appears to be the case, much more knowledge is needed.

Summary

- There is no overall approach that fits with the environment—and management practices—that will control ostertagiosis.
- Schemes that recognize that some animals are much more at risk than others and that strive to assure that the at-risk population is exposed to fewer worms or, if exposed, is treated differently may have a chance of success.
- Programs based on chemical control alone will likely fail unless the season of transmission is very short or new anthelmintics with completely different modes of action are discovered.
- Effective vaccines may be produced, but will not likely be practical in young animals at highest risk. However, they may lessen pasture contamination and subsequent exposure.

OTITIS MEDIA/INTERNA

BASICS

DEFINITION

Otitis is an infection of the middle and inner ear usually associated with respiratory infections caused by bacteria or *Mycoplasma* sp. These infections enter the ear either by ascending the eustachian tube or by hematogenous seeding.

PATHOPHYSIOLOGY SYSTEMS AFFECTED

CNS

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

- There is no apparent breed or sex predisposition. Incidence appears to be biphasic.
- Calves and lambs less than 1 month of age have a higher incidence, as do calves 6–9 months of age. The higher incidence in both age groups probably relates to an increased risk of respiratory disease caused by common management strategies.

SIGNS

- Affected calves typically have clinical signs suggestive of sepsis, scleral injection, and fever. Ataxia of varying degree is usually present. Severely affected animals, particularly neonates, may be moribund, complicating the diagnosis. In these animals, specific neurologic signs may be difficult to recognize.
- The most consistent and prominent clinical signs are neurologic and are usually referable to cranial nerve VII dysfunction. These include drooped or immobile ear, inability to close palpebrae, and a loss of facial sensation on the same side as the lesion.
- Cranial nerve VIII dysfunction also is common, resulting in head tilt and circling toward the lesion. Involvement of additional cranial nerves and cortical involvement are uncommon. Strabismus and nystagmus are often observed.
- Otoloscopic examination is difficult in calves and probably of less value than in companion animals. In some cases, purulent discharge from the ear canal is present.
- Affected calves often have concomitant bacterial or mycoplasmal respiratory disease, and thoracic auscultation may reveal crackles. Dyspnea and hyperpnea also may be present.
- In outbreaks associated with *Mycoplasma* sp. pneumonia, polyarthritis and conjunctivitis may be present in affected calves or their herdmates.

CAUSES

- Respiratory pathogens *Mannheimia hemolytica* and *Mycoplasma* sp. are the most common isolates from animals with acute disease.
- *Arcanobacter pyogenes* is frequently isolated from chronic lesions, but these isolates probably do not reflect etiology. Rather, they can reflect the normal progression of a chronic inflammatory process in a ruminant.
- A variety of ubiquitous environmental bacteria has been isolated from affected animals.

RISK FACTORS

- Preexisting respiratory disease is likely the most important risk factor. Among older calves, 6–9 months, strategies that increase the incidence of shipping fever will likely increase disease incidence.
- Inadequate vaccination against respiratory disease, mixing animals from multiple sources, and inadequate preconditioning programs should all be considered risk factors.

- In neonatal calves, group housing, inadequate passive transfer of colostral immunoglobulins and feeding raw milk, particularly waste milk on dairies with endemic *Mycoplasma* mastitis, are important additional risk factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- In older calves, common differential diagnoses include listeriosis, thromboembolic meningoencephalitis caused by *Haemophilus somnus* and brainstem abscesses.
- Otitis is usually differentiated from other differentials of asymmetrical brainstem disease because portions of the central nervous system exclusive of CN VII and VIII are rarely affected.
- In younger calves, the primary differential is bacteremia caused by coliform bacteria.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

IMAGING

Radiography may be used to identify lesions in the bulla; however, this procedure is not recommended. Most food-animal practitioners lack the resources to produce quality skull films and experience interpreting films. Furthermore, this procedure is probably not justifiable based on cost and benefits.

OTHER DIAGNOSTIC PROCEDURES

Ancillary Diagnostic Procedures

- Ancillary diagnostic procedures are rarely needed to establish a diagnosis in individual animals. Specific etiologic diagnosis occasionally may be warranted to permit specific targeted diagnostic procedures and herd intervention strategies.
- Diagnostic necropsy should be performed on dead or moribund animals, particularly when multiple animals are affected.
- Cultures of brain and lung tissue should be performed. When necropsy specimens are not available, specific efforts should be made to characterize the source and etiology of ongoing herd respiratory disease.
- Transtracheal wash or bronchoalveolar lavage cytology and culture may permit identification of the offending pathogens.
- *Mycoplasma* sp. are laborious and difficult to culture, and some laboratories will use PCR to identify *Mycoplasma* sp.
- Cerebrospinal fluid analysis may be helpful in differentiating causes of asymmetrical brainstem disease in feedlot cattle. Otitis will cause either a normal CSF composition or, alternatively, a CSF with increased concentrations of protein and neutrophils.
- Thromboembolic meningoencephalitis will typically result in a CSF that has a high cell count, a high protein concentration, a visible yellow color, and a preponderance of neutrophils.
- Listeriosis will generally cause milder increases in CSF cell counts and protein concentrations with the predominant cell type being mononuclear cells. Likewise, culture of the CSF may support specific differential diagnoses; however, negative CSF cultures are common.
- In those animals with polyarthritis in concert with middle ear infections, arthrocentesis with culture and cytology may be useful in determination of the specific etiology.
- Septicemia and TME tend to cause more dramatic changes in joint fluid composition and the predominant cell type is the neutrophil with both agents.

Herd Diagnostic Procedures

- In dairy herds with no previous history of *Mycoplasma* mastitis, the recognition of otitis should encourage practitioners to reevaluate the herd status with regard to *Mycoplasma* sp. mastitis, particularly if the herd has practiced feeding waste milk to calves.
- Bulk tank cultures performed on three sequential days are reasonable, low-cost strategies to screen herds for *Mycoplasma* sp. mastitis.
- When multiple cases of otitis are recognized in calves less than 1 month of age on a dairy, practitioners should establish the effectiveness of colostrum administration practices. Serum protein concentration should be determined on all calves less than 10 days of age. Calves with serum protein concentrations less than 5.2 g/dL should be classified as having inadequate passive transfer.
- If more than 20% of calves have less than adequate passive transfer status, immediately targeted intervention should be

undertaken to correct deficiencies.

TREATMENT

- Antimicrobial treatment is generally used in affected calves. If *M. hemolytica* or *P. multocida* has recently been isolated from clinically ill calves on the premises, the sensitivity pattern of these isolates may be used to guide therapeutic decisions. Pending return of laboratory results, the practitioner may assume that antibiotics deemed effective in the treatment of bovine pneumonia are appropriate for treatment of otitis.

- If the practitioner suspects or has demonstrated the involvement of *Mycoplasma* sp., antibiotic selection should be based upon potential efficacy against *Mycoplasma* sp.
- Reasonable choices would include tylosin, tilmicosin, and florfenicol. Antibiotic sensitivity testing of *Mycoplasma* sp. isolates is problematic and most laboratories lack the ability to provide these results. Furthermore, in vitro susceptibility may have little relationship with in vivo efficacy.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

- Correction of underlying conditions that predispose calves to respiratory disease should be a primary goal.
- In a feedlot setting adequate preconditioning programs including single sourcing of pen lots and immunization programs for respiratory viruses and *M. hemolytica* and bunk adjustment are important prevention factors.
- On dairy farms, efforts should focus on adequacy of passive transfer in calves, elimination of group housing for young calves, and avoiding the feeding of waste milk.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Among older calves, 6–9 months, strategies that increased the incidence of shipping fever will likely increase incidence. In neonatal calves, group housing, inadequate passive transfer of colostral immunoglobulins, and feeding raw milk, particularly waste milk on dairies with endemic *Mycoplasma* sp. mastitis, are important additional risk factors.
- When multiple cases of otitis are recognized in calves less than 1 month of age on a dairy, practitioners should establish the effectiveness of colostrum administration practices.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

All ruminant species are affected.

BIOSECURITY

Avoid buying stock from comingled groupings (i.e., sale barns). Quarantine of newly arriving stock can be helpful in the

diagnosis and prevention of the disease.

PRODUCTION MANAGEMENT

- Inadequate vaccination against respiratory disease, mixing animals from multiple sources, and inadequate preconditioning programs should all be considered risk factors.
- In a feedlot setting adequate preconditioning programs including single sourcing of pen lots and immunization programs for respiratory viruses and *M. hemolytica* and bunk adjustment are important prevention factors.
- On dairy farms, efforts should focus on adequacy of passive transfer in calves, elimination of group housing for young calves, and avoiding feeding of waste milk.

OVARIAN CYSTIC DEGENERATION

BASICS

DEFINITION

Ovarian cystic degeneration is a condition seen in dairy cattle that impairs reproductive performance. Although, the exact etiology is not known, the condition results from failure of dominant follicles to ovulate.

PATHOPHYSIOLOGY

- Disruption of the hypothalamic—pituitary—ovarian axis.
- Failure of a pulsatile or surge release of GnRH from the hypothalamus.

SYSTEMS AFFECTED

- Endocrine/metabolic
- Reproductive

GENETICS

A genetic predisposition has been suggested related to high milk production.

INCIDENCE/PREVALENCE

15%–20% in lactating dairy cows

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Bovine

Breed Predisposition

Reported more commonly in Holstein cattle, related to the predominance of this breed throughout the world and affinity for high milk production.

Mean Age and Range

There is no specific age distribution.

SIGNS GENERAL COMMENTS

The majority of cases are found during diagnosis of pregnancy or in cows presented because of anestrus.

HISTORICAL FINDINGS

Cows may have a history of anestrus.

PHYSICAL EXAMINATION FINDINGS

- Examination of the genital tract to assess ovarian status
- Diagnosis of ovarian cystic degeneration is based on the finding of a follicle > 15 mm in diameter, the absence of uterine tone, and a corpus luteum.

RISK FACTORS

Any stressful condition including:

- Calving difficulty
- High milk production
- Mastitis
- Uterine infection (metritis)
- Lameness
- Poor body condition

- Excessive use of estrogenic hormones

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Preovulatory follicle
- Cystic corpus luteum

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Milk or blood progesterone concentration may help distinguish a luteal from a follicular cyst.

IMAGING

Use of ultrasonography to evaluate ovarian structures

DIAGNOSTIC PROCEDURES

- Palpation of the uterus for tone
- Ultrasonography or palpation of the ovaries for presence of a folliclelike structure.
- History of anestrus

MEDICATIONS

DRUGS OF CHOICE

- Gonadotropin releasing hormone (GnRH)
- Prostaglandins F2 α
- Progesterone

CONTRAINDICATIONS

- Estrogenic compounds
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

It is imperative that the clinician differentiate the proestrus and estrus condition from a cystic ovary condition during examination of the genital tract.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

Progesterone

**FOLLOW-UP****PATIENT MONITORING**

After hormonal treatment, careful observation for estrus is imperative in order to inseminate the cow on a timely basis.

PREVENTION/AVOIDANCE

Reduce stressful condition on dairy farms.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Most cows affected with ovarian cystic degeneration respond favorably to treatment in terms of resumption of cyclicity.
- However, fertility is compromised in cows with this condition, who experience prolonged days open and calving interval.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

N/A

AGE-RELATED FACTORS

A higher incidence has been observed in multiparous cows.

ZOONOTIC POTENTIAL

OVARIAN HYPOPLASIA, BURSAL DISEASE, SALPINGITIS

BASICS

DEFINITION

- Ovarian hypoplasia: hypoplastic degeneration of the ovary
- Bursal disease: diseases associated with the ovarian bursa
- Salpingitis: inflammation of uterine tube or oviduct
- Factors that interfere with ova transport in the bursa (i.e., bursitis) and uterine tube (i.e., salpingitis; occlusions) or impair semen viability and transport (uterine adhesion, endometritis, obstruction of the uterotubal junction) may be the cause of repeat breeding animals.

PATHOPHYSIOLOGY

Ovarian Hypoplasia Occurs as an autosomal recessive trait. The condition can be partial or complete and unilateral or bilateral. The ovary undergoes incomplete development and a part or the whole affected ovary lacks a normal number of primordial follicles.

Bursal Disease

Causes include trauma; aggressive per-rectal palpation of the reproductive tract; developmental defects such as paraovarian cysts; and shallow, narrow, or closed bursa.

Salpingitis

Causes include ascending infection from the uterus, descending infection, anomalies such as segmental aplasia, and aggressive irrigation of infected uterus with inappropriate agents (including estrogen).

SYSTEMS AFFECTED

Reproductive

GENETICS

Ovarian hypoplasia: single recessive autosomal gene with incomplete penetration

INCIDENCE/PREVALENCE

- Slaughtered bovine reproductive tract examinations revealed the following incidence rates:
 - Ovarian hypoplasia—1.9% of slaughtered cattle of which 87.1% affected the left ovary, 4.3% affected the right ovary, and 9.6% affected both ovaries
 - Bursal disease—4.9% incidence rate in slaughter study
 - Salpingitis—10.5% incidence rate in study animals, of which only 4.8% were noted as detected by per-rectum palpation.
- In some instances, bursal disease and salpingitis occur together

GEOGRAPHIC DISTRIBUTION

N/A

Species

Bovine, ovine, caprine, camelids; potentially all ruminant species

Breed Predilections

- Ovarian hypoplasia: Swedish highland cattle, shorthorn cattle
- Salpingitis has been reported with a much higher incidence in water buffalo than in domestic cattle.

Mean Range and Range

None

Predominant Sex

Female

SIGNS GENERAL COMMENTS HISTORICAL FINDINGS

Infertility

PHYSICAL EXAMINATION FINDINGS

Ovarian Hypoplasia

The affected hypoplastic ovary is small, thin, narrow, and firm. It may be so small that it can difficult to locate by palpation alone. In severe cases, only a cordlike thickening can be found in the cranial border of the ovarian ligament. It may palpate as a pea or kidney-bean-like structure in partial hypoplasia or as a shrunken structure in total ovarian hypoplasia.

Bursal Disease

In cases of adhesion, the ovary is difficult to move. *Bursal cysts* develop from adhesions of the fimbria to the ovary and contain fluid from the tube that flows into the bursa causing distension.

Salpingitis

Tubo-ovarian cysts—in cases of salpingitis, clear fluid accumulates in the proximal portion to reflux into the bursa. The cranial portions of the uterine tube distend in a cystic manner.

CAUSES

Infectious

- Salpingitis and bursal disease: ascending infection from the uterus following abortion, retained placenta, septic metritis, and pyometra. A variety of infectious organisms including *Arcanobacterium pyogenes*, *Streptococci* spp., *Staphylococci* spp., *Campylobacter* spp., *Hemophilus somnus*, *Mycobacterium tuberculosis*
- *C. fetus* subsp. *venerealis*—is an obligate parasite of bovine genitalia. The organism localizes in the anterior vagina and cervix during the ovulatory phase but does not invade the uterus and oviducts until progesterone release. It then causes endometritis and salpingitis for several weeks to a few months during which the animal is infertile. Animals usually regain fertility within 5 months and the subsequent immunity lasts about a year.

Traumatic

Aggressive per-rectal palpation of reproductive tract

Degenerative and Anatomic

- Ovarian hypoplasia
- Partial hypoplasia and degenerative changes after BVD vaccination is reported.
- Salpingitis and bursal disease: anomalies such as segmental aplasia of the paramesonephric duct and paraovarian cyst

RISK FACTORS

- Ovarian hypoplasia: genetic and breed predisposition possible
- Salpingitis and bursal disease: genetic predisposition for segmental aplasia and paraovarian cyst, aggressive palpation, and intrauterine infusion of inappropriate agents

DIAGNOSIS

Repeat Breeding

- Anaplasmosis
- Bad artificial insemination technique
- Bluetongue
- Brucellosis
- Campylobacteriosis
- Endometritis
- Erroneous artificial insemination timing
- Erroneous heat detection
- Fescue toxicity
- Follicular cysts

- Heat stress
- Inadequate number of bulls
- Inadequate uterine involution
- Leptospirosis
- Malnutrition
- Oviduct bursal adhesions
- Pneumovagina
- Poor semen quality
- Selenium deficiency
- Trichomoniasis
- Urine pooling
- Uterine tumors
- Zearalenone toxicity

Anestrus

- Erroneous heat detection
- Freemartinism
- Heat stress
- Luteal cysts
- Malnutrition
- Nursing beef cows
- Poor footing
- Postpartum period
- Pregnancy
- Pyometra

Cyclic Irregularities

- Bovine viral diarrhea virus (BVDV)
- Campylobacteriosis
- Cystic ovaries
- Endometritis
- Heat stress
- Infectious bovine rhinotracheitis (IBR)
- Intrauterine therapy
- Leptospirosis
- Poor heat detection
- Trichomoniasis

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Culture and sensitivity may be helpful to rule out bacterial causes.

IMAGING

Ultrasonographic imaging of the reproductive tract may help to increase the diagnostic accuracy.

DIAGNOSTIC PROCEDURES

Per-rectal palpation and ultrasonographic imaging of the reproductive tract is mandatory. The use of a dye-test or embryo-flush technique to diagnose the distended tube or oviductal blockage can be helpful. It allows differentiation of a unilateral or bilateral condition.

PATHOLOGIC FINDINGS

Ovarian Hypoplasia

- Hypoplastic ovaries are small, thin, narrow, and firm; the ovary may be so small that it is difficult to locate.

- In severe cases, only a cordlike thickening of the cranial border of the ovarian ligament may be evident. It may palpate as a pea or kidney-bean-like structure in partial hypoplasia or as a shrunken structure in total ovarian hypoplasia.

Bursal Disease

Pathologic lesions may range from mild adhesions of a few fibrous threads between the bursa and the ovary to extensive ovaribursal lesions. The lesions include narrow, shallow, or closed bursa, roughness of the internal wall of the bursa, and cysts of the bursa.

Salpingitis

- Hydrosalpinx—secondary to segmental aplasia or uterine/oviductal blockage due to adhesions distally, proximally, or at both ends of oviduct
- Pyosalpinx—accumulation of pus in the oviduct following extensive uterine infection
- The oviduct usually distends to a diameter of 0.5–2.0 cm (depending on species) containing clear mucus or pus; it is elongated, coiled, and thin walled on palpation.

TREATMENT

PREGNANCY

In general, treatment of these conditions is not satisfactory. However, correct diagnosis, chronicity, and specific disease agent may determine treatment success and failure.

OVINE PROGRESSIVE PNEUMONIA

BASICS

DEFINITION

- Ovine progressive pneumonia (OPP) is a chronic disease of adult sheep and goats. The etiological agent is ovine lentivirus (OvLV) (also known as visna-maedi virus, ovine progressive pneumonia virus) and the clinical signs include progressive emaciation, dyspnea, and the development of opportunistic infections.
- Chronic active inflammation can occur as well in the lymph nodes, joints, mammary glands, and central nervous system.

PATHOPHYSIOLOGY

- OvLV is transmitted in utero and also by aerosol, contact, and ingestion of infected milk. Infection is then established in monocytes and macrophages and spreads to the lungs, lymph nodes, choroids plexus, bone marrow, mammary glands and kidneys. OvLV causes a persistent infection in the face of humoral and cellular immunity and results in the development of immune-mediated lesions in multiple organ systems.
- Sheep infected tend to be afebrile and maintain a normal appetite.

SYSTEMS AFFECTED

Respiratory

- The lungs are the most common target organ. Infection of the lungs causes a diffuse lymphoproliferative interstitial pneumonia with infiltration of lymphocytes, plasma cells, and macrophages into the interalveolar septae.
- Hyperplasia of the alveolar epithelium and terminal bronchial smooth muscle may also occur. On necropsy, the lungs are grossly enlarged and very heavy.
- Vertical rib impressions may be seen on the exterior lung surface.

Mammary

- *Mastitis*: Indurative mastitis (“hardbag”) is characterized by a large, hard udder with no abnormal secretions. The infection may be symmetrical or asymmetrical.
- In advanced cases, the udder is enlarged, teats are limp, and there is little milk in the teat cistern. The milk is normal in appearance.

Musculoskeletal

- *Arthritis*: The carpal joints are the most common joints infected and are obviously swollen. The swelling is bilateral.
- Lameness and emaciation are common sequelae.

Central Nervous System

- *Meningoencephalitis*: The initial signs of neurological involvement are ataxia, circling, stumbling, and unilateral proprioceptive deficits.
- Neurological signs can progress to rear limb paralysis and quadriplegia.

GENETICS

- Susceptibility to infection may vary due to breed.
- Rambouillet seem to be more resistant to infection, whereas Finnish Landrace and Texel are highly susceptible.

INCIDENCE/PREVALENCE

- Prevalence of infection varies between farms, breeds, and countries.
- Seroprevalence of OPP in ewes in the United States ranges from 1% to 70% and increases with age. Some flocks can approach 100% infectivity.
- Texas has an exceptionally low prevalence of infection (1%). Ewes culled in other states have seroprevalence rates of 30%–67%.
- The overall prevalence of the disease in the United States is not known.

GEOGRAPHIC DISTRIBUTION

- OPP occurs in all major sheep-producing countries with the exception of Australia, New Zealand, Iceland, and Finland.
- In the United States, the infection appears to be most common in the western states.

SIGNALMENT

Species

Ovine, rare in goats

Breed Predilection

- Texel and Finnish Landrace are the breeds that are most commonly affected.
- Rambouillet sheep appear to be most resistant to the infection.
- Highly susceptible breeds include Border Leicester, Finnsheep, Finn-crosses, Corriedales, Dorsets, and North Country Cheviots.
- The Ile de France has been shown to be resistant to infection.

Mean Age and Range

- OPP is rarely seen in animals less than 2 years of age and natural disease is usually observed in 2- to 3-year-old animals.
- Adults of any age, however, can be infected.

Predominant Sex

Both male and female animals can be infected.

SIGNS

- Emaciation and increasing respiratory distress are the most common signs.
- Animals maintain a normal appetite, are afebrile, rarely cough, and are not depressed.
- Indurative mastitis, arthritis, and meningoencephalitis may occur also.

DIAGNOSIS

- Diagnosis is difficult, as many sheep show no clinical signs of infection. Symptoms, when evident, may reflect many different diseases.
- Clinical signs are compared to necropsy findings as well as serologic tests.
- Characteristic lung lesions include oversized, heavy, grayish-blue discolored lungs. There often are lesions of active secondary bacterial pneumonia in the anteroventral areas of the lung.

DIFFERENTIAL DIAGNOSIS

- Adenovirus/adenomatosis
- Caseous lymphadenitis
- Chlamydia
- Chronic pulmonary adenomatosis
- Mycoplasma
- Nasal bot
- Nasal myosis
- Neoplasia
- Parainfluenza type 3
- Parasitic bronchitis
- Pasteurellosis
- Selenium toxicity
- Tuberculosis

CBC/BIOCHEMISTRY/URINALYSIS

Not diagnostic

OTHER LABORATORY TESTS

- The two most commonly used laboratory serologic methods are agar gel immunodiffusion test (AGID), and enzyme-

linked immunosorbent assay (ELISA) test.

- AGID is less sensitive than the ELISA, and is prone to false negative results. However, due to its ease of performance, it is generally the test of choice with most laboratories.
- The ELISA test is more sensitive than the AGID test because it can detect an infected animal 2 weeks postinfection.
- Detection of OPP virus can also be done through culture. This may require up to 12 weeks before results are available.

IMAGING

Not diagnostic

TREATMENT

- Treatment of OPP is not effective.
- Most sheep die due to secondary bacterial pneumonia. Antibiotics may be indicated to prolong the sheep's life a few weeks or months. However, humane euthanasia should be considered upon laboratory confirmation. Infected animals remaining in the flock can continue to infect.
- Control of the disease may include periodic flock testing, culling of positive animals, removing lambs from ewes at birth, feeding pasteurized colostrum/milk replacer, purchasing seronegative replacement stock and improved biosecurity measures.
- Two methods of control: test and remove infected individuals and isolate and artificially rear progeny.
- Using these methods, some producers have been successful in the eradication of OPP.
- The most important aspect of control is to ensure the purchase of replacement animals from flocks that test negative for OPP.
- Rams should also be tested and found negative prior to incorporation into the breeding flock.

MEDICATIONS

N/A

FOLLOW-UP

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY

- Since OPP is not treatable and is difficult to eradicate from flocks, lambs that are born to seropositive ewes should be removed from their dams before they nurse, raised in isolation, and fed bovine colostrum and milk replacer.
- An alternative to artificial rearing may be fostering lambs to seronegative ewes.

RUMINANT SPECIES AFFECTED

Sheep, goats

BIOSECURITY

- Control of infection requires testing of animals on an annual basis. This is a minimum time period with more frequent testing in known infected flocks.
- Seropositive animals and their progeny less than 1 year of age are culled.
- An alternative to culling is artificial rearing of lambs or fostering of lambs to seronegative ewes.
- Seronegative animals must remain isolated from infected sheep and any equipment that has been in contact with seropositive animals.
- Visitation to seronegative herds should be limited to personnel who have no contact with infected animals.
- New additions to the herd must be seronegative.

OVINE PULMONARY ADENOCARCINOMA

BASICS

OVERVIEW

- A type D retrovirus called ovine pulmonary adenomatosis retrovirus (OPARV) causes a contagious disease characterized by the formation of pulmonary tumors in sheep.
- The disease is known as ovine pulmonary adenomatosis (OPA); however, it is also referred to as ovine pulmonary carcinoma, jaagsiekte, and sheep pulmonary adenocarcinoma.

SYSTEMS AFFECTED

Pulmonary and lymphoid tissues

GENETICS

- There appears to be some breed predilection.
- There is some evidence that the presence of endogenous viral sequences in ovine genomes may increase the OPA susceptibility in sheep.

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

- OPA is found in sheep populations throughout the world; however, Australia and New Zealand are free from the disease.
- OPA is a significant problem in sheep-raising countries where it is enzootic. OPA is an economically important disease in Scotland, South Africa, and Peru; it is a minor disease in Canada and the United States.

SIGNALMENT

Species

- Sheep
- Goats: the disease has been experimentally transmitted from sheep to goats. Goats have a low susceptibility to infection. The disease appears to occur naturally at a low prevalence in goats.

Breed Predilections

Some breeds appear to be more susceptible to OPA.

Mean Age and Range

- The normal course of overt disease occurs in adult sheep between 3–4 years of age; lambs are more susceptible to infection if exposed prior to 10 weeks of age.
- The incubation period ranges from 3 weeks in lambs to several years in older animals.
- Average duration of clinical signs is 2 months (range of a few days to 6 months).
- Tumors were detected within 10–20 days following experimental inoculation of newborn lambs.
- The peak incidence of OPA after natural infection is thought to be 3 to 4 years.

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Marked dyspnea, sporadic coughing, and copious watery nasal exudate
- Weight loss and increased secretion from the lungs.

CAUSES AND RISK FACTORS

Lateral Transmission

Transmission occurs by aerosol and, experimentally, by contact. OPA is highly contagious and susceptibility is age

dependent.

Vertical Transmission Via Embryos and Semen

OPA has not been detected in embryos or uterine fluids. However, during the later stages of disease, exposure of embryos, ova, and semen to virus may be possible.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Epithelial hyperplasia, a sequela to chronic infections of sheep
- Maedi-visna
- Verminous pneumonia

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Detection of infected sheep prior to development of clinical disease may be extremely difficult.
- An ELISA using a recombinant protein component of the putative virus as the antigen has been utilized.
- Using PCR, major differences between endogenous and exogenous sequences have been identified in the env TM and 3 unique sequence (U3) regions. Using primers in the U3 region, OPARV DNA can be detected in tumors in lung tissue, lung secretions of infected sheep, lymphoid tissues, and peripheral blood mononuclear cells.
- Blocking enzyme-linked immunosorbent assay (B-ELISA) and an immunohistochemical technique, which specifically detects OPARV in transformed epithelial cells of the alveoli of OPA-affected sheep, have been developed.
- A competition radioimmunoassay (RIA) has also been used to detect OPARV antigen in tumor cell homogenates, lung fluid, and cell culture supernatant fluids in sheep.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Detection of subclinical infection is difficult. Field diagnosis relies on identifying overt animals within a flock with typical clinical and postmortem symptoms.
- The presence of the disease may not be recognized in flocks containing a predominance of animals less than 4 years of age.
- When purchasing new stock, the infection status of individual animals depends on the disease status of the originating flock.

PATHOLOGIC FINDINGS

Histopathology

- Pulmonary tissue pathological changes occur as multiple, well-circumscribed nodules of transformed secretory epithelial cells, multifocal nodules of neoplastic cuboidal epithelial cells in acinar or papillary patterns, peribronchiolar and interstitial lymphoid hyperplasia, type II pneumocytes and nonciliated bronchiolar (Clara) cells, and fibromuscular proliferation.
- Metastases are found most commonly in the bronchial or mediastinal lymph nodes in 10% to 50% of cases.
- Virus replicates actively in the transformed epithelial cells of the lung, and viral DNA and RNA have been detected in lymphoid tissues.
- Electron microscopically, cells have microvilli, tight junctions, and cytoplasmic lamellar bodies reflecting alveolar type II cells. Serum precipitating antibodies to ovine lentivirus are seen.
- Lung fluids have been shown to contain a 26-kd peptide that cross-reacts with a primate-derived type D retrovirus as detected by immunoblotting or interspecies competition radioimmunoassay.
- Recent studies document the presence of type D-related retrovirus antigen in ovine pulmonary carcinoma (OPC) in the United States.

TREATMENT

Not effective. Humane euthanasia is indicated where infection is suspected.

MEDICATIONS

FOLLOW-UP

PREVENTION/AVOIDANCE

Due to the long preclinical incubation period, OPA may disseminate widely in a flock prior to disease recognition.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Grave; 95% of all clinical cases die. Surviving animals spread the disease.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Adult sheep between 1 and 4 years of age with 4 years of age being the norm; lambs are more susceptible to infection if exposed prior to 10 weeks of age

Author: Scott R. R. Haskell

OXALATE TOXICITY

BASICS

OVERVIEW

- Due to ingestion of plants containing large amounts of soluble potassium and sodium oxalate salts that when absorbed form insoluble calcium and magnesium oxalate salts
- Associated with ingestion of a number of different plant species: the most commonly seen include *Halogeton glomeratus* (halogeton), *Sarcobatus vermiculatus* (greaseweed, black greaseweed), and *Oxalis* (shamrock, soursob, sorrel).
- Many other plants contain oxalates but are less commonly associated with toxicity including, but not limited to, *Amaranthus* (red-pig root), *Chenopodium* (lamb's quarters), *Rheum raphanistrum* (rhubarb), *Panicum* spp. (elephant grass), and *Alocasia* (elephant's ear).
- Concentration of the oxalates depends on season, stage of plant growth, weather, soil, geographic area, and variation between plant species.
- Ruminants are able to detoxify oxalates in the rumen by bacterial degradation and this accounts for decreased toxicity in ruminants compared to some other species.
- Factors affecting the toxicity following ingestion include the amount and rate of ingestion, previous adaptation to the plant in allowing increased bacterial degradation (can occur over 2–3 days), and volume of other nontoxic plants in rumen.
- Rapid absorption of oxalates and formation of insoluble calcium and magnesium salts yields a rapid decline in serum calcium and magnesium levels. Acutely, these animals may present with signs commonly seen with hypocalcemia due to impaired cellular membrane function.
- More chronic ingestion will yield formation of oxalate-containing urinary stones and oxalate nephrosis (due to precipitation of these salts in the tubules).
- These plants grow throughout continental North America, however, the ones most commonly associated with toxicity (halogeton and greaseweed) are found mainly in the western portions of the country.
- Toxicity most commonly occurs when unadapted sheep or cattle are placed in or move through areas containing large stands of these plants.
- Local oxalate crystal formation in the rumen wall may induce a rumenitis or more severe gastroenteritis.

SIGNALMENT

- All ruminant species and swine can be affected, but the disease is seen more commonly in sheep.
- Acute exposure to the plant in unadapted animals is important in toxicity.

SIGNS

- Acute toxicity present with signs of hypocalcemia.
- Signs occur within several hours and death can occur within 12 hours.
- First signs may include dullness, anorexia, belligerence (mainly cattle), stiffness, weakness, muscle tremors, tetany, and recumbency. As disease progresses without treatment, coma and death may occur.
- Rumenitis, rumen stasis, and gastroenteritis
- If animal lives through acute stages, then azotemia and kidney failure ensue.
- Azotemia may be associated with increased depression, anorexia, and death.

CAUSES AND RISK FACTORS

- Ingestion of plants containing high levels of soluble oxalate salts
- Most commonly halogeton or greaseweed
- Ingestion of large amounts rapidly is a risk factor.
- Increased rumen fill by nontoxic forage is protective.

- Slow adaptation to oxalate plants over a period of 4 days can increase the rumen's ability to degrade the oxalates by up to 30%.
- Diets high in calcium may be protective due to formation of insoluble calcium oxalate salts in the GI tract.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypocalcemia of other causes, including lactational hypocalcemia (cattle) and gestational hypocalcemia (sheep and goats)
- Hypomagnesemia of other causes including grass tetany, lactation tetany, wheat pasture tetany, transport tetany, and grass staggers
- Other causes of acute renal failure—ischemia, heavy metal toxicosis (arsenic, mercury, lead), drug-related nephropathies, *Quercus* (oak toxicity), pigment nephropathies (hemoglobin, myoglobin), and monensin toxicity
- Other urinary tract disease—pyelonephritis, urolithiasis (struvite and silicates, calcium carbonate), and amyloidosis
- History of exposure to oxalate-containing plants is helpful in differentiating oxalate toxicity from other processes.

CBC/BIOCHEMISTRY/URINALYSIS

- Oxalate crystals in urine (may not be present in acute cases)
- With chronic toxicity, an azotemia would be consistent with but not diagnostic of oxalate toxicity.

OTHER LABORATORY TESTS

Quantification of oxalate levels in suspect forage

IMAGING

Transabdominal or transrectal ultrasound of the kidneys may demonstrate perirenal edema (especially if pigweed is the plant involved) or cortical hyperechogenicity due to deposition of crystals in tissue.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Depends on the severity, chronicity, and plant of oxalate origin
- *Amaranthus* spp. (pigweed) often have perirenal edema in pig and cattle.
- Acute cases may have enlarged edematous, red kidneys, while more chronic cases may have smaller kidneys with histopathologic evidence of renal tubular nephrosis and oxalate crystal formation.
- Rumen wall may be hemorrhagic due to oxalates in the wall.
- Histopathology may demonstrate oxalate crystals in rumen wall.

TREATMENT

- Evaluate rest of the herd for early evidence of disease.
- Consider relocating rest of herd to a new area without plants or try to slowly introduce oxalate-containing forage and maintain intake with additional nontoxic forage to dilute the oxalates.
- Adaptation to oxalate forage should be done by cautiously allowing animals to graze for increasing periods of time over a minimum of 4 days.
- Add supplemental dicalcium phosphate to the diet to bind oxalates in the GI in the form of dicalcium phosphate-containing salts of alfalfa pellets.
- Hospitalization and fluid therapy to actively diurese the patient may slow down renal crystaluria and subsequent nephrosis.

MEDICATIONS

DRUGS OF CHOICE

- Hypocalcemic or hypomagnesimic patients should receive a slow IV infusion of 23% calcium gluconate or a commercially available mixture of calcium, magnesium, and glucose.
- IV fluids for diuresis is indicated.

CONTRAINDICATIONS

- Infusion of IV calcium should be done slowly and the heart rate and rhythm monitored. Calcium infusion should be discontinued if any abnormalities are observed.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

- Cases with renal involvement should have repeated serum chemistries and urinalysis to monitor renal function, evaluate efficacy of diuresis, and determine when fluids can be safely discontinued.
- Electrolytes, PCV, acid-base status, and albumin should be monitored in cases that survive severe renal compromise, as alterations in these values may continue after treatment.

PREVENTION/AVOIDANCE

- If possible, avoid grazing oxalate-containing forages.
- Cautiously and slowly introduce oxalate forages over a period of 4 or more days.
- Increase calcium diphosphate in the diet (this may have an effect on DCAD balance and induce other metabolic syndromes if done long term).

POSSIBLE COMPLICATIONS

Chronic renal failure

EXPECTED COURSE AND PROGNOSIS

- Severely affected animals often succumb to renal failure if they survive the acute disease process.
- Early treatment of less-severely affected cases may be successful.
- Aggressive fluid therapy and diuresis may improve the prognosis in animals with renal involvement.

PAPILLOMATOSIS

BASICS

DEFINITION

- Papillomatosis occurs when ruminants are infected with one of several distinct papillomaviruses.
- Infection with a bovine papilloma virus can result in the formation of fibropapillomas or epithelial papillomas.

PATHOPHYSIOLOGY

- Six bovine papillomaviruses have been identified, with distinct tissue tropisms.
- Subgroup A contains BPV-1, -2, and -5 and causes fibropapillomas of the skin.
- Subgroup B contains BPV-3, -4, and -6, viruses that induce epithelial papillomas.
- Most papillomas spontaneously regress.
- With appropriate cofactors, progression to SCC or malignant bladder cancer may occur.

SYSTEMS AFFECTED

- Skin
- Gastrointestinal
- Urologic
- Reproductive

GENETICS

N/A

INCIDENCE/PREVALENCE

- PPD is more common in dairy cattle than beef cattle.
- At culling, 26% of dairy cattle demonstrated PPD compared with 4% of beef cattle.
- Cutaneous papillomatosis is a common disease in cattle.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

- Most cattle are infected under 18 months of age except for cattle infected with BPV-3.
- BPV-3 can infect cattle of any age.
- There is no reported gender or breed predilection in cattle.
- Saanen goats are more commonly infected than other goats.
- PPD is more common among dairy cattle than beef cattle.

SIGNS

- Lesions typically appear 1–4 months after infection.
- Typically, these are hairless tumors of the skin (head, neck, dewlap) and udder.
 - Often gray in color, firm with a dry, horny surface
 - Vary widely in size from 1 mm to several cms in diameter
 - May be wide based, cauliflowerlike in appearance, or pedunculated with a narrow base.
 - The number of lesions can vary from one to hundreds.
- Atypical warts are nonpedunculated, flat, circular masses, with delicate, frondlike protuberances. They may have hair growing through them.
- Can also involve the genital mucosa, alimentary tract, or bladder.
- Papillomas involving the cornea and interdigital space may also be viral in origin.

- Interdigital papillomatosis causes marked lameness with accompanying weight loss and decreased milk production.
- Papillomatosis of the alimentary tract can cause problems with breathing, eating, bloating, rumen atony, and weight loss.
- Many papillomas regress spontaneously.
- Teat papillomas may regress during the nonlactating period, and then recur at the next lactation.

CAUSES

- BPV-1 causes teat frond and penile fibropapillomas.
- BPV-2 infects the skin of the head and neck most commonly, but may involve contiguous skin as well.
- BPV-3 infects epithelial cells and is the cause of “atypical warts.”
- BPV-4 typically causes papillomas in the alimentary tract and bladder.
- BPV-5 is the causative agent of the “rice-grain papillomas” of the teat and udder.
- BPV-6 has been isolated from teat frond papillomas.
- Immunity to one BPV does not protect against other types.
- PPD is thought to have a bacterial component to the development of this lesion.

RISK FACTORS

- Diffuse alimentary papillomatosis typically occurs in immunosuppressed animals, such as those ingesting bracken fern.
- Animals with inherent deficiencies in cell-mediated immunity may also be susceptible to widespread alimentary papillomatosis.
- Infection from one animal to another can occur through the presence of sharp or abrasive elements on the farm, or through the use of shared halters, brushes, etc.
- Exposure to cofactors, such as significant skin trauma (branding), ingestion of carcinogens/mutagens (such as bracken fern), or exposure to sunlight may result in malignant transformation to SCC and bladder cancer.
- Papillomatous digital dermatitis (or interdigital papillomatosis) is more commonly seen in first parity cows, in cows loose-housed, and in single-use cows (e.g., dairy).
- In herd situations, vaccination of uninfected cattle with an autogenous vaccine derived from the premises may be protective against infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Squamous cell carcinoma
- Dermatophilosis

CBC/CHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Diagnosis is typically based on examination of the lesion.
- Histopathology can be used to differentiate between papillomas and SCC.

PATHOLOGIC FINDINGS

- Fibropapillomas have a distinct fibromatous portion as well as a hyperplastic epithelial component.
- Purely epithelial papillomas demonstrate hyperplastic epidermis with extensive keratinization.
- In regressing lesions, the fibroblasts may appear to have shrunken nuclei and an indistinct cytoplasm, as well as fewer mitotic figures in both the fibromatous and epithelial components.

TREATMENT

APPROPRIATE HEALTH CARE

- Many papillomas will regress spontaneously within 12 months.
- Vaccination with an autogenous or commercial vaccine may help prevent infection in other animals in the herd.
- Minor surgical procedures (such as dehorning) have been implicated in the spread of the virus.
- Although used in practice, there is little evidence that vaccination with an autogenous vaccine speeds regression of pre-existing papillomas, and may increase the duration of the disease.
- Partial excision combined with autogenous vaccine may be beneficial in calves with small papillomas.
- PPD is best treated with complete surgical removal of the involved tissue.
- Some cattle with PPD will respond to treatment with antibiotics.

ACTIVITY

N/A

DIET

No changes needed

CLIENT EDUCATION

- Depending upon site, lesions may regress and recur (teat papillomas) or regress and never recur.
- Avoidance of sharp or abrasive elements on farms with ongoing infections, as well as avoidance of shared halters, brushes, etc., will help prevent cow-to-cow transmission.

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUGS OF CHOICE

- Topical oxytetracycline has shown some benefit in the treatment of PPD of the dewclaw or on the heels, but is less effective on lesions involving the interdigital cleft.
- Drug withdrawal periods must be maintained.

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

Vaccination of uninfected cattle with an autogenous or commercial vaccination may prevent infection with BPV-1 or BPV-2.

POSSIBLE COMPLICATIONS

Infection with BPV can act as a cofactor in the neoplastic transformation of epithelial cells and the development of SCC and bladder tumors.

EXPECTED COURSE AND PROGNOSIS

- Most papillomas will regress spontaneously within 12 months.
- Animals with severe, generalized fibropapillomatosis have a poor prognosis (> 20% of the body affected).
- Atypical warts do not regress.
- PPD typically requires complete surgical excision for long-term control.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Immunosuppression or defects in T-cell-mediated immunity play a role in the development of diffuse alimentary papillomatosis and generalized cutaneous fibropapillomatosis.

AGE-RELATED FACTORS

Most cattle are infected under 2 years of age.

ZOONOTIC POTENTIAL

None known

PREGNANCY

Lactation cycle can influence regression and recurrence of teat papillomas.

RUMINANT SPECIES AFFECTED

- Cattle are frequently affected.
- Sheep develop lesions similar to bovine papillomas in lightly haired regions such as the ear, muzzle, eye, and vulva.
- There has been successful transmission of papillomas from affected sheep to unaffected sheep using cell- and bacteria-free inocula.
- These lesions in sheep may undergo malignant transformation to SCC.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Vaccination of uninfected cattle with an autogenous or commercial vaccination against the L1 and L2 viral capsid proteins from BPV-2 and BPV-4 may prevent infection.
- Avoidance of sharp or abrasive elements on farms with ongoing infections, as well as avoidance of shared halters, brushes, etc., will help prevent cow-to-cow transmission.

PARAINFLUENZA-3 (PI-3)

BASICS

OVERVIEW

- Parainfluenza-3 (PI-3) is an RNA virus in the paramyxovirus family.
- Worldwide distribution
- Infection is very common.

SIGNALMENT

Infection seen most commonly in young animals (2 months to 12 months of age)

SIGNS

- Most infections are subclinical with no detectable signs.
- Coughing, nasal discharge, slight fever, followed by recovery in a few days

CAUSES AND RISK FACTORS

- Aerosol and direct contact are the means of viral spread.
- Close contact, inadequate ventilation, and stress increase likelihood of spread.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other mild, uncomplicated viral respiratory infections:

- IBR
- BRSV
- BVDV
- Other viruses (bovine respiratory coronavirus, bovine adenovirus, etc.)

CBC/BIOCHEMISTRY/URINALYSIS

No specific changes

OTHER LABORATORY TESTS

- Virus isolation—lung tissue, transtracheal wash, nasal or laryngeal swab
- Serology
- Positive results on either test may not indicate the primary cause of disease since infection with PI-3 is very widespread.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Gross lesions—PI-3 lesions are rarely seen on postmortem examination due to the high rate of recovery in uncomplicated cases. Mild inflammation and hyperemia of the mucosa of nasal passages and upper airways, enlargement of the respiratory lymph nodes, and mild pneumonitis may be seen.
- Histopathologic lesions—acute necrotizing bronchitis and bronchiolitis may be seen. Alveoli contain leukocytes, fibrin, and fluid. Cytoplasmic viral inclusion bodies may be seen.

TREATMENT

- Clinically affected animals should have constant access to fresh, palatable feedstuffs and clean water.
- Animals should be cared for in a low-stress, low-competition environment.

MEDICATIONS

DRUGS OF CHOICE

- No specific treatment
- Treat as undifferentiated bovine respiratory disease.

CONTRAINDICATIONS

None

POSSIBLE INTERACTIONS

None

FOLLOW-UP

PATIENT MONITORING

Worsening of clinical signs may indicate secondary bacterial pneumonia (BRDC).

PREVENTION/AVOIDANCE

- Vaccination
 - Both killed and modified-live parenteral vaccines are commercially available. Typically, PI-3 is included with other viral antigens in a multivalent vaccine.
 - A vaccine for intranasal administration containing temperature-sensitive, modified-live strains of PI-3 and IBR is commercially available.
 - Currently, there are no data from field trials supporting an advantage for PI-3 vaccination.
 - Nonspecific BRDC prevention measures

POSSIBLE COMPLICATIONS

PI-3 infection can predispose to secondary bacterial pneumonia (BRDC).

EXPECTED COURSE AND PROGNOSIS

Spontaneous recovery following mild course of illness is likely in uncomplicated viral infection.

MISCELLANEOUS

ASSOCIATED CONDITIONS

BRDC may follow PI-3 infection.

AGE-RELATED FACTORS

Infection is more common in young (2–12 months) animals.

ZOONOTIC POTENTIAL

None

PREGNANCY

Not associated with abortion or teratogenesis

RUMINANT SPECIES AFFECTED

Bovine, ovine, caprine

BIOSECURITY

None. Virus is ubiquitous in most cattle populations.

PRODUCTION MANAGEMENT

Uncomplicated PI-3 infection has minimal to no production importance. However, BRDC is the most economically significant disease in the beef industry.

PARASITE CONTROL ON DAIRIES

BASICS

DEFINITION

Parasite control programs on dairies are aimed at decreasing clinical and subclinical disease. This is achieved by decreasing the exposure to parasites and by strategic treatment of exposed or infested animals.

OVERVIEW

- Because most internal parasites of cattle require pasture or grasslands in their life cycles, cattle in dry-lot or confinement dairies are at small or no risk for disease from the nematode parasites.
- Dairy cattle or replacements that are pastured are at risk, and parasite control programs should be considered.
- Young cattle are at risk of coccidiosis from oral-fecal contamination when they are raised in groups. Young cattle and cattle in their first year on pasture require parasite control.
- Adult cattle tend to develop immunity to nematodes and coccidia with exposure and may not benefit from anthelmintic treatment. Cattle on highly infected pastures will benefit from treatment.

SYSTEMS AFFECTED

Gastrointestinal, immune, and respiratory

GENETICS

N/A

INCIDENCE/PREVALENCE

- Nematode parasitism is common whenever cattle are pastured. Confined cattle are not at risk of nematode parasitism owing to the life cycle of the parasites.
- The reservoirs for coccidiosis and cryptosporidiosis are primarily the calves in a population, although older cattle can be a source of *Coccidia* and *Cryptosporidium parvum* on a farm.
- *Neospora* is very common in dairy cattle in North America.

GEOGRAPHIC DISTRIBUTION

Worldwide

Epidemiology

- Cattle exposed to the infectious portion of nematode and liver fluke (pasture) of parasites are at risk.
- Young cattle are at risk for coccidiosis and cryptosporidiosis. Cattle develop immunity to both with exposure history.
- Neosporosis has been associated with canine species interactions (the definitive host) but actual initial infection in a cow or herd has not been documented. Once infected, cattle remain infected and tachyzoites cross the placenta and infect the fetus (vertical transmission).
- Coccidia and cryptosporidia require fecal-oral contamination for transmission, and sanitation is the primary management factor associated with disease from either organism. The reservoir for all of the parasites is older cattle.

SIGNALMENT

Species Affected

Bovine

Breed Predilections

N/A

Mean Age and Range

- Because cattle develop immunity to most parasites with exposure, younger cattle are most susceptible. Exceptions are liver flukes and *Neospora*.
- Mean age and range of clinical disease and infection for cryptosporidia is from 5 days to 3 months and from 21 days to

12 months for coccidiosis.

Predominant Sex

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

N/A

CBC/BIOCHEMISTRY/URINALYSIS

Parasitized cattle may have eosinophilia.

OTHER LABORATORY TESTS

- Fecal egg counts can be used to detect nematode parasitism, but the technique is not specific or sensitive for disease.
- Fecal sedimentation can diagnose liver flukes.
- Coccidia can be visualized on fecal flotation.
- Cryptosporidia can be diagnosed by using acid-fast stains on fecal smears.
- Serology can be used to diagnose cows infected with *Neospora*, but confirmation of abortion requires either necropsy of the fetus with detection of *Neospora* lesions associated with mortality or case-control studies using serology.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Necropsy exam with histochemistry is the most sensitive and specific way to diagnose parasitism in cattle.

TREATMENT

CLIENT EDUCATION

Clients should be advised that they must adhere to the parasite control program in order to achieve decreased parasite loads in the pastures.

MEDICATIONS

PRECAUTIONS

Anthelmintic drugs should be used only as labeled and the labeled withholding periods must be followed for each drug.

FOLLOW-UP

PATIENT MONITORING

Fecal egg counts can be used to monitor parasitism in cattle and the effectiveness of the program.

PREVENTION/AVOIDANCE

Maintain contagious disease control procedures in calves; do not overcrowd pastures.

POSSIBLE COMPLICATIONS

Animals should not be treated with avermectin drugs when the larval migration of *Hypoderma* is near CNS tissue.

MISCELLANEOUS

Parasites of Dairy Cattle

- The nematode that causes the greatest pathology and economic loss in cattle is *Ostertagia*.
- Other nematodes that infect cattle include: *Cooperia*, *Haemonchus*, *Trichostrongylus*, and *Nematodirus*. Lungworms, *Dictyocaulus*, also parasitize cattle.
- Protozoal parasitism in dairy cattle includes coccidiosis from *Isospora* and *Eimeria*, cryptosporidiosis from *C. parvum* and sometimes *C. muris*, and neosporosis from *Neospora caninum*.
- Nematode and lungworm parasite control programs based on avermectins or moxidectin should be used when dairy cattle are grazing.
- A common program is to treat cattle twice early in the grazing season, approximately 6 to 8 weeks apart. Another approach is to treat at the beginning of the pasture season and again at the end. Heavily infested pastures may require treating every 3 weeks with nonivermectin drugs or every 5 weeks with ivermectin. Fecal egg counts can be used to monitor the program and estimate the level of infestation of the pasture.
- Coccidiosis is mainly a disease of young confined animals. The primary prevention measure is sanitation in the calf housing, especially the feed area, because the route of transmission is fecal-oral. Calves raised in individual hutches should not be exposed to coccidia and therefore do not need prophylaxis. The coccidiostats lasalocid or monensin (1 mg/kg bwt continuously) in the feed in group housing prevents clinical disease. Calves develop immunity as they age, and adult cattle do not require coccidiostats. Calves with clinical coccidiosis should be treated with sulfamethazine (110 mg/kg bwt for 5 days).
- Cryptosporidia have a short prepatent period (5 days) and a low infectious dose and often infect young calves. There are no documented effective drugs available for prevention or treatment of cryptosporidia in cattle in the United States. Contagious disease control procedures such as improved sanitation and strict adherence to working only from young to old animals during feeding and treatment should be employed in the calf housing system.
- *Neospora* infection in dairy cattle is common and the main route of transmission is vertical from dam to calf. Cattle are a secondary host for the parasite and are infected for life. *Neospora* can be a cause of second trimester abortions. A vaccine is licensed in the United States to control abortions from *Neospora*.

PREVENTION

N/A

ASSOCIATED CONDITIONS

Anemia, weakness, decreased growth, diarrhea, decreased immune response

PARASITE CONTROL PROGRAMS—SMALL RUMINANTS

BASICS

OVERVIEW

- In most of North America, *Haemonchus contortus* is the most important nematode pathogen of small ruminants and *Trichostrongylus colubriformis* is the next most common and important. *Teladorsagia (Ostertagia) circumcincta* is an important pathogen in cool climates but is rarely seen in the southern United States. Other species such as *Trichostrongylus axei*, *Cooperia* spp., *Oesophagostomum*, *Trichuris ovis*, *Strongyloides papillosus*, and *Bunostomum* are less common and by themselves usually do not cause important levels of disease.
- The number of FDA-approved drugs available for use in the treatment of parasites in small ruminants is severely limited.
- Extralabel anthelmintic drug use is a standard practice in small ruminants, but this is an exclusive privilege of the veterinary profession and is only permitted when a bona fide veterinarian-client-patient relationship exists and an appropriate medical diagnosis has been made.
- Anthelmintic resistance is extremely prevalent in gastrointestinal nematodes (GIN) of small ruminants and camelids and must be calculated into all treatment decisions.
- Because multiple-drug-resistant parasites are becoming quite prevalent, now and in the future, anthelmintics must be thought of as extremely valuable and limited resources that must be preserved.
- Recipe-based anthelmintic treatment programs can no longer be recommended. An integrated scheme using “smart drenching” principles and a medically based selective approach to treatment should be implemented wherever possible.
- Goats metabolize drugs more rapidly than do other ruminants and therefore should receive a dose one and a half to two times greater than is required for sheep and cattle.

SYSTEMS AFFECTED

Predominantly gastrointestinal

SIGNALMENT

- Ruminants and pseudoruminants of all ages
- Young recently weaned and periparturient animals are at the greatest risk for severe disease.

SIGNS

Haemonchus contortus

Anemia, hypoproteinemia, weakness, weight loss, poor hair coat, death

Other GI Nematodes

Diarrhea, weight loss, anorexia, poor hair coat, and to a much lesser extent than in *H. contortus*, anemia and hypoproteinemia

CAUSES AND RISK FACTORS

- Poor nutrition
- Overstocking of pastures
- Young, recently weaned animals are highly susceptible to infection.
- Periparturient ewes/does from approximately 2 weeks before to 8 weeks after parturition have a clinically significant suppression in immunity of GI nematodes.
- Drug-resistant parasites

PRODUCTION MANAGEMENT

Smart Drenching

Smart drenching is an approach whereby we use the current state of knowledge regarding host physiology, anthelmintic pharmacokinetics, parasite biology, dynamics of the genetic selection process for resistance, and the resistance status of worms on the farm to develop strategies that maximize the effectiveness of treatments while also decreasing the selection of drug resistance. A smart drenching approach requires that a medically-based program be used for parasite control, rather than adherence to some calendar-based recipe. The following are the components to a smart drenching program:

FAMACHA—Selective Rather Than Whole-Herd Treatment

- This is the newest approach to smart drenching and is probably the most important component of a program designed to delay the development of resistance.
- In this method, the ocular mucous membranes of sheep and goats are classified into five categories through color comparison of sheep conjunctivae. Using a laminated color chart illustrating the different classifications, FAMACHA enables identification of individual animals in need of anthelmintic treatment and provides a means to implement a selective treatment program.
- FAMACHA can be used only where *H. contortus* is the primary parasite.

Know the Resistance Status of the Worms Infecting the Herd

- With the prevalence of resistance so high, it is critical that anthelmintic efficacy be determined on each farm and be monitored every 2 to 3 years.
- There are two methods for determining resistance on a farm: (1) perform an on-farm fecal egg count (FEC) reduction test; (2) send in a fecal sample to a lab offering the DrenchRite larval development assay.

Keep Resistant Worms Off the Farm

- Anthelmintic-resistant worms can come from only two sources: either they are home-grown by selection with drug treatment or they are purchased.
- All new additions to the herd or flock should be quarantined in a dry lot (without any grass) or on concrete and aggressively dewormed upon arrival.
- Recommended protocol: withhold feed for 24 hours (free choice water), and then deworm sequentially with moxidectin, levamisole, and albendazole at recommended individual-drug dosage. After 14 days, a FEC should be performed and the animal should be allowed to enter the herd only if the fecal test is negative.

Administer the Proper Dose

- Underdosing exposes worms to sublethal concentrations of drug, which increases the selection for resistance, and several studies have demonstrated that sheep/goat producers often underestimate the weight of their animals.
- Animals should be weighed individually or dosed according to the heaviest animals in the group (except when treating with levamisole in goats where overdosing can be risky).
- Check accuracy of dosing equipment on a regular basis.

Utilize Host Physiology to Maximize Drug Availability and Efficacy

- All oral anthelmintics should be delivered into the rumen. This is accomplished by delivering drugs over the back of the tongue using a properly designed drenching apparatus. Presenting a drench to the buccal cavity, rather than into the pharynx/esophagus, can stimulate closure of the esophageal groove with significant drench bypassing the rumen.
- Once in the rumen, the duration of drug availability as it is absorbed from the rumen and flows to more distal sites of absorption is largely dependent on the flow-rate of the digesta. Restricting feed intake for 24 hours prior to treatment decreases digesta transit flow rate, thereby increasing drug availability and efficacy. This recommendation is most useful for BZ and AM drugs. It is not useful for levamisole.
- Similar increases in efficacy can be achieved by repeating the dose in 12 hours. For levamisole, treatment should be repeated after 24 hours.

- Pour-on formulations designed for cattle are poorly absorbed in small ruminants. If used, these products should be administered only orally.

Drug Selection and Rotation

- Two different anthelmintics (from different drug classes) given together will produce a synergistic effect, which may significantly increase the efficacy of treatment compared to the individual drugs. This synergistic effect is most pronounced when the level of resistance is low, but once high-level resistance to both drugs is present, the synergistic effect will be lost.
- Rotation of anthelmintics is an overblown concept that gives farmers and veterinarians a false sense that they are actually doing something worthwhile in terms of resistance prevention. Rotation actually does very little to prevent the development of anthelmintic resistance, and is not a replacement for proper resistance-prevention measures.
- Instead of a calendar-based rotation, drug choice should be made after considering many factors, the most important of which are the number of drugs that remain effective on that farm (and level of effectiveness) and the degree of parasite-induced illness in the animals being treated.

Reduce the Frequency of Treatment Through the Use of Sound Pasture Management

- Good pasture management can significantly reduce the impact of parasitism and the dependence on dewormers.
- History has taught us that anthelmintics alone will not successfully control parasites and a more sustainable approach to small ruminant parasite control and husbandry is required.
- Managing pastures so that safe grazing areas (low larval contamination) are available will permit movement of animals to a safe area, reducing the number of treatments that are needed.
- To prevent the rapid development of drug resistance, it is important that animals not be treated immediately before a move to safe pasture unless a significant proportion of the animals is left untreated.
- Few parasites are acquired when animals browse forage high off of the ground, therefore browse areas should be utilized as much as possible.
- Reducing stocking rates will greatly decrease the number of parasites that sheep and goats are exposed to and also will improve the quality and quantity of forage available to the animals. Overstocking can often make control of *H. contortus* nearly impossible.

Albendazole	BZ	Yes	No	Sheep: 7.5 Goats: 15–20	Paste Suspension	High	Sheep: 7 days Goats: ND	NE
<i>Remarks: Do not use within 30 days of conception.</i>								

^aIn the southern United States. Prevalence of resistance has not been established elsewhere.

^bApproved in big-horned sheep and wildlife.

^cLabel dose is 5.0 mg/kg but 10 mg/kg is recommended.

^dListed WDTs are for the 5 mg/kg dose. If used at the 10 mg/kg level, these WDTs should be extended.

PARASITIC PNEUMONIA

BASICS

DEFINITION

Alveolar and interstitial pneumonia in ruminants can be caused by the lungworm *Dictyocaulus viviparus* and aberrant migration of *Ascaris suum* larvae in cattle, and the lungworms *Dictyocaulus filaria*, *Protostrongylus rufescens*, and *Muellerius capillaris* in sheep and goats.

PATHOPHYSIOLOGY

- Generally, lungworms have a prepatent phase when larvae are migrating and adults are not present in large airways, and a patent phase when adults are present in large airways. *D. viviparus* and *D. filaria* have direct life cycles.
- Adults live in the trachea and bronchi, lay eggs, hatch quickly. First larval stage L1 are coughed up, swallowed, passed in feces, then develop in environment. Third larval stage L3 migrate onto grass and are ingested, penetrate intestine, and are taken by lymphatic drainage to mesenteric lymph nodes. Fourth larval stage L4 travel through blood and lymphatics to lungs, lodge in pulmonary capillaries of caudoventral lung lobes, enter alveoli, and molt to adults in bronchioles.
- *P. rufescens* and *M. capillaris* have indirect life cycles.
- Adults live in trachea and bronchi, lay eggs, hatch quickly. L1 are coughed up, swallowed, passed in feces. They enter snail or slug intermediate host, develop to L3. Intermediate host and L3 migrate onto grass and are ingested, penetrate intestine, and are taken by lymphatic drainage to mesenteric lymph nodes. L4 travel through blood and lymphatics to lungs, lodge in pulmonary capillaries of caudoventral lung lobes, enter alveoli, and molt to adults in bronchioles.
- *A. suum* can infect cattle exposed to large amounts of eggs in pens heavily contaminated by swine. Cattle are typically affected about 10 days after exposure, with signs due to allergic reaction to the larvae migrating through the lungs. Larvae in the alveoli initiate allergic reaction, with eosinophilic exudate being produced, causing coughing and tachypnea. More larvae tend to be aspirated into the caudoventral lung lobes, with consolidation developing there and in the interstitium as larvae migrate.
- Adult worms in the trachea and bronchi cause inflammation. Generally, larvae in the alveoli cause inflammatory reaction with eosinophilic exudate blocking bronchioles and causing coughing and tachypnea.
- Adult worms in larger airways cause marked inflammatory response with consolidation of caudoventral lung lobes.

SYSTEMS AFFECTED

Respiratory

GENETICS

N/A

INCIDENCE/PREVALENCE

- Mainly areas with mild climate, high rainfall, intense irrigation, in late summer through fall.
- In southern United States, maximum *D. viviparus* infection in calves may be from December to March.
- Typically occurs in groups of animals on pasture

GEOGRAPHIC DISTRIBUTION

Worldwide, mainly northern temperate climates

SIGNALMENT

Species

All ruminant species

Breed Predilections

- Beef cattle tend to be less affected by *D. viviparus* since management is more extensive, therefore infective larvae are not as concentrated.
- Mainly a disease of dairy calves

Mean Age and Range

- *D. viviparus* infection tends to occur in cattle less than 1 year old, or previously unexposed adults, turned out onto infected pasture.
- Infection also occurs in older cattle, previously infected and considered immune, reinfected when they are moved from nonendemic to endemic areas.

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

Areas of high rainfall or intense irrigation, young animals turned out onto infected pasture, older animals moved from nonendemic to endemic areas

PHYSICAL EXAMINATION FINDINGS

Marked coughing (inconsistent finding in sheep and goats), tachypnea, dyspnea, fever (high fever in *A. suum* larval migration), anorexia, weight loss, harsh breath sounds, and widespread crackles and wheezes on lung auscultation (crackles over dorsal half of lungs in *D. viviparus* infection in cattle)

CAUSES

- Cattle—*D. viviparus*, aberrant migration of *A. suum*
- Sheep and goats—*D. filaria*, adults in trachea and bronchi, most pathogenic. *P. rufescens*, adults in bronchioles, lesions smaller, less pathogenic. *M. capillaris*, adults in lung parenchyma, which become encysted so relatively benign; most common but least pathogenic lungworm of sheep and goats; more pathogenic in goats than in sheep; causes a more diffuse inflammation and interstitial pneumonia in goats.

RISK FACTORS

Exposure to vector (snail or slug) habitat (i.e., marshy land, wet muddy areas around waterholes, areas of high rainfall, intense irrigation)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute bovine pulmonary emphysema and edema or ABPEE (atypical interstitial pneumonia, fog fever)—cattle over 2 years old suddenly switched from sparse dry forage to lush green pasture.
- Bacterial/viral bronchopneumonia

CBC/BIOCHEMISTRY/URINALYSIS

May see increase in eosinophils from 2 to 6 weeks after infection

OTHER LABORATORY TESTS

Baermann sedimentation technique on feces or fluid from transtracheal aspirate to look for lungworm larvae; need to check several animals in herd

IMAGING

- Radiography—may see consolidation of caudoventral lung lobes
- Endoscopy—may see adult lungworms in large airways

OTHER DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Prepatent phase—lungs grossly normal, few atelectic lobules in caudoventral lung lobes. May see larvae in microscopic smears of bronchial exudate, and eosinophilic infiltration
- Patent phase—bilaterally symmetrical caudoventral lung consolidation. See adult worms in trachea and bronchi, with hemorrhage and fluid exudate.
- *D. filaria*—adult worms mainly in caudodorsal diaphragmatic lung lobes
- *M. capillaris*—adult worms mainly in lung parenchyma, form grayish nodules 2–3 mm in diameter in subpleural tissue of

sheep.

PARASITIC SKIN DISEASES

BASICS

OVERVIEW

- Mange: parasitic skin disease of ruminants
- Infectious causes include *Chorioptes bovis*, *Sarcoptes scabiei-var ovis*, *Psoroptes ovis*, *Psoroptes cuniculi*, *Psororegates ovis*.
- In cattle, infestations with *P. ovis* are responsible for a severe dermatitis. The disease is very common in some breeds of beef cattle, whereas dairy cattle such as Friesian-Holstein are considered resistant. Immunological as well as nonimmunological factors may be responsible for the breed-related susceptibility or resistance to *P. ovis*.

SYSTEMS AFFECTED

Skin/exocrine, production management

GENETICS

Unknown

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

- *Chorioptes bovis*—Eradicated and REPORTABLE; seen most often in Europe, New Zealand, and Australia
- *Sarcoptes scabiei-var ovis*—rare, REPORTABLE
- *Psoroptes ovis*—eradicated and REPORTABLE
- *Psoroptes cuniculi*—REPORTABLE in Texas only
- *Psororegates ovis*—REPORTABLE; common in many parts of the world

SIGNALMENT

- Any age or breed; the lesions of psoroptic mange are particularly severe in angora goats.
- Llamas are susceptible to sarcoptic, psoroptic, and chorioptic mange, and symptoms are similar to sheep and goats.

Species/Breed Predilections

Any age or breed may be affected. The lesions of psoroptic mange are particularly severe in angora goats. Llamas are susceptible to sarcoptic, psoroptic, and chorioptic mange, and symptoms are similar to sheep and goats.

P. ovis is very common in some breeds of beef cattle, whereas dairy cattle such as Friesian-Holstein are considered resistant.

Mean Age and Range

Any age may be affected.

Predominant Sex

N/A

SIGNS

Sarcoptic Mange

- Very pruritic, crusts, scabs, and self-trauma/mutilation
- Goats—lesions may be generalized, lymphadenopathy may be seen.
- Sheep—affects nonwooly skin, usually seen on head and ears initially
- Llamas—thickened skin and lesions similar to sheep and goats

Chorioptic Mange

Pruritic papules, crusts, and ulcers usually start on feet and legs and spread to the hindquarters, scrotum. Can be generalized

Psoroptes Ovis

Pruritic scaly crusts mostly on the wooly parts of the body

Psoroptes Cuniculi

- Ears, causing excess wax production initially, but can spread to head, neck, and body
- Causes significant mohair damage in angora goats

Demodectic Mange

- Nonpruritic
- Goats—nodules and papules on face, neck, shoulders, and sides; nodules contain a thick grayish exudate full of mites.
- Sheep—nodular periocular lesions

Psororegates Ovis

- Pruritic and scaly, lesions on thorax, flanks, and thighs
- May cause weight loss and wool damage

CAUSES AND RISK FACTORS

- Chorioptic and psoroptic mange are seen most often in the winter.
- *Psoroptes cuniculi* is a common mite in rabbits.
- Demodex is a normal skin mite transmitted from the mother to neonate. Underlying diseases may predispose to demodex overgrowth.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dermatophilosis, lice, lymphosarcoma, dermatophytosis, photosensitization, *Staphylococcus* sp. dermatitis, tuberculosis, contagious ecthyma (ORF), foot-and-mouth disease, scrapie, poxvirus, pemphigus, herpes, contact dermatitis, trombiculidiasis, nutrient deficiency (selenium, zinc, vitamins A, D, or E), pseudorabies

CBC/BIOCHEMISTRY/UA

CBC may show an inflammatory leukogram.

OTHER LABORATORY TESTS

N/A

DIAGNOSTIC PROCEDURES

- Skin scrapings, biopsy, ear swabs, bacterial culture, and sensitivity
- The practitioner needs to differentiate demodex nodules from the nodules of tuberculosis. Mites may not always be found; a treatment trial may be warranted.

IMAGING

N/A

TREATMENT

Nonpharmacologic: ensure feeding, management, nutrition, and hygiene procedures are adequate. All in-contact animals need to be treated. For reportable conditions, call the state/provincial/governmental veterinarian for specific quarantine and treatments.

MEDICATIONS

DRUGS OF CHOICE

- Although not always approved for treatment of certain conditions in target species, ivermectin at 0.2 mg/kg SQ (may need to be repeated in 2 weeks) treats most external parasites. The determination of meat and milk drug withdrawal time

needs to be determined prior to treatment.

- Various dips are approved for treatment: 2% lime sulfur for use in lactating goats once weekly for 4–12 dips.
- Antibiotics may be indicated for secondary skin infections.
- There are no effective treatments reported for *Demodex*, which may resolve spontaneously. Localized lesions may be incised, expressed, and infused with Lugol's iodine.

CONTRAINDICATIONS

- Steroid use will allow mites to proliferate and is contraindicated.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

Monitor clinical signs and/or repeat skin scrapings.

PREVENTION/AVOIDANCE

- Quarantine new animals before introducing into the herd/flock.
- *Psoroptes*—2-week life cycle on the host, can live off host for 3 weeks
- *Chorioptes*—2–3-week life cycle, live off host 3 days
- *Sarcoptes*—10–17-day life cycle, life cycle off host is variable
- *Psorergates*—35-day life cycle on host, can live 3–4 days off host

POSSIBLE COMPLICATIONS

Repeat infections are possible.

EXPECTED COURSE AND PROGNOSIS

Prognosis for *Demodex* sp. is guarded, for other mites is fair to good with adequate diagnosis and subsequent treatment.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Pruritic, crusts, scabs, and self-trauma/mutilation
- Goats—lesions may be generalized, lymphadenopathy may be seen.
- Sheep—affects nonwooly skin, usually seen on head and ears initially
- Llamas—thickened skin and lesions similar to sheep and goats

AGE-RELATED FACTORS ZOONOTIC POTENTIAL

- *Sarcoptes scabiei* is zoonotic and can cross between species.
- The practitioner needs to differentiate demodex nodules from the nodules of tuberculosis.

PREGNANCY

N/A

BIOSECURITY

- Quarantine new animals before introducing into the herd/flock.
- Isolate affected herd members or whole herds/flocks.
- For reportable conditions, call the state/provincial/governmental veterinarian for specific quarantine and treatments.

PARELAPHOSTRONGYLUS TENUIS: CEREBROSPINAL NEMATODIASIS

BASICS

DEFINITION

Aberrant migration of the larvae of *Parelaphostrongylus tenuis* into the central nervous system of small ruminants, camelids, and certain cervidae species.

PATHOPHYSIOLOGY

- The natural host for *P. tenuis* is the white-tailed deer (*Odocoileus virginianus*). Clinical signs or pathological findings associated with *P. tenuis* infestation in this species are rare. In white-tailed deer, adult meningeal worms reside in the subdural space and the cranial venous sinuses.
- Eggs laid in the meninges develop, hatch, penetrate blood vessels, and are carried to the lungs, whereas eggs deposited in the venous circulation are carried to the lungs where they embryonate and hatch. The first stage larvae move up the bronchi and trachea, are ingested, pass in the feces, and penetrate certain terrestrial slugs and snails.
- Development of infective larvae within the intermediate host requires three to four weeks. Ingesting infested slugs and snails infects white-tailed deer.
- Ingested larvae penetrate the abomasal wall, migrate through the peritoneal cavity via nerves to the dorsal gray columns of the spinal cord, and become adults in 20 to 30 days. They then migrate to the subarchnoid space, probably by the dorsal nerve rootlets.
- The prepatent period is approximately 90 days, and the life cycle is complete in 4 months.
- When aberrant hosts such as sheep, goats, camelids, and certain cervidae ingest infected snails and slugs, the larvae are released in the gut and migrate to the spinal cord and/or brain where they may cause inflammation and neural tissue damage. Generally, they do not reach maturity.

Figure 1.

SYSTEMS AFFECTED

Nervous

GENETICS

There is no known genetic basis for this condition.

INCIDENCE/PREVALANCE

There are no published reports regarding the incidence/prevalence of this condition.

GEOGRAPHIC DISTRIBUTION

The distribution of this problem reflects the range of the white-tailed deer, which is southern Canada, conterminous United States with the exception of parts of the Southwest, Mexico to Bolivia, and northeast Brazil. Additionally, the intermediate hosts (snails and slugs) prefer low-lying to swampy areas that have trees.

SIGNALMENT

Species

Sheep, goats, camelids, and certain species of cervidae including moose, elk, antelope, reindeer

Breed Predilection

There is no reported breed predilection. However, this problem is more likely to occur in animals that graze low-lying, treed areas with a high density of white-tailed deer. Therefore, it is more frequently observed in goats managed for meat and/or fiber rather than dairy goats based on housing differences. Meat and fiber animals are more likely to have access to pasture, whereas dairy goats more frequently are housed with limited access to pasture.

Mean Age and Range

Most clinically affected animals are at least 6 months of age, which may reflect the time required from ingestion of infective larvae to their arrival in the nervous system.

Predominant Sex

There is no sex predilection associated with this condition.

SIGNS

- The clinical signs vary and depend upon the number of migrating parasites present and the portion or portions of the nervous system affected. Both upper and lower motor neuron and brain signs have been reported including:
 - Blindness
 - Circling
 - Lameness
 - Paralysis and/or ataxia in one or more limbs (may see a dog sitting posture if both hind limbs are affected)
 - Paresis
 - Spastic gait
- The observed signs may change as the migratory pattern of the parasites change, they may remain static, spontaneous recovery may occur, especially if the neurologic damage is minor, or the animal may die. If only the spinal cord is involved, an affected animal will appear bright and alert, and usually display a normal appetite.
- Brain involvement can produce a variety of clinical signs that may mimic other central nervous system diseases.

CAUSES AND RISK FACTORS

- The major cause for cerebrospinal nematodiasis in North America is *Parelaphostrongylus tenuis*; however, other parasites such as *Oestrus ovis* and *Coenurus cerebralis* have also been reported.
- The major risk factor for infestation is grazing low-lying, treed pastures in the late summer and into the fall that are cohabited by the natural host for *P. tenuis* the white-tailed deer. After a killing frost, the risk for infestation to occur when susceptible animals utilize these types of pastures is greatly decreased.

DIFFERENTIAL DIAGNOSIS

The following list of rule-outs should be considered when brain-related neurologic signs are observed:

- Caprine arthritis-encephalitis (goats less than 6 months of age)
 - Encephalitic listeriosis
 - Heat stress (camelids)
 - Metabolic disease
 - Polioencephalomalacia
 - Rabies
 - Scrapie (rare in goats)
 - Space occupying lesion in the brain, especially abscess
 - Toxicity (lead, salt, plants)
 - Trauma
- The following list of rule-outs should be considered when spinal cord and/or peripheral nerve-related signs are observed:
- Heat stress (camelids)
 - Metabolic disease
 - Myositis
 - Nutritional deficiencies, especially copper and vitamin E and selenium
 - Rabies
 - Space occupying lesion in or around the spinal cord, especially abscess
 - Trauma

CBC/BIOCHEMISTRY/URINALYSIS/OTHER LABORATORY TESTS

There are no specific tests for diagnosis of *P. tenuis*, however, a complete blood count, serum chemistry analysis, and urinalysis may be useful to rule in or rule out other conditions.

IMAGING

There are no specific imaging examinations for detecting this condition, although these tests are useful for detecting spinal

cord or brain trauma, and space-occupying lesions, which are differential diagnoses for the condition.

CEREBROSPINAL FLUID (CSF) ANALYSIS

The most useful ancillary diagnostic aid is CSF cytology and detection of an eosinophilic pleocytosis. Although this is not pathognomonic for *P. tenuis*, it is highly suggestive for cerebrospinal nematodiasis. A mononuclear pleocytosis may also be observed and is less specific for parasite migration.

PATHOLOGIC FINDINGS

There are no detectable gross postmortem findings. A definitive diagnosis requires histopathologic identification of the parasite within the brain or spinal cord.

TREATMENT

Nursing Care

- The amount of supportive care needed will be determined by the extent and location of the neurological damage in an affected animal. For example, an animal with mild impairment at the level of the spinal cord, associated with paresis in one or two limbs and no loss of appetite would require minimal assistance. In such cases, an animal should be penned by itself or with a few nonaggressive companions, in an area that is well bedded with a nonskid floor.
- Food and water should be readily accessible. Encouraging mild to moderate exercise is important to promoting muscle strength and function.
- Animals showing more severe signs, such as paralysis of the forelimbs, hind limbs (dog sitting posture), or both, will require intensive nursing care. This may include using a sling or a water floatation tank to support the animal and provide physical therapy. Food and water need to be immediately accessible.
- Animals that have signs associated with brain level lesions present the greatest challenge since these animals are often recumbent and inappetent. Besides physical therapy, enteral feeding via stomach tube or temporary rumen fistula may be required. Parenteral nutrition via intravenous feeding may also be a consideration.

CLIENT EDUCATION

Damaged nervous tissue may take 6 months or longer to heal, or for an animal to develop compensatory skills. It is useful to discuss with a client the fact that the more severe the neurological damage, the poorer the prognosis, and, if recovery is to occur, it may take a long time and require intensive nursing care.

SURGICAL CONSIDERATIONS

NA

MEDICATIONS

DRUG(S) OF CHOICE

- Anthelmintic
- Fenbendazole—20 to 50 mg/kg, PO q24 for 5 days
- Anti-inflammatory
Flunixin meglumine—1 mg/kg IV (the preferred route since this product results in tissue irritation when used IM or SQ), q12, for 2 to 3 days
Dexamethazone—0.1 mg/kg, IV, IM or SQ (Avoidance of the IM is recommended in food-producing animals to avoid injection-site lesions.) CAUTION: Do not use in pregnant animals since it may induce abortion.
- Vitamins and mineral supplements
- E/Se, B-complex, A, D—use as directed on an individual product label

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

- An animal's pregnancy status is an important consideration if steroid-type anti-inflammatory drugs are being considered in the treatment protocol. Drugs such as dexamethazone may induce abortion.
- Use of anthelmintic products in the avermectin family (ivermectin) are not recommended for treatment. These products do not cross an intact blood brain barrier. With inflammation, as may be present with this disease, these products may cross and result in a toxic reaction (lethargy, ataxia, recumbency, death). Because the signs of toxicity resemble clinical signs of meningeal worm infestation, it may be difficult to identify a toxic reaction.

POSSIBLE INTERACTIONS

None

ALTERNATIVE DRUGS

NA

FOLLOW-UP

PATIENT MONITORING

See nursing care.

PREVENTION/AVOIDANCE

Prevention is directed toward the following:

1. Minimize exposure of susceptible animals to infected snails. In locations that have four distinct seasons, the potential for animals to ingest snails infested with the infective third-stage larvae of *P. tenuis* is greatest in late summer until the first killing frost. Therefore, restricting access to low-lying, snail and deer infested pastures during this time is recommended. During hot, dry summers, snail population growth will be inhibited; therefore, pasture access may be continued longer into the summer. Cool, moist summers will favor snail population growth, which will prompt limiting pasture access earlier in the season. In milder climates, access to these pastures should be restricted year round.
2. Strategic anthelmintic treatments. Before *P. tenuis* migrates into the CNS, it is susceptible to several commercially available products including ivermectin and fenbendazole using dosages recommended for treatment of gastrointestinal parasites in the species. The recommended interval of therapy varies from every 4 to 6 weeks to every 3 to 4 weeks since there may be some species and individual animal differences in how rapidly infective larvae reach the CNS. For some management situations, using a continuous treatment approach with the addition of a product to the feed or providing it in combination with a supplement block may be effective and less labor intensive.

POSSIBLE COMPLICATIONS

NA

EXPECTED COURSE AND PROGNOSIS

See nursing care and client education.

MISCELLANEOUS

ASSOCIATED CONDITIONS

PATENT URACHUS

BASICS

OVERVIEW

- The urachus connects the fetal bladder and the allantoic sac during gestation.
- The urachus normally shrinks and closes after birth and becomes the vestigial round ligament of the bladder.
- Patent urachus is the result of a persistent urachal stalk that remains open and dribbles urine in the neonate.
- This condition is much less common in calves than in foals.
- Patent urachus may predispose the neonate to septicemia.

SYSTEMS AFFECTED

Production management, musculoskeletal, hemolymphatic, urinary

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on species

SIGNALMENT

Sporadic postnatal condition of calves, lambs, and kids; has been diagnosed in the white rhinoceros calf (*Ceratotherium simum simum*).

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

The cardinal clinical sign of patent urachus is dribbling of urine from the umbilicus.

CAUSES AND RISK FACTORS

Umbilical infection may contribute to the development of patent urachus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other umbilical masses, such as persistent urachus, urachal cyst, umbilical abscess, umbilical hernia, infected umbilical arteries, vein, and/or urachus

CBC/BIOCHEMISTRY/URINALYSIS

- A neutrophilic leukocytosis and hyperfibrinogenemia may be present in cases of septicemia.
- Neonates with concurrent failure of passive transfer usually have a low plasma protein level.

OTHER LABORATORY TESTS

BUN and creatinine analysis of the fluid should be identical to urine.

IMAGING

Ultrasonography may confirm that the structure attaches to the urinary bladder.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

N/A

TREATMENT

- If the urachus does not close by 24 hours after birth, surgical resection is suggested to decrease the chances of development of septicemia.
- Surgical intervention also allows removal of other umbilical structures that may be affected.
- Surgery involves a ventral midline laparotomy with resection of the urachus and the tip of the bladder.
- If surgical resection can not be performed, broad-spectrum antimicrobial therapy should be initiated and the urachus chemically cauterized with silver nitrate or 7% iodine to promote closure.

MEDICATIONS

DRUGS OF CHOICE

Broad-spectrum parenteral antibiotics to prevent septicemia should be administered whether surgical or medical therapy is chosen.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PEDICULOSIS OF SHEEP AND GOATS

BASICS

OVERVIEW

- Lice are small wingless insects 1 to 2 mm long belonging to the order Phthiraptera.
- Two suborders of lice are ectoparasites of veterinary importance: Mallophaga (biting/chewing lice), and Anoplura (sucking lice).
- Lice are highly specific with respect to host species.
- Sheep lice are specific with respect to the part of the body that is colonized.
- Lice are permanently ectoparasitic, spending the entire life cycle on the host.
- Transmission is by direct close contact.
- The most economically important species is the sheep body louse *Bovicola ovis*.

SYSTEMS AFFECTED

Skin, production management

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

- Lice of sheep and goats have worldwide distribution, except *Linognathus africanus*, which is restricted to the subtropics.
- The ked, a wingless blood-sucking fly of the family Hippoboscidae, is an obligate ectoparasite with worldwide distribution.

SIGNALMENT

Species

Sheep and goats

Breed Predilections

N/A

Mean Age and Range

All age groups can be affected, but heavy infestation of preweaning animals is rare.

Predominant Sex

N/A

SIGNS

- Sheep infested with *Bovicola ovis* are irritated by the lice. Lousy sheep bite at their fleece and rub against fences, posts, and trees.
- The greatest numbers of lice are in the fleece along the dorsal midline near the withers, on the sides of the body between the elbow and flank, and along the throat.
- The fleece is damaged and wool lost from the fleece accumulates on structures within the sheep's environment.
- The fleece becomes felted (cotted), contains increased amounts of wool grease and suint, and is discolored yellow/brown.
- *Bovicola ovis* infestation has been linked to the pelt fault "cockle."
- Sheep keds cause signs of annoyance resembling heavy louse infestation. The wool is stained brown and has a musty odor.
- Local induration of the skin around ked bites results in "ked-cockle" of pelts.

HISTORICAL FINDINGS

Sheep

- Biting: *Bovicola ovis* (body louse)
- Sucking: *Linognathus pedalis* (foot louse), *Linognathus ovillus* (face louse), and *Lignonathus africanus* (African sheep louse/blue louse)
- Ked: *Melophagus ovinus*

Goats

- Biting: *Bovicola caprae* (common/milch goats), *Bovicola limbatus* and *Bovicola crassipes* (Angora goats)
- Sucking: *Linognathus stenopsis*
- Ked: *Melophagus ovinus* (rare).

Ecology

- Lice are sensitive to temperature and humidity.
- In temperate regions, louse populations on pastured sheep are greatest during the cooler months.
- *Bovicola ovis* infestation is absent from permanently very hot, dry areas.

CAUSES AND RISK FACTORS

Heavy lice infestation often reflects debilitation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Mite infestation, pruritic diseases, photosensitivity, topical allergies

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Part the fleece to examine the staple for lice.
- Body lice cluster within the fleece, therefore multiple sites must be examined.
- Adult keds, pupae, and ked feces are readily apparent in the fleece. The wool is stained by ked feces and has a characteristic musty odor.

PATHOLOGIC FINDINGS

N/A

TREATMENT

Flocks can be kept free of lice and keds if strict quarantine is employed to prevent infestation.

MEDICATIONS

DRUGS OF CHOICE

- Saturation dipping with either synthetic pyrethroid or organophosphate insecticides eliminates louse infestation, if animals are thoroughly wetted to the skin.
- Saturation dipping is most effective if performed 6 to 8 weeks after shearing.
- Pour-on synthetic pyrethroid formulations can eliminate lice or reduce louse numbers, depending on wool length and

type.

- Formulations of available insecticides vary widely. Recommendations for treatment must match the formulation, the treatment type (saturation/pour-on), the wool length, and the wool type, while taking into account seasonal factors and withholding periods.
- To achieve satisfactory results, the manufacturer's instructions must be followed precisely.
- Strict attention must be paid to worker health and safety, and environmental waste management.
- Eradication requires simultaneous treatment of the entire flock.

CONTRAINDICATIONS

- Diarrhea and fecal soiling: the dip-wash used for saturation dipping rapidly becomes polluted. Some formulations of chemical become adsorbed to organic particulates, then settle out and are degraded.
- Foot rot and foot abscesses: the dip-wash becomes contaminated with bacteria.
- Dirty/dusty sheep: the dip-wash becomes contaminated with dirt.
- Saturation dipping of sheep with long wool is ineffective because the dip-wash fails to penetrate the fleece to the skin.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

Maintain strict herd/flock quarantine.

POSSIBLE COMPLICATIONS

- Treatment failure due to inadequate insecticide application
- Immersion plunge or saturation shower dipping with heavily contaminated dip-wash can result in “post-dipping lameness”; a septic arthritis caused by *Erysipelothrix rhusiopathiae*.
- Saturation dipping late in the day, with insufficient time for sheep to dry before nightfall, can precipitate pneumonia, dermatophilosis (“mycotic” dermatitis) caused by *Dermatophilus congolensis*, fleece rot caused by *Pseudomonas aeruginosa*, or wool discoloration from chromogenic bacteria.
- Plunge or shower dipping sheep with unhealed shearing cuts can result in pyogenic infections, clostridial malignant edema, tetanus, other necrotizing anaerobic infections, and caseous lymphadenitis.
- Unrested sheep that are saturation dipped while hot are prone to pneumonia.

EXPECTED COURSE AND PROGNOSIS

Persistent without treatment

MISCELLANEOUS

ASSOCIATED CONDITIONS

Melophagus ovinus transmits the nonpathogenic *Trypanosoma melophagium*.

AGE-RELATED FACTORS

All age groups can be affected, but heavy infestation of preweaning animals is rare.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Sheep and goats

BIOSECURITY

- Flocks can be kept free of lice and keds if strict quarantine is employed to prevent infestation.
- Isolation and quarantine of new stock entering the herd/flock
- Treat and or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT

Some countries have statutory provisions with respect to livestock movement and insecticide dipping in order to prevent lice spreading to noninfested properties.

PENILE DEVIATIONS

BASICS

OVERVIEW

- Penile deviation is a common cause of copulation failure in bulls.
- The heritability of penile deviation is low.
- The spiral or corkscrew penile deviation is the most common deviation observed in bulls.
- Spiral deviation of the penis occurs at the peak of erection.
- Up to 50% of normal bulls have been shown to develop spiral deviation during copulation.
- Spiral deviation is often noticed in normal bulls during masturbation, following intromission, and when erection is produced by an electroejaculator; it is not considered pathologic until its occurrence is observed on repeated natural breeding trials in which it occurs prior to intromission.
- Ventral or rainbow deviation is less common than spiral and also prevents intromission.
- S-shaped penile deviation is relatively rare.
- Lateral deviations may occur secondary to trauma of the penis or prepuce when resultant scars or adhesions of the elastic tissue pull the penis to one side or the other.

SIGNALMENT

The majority of penile deviations occur in the polled beef breeds such as polled Hereford and Angus.

SIGNS

- The spiral configuration, caused by the dorsal apical ligament slipping off to the left, results in a counterclockwise spiral of the penis as viewed from the rear.
- Ventral penile deviation occurs when the dorsal apical ligament is thin and stretched to the point that it is incapable of holding up the distal portion of the penis during erection.
- S-shaped deviation occurs when the dorsal apical ligament is sufficient in strength but insufficient in length resulting in the characteristic S-shape during erection.

CAUSES AND RISK FACTORS

- Spiral deviation occurs in bulls between 2 1/2 and 5 years of age.
- The S-shaped deviation usually occurs in older bulls with an excessively long penis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Ventral penile deviation may be confused with persistent frenulum, which can also result in ventral position of the penis during erection.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Corkscrew deviation can only be definitively diagnosed by observation of its occurrence during natural breeding.

attempts.

- Ventral deviation can be diagnosed with the use of an electroejaculator.

PATHOLOGIC FINDINGS

Abnormalities of the dorsal apical ligament may result in corkscrew, ventral, or S-shaped deviations.

TREATMENT

- The fascia lata or mesh implant techniques are used for repair of both spiral and ventral penile deviations.
- The objective of these techniques is to surgically create a firm union of the dorsal apical ligament to the tunica albuginea to prevent slippage or stretching of the dorsal apical ligament.
- There is no surgical treatment for S-shaped deviations.
- Lateral deviations may be corrected by careful removal of scar tissue.

MEDICATIONS

DRUGS OF CHOICE

Postoperative antibiotics are administered for 7 days after surgical treatment.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

The prognosis for return to breeding soundness after surgery is considered more favorable with spiral than ventral deviations.

MISCELLANEOUS

Bulls undergoing surgical correction of penile deviations can be used for breeding at 60 days postop.

PENILE HEMATOMA

BASICS

OVERVIEW

- Hematoma of the penis, also referred to as “ruptured penis,” “broken penis,” or “fractured penis,” is common in bovine species and rare in others
- Penile hematoma occurs during coitus when the cow slips or goes down under the weight of the bull or when the penis is thrust against the perineum of the cow during breeding attempts.
- The corpus cavernosum penis (CCP) is a closed system, and during erection, blood pressure within the CCP may exceed 14,000 mm of Hg.
- Sudden angulation of the penis may increase the blood pressure and result in a hematoma.
- Penile hematoma results from a tear of the tunica albuginea into the CCP; the tear usually occurs on the dorsum of the penis at the distal sigmoid flexure opposite the insertion of the retractor penis muscles where the tunica albuginea is thinner.
- Tears in the tunica albuginea are between 2–7.5 cm long, transverse, and usually do not extend over 180° circumferentially.
- The swelling due to hematoma is a result of blood from the CCP being forced into the peripenile tissues.
- The size of the hematoma is not related to the length of the tear in the tunica albuginea but to the number of coital attempts the bull makes following rupture.

SIGNALMENT

- Aggressive young bulls used in range breeding are prone to penile hematoma.
- Heavy beef bulls, commonly 2- to 4-year-old Herefords, have been reported to be predisposed to penile hematoma.

Recurrence of penile hematoma is common, but surgical repair lessens the risk; 50% recur with medical treatment but only 25% recur with surgical treatment.

SIGNS

- Diagnosis is based on physical exam and the presence of a large swelling immediately cranial to the scrotum.
- Owners often first notice the presence of a prolapsed prepuce, which may result secondary to the swelling of the hematoma.
- The swelling is soft until the clot begins to form by about the fourth day; by 10 days the clot begins to organize and the swelling becomes quite firm.
- Bruising of the skin over the hematoma may be apparent in light-skinned bulls.

CAUSES AND RISK FACTORS

- Sudden angulation of the penis during erection may result in rupture of the tunica albuginea and hematoma formation.
- Factors contributing to penile hematoma might include excessive body weight causing awkwardness, partial desensitization, or deviations of the penis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Preputial abscess and rupture of the urethra can be confused with the swelling created by a penile hematoma.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Physical examination; ultrasonography

PATHOLOGIC FINDINGS

N/A

TREATMENT

- Medical treatment consists of parenteral antibiotics, warm local hydrotherapy for 2–3 weeks, and sexual rest for 60–90 days; spontaneous recovery occurs in > 50% of the cases given 90 days sexual rest.
- Surgical treatment involves removal of the blood clots and repair of the rent in the tunica albuginea.
- Surgery should be performed between 5 and 10 days posttrauma; a second chance for surgical repair is after 21 days when fibrosis dissipates.
- Surgical repair probably reduces the incidence of complications.
- Sexual rest should be provided for 60 days after surgery.

MEDICATIONS

DRUGS OF CHOICE

Parenteral antibiotics may be administered for 10 days during medical therapy or for 10 days postoperatively if surgery is performed.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

Undesirable sequelae that may occur secondary to penile hematoma and/or its treatment include recurrence of the hematoma, adhesions of elastic layers to the tunica albuginea or to the skin preventing complete extension of the penis, analgesia of the penis due to damage of the dorsal penile nerve, abscessation, or vascular shunts.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Recurrence of penile hematoma is common, but surgical repair lessens the risk; 50% recur with medical treatment but only 25% recur with surgical treatment.

AGE-RELATED FACTORS

- Aggressive young bulls used in range breeding are prone to penile hematomas.
- Heavy beef bulls, commonly 2- to 4-year-old Herefords, have been reported to be predisposed to penile hematoma.

PERICARDITIS

BASICS

DEFINITION

Inflammation of the pericardium that results in accumulation of fluid or exudate within the pericardial sac

OVERVIEW

- Uncommon disease
- In cattle, most commonly seen as traumatic pericarditis following perforation of pericardial sac by an infected, metallic, foreign body originating from the reticulum
- Less frequently occurs as result of blood-borne infection (septicemia) or direct extension of infection (pleuropneumonia, pleuritis, myocarditis)
- Three forms described: (1) effusive pericarditis with nonseptic fluid accumulation in pericardial sac, (2) fibrinous pericarditis with accumulation of fibrin \pm fluid in pericardial sac, and (3) constrictive pericarditis with fibrosis and thickening of the pericardial sac
- Most cases are fibrinous and septic in ruminants but occasionally are idiopathic and nonseptic.

PATHOPHYSIOLOGY

- Results from trauma, hematogenous or direct spread of infection, or idiopathic
- Initially, inflammation of pericardium with hyperemia, fibrin deposition, and little exudate results in pain and “rubbing” sound when pericardium and epicardium move together during heart movement.
- As fluid accumulates in the pericardial sac, friction sounds decrease, heart sounds become muffled, and tachycardia progresses.
- Heart chambers become compressed due to presence of fluid and fibrin leading to incomplete filling and congestive heart failure.
- Gas will also be present in sac if infection is due to a gas-producing organism.
- Suppurative pericarditis results in toxemia following systemic absorption of bacterial toxins.
- Nonsuppurative pericarditis: fluid is resorbed and adhesion(s) formed between pericardium and epicardium during recovery stage.
- Suppurative pericarditis may result in organization of adhesion(s) and restriction of cardiac movement, and heart failure.
- Necropsy lesions
 - Fluid accumulation in pericardial sac
 - Fibrin tags on pericardial and epicardial surfaces
 - Thickening of epicardium and pericardium
 - \pm Pericardium adhered to epicardium
 - Lesions of congestive heart failure
 - Embolic lesions to other organs
- Seen worldwide
- Mature cattle
- Goats may be slightly more prone to disease than sheep because of eating habits.
- No sex or breed predilection

Septic Pericarditis

- *Early stages*
 - Pain, hypophagia, tachypnea, intermittent fever, elbow abduction, arched back
 - Tachycardia, pain on palpation of thoracic wall over cardiac region, “friction rub” on auscultation of heart

- ± Signs of pneumonia, pleural effusion, peritonitis
- *As fluid accumulates in pericardial sac*
 - Muffling of heart sounds
 - Bilateral jugular distention ± abnormal pulsation
 - “Splashing or washing machine murmur” with heart beat if gas is present in pericardium
 - Decreased palpability of apex beat
 - Expanded area of cardiac dullness
 - Progressive tachycardia
 - Weakened peripheral pulses
 - Dyspnea
 - Lung sound over ventral thorax may be decreased.
- Signs of toxemia
- Signs of congestive heart failure
- Death or survival
- Survivors experience stage of chronic pericarditis with additional signs
 - Myocarditis
 - ± Arrhythmias
 - Return of more normal heart sounds and heart rate as effusion resolves
- Complete recovery is uncommon

CAUSES AND RISK FACTORS

- In cattle, most commonly traumatic in origin secondary to “Hardware Disease”
- Extension from other focus of infection (i.e., pleuropneumonia)
- Secondary to lymphoma or other neoplasm
- Component of diseases causing polyserositis
- Idiopathic
- Penetrating foreign body
- Hypoproteinemia
- In goats: pericardial effusion or pericarditis seen with mycoplasmosis, viral goat dermatitis, false blackleg, enterotoxemia due to *Clostridium perfringens* type D, and caprine tuberculosis
- Suspected based on findings of pericardial rub or “sloughing” sound with heart beat, muffling of heart sound, venous congestion, and decreased pulse pressure
- Confirmed based on echocardiography and pericardiocentesis
- History and physical examination
 - Tachycardia
 - Pleural friction rub
 - Muffling of heart sounds
 - Decreased pulse pressure
 - Venous congestion
 - ± Fever
 - ± Obvious sites of infection
- Complete blood cell count and fibrinogen concentration
- Echocardiography
 - Most valuable diagnostic procedure
 - Differential effusive from fibrinous pericarditis
- Pericardiocentesis
 - Fluid analysis (cell counts, protein concentration) and cytology
 - Bacterial and mycoplasma culture and sensitivity
 - Isolation of viral agent

- Fluid not useful for diagnosis of heartwater (cowdriosis)
- With systemic mycoplasmosis, organism is better isolated from other sites.
- Thoracic radiography
 - May be of limited value if pleural effusion present
 - Difficult to accurately evaluate size and shape of heart in mature cattle
- Serum chemistry panel often reflects accompanying changes in other organ(s).

DIFFERENTIAL DIAGNOSIS

- Pasteurellosis or mycoplasmosis in cattle, sheep, and goats
- Cattle: Black disease, infection with *Haemophilus* spp., *Pseudomonas aeruginosa*, *Actinobacillus suis*, sporadic bovine encephalomyelitis, tuberculosis
- Sheep and goats: *Staphylococcus aureus* infection
- Infectious endocarditis
- Right- or congestive heart failure
- Pleuropneumonia/pleuritis
- Mediastinal or pleural abscess or mass
- Hydropericardium
 - Gossypol toxicity
 - Clostridial intoxication in sheep
 - Lymphomatosis
- Toxic myocardial necrosis
- Heartwater (cowdriosis) in Africa and Caribbean

CBC/BIOCHEMICAL/URINALYSIS

- Complete blood cell count
 - ±Anemia of chronic disease
 - Primarily leukocytosis ± left shift; monocytosis
 - May have leukopenia with left shift
 - Hyperfibrinogenemia
 - Cattle have less consistent leukocyte response compared to other species.
- Serum chemistry panel often reflects accompanying changes in other organ systems, hydration status, or hypophagia.
 - Azotemia
 - Elevated GGT
 - Elevated creatine kinase if recumbent
 - Electrolyte or acid-base abnormalities from anorexia

OTHER LABORATORY TESTS IMAGING

- Echocardiography
 - Determine presence, amount, and character of pericardial effusion
 - Determine presence of chamber collapse; usually right atrium first and then right ventricle, followed by left side as fluid accumulation increases.
 - Interventricular septal motion is increased or paradoxical.
 - Pericardial effusion is imaged between the pericardium and epicardium, around both ventricles with less between the descending aorta and left ventricular free wall.
 - Clear anechoic effusion is most consistent with a transudate.
 - More echogenic fluid with fibrin is typical of septic or traumatic pericarditis.
- Thoracic radiography
 - Evaluate size and shape of heart—difficult in mature cattle.
 - Cardiomegaly, obscured cardiac silhouette, vena cava, and diaphragm, dorsal displacement of trachea
 - Enlarged pericardium, fluid line with gas cap above it
 - Determine presence and character of pleural fluid, evaluate lung parenchyma.

- ±Identify metallic foreign body.

DIAGNOSTIC PROCEDURES

- Echocardiography
- Pericardiocentesis
 - Cattle: 18-gauge spinal needle (4–8 inches) or small chest tube
 - Clip and surgically prepare site on left thorax
 - Inject local anesthetic over dorsal aspect of 6th rib and around front of it blocking skin and subcutaneous tissue down to parietal pleura.
 - Skin puncture with scalpel in left 5th intercostal space just dorsal to elbow
 - Needle or trocar is advanced through skin incision, at the anterior aspect of the 6th rib.
 - Normal pericardial fluid has protein content of < 2.5 g/dl; cell count < 5000/ μ l; mononuclear cell is predominant cell type.
 - Goats: One source recommends using the right 4th intercostal space low on the chest wall as the procedure site to avoid lung and coronary arteries. Animal maybe standing or in lateral recumbency. Chemical restraint is advisable, diazepam.
 - Risks: pneumothorax, cardiac puncture, hemorrhage due to laceration of coronary artery or myocardium, death from fatal arrhythmia or cardiac tamponade, contamination of pleural space with pericardial fluid
- Electrocardiogram
 - Diminished amplitude of QRS complexes
 - Arrhythmia present
 - Electrical alternans in cattle
- Thoracic radiographs

TREATMENT

Septic Pericarditis

- Treatment is long term, costly, and often unsuccessful.
- Rumenotomy to remove penetrating foreign body, if present
- Ideally, choice of antimicrobial agents is based on culture and sensitivity results on pericardial fluid.
- Broad-spectrum, parenteral, bactericidal, antimicrobial therapy administered when causative agent not is identified
- Analgesic and anti-inflammatory drugs as needed
- Pericardiocentesis to drain fluid and lavage of pericardial space with isotonic, nonirritating fluid followed by installation of antimicrobial drug
- If unresponsive, thoracotomy and pericardectomy or pericardiostomy to provide drainage or to perform marsupialization of pericardium to body wall
- Diuretics and restriction of dietary salt if congestive heart failure is present
- Supportive care to maintain hydration and nutritional status and electrolyte and acid-base balance
- Appropriate treatment of secondary organ disease or dysfunction
- Early withdrawal of therapy may result in relapse.
- Often, extralabel use of antimicrobial is required because few are labeled for long-term therapy.

Idiopathic Effusive Pericarditis

- Drain fluid from pericardial sac.
- Corticosteroid therapy or nonsteroidal anti-inflammatory drugs; caution in pregnant animals (abortifacient)
- Supportive care to maintain hydration and nutritional status and electrolyte and acid-base balance
- Diuretics and restriction of dietary salt if congestive heart failure is present

MEDICATIONS

DRUGS OF CHOICE

- Penicillin: 22,000 IU/kg: Aqueous potassium penicillin IV QID or procaine penicillin IM BID
- Amoxillin: 10 mg/kg IM BID
- ± Rifampin: 5 mg/kg PO BID, as supplemental therapy to enhance antibiotic penetration into lesion
- Anti-inflammatories
 - Flunixin meglumine (Banamine) 1.1 mg/kg SID or 0.5 mg/kg BID (caution: may induce abomasal ulcers)
 - Aspirin: 30–100 mg/kg PO every 12 to 24 hours
- Furosemide: 0.5 to 1.0 mg/kg IV every 12 to 24 hours
- Potassium supplement (50–200 g/day PO) if on potassium-wasting diuretics
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Complete recovery is uncommon with septic pericarditis.
- Prognosis for septic pericarditis is not better than guarded (30%).
- Chronicity of condition is a major factor in outcome.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Reticuloperitonitis
- Cardiac arrhythmias including sinus tachycardia, premature ventricular contractions, and atrial fibrillation
- Toxemia
- Septic embolism to other organs
- Congestive heart failure
- Myocardial disease

PERINATAL LAMB MORTALITY

BASICS

OVERVIEW

- Lamb mortality data suggest a regional lamb loss pattern influenced by weather, management practices, nutrition, housing, and genetic factors.
- Preweaning loss typically consumes 10%–35% of the annual lamb crop and is often viewed by producers as a “normal” event.
- Diseases involving neonates usually occur with little warning, consequences to the newborn are severe, and treatment is unrewarding. Consequently, prevention is more important than individual animal treatment.
- Prevention program strategy requires basic knowledge of when, where, and how lamb losses occur and the association involving management decisions and mortality.

Categorizing Lamb Losses

- Timing—most losses occur during first week of life (see [Figure 1](#)).
- Especially first through third day following birth

[Figure 1.](#)

Most Neonatal Mortality Occurs During The First Week Of Life

[Figure 2.](#)

Mortality Rates Are Highest During Days 1, 2, & 3 Following Birth

- Losses occurring during last 3 weeks of gestation and first 3 weeks following birth: prepartum (15% of mortality); partum (20% of mortality); postpartum (65% of mortality) (see [Figure 2](#))
- Causes—management practices can both prevent and contribute to mortality.
 - Most due to management, not infectious processes
 - Intensive management systems increase importance of infectious diseases.
 - On-the-farm gross postmortem examination is useful in grouping losses into very basic categories.
 - Categorization focuses control measures
 - Four broad loss categories define 70%– 80% of mortality: (1) starvation, hypothermia, and exposure; (2) stillbirth or stillbirth/dystocia; (3) pneumonia; and (4) abortion (see [Table 1](#)).

Postmortem Examination of the Lamb

Gross postmortem by practitioner

- Economical means of confirming cause
- Diagnostic lab—for persistent or undiagnosed problems
- Educational tool for producers
- Examine all to document flock trends
- Focus control programs by classifying into four to six basic categories
- Caution: Use caution (especially women of childbearing age) when handling dead lambs and placentas, especially if abortion is a problem.

Production Management Summary

- Major losses occur early in life
 - Four major areas of loss with individual flock patterns
 - Often unable to affect change during the same lambing season
- Individual flock mortality information is a useful tool for directing disease control measures toward the appropriate management problem.
- Production goals for lamb loss
 - Less than 5% loss, difficult to achieve
 - 5%–10% range, a good goal
 - 15%–20% and up is typical
- Prevention programs should encompass environment, weather, forage resources, available markets, disease prevention,

nutrition, genetic selection, maternal behavior, and labor and facility resources.

Table 1 Gross Postmortem Guide for Categorizing Ten Common Flock Loss Patterns

Note: 2⁰ = secondary.

Suggestive Lesions/Common Observations			
External	Thorax	Abdomen	Comments
1. Stillbirth (SB)			
Term lamb by weight and wool	Adequate SQ fat cover over ribs	No excess fluid or blood	Stillborn lambs are a good "normal" for comparing and contrasting findings during other postmortem exams SB typically involves 3%–5% of the annual lamb crop Difficult to reduce below the 3%–5% level
Commercial lambs 9–11 lb	Absence of rib fractures and bruising to chest wall	Abomasum contains serum-colored fluid and no milk	
No evidence of fetal death	Absence of SQ serosanguinous fluid	Kidney fat normal amount and color (tan fat)	
Wool tight to skin	No excess fluid or blood in chest	No adhesions, abscesses, or discolored bowel	
Lack of fetid odor	Nonaerated purple-colored lung with liverlike consistency	Liver firm, intact, and not swollen	
No deformities	Normal amount of fat in coronary groove		
Covered w/ mucus			
Feet rounded and soft w/clean soles			
Umbilical cord fresh, not dry			
2. Stillbirth Related to Dystocia (Same as SB above except. . .)			
Meconium staining:	Rib fractures	Ruptured liver with blood in abdomen common	Owner history may be helpful Some lambs may exhibit small areas of partially inflated lung tissue resulting from attempts to breathe
mustard-colored mucus	• Bruising	Umbilical or abdominal herniation due to maternal straining	
Swollen tongue, head, limb, or tail	• Obvious fractures		
Found in a position suggesting dystocia	• Blood in chest from lacerated veins or arteries, usually not clotted		
	Agonal hemorrhage on pleural surface common		
3. Hypothermia/Starvation Complex (H/S)¹			
Simple Hypothermia	Simple Hypothermia	Simple Hypothermia	50% of all lambs that die during the first week of life die from H/S Complex Presence and amount of milk in abomasum can be variable. If weather severe, H/S can occur in lambs with a full stomach! Milk may also be given by owner just prior to death In older lambs, often presence of odd feed and no milk. Brown/tan fat depletion and adrenal gland changes most obvious if weather more conducive to lamb survival (i.e., lambs survives long enough for changes to occur)
Less than 6 hr old	Lungs: pink, spongy, and inflated	Abomasum: may/may not contain milk	
Often still wet	Small amount of serum-colored fluid in thorax	Perirenal tan fat present, not depleted	
Weather and exposure +/- able to rise	Coronary groove fat present	Hypothermia 2 ⁰ to starvation	
If recumbent, rounded, soft, clean soles	External rib fat not depleted: same as SB lamb	Abomasum usually empty, thick, muscular, and contracted	
If stood and walked, soles worn, hard w/ manure and dirt	Evidence of rib trauma may/may not be 2 ⁰ to H/S	Perirenal fat depleted	
Umbilical cord fresh	Hypothermia 2 ⁰ to Starvation	Kidney easily visualized	
Hypothermia 2 ⁰ to Starvation	Lungs: pink, spongy, and inflated	Depleted fat a "watery"/ dark purple color	
Over 6 hr old	Coronary groove fat depleted	Adrenal gland enlarged and easily visualized	
Usually dry	External rib fat depleted		
Severe weather exposure may/may not be present	Evidence of rib trauma may/may not be 2 ⁰ to H/S		
Evidence of standing and walking: Soles worn, hard, and coated with manure/dirt			
4. Pneumonia			
Usually > 4 hr old	Sharp line of demarcation between normal pink/spongy and consolidated red/purple affected lung tissue	Often concurrent lesions due to H/S or other causes: 1 ⁰ or 2 ⁰ cause/effect relationship	In farm flock management systems losses occur very early in life.
Usually dry	Cranioventral orientation to lesions: Abscesses +/-	Abomasal ulcers common (stress)	
Evidence of standing and walking: soles worn, hard, and coated with manure/dirt	Adhesions +/- Septicemia		
Weather often transitional	• Entire lung purple and edematous		
	• Pericardial fluid +/- fibrin clots		
	• Petechial hemorrhage on heart surface		

Suggestive Lesions/Common Observations			
External	Thorax	Abdomen	Comments
5. Abortion			
<i>Campylobacteriosis</i>	<i>Campylobacteriosis</i>	<i>Campylobacteriosis</i>	Independent of cause, most occur during last month of gestation
Previously vibriosis	Similar to SB lambs	Serosanguinous fluid SQ	Individual farm problem usually
Abortion, stillbirths, and weak lambs that die shortly after birth	Often areas of partial inflation due to immature lung function (respiratory distress syndrome)	Liver swollen (+/-)	5%–25% rate
Abortions @ 132 days of gestation	<i>Toxoplasmosis</i>	Gray/tan doughnut-shaped necrotic foci in liver	1%–2% rate considered “normal”
Fetus +/- “potbellied” appearance	Lungs vary from stillbirth, normal to mummified	<i>Toxoplasmosis</i>	Transmission oral via ingestion
Ewes not sick	Thoracic fluid: Toxoplasma titer	Variable: normal, mummified to stillbirth appearance	
Placenta unremarkable	good field diagnostic tool	<i>Chlamydia (EAE)</i>	
History: outside ewes added to flock	<i>Chlamydia (EAE)</i>	Variable: normal to stillbirth	
<i>Toxoplasmosis</i>	Lungs vary from stillbirth to normal		
Abortion, stillbirth, mummified fetuses, weak lambs, open ewes			
Mummified fetuses common			
White focal 1–2 mm lesions on cotyledons			
No intercotyledonary lesions			
<i>Chlamydia (EAE)</i>			
Abortion, stillbirth, weak lambs			
Sick ewes			
Placenta			
Necrotic cotyledon			
Thickened intercotyledonary areas			
May occur in successive years			
6. Trauma			
Fractured limbs	Fractured ribs	Ruptured liver	Suspect blood loss when generalized pallor to tissues
Owner history	Hemothorax	Hemoperitoneum	
Often 2 ^o to H/S, dystocia, and processing procedures	Punctured lung	• Liver rupture	
		• Postcastration	
		• Postdocking	
7. Scours			
<i>E. coli</i>	<i>E. coli</i>	<i>E. coli</i>	Secondary lesions consistent with H/S common
• First week of life	Normal inflated lungs	Bowel: thin, distended, fluid-filled, and discolored	Individual flock problem
• Mostly day 2 to 4	Septicemia: Petechial hemorrhage on heart surface	Perforation w/ adhesions and peritonitis often secondary	Often related to transitional weather
• Affected lambs down and dead within 24 to 48 hr	<i>Coccidiosis</i>	<i>Coccidiosis</i>	
Tail and rump area wet from scours	Normal inflated lungs	Bowel: thin, distended, fluid-filled	
Watery, white, feces			
<i>Coccidiosis</i>			
Common in 4–6-week-old lambs			
Rectal straining			
Blood in feces rare			
8. Navel-ill (Joint-ill)			
Common in lambs 10–30 days old	Normal inflated lungs	Liver abscesses	Common following transitional weather
Thin/weight loss	2 ^o pneumonia common	Peritonitis	Common in 2–3-week old lambs
Lameness/swollen, infected joints		Thick, infected umbilical vessels	

Suggestive Lesions/Common Observations			
External	Thorax	Abdomen	Comments
9. Intestinal Blockages			
Bloated, distended tight abdomen History of abdominal pain	Normal inflated lungs	Purple bowel discoloration localized to area of blockage: misdiagnosis as overeating disease Volvulus, torsion intussusception Strangulation of abdominal hernia	Common in lambs raised on milk replacer
10. Enterotoxemia (<i>Clostridium perfringens</i> type C & D)			
Sudden death	Normal inflated lungs	Type C—bowel	
Type C: 1–3-day-old lambs	Pericardial fluid +/- fibrin clots	• Milk engorged abomasum	
Similar to <i>E. coli</i> except diarrhea rare	+/- petechial hemorrhage on heart surface	• Hemorrhagic abomasitis	
Type D: lambs older than 4 weeks of age		Type D—bowel	
• Common in creep-fed and feedlot lambs		• Change often minimal	
• Exception: common in orphan lambs on replacer		• Petechial hemorrhage	
		• Purple bowel	

¹ Answer these three basic postmortem questions: (1) Did it breathe? (2) Did it nurse? (3) Fat cover?

PERIORBITAL STAPHYLOCOCCAL DERMATITIS

BASICS

DEFINITION

- Periorbital facial dermatitis is a contagious bacterial infection of sheep caused by *Staphylococcus aureus*.
- This is of major economic impact as more than 50% of a flock can be affected and affected ewes may not suckle lambs.

PATHOPHYSIOLOGY

- Caused by combination of microtrauma to the skin and rapid replication of resident *S. aureus* organisms found in the nostrils and on the skin.
- Microtrauma to the skin of the face and legs may occur from trauma that occurs during feeding at troughs or while feeding on rough pastures (i.e., thistles).
- Large numbers of bacteria are found in the exudate and readily transmitted by direct contact to other sheep.
- Death is uncommon, but the infection may invade the deep dermal and subcutaneous tissues causing sepsis and ulcers.
- Immunity is short-lived as reinfection can occur within 40 days of resolution.

SYSTEMS AFFECTED

Skin

GENETICS

N/A

INCIDENCE/PREVALENCE

- Highly contagious and up to 50% of a flock may be affected
- Most common in later winter and early spring

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Most commonly affects adult sheep, no sex or breed predisposition

- Blood smears on face are often first signs; lesions bleed easily and large amounts of blood may be found on the face and wool.
- Small ulcers at site are found upon closer inspection especially on the nasal and maxillary bones, orbital rim, ears, and base of horns.
- Lesions involve both the pigmented and unpigmented skin of the face, and are present over the nasal and maxillary bones and around the eyes, ears, and base of horns.
- Swollen, painful necrotic ulcers exuding blood and pus are found at affected sites.
- Affected sites ulcerate and may be 4–5 cm in diameter and with time will form scabs that bleed readily if removed.
- Ulcerated areas heal by granulation tissue.
- Lesions take up to 1 month to heal, and it can take several months before disease resolves in a flock.
- Staphylococcal lesions may develop on the legs, udders, and teats of affected sheep.
- Mastitis may occur in sheep if teat/udder is involved.
- Affected sheep are afebrile and have normal appetites.

CAUSES AND RISK FACTORS

- Disease is caused by various strains of *S. aureus* that produce coagulase positive alpha, beta, and gamma hemolysins.
- Organism enters skin through small penetrating wounds around the face.
- The disease is highly contagious among sheep and is spread by close head-to-head contact among sheep.
- Overcrowding, inadequate space at feed troughs, and cold, wet weather may predispose sheep to disease.

- Disease is most common in sheep housed outdoors in winter and spring.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Culture is needed to confirm diagnosis because ulcers on teats and udders can also be caused by *Pasturella haemolytica*.
- Lesions on the legs must be differentiated from dermatophilosis.
- Photosensitization caused by pithomycotoxicosis (facial eczema) occurs in the summer and autumn and is associated with liver toxicity; death is common.

CBC/BIOCHEMICAL/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

N/A

DIAGNOSTIC PROCEDURES

Bacterial culture and sensitivity and isolation of *S. aureus*

PATHOLOGICAL FINDINGS

Skin biopsy shows suppurative intraepidermal pustular dermatitis and superficial folliculitis.

TREATMENT

- Affected sheep should be separated from flock.
- Lesions will usually self-heal within several weeks.
- Individual sheep may benefit from parenteral antibiotic and hydrotherapy to remove exudate.
- Topical antibiotics and/or drying agents (iodine, chlorhexidine) applied to open ulcers may prevent secondary colonization of the lesions by other bacteria and speed healing.
- Trough space should be increased to limit contact of heads.
- Clinically affected sheep should be removed from flock to avoid spread of this contagious disease.

MEDICATIONS

Parenteral antibiotics selected through culture and susceptibility testing with sensitivity to the strain of *Staphylococcus aureus*

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

Increase space at feed troughs to minimize head to head contact.

POSSIBLE COMPLICATIONS

- Mastitis in ewes
- Reluctance of ewes to suckle lambs

EXPECTED COURSE AND PROGNOSIS

Outbreaks in a herd/flock may take several months to run their course.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Mastitis

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

S. aureus is a primary bacterial pathogen of humans, and although there are no known reports of transmission from sheep to people, gloves should be worn when handling affected sheep.

PESTE DES PETITS RUMINANTS

BASICS

Peste des petits ruminants (PPR) is an acute viral disease of small ruminants, especially goats. The course of the disease is similar to rinderpest in cattle and the two viruses are closely related.

PATHOPHYSIOLOGY

- PPR virus is transmitted by close contact and is present in ocular, nasal, oral, and fecal secretions.
- Most infections occur through inhalation of aerosols, and the virus invades the body through the upper respiratory tract epithelium. Fomites may play a role in infection.
- Once in the body, the virus has an affinity for lymphoid and epithelial tissue.
- Animals may be infectious during the incubation period, which lasts from 3 to 10 days, but no known carrier state exists.
- Sheep are less susceptible to PPR than goats.
- A peracute form with higher mortality occurs frequently in goats.

SYSTEMS AFFECTED

- Gastrointestinal—oral cavity, esophagus, abomasums, small intestine, large intestine
- Respiratory—nasal cavity, larynx, trachea, lungs
- Ophthalmic—conjunctiva
- Hemic/lymphatic/immune—spleen

GENETICS

N/A

INCIDENCE/PREVALANCE

- The prevalence of PPR in enzootic areas is low with new infections existing continuously.
- Epizootics may occur when a susceptible population moves into the area and are often characterized by ~100% mortality among sheep and goats.

GEOGRAPHIC DISTRIBUTION

PPR is found in west and central Africa, the Middle East, and India.

SIGNALMENT

Species

Goats, sheep, cattle, gazelle, gemsbok, deer

Breed Predilections

None

Mean Age and Range

4–8 months; all ages

Predominant Sex

None

- Decreased appetite
- Serous nasal discharge that becomes mucopurulent—may be profuse and block nasal passages
- Matted eyelids
- Diarrhea—profuse but nonhemorrhagic
- Coughing
- Dull coat
- Dry muzzle

- Abortions

PHYSICAL EXAMINATION FINDINGS

- Serous nasal discharge that becomes mucopurulent—may be profuse and block nasal passages
- Fever—104–106°F (40–41°C)
- Necrosis of nasal mucous membranes
- Necrotic foci on the gingiva, dental pad, hard palate, cheeks and associated papillae, and tongue
- Putrid odor of the mouth
- Diarrhea—profuse but nonhemorrhagic
- Congested conjunctiva
- Dyspnea
- Coughing
- Dehydration
- Emaciation

PPR is caused by PPRV, which is a paramyxovirus of the genus *Morbillivirus*. It is antigenically very similar to the rinderpest virus.

RISK FACTORS

Poor nutritional status, stress from movement, and concurrent parasitic and bacterial infections may enhance the severity of disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rinderpest
- Pasteurellosis
- Foot-and-mouth disease
- Nairobi sheep disease
- Contagious caprine pleuropneumonia
- Contagious ecthyma
- Bluetongue
- Heartwater
- Coccidiosis
- Plant or mineral poisoning

CBC/BIOCHEMISTRY/URINALYSIS

None

OTHER LABORATORY TESTS

- Virus isolation from clear tears, noncoagulated blood, or antibiotic-treated erosion debris
- Hemagglutination inhibition test using tears and nasal fluids
- Virus neutralization of neutralizing antibodies
- ELISA of serum for neutralizing antibodies
- AGID of serum for neutralizing antibodies
- PCR
- Paired sera samples showing a fourfold or greater rise in antibody titer

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Virus isolation—unclothed blood, lymph nodes, tonsils, spleen, and lungs
- Immunohistochemistry—mesenteric lymph nodes, spleen, lung, tonsils, ileum, and large intestine

- Samples should be placed on frozen cold packs and delivered to the laboratory within 12 hours of necropsy.

PATHOLOGIC FINDINGS

Gross Lesions

Emaciation; conjunctivitis; erosive stomatitis of the lower lip, gingiva, tongue; commissures of the mouth, hard palate, pharynx, and upper third of the esophagus; erosions of the abomasum; mild erosions in the small intestine; severe ulceration of Peyer's patches; congestion around the ileocecal valve, ceco-colic junction, and in the rectum; congestion of the mucosal folds in the colon and rectum ("zebra stripes"); small erosions and petechiae of the nasal mucosa, turbinates, larynx, and trachea; lung infiltration; enlarged and congested spleen

Histopathology

Multinucleated giant cells with inclusions in the lungs; empty germinal centers in lymph nodes; eroded mucosa in oral and nasal cavities, gastrointestinal tract, and lungs; bronchopneumonia with consolidation and atelectasis

TREATMENT

APPROPRIATE HEALTH CARE

- No specific treatment for individual animals
- Control of secondary bacterial and parasitic infections
- Herd preventative care—vaccination with attenuated Nigerian 75/1 isolate of PPR in some parts of the world; not available in the United States

NURSING CARE

Infected animals should be provided with basic supportive care by replacement of lost fluids and restoration of electrolytes.

ACTIVITY

Restrict movement to prevent respiratory distress

DIET

Avoid feeding rough/coarse feeds to reduce irritation to mucosal erosions

CLIENT EDUCATION

Clients need to be educated in the importance of vaccination to prevent infection in countries where it is approved for use.

SURGICAL CONSIDERATIONS

None

MEDICATIONS

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Animals should be monitored for respiratory distress due to blocked nasal passages.

PREVENTION/AVOIDANCE

Animals in endemic areas should be vaccinated with the attenuated Nigerian 75/1 isolate of PPR. The vaccine is protective for approximately 1 year.

POSSIBLE COMPLICATIONS

Exposure of naïve flocks/herds of sheep or goats to wild-type PPR may result in 100% mortality.

EXPECTED COURSE AND PROGNOSIS

- Animals suffering from acute PPR usually have a poor prognosis. The severity and outcome of the disease is correlated with the extent of the lesions in the mouth.
- Lesions that resolve in 2–3 days have a good prognosis.
- Respiratory symptoms and foul mouth odor are indicative of a poor prognosis.
- Recovered animals are immune for life.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Secondary bacterial and parasitic infections

AGE-RELATED FACTORS

Young animals, 4–8 months of age, often have worse clinical disease than adult animals.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Abortions may occur in pregnant animals.

PETROLEUM PRODUCT POISONING

BASICS

DEFINITION

Ingestion, inhalation, or topical administration of petroleum products resulting in morbidity and mortality

PATHOPHYSIOLOGY

- Naturally occurring and refined petroleum products exist in complex mixtures often containing hundreds of compounds contributing to variability in clinical signs, pathology, and outcome.
- Products with highly volatile hydrocarbon fractions (e.g., gasoline, kerosene) are more likely to result in aspiration after ingestion compared to compounds of low volatility or high viscosity.
- Exposed or weathered products are less toxic if the volatile fractions have had time to evaporate.
- Ingestion of unweathered, highly volatile, petroleum products target the lung either by eructation and inhalation, aspiration during emesis, or hematogenous exposure.
- Hypoxia, chemical pneumonia, and aspiration pneumonia are the most common sequelae.
- The gastrointestinal tract, liver, kidney, and brain are also targeted. Expansion of hydrocarbon in the rumen results in bloat and rumen stasis.
- Petroleum products and associated chemical additives are caustic to gastrointestinal mucosa resulting in gastroenteritis, colitis, mucosal edema, and hemorrhage.
- Dermal lesions occur when petroleum products are applied topically or used as a vehicle for insecticide sprays or dips resulting in contact dermatitis.

SYSTEMS AFFECTED

- Cardiovascular—dehydration, increased or decreased heart rate, arrhythmia, cardiac arrest
- Endocrine/metabolic—pyrexia
- Gastrointestinal—anorexia, salivation, vomiting, decreased rumen motility, bloat, oil in feces and rumen contents, diarrhea or constipation
- Hemic/lymphatic/immune
- Hepatobiliary
- Herd health—milk tainted with fuel odor, decreased milk production
- Musculoskeletal—reluctance to move, recumbency, weight loss, lameness
- Nervous—depression, excitability, shivering, head tremors, ataxia, decreased menace response and palpebral reflex, opisthotonos, coma, death
- Ophthalmic—blindness
- Renal/urologic
- Reproductive—abortion
- Respiratory—tachypnea, dyspnea, aspiration pneumonia, fuel/oil odor to breath, coughing
- Skin—blistering, drying, cracking, unthrifty

GENETICS

None

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Common in areas where animals and oil production or petroleum waste exist within close proximity

SIGNALMENT

Breed Predilections

None

Mean Age and Range

None

Predominant Sex

None

SIGNS GENERAL COMMENTS

Clinical signs or death commonly seen within 24 hours after ingestion

HISTORICAL FINDINGS

- Animals may be found dead; multiple animals are usually affected; younger animals may be more at risk due to curiosity and inquisitive nature.
- Animals that survive may do poorly for weeks after exposure.

PHYSICAL EXAMINATION FINDINGS

Oily, nasal discharge, dyspnea, tachypnea, petroleum odor on breath and feces, decreased rumen motility, bloat, recumbency, displaced abomasum, CNS signs, sudden death

CAUSES

- Ingestion or inhalation of petroleum products
- In cattle, reported toxic doses of unweathered oil and weathered oil are 2.5–5.0 ml/kg BW and 8.0 ml/kg BW, respectively.
- Experimental exposure of goats to kerosene resulted in morbidity at 10 and 20 ml/kg BW and mortality at 40 ml/kg BW.

RISK FACTORS**Environmental Factors**

- Contamination of feed or water supply by petroleum product as a result of broken pipes; leaky valves; heating, fuel, or lubricating oil spills; contact with drilling muds and fluids; or leaking fuel storage tanks.
- Direct access to petroleum drilling slush or mud pits, used motor oil, or road-oil used for dust control are risk factors.
- Rainfall may bring petroleum products to water or soil surface long after a spill occurs.
- Poor-quality pasture may contribute to ingestion; however, animals willingly consume large volumes of petroleum even if uncontaminated, good-quality feed and water are available.

Animal Factors

- Age, preexisting health, hydration, and nutritional status, duration of exposure, duration of time to treatment
- Direct application of petroleum product either topically or by drench may result in toxicosis.

Petroleum Factors

Amount of petroleum product consumed, viscosity, volatility (higher volatility and lower viscosity increases the likelihood of aspiration), chemical composition of product, toxicity of chemical additives, weathered (less toxic) vs. unweathered product (more toxic)

**DIAGNOSIS**

- History of exposure and petroleum odor on breath and in feces is supportive.
- Gas chromatography of GI contents and suspected source is diagnostic.

DIFFERENTIAL DIAGNOSIS

Lead or other heavy metal exposure, chemicals used in petroleum extraction, organophosphate ester poisoning

CBC/BIOCHEMISTRY/URINALYSIS

Results vary with exposure

- Increased PCV, HGB, Fib, TPP, leukopenia initially followed by leukocytosis
- Elevated AST, GGT, BUN, creatinine, LDH, CPK, cholesterol
- Decreased potassium, calcium, glucose

OTHER LABORATORY TESTS

- Gas chromatography “fingerprinting” of rumen contents or liver, lung, or kidney tissue, and the suspected source of poisoning
- Heavy metal analysis of liver, GI contents, kidney, and brain to rule out other causes
- Acetylcholinesterase level in blood and brain tissue to rule out organophosphate toxicity

IMAGING

Thoracic radiography in smaller ruminants has prognostic value.

DIAGNOSTIC PROCEDURES

Tracheal wash and culture

PATHOLOGICAL FINDINGS GROSS PATHOLOGY

Respiratory Tract

Cranial and middle lung lobe most often affected; consolidation, dark red to purple, mottled, abscesses, lesions are usually bilateral, serofibrinous exudate, pleural adhesions, tracheitis.

Gastrointestinal

Esophagitis, bloat, enteritis, colitis, foul odor to GI tract, petechial hemorrhages of GI tract, bloody intestinal contents.

Histopathological Lesions

- Lung—necrotizing bronchopneumonia
- GI tract—mucosal and submucosal congestion and mucosal and serosal hemorrhage
- Heart—myocardial degeneration and necrosis, mineralization, congested myocardial and epicardial blood vessels, infiltrations of lymphocytes, macrophages, and neutrophils
- Kidney—renal tubular degeneration, interstitial nephritis, granular eosinophilic casts mixed with inflammatory cell infiltrates, renal vessel thrombi
- Liver—periportal fatty degeneration and periportal infiltration of lymphocytes and plasma cells, bile duct hyperplasia
- Brain—meningeal hyperemia, meningeal/choroid edema, parenchymal hemorrhage

TREATMENT

Remove from source; use esophageal tube to relieve bloat (use of a trocar increases risk of peritonitis); administer saline laxative.

APPROPRIATE HEALTH CARE NURSING CARE

IV fluids may be helpful, supportive care by system.

ACTIVITY

Restrict activity.

DIET

Modifications to diet will depend on rumen motility. Some animals continue to eat but are depressed, while others will be anorectic for days to weeks.

CLIENT EDUCATION SURGICAL CONSIDERATIONS

Rumenotomy and transfaunation may be indicated.

MEDICATIONS

DRUGS OF CHOICE

Broad-spectrum antibiotics, IV or IM for more than 7 days may be indicated.

CONTRAINDICATIONS

- Rumen lavage via orogastric or nasogastric tube increases risk of aspiration.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing

animals.

POSSIBLE INTERACTIONS ALTERNATIVE DRUGS

Sheep who received artificial surfactant administered intratrachially after experimental exposure to kerosene via direct application to lungs have improved outcome over control animals.

FOLLOW-UP

PATIENT MONITORING

Physical examination and routine bloodwork as warranted by clinical findings.

PREVENTION/AVOIDANCE

- Fence off areas to keep animals away from potential sources.
- Locate petroleum storage tanks more than 500 feet and downhill from well or surface water.
- Inspect all tanks, pipes, and valves associated with petroleum storage and extraction facilities regularly for corrosion and leakage.
- Place used oil in secure containers prior to disposal.
- Do not reuse petroleum storage containers for feed or water.

POSSIBLE COMPLICATIONS EXPECTED COURSE AND PROGNOSIS

- Highly variable depending on type of compound and severity of exposure
- Some animals that survive the initial exposure will have few clinical signs while others will do poorly for weeks to months requiring culling or euthanasia.
- Animals with aspiration pneumonia have a guarded to poor prognosis.

MISCELLANEOUS

RELATED CONDITIONS

AGE-RELATED FACTORS

ZOONOTIC POTENTIAL

- Inhalation of petroleum vapors is potentially toxic.
- Many compounds associated with petroleum products are known carcinogens.

PREGNANCY

Abortions have been attributed to petroleum exposure.

RUMINANT SPECIES AFFECTED

All ruminant species are susceptible.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Poor-quality pasture may contribute to ingestion; however, animals willingly consume large volumes of petroleum even if uncontaminated, good-quality feed and water are available.
- Fence off areas to keep animals away from potential sources.

PHARMACOLOGY OF MASTITIS: BOVINE

BASICS

OVERVIEW

- Mastitis is inflammation of the mammary gland caused by a pathogenic organism.
- Clinical mastitis is characterized by abnormal milk composition, gland swelling and/or pain, and/or illness of the cow. Bacteria are generally present in this milk. Decreased milk production is observed.
- Subclinical mastitis is characterized by seemingly normal milk with an increase in somatic cell count (SCC), and can also be determined by culturing high SCC milk. Bacteria are present in this milk. Decreased milk production is observed.
- Chronic mastitis is characterized as an infection that has a long duration and may show periodic clinical symptoms.
- Mastitis-control programs that are effective and cost efficient rely heavily on prevention rather than on treatment.
- Therapeutic intervention may be a necessary part of most control programs and may include antibacterial treatment as well as anti-inflammatory therapy.
- Homeopathy and other alternative therapies may offer improved and complementary mastitis treatment options.

SIGNS

N/A

CAUSES AND RISK FACTORS

Contagious Mastitis

The major causes are *Streptococcus agalactiae* and *Staphylococcus aureus*. The major reservoir for these pathogens is infected udders.

- *Corynebacterium bovis* is a minor contagious mastitis pathogen that spreads rapidly in cases where proper teat dipping programs are not in place.
- *Mycoplasma* species are also contagious pathogens—of greatest concern is *M. bovis*.
- *Streptococcus dysgalactiae* is usually considered an environmental pathogen but is spread from cow to cow like other contagious pathogens.

Environmental Mastitis

Pathogens of an environmental origin can cause environmental mastitis.

- These pathogens include gram-negative rods (*Serratia* sp., *Pseudomonas* sp., and *Proteus* sp.), coliforms (*Escherichia coli*, *Klebsiella* sp., and *Enterobacter* sp.), and streptococci other than *agalactiae* (these organisms are usually referred to as environmental streptococci).
- Of these environmental streptococcal species, the most commonly isolated is *Strep. uberis*.

DIAGNOSTIC PROCEDURES

N/A

TREATMENT

- Preventative measures for the control of mastitis caused by contagious bacteria (*Streptococcus agalactiae* and *Staphylococcus aureus*) should include the development of a program to prevent spread at milking time and culling or isolating chronic cows.
- Preventative measures for the control of mastitis caused by environmental bacteria center around controlling the number of bacteria to which the teat is exposed. A cow's environment should be clean and dry and free of manure, mud, or pools of standing water. Free stalls should be designed and maintained properly. Bedding materials should be selected to limit the amount of nutrients available to environmental bacteria—sand or crushed limestone will be lower in nutrients and moisture and therefore lower in bacteria.
- Germicidal teat dip, both premilking and postmilking, should be routinely used to prevent contagious and environmental mastitis.
- Proper milking procedures should be followed and all equipment needs to be adequately cleaned and maintained.
- Culling is a necessary part of any mastitis control program. It will help by eliminating the source (the infected cow) of contagious bacteria—mainly *Mycoplasma* spp. and *Staph. aureus*. Hopeless cases of mastitis should not be treated. Cases of mastitis caused by *Nocardia* spp., *Prototheca* spp., *Serratia* spp., *Pseudomonas* spp., *Actinomyces* spp., *Mycobacterium* spp., yeasts, fungi, and other unusual pathogens are usually not responsive to antibiotic therapy and culling is the next logical choice in preventing the spread of infection to the rest of the herd.
- Segregation may be useful in herds that have significant *Mycoplasma* or *Staph. aureus* problems. However, this can be expensive because infected cows need to be identified. Culturing milk samples routinely does this. In order for this to be effective, infected cows must be identified early and accurate maintenance records must be kept.

MEDICATIONS

DRUGS OF CHOICE

- Therapeutic management of clinical mastitis should address the efficacy of the drug, the economics of the treatment, and the possible residues left in the milk after treatment. *Culture and sensitivity results should be evaluated for mastitic*

organisms prior to implementing a treatment program.

- **Dry cow therapy:** treatment of all quarters is recommended after the last lactation with commercial intramammary (IMM) antibiotics to reduce the number of new infections during the dry period. This is more effective than treatment during lactation because higher doses of antibiotics can be used without risk of residues ending up in milk.
- **Treatment during lactation:** mastitis control based solely on therapy during lactation can be very expensive and is not very effective. Preventative measures should be the most important part of a mastitis control program. This method of mastitis treatment has been successful in herds with *Strep. agalactiae*. Antibiotic treatment of cows during lactation infected with *Staph. aureus* is of limited value. Cure rates are usually less than 50%. *Mycoplasma* infections are not responsive to antibiotic therapy.
- Aminoglycosides and cephalosporins may have a high proportion of susceptible isolates in vitro, and because of this, they are often selected for use in treating coliform mastitis.
- Ceftiofur sodium may be useful against gram-negative pathogens to help prevent or treat systemic infections. Because it does not diffuse into the mammary gland, it is approved for use in lactating cows if the labeled dose of 1–2.2 mg/kg q 24 hours is administered intramuscularly, and no milk withholding time is required. Ceftiofur is not recommended for intramammary infusion.
- Dietary vitamin E and selenium may help in reducing the incidence of environmental mastitis, especially in dry cows. It is recommended that dry cows receive 1000 IU supplemental vitamin E per cow per day and that lactating cows receive 400 to 600 IU per cow per day. The selenium content of the diet should be 0.3 ppm for lactating cows and dry cows.
- Endotoxin-induced shock is a primary problem in cases of coliform mastitis and the infected cow may benefit most from fluid therapy and not antibiotic treatment.
- Anti-inflammatory drugs may be helpful when used to treat acute environmental mastitis. These are cyclooxygenase inhibitors (nonsteroidal anti-inflammatory drugs) and corticosteroids. There is no evidence that the treatment with anti-inflammatory drugs positively affects the survival or production of the cow.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) have been advocated for the relief of symptoms of endotoxic shock and in therapy of coliform mastitis. Aspirin, flunixin meglumine, phenylbutazone, ibuprofen, carprofen, and flurbiprofen have all been used in experimental coliform mastitis and in experimental endotoxin-induced mastitis.
- Dexamethasone, fluoroprednisolone, betamethasone, and flumethasone have also been utilized in treating animals experimentally challenged with coliform mastitis.
- Vaccines: J-5 (R mutant) *E. coli* antigen vaccines are used to enhance resistance to intramammary coliform infections. Administration of the vaccine during the dry period has been reported to reduce the severity of coliform infections in intramammary challenge studies with *E. coli*.
- There is no vaccine that has proven successful in controlling mastitis caused by environmental streptococcus.

Antibiotic Treatment for Gram-Negative Bacteria

The following are antibiotic treatment options for acute mastitis caused by gram-negative bacteria. In some cases they have proven effective against some gram-positives as well. Culture and sensitivity results should be evaluated for mastitic organisms prior to implementing a treatment program.

- Sulfadiazine/trimethoprim or sulfadoxine/trimethoprim: 25 mg/kg IV or IM once daily for 2–4 days and polymyxin B sulfate 100 mg (cir. 8000 IU) or colistin sulfate 100 mg (cir. 20,000 IU) in 10–20 mL water for intramammary injection once daily for 2 or 3 days.
- Gentamicin sulfate 5 mg/kg IV or IM once daily for 3–5 days and gentamicin sulfate 100–150 mg intramammary once daily for 2 or 3 days.
- Ampicillin trihydrate 10 mg/kg IM twice daily for 2 or 3 days and cephalirin sodium 200 mg intramammary after each milking for three consecutive milkings.
- Polymyxin B sulfate or colistin sulfate 5 mg/kg IM twice daily for 2 days and cephalirin sodium 200 mg intramammary after each milking for three consecutive milkings.

Antibiotic Treatment for Gram-Positive Bacteria

The following are antibiotic treatment options for acute mastitis caused by gram-positive bacteria. Culture and sensitivity results should be evaluated for mastitic organisms prior to implementing a treatment program.

- Sulfadiazine/trimethoprim or sulfadoxine/trimethoprim 25 mg/kg IV or IM once daily for 3–5 days and hetacillin potassium 62.5 mg or amoxicillin sodium 62.5 mg intramammary after each milking for six consecutive milkings.
- Ampicillin trihydrate 10 mg/kg IM twice daily for 3–5 days and cloxacillin sodium 200 mg intramammary after each

milking for six consecutive milkings.

- Erythromycin lactobionate or tylosin tartrate 10 mg/kg loading dose IV followed by erythromycin base or tylosin base 5 mg/kg IM twice daily for 3–5 days and erythromycin 300 mg intramammary after each milking for six consecutive milkings.
- Sulfamethazine sodium 100 mg/kg loading dose IV, followed by 50 mg/kg IV once daily for 3–5 days and amoxicillin sodium 62.5 mg intramammary after each milking for six consecutive milkings or cloxacillin sodium 200 mg intramammary after each milking for six consecutive milkings or procaine penicillin 100,000 IU intramammary after each milking for four to six consecutive milkings.

Homeopathy and Other Alternative Therapies

- Antibiotics are widely used in the treatment and prophylaxis of mastitis, but their antibacterial and therapeutic efficacy continues to decrease. New methods of mastitis prophylaxis including the use of vaccines and biological response modifiers have been reviewed.
- Different methods of immunomodulation for the prevention of mastitis have shown promise in experimental trials. Improving nutrition, housing, and the environment of dairy cattle are still crucial in the prevention of mastitis, especially during the most susceptible postparturient period.
- Other alternative immunomodulators that have shown promise in mastitis treatment during the lactating period include herbal gels, herbal extracts, ginseng, saponin, propolis, and antibacterial proteins.
- In a Swedish study on the effect of subcutaneous injections of ginseng on cows with subclinical *Staphylococcus aureus* mastitis, the results indicate that ginseng treatment can activate the innate immunity of cows and may contribute to the cow's recovery from mastitis. Ginseng may have potential to stimulate immune function in dairy cows.
- Anecdotally, combinations of silica, phytolacca, belladonna, *Calcarea fluorica*, bryonia, ipecacuanha, arnica, and conium have been found effective in the medical management of mastitis.
- Increasing the ongoing desire to decrease the use of antibiotic drugs, to cut down on treatment expense, and to find alternative treatment solutions when regular conventional therapies are not successful are factors that have increased interest in alternative therapies.
- Scientific research is needed to evaluate alternative therapeutic efficacy of currently used treatments.
- Qualified, well-trained homeopaths or herbalists are needed to assure quality treatment results.
- Complementary therapies such as homeopathy and alternative therapies are becoming increasingly needed in veterinary medicine today.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered.

FOLLOW-UP

N/A

POSSIBLE COMPLICATIONS

- Untested combinations of products should not be used.
- Compounding of intramammary products is illegal and may result in violative antibiotic residues in both meat and milk.
- Multiple dose containers should never be used between mammarys due to the risk of contamination with organisms such as *Mycoplasma* spp. or *Staph. aureus* that can be spread to other quarters or other cows in the herd. These bacteria are not susceptible to antibiotic therapy.
- Great care should be used when infusing dry cow products through the streak canal because environmental contaminants may be inadvertently forced through the canal and cause additional infections. Environmental contaminants are not susceptible to dry cow treatment products.
- Products approved by the FDA for use during lactation are uniformly ineffective against coliform bacteria.

PHENOXYL TOXICITY

BASICS

OVERVIEW

- These are chlorophenoxylic herbicide compounds, such as 2,4-D and MCPA. They are used to control weeds and aquatic plants, to increase fruit durability in storage, and to prevent premature fruit dropping. Exposure is from accidental ingestion of concentrates or sprays, occasionally from chronic ingestion of treated forages. These herbicides are relatively nontoxic unless ingested in a concentrated form.
- Repeated and massive doses are needed to cause poisoning in ruminants.
- These agents can cause liver and kidney failure, hypotension, and increased cancer risk; also can see hemolysis.
- Types—2,4-D, 2,4-DB, dalapon, MCPA, Sivex, 2,4,5-T
- The advent of commercial farming prompted the development of selective weed control chemicals. These organic herbicides are plant growth regulators altering the metabolism of plants and are associated with potential teratogenicity.
- A side effect of the compound's use is the increased levels of nitrates or cyanide in plants that can cause secondary poisoning to ruminants prior to the plants death.
- Some toxic weeds become more palatable after treatment such as jimsonweed and nightshade.
- Essentially, usage has been stopped because of the toxic contaminants of dioxins (TCDD, HCDD).

SIGNALMENT

- Ten days exposure is required to produce poisoning.
- Calves have been poisoned by a single oral dose of 200 mg/kg BW.

SIGNS

- See clinical signs from massive and repeated exposures.
- Anorexia, depression, rumen atony, muscle weakness, especially hind limbs
- Diarrhea, ulceration of oral mucosa, bloating
- Animals progressively become emaciated and moribund.

CAUSES AND RISK FACTORS

- Feeding up to 2000 ppm herbicide in the diet amounted to 1 ppm in liver and kidneys and < 0.05 ppm in the muscle and fat.
- Herbicide residues are not likely to be at >300 ppm in or on forage immediately after treatment at recommended rates for brush and weed control. Residues decline rapidly. The forage $t_{1/2}$ is 1–2 weeks.
- Meat residues occur only with extremely high exposure during continuous ingestion of freshly treated vegetation.
- Withdrawal of animals from treated forages for 1–2 weeks prior to slaughter should decrease any residues.
- Herbicide-treated forages don't seem to affect rumen microbial functions or development in the rumen; they are not readily degraded by ruminal microorganisms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Mb toxicity/Cu deficiency
- Severe parasitism
- Diseases causing anorexia, depression, rumen atony, muscle weakness, especially hind limbs
- Diseases causing diarrhea, ulceration of oral mucosa, bloating

- Abomasal torsion
- Acidosis/grain overload
- Bovine viral diarrhea virus (BVD)
- Cathartic/laxatives
- Coccidiosis
- Colitis/typhilitis
- Displaced abomasum
- Enteritis
- Heart failure
- Indigestion
- Intussusception
- Jejunal hemorrhage syndrome
- Johne's disease
- Liver failure
- Malignant catarrhal fever
- Molybdenosis/copper deficiency
- Parasitism
- Parasympathomimetic drugs
- Peritonitis
- Poisonous plants: acorn (oak), *Brassica* spp., fungal toxicity, mushroom, oleander, pokeweed, pyrrolizidine alkaloids, rattlebox, selenium accumulators, *Solanum* spp., St. John's wort
- Salmonellosis
- Sepsis/toxemia/enterotoxemia
- Toxins: aflatoxin, arsenic, chlorpyrifos (Dursban), copper, herbicides, levamisole, lincomycin, monensin, nicotine, phosphorus fertilizers, propylene glycol, sodium bicarbonate, sulfur, trichothecene, zinc
- Uremia/renal failure
- Winter dysentery
- Xylazine, large doses
- Diseases causing weight loss and emaciation

CBC/BIOCHEMISTRY/URINALYSIS

- Major elimination by the kidneys
- CBC/biochemistry/urinalysis is indicated to monitor parameters for treatment.
- No parent compounds or metabolites found in milk from orally dosed cattle.

OTHER LABORATORY TESTS

High levels of compound in kidney and liver, decreased levels in fat and muscle

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Feed analysis, chemical analysis

PATHOLOGICAL FINDINGS

- Epicardial hemorrhage
- Hydropericardium
- Bright green, undigested feed from ruminal stasis
- Liver swollen, friable
- Kidneys congested
- Hyperemia, enlargement of lymph nodes and mesenteric vessels
- High levels in liver and kidney, decreased levels in fat and muscle

TREATMENT

- Activated charcoal, alkaline diuresis
- Control seizures; diazepam, phenobarbital

MEDICATIONS

DRUGS OF CHOICE

Control seizures: diazepam, phenobarbital

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

- Keep toxic chemicals away from livestock. Do not apply toxic chemicals to fields or crops on which animals may feed.
- Consult manufacturer and FARAD if accidental exposure occurs.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PREVENTION/AVOIDANCE

- Withdrawal of animals from treated forages for 1–2 weeks prior to slaughter would decrease any residues.
- Meat residues occur only with extremely high exposure during continuous ingestion of freshly treated vegetation.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Depends on quantity ingested; fair to poor depending on treatment and amount of agent consumed.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- A side effect is the increased levels of nitrates or cyanide in plants that can cause secondary poisoning before the plant dies.
- Some toxic weeds become more palatable after treatment, such as jimsonweed and nightshade.

PHOSPHORUS DEFICIENCY/EXCESS

BASICS

DEFINITION

- Phosphorus (P) deficiency = a disorder (hypophosphatosis) caused by decreased total body P, which can manifest with reduced serum P concentrations (hypophosphatemia $\sim < 2.0$ mg/dL) below the established reference interval for a particular species and breed.
- Phosphorus excess = a condition reflected by elevated serum P concentrations (hyperphosphatemia $\sim > 6.0$ mg/dL) above the established reference interval for a particular species and breed due to endogenous or exogenous etiologies.

PATHOPHYSIOLOGY

- Altered bone growth and mineralization disorders are the primary manifestation related to P deficiency and excess with a few key exceptions.
 - Liver toxicosis with white/yellow P ingestion
 - Postparturient hemoglobinuria (PPH) with dietary P deficiency
- 80% of the P in the body is stored in bones and teeth of which 90% is stored in the form of hydroxyapatite used to form the mineralized matrix of bone.
- Remaining 20% of body P is in intracellular soft tissues (minor extracellular-serum portion) where it is involved in critical roles.
 - Maintenance of cellular structural proteins (phospholipids, nucleic acids, phosphoproteins)
 - Cellular energy transfer and storage and muscle contraction (ATP, ADP, AMP)
- Ruminant's absorption of dietary P primarily in the forestomachs and loss of excess body P via saliva (predominant) and urine with hormonal influence on both absorption and excretion. Grains generally lower in P concentration than forage and plant concentration correlates with soil concentration.
- Typical serum P assays measure only inorganic fraction (P_i), which exists in several forms (predominately HPO_4^{2-} and $H_2PO_4^-$ in a 4:1 ratio).
- There is rapid translocation between the intracellular and serum P pools. Serum P_i measurement is an unreliable indicator of total body P stores.
 - Hypophosphatemic animals likely have reduced body stores of P
 - Animals with reduced body stores of P may not be hypophosphatemic
 - Serum P_i concentrations influenced by the following variables:
 - Rate of renal clearance—decreased glomerular filtration rate (GFR) leads to elevation of serum P_i
 - Rate of renal tubular reabsorption
 - (1) Parathyroid hormone (PTH) decreases tubular reabsorption, decreasing serum P_i
 - (2) Calcitonin hormone decreases tubular reabsorption, decreasing serum P_i
 - (3) Growth hormone (GH) increases tubular reabsorption, increasing serum P_i
- Rate of gastrointestinal (GI) absorption
 - (1) 1,25-dihydroxycholecalciferol (1,25-DHCC, calcitriol, active vitamin D) increases GI absorption, increasing serum P_i
 - (2) Reduced dietary P results in decreased GI absorption, decreasing serum P_i
- Shift from serum pool to intracellular pool—insulin, carbohydrate loads, respiratory alkalosis shifts serum P_i to the intracellular pool, decreasing serum P_i
- Resorption rate of bone—PTH increases osteocyte and osteoclast release of P from bone

- Age of animal—younger animals have increased GH levels, which increases tubular reabsorption, increasing serum P_i

Regulation of P absorption/secretion

- Decreased serum P_i >
- Increased active vitamin D from the kidney > increased GI P and Ca absorption > increases serum P_i and Ca
- Increased serum Ca >
 - (a) Decreased PTH from parathyroid gland >
 - (1) Increased renal tubule reabsorption of P > increases serum P_i
 - (2) Decreased P secretion in saliva > decreased GI loss of P > increases serum P_i
 - (b) Increased calcitonin from thyroid C cells > decreases renal tubule reabsorption of P and Ca > decreases serum P_i and Ca
- Increased serum P_i >
 - (1) Decreased active vitamin D from the kidney >; decreased GI P and Ca absorption >; decreases serum P_i and Ca
 - (2) Decreased serum Ca >;
 - (a) Increased PTH from the parathyroid gland >;
 - (1) Decreased renal tubule reabsorption of P >; decreases serum P_i
 - (2) Increased P secretion in saliva >; increased GI loss of P >; decreases serum P_i
 - (b) Decreased calcitonin from thyroid C cells >; increased renal tubule reabsorption of P and Ca >; increases serum P_i and Ca

SYSTEMS AFFECTED

- Bone
 - P deficiency: osteopenia (reduced bone mass), osteomalacia (demineralized matrix), rickets (defective endochondral ossification, accumulation of unmineralized matrix)
 - P excess: osteodystrophia fibrosa (fibrous connective tissue replaces cortical bone)
- Red blood cells—hemolysis (P deficiency)
- White blood cells—reduced chemotaxis and phagocytosis (P deficiency)
- Muscle—weakness (P deficiency)
- Liver—periportal necrosis (white/yellow P toxicity)/central lobular necrosis (PPH)
- Reproduction—reduced reproductive rates (P deficiency)

GENETICS

N/A

INCIDENCE/PREVALENCE

- P deficiency: hypophosphotosis and hypophosphatemia: sporadic, 1–2 in herd
- P excess: P toxicosis and hyperphosphatemia: sporadic

GEOGRAPHIC DISTRIBUTION

P Deficiency: Hypophosphotosis and Hypophosphatemia

- Osteomalacia/rickets: worldwide but most cases South Africa, Australia, New Zealand, and dry tropical regions (regional soils deficient in P); southern and northern latitudes (reduced levels of sunlight with reduced amounts of active vitamin D)
- PPH: worldwide; North America, New Zealand

P Excess: P Toxicosis and Hyperphosphatemia

Osteodystrophia fibrosa/P toxicosis: worldwide

SIGNALMENT

Species

- P deficiency: hypophosphotosis and hypophosphatemia
 - Osteomalacia/rickets: all ruminants; cattle >; sheep and goats
 - PPH: cattle
- P excess: P toxicosis and hyperphosphatemia—osteodystrophia fibrosa: all ruminants; goats >; cattle and sheep

Breed Predilection

- P deficiency: hypophosphotosis and hypophosphatemia
 - Osteomalacia/rickets: N/A
 - PPH: dairy cattle
- P excess: P toxicosis and hyperphosphatemia—osteodystrophia fibrosa: N/A

Mean Age and Range

- P deficiency: hypophosphotosis and hypophosphatemia
 - Osteomalacia: older adult
 - Rickets: growing young <1 year
 - PPH: North America—older adult (3–10 years, within 6 weeks of calving), New Zealand—any age adult
- P excess: P toxicosis and hyperphosphatemia—osteodystrophia fibrosa:

N/A

Predominant Sex

- P deficiency: hypophosphotosis and hypophosphatemia
 - Osteomalacia/rickets: N/A
 - PPH: cow
- P excess: P toxicosis and hyperphosphatemia—osteodystrophia fibrosa/P toxicosis: N/A

SIGNS

P Deficiency: Hypophosphotosis and Hypophosphatemia

- Osteomalacia: shifting lameness, poor growth rate, dull hair coat, decreased feed consumption, weight loss, reduced milk production, reduced reproductive performance, pica, kyphosis, lordosis, spontaneous nonhealing fractures, and a long and lean appearance
- Rickets: stiffness, lameness, joint enlargement, enlarged costochondral junction, arched back, bow-legged, and decreased growth rate.
- PPH: weakness, marked decrease in milk production, red-brown urine, pallor of mucous membranes, pounding jugular pulse, tachycardia, tachypnea, and jaundice. See signs of osteomalacia.

P Excess: P Toxicosis and Hyperphosphatemia

- Osteodystrophia fibrosa: stiffness, shifting lameness, loss of appetite, progressive cachexia, and anemia, swelling of jaw and mandible, and fractures
- P toxicosis: diarrhea, abdominal pain, garliclike breath odor, jaundice, and convulsions

CAUSES

P Deficiency: Hypophosphotosis and Hypophosphatemia

- Decreased GI absorption
 - Diet deficient in P (green grains, P poor soil)
 - P binding agents (diet high in Ca, Al, Mg, and fat)
 - Hypovitaminosis D (lack of sunshine; bile duct aplasia)
 - Intestinal malabsorption disease
 - Starvation, wasting disease
- Increased urinary excretion of P
 - Diuresis
 - Increased PTH due to primary hyperparathyroidism (functional tumor of parathyroid gland)
- Movement of extracellular P into the intracellular pool
 - Hyperinsulinism (glucose infusion; insulinoma)
 - Respiratory alkalosis
- Inadequate mobilization of P from bone stores (postparturient paresis)

P Excess: P Toxicosis and Hyperphosphatemia

- Spurious—hemolysis of sample or delay in removal of serum from clot (release of P from RBC)
- Decreased urinary excretion
 - Decreased GFR—dehydration; renal failure (renal hyperparathyroidism); obstruction of urinary tract

- Rupture of urinary bladder
- Decreased PTH concentration (primary hypoparathyroidism)
- Acromegaly
- Increased P absorption from GI
 - Diet high in P content (nutritional hyperparathyroidism)
 - Hypervitaminosis D
 - Intestinal necrosis—shift of P from intracellular pool to serum and increased absorption of GI P
 - Ingestion of fertilizer
 - Ingestion of fireworks
 - Ingestion of rodenticides with P
- Shift of P from intracellular pool to extracellular pool (serum)
 - Myopathy, muscle necrosis
 - Tumor lysis syndrome
- Other
 - Osteolytic bone lesion (neoplasia)
 - Young animal

RISK FACTORS

P Deficiency: Hypophosphotosis and Hypophosphatemia

- All
 - P deficient soil (regional, heavy rains, continuous removal of crops)
 - Concurrent vitamin D, manganese, zinc, or vitamin A deficiency
 - Anorexia/starvation
 - Environmental stress
 - Winter (reduced sunlight)
 - Grazing green cereal crops
- Osteomalacia—older adult animal
- Rickets—weaned, young growing animal
- PPH
 - High production, early postpartum period, lactation
 - Concurrent Cu deficiency
 - Diet of lush rye, Egyptian clover, green alfalfa, turnips, beet pulp, rape, and kale
 - New Zealand: late summer, first to second lactation cycle

P Excess: P Toxicosis and Hyperphosphatemia

Osteodystrophia fibrosa: diets high in P and deficient in Ca (high grain-to-forage ratio)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

P Deficiency: Hypophosphotosis and Hypophosphatemia

- Osteomalacia/rickets
 - Fluorosis arthritis
 - Cu or Mg dietary deficiency
 - Phositis due to any cause
 - Hyperparathyroidism
 - Vitamin D deficiency
- PPH
 - Babesiosis

- Theileriosis
- Bacillary hemoglobinuria

P Excess: P Toxicosis and Hyperphosphatemia

- Dehydration
- Renal failure or obstruction of urinary tract
- Myopathy
- Liver failure due to a variety of metabolic, toxic, and infectious causes

CBC/BIOCHEMISTRY/URINALYSIS

P Deficiency: Hypophosphotosis and Hypophosphatemia

CBC

- Osteomalacia/rickets—N/A
- PPH—moderate to marked anemia, polychromasia and basophilic stippling of RBC, nucleated red blood cells, anisocytosis of RBC

Blood Chemistry

- Osteomalacia/rickets
 - +/- Hypophosphatemia (1.5–3.5 mg/dL)
 - +/- Hypocalcemia
- PPH
 - Hypophosphatemia common (<1.5 mg/dL)
 - Increased AST activity (ischemic liver necrosis)
 - Increased total bilirubin concentration (intravascular hemolysis—primary indirect bilirubin)

Urine

- Osteomalacia/rickets
 - +/- Hypophosphatemia (1.5–3.5 mg/dL)
- Decreased fractional excretion of P ($[P_{\text{Urine}}/P_{\text{Serum}}] \times [Cr_{\text{Serum}}/Cr_{\text{Urine}}] \times 100$), normally 0.0–0.53% in sheep
- PPH
 - Hemoglobinuria (without RBC)
 - Bilirubinuria
 - Proteinuria

P Excess: P Toxicosis and Hyperphosphatemia

CBC

Osteodystrophia fibrosa/P toxicosis—N/A

Blood Chemistry

- Osteodystrophia fibrosa
 - Hyperphosphatemia
 - +/- Hypocalcemia
 - Hyperphosphatasemia (increased ALP)
- P Toxicosis
 - +/- Hyperphosphatemia
 - +/- Hypocalcemia
 - Increased AST (liver necrosis)
 - Increased total bilirubin (liver necrosis)

Urine

Osteodystrophia fibrosa/P toxicosis—increased fractional excretion of P

OTHER LABORATORY TESTS

P toxicosis: calculate ingested dose of P—approximate lethal dose is 1–4 mg/kg

IMAGING

Radiographic

P Deficiency: Hypophosphotosis and Hypophosphatemia

- Osteomalacia: thin cortices of long bones, reduced bone density (30% loss of mineral matrix required for visualization), noncalloused bone fractures
- Rickets: diaphyses of bones are shorter and broader than normal, cortices are increased in width, clublike thickening in metaphysis, irregular persistence of cartilage at physis, bowed long bones, domed cranium, prominent costochondral junctions

P Excess: P Toxicosis and Hyperphosphatemia

Osteodystrophia fibrosa: reduced bone density, subperiosteal bone resorption, loss of dura dentis

DIAGNOSTIC PROCEDURES

- Measure bone ash:organic ratio with bone biopsy
 - Normal bone: ash:organic ratio of 3:2
 - Rickets/osteomalacia/osteodystrophia fibrosa: ash:organic ratio of 1:2–1:3
- Analysis of dietary P and Ca concentration

PATHOLOGIC FINDINGS

Osteomalacia

- Gross pathology—soft and brittle bones, thin cortices with large marrow cavities, noncalloused fractures
- Histopathology—accumulation of excess unmineralized osteoid on trabecular bone surfaces

Rickets

- *Gross pathology*—bowed long bones, domed cranium, prominent costochondral junctions, clublike thickening in metaphyseal region (rachitic metaphysis), retarded mandibular growth
- *Histopathology*—failure of osteoid and cartilaginous matrix to mineralize, overgrowth of fibrous tissue in metaphysis, persistent cartilage, and irregular physis

PPH

- *Gross pathology*—thin watery blood, jaundice of soft tissue, distended gall bladder, red-brown colored urine, liver with a nutmeg pattern
- *Histopathology*—central lobular coagulative hepatic necrosis, bile and hemosiderin pigment in renal tubular epithelial cells, and hemoglobin in tubules

Osteodystrophia Fibrosa

- *Gross pathology*—thickening of flat bones particularly of the jaw and skull, soft bones, noncalloused fractures
- *Histopathology*—extensive erosion of periosteal and cortical bone by numerous osteoclasts, compact bone replaced by fibrocellular tissue, herniation of articular cartilage into the epiphysis

P Toxicosis

Severe icterus and fatty liver with periportal necrosis

TREATMENT

APPROPRIATE HEALTH CARE

Osteomalacia/Rickets/PPH

- Correct any dietary deficiency in P, Ca, or vitamin D. Ideal dietary ratio of Ca:P is 2:1
 - Cattle: 150–300 kg body weight require 9–18 g/day of P
 - Sheep: 10–100 kg body weight require 1.9–4.8 g/day of P
- Adequate sunlight (osteomalacia/rickets)

Osteodystrophia Fibrosa

- Nutritional cause: correct excess dietary P
- Renal cause

P Toxicosis

Remove source of exposure

ACTIVITY

N/A

CLIENT EDUCATION

Osteomalacia/Rickets/Osteodystrophia Fibrosa

Gross bone deformities unlikely to resolve following correction of dietary P concentration.

PPH

Animals that survive initial hemolytic crisis will likely succumb later due to hemoglobin-induced renal failure. *P Toxicosis* Recovery from acute abdominal pain often followed in 3–5 days by liver failure and death.

SURGICAL CONSIDERATION

PHOTODERMATITIS

BASICS

DEFINITION

- Dermatitis caused by photodynamic agents present in the skin.
- The source of these photodynamic agents in livestock are endogenous substances or plant material.
- Stimulation of photodynamic agents by ultraviolet light results in generation of free radicals resulting in tissue damage.

SIGNALMENT

- Ruminants especially cattle and sheep and monogastrics are all affected.
- Congenital defective hepatic function leading to secondary photosensitization occurs in lambs of the Corriedale and Southdown breeds.

SIGNS

- Signs include erythema, edema, and sloughing off of skin around unpigmented areas or areas exposed to ultraviolet rays.
- Common sites include eyelids, conjunctiva, ears, muzzle, dorsum of the body, perineum, and teats.
- Icterus is associated with secondary photodermatitis due to hepatic insufficiency.

CAUSES

- The principal photodynamic agents are endogenous porphyrins and phylloerythrin from plant material.
- Primary photodermatitis is due to ingestion of exogenous photodynamic agents. Plants containing photodynamic agents include *Hypericum* spp. (St John's wort), *Lolium perenne* (perennial ryegrass), *Cymopterus* (wild carrot). Chemicals including phenothiazine and rose Bengal and acaridine dyes have been reported to cause photosensitization.
- Secondary photodermatitis results from accumulation of phylloerythrin in plasma due to insufficient hepatobiliary excretion. Plants that contain hepatotoxins include lantana, cyanobacteria, lupins, ragwort, *Crotalaria* spp., and *Tribulus* spp.
- Mycotoxins in stored feeds also can cause hepatotoxicity.
- Inherited aberrant defective functions of enzymes involved in porphyrin-heme synthesis may result in excessive production of porphyrins, which are photodynamic.
- Congenital photodermatitis occurs in Corriedale and Southdown breed of sheep and results from defective bile excretion.

RISK FACTORS

Exposure of animal to plants containing primary photodynamic agents or plant containing hepatotoxins predisposes animal to photodermatitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- These include dermatophytosis and infectious bovine keratoconjunctivitis. Keratoconjunctivitis is not accompanied with dermatitis.
- Dermatophytosis will affect both pigmented and nonpigmented areas and the organisms can be isolated from the lesions.

CBC/BIOCHEMISTRY/URINALYSIS

There are no specific laboratory findings with photodermatitis. Elevated levels of plasma bilirubin may be observed with secondary photodermatitis. Liver enzymes may be elevated.

OTHER LABORATORY TESTS

Liver biopsies may be useful in secondary photodermatitis.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Submission of potential toxic plants to diagnostic laboratory for species confirmation

**TREATMENT**

- Animals should be removed from the source of dynamic agent or exposure to sunlight.
- Supportive therapy may be required for severe cases.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Icterus is associated with secondary photodermatitis due to hepatic insufficiency.

PHOTOSENSITIZATION

BASICS

OVERVIEW

- Photosensitization is an abnormal reaction of the skin to sunlight due to the presence of a photodynamic agent in the dermis. Photodynamic agents absorb certain wavelengths of ultraviolet (UV) light, producing free radicals, which react with proteins in the dermal tissue, causing damage.
- Photosensitization can be divided into three categories: Type I (primary photosensitization), Type II (photosensitization due to aberrant pigment synthesis), and Type III (secondary or hepatogenous photosensitization).

PATHOPHYSIOLOGY

- In Type I photosensitization, the photodynamic agents are absorbed into the blood from the gastrointestinal tract (GI) and react with UV light at the skin surface. Type I reactions may also occur with direct contact to the photodynamic agent (plant, chemical). Once in the dermis, the photodynamic agent absorbs the energy of a light photon and forms free radicals. The oxygen free radical reacts with amino acids, nucleic acids, and membrane lipids in the capillary endothelium and surrounding tissues, causing tissue destruction.
- Type II photosensitization is due to a genetic defect in the individual. The photodynamic agent is a pigment that is produced endogenously by an aberrant metabolic process.
- Type III photosensitization is secondary to liver damage. Chlorophyll is metabolized by microbes in the GI tract, forming phylloerythrin. Phylloerythrin, a photodynamic metabolite of chlorophyll, is absorbed into the blood stream. Normally phylloerythrin is removed from the blood by the liver, and excreted in bile. With liver damage or biliary obstruction, phylloerythrin cannot be excreted, and thus enters the general circulation. Liver damage can occur from toxins, bacteria, viruses, or neoplasia. Secondary photosensitization is intensified when the consumption of chlorophyll from green plants is high.

SYSTEMS AFFECTED

- Skin/exocrine
- Hepatobiliary

GENETICS

- White- or light-skinned breeds are at higher risk for Type I or Type III photosensitivity. Black-skinned animals are rarely affected with photosensitization of any type.
- Type II photosensitization has been reported to occur as an inherited autosomal recessive congenital disease in Holstein, Ayrshire, and Shorthorn cattle and Southdown and Corriedale sheep.
- In bovine erythropoietic porphyria (“pink tooth”), affected cattle are deficient in uroporphyrin III cosynthetase, an enzyme needed for proper formation of hemoglobin. Uroporphyrin and coproporphyrin accumulate in the bones, teeth, skin, and urine, as well as other tissues and secretions. Accumulations of porphyrin metabolites in the skin predispose the animals to photosensitization.
- Southdown lambs may have a congenital defect that can cause hyperbilirubinemia and results in hepatogenous photosensitization. Corriedale lambs can have a similar condition, which is characterized by a failure to excrete phylloerythrin and conjugated bilirubin that also results in hepatogenous photosensitization.

INCIDENCE/PREVALENCE

Late spring, summer, and early fall are most common, but if photosensitizing plants are baled into hay, signs may be seen year round.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

All ruminant species

Breed Predilections

White- or light-colored breeds

Mean Age and Range

Affects all ages, but young may be more susceptible

Predominant Sex

Affects both sexes equally

SIGNS

- Photosensitization occurs most frequently in hairless and white-skinned areas of the body. Eyelids, lips, ears, nose, white blazes, coronary bands, and other white areas are most commonly involved.
- Signs may be more severe in areas of the body that receive more sunlight (head, neck, back).
- In contact photosensitization, only areas of contact with the photodynamic agent are affected. The affected area first becomes erythematous, edematous, and painful. Honey-colored serum begins to seep from the thickened skin, and extensive scabs can form after 1–2 days. Secondary bacterial infections of the skin can occur.
- Animals tend to be very pruritic in the early stages. As signs progress, they resist handling and may not want to eat due to the discomfort. Occasionally, the eyes will be affected and these animals may become blind. Death is due to starvation or misadventure.
- Signs consistent with hepatic encephalopathy (e.g., ceaseless walking, head pressing, behavior changes, etc.) are seen with secondary photosensitization.
- With plant ingestion, signs may appear from 24 hours to several months after the first ingestion.
- With drug eruptions, cutaneous lesions are noted 24–48 hours after drug administration, although there may occasionally be a longer interval.

PHYSICAL EXAMINATION FINDINGS

Animals may be restless and pruritic with reddened and swollen eyelids, muzzle, and lips. Affected animals may also exhibit tachypnea, tachycardia, hyperthermia, diarrhea, salivation, and jaundice (if Type III).

CAUSES

Plants: see Tables [1](#) and [2](#)

Pharmaceuticals

- Antibiotics (penicillin, sulfas, tetracycline)
- Anticonvulsants
- Local anesthetics
- Nonsteroidal anti-inflammatory agents (NSAIDs), antipyretics (aspirin, phenylbutazone)
- Phenothiazines
- Thiazides

Chemicals

- Carbon tetrachloride
- Copper
- Methylene blue
- Phenanthridium
- Phosphorus

Fungal

Pithomyces chartarum, *Aspergillus* spp., and *Fusarium* spp. can all produce hepatotoxic mycotoxins and cause secondary photosensitization.

[Table 1](#) Plants That Cause Type I (Primary) Photosensitization

Latin Name	Common Name	Toxin
<i>Hypericum</i> spp.	St. Johns wort	Conjugated quinone (hypericin)
<i>Fagopyrum esculentum</i>	Buckwheat	Conjugated quinone (fagopyrin)
<i>Heracleum mantegazzianum</i>	Giant hogweed	Furocoumarins
<i>Ammi majus</i>	St. Anne's lace	
<i>Cymopterus</i> spp.	Spring parsley	
<i>Thamnosma texana</i>	Dutchman's breeches	

Table 1 Plants That Cause Type III (Secondary) Photosensitization

Latin Name	Common Name	Toxin	Mechanism of Action
<i>Senecio</i> spp.	Ragwort, groundsel, senecio	Pyrrolizidine Alkaloids (PA)	PAs are metabolized by the liver and the activated pyrrole form alkylates DNA in the hepatocyte, which impairs cell division. This prevents the hepatocyte from undergoing binary fission to regenerate hepatocytes, resulting in hepatocytomegaly and karyomegaly. When large numbers of hepatocytes die, the necrosis triggers a regenerative response accompanied by bile duct proliferation.
<i>Crotalaria</i> spp.	Crotalaria, rattlebox		
<i>Amsinckia intermedia</i>	Fiddleneck		
<i>Echium</i> spp.	Blueweed, viper’s bugloss		
<i>Heliotropium</i> spp.	Heliotrope		
<i>Symphytum</i> spp.	Comfrey		
<i>Cynoglossum officinale</i>	Hound’s tongue	Microcystins	Microcystins cause disruption of the actin filaments of the hepatic cytoskeleton, leading to cellular collapse.
<i>Microcystis</i>	Blue green algae		
<i>Anabaena</i>			
<i>Oscillatoria</i>			
<i>Nodularia spumigena</i>			
<i>Lantana</i> spp.	Lantana, shrub verbena, yellow sage	Triterpenoid compounds	Triterpenoids affect hepatocytes by inhibiting secretory function and decreasing bile canaliculi ATPase activity resulting in cholestasis and jaundice.
<i>Lippia</i> spp.	White brush		
<i>Helenium</i> spp.	Sneezeweed	Sesquiterpene lactones	Sesquiterpene lactones bind to sulfhydryl groups and other nucleophilic components, inhibiting numerous aerobin and anaerobin enzymes.
<i>Hymenoxys</i> spp.	Rubberweed, bitterweed		
<i>Tetradymia</i> and <i>Artemisia</i> spp.	Horsebrush Black sagebrush	Furanos sesquiterpenens Sesquiterpene lactones	Tetradymol metabolites uncouple oxidative phosphorylation in electron transport. Phylloerythrin from other plants must be eaten to result in the development of photosensitization.
<i>Panicum</i> spp.	Panicum, Kleingrass	Disogenin	Lithogenic steroidal saponins (disogenins) are responsible for formation of crystals in the bile ducts resulting in hepatogenous photosensitization.
<i>Tribulus terrestris</i>	Puncture vine, goathead		
<i>Nolina</i> spp.	Sacahuiste, bunchgrass		
<i>Agave lecheguilla</i>	Agave, lecheguilla		
<i>Kochia scoparia</i>	Kochia	Unknown, possibly saponins	Secondary photosensitization
<i>Trifolium hybridum</i>	Alsike clover	Unknown	Primary photosensitization has been seen with ingestion and possibly contact. Secondary photosensitization has been seen with long-term ingestions.
<i>Phyllanthus abnormis</i>	Abnormal-leaf Flower	Unknown	Secondary photosensitization
<i>Descurainia pinnata</i>	Tansymustard		
<i>D. sophia</i>	Flixweed		
<i>Brassica rapa</i>	Turnip	Nitriles?	Unknown photosensitization
<i>B. napus</i>	Rape		
<i>B. oleracea</i>	Kale		
<i>Lotus corniculatus</i>	Bird’s-foot trefoil	Unknown	Unknown photosensitization
<i>Trifolium incarnatum</i>	Crimson clover		
<i>T. subterraneum</i>	Subterranean clover		
<i>T. pratense</i>	Red clover		
<i>Medicago denticulate</i>	Burclover		
(polymorpha)			
<i>M. sativa</i>			
<i>M. lupulina</i>			
<i>M. minima</i>	Black medic		
<i>Avena sativa</i>	Small burclover		
<i>Sorghum</i>	Oats		
<i>Sorghum</i>	Sorghum		
<i>Triticum</i>	Wheat		
<i>Chamaesyce (Euphorbia) maculata</i>	Spotted spurge		

Neoplasia

Any neoplasia that affects hepatic function can cause secondary photosensitization.

RISK FACTORS

Any underlying liver disorder or genetic defect that decreases excretion of phylloerythrin

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pemphigus foliaceus
- Irritant dermatitis
- Allergic dermatitis
- Folliculitis/furunculosis
- Dermatophytosis
- Chemical burns
- Thermal burns
- Malignant catarrhal fever
- Pediculosis
- Demodectic mange

CBC/BIOCHEMISTRY/URINALYSIS

- Elevations in GGT, AST, and ALP (most common)
- Elevations in SDH, GLDH, LDH (early in syndrome)
- Hyperbilirubinemia
- Inflammatory leukogram may be present.

OTHER LABORATORY TESTS

- Elevated bile acids
- Prolonged BSP clearance time
- Plasma phyloerythrin ($>$; 10 $\mu\text{g/dl}$ is diagnostic)

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Skin or liver biopsies can be performed on valuable animals.

PATHOLOGIC FINDINGS

- Dermal lesions vary from minimal reddening to urticarial lesions with erythema and swelling, to skin necrosis. The skin may have a gelatinous appearance extending down into the deeper corium. Microscopically, edema will be accompanied by necrosis and a polymorphonuclear infiltrate in the deeper corium. Both the epidermis and the superficial dermal vasculature may be damaged.
- Animals with secondary photosensitization will have hepatic and other systemic lesions. Bright yellow fat, hepatomegaly, liver cirrhosis, hepatic necrosis, and ascites are common. Depending on the extent of the liver damage, bruising and hemorrhage may be seen.
- If toxicosis is due to PAs, then hepatocytomegaly (always present), fibrosis, and bile duct proliferation may be seen.
- With disogens, birefringent crystals may be evident in the bile ducts (small ducts may be obstructed), skin, kidney, adrenal gland, and heart.

TREATMENT

APPROPRIATE HEALTH CARE

Therapy involves removing the animal from sunlight and preventing reexposure to the photodynamic agent. All drugs being administered when photosensitization occurred should be stopped. If the liver is involved, appropriate therapy for liver disease must be given.

NURSING CARE

As many affected animals stop eating and drinking, supplemental feeding and fluid therapy are important. Mortality primarily occurs in lambs because the ewe's udders are so painful that lambs are not permitted to nurse. Cows also refuse to let calves nurse, but calf losses are usually low. Soothing skin medication or other pain relief can hasten healing.

ACTIVITY

Prevent animal exposure to UV light. Let out on dry pasture only at night.

DIET

Avoid any additional photosensitizing plants.

CLIENT EDUCATION

Clients need to inspect hay and pastures for any phototoxic plants.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- Pain relief with NSAIDs (e.g., flunixin 1.1–2.2 mg/kg PO or IV q 6–12 h; 72-hour milk withdrawal, 10-day meat withdrawal) if hepatopathy is not involved.
- Antibiotics if pyoderma is present (e.g., ceftiofur 1.1–2.2 mg/kg IM q 24 h; no milk or meat withdrawal)

CONTRAINDICATIONS

- If signs are due to a drug reaction, avoid using any related medications in the treatment of clinical signs.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

If secondary photosensitization, use caution when using drugs that must be metabolized by the liver.

POSSIBLE INTERACTIONS ALTERNATIVE DRUGS

Liver protectants and blood transfusions may be attempted to prolong life in valuable animals.

FOLLOW-UP

PATIENT MONITORING

Monitor until dermal lesions have resolved or until liver values return to normal.

PREVENTION/AVOIDANCE

- Avoid future exposures to any implicated compounds and related substances.
- Avoid grain and hay contaminated by species of plants known to cause photosensitization.
- Control photosensitizing plants by spraying pastures and crop land with herbicides. Plants along trails and in shipping areas should be removed.
- Supplementation of phosphorus and cobalt may lessen PA effects.
- Less-valuable animals or more resistant species may be used to “pregraze” pastures (e.g., sheep/goats may be used to graze groundsel before cattle).
- Provide supplemental feeding with more nutritious and palatable forage with contaminated pastures and follow a range management program that prevents overgrazing.
- Avoid exposure to blue-green algae by fencing off contaminated ponds.
- Facial eczema can be prevented by breeding animals for resistance, oral dosing with zinc, and spraying pastures with fungicides.

POSSIBLE COMPLICATIONS

Prolonged grazing of *Echium* and *Heliotropium* may result in chronic copper poisoning of sheep.

EXPECTED COURSE AND PROGNOSIS

- Type I has a good prognosis. Type III has a poor prognosis due to liver involvement.
- The skin eruptions usually subside within 24 to 48 hours after exposure ceases, although lesions may persist up to 6 months.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Pyoderma

AGE-RELATED FACTORS

Affects animals of all ages, but increased mortality in young animals

ZOONOTIC POTENTIAL

PA metabolites are secreted in milk.

PREGNANCY

PAs cross the placenta and can affect the fetus, leading to increased calf losses, even with clinically normal dams.

RUMINANT SPECIES AFFECTED

All ruminant species may be affected.

PINE NEEDLE TOXICITY

BASICS

OVERVIEW

Ingestion of pine needles, bark, or new growth tips of several species of pine causes abortions in cattle and, less frequently, systemic toxicity in cattle and sheep.

PATHOPHYSIOLOGY

- Amount of toxic principle varies considerably with geographic location and season.
- Abortifacient effects most often occur with ingestion of 1 kg needles/day for several days or higher amounts for 2–3 days.
- Clinical signs: 24 hours to several weeks postexposure.
- Mechanism: It is thought that the diterpene acids, of which isocupressic acid is the most common, are metabolized in the rumen or liver to abortifacient metabolites. The toxins appear to modify hormonal effects responsible for the normal increase in uterine blood flow that occurs with increasing pregnancy. Results are an increase in caruncular arterial tone and decrease in uterine blood flow, which causes premature parturition. There may also be an effect on progesterone-producing cells in the corpus luteum, causing a direct decrease in progesterone levels and termination of pregnancy.
- No effect on overall fertility
- Other abietane diterpenes present are thought to be responsible for systemic toxicity (higher concentration in new growth tips and bark than in needles).

SYSTEMS AFFECTED

Reproductive, respiratory, renal, systemic

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

- *P. ponderosa* (ponderosa or western yellow pine) is the most widespread found across much of western North America.
- *P. contorta* (lodgepole or limber pine) is found in the Sierra-Cascade range and the Rockies.
- *P. radiata* (Monterey pine) found around Monterey, California and cultivated in New Zealand.
- Other plants containing toxic principle that also cause abortion in livestock: *Communis juniperus* (common juniper) in North America and New Zealand. *Cupressus macrocarpa* (Monterey cypress) is native to Monterey, California, and is a widespread ornamental.

SIGNALMENT

- Abortion: cattle and bison (though bison rarely eat pine needles) susceptible from midgestation to parturition. Risk increases with length of pregnancy.
- Toxicity: cattle, bison, sheep
- Goats, deer, and elk unaffected

SIGNS

Reproductive

- Early parturition with depression, mucoid vulvular discharge (often bloody), weak uterine contractions, incomplete cervical dilation, uterine hemorrhage, dystocia, birth of dead or small weak calf
- Maternal complications include retained placenta, septic metritis, agalactia, anorexia, rumen stasis, and death (if untreated).

- While significant exposure does not cause abortion in sheep, the number of dead lambs born at term may increase.

Systemic

- Toxicosis in cows from a diet of 10%–15% new growth tips or very high doses of pine needles: depression, anorexia, rumen stasis, dyspnea, peripheral neuropathy, nephrosis, and death.
- In cattle and sheep, when 15%–40% of their diet consisted of pine needles, there were altered rumen fluid dynamics including fluid rate of passage, decreased volatile fatty acids, and decreased nitrogen intake and digestibility (supplemental protein has no effect on symptoms).

CAUSES AND RISK FACTORS

- Ingestion of pine needles of any age or state, although green needles more likely to be ingested
- Pregnant cows at increasing risk from midgestation to term, with greatest risk in last trimester
- Decreased temperatures and/or increased snow cover in winter
- Harsh weather that forces cows to seek shelter under pine trees
- Crowded feeding areas

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Abortion caused by BVD or IBR viruses, neosporosis, leptospirosis, brucellosis, selenium deficiency, or foothill abortion (EBA).

CBC/BIOCHEMISTRY/URINALYSIS

Systemic toxicity: azotemia, hypercreatinemia, proteinuria, and elevation of AST and SDH

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Combination of access to pine needles, presence of risk factors, and clinical signs

PATHOLOGIC FINDINGS

- Reproductive—dams that die exhibit heavy uterine exudate with necrotic placental tissue, edema, and focal ulceration of endometrium and necrosis in the caruncles. Stillborn calves may show malacia of white brain (cerebral leukomalacia) matter or may appear normal.
- Systemic—nephrosis, vacuolation of basal ganglia neuropil, perivascular and myelinic edema

TREATMENT

- Supportive care for calf
- Removal of placenta and treatment for uterine infection in the cow
- Systemic treatment of bacterial infection, dehydration, and malnutrition in any affected animal

MEDICATIONS

DRUGS OF CHOICE

Broad-spectrum antibiotics to treat uterine and/or systemic bacterial infection

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Fence pregnant cows in the last trimester away from pines and provide supplemental feed.
- For all cattle, when feeding supplemental feed, do so over a larger area to ensure all animals access.
- Remove young stands of pines where appropriate

POSSIBLE COMPLICATIONS

Dams: retained placenta, septic metritis, agalactia, anorexia, rumen stasis, and death (if untreated)

EXPECTED COURSE AND PROGNOSIS

- Dams usually recover with treatment but death has been reported.
- Calf prognosis is dependent on stage of development at birth and supportive treatment for premature birth.
- Incidence of abortion 0%–100%

MISCELLANEOUS

ASSOCIATED CONDITIONS

Nutritional deficiency

PLANTS PRODUCING ACUTE RESPIRATORY DISTRESS SYNDROME

BASICS

OVERVIEW

- An afebrile pneumonia like disease of cattle but occasionally observed in other ruminants.
- Rapid death may result.
- Several etiologies exist for the disease including rapidly changing animals from poor to lush pasture, and the plant *Perilla frutescens* (purple mint, perilla mint). Moldy sweet potatoes, rape, kale, turnips, and moldy pink half-runner beans are also associated with the disease.
- Many lush grasses are associated with ARDS including Bermuda, fescue, alfalfa, and Kleingrass. In the southeastern United States, *Perilla frutescens*, or purple mint, is often associated with ARDS. *Perilla* is an annual weed that grows to a height of 1–2 meters. *Perilla* is readily identified by its square stem and is common along wood lines and waste areas. The plant has small terminal white flowers and a characteristic minty fragrance.
- Lush pasture of many grasses contains high quantities of L-tryptophan. Dry, nonsucculent pastures contain lower quantities of L-tryptophan.
- Perilla mint contains 3-substituted furans (perilla ketone, egomaketone, and isoegomaketone).
- L-tryptophan in high quantities can lead to pneumotoxicosis.
- Three-substituted furans can be pneumotoxic by their direct effects on the lung.
- The condition is often referred to as bovine asthma, or AIP, in the United States and fog fever in the United Kingdom.

SIGNALMENT

- All ruminants, but cattle primarily
- Horses have been affected by perilla mint.

SIGNS

- The clinical course is rapid and cattle may be found dead in 12–24 hours, especially if stressed.
- Animals are observed breathing very rapidly and shallow with their mouths open. Foam is evident around their mouth. An expiratory grunt is very audible from 100 feet or more. Animals may be extremely cyanotic and die quickly if stressed.

CAUSES AND RISK FACTORS

Animals are susceptible whenever moved from dry nonsucculent pasture to lush pasture. Signs may appear within 1 week following the transfer.

- L-tryptophan is metabolized by rumen microorganisms to indoleacetic acid, which is subsequently decarboxylated by *Lactobacillus* spp. to 3-methylindole (3-MI). The 3-methylindole is absorbed and metabolized by the lung mixed-function oxidase system to produce pneumotoxicosis.
- Usually observed in the fall when cattle are moved from summer pasture to lush fall growth, it has been observed in spring when cattle are turned out on lush pasture after being fed hay over the winter.
- If caused by *Perilla frutescens*, usually observed from August through October when this plant reaches maturity. The seed heads are the most toxic. Has been observed in cattle eating hay containing purple mint.

DIAGNOSIS

- Other causes of pneumonia
- Hardware disease in cattle due to the pronounced expiratory grunt

- Organophosphate toxicosis

CBC/BIOCHEMISTRY/URINALYSIS

N/A

IMAGING

- Thoracic radiography
- Pulmonary emphysema and edema are common.
- Emphysematous bullae may be observed on the lung surface.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Lungs are enlarged and heavy due to edema, cellular proliferation, and congestion. Foam fills many airways.
- Interlobular edema and emphysema are commonly observed. Emphysematous bullae are often observed on the lung surface.
- Emphysema may extend into the mediastinum and subcutaneous cervical and thoracic areas.
- Microscopically, alveolar epithelial hyperplasia of type 2 pneumocytes is common along with interstitial emphysema, edema, and hyaline membranes.

TREATMENT

- No specific treatment
- Keeping animals as calm as possible is important.
- If stressed, animals often become anoxic and die.
- Remove animals from etiology (i.e., purple mint or lush pasture). Place on dry feed.

MEDICATIONS

DRUGS OF CHOICE

- No specific drugs are effective.
- Symptomatic treatment such as corticosteroids, atropine, diuretics, antihistamines, and antibiotics.
- Avoid stress (if possible) when treating.
- Weigh the value of therapeutic pharmacology versus the stress involved with handling and treatment.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Gradually introduce cattle to lush pasture after feeding on nonsucculent, if possible.
- Inhibit certain ruminal microflora that reduce L-tryptophan to 3-MI with monensin or lasalocid.
- Avoid exposure to perilla mint.
- Supply ample good pasture as perilla is usually consumed only when other better forage is lacking.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Very guarded early prognosis as death may occur within 12–24 hours.
- Clinical course may last 2–3 weeks.
- If animals survive 2 or 3 days and are not stressed, prognosis improves.
- Even severely affected animals may return to normal in 2–3 weeks when the type 2 pneumocytes resolves to type 1.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Animals are observed breathing very rapidly and shallow with mouths open. Foam is evident around mouth. An expiratory grunt is very audible from 100 feet or more. Animals may be extremely cyanotic and die quickly if stressed.

AGE-RELATED FACTORS

Calves fed the flowering perilla plant develop the toxic syndrome, while those fed earlier plants (collected before seed stage) and late plants (collected after frost) remain asymptomatic.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

PRODUCTION MANAGEMENT

The time of year when perilla reaches the seed stage often corresponds to periods when pasture grass is scarce forcing cattle to consume plants not normally eaten when ample desirable forage is available.

PNEUMOTHORAX

BASICS

OVERVIEW

- A pneumothorax is a collection of air or gas in the pleural space (the space surrounding the lungs).
- Pleural pressure is normally negative with respect to alveolar and atmospheric pressures throughout the respiratory cycle.
- A negative pleural pressure is maintained by two forces applied to the pleural space simultaneously and in opposition: (a) elastic forces that tend to collapse the lung and (b) recoil forces that tend to expand the chest wall.
- Normal end-expiratory pleural pressure is approximately -5 cm H₂O.
- Pleural pressure becomes more negative (-7.5 cm H₂O) during inspiration when the chest wall expands through the effort of the inspiratory muscles (diaphragm and external intercostal muscles).
- The onset of a pneumothorax disconnects the lung/chest wall unit and the chest wall expands controlled only by recoil forces, while the lung collapses under the influence of its own elastic properties.
- During pneumothorax, pleural and atmospheric pressures progressively equilibrate causing the lung to reach its minimal volume.

PATHOPHYSIOLOGY

- In cattle, there is evidence to support an association between rupture of emphysematous bullae during straining, coughing, and effort of parturition and the development of closed pneumothorax.
- Most commonly, the problem is confined to one hemithorax because cattle have a complete mediastinum. Occasionally, rupture of pulmonary bullae can occur bilaterally leading to severe dyspnea and acute death.
- Penetrating thoracic trauma, although rare in ruminants, can lead to pneumothorax by disruption of the integrity of the chest wall. Wounds that cause pneumothorax are most commonly located on the lateral chest wall and may be associated with rib fractures. Pectoral wounds are very rarely associated with pneumothorax.

SYSTEMS AFFECTED

Respiratory

GENETICS

N/A

INCIDENCE/PREVALENCE

- There is no specific incidence rate reported for pneumothorax.
- In feedlot cattle, however, mortality rates of up to 0.5% have been associated with atypical interstitial pneumonia, emphysema, and pneumothorax.

SIGNALMENT

- Not common in ruminants. When encountered, it is most common in dairy calves and adult dairy cattle. Case reports describe pneumothorax in bulls.
- In the beef feedlot industry, atypical interstitial pneumonia poses a substantial risk of pneumothorax.
- Chest trauma may result in a pneumothorax in other ruminant species, although the incidence of penetrating chest trauma is unknown in small ruminants and llamas.

SIGNS

- Inspiratory dyspnea
- Tachycardia
- Open-mouth breathing
- Cattle are alert and anxious.

- Pronounced abdominal effort during respiration
- Cyanosis in severe cases
- Auscultation: the affected side of the thorax (hemithorax) is almost silent while normal or slightly increased respiratory sounds are audible on the unaffected side.
- Percussion performed during auscultation may produce a “ping” on the affected hemithorax.
- Subcutaneous emphysema is not uncommon.

RISK FACTORS

- Pneumothorax in cattle is associated with bovine respiratory syncytial virus (BRSV) infection (acute interstitial pneumonia) and, less commonly, with acute pneumotoxiosis.
- Atypical interstitial pneumonia and acute respiratory distress may be predisposing factors in beef cattle.
- Trauma

DIAGNOSIS

- Assessing the clinical presentation in conjunction with the predisposing factors mentioned above makes the diagnosis. Clinical signs are often sufficiently straightforward to allow a diagnosis.
- Presence of a thoracic wound should always warrant a thorough evaluation of chest wall integrity.
- The diagnosis is confirmed by obtaining thoracic radiographs.

TREATMENT

- In case of thoracic trauma, the wound should be explored to verify the presence of and remove any rib fragments. The wound should be closed primarily, if possible, or covered with a dressing that allows an airtight seal to occur.
- The hemithorax should be suctioned in order to aspirate the air contained in the pneumothorax. This can be accomplished by using standard suction/vacuum equipment attached via tubing to a sterile teat cannula placed in the dorsal-and caudal-most aspect of the thorax.
- Alternatively, air can be aspirated by using a large syringe connected to a teat cannula via a three-way stopcock.
- Placement of a chest tube connected to a commercially available continuous flow evacuation device has been reported as a successful and simple method for pneumothorax evacuation in bulls.
- These measures may fail in case of ruptured bullae because air continuously leaks through the disrupted lung parenchyma. In these cases, however, it is worth continuing the evacuation process chronically because the ruptured lung parenchyma will eventually heal.
- In mild cases, air will gradually reabsorb following healing of the lesion without evacuation.
- Broad-spectrum antibiotic administration is indicated in case of thoracic trauma or when concurrent bacterial pleuritis and pneumonia are suspected or in case of a chest wound.

POLIOENCEPHALOMALACIA

BASICS

OVERVIEW

- Polioencephalomalacia is a syndrome/lesion that can have several underlying causes in ruminants but typically results from a disturbance in thiamine metabolism.
- Traditionally described as the result of thiamine deficiency but elevated dietary sulfur is also a cause of this syndrome. Within the rumen, the elevated dietary sulfur is transformed to hydrogen sulfide.
- High-concentrate diets that lower rumen pH have been implicated as a cause of polioencephalomalacia due to the increase in thiaminase-producing bacteria.
- The treatment of the syndrome, regardless of the cause, is similar.
- Prevention and management of the syndrome benefits from an understanding of causative factors.

SYSTEMS AFFECTED

CNS primarily

Sources

Sulfur toxicosis causing

polioencephalomalacia; sources of sulfur:

- High sulfate water (gyp water)
- Molasses
- Elemental sulfur
- Gypsum or ammonium sulfate added to concentrate diets
- Cruciferous forages
- Some grain processing by-products
- Thiamine deficiency
 - Ingestion of thiaminase-containing plants (bracken fern)
 - Ampromium treatment for coccidiosis
- Acute lead intoxication can have similar lesions.
- Water deprivation/sodium ion toxicosis may have similar lesions.

Toxic Dose: Sulfur

- The NRC recommendation for sulfur intake is less than 0.3% of diet.
- The maximum tolerated dose is 0.4% of diet.

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Some areas may have elevated sulfur concentration in the groundwater. These levels can increase the risk of toxicosis.

SIGNALMENT

Species

All ruminants are susceptible.

Breed Predilections

N/A

Mean Age and Range

Young animals are more susceptible to polioencephalomalacia.

Predominant Sex

N/A

SIGNS

- Alteration of vision
- Head pressing
- Ear twitching
- Muscle tremors
- Depression
- Lethargy
- Opisthotonus
- Ataxia
- Recumbency
- Coma
- Death

CAUSES AND RISK FACTORS

- High-sulfate-containing water: If the animal's only source of water contains high concentrations of sulfur, there is an increased risk of toxicosis.
- Young animals on a high-grain diet
- Treatment of coccidiosis with amprolium
- Young animals are more susceptible than older.

**DIAGNOSIS**

- Presence of clinical signs
- Elevated sulfur content of feedstuff and/or water
- Possible odor of hydrogen sulfide (rotten eggs) of cattle

DIFFERENTIAL DIAGNOSIS

- Rabies
- Acute lead intoxication
- Water deprivation/sodium ion toxicosis
- Selenium "blind staggers"
- Vitamin A deficiency
- Ethylene glycol toxicity

CBC/BIOCHEMISTRY/URINALYSIS

Not specific for this syndrome

OTHER LABORATORY TESTS

Hydrogen sulfide gas from the gas cap of the rumen

- Draw off gas and test for hydrogen sulfide using a precision gas sampler
- Gastec sampler with sulfide analyzer tube (Sensidyne, Clearwater, Florida)

PATHOLOGIC FINDINGS***Gross Necropsy Findings***

- Swelling and flattening of cerebral gyri
- Pale yellow discoloration of the cerebral cortical grey matter
- Necrotic lesions may autofluoresce under ultraviolet light.

HISTOPATHOLOGICAL FINDINGS

- Neurons are shrunken and necrotic.
- Nuclei are small and faded or absent.
- Evidence of phagocytic cells in the brain

TREATMENT

- Identification and removal of source
- Symptomatic and supportive therapy
 - Provide roughages for animals on high-concentrate diets
 - Thiamine (vitamin B₁) 10–20 mg/kg up to TID intramuscularly or subcutaneously depending on severity of clinical signs and suspected cause; often mixed results
 - Possibly corticosteroids to reduce swelling and edema
 - Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Provide alternative sources of water
- Dilution of high-sulfate sources of water
- Careful attention to the addition of any type of sulfur to the diet (prevent a mixing error)
- Provide adequate dietary thiamine when being treated for coccidiosis as amprolium acts as a thiamine antagonist for coccidia.

MISCELLANEOUS

- The exact mechanism of action of sulfur in causing polioencephalomalacia is not fully elucidated; possible mechanisms:
 - Sulfide has been shown to inhibit cellular respiration similar to cyanide by inhibiting cytochrome c oxidase
 - The production of free radicals from sulfides has been proposed.
- When estimating the total intake of sulfur, both feed and water sources must be estimated.
 - Sulfur in water can be a significant source.
 - The sulfur in water is generally in the sulfate form.
 - The sulfate form needs to be converted to elemental sulfur.

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Younger animals are more susceptible to polio than mature animals.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

All ruminant species

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- High-sulfate-containing water must be monitored. If the animal's only source of water contains high concentrations of sulfur, there is an increased risk of toxicosis.
- Young animals on a high-grain diet need to be monitored for overconsumption.

POLYARTHRITIS

BASICS

DEFINITION

Inflammation of multiple joints resulting in persistent lameness

SIGNALMENT

Varies with the specific syndrome and etiology. All ruminant species can become affected.

SIGNS

- The clinical signs typically observed in cattle with polyarthritis include shifting leg lameness, stilted gait, and unwillingness to move. Close examination usually reveals multiple visibly swollen and distended joints.
- Joint capsules are palpably distended and pressure on the joint will cause increased distention of the joint at an alternate site. Warmth and pain upon palpation of joints may be observed.
- Clinical syndromes presenting with multiple distended and/or painful joints
 - *Mycoplasma* spp. arthritis
 - *Hemophilus somnus* arthritis
 - Chlamydial arthritis
 - Polyarthritis secondary to septicemia
 - Polyarthritis secondary to bacterial endocarditis
 - Osteochondrosis
 - Septic physisitis secondary to salmonellosis
- The reader is referred to chapters discussing these syndromes and diseases for additional detail.

RISK FACTORS

Varies with the specific syndrome and etiology

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Mycoplasma* spp. arthritis
- *Hemophilus somnus* arthritis
- Chlamydial arthritis
- Polyarthritis secondary to septicemia
- Polyarthritis secondary to bacterial endocarditis
- Osteochondrosis
- Septic physisitis secondary to salmonellosis

Diagnosis Criteria

- Herd histories of preceding or concurrent outbreaks of respiratory disease will greatly increase the likelihood of mycoplasmal, *Hemophilus somnus*, or chlamydial disease.
- Polyarthritis secondary to septicemia is seen almost exclusively in calves less than 1 month of age. Most affected calves will have additional diagnoses of clinical signs strongly supportive of septicemia including omphalophlebitis, hypopion, fever, and scleral injection.
- Age of onset will vary among the common causes of polyarthritis. Polyarthritis secondary to calf septicemia is diagnosed in very young calves. Chlamydial arthritis is most common preweaning. *Mycoplasma* and *Hemophilus* polyarthritis are

most common in recently weaned calves. Osteochondrosis is most common in cattle between 1 and 2 years of age. Polyarthritis secondary to endocarditis is typically seen in adult cattle.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS IMAGING

IMAGING

Radiography is a useful adjunct to the diagnosis of polyarthritis. Osteochondrosis with or without degenerative joint disease and septic physitis can readily be confirmed or ruled out by radiographic examination.

OTHER DIAGNOSTIC PROCEDURES

Ancillary diagnostic procedures:

- Arthrocentesis and analysis of joint fluid is the single most useful test in most animals with polyarthritis. Cattle with polyarthritis caused by *H. somnus* or endocarditis will generally have joint fluid with a profound increase in leukocytes and the predominant cell type being the neutrophil.
- Joint fluid in cattle with *Mycoplasma* spp. infection has a less dramatic increase in cell numbers and the predominant cell type is mononuclear cells.
- Cattle with either osteochondrosis or septic physitis secondary to salmonellosis will generally have near normal joint fluid composition.
- Microbiologic culture procedures or polymerase chain reaction (PCR) assays may be useful in the identification of the offending pathogens. However, it should be noted that negative results are common and should not exclude the possibility of a diagnosis.
- Serologic tests are available for chlamydia.

TREATMENT

Varies with the specific syndrome and etiology (see Weightloss: Bovine, Ligamentous Injuries of the Stifle, Common Hoof Lameness of Cattle, Septic Arthritis, Osteochondrosis, Cattle Lameness and Angular Limb Deformity).

MISCELLANEOUS

ASSOCIATED CONDITIONS

See Septic Arthritis, Osteochondrosis, Angular Limb Deformity, Common Hoof Lameness of Cattle, and Bovine Footrot above.

AGE-RELATED FACTORS

- Polyarthritis secondary to calf septicemia is diagnosed in very young calves. Chlamydial arthritis is most common preweaning.
- *Mycoplasma* and *Hemophilus* polyarthritis are most common in recently weaned calves.
- Osteochondrosis is most common in cattle between 1 and 2 years of age.
- Polyarthritis secondary to endocarditis is typically seen in adult cattle.
- Polyarthritis secondary to septicemia is seen almost exclusively in calves less than 1 month of age.

ZOONOTIC POTENTIAL

Chlamydia spp. and *Salmonella* spp. should be considered zoonotic agents and care should be used in sample collection.

PREGNANCY

Chlamydia spp. and *Salmonella* spp. can cause abortion in herds/flocks.

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species are affected.

BIOSECURITY

See specific chapters, such as Bovine Footrot, Common Hoof Lameness of Cattle.

PRODUCTION MANAGEMENT

See specific chapters, such as Common Hoof Lameness of Cattle.

POLYCYTHEMIA

BASICS

DEFINITION

- An increase in the RBC count, Hgb concentration, and PCV (or Hct) due to either a relative or absolute increase in the number of circulating RBCs
- The term “polycythemia” is used commonly, but because RBCs are primarily affected, a better term is “erythrocytosis.”

PATHOPHYSIOLOGY

- RBC numbers are affected by changes in plasma volume, splenic contraction, erythrocyte attrition or destruction, erythropoietin secretion, and rate of bone marrow production (erythropoiesis). Erythropoiesis is also influenced by production of hormones from the adrenal cortex, ovaries, testes, anterior pituitary, and thyroid glands.
- A normal PCV is maintained by an endocrine feedback loop. Decreased arterial PO_2 results in renal hypoxia. The kidney responds by increasing EPO secretion. EPO acts on the bone marrow to increase the rate of erythropoiesis. Increased erythropoiesis results in an increase in the circulating RBC mass.
- Polycythemia, or erythrocytosis, can be classified as either “relative” or “absolute.” Relative polycythemia may be transient or persistent. Transient relative polycythemia is caused by splenic contraction, which introduces high hematocrit blood into the circulation. Splenic contraction is mediated by epinephrine and primarily occurs in excitable animals. Transient relative polycythemia is a rare occurrence in ruminants.
- *Relative polycythemia* occurs when there is a decrease in plasma volume. Dehydration and fluid shifts are the most common cause and result in a relative increase in circulating RBC.
- *Absolute polycythemia* is caused by a true increase in the RBC mass as a result of increased erythropoiesis. Absolute polycythemia may be classified as either primary or secondary.
 - *Primary absolute polycythemia* (polycythemia vera) is considered a well-differentiated myeloproliferative disorder independent of EPO control.
 - *Secondary absolute polycythemia* is caused by overproduction of RBCs due to increased EPO concentration. Increased EPO secretion may be an appropriate response to chronic hypoxia (e.g., cardiac insufficiency), or an inappropriate and excessive production of EPO in an animal with normal PO_2 (e.g., erythropoietin-secreting renal tumor).

SYSTEMS AFFECTED

- Hemic/lymphatic/immune—moderate to marked erythrocyte hyperplasia in the bone marrow, hyperviscosity
- Cardiovascular—hyperviscosity results in sluggish blood flow and poor tissue perfusion/oxygenation.
- Respiratory—dyspnea, tachypnea, cyanosis result from poor tissue oxygenation.
- Nervous—lethargy, ataxia, blindness, and seizures due to decreased oxygen delivery to CNS tissue.
- Renal/urologic—chronic hypoxia and thrombosis may lead to renal tubular necrosis.

GENETICS

Familial erythrocytosis has been described in cattle.

INCIDENCE/PREVALENCE

Absolute polycythemia is rare in ruminants. Relative polycythemia is much more common.

GEOGRAPHIC DISTRIBUTION

- Animals at altitudes of > 6000 ft have higher RBC counts than animals at sea level.
- Among ruminants, cattle are the most susceptible to developing polycythemia due to high altitudes.

SIGNALMENT

Reference values for RBC, Hgb, and PCV vary with ruminant species. South American camelids have higher RBC counts and Hgb concentration than cattle, sheep, or goats, but PCVs are similar.

SIGNS

HISTORICAL FINDINGS

- *Transient relative polycythemia*: excitement or extreme pain
- *Relative polycythemia*: lethargy, anorexia
- *Absolute polycythemia*: weakness, lethargy, anorexia, dyspnea, tachypnea

PHYSICAL EXAMINATION FINDINGS

- *Relative polycythemia*: Dehydration (sunken eyes, decreased skin turgor, etc.) due to vomiting, diarrhea, or decreased water intake
- *Absolute polycythemia*: Depressed mental status, prominent sublingual and episcleral vessels, brick-red and/or cyanotic mucous membranes, retinal hemorrhage, \pm epistaxis, increased bronchovesicular lung sounds (due to pulmonary congestion)
- *Primary absolute polycythemia*: possible splenomegaly and hepatomegaly as reported in people with polycythemia, but these signs as well as primary polycythemia are rarely observed in domestic animals. Polyuria and polydipsia due to impaired vasopressin release.
- *Secondary absolute polycythemia caused by hypoxia*: heart murmur, weak pulses, prominent jugular veins, cyanosis, dyspnea, and abnormal lung sounds
- *Secondary absolute polycythemia due to inappropriate EPO secretion*: clinical signs include those listed above in addition to signs of neoplasia, space-occupying renal or hepatic lesions, or an endocrine disorder.

Table 1

Mechanism	Relative Polycythemia Dehydration	1° Absolute Polycythemia Myeloproliferative Disorder	2° Absolute Polycythemia Hypoxia	2° Absolute Polycythemia Increased EPO
PCV	\uparrow - $\uparrow\uparrow$	$\uparrow\uparrow$ - $\uparrow\uparrow\uparrow$	$\uparrow\uparrow$ - $\uparrow\uparrow\uparrow$	$\uparrow\uparrow$ - $\uparrow\uparrow\uparrow$
Plasma protein	\uparrow	N	N	N
EPO	N	N - \downarrow	$\uparrow\uparrow$	$\uparrow\uparrow$ - $\uparrow\uparrow\uparrow$
PO ₂	N	N	\downarrow	N
WBC	N	N - \uparrow	N	N
Plts	N - \uparrow	N - \uparrow	N - \uparrow	N

N = normal, \uparrow = slight increase, $\uparrow\uparrow$ = moderate increase, $\uparrow\uparrow\uparrow$ = extensive increase, and \downarrow = slight decrease in the listed hematologic parameters

CAUSES

- *Transient relative polycythemia*: excitement, pain, seizures, restraint
- *Relative polycythemia (common)*: vomiting, diarrhea, decreased water intake, diuresis, polyuric renal disease, internal H₂O shift from plasma to interstitial space (edema) or gastrointestinal tract lumen.
- *Primary absolute polycythemia*: rare myeloproliferative disorder in ruminants and camelids
- *Secondary absolute polycythemia due to hypoxia*: chronic primary pulmonary disease, cardiac disease, congenital heart defects that result in left to right shunting (e.g., Tetralogy of Fallot), high altitude
- *Secondary absolute polycythemia due to inappropriate EPO secretion (rare)*: renal cysts; hydronephrosis; renal, hepatic, or intestinal tumors secreting EPO or an EPO-like substance; endocrine disorders; androgenic steroids (endogenous or exogenous)

RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Transient relative polycythemia* typically occurs in young, healthy, and excitable animals.
- A mildly to moderately increased PCV and total plasma protein with concurrent clinical findings of dehydration support a diagnosis of relative polycythemia.
- *Primary absolute polycythemia* (polycythemia vera) is diagnosed by eliminating causes of relative and secondary absolute

polycythemia.

- *Secondary absolute polycythemia* is a physiologically appropriate response to conditions that cause tissue hypoxia.

CBC/BIOCHEMISTRY/URINALYSIS

Transient Relative Polycythemia

- CBC: (1) Mild to moderate increases in RBC, Hgb, and PCV; (2) leukocytosis, mild neutrophilia, and lymphocytosis; (3) plasma proteins typically normal.
- Serum biochemistry/Urinalysis: no characteristic changes

Relative Polycythemia and Absolute Polycythemia

Differentiation among the causes of relative and absolute polycythemia initially require assessment of a CBC and plasma protein (see [Table 1](#)). Additional tests confirm the diagnosis.

OTHER LABORATORY TESTS

- PO₂
- Renal, adrenal, and hepatic function tests
- EPO assay (low availability for ruminants)
- Bone marrow cytologic evaluation reveals erythroid hyperplasia in cases of any cause of absolute polycythemia.

IMAGING

Absolute Polycythemia Radiographic or ultrasonographic imaging may reveal evidence of renal or hepatic neoplasms, renal cysts, hydronephrosis, or cardiopulmonary disease.

OTHER DIAGNOSTIC PROCEDURES

N/A

TREATMENT

Transient Relative Polycythemia

Treatment is not warranted as RBC counts typically return to normal within a few hours.

Relative Polycythemia

Rehydration and correction of underlying condition leading to dehydration

Primary Absolute Polycythemia

Removal of excess RBCs by repeated phlebotomy

Secondary Absolute Polycythemia

- Removal of excess RBCs by phlebotomy is typically recommended when PCV > 60% to decrease blood viscosity, but may be offset by the need to maintain tissue oxygenation. Supplemental O₂ therapy may improve tissue oxygenation initially.
- Specific therapy for decreasing RBC mass: Phlebotomy to keep PCV less than 50% (or in the high normal range) to control hypervolemia and hyperviscosity. A guideline of 20 ml/kg of blood removed every 2 to 3 days is advised. Iron deficiency may ensue requiring decreased frequency of therapeutic phlebotomy or iron supplementation.

ACTIVITY

Restriction of activity may be indicated.

CLIENT EDUCATION

N/A

MEDICATIONS

DRUGS OF CHOICE

Relative Polycythemia

Rehydration with IV fluids appropriate for the primary cause (e.g., polyuric renal failure, diarrhea, etc.) and to correct any

electrolyte and acid-base imbalances.

Absolute Polycythemia

Hydroxyurea (30 mg/kg, PO q 24h) is used in people and occasionally in dogs with primary absolute polycythemia with some benefit.

CONTRAINDICATIONS

- Phlebotomy may be contraindicated in patients with hypoxia.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Rapid removal of blood during phlebotomy can result in severe hypotension and cardiovascular collapse.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

For polycythemia vera: chlorambucil and bisulfan have been used with limited success in dogs and cats. A safe and effective dose in ruminants or camelids is unknown. Consultation with a veterinary oncologist is advised for current treatment options. Withdrawal periods have not been determined for these medications.

FOLLOW-UP

PATIENT MONITORING

- PCV, PP, and body weight 2–3 times per day in markedly dehydrated animals or until normovolemia has been reestablished
- Respiration and heart rate, mucous membrane color
- Initially, in patients with primary absolute polycythemia receiving myelosuppressive drugs, a CBC is advised at least weekly. Monthly CBCs (monitor RBC, WBC, and Plts) following stabilization of PCV for adjustment of chemotherapy dosage and as phlebotomies are required.

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

- Chemotherapy-induced bone marrow suppression with subsequent leukopenia and thrombocytopenia
- Hyperviscosity associated with PCV > 60% may lead to thrombosis and/or hemorrhage (epistaxis most common).

EXPECTED COURSE AND PROGNOSIS

- The long-term prognosis for patients with absolute polycythemia is dependent upon the severity and cause for the disorder. Congenital cardiac defects and neoplastic diseases generally carry a guarded to poor prognosis.
- Familial erythrocytosis in cattle and primary polycythemia may be managed by phlebotomy, but long-term studies evaluating effectiveness of treatment in affected ruminants are lacking.

POSTERIOR VENA CAVA THROMBOSIS SYNDROME

BASICS

DEFINITION

- An embolic pneumonia characterized by multifocal abscessation, which is caused by septic emboli that originate from a septic thrombus in the caudal vena cava.
- The septic thrombi in the vena cava are most often sequelae from liver abscesses caused by ruminal acidosis.

PATHOPHYSIOLOGY

- Feedlot cattle and dairy cattle that are fed rapidly fermentable high-carbohydrate grain diets commonly experience ruminal acidosis.
- Acidosis of rumen results in rumenitis and damage to rumen epithelium.
- Bacteria such as *Fusophorum necrophorum* and *Actinomyces pyogenes* (*Arcanobacterium pyogenes*) enter the portal blood stream and are transported to the liver.
- Liver abscessation occurs.
- If liver abscesses infiltrate the caudal vena cava, a septic thrombus can form.
- Septic emboli from thrombus then enter the pulmonary arterial system and cause an embolic pneumonia.
- Abscessation in the lung may erode pulmonary arterial vasculature in the lung and cause sudden death due to hemorrhage from the respiratory tract.

SYSTEMS AFFECTED

GENETICS

N/A

INCIDENCE/PREVALENCE

- 1.3% of feedlot deaths
- 1.6–7.3 cases per 100,000 head on feed

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Species

Cattle

Breed Predilections

- Feedlot cattle
- Dairy cows on high-grain diets

Mean Age and Range

- More common in yearling feedlot cattle and adult dairy cattle
- Uncommon in cattle less than 1 year of age
- 68% of cases in feedlot yearlings occur in first 90 days on feed

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Chronic history of weight loss
- Coughing

- History of episodes of epistaxis
- May exhibit acute respiratory distress
- May be found suddenly dead

PHYSICAL EXAMINATION FINDINGS

- Tachypnea
- Tachycardia
- May be febrile
- Respirations appear painful
- Mild expiratory grunt
- Epistaxis
- Hemoptysis
- Pale mucous membranes due to anemia
- Hemic murmurs
- Coughing
- Melena caused by coughing up and swallowing blood
- Subcutaneous emphysema
- Widespread rhonchi on auscultation of advanced cases
- Up to 50% of cases may die suddenly because of acute hemorrhage from the respiratory tract.

CAUSES

Primary Agents

- *Fusobacterium necrophorum*
- *Arcanobacterium pyogenes* (*Actinomyces pyogenes*)
- *Staphylococcus*
- *Streptococcus*
- *Escherichia coli*

Secondary Agents

N/A

RISK FACTORS

- Highly fermentable carbohydrate-based diets
- Sudden increase in the proportion of grain in the diet
- Thrombi may also originate from other sources of infection, such as jugular phlebitis, mastitis, metritis, foot rot

DIAGNOSIS

- Anaphylaxis
- Atypical interstitial pneumonia
- Hypersensitivity pneumonitis
- Lungworm

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia
- Neutrophilic leukocytosis with a left shift
- Hypergammaglobulinemia due to chronic infection

OTHER LABORATORY TESTS IMAGING

- Increase in lung density
- Distinct opacities related to embolic infarcts may be evident.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Hepatic abscessation
- Thrombus in posterior vena cava
- Hepatomegaly
- Ascites
- Multiple pulmonary abscesses
- Intrapulmonary hemorrhage
- Swallowed blood evident in rumen

TREATMENT

APPROPRIATE HEALTH CARE

- Case fatality rate is close to 100%.
- Salvage is the only realistic option although condemnation of carcass is highly likely.
- Euthanasia should be considered.
- Antibiotic therapy may be attempted but is largely unsuccessful.

POSTPARTURIENT HEMOGLOBINURIA

BASICS

DEFINITION

This uncommon and sporadic condition causes intravascular hemolysis in cattle shortly after parturition, resulting in anemia and hemoglobinuria.

PATHOPHYSIOLOGY

- The exact etiology of this disease is not entirely known; however, inadequate dietary phosphorus leading to hypophosphatemia is often detected in affected cows. Hypocupremia may also be a predisposing factor.
- Hypophosphatemia alters erythrocyte metabolism, making red blood cells more susceptible to intravascular hemolysis. Hypocupremia predisposes erythrocytes to oxidative damage and Heinz body formation, also leading to intravascular hemolysis.

SYSTEMS AFFECTED

- Hemic: regenerative anemia, intravascular hemolysis, hemoglobinemia, hemoglobinuria, icterus
- Cardiovascular: hypoxemia
- Renal: pigment nephropathy
- Metabolic: ketosis

GENETICS

N/A

INCIDENCE/PREVALENCE

Although the condition is sporadic and the incidence is low, the mortality rate is high.

GEOGRAPHIC DISTRIBUTION

- Cases have been reported worldwide.
- In the United States, disease is more common in the winter months in northern states.

SIGNALMENT

Species

Cattle

Breed Predilections

Most common in dairy breeds

Mean Age and Range

Multiparous cows within the first month of calving

Predominant Sex

Female

SIGNS

GENERAL COMMENTS

High-producing dairy cattle appear to be most susceptible.

HISTORICAL FINDINGS

Recent calving, progressive depression, weakness and lethargy, anorexia, decreased milk production, red to brown discolored urine

PHYSICAL EXAMINATION FINDINGS

- The clinical signs depend on the severity and rate at which hemolysis occurs.
- Weakness and recumbency are expected as the condition progresses. In severe cases, signs of hypovolemic shock may be present, including tachycardia, tachypnea, pallor of the mucous membranes, lack of episcleral vessels, and cool extremities.

- A low-grade fever may be present. A grade I to III/VI systolic murmur may be audible over the heart base as blood viscosity decreases with advancing anemia.
- When the plasma hemoglobin concentration exceeds the renal threshold, hemoglobinuria will occur. Within 1 to 2 days, icterus of the mucous membranes and sclera will develop.

CAUSES

- Low dietary phosphorus
- Low dietary copper
- Parturition
- Ingestion of alfalfa hay or sugar beet that may contain saponins
- Copper deficiency

RISK FACTORS

- High-producing multiparous dairy cow consuming diets low in phosphorus are at greatest risk of disease.
- Drought conditions, grazing phosphorus-deficient soil, prolonged housing, and exposure to extremely cold weather may also predispose to the disease.
- Consumption of rape, turnips, or other cruciferous plants, and large amounts of beet pulp or cold water are associated with the disease.
- In New Zealand, low blood and liver copper levels and grazing copper-deficient pastures are additional risk factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Any cause of intravascular hemolysis in the cow would cause similar signs: babesiosis, bacillary hemoglobinuria, leptospirosis, onion, rape, or kale plant toxicity, copper toxicity, and autoimmune hemolytic anemia.

CBC/BIOCHEMISTRY/URINALYSIS

- Anemia
- Regenerative anemia 5 to 7 days after onset (signs of regeneration include an increased MCV, anisocytosis, polychromasia, basophilic stippling, reticulocytes)
- Hemoglobinemia (pink plasma, MCH, and MCHC increased)
- Hemoglobinuria
- Hyperbilirubinemia (unconjugated)
- Azotemia
- Acidosis
- Ketonuria

OTHER LABORATORY TESTS

- Decreased serum phosphorus concentrations are evident.
- In New Zealand cases, decreased blood copper concentration and Heinz bodies in erythrocytes have been noted.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

Hemoglobinuria and widespread icterus

TREATMENT

APPROPRIATE HEALTH CARE

Emergency inpatient or outpatient care

NURSING CARE

- Intravenous fluid therapy with polyionic isotonic fluids is indicated.
- When anemia is severe and clinical or laboratory evidence of hypoxemia is evident (intense lethargy or weakness, profound tachycardia or tachypnea, severe anemia, acidosis, increased anion gap), a whole blood transfusion is indicated.
- The normal total blood volume is approximately 8% of the body weight (i.e., $0.08 \times$ body weight in kilograms equals the total blood volume in liters). Typically, transfusing 1/4 to 1/3 of the total blood volume is adequate.

ACTIVITY

Confined

DIET

Increase dietary phosphorus intake.

CLIENT EDUCATION

Increase dietary phosphorus intake in unaffected herd mates.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- Sodium acid phosphate ($\text{NaH}_2\text{PO}_4\text{H}_2\text{O}$; 60 grams in 300 mls of sterile water) should be given intravenously, followed by subcutaneous dosing every 12 hours for 2 days.
- Oral phosphorus supplementation should be supplied in the form of bonemeal or dicalcium phosphate.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Avoid concurrent use of potentially nephrotoxic drugs.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Heart rate, respiratory rate, attitude, appetite, PCV, serum phosphorus and copper concentrations, creatinine

PREVENTION/AVOIDANCE

Ensure adequate dietary phosphorus and copper intake in the early postpartum period.

POSSIBLE COMPLICATIONS

- Renal disease from hemoglobinuria
- Ketosis
- Death from hypoxemia

EXPECTED COURSE AND PROGNOSIS

- The prognosis is guarded to poor, even with appropriate treatment.
- The clinical course is acute, progressing to recumbency in 3 to 5 days. In severe cases, death can occur within hours.
- Surviving cows may need a 4-week period of convalescence.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Ingestion of feeds that contain saponins may predispose to hemolysis.

PRECOCIOUS UDDER

BASICS

OVERVIEW

- A precocious udder is a mammary system that is more developed than usual at a given age or stage of lactation.
- Enlargement of the mammary gland generally begins near puberty.
- During puberty, mammary gland growth occurs in the female mostly due to increased amounts of connective tissue and fat deposition.
- Estrous periods stimulate the development of secretory and duct tissues. Growth of lactation tissue is dependent on two hormones: estrogen from developing follicles and progesterone from the corpus luteum.
- Cyclic secretion of estrogen stimulates duct development of the mammary gland.
- Progesterone secretion is cyclic in nonpregnant animals, and nearly continuous in pregnant animals, and causes secretory tissue development.
- Gynecomastia in male goats can occur (e.g., Alpine and Saanen breeds) especially during the summer months.

SYSTEMS AFFECTED

- Endocrine/metabolic
- Reproductive
- Mammary
- Skin/exocrine

SIGNALMENT

- Precocious udders are most commonly seen in young milking breeds of goats such as the Saanen, Alpine, Toggenburg, LaMancha, and Nubian.
- Young kids may develop precocious udders more frequently during springtime.
- It has also been described in cattle and sheep much less commonly.

SIGNS

- Early development of the mammary gland in the absence of pregnancy is the most common sign of precocious udder.
- Goat kids may be born with significant udders containing milk (witch's milk).

CAUSES AND RISK FACTORS

- Onset of puberty
- Prolonged progesterone production of false pregnancy
- In utero hormone stimulation
- Increased hormone receptors
- Exposure to high levels of estrogen
- Artificial lactation-induction programs
- Spring season (increased levels of prolactin)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Mastitis
- Persistent corpus luteum

- Infection due to inappropriate suckling
- Intersex
- Neoplasia
- Fatty udder due to overconditioning
- High estrogen levels in feed (e.g., clover, moldy corn)

CBC/CHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Imaging (ultrasound) may be useful to rule out neoplasia.

DIAGNOSTIC PROCEDURES

- The udder should be symmetrical, firm to soft tissue consistency, and free of irregular lumps.
- Rule out mastitis by evaluating any secretions that are present for signs of inflammation.
- If abnormalities are found on palpation, especially in older lactation animals, imaging or biopsy of the mass is warranted to rule out neoplasia.

PATHOLOGIC FINDINGS

N/A

TREATMENT

- The generally accepted treatment for a precocious udder is to do nothing.
- Once mastitis is ruled out, separate the animal from others, especially young stock that may try to nurse.
- Hydrotherapy
- Feeding management to dry off the animal (e.g., increase the level of poor-quality hay in the diet and eliminate grain).
- If the milk production is persistent, the teats leak, or the animal is very uncomfortable and/or painful, it might be necessary to initiate milking. It should be noted that if milking is instituted, an increased risk of mastitis can be seen.
- The effect of milking on the lifetime production of the animal has not been documented.
- In pet goats with large udders, amputation may be necessary.
- Although not tested, an ovariectomy may prevent this problem in pet goats.
- With gynecomastia in male goats, reduce energy and protein intake levels during spring and summer months.

MEDICATIONS

DRUGS OF CHOICE

- PGF2 α (5 mg IM has been utilized with persistent CL)
- NSAIDs if painful (flunixin meglumine 1–2 mg/kg IV or IM)
- Diuretics and steroid treatment may be helpful (furosemide 2–10 mg/kg IM, dexamethasone (0.1–1.0 mg/kg IM))

CONTRAINDICATIONS

N/A

POSSIBLE INTERACTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PREGNANCY DIAGNOSIS IN THE BOVINE

BASICS

OVERVIEW

- Accurate early diagnosis of pregnant and nonpregnant cows is essential for optimization of reproductive performance, particularly in dairy cattle.
- Methods for diagnosis of nonpregnant or pregnant status include behavioral observation, clinical techniques, and laboratory evaluation.

SYSTEMS AFFECTED

Reproductive

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Bovine

Breed Predispositions

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

DIAGNOSIS

Behavioral Observation

- Return to estrus is considered a strong indication that a cow is not pregnant. Up to 5% of pregnant females may display some signs of estrus.
- Nonreturn to estrus can be an indication of pregnancy; however, females that have persistent corpus luteum function (pyometra) or are truly anestrus contribute greatly to increase in false positive diagnosis.

Clinical Diagnosis

Transrectal Palpation

Per-rectum palpation of the uterus and its contents is the oldest and most commonly used technique for diagnosis and staging of pregnancy. Positive diagnosis of pregnancy is only established if one of the following is identified

- Presence of fetal membrane slip
- Palpation of the amniotic vesicle
- Palpation of placentomes
- Palpation of the fetus

Fetal Membrane Slip

- Characteristic crisp slip of the chorioallantois within the lumen of pregnant uterus
- May be present as early as 30 days of pregnancy
- Very reliable after 35 days

Amniotic Vesicle

- Spherical turgid, fluid-filled structure within the pregnant horn
- Palpable as early as 28 days after conception
- Size of the amniotic vesicle is very helpful for staging pregnancy between 30 and 55 days
- Helpful in the diagnosis of twin pregnancies
- Difficult to palpate after 60 days
- Rough manipulation of the amniotic vesicle has been associated with pregnancy loss and atresia ani/coli.

Placentomes

- Characteristic of ruminant placentation
- Numbers 80 to 120 arranged in two dorsal and two ventral rows
- Palpable as early as 75 days of pregnancy
- Size of placentomes is very helpful in estimating stage of pregnancy
- Most consistent size immediately cranial to the cervix
- False positive: placentomes are present following abortion or death of the fetus, mistaking ovary for placentomes
- False negative increase between 5 and 6 months of pregnancy

Fetus

- Palpable starting at 65 days of pregnancy when amniotic sac becomes more flexible
- At early stages, the whole fetus can be grasped directly.
- Easy to palpate up to 5 months and between 7 and 9 months
- Difficult to palpate between the fifth and seventh months

Accuracy and Safety of Palpation Per Rectum

- Very accurate with moderate degree of expertise after 35 days
- Should take into account early pregnancy loss (5%–12%)
- Very safe if used by a trained person
- Rough manipulation of the amniotic vesicle may result in pregnancy attrition.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Progesterone

- Progesterone is produced by the corpus luteum. In absence of maternal recognition of pregnancy, progesterone falls to basal levels (below 1 ng/ml) around day 17 or 19 after insemination
- Determination of progesterone level in milk or serum can be used to accurately identify nonpregnant cows.
- Elevated milk or serum progesterone levels (> 2 ng/ml) suggests maintenance of corpus luteum activity and possible pregnancy
- Low milk or serum levels (< 1 ng/ml) are very specific for diagnosis of nonpregnancy
- Sensitivity of this test depends on the assay used (RIA or ELISA techniques are more sensitive)
- Progesterone assay is best accomplished 18 to 24 days after insemination
- Cow-side tests for use on serum or milk are available
- In-line milk progesterone tests are becoming available

Pregnancy-specific Proteins

- The trophoblastic binucleate cells from the early ruminant conceptus produce large amounts of specific proteins that can be detected in maternal circulation and can be used for pregnancy diagnosis.
- The most commonly used pregnancy-specific proteins are bovine pregnancy-specific protein B (bPSPB) and to a lesser extent bovine pregnancy-associated glycoprotein 1 (bPAG-1).
- A test for bPSPB is available commercially from several laboratories.

- Sensitivity and specificity of bPSPB increases from 75% and 85% at 26–27 days to 100% and 85% by days 37–45, respectively.
- Specificity of bPSPB is 90%–92% after day 45.
- Sensitivity of bPAG-1 increases from 81% at 26–27 days to 100% by day 44. However, its specificity is low and only reaches 71% at 60 days.
- Problems with these techniques
 - Both of these proteins can be detected in the postpartum period up to 70–100 days after calving and leads to increased false positives in this period.
 - These proteins can be detected for a long time after abortion or early embryonic death and may lead to false positive results.
 - Results are not immediate and therefore action on open cows cannot be taken immediately.
 - Pregnancy confirmation at a later date is still advised, particularly in herds that are experiencing early embryonic death/pregnancy loss.
 - Uterine and ovarian pathologies may go unnoticed for a long time.

Early Conception Factor (ECF)

- Early conception factor is a pregnancy-associated glycoprotein produced as early as 24 hours postfertilization.
- A proprietary milk or serum cow side test is commercialized under the name of ECF and is supposed to identify nonpregnant cows with high accuracy between 6 and 30 days postinsemination.
- A high accuracy of 93%–100% for identification of open cows has been reported for this test but is contested by other studies and field experiments.

Interferon-tau (IFN- τ)

Maintenance of corpus luteum function is essential for the maintenance of pregnancy.

- Interferon-tau (IFN- τ), previously called trophoblastic, of trophoblast protein-1 is the initial requisite signal for pregnancy recognition in ruminants.
- IFN- τ inhibits corpus luteum regression by suppressing the pulsatile release of PGF2 alpha from the endometrium.
- IFN- τ can be detected in blood between days 15 and 30 postconception.
- Commercial tests (SUREBRED) are being tested for diagnosis of pregnancy at day 18 postinsemination.
- Initial results of these tests show a sensitivity of 99% and specificity at 97%.
- The advantage of this test is that heat detection can be focused on cows that test negative at 18 days.
- Cows determined to be pregnant should still be examined at a later date by transrectal method.

General Recommendations for Pregnancy Diagnosis

- Early pregnancy diagnosis techniques should focus on accurate identification of nonpregnant cows.
- The appropriate diagnostic technique to be used in a herd will depend on several factors (heat detection efficiency, method of breeding, cost of labor, cost of the technique, pregnancy rate, size of the herd, etc.). An efficient system should be designed in collaboration between the attending veterinarian and the herd manager.
- Regardless of the method used for pregnancy diagnosis, cows should be reexamined at a later date for confirmation of pregnancy status if the fetus was not palpated.
- Direct examination of the genital tract by transrectal palpation and/or ultrasonography should continue to be used for confirmation of pregnancy status, staging of pregnancy in bull bred dairy cows, and early diagnosis of pathologies of the reproductive tract

IMAGING

Ultrasonography

- Pregnancy diagnosis by ultrasonography is best accomplished using a linear array 5 MHz transducer (7 MHz transducers are more accurate before day 28 of pregnancy but are not commonly used in cattle practice).
- Diagnosis of pregnancy with ultrasonography is possible as early as 25 days in heifers and 27 days in cows.
- Accuracy of pregnancy diagnosis using transrectal ultrasonography increases with gestational age and sensitivity and the specificity of the technique approaches 100% at 32 days.
- Specificity is increased if the operator uses presence of fetal heartbeat as a sign of pregnancy rather than just fetal fluid. This is easily accomplished at 29 days but requires increased examination time.

- Ultrasonography increases the accuracy of diagnosis of twins and early pregnancy loss.
- Ultrasonography can be used to estimate gestational age (amniotic vesicle diameter, fetal head biparietal diameter, fetal crown-rump length).
- Ultrasonography can be used to determine fetal gender by identification of the position of the genital tubercle (55 days), penis, scrotum, vulva, or udder.

PREGNANCY TOXEMIA: SHEEP AND GOATS

BASICS

DEFINITION

- Pregnancy toxemia is a common metabolic disease in sheep and goats that results from the inability of the dam to maintain glucose homeostasis in the face of increasing energy demands from multiple fetuses during late gestation.
- The condition is characterized by anorexia, weakness, and depression, and occurs during the last 2 to 4 weeks of pregnancy in does and ewes.

PATHOPHYSIOLOGY

- The fetal placental unit requires glucose for energy and may consume up to 40% of the maternal glucose production during the rapid growth that occurs during the last weeks of gestation.
- If the dam is unable to maintain glucose homeostasis, body fat stores will be converted to glucose with the undesirable production of ketone bodies that will eventually result in the ketonemia and ketonuria present in clinical pregnancy toxemia.
- Insulin function is critical in glucose uptake by cells and may be an important factor in glucose homeostasis and ultimately in the susceptibility of individual animals to development of pregnancy toxemia.
- Pregnancy toxemia is caused by a negative energy balance due to an increased energy demand of rapid fetal growth during late gestation and insufficient intake.
- The cause of pregnancy toxemia has been hypothesized to result from a suppression of endogenous glucose production by elevated ketone body concentrations.
- Hyperketonemia may invoke sustained hypoglycemia and place the ewe into a vicious cycle that will probably make the animal refractory to treatments.

SYSTEMS AFFECTED

- Nervous: effects on the central nervous system are associated with the effects of hypoglycemic encephalopathy and include depression, incoordination, mental dullness, stargazing, tremors, and blindness.
- Musculoskeletal: muscle weakness, recumbency
- Endocrine/metabolic: metabolic acidosis is a common feature.
- Gastrointestinal: rumen function is compromised and ewes are often constipated.
- Reproductive: multiple fetuses are usually present and are usually in peril if the ewe does not respond rapidly to treatment.
- Hepatobiliary: overconditioned dams will often have severe hepatic lipidosis.

GENETICS

- Variation in clinical incidence within flocks and between flocks suggests that some animals may be genetically susceptible to development of pregnancy toxemia.
- The key factor may be associated with the ability of insulin to function in glucose uptake at the cellular level and ultimately help maintain glucose homeostasis in the face of increased demand from the fetuses.
- Highly prolific sheep may be predisposed to pregnancy toxemia due to reduced rumen capacity and increased glucose demand from four or more fetuses; however, nutritional management is usually the primary predisposing factor.

INCIDENCE/PREVALENCE

- Varies widely between flocks/herds and production styles
- Usually presents with isolated cases in well-managed flocks; however, outbreaks have occurred if nutritional and management factors put all individuals at risk.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Primarily affects sheep and goats, rarely cattle

Breed

Prolific breeds may be at greater risk for nutritional mismanagement.

Mean Age and Range

Mature ewes primarily affected, rare in first-time lambers

Predominant Sex

Late gestation females

SIGNS

HISTORICAL FINDINGS

Late gestation, heavy with multiple fetuses, possibly recently sheared, stands off by itself, off feed, depressed, recumbent, weakness and mental dullness, blindness, disoriented, head pressing, and teeth grinding

PHYSICAL EXAMINATION FINDINGS

Anorexia, ketones on the breath, weakness, depression, incoordination, mental dullness, impaired vision, followed by recumbency and death within 3 to 4 days without treatment.

CAUSES

- Pregnancy toxemia is caused by an inability of the dam to maintain glucose homeostasis in the face of increased demand from the fetal-placental unit in late gestation.
- Individual cases will fit in one of the following broad categories:

Primary Pregnancy Toxemia

- Failure to increase nutritional plane to compensate for increased fetal demand for glucose during late gestation
- Often a simple management change such as shearing or a sudden storm that results in brief periods of feed deprivation may trigger clinical disease in animals that may have subclinical ketosis.

Fat Ewe Pregnancy Toxemia

Overconditioning of the dam during early gestation resulting in increased abdominal fat and reduced rumen capacity, possible hepatic lipidosis that also impairs glucose metabolism

Starvation Pregnancy Toxemia

Ewes in poor body condition associated with mismanagement or unavailability of feedstuffs, more common in range situations

Secondary Pregnancy Toxemia

Concurrent disease in affected ewes, examples would include lameness or pneumonia

RISK FACTORS

Dams with multiple fetuses, late gestation, improper, declining, or interrupted nutritional inputs

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypocalcemia
- Listeriosis
- Polioencephalomalacia
- Hypomagnesemia
- Trauma
- Parasitism
- Meningeal worm

Table 1

Parameters of Glucose Metabolism in Normo- and Hyperketonemic Sheep

	Reproductive Phase		
	Nonpregnant/Nonlactating	Pregnant	Lactating
Day of experiment ^a	> 100	-9.57 +/- 7.44	19.29 +/- 5.96
Normoketonemia ^b	2.92 +/- 0.3	3.35 +/- 1.6	2.85 +/- 0.6
Hyperketonemia ^c	2.06 +/- 0.2	2.23 +/- 1.5	1.97 +/- 0.9

^aDay of experiment with respect to parturition

^bConcentration of blood glucose in blood plasma (mmol/L)

^cConcentration of blood glucose in blood plasma (mmol/L)

CBC/BIOCHEMISTRY/URINALYSIS

CBC

Some ewes with pregnancy toxemia will have nonspecific but marked neutrophilia (reaching 35,000 neutrophils/ μ l).

Biochemistry

Blood glucose and calcium concentrations are typically low; samples for blood glucose should be removed from the blood clot as soon as possible.

- Nonesterified fatty acids, betahydroxybutyrate, and acetoacetate concentrations are elevated; urea concentrations are normal.
- Impaired intravenous glucose tolerance test, not practical in a clinical practice
- High circulating concentrations of ketone bodies may suppress endogenous synthesis of glucose and facilitate development of pregnancy toxemia. In addition, the hyperketonemia may render the ewe refractory to treatment (see [Table 1](#)).
- Ewes are often acidotic with lower than normal serum concentrations of potassium and calcium.
- Circulating concentrations of both NEFA (> 500 μ Eq/L) and betahydroxybutyrate (> 1 mmol/L) are increased.

Urinalysis

Elevated ketones on urinalysis; ketonuria is present and usually detected before ketonemia.

OTHER LABORATORY TESTS

N/A

IMAGING

Ultrasound could potentially be used to determine the viability of fetuses in clinical pregnancy toxemia to better evaluate potential treatment strategies.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Gross necropsy findings vary with body condition and initiating causes. Multiple fetuses are usually present.
- Body fat reserves may be depleted with pronounced serous atrophy in the thin ewe syndrome or abundant in the overconditioned ewe.
- Fatty degeneration of the liver may be present in some ewes; however, the severity of this change is difficult to evaluate grossly.
- Histologic lesions include hepatic lipidoses and neuronal necrosis and astrocytosis.
- Complete postmortem examinations are rarely performed.

TREATMENT

APPROPRIATE HEALTH CARE

- Pregnancy toxemia is best managed as a flock or herd problem and addressed through appropriate nutritional and

management changes. Treatment costs and prognosis should be considered before any treatment is recommended. Individual animals should be segregated from the flock for treatment and monitoring purposes.

- The first step in treating pregnancy toxemia in ewes is to remove the fetuses by cesarean section or by inducing parturition.
- Induction of parturition in ewes is usually accomplished with 15 to 20 mg of dexamethasone, and with either dexamethasone (10 mg) or prostaglandin F₂ α (10 μ g) in does.
- The ketosis should be treated by administering 250–500 ml of glucose (10%–20% solution) intravenously, followed by a slow infusion of 5%–10% glucose.
- Other underlying conditions, such as acidosis and hypocalcemia, must be corrected also.
- Propylene glycol (15–30 ml every 12 hours) or sodium propionate are routinely used as glucose precursors. Precautions should be taken when administering the propylene glycol, as excessive amounts may lead to acidosis and/or cause diarrhea.

NURSING CARE

- The goal of therapy in pregnancy toxemia is to restore glucose homeostasis as soon as possible.
- Multiple electrolyte, acid-base, and fluid imbalances in addition to low blood glucose levels will need to be considered in any potential treatment plan.

ACTIVITY

The affected dam should be isolated to reduce expenditures of energy and limit competition for feed resources.

DIET

High-quality forages and concentrates should be offered in an attempt to stimulate intake.

CLIENT EDUCATION

Repeated and prolonged treatments will be needed. The owner will need to evaluate the economics of therapy versus probable outcomes.

SURGICAL CONSIDERATIONS

Cesarean section may be needed to remove the fetal drain on glucose production. Often the fetuses are nonviable and the procedure is used to save the dam.

MEDICATIONS

DRUGS OF CHOICE

- There are no specific drugs of choice, however, several drugs are occasionally used in individual cases of pregnancy toxemia in combination with glucose, fluid, and electrolyte imbalances.
- Dexamethasone 20–30 mg IM, for induction of parturition, response may be variable depending on the clinical condition of the dam
- Protamine zinc insulin 20–40 units intramuscularly every other day in combination with glucose and fluid therapy
- Recombinant bovine somatotropin (not currently approved for use in sheep) 160 mg of slow-release formulation may increase efficiency of glucose and ketone utilization.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Feed intake is a critical factor in monitoring for treatment success. If the animal is recumbent for a prolonged period, the odds of recovery are substantially reduced.

PREVENTION/AVOIDANCE

- Prevention of future cases of pregnancy toxemia is best accomplished by evaluation of nutritional and management practices within the flock.
- Designing nutritional programs that meet the animals' requirements based on the stage of production and relevant environmental and management conditions can prevent most cases of pregnancy toxemia.
- Dividing large groups based on expected production may help the producer more effectively meet the requirements of highly productive individuals.
- The common occurrence of twins and triplets in ewes increases the nutrient requirements of the ewe during the last trimester of pregnancy. Consequently, excellent-quality forage must be provided.
- Last, a plasma concentration of betahydroxybutyrate of 0.8 mmol/L or higher is diagnostic of the need for increased energy consumption. This is a good clinicopathologic tool for diagnosing malnutrition before irreversible pregnancy toxemia develops.

POSSIBLE COMPLICATIONS

Complications during birth, failure to expel the placenta and difficulties during early lactation are all common issues in dams that survive to the induced or natural initiation of parturition.

EXPECTED COURSE AND PROGNOSIS

- Treatment is often unrewarding and, in many cases within commercial flocks, economically unfeasible. The prognosis is usually poor for recovery if recumbency is prolonged.
- Termination of the pregnancy by induction with dexamethasone or cesarean section is unpredictable for the survival of the fetuses, and if delayed too long, for the dam as well.

MISCELLANEOUS

ASSOCIATED CONDITIONS

May be associated with concurrent hypocalcemia. Calcium therapy is combined with glucose or glucose-precursor therapy.

AGE-RELATED FACTORS

More common in older ewes, not associated with first-time lambers

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Pregnancy toxemia is present in dams in late gestation.

RUMINANT SPECIES AFFECTED

Sheep, goats, and rarely cattle

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

PREPUTIAL PROLAPSE

BASICS

OVERVIEW

- Lacerations, contusions, and prolapse of the prepuce are the most common problems that affect the breeding ability of range bulls.
- Most preputial lesions are acquired during the breeding season.
- Damage usually affects the internal prepuce and occurs during the act of coitus or immediately after when the penis is extended and the prepuce is most dependent.
- Preputial lacerations may occur during breeding when there is “bunching” of excess preputial tissue immediately prior to the breeding lunge causing the tissue to burst ventrally in a longitudinal direction when the prepuce impacts upon the pubis of the cow. Because of the elastic layers and retraction of the penis, there is a marked tendency for healing to occur in a transverse manner shortening the effective length of the prepuce as it heals.
- Bulls that frequently have some prepuce exposed may develop abrasions and lacerations of the prepuce from exposure to environmental factors (including frostbite) although this is less common than lesions caused by breeding injuries.
- Initial trauma may lead to edema, further prolapse, more trauma, abscessation, and eventually fibrosis of the preputial tissue.

SIGNALMENT

- Habitual prolapse of the prepuce is common among *Bos indicus* breeds.
- Santa Gertrudis, Beefmaster, Brangus, Angus, and polled Hereford bulls have a higher incidence of preputial injuries.

SIGNS

- Traumatic injury results in edema formation and preputial prolapse.
- Abscesses and fibrosis may be present.

CAUSES AND RISK FACTORS

- Predisposition to preputial prolapse probably involves four hereditary anatomic features including a pendulous sheath, an excessively long prepuce, a large preputial orifice, and the absence of retractor prepuce muscles.
- In polled breeds, especially polled Hereford and Angus, the caudal preputial retractor muscles are frequently absent or rudimentary.
- The sheath and prepuce of *Bos indicus* bulls are more pendulous averaging 5.5 cm longer than *Bos taurus* breeds.

DIAGNOSIS

N/A

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

N/A

TREATMENT

- Treatment is initially aimed at medical management.
- The injured prepuce should be soaked in a warm dilute betadine and Epsom salt solution, treated topically with antimicrobial ointment, and replaced into the preputial cavity.
- The prepuce is held in a normal position by placement of a tube, which is taped to the sheath.
- Medical treatment is continued daily until the lesion is adequately healed.
- The object of medical treatment is to get control of edema, cellulitis, and necrosis and establish a healthy bed of granulation tissue.
- After medical treatment, surgery may be indicated depending on the severity of the trauma and the desire of the owner.
- Surgery is indicated if fibrous tissue development prevents normal extension of the prepuce or if there is habitual prolapse of the prepuce.
- The most commonly performed surgical technique is the reefing procedure (resection-anastomosis); this technique is employed to revise damaged preputial tissues and shorten the prepuce.
- The prepuce is measured prior to incision to assure that the final preputial length will be at least twice the length of the free portion of the penis.
- If the value of the bull does not warrant surgery, salvage is an option.

MEDICATIONS

DRUGS OF CHOICE

- Topical antimicrobials are utilized during medical treatment.
- Parenteral antibiotics are given perioperatively.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

Sexual rest is recommended for at least 60 days after surgical treatment.

PSEUDOCOWPOX

BASICS

OVERVIEW

- Pseudocowpox is a parapoxvirus that affects cattle but is closely related to contagious ovine ecthyma (orf) in sheep and bovine papular stomatitis in cattle.
- The lesions are small, 2–5-mm erythematous macules and papules that develop on the teats, udders, and perineum.
- These lesions eventually rupture and crust over.

SIGNALMENT

- Most cases involve adult milking cows and tend to occur in cyclic infections with the introduction of naïve animals and the waning of immunity in previously exposed older animals.
- The disease tends not to affect dry cows, heifers, and bulls.
- Calves suckling infected teats can develop oral lesions.

SIGNS

- Animals rarely develop fevers but may have a drop in milk production due to teat irritation.
- Lesions begin as small macules and papules 2–5 mm in diameter, on the teat, udder, and perineum, which slowly expand to round, reddened, raised lesions 1–2 cm in diameter with an overlying ring-shaped scab or crust.
- In nursing calves, the lesions may be located in the oral cavity with raised, umbilicated, circular ulcers on the tongue or palate.

CAUSES AND RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Herpesvirus mammillitis: usually begins as small, 2–3-mm vesicles or pustules that rupture forming small, slow-healing ulcers. These can coalesce forming larger lesions that are slow to heal.
- Bovine papular stomatitis: usually occurs in suckling calves but can occasionally be seen on the teats and udder of infected cattle. Lesions are often umbilicated with a central scab.
- Cowpox: disease primarily of Europe with lesions having an umbilicated appearance on the udder and teat.
- Foot-and-mouth disease: vesicles, which ulcerate, can be seen on teats. Usually, the oral vesicles and vesicles in the interdigital space are commonly seen associated with teat lesions, which would make it easy to differentiate from pseudocowpox.
- Vesicular stomatitis: vesicles and ulcers can be seen on teats, however most vesicles are usually associated with lesion in the mouth and occasionally on feet.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Electron microscopic evaluation of the scab will identify parapoxvirus particles.
- Virus isolation from infected scabs can assist in the identification of the virus.

PATHOLOGIC FINDINGS

Gross Findings

- Small, 2–5-mm erythematous macules and papules develop on the teats, udder, and perineum, which rupture and crust over.
- As the lesions progress, they enlarge to 1–2 cm in diameter with an erythematous outer rim and a peripheral ring-shaped scab. If the scab is removed, you have an ulcerated lesion that slowly heals. This differs from cowpox in that the lesion is not umbilicated.

Histopathologic Findings

- The lesion is primarily epithelial with the epidermis undergoing vacuolar degeneration and vesicle formation.
- Older lesions have neutrophils filling the vesicle. Eosinophilic intracytoplasmic inclusions are present in the vacuolated epithelium.

TREATMENT

The lesions of pseudocowpox are usually self-limiting and require little care other than keeping the lesion free of debris and preventing secondary bacterial infections of the open sore.

MEDICATIONS

N/A

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Little immunity is present after infections.
- Animals probably transmit the disease during milking.

POSSIBLE COMPLICATIONS

Secondary bacterial mastitis or dermatitis can occur in lesions.

EXPECTED COURSE AND PROGNOSIS

Most animals recover without any problems.

MISCELLANEOUS

ASSOCIATED CONDITIONS

AGE-RELATED FACTORS

Calves may become infected with the virus and have lesions in the mouth from suckling on infected teats.

ZOONOTIC POTENTIAL

- This disease can be transmitted to herdsmen working on infected animals.
- Lesions develop on the hands (fingers) and face.
- These lesions are usually discrete, round, slow-healing ulcers.

PSEUDORABIES

BASICS

OVERVIEW

- Pseudorabies is a reportable disease caused by a DNA herpesvirus. The name is derived from the clinical similarities to rabies. The primary host is the pig.
- Pseudorabies in ruminants occurs as acute encephalitis.

SYSTEMS AFFECTED

CNS, skin, production management

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Worldwide distribution

SIGNALMENT

- Swine are the primary host.
- Natural infections can occur in sheep, goats, and cattle.
- Dead-end hosts include rats, feral animals, dogs, and cats.

Species

Sheep, goats, and cattle; potentially all ruminants

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

Either sex appears affected equally

SIGNS

- Ruminants have an incubation period of 4–7 days.
- Duration of illness ranges from 8 hours to 3 days. Many animals die suddenly without showing clinical signs of illness.
- The term “mad itch disease” in cattle resulted from the intense pruritis at the point of dermal contact with the pathogen. The animal begins licking at the area, then scratches the skin against inanimate objects. This may progress until the animal becomes frenzied. The result is alopecia, redness, ulcerations, and secondary bacterial infections.
- Goats do not usually exhibit intense pruritis. Signs usually include restlessness, screaming, and profuse sweating.
- The medulla in cattle, sheep, and goats becomes involved as the disease progresses leading to paralysis of the pharynx, salivation, cardiac irregularities, and labored respiration.
- Behavioral changes often occur. Most animals become depressed, but some may become aggressive or fearful. There may be grinding of teeth, bellowing, or stamping of feet.
- Other signs include paresthesia, fever, ataxia, hyperesthesia, head-pressing, CP deficits, and convulsions.
- Signs progress to convulsions, recumbency, paralysis, and death.

CAUSES AND RISK FACTORS

- Close contact with swine is the primary source of infection for sheep, goats, and cattle.
- Pseudorabies is a herpesvirus. Swine that have recovered from infection may be asymptomatic but continue to be latent

carriers with infection of the trigeminal ganglia. Recrudescence occurs under stressful conditions.

- In ruminants, latency is not a common mechanism of disease transmission.
- Infection can occur after intranasal, oral, intradermal, or subcutaneous exposure to the virus. Virus spreads by axonoplasmic transport to the CNS.
- Virus may be present in nasal mucosa, secretions, and saliva during acute infection.
- Possible spread of the disease may be due to dead-end hosts such as rats, feral animals, dogs, or cats moving between farms. These sources of infection have a transient infective period.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rabies
- Polioencephalomalacia
- Meningitis
- Hypomagnesemia
- Toxicity—organophosphate, carbamate, lead, arsenic, or salt poisoning
- Enterotoxemia

CBC/BIOCHEMISTRY/URINALYSIS

Usually normal

OTHER LABORATORY TESTS

CSF findings are consistent with encephalitis. Pleocytosis with increased mononuclear cells (50–200 cells/dL) and increased protein concentration (100–200 mg/dL)

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Isolation of virus in cell culture or in rabbits from infected nervous tissues. Segments of the sensory parts of the spinal cord serving the pruritic sites contain high concentrations of the virus.
- Immunofluorescent antibody test—brain tissue
- Rising antibody titers with paired serum tests

PATHOLOGIC FINDINGS

GROSS FINDINGS

- Alopecia, edema, dermal abrasions occur at the pruritic site with the possible presence of secondary bacterial pathogens.
- There is possible swelling or edema of regional lymph nodes.

HISTOPATHOLOGICAL FINDINGS

- Nonsuppurative meningoencephalitis
- Mononuclear cuffing
- Neuronal degeneration and necrosis
- Moderate perivascular cuffing of lymphocytes
- Eosinophilic intranuclear (Cowdry type A) inclusion bodies found in neurons and glial cells
- Some foci of microglial proliferation

TREATMENT

- No effective treatment
- Supportive therapy and prevent self-injury due to pruritis if possible

MEDICATIONS

None

CONTRAINDICATIONS

Do not vaccinate ruminants with modified live virus vaccines targeted for use in swine. There have been reports of sheep infected by use of syringes contaminated with the MLV vaccine for swine.

FOLLOW-UP

None

PREVENTION/AVOIDANCE

- Prevent exposure of ruminants to swine and rats.
- Recovered swine should be culled as natural infections can result in the typical herpesvirus latency and a carrier state.
- Environmental inactivation of the virus can be achieved by drying, 6 hours of contact time with ultraviolet light, and high temperature (37°C).
- Contaminated pens can be disinfected with 10% bleach solution, quaternary ammonium compounds, iodines, or phenolics. At least 5 minutes of contact time is required before rinsing.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

The majority of affected ruminants dies within 2 to 3 days of the onset of clinical signs.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Infectious bovine rhinotracheitis (IBR) virus shares common antigens with the pseudorabies virus. Serologic tests can be affected by heterospecific antibodies to the IBR virus cross-neutralizing pseudorabies virus antibodies.
- Behavioral changes often occur. Most animals become depressed, but some may become aggressive or fearful. There may be grinding of teeth, bellowing, or stamping of feet.
- Other signs include paresthesia, fever, ataxia, hyperesthesia, head-pressing, CP deficits, and convulsions.
- Signs progress to convulsions, recumbency, paralysis, and death.

AGE-RELATED FACTORS

None

ZOONOTIC POTENTIAL

Humans are generally resistant to pseudorabies virus. There have been reports of pruritis when skin wounds came in direct contact with infected tissues.

PYELONEPHRITIS

BASICS

OVERVIEW

- Pyelonephritis is a bacterial infection of the kidney due to ascending infection by *Escherichia coli* or *Corynebacterium renale* (several serotypes are normal inhabitants of the caudal reproductive tract of cows) from the lower urinary tract.
- *C. renale* possesses pili that facilitate attachment to and colonization of the urinary tract mucosa.

Mean Age and Range

N/A

Predominant Sex

Female

SIGNS

- Acute primary pyelonephritis causes fever 103.5°F to 105.5°F (39.7°C to 40.8°C), anorexia, and sudden drop in milk production.
- Some cows exhibit signs of colic such as treading, restlessness, kicking at the abdomen, tail swishing.
- Stranguria, polyuria, kyphosis, hematuria (occasionally with blood clots), and pyuria may also be present.
- Chronic pyelonephritis is associated with weight loss, poor production, anorexia, diarrhea, polyuria, and anemia.
- In chronic cases, lordosis and stretching may be present due to chronic renal pain, and stranguria and gross abnormalities of the urine may be less apparent.
- Signs in subclinical cases of pyelonephritis may be masked by signs associated with concurrent postparturient problems such as mastitis, metritis, or abomasal displacement.

CAUSES AND RISK FACTORS

Physical damage to the mucosa of the lower urinary tract, such as occurs with dystocia, bladder paralysis, or catheterization, may predispose to pyelonephritis. Rectovaginal lacerations/fistula may also predispose to development of pyelonephritis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Emboli nephritis, cystitis, gastrointestinal disorders with associated colic, enzootic hematuria, urolithiasis, vaginitis, vulvar trauma, perivaginal abscess, pelvic entrapment of the bladder

CBC/BIOCHEMISTRY/URINALYSIS

- Neutrophilic leukocytosis and hyperfibrinogenemia often seen on CBC.
- Abnormalities on urinalysis may include presence of RBCs, WBCs, protein, and bacteria. Proteinuria is very significant in most cases of pyelonephritis.
- Hypoalbuminemia, more severe in chronic cases, is usually present.
- Hypergammaglobulinemia (> 5 g/dl) occurs in most chronic cases.
- Increased BUN and creatinine may occur and azotemia may be due to prerenal (dehydration), renal (bilateral pyelonephritis with renal failure), or postrenal causes (obstruction of the ureters or urethra by blood clots or fibrin).

OTHER LABORATORY TESTS

- Urine culture to determine etiology and antimicrobial sensitivity is of utmost importance to the patient.
- Urine collection by catheterization is optimal for bacterial culturing.

IMAGING

Ultrasonography of the kidneys is a valuable tool and may supply important prognostic information.

DIAGNOSTIC PROCEDURES

- Rectal palpation is useful if the left kidney is enlarged. If only the right kidney is involved, rectal palpation may not be as useful unless the kidney is massively enlarged.
- Vaginal palpation allows for detection of unilateral or bilateral ureteral enlargement that may not be detectable on rectal palpation.
- Presence of blood, blood clots, fibrin, or pus on gross examination of the urine may be diagnostic in acute cases.

PATHOLOGIC FINDINGS

- Gross renal enlargement in acute cases
- Cross section of the affected kidney(s) shows a gray, viscous, odorless, exudate in the renal pelvis with extension into the medulla and cortex.
- Renal abscesses may be present in chronic cases of pyelonephritis.
- Hemorrhage, ulceration, and fibrin deposition may be present on the mucosa of the bladder and urethra.
- One or both ureters may be enlarged and filled with purulent debris.

TREATMENT

- Antimicrobial choice is based on results of urine culture and sensitivity and the ability of the drug to achieve high concentrations in the urine without being nephrotoxic. The drug chosen must also be one that is approved for use in cattle.
- In cases of unilateral chronic pyelonephritis, nephrectomy may be indicated.
- Drug withdrawal times for meat and milk must be maintained.

MEDICATIONS

DRUGS OF CHOICE

- Procaine penicillin G is the usual drug of choice. *C. renale* is uniformly sensitive to penicillin and *E. coli* is often sensitive to the resulting high concentrations of penicillin in the urine. Ceftiofur sodium or ceftiofur hydrochloride has also produced favorable results.
- Long-term (3 weeks) antimicrobial therapy is crucial to treatment success.

CONTRAINDICATIONS

N/A

FOLLOW-UP

- Prognosis for uncomplicated acute cases of pyelonephritis treated with long-term antimicrobial therapy is good.
- Cases of pyelonephritis secondary to bladder paralysis, rectovaginal fistula, or other functional problems have a poorer prognosis because of the likelihood of recurrence.
- Chronic cases of pyelonephritis tend to have a poor prognosis because of the potential for abscess formation in the kidney(s) and loss of renal parenchyma.

MISCELLANEOUS

- Prevention and control are achieved by isolation of affected animals to prevent spread followed by disinfection of heavily contaminated areas.
- Practice aseptic technique when performing urogenital and obstetrical procedures.
- Embolic nephritis is much less common than pyelonephritis but may result from a bacteremia stemming from a primary disease (e.g., mastitis, metritis, septic arthritis, endocarditis) in calves and cows.
- Clinical signs of embolic nephritis are related to the primary condition.
- Urinalysis findings are similar to those in cases of pyelonephritis.
- Treatment is aimed at the primary or underlying condition.
- Embolic nephritis is often an incidental finding at necropsy.

PYOMETRA

BASICS

OVERVIEW

- Pyometra is defined as an intrauterine accumulation of a purulent exudate within the uterus concurrent with the presence of a corpus luteum and anestrus.
- Occurs in both dairy and beef cows, sheep, and dairy goats.

SIGNALMENT

- Lactating dairy cows in the postovulatory phase of the postpartum period.
- Beef or dairy cows exposed to bull infected with *Tritrichomonas foetus*.

SIGNS

- Failure to show estrus
- Persistent corpus luteum
- Fluid accumulation within a thickened uterus in the absence of positive pregnancy signs
- Mucopurulent discharge from the reproductive tract

CAUSES AND RISK FACTORS

- Failure of the endometrial luteolytic mechanism results in maintenance of the corpus luteum and concurrent failure to cycle.
- Cows that cycle early postpartum that have concurrent endometritis
- Animals with retained fetal membranes with or without dystocia after parturition
- Embryonic death associated with infection
- Cows bred to a *Tritrichomonas foetus*-infected bull.

DIAGNOSIS

- Uterus is fluid filled, thickened, or thin and is usually atonic.
- Thick, purulent debris and a lack of fetal members are detected on palpation.

DIFFERENTIAL DIAGNOSIS

- Mucometra
- Pregnancy
- Macerated fetus

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

PATHOLOGIC FINDINGS

Uterine content may include the following bacteria: *Arcanobacter pyogenes*, *Fusobacterium necrophorum*, *Bacteroides* spp. and *Tritrichomonas foetus*.

TREATMENT

MEDICATIONS

- Prostaglandin F2 alpha (35 mg) or cloprostenol (500 ug) treatments repeated at 14-day intervals in cattle
- Drug withdrawal times must be maintained for meat and milk within food-producing animals.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Management of the transition dairy cow to prevent the incidence of dystocia and retained fetal membranes
- Prebreeding examinations

PYRROLIZIDINE ALKALOIDS

BASICS

OVERVIEW

- Among ruminants, most cases of pyrrolizidine alkaloid (PA) poisoning occur in cattle.
- Sheep and goats are relatively resistant to PA intoxication.
- Llamas and alpacas appear to be similar to sheep and goats when it comes to susceptibility.
- The three plant families Compositae, Leguminosae, and Boraginaceae contain the majority of PA-containing plants.
- The genera *Senecio* (*S. vulgaris*, common groundsel; *S. jacobaea*, tansy ragwort; *S. riddelli*, Riddell's groundsel; *S. flaccidus*, threadleaf groundsel) and *Cynoglossum officinale* (houndstongue) have been implicated in most of the animal poisonings in the United States.
- Plants in the genera *Amsinckia*, *Crotalaria*, *Heliotropium*, and *Echium* less commonly cause poisonings either because they are not palatable or do not grow in dense enough stands to pose a significant risk.
- Poisonings generally occur as a result of cattle grazing heavily contaminated pastures (rare—most of these plants are not palatable) or consuming contaminated hay (most common route). Exposures are typically over several weeks to months duration.
- The alkaloid content can vary tremendously among plants; concentrations vary with respect to age and stage of maturity of the plant, and soil and weather conditions.
- Poisonings are most commonly chronic in nature; acute exposures are rare.
- This is generally a herd problem, although individual animals may be selected.
- The clinical signs can be slow and insidious, with general debilitation and weight loss a common complaint. Some affected animals show abrupt onset of signs associated with hepatoencephalopathy.
- The liver is the primary target; kidney, lung, and heart tissue are less commonly affected.
- Megalocytosis, biliary hyperplasia, and fibrosis are commonly reported histologic findings on postmortem examination of the liver.
- Prognosis is guarded to grave for affected animals.

PATHOPHYSIOLOGY

- PAs are rapidly absorbed from the gastrointestinal tract.
- They undergo extensive metabolism in the liver. Some PAs are detoxified to harmless metabolites, but some are converted to highly toxic pyrroles.
- It is these pyrroles that alkylate DNA, leading to inhibition of cell mitosis and the ultimate histologic change of megalocytosis. As these megalocytes die, they are replaced by fibrous connective tissue.
- Though the liver is the primary target, lung, kidney, and heart tissue may be affected as well.

SYSTEMS AFFECTED

Hepatobiliary (megalocytosis, necrosis, fibrosis, biliary hyperplasia), renal (megalocytosis of the proximal convoluted tubules, glomerular atrophy, tubular necrosis), lung (hemorrhage and edema), and heart (necrosis)

GENETICS

N/A

INCIDENCE/PREVALENCE

- Unpredictable and uncommon; however, it is one of the more common causes of plant intoxication in some areas of the United States.
- Poisonings can occur all year round through grazing contaminated pastures or ingesting heavily contaminated hay.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Cattle

Species

- Cattle are most susceptible.
- Sheep, goats, llamas, and alpacas are relatively resistant.
- Resistance appears to be partly due to differences in rumen metabolism.

Breed Predilections

N/A

Mean Age and Range

Young animals appear to be more sensitive.

Predominant Sex

N/A

SIGNS

- Some animals suffer chronic weight loss and debilitation associated with chronic liver insufficiency.
- Weakness and sluggishness
- Secondary photosensitivity and icterus
- Some animals exhibit an abrupt onset of signs associated with hepatic encephalopathy—mania, derangement, aimless walking, head pressing, blindness, and ataxia.
- Less commonly observed signs include inspiratory dyspnea (reported in horses), GI impactions, ascites, diarrhea.

CAUSES AND RISK FACTORS

- A minimum of 2–4 weeks, up to several months, of exposure to these plants is generally required in order to induce toxicity.
- Acute exposures can occur if animals ingest 5%–10% of their body weight of plant material within a few days to a few weeks (rare).
- It is more common to see poisonings in animals that ingest 25%–50% of their body weight in plant material over a period of several months.
- Signs can occur suddenly in animals where the exposure to PA-containing plants ceased weeks or months previously.
- Approximate chronic toxic dose (for tansy ragwort) for an adult cow is 0.4 kg dry plant or 1.7 kg fresh plant per day for several weeks.
- For Riddell's groundsel, approximately 33 g dry or 176 g fresh plant daily for 3 weeks could be toxic to an adult cow.
- An approximate toxic dose of threadleaf groundsel in adult cows is 150 g dry or 750 g fresh plant daily for two weeks.
- A daily dose of 136 g dry or 680 g fresh houndstongue daily could be toxic to cattle over a period of a few weeks.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Acute hepatitis or cholangiohepatitis, liver abscess, viral or bacterial encephalitis, aflatoxicosis, exposure to nitrosamines, hepatotoxic cyanobacteria

CBC/BIOCHEMISTRY/URINALYSIS

Inflammatory leukogram can be observed.

- Hyperbilirubinemia
- Elevations in gamma-glutamyl transpeptidase, alkaline phosphatase, aspartate aminotransferase, and sorbitol dehydrogenase may also be elevated.
- Hypoalbuminemia, hypoproteinemia, and low blood urea nitrogen are less-consistent abnormalities.

OTHER LABORATORY TESTS

- Severely elevated bile acids

- Characteristic histological lesions of a liver biopsy

IMAGING

Ultrasound may reveal a small liver.

DIAGNOSTIC PROCEDURES

- One should examine the diet for the presence of PA-containing plants.
- Pyrrole testing of blood or hepatic tissue can be done, but it is not commonly performed at diagnostic laboratories. The analysis is not quantitative or sensitive, particularly in the late stages of the disease.

PATHOLOGIC FINDINGS

- Poor body condition
- Jaundice
- Ascites and generalized edema
- Small, pale, firm liver with mottled cut surface may be visualized on necropsy.
- Characteristic lesions of hepatic megalocytosis with piecemeal necrosis, biliary hyperplasia, and generalized fibrosis.
- Other less-commonly recognized lesions include myocardial necrosis, gastrointestinal edema and hemorrhage, adrenal cortical hypertrophy, pulmonary edema, interstitial pneumonia, and status spongiosus of brain tissue (not all reported in ruminants).

TREATMENT

- Find and remove the suspect source or remove animals from the contaminated environment.
- Most animals respond poorly to treatment, because by the time the disease is diagnosed, adequate regeneration of the liver is not possible.
- No specific treatment regime has been shown to be effective in treating these animals.
- Dietary changes could include switching to one that is highly digestible, high in calories, and low in protein.
- Treatment is typically not an economically viable option for most producers.

MEDICATIONS

N/A

CONTRAINDICATIONS

N/A

FOLLOW-UP

Serum chemistry panels should be run periodically to evaluate liver function.

PATIENT MONITORING

Monitor appetite and weight and serum chemistries to evaluate liver enzymes, albumin, and protein.

PREVENTION/AVOIDANCE

- Be able to recognize PA-containing plants either in the pasture or in hay.
- Avoid feeding “weedy” hay.
- Appropriate herbicide use can control the growth of these plants in the field.
- Sheep and goats can perhaps be used to control stands of these plants through rotational grazing.

POSSIBLE COMPLICATIONS

- Avoid using medications that require extensive hepatic metabolism.
- Pneumonia and chronic wasting

EXPECTED COURSE AND PROGNOSIS

- The more severely affected animals have a poor prognosis. Many are euthanized due to debilitation and poor response to therapy, or because of financial constraints.
- Patients showing severe neurological signs often do not respond well to treatment.
- Some patients may survive after several months of intensive supportive care, but often are not able to regain their former activity or production level.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Young animals appear to be more susceptible.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

PAs have been shown to cross the placenta and some are secreted into the milk. The risk of these routes having a significant impact on the developing fetus or nursing young is extremely low.

RUMINANT SPECIES AFFECTED

Cattle are most susceptible of all ruminants; sheep and goats are relatively resistant; and llamas and alpacas are thought to be more like sheep and goats.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Avoid feeding “weedy” PA-containing hay. Be able to recognize these plants in pastures or hay.

SYNONYMS

Q FEVER

BASICS

DEFINITION

- Q (Query) fever is a rickettsial disease affecting primarily humans, cattle, sheep, and goats caused by the organism *Coxiella burnetii*. Other species less commonly affected include dogs, cats, rabbits, a variety of wild and domestic mammals, and birds.
- The majority of *C. burnetii* infections in ruminants are unapparent, but abortion and infertility are common manifestations when naïve herds are exposed to the organism.
- Epidemiologically, two cycles of the infection are recognized. The first is maintained in wildlife species, where mainly ticks transmit the organism. The second is preserved in livestock species; ingestion and inhalation of the organism are the main avenues of transmission.
- In humans, Q fever is considered an occupational hazard with the majority of infections occurring in livestock workers, veterinarians, and personnel of animal research facilities.

PATHOPHYSIOLOGY

- *C. burnetii*, an obligate, intracellular, gram-negative, rickettsial agent, replicates within the phagolysosome of infected cells.
- Organisms localize in the mammary glands, supramammary lymph nodes, uterus, and placenta in domestic ruminants.
- The organism can be shed in milk, urine, feces, the placenta, and parturient discharges during subsequent pregnancies and lactations.
- In chronically infected animals, *C. burnetii* is also shed in the feces and urine.
- As with other infections, the initial antibody response is mediated by IgM, subsequently switching to a predominately IgG reaction. A characteristic of *C. burnetii* is its phase variation due to partial loss of polysaccharide that results in antigenic drift. During the acute phase of infection, ELISA can detect predominately IgM antibodies against phase II antigens. Later, IgG, IgA, and to a lesser extent IgM antibodies against phase I antigens appear. Studies to characterize the cellular immune response against phase I and II *C. burnetii* antigens in domestic animals are lacking.

SYSTEMS AFFECTED

Reproductive—abortion, stillbirths, neonatal death

GENETICS

N/A

INCIDENCE/PREVALENCE

- Information on the prevalence of Q fever in animal species is limited.
- Q fever can be endemic in areas where reservoir animals are found.
- The animal reservoir is large and includes many wild and domestic mammals, birds, and arthropods. However, the primary reservoirs are considered to be cattle, sheep, goats, and ticks. Other animal species, including dogs, cats, rabbits, horses, pigs, rodents, pigeons, and other fowl, may also serve as reservoirs of *C. burnetii*.
- In endemic areas, up to 25%–50% of animals may have antibodies to *C. burnetii*.

GEOGRAPHIC DISTRIBUTION

Q fever is found worldwide and has been reported on all continents except New Zealand.

SIGNALMENT

Species

Many species of animals have been found to be infected with *C. burnetii*. Sheep, goats, cattle, and ticks (ixodid and argasid) are considered the primary reservoirs.

Breed Predilections

N/A

Mean Age and Range

The greatest mortality is seen in fetal or newborn animals. Adult animals are usually asymptomatic.

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

The incubation period for Q fever is variable.

HISTORICAL FINDINGS

- Affected adult ruminants are usually asymptomatic; when clinical disease occurs, reproductive failure is usually the only symptom seen. This can be manifested as abortions, stillbirths, retained placentas, infertility, or weak newborns.
- Late-term abortions are typically seen and occur over a 2–4 week period. Of the whole flock or herd, 5%–50% may be affected.

PHYSICAL EXAMINATION FINDINGS

- Affected adult ruminants are usually asymptomatic.
- In sheep and goats, anorexia and abortions are the most common signs noted.
- In cattle, infertility, sporadic abortion, and low birth weights are seen.

CAUSES

- Parturient materials containing *C. burnetii* are highly infective and can contain a large number of the organism.
- *C. burnetii* is tremendously stable in the environment and can be transmitted to other animals via aerosol (airborne droplets or contaminated dust) and direct contact with placental tissues and parturient fluids, feces, or urine of infected animals.
- Fomites (e.g., wool, bedding, clothing), ingestion of parturient material, contaminated water or raw milk, or arthropods may also play a role in transmission.

RISK FACTORS

- *C. burnetii* is transmitted mainly through inhalation of the organism present in contaminated dust or droplets emanating from placental tissue, birth fluids, and excreta of infected animals.
- The infective dose of *C. burnetii* is very low, and it is considered that one to ten organisms can initiate an infection. In addition, due to the highly resistant nature of the organism to adverse environmental conditions, particles carrying *C. burnetii* can remain infectious for months and be transported by wind currents.
- Direct contact with infected animals or ingestion of contaminated materials or raw milk from infected animals are alternative routes of transmission.
- Additionally, naïve herds are very susceptible and abortion storms are possible.

DIAGNOSIS

- *C. burnetii* does not stain well with the traditional Gram technique, but takes a red color with the Gimenez, modified Ziehl-Neelsen, or Macchiavello stains and purple with Giemsa stain.
- *C. burnetii* does not grow on artificial media, but can be isolated in cell culture, embryonated chicken eggs, and some laboratory animals, such as mice and guinea pigs.
- *C. burnetii* can be detected from vaginal discharges, the placenta, placental fluids, aborted fetuses, as well as milk, urine, and feces.
- Diagnosis is based on histopathology and demonstration of viral antigen or antibody. The organism is not usually detected by Gram stains but may be with modified Ziehl-Neelsen or Gimenez stain.
- The demonstration of *C. burnetii*-specific antibodies in the serum of animals is the most practical method to establish a diagnosis of Q fever.
- In domestic animals, CF, IFA, and ELISA are most often used. Phase II antibodies dominate the humoral immune response in the acute phase of the infection, whereas phase I antibodies are prominent in the chronic phase.

- Serological tests are good indicators of previous exposure but provide no information on the infectious status of individual animals.
- *C. burnetii* is a biohazard level three zoonotic agent, so personal protective measures should be taken.
- A major problem in the identification of Q fever cases in humans is that often the clinical signs of acute infection are nonspecific and easily confused with those of other diseases. In the acute phase, Q fever in humans can be manifested as fever, chills, retrobulbar headache, myalgia, chest pain, respiratory distress, and liver failure, yet in the majority of cases the infection is asymptomatic. The disease may progress in a small proportion of infected individuals to a chronic phase characterized by chronic heart failure due to endocarditis, granulomatous hepatitis, osteomyelitis, or by chronic inflammation in several other organs. At this stage, the infection is often life threatening and complicated by the fact that antibiotic therapy is generally not effective. Q fever is more frequent among HIV-infected patients and other immunocompromised individuals.

DIFFERENTIAL DIAGNOSIS

Differentials include other causes of abortion and infertility, such as brucellosis, leptospirosis, campylobacteriosis, salmonellosis, listeriosis, chlamydiosis, mycotic abortion, toxoplasmosis, BVD, or IBR.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Isolation methods are dangerous to laboratory personnel and are rarely used for diagnosis.
- PCR is becoming a more common method of identifying specific fragments of *C. burnetii*. DNA can be amplified from fresh or frozen samples, including buffy coats, milk, placenta, fetal tissue, vaginal swabs, feces, and other biological specimens.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Placentitis is the most characteristic lesion in ruminants. The placenta is typically leathery and thickened. It may contain large amounts of creamy, white-yellow exudate at the edges of cotyledons and in the intercotyledonary area.
- Lesions in aborted fetuses are usually nonspecific. Pneumonia has been noted in goats and cattle.
- Histologically, lesions are characterized by severe necrotic placentitis with infiltration of neutrophils and mononuclear cells, focal exudation of fibrin, and mineralization in the stroma and villi.
- Organisms can be observed in placental trophoblast cells, particularly at the base of the cotyledonary villi.

TREATMENT

Because *C. burnetii* replicates in phagolysosomes of infected cells, the effectiveness of antibiotics is theoretically limited by their ability to penetrate these organelles and remain active at the low pH that prevails in this environment.

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

N/A

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

- Q fever is a zoonotic disease.
- Clients should be educated on routes of transmission of *C. burnetii* and vector control methods.

- Pregnant women are at the greatest risk, so should be advised to avoid periparturient ruminants.
- Additionally, persons with valvular heart disease or weakened immune systems are more susceptible.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- Little is known about the effectiveness of treating animals with antibiotics.
- In enzootic herds, tetracycline may be given in water in the weeks preceding parturition. This may help reduce shedding of the organism in birthing materials and may suppress the number of abortions. However, it will not eliminate infection or eradicate the “carrier” state of *C. burnetii* infection.
- Antibiotics that have been shown to be effective in the treatment of acute human Q fever include the macrolides, cotrimoxazole, rifampin, chloramphenicol, and the fluoroquinolones.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- *C. burnetii* is tremendously stable in the environment.
- Pregnant animals should be segregated to reduce the spread of the organism. When possible, parturition should take place indoors and in separate facilities.
- Following parturition, placentas, aborted materials, and fetal tissues should be disposed of appropriately.
- Birth products should be incinerated and lambing areas cleaned and disinfected with Lysol, bleach, or hydrogen peroxide.
- Cleaning and sanitation measures as well as vector control should be attempted but do not usually control the spread of the disease.
- Carcasses should be buried or burned.
- *C. burnetii* is highly resistant to physical and chemical agents. Variable susceptibility has been reported for hypochlorite, formalin, and phenolic disinfectants; a 0.05% hypochlorite, 5% peroxide, or 1:100 solution of Lysol may be effective. High-temperature pasteurization destroys the organism.
- Education of clients should focus on potential sources of infection and ways to reduce environmental contamination from infected placental membranes and aborted materials.
- Q fever vaccines effectively protect animals against abortion, low fetal weight, and chronic infertility, but they have not prevented infection and/or the shedding of the organism in fluids and birth products. Q fever vaccines for humans and animals are available in many countries but not in the United States.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- In small ruminants, several abortions may be followed by uncomplicated recovery; in other cases, the disease may recur yearly.
- Pregnancy subsequent to *Coxiella* abortions are generally carried to term. However, ewes can remain chronically infective and continue to shed organisms.
- Organisms may be shed in milk and feces for several days after parturition.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Adult animals are typically asymptomatic.
- The greatest mortality rates are seen in fetuses or young neonates of sheep, goats, and cattle.

ZOONOTIC POTENTIAL

- Humans are highly susceptible to infection by exposure to aerosols when assisting parturition, handling infected placental tissues, performing necropsy on aborted fetuses, during slaughter or laboratory procedures, and drinking raw, unpasteurized milk.
- In the acute phase, Q fever in humans can be manifested as fever, chills, retrobulbar headache, myalgia, chest pain, respiratory distress, and liver failure, yet in the majority of cases the infection is asymptomatic.
- Exanthema (rash) occurs in about 10% of cases.
- Complications are not common but may include endocarditis, cirrhosis, aseptic meningitis, encephalitis, osteomyelitis, and vasculitis. At this stage, the infection is often life threatening and complicated by the fact that antibiotic therapy is generally not effective.
- The organism can be transplacentally transmitted so is of great risk for pregnant women; abortions, neonatal deaths, premature births, low birth weights, or placentitis may occur.
- The overall case-fatality rate for Q fever ranges from less than 1% to 2.4%.
- Q fever is more frequent among HIV-infected patients and other immunocompromised individuals.
- Milk destined for human consumption should be pasteurized. Pregnant women, immunosuppressed individuals, and people with vascular heart disease should be prevented from performing at-risk jobs.

PREGNANCY

Q fever causes abortion, stillbirths, retained placentas, infertility, and weak newborns in sheep, goats, and cattle.

RUMINANT SPECIES AFFECTED

Sheep, goats, cattle

BIOSECURITY

- Practical control is difficult because of environmental stability and infectivity of animals, arthropods, and humans.
- Efforts to control the spread of Q fever should include segregation of infected animals, especially those that are periparturient, vector control measures, and prompt cleaning and disinfection following parturition.
- Animals infected with *C. burnetii* should be maintained under animal biosafety level 3 (ABSL-3) conditions, and research and animal care staff should use personal protective equipment conforming to ABSL-3 practices. A comprehensive occupational health and safety program should be in place to ensure a safe working environment.

PRODUCTION MANAGEMENT

For livestock, control measures include good animal husbandry and implementing cleaning and disinfection protocols.

Research Facilities: Considerations

- Although infection among domestic livestock is often inapparent, it may constitute a significant health hazard for livestock workers and research personnel.
- Several Q fever outbreaks in biomedical research facilities utilizing pregnant ewes have been described, with large numbers of individuals developing clinical illness or at least seroconverting to the agent.
- Biomedical scientists are known to be at increased risk of exposure when utilizing cattle, goats, or sheep in environments

where contaminated dust, urine, feces, amniotic fluid, placentas, and newborn animals may occur.

- The following steps can be taken to minimize and control the potential risk to research personnel when working with domestic livestock in research facilities. Whenever possible, use male or nonpregnant animals in research programs. Procure animals from Q fever-free sources (cumulative and consistent negative Q fever serology on a herd/flock). Monitor individual animals for organism shedding (PCR assays on biological samples from animals presenting a potential risk). Standard operating procedures (SOPs) should be developed and followed to facilitate appropriate animal care and use. Animals infected with *C. burnetii* should be maintained under animal biosafety level 3 (ABSL-3) conditions, and research and animal care staff should use personal protective equipment conforming to ABSL-3 practices. A comprehensive occupational health and safety program should be in place to ensure a safe working environment.

RABIES

BASICS

OVERVIEW

- Rabies is a rhabdovirus causing an acute viral encephalomyelitis. Rabies virus is perhaps the most important cause of encephalitis in cattle because of the public health implications. The virus can affect any mammal including humans.
- Once clinical signs appear, the disease is invariably fatal.
- Prevention and control of the disease in cattle can be best achieved in many areas of the world by regional oral vaccination of foxes and other wild carnivore species.
- Penetration of dermis or mucous membranes by virus-laden saliva is most commonly via a bite wound inflicted by an infected animal. The virus then travels to the CNS via peripheral nerves.
- Humans risk exposure by reaching into the mouth of an infected animal looking for a foreign body in the mouth or throat. Foreign body may be suspected due to inability to swallow or hypersalivation.

SYSTEMS AFFECTED

CNS

GENETICS

N/A

INCIDENCE/PREVALENCE

- In a recent U.S. survey, during 2002, 49 states and Puerto Rico reported 7967 cases of rabies in nonhuman animals and 3 cases in human beings to the Centers for Disease Control and Prevention, an increase of 7.2% from the 7436 cases in nonhuman animals and 1 case in a human being reported in 2001. More than 92% (7375 cases) were in wild animals, whereas 7.4% (592) were in domestic species (compared with 93.3% in wild animals and 6.7% in domestic species in 2001).
- Rabies among sheep and goats increased 400% from 3 cases in 2001 to 15 in 2002.
- The relative contributions of the major groups of animals were as follows: raccoons (36.3%, 2891 cases), skunks (30.5%, 2433), bats (17.2%, 1373), foxes (6.4%, 508), cats (3.8%, 299), dogs (1.2%, 99), and cattle (1.5%, 116).

GEOGRAPHIC DISTRIBUTION

Worldwide distribution

SIGNALMENT

- Different strains of the rabies virus are endemic to a specific host population within a given geographic region. In the United States, for example, raccoons are the primary host species along the eastern seaboard, skunks in the north central and south central states, and the fox in Texas. Various species of bats also carry different strains of the rabies virus.
- The disease can be spread to warm-blooded animals including humans.

Species

Affects all mammals

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- Early clinical signs are nonspecific and highly variable between individuals.

- Two principal manifestations of the disease are generally recognized although an individual can exhibit signs from either form.

Furious Form

- Restlessness with an expression of alertness and anxiety with dilated pupils
- Exaggerated response to auditory or tactile stimuli; affected individual may attack with minimal provocation.
- Animals may charge through stall doors or gates and roam extensively.
- Other signs can include bloat, convulsions, pruritis, pica, or tenesmus.
- Affected animals become progressively ataxic and eventually develop paresis.
- Coma and death follow.

Paralytic or “Dumb” Form

- Initial signs often include anorexia, depression, ataxia, shifting leg lameness, and fever.
- Paralysis of the masseter muscles
- Laryngeal and pharyngeal paralysis
- Cattle may bellow incessantly with altered phonation.
- There is often profuse salivation and inability to swallow.
- There is an abrupt cease of lactation in dairy cattle.
- There may be flaccidity of the tongue, tail, anus, and urinary bladder. Some animals exhibit long periods of tenesmus.
- If able to stand, animals have a wide-base stance. Knuckling of the hind fetlock joints may occur.
- Paresis progresses rapidly to paralysis to all parts of the body.
- Coma and death follow.

CAUSES AND RISK FACTORS

- Penetration of dermis or mucous membranes by virus-laden saliva is most commonly via a bite wound inflicted by an infected animal. The virus then travels to the CNS via peripheral nerves.
- Humans risk exposure by reaching into the mouth of an infected animal looking for a foreign body in the mouth or throat. Foreign body may be suspected due to inability to swallow or hypersalivation.
- Antigenic variations in the rabies virus result in different reservoir species depending on geographic area, although extension to other species is common.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Behavioral aggression unrelated to disease
- Oral or esophageal foreign body
- Metabolic or digestive disorders: Indigestion, milk fever, nervous ketosis, primary bloat
- Any neurological disease: CNS tumor, encephalitis, spongiform encephalopathies such as scrapie in sheep, bovine spongiform encephalopathy in cattle, or chronic wasting disease in elk and deer.
- *Oestrus ovis* infestations in sheep
- Pseudorabies
- Neurotoxins such as carbamates or organophosphates
- Other viral encephalitis diseases in ruminants include bovine herpesvirus encephalomyelitis, pseudorabies, malignant catarrhal fever, ovine and caprine lentiviral encephalitis, West Nile virus encephalitis, Borna disease, paramyxoviral sporadic bovine encephalomyelitis, and ovine encephalomyelitis (louping-ill).

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

CSF may be normal or have increased protein, mononuclear cells, neutrophils, eosinophils, or xanthochromia.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Immunofluorescence, PCR, complement fixation and agar-gel immunodiffusion can detect antigens of the rabies virus in fresh brain tissue.

PATHOLOGIC FINDINGS

GROSS FINDINGS

No gross findings specific to rabies infection

HISTOPATHOLOGICAL FINDINGS

- Negri bodies, cytoplasmic inclusion bodies containing rabies viral antigen, may be found in the hippocampus, cerebellum, or medulla oblongata using peroxidase-antiperoxidase staining techniques or electron microscopy. These cytoplasmic inclusion bodies are considered diagnostic for rabies but may not be present in up to 30% of cases.
- Diffuse encephalitis with perivascular cuffing and neuronal necrosis. Collections of proliferating glial cells may be found replacing neurons.

TREATMENT

- No effective treatment
- Any animal suspected of being exposed to rabies must be securely quarantined as required by local and state statutes.

MEDICATIONS

N/A

CONTRAINDICATIONS

N/A

FOLLOW-UP

PATIENT MONITORING

- Rabies suspect cases must be securely quarantined in an isolation unit. Feed and water without entering isolation unit if possible.
- Monitor for behavioral, attitude, or clinical signs suggestive of rabies.
- Check local and state regulations on specific requirements.

PREVENTION/AVOIDANCE

- Inactivated vaccines are the only licensed product for prevention of rabies in livestock in the United States. The modified-live vaccines that are available for use in domestic dogs and cats may potentially produce fatal allergic or viral encephalitis when injected in ruminants.
- Due to the extreme public health concerns, state, provincial, and local regulations have been put in place and must be followed completely.
- A few geographic regions of the world including the United Kingdom, Hawaii, Australia, and New Zealand have eradicated or have remained free of the rabies virus because of their island status. These and other such areas have rigorous enforcement of strict quarantine restrictions.
- The Compendium of Animal Rabies Control is compiled and updated annually by the National Association of State Public Health Veterinarians (NASPHV) and summarizes the most current recommendations for the United States and lists all USDA-licensed rabies vaccines.
- Environmental disinfection can be accomplished with household bleach in a 1:32 dilution (4 ounces per gallon).

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Incubation period varies from a few weeks to a year. There have been rare cases with potential incubation of several years. The average incubation period is 2–6 months. Animals bitten near the head have shorter incubation periods than those bitten on an extremity or on the trunk.
- Once clinical signs are exhibited, the disease is invariably fatal. Death occurs within 10 days of the first symptoms.

MISCELLANEOUS

ASSOCIATED CONDITIONS

None

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

Extreme risk. Observe strict quarantine of rabies suspect animals.

PREGNANCY

Disease is fatal to infected dam.

RADIATION TOXICITY

BASICS

OVERVIEW

- Possible sources of ionizing radiation that might affect ruminant livestock are thermonuclear explosions, nuclear reactor accidents, fuel reprocessing plant accidents, and bioterrorism acts.
- Grazing livestock could be subjected to beta radiation exposure from ingestion, inhalation, and skin retained radioactive particles.
- Cattle are more sensitive to ingested fallout radiation than other species.
- One study showed that productivity of most livestock surviving an LD50/60 exposure is temporarily reduced and the overall long-term effects are small.
- Radioisotopes of iodine in milk are extremely accumulative and easily passed on.
- In the event of a nuclear accident, the feeding of stored feed or moving livestock to uncontaminated pastures would be the best protective action to follow.
- With any nuclear accident, severe problems of human health would arise prior to any detrimental effects on livestock.

PATHOPHYSIOLOGY

Adapted from RADNET, Center for Biological Monitoring

- ^{85}Kr (Krypton-85, a gas). ^{85}Kr is an inert unreactive gas and does not bioaccumulate in biological pathways. The exposure pathways are external exposure and absorption.
- ^{131}I (Iodine-131) [short-lived ($1/2\ T = 8\ \text{days}$)] is a biologically significant radionuclide and is very volatile. It is easily accumulated after consuming contaminating forage. Its target organ is the thyroid.
- ^{134}Cs (Cesium, $1/2\ T = 2.062\ \text{years}$) and ^{137}Cs ($1/2\ T = 30.174\ \text{years}$) are among the most biologically significant radionuclides due to their mobility and radiological toxicity. Cesium follows the potassium cycle in nature and its target organ is the entire body.
- ^{89}Sr (Strontium, $1/2\ T = 50.55\ \text{days}$) and ^{90}Sr ($1/2\ T = 28.82\ \text{years}$) follow the calcium cycle in nature and are bone-seeking radionuclides.
- ^{103}Ru (Ruthenium, $1/2\ T = 39.8\ \text{days}$) and ^{106}Ru ($1/2\ T = 1\ \text{year}$) are particularly ubiquitous components of nuclear reactor accidents but also have low radiotoxicity. Their target is the lower large intestine.
- ^3H (Tritium, $1/2\ T = 12.346\ \text{years}$) is a ubiquitous component of nuclear industries and is a volatile form of radioactive water. Tritium achieves equilibrium in the environment, it becomes tissue bound, and its target is the whole body.
- ^{239}Pu (Plutonium, $1/2\ T = 24,131\ \text{years}$) is among the most biologically significant and highly radioactive of all radionuclides. As an alpha emitter, plutonium is particularly hazardous if inhaled either directly from the plume passage or from resuspended ground deposition activity. Due to its long half-life, ^{239}Pu is the most important radioisotope in the very late stages of a nuclear accident (100 years to 10,000 years). Plutonium is a bone-seeking radionuclide. In its oxide form it is not readily absorbed through the gut; upon aging, it can change its chemical form and become more biologically available in the years after ground deposition.
- ^{99}Tc (Technetium, $1/2\ T = 212,000\ \text{years}$) is associated with nuclear fuel reprocessing and fuel reprocessing accidents. It is a very volatile radionuclide and is impossible to filter or control.
- ^{241}Am (Americium, $1/2\ T = 432\ \text{years}$) is a decay product of ^{241}Pu ($1/2\ T = 14.355\ \text{years}$) and intensifies as ^{241}Pu decays. ^{241}Pu is a highly mobile and radiotoxic isotope with high concentration ratios in both freshwater and marine environments.
- ^{238}Pu (Plutonium, $1/2\ T = 87.71\ \text{years}$) is the third most common constituent in spent fuel and is one of the most

biologically significant radionuclides associated with an accident at a fuel reprocessing facility. ^{238}Pu is the principal component of nuclear-powered satellite accidents.

SYSTEMS AFFECTED

Potentially all, depending on the type of radiation absorbed.

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide depending on species and environment

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Clinical signs of radiation toxicity are dependent upon species variations (e.g., marked delayed reaction of the acute hematologic response in cows). Species-specific number of hemopoietic stem cells may explain the morbidity and mortality differences between species after high doses of irradiation.
- Mortality due to acute radiation syndrome varies by species.
- Cattle commonly develop cataracts later in the disease process.
- Radiation sources can include radiation exposure accidents, nuclear weapon detonations, and bioterrorism acts perpetrated upon livestock.

PHYSICAL EXAMINATION FINDINGS

CAUSES AND RISK FACTORS

There are four pathways of exposure to contamination secondary to nuclear accidents of any kind:

- Inhalation: plume inhalation and resuspended ground deposition inhalation can occur in grazing livestock
- External exposure: facility radiation shine, plume cloud shine, and ground shine
- Dermal absorption
- Ingestion: ingestion from foliar/forage and surface contamination and the ingestion of contamination via indirect pathways (e.g., the incorporation of contaminated plant materials into processed feedstuffs and distribution to distant areas unaffected by original deposition/fallout/plume).
- Other associated pathways can include:
 - Chronic gaseous emissions
 - Gaseous reactor plume pulse discharges
 - Liquid discharges
 - Specific nuclear accidents
 - Chronic hot particle contamination
 - Liquid emissions
 - Airborne particulates

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

N/A

CBC/BIOCHEMISTRY/URINALYSIS

- Acute hematologic response in cows
- CBC is generally grossly affected in severe accidents.

OTHER LABORATORY TESTS

Radioisotopes of iodine in milk

IMAGING

OTHER DIAGNOSTIC PROCEDURES

- The Federal Emergency Management Agency (FEMA) has a surface contamination guideline of “300 counts per minute above background” for authorized persons entering an emergency operations center (EOC) during an accident at an NRC-licensed nuclear facility. Three hundred counts per minute (300 cpi) equals 660 pCi (Picocurie) per person; it can be assumed that each authorized person has an absolute minimum of 1 square meter of surface area.
- Microcuries/square meter limits are set in humans.
- No guidelines have been set for livestock.
- The 1982 U.S. Department of Health and Human Services emergency protection action guideline (PAG) is nuclide specific and includes the initial ground deposition action guidelines for humans affected by fallout.
- Other readings include:
 - Picocuries (1 microcurie = 1,000,000 picocuries)
 - Counts per minute (1 count/minute = 2.2 picocuries/minute.)

PATHOLOGIC FINDINGS

TREATMENT

- There is no specific therapy for the acute radiation syndrome.
- For severely exposed animals, euthanasia and disposal concerns must be addressed. This is especially disconcerting in the case of a mass mortality event. Contact the state/provincial Environmental Protection Agency for disposal requirements.
- For high-dose injury, no methods have been developed to reverse the fibrosing endarteritis that eventually leads to tissue death.
- The accidental fuel element meltdown at Chernobyl, USSR, resulted in many cases of acute radiation syndrome. More than 100,000 people were exposed to high levels of radioactive fallout. The radiation plume had an incredible effect on livestock in the plume fallout zone worldwide.

MEDICATIONS

CONTRAINDICATIONS

- Milk and meat must not be consumed from exposed food-producing animals.
- Do not feed contaminated feed to livestock.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

FOLLOW-UP

PATIENT MONITORING

PREVENTION/AVOIDANCE

- Avoid using surface water supplies and rainwater for livestock.
- All subsurface water sources and most public drinking water sources are relatively safe after most types of nuclear accidents.
- Humans and animals should avoid consuming foods/feed subject to rapid secondary pathway contamination (e.g., forage → cow/sheep/goat → milk/cheese pathway → human). Use animal feed produced and/or packaged prior to plume passage.
- Shelter livestock from plume damage; use uncontaminated feeds.
- Avoid exposure to surface ground contamination by keeping livestock indoors as much as possible.
- Avoid exposure of animals to contaminated surface water (puddles and rain).
- Avoid tracking in ground deposition to animal facilities: remove contaminated clothing and footwear prior to entering barns and animal housing.
- Avoid feeding contaminated hays from surface deposition (especially leafy pasture plants with foliar contamination).
- Postnuclear accident, if animals have avoided inhalation of the passing plume and if they can avoid extensive exposure to ground deposition, the livestock's principal pathway of exposure will be the ingestion pathway.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Severity of biological response depends upon target organ dose, dose rate, and dose fractionation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Following the Chernobyl nuclear accident, sheep and cattle in Wales, England, and Scotland became contaminated with radionuclides (primarily ^{134}Cs and ^{131}I). The maximum levels of contamination were of the order of 4000 Bq/kg of cesium-137 and 2000 Bq/kg of cesium-134 in muscle and 2,000,000 Bq/kg of iodine-131 in the thyroid gland. Bq/kg corresponds to the limit of detection of a Becquerel per unit mass or the decrease of one radioactive atom per second in one kilogram of material (used for samples of animal or vegetal origin).

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Sources of ionizing radiation that could contribute to radioactivity in the food chain to humans are reactor accidents, fuel reprocessing plant accidents, and thermonuclear explosions.
- Avoid consuming foods subject to rapid ingestion pathway contamination (e.g., forage → cow/sheep/goat → milk/cheese pathway → human).
- With any nuclear accident, severe problems of human health would arise before any detrimental effects on livestock could be detected.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected.

BIOSECURITY

The types of accidents and the principal radionuclides:

- Nuclear reactors (I-131; Cs-134 + Cs-137; Ru-103 + Ru-106)
- Nuclear waste storage facilities (Sr-90; Cs-137; Pu-239 + Am-241)
- Nuclear fuel reprocessing plants (Sr-90; Cs-137; Pu-239 + Am-241)
- Nuclear weapons (i.e., dispersal of nuclear material without nuclear detonation) (Pu-239) and radioisotope thermoelectric generators (RTGs) and radioisotope heater units (RHUs).

PRODUCTION MANAGEMENT

- Precautionary actions include moving animals to protective shelter, covering potentially exposed feed products, corralling livestock and isolation from the radioactive plume, and providing protected feed and water.
- The blending of contaminated livestock feed with uncontaminated feed is illegal because this is a violation of the Federal Food, Drug and Cosmetic Act (FDA 1991).

TREATMENT

APPROPRIATE HEALTH CARE

- Identify and eliminate predisposing factors if possible.
- Administer caudal epidural.
- Clean prolapse with warm water and soap.
- Evaluate tissue for necrosis and trauma.
- Reduce prolapse by manual manipulation.

- Circumferential purse string sutures using umbilical tape are placed around anus.
- Sutures can be preplaced if straining is occurring.
- Sutures are removed in 3–4 days.

NURSING CARE

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

Animal's value should be discussed when deciding on treatment options.

SURGICAL CONSIDERATIONS

- Severely traumatized or necrotic rectal tissue may necessitate amputation.
- Commercial prolapse rings or open-ended tube (PVC pipe) is inserted into the rectum.
- Elastator band can be placed over rectal tissue anterior of damaged tissue.
- Ring and necrotic tissue will slough in 1–2 weeks.
- Surgical amputation or submucosal resection is also an option.

MEDICATIONS

DRUGS OF CHOICE

- Broad-spectrum antibiotic therapy might be considered if tissue necrosis is severe.
- Drug withdrawal periods must be determined and maintained.
- Topical agents such as 50% dextrose and lubricating gel may aid in reduction of prolapse.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

Sedation may assist in reducing tenesmus.

FOLLOW-UP

PATIENT MONITORING

Remove purse-string sutures in 3–4 days.

PREVENTION/AVOIDANCE

Difficult to prevent; eliminate potential risk factors if possible.

POSSIBLE COMPLICATIONS

- Severe straining may cause prolapse to reoccur.
- Inappropriately placed sutures may cause cellulitis.
- Premature sloughing of prolapse ring may result in severe peritonitis or evisceration.

EXPECTED COURSE AND PROGNOSIS

- Prognosis is guarded.
- Tendency for prolapses to reoccur unless predisposing factors are eliminated.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Enteritis
- Vaginal or uterine prolapse
- Bloat
- Urolithiasis

REHYDRATION THERAPY: ORAL

BASICS

OVERVIEW

- Numerous diseases result in dehydration, electrolyte, and acid/base abnormalities.
- Correction of these deficits can greatly influence the clinical outcome of these diseases.
- In small animals and equines, intravenous (IV) fluid therapy is most commonly used. In many instances, intravenous fluid therapy in ruminants is not practical or possible.
 - The size of the animal, lack of proper restraint facilities, time requirements, and owner compliance all limit the use of IV fluids.
 - Another major limitation to the use of IV fluids in ruminants is expense versus the value of the animal.
- Oral fluid and electrolyte therapy is a valuable alternative to IV fluid therapy in situations where IV fluid therapy is not practical or possible.
 - Oral fluid therapy can be administered quickly and inexpensively in most cases.
 - Oral fluid therapy is very effective when used appropriately.
 - Oral fluid therapy is the preferred method of treatment for most diarrheic calves.
 - Oral fluid therapy is inappropriate in some cases because it will not adequately correct some severe imbalances.
- Oral fluid therapy can be used in conjunction with IV fluids in many cases. Combining oral and IV fluids may help overcome the limitations of both methods used alone.
- Oral fluid therapy is most commonly used in neonatal calves and adult cattle, but it can be used effectively in other ruminant species as well.

PATHOPHYSIOLOGY

- The most common cause of dehydration in neonatal calves is diarrhea often accompanied by metabolic acidosis.
 - This diarrhea may be hypersecretory, malabsorptive, and/or osmotic depending on the cause.
 - Some organisms release toxins that cause a hypersecretory diarrhea.
 - Some organisms directly damage the villous lining of the intestinal tract causing a malabsorptive diarrhea.
 - Increased passage of undigested nutrients into the colon promotes bacterial fermentation and results in an osmotic diarrhea.
 - Metabolic acidosis occurs in diarrheic calves due to increased loss of bicarbonate in the feces.
- Dehydration in adult cattle can result from numerous disease processes.
 - The pathophysiology of the dehydration varies depending on the disease process involved, but it usually includes decreased fluid intake, increased fluid loss through diarrhea, or sequestration of fluid within the gastrointestinal (GI) tract.
 - Unlike neonates, adult cattle dehydration is often accompanied by alkalosis rather than acidosis.
- Diseases causing dehydration in other ruminant species are similar to those of cattle. Pregnancy toxemia in small ruminants and heat stroke in camelids often requires fluid therapy to support the fluid and nutritional needs of the animal.

SYSTEMS AFFECTED

- Diseases resulting in dehydration and electrolyte imbalances in ruminants most commonly affect the GI tract, pleural/peritoneal space, mammary gland, or reproductive system.
- The resulting dehydration and electrolyte abnormalities affect virtually all systems within the body to some degree.

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

Diseases causing dehydration and electrolyte abnormalities may affect all neonatal calves, adult cattle, sheep, goats, and camelids.

SIGNS

- Signs of dehydration include enophthalmia, decreased skin elasticity, tachycardia, dry or tacky mucous membranes, and cold extremities.
- Signs of acidosis in neonatal calves include depression, recumbency (sternal progressing to lateral), weakness, and loss of a suckle reflex.

CAUSES

Neonatal Calves

- *E. coli*
- Rotavirus
- Coronavirus
- Salmonellosis
- Cryptosporidiosis
- Overconsumption of milk
- Poor quality milk replacers

Adult Cattle

- Gastrointestinal disease
 - Abomasal displacement/volvulus
 - Intussusception
 - Mesenteric volvulus
 - Vagal indigestion
 - Salmonellosis
 - Clinical parasitism
- Carbohydrate engorgement (grain overload)
- Peritonitis/pleuritis (hardware disease)
- Toxic mastitis
- Toxic metritis
- Fatty liver: ketosis

Small Ruminants

- Gastrointestinal disease: Clinical parasitism; intestinal accidents
- Pregnancy toxemia
- Heat stroke (camelids)

RISK FACTORS

- Failure of passive transfer is the major risk factor for the development of diarrhea in neonatal calves.
- Thin or excessive body condition in late pregnancy is a risk factor for the development of pregnancy toxemia in small ruminants.

DIAGNOSTIC PROCEDURES

Dehydration is usually assessed by evaluation of several clinical features including skin tent, degree of enophthalmia, cold extremities, cold interior of mouth, heart rate, pulse character, etc.

- *Measurements of packed cell volume (PCV) and total plasma protein (TP) are useful for assessing the response to fluid therapy.*

- Unless these values are markedly abnormal, the usefulness of a single measurement is questionable due to the large variability in the normal values for these parameters.

- Changes in these values in response to fluid therapy are useful for assessing the response to therapy.

- *Several methodologies for estimating the degree of dehydration based on clinical findings are available.*

- Following is one example:

6–7% dehydration—slight enophthalmia, slightly increased skin turgor, moist mucous membranes

8–9% dehydration—eyes obviously sunken, obviously increased skin turgor, tacky mucous membranes

10–12% dehydration—eyes deeply sunken in orbits, skin tents and does not return, dry mucous membranes, obvious depression

- The accuracy of these estimates is questionable and exact estimation of the degree of dehydration is not critical.

- Making an estimate of dehydration and then carefully monitoring the response to therapy is more important and more accurate than trying to pinpoint the exact degree of dehydration.

- One of the most important decisions to make is the decision to use oral or IV fluids.

1. Calves that are estimated to be greater than 8% dehydrated (marked enophthalmia, prolonged skin tent, dry mucous membranes, and moderate to severe depression) should be treated with IV fluids.

2. Calves that are less than 8% dehydrated can usually be treated with oral fluids.

- *Acid/base status is best evaluated by blood gas analysis. The amount of base needed to correct the acidosis can be determined using the base deficit (BD) and the following equation:*

$BD \times 0.6 \times \text{Body weight in kilograms} = \text{base requirement in milliequivalents (mEq)}$

0.6 is a correction factor for the “bicarbonate space” in a neonate. For an adult, 0.3 is the appropriate factor.

- *If blood gas analysis is not available, the degree of acidosis may be estimated using clinical evaluation of the patient.*

- Calves

- Calves that are significantly acidotic exhibit depression, weakness (which may range from difficulty standing to complete lateral recumbency), and loss of a suckle reflex.

Several methodologies for clinical assessment of acidosis have been published. Following is one example:

1. Calves less than one week old with a depression score of mild, moderate, or severe have an estimated base deficit of 6, 9, and 12 mEq, respectively.

2. Calves older than one week of age with a depression score of mild, moderate, or severe have an estimated base deficit of 9, 12, and 15 mEq, respectively.

3. This estimated BD can then be used in the equation given above to estimate the total mEq of base needed.

Another, simpler, rule of thumb is that calves showing clinical depression due to acidosis usually have a BD of 10–15 mEq with older calves tending to be more acidotic.

1. Important factors to consider include the severity of clinical signs and the age of the calf.

2. Calves older than a week of age tend to be more acidotic than a younger calf exhibiting similar clinical signs.

3. Calves that have lost the ability to stand and lost a suckle reflex should be treated with IV fluids. Oral fluid therapy will most likely not be sufficient in these calves.

- Adult Animals

Similar estimates of dehydration can be used for adult animals.

1. Adult cattle are alkalotic more often than acidotic and it is usually not necessary to directly correct the alkalosis.

2. Grain overload is a common condition that results in acidosis.
3. Correcting the dehydration will allow the kidneys to correct the alkalosis.

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

Fluid therapy for ruminants must often be administered in the field but hospitalization, if possible, will facilitate fluid administration and assessment of response to therapy.

NURSING CARE

Sick calves should be kept in a warm, draft-free environment to reduce increased metabolic demands caused by cold stress.

ACTIVITY

One of the advantages of oral fluid therapy over IV therapy is that the animal does not have to be restrained for prolonged periods of time.

DIET

Calves with severe diarrhea should be taken off of milk for a short period of time because impaired absorption of nutrients may exacerbate the diarrhea when they reach the colon.

CLIENT EDUCATION

- Oral electrolyte therapy can be administered via a nipple bottle or via an esophageal feeder. If clients are going to be responsible for administering oral fluids, they must be properly trained to use an esophageal feeder.
- Oral fluids can be administered to adult ruminants via orogastric intubation, nasogastric intubation, or commercially available cattle fluid pump systems.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

Calves

- Numerous oral electrolyte preparations are commercially available.
- Many of these preparations contain an alkalinizing agent.
 - Bicarbonate is the most common.
 - Other metabolizable bases include lactate, acetate, and citrate.
- Inclusion of glycine and/or glucose will increase the intestinal absorption of sodium ions through cotransporters on intestinal epithelial cells. Inclusion of glutamate does not appear to be beneficial.
- Some of these preparations contain higher amounts of glucose and are described as “high-energy” supplements.
 - These products should be used if the calf is in poor body condition or is going to be held off of milk for several days.
 - These products supply about one-half of the energy content of whole milk.
- Maintenance fluid requirements are about 50 mls/kg/day. Ongoing losses must be considered and may range from 1 to 6 liters in calves with diarrhea. Oral fluids may be administered twice daily or up to several times daily.

Adults

- Mixing feed-grade salts in water may make oral fluids/electrolytes for adult ruminants.
- Following is one common formulation:
 - 140 grams sodium chloride
 - 30 grams potassium chloride

10 grams calcium chloride
Mixed in 20 liters of water

- It is usually not necessary to directly correct the alkalosis.
- If acidosis is present, bicarbonate can be supplied by estimating the BD (usually 5–8 mEq/kg) and mixing bicarbonate (baking soda) in water. If acidosis is severe, IV fluid therapy may be necessary.

Other

- Oral fluid and IV fluid may be used in conjunction in some cases, especially in adults.
 - Giving 10–20 liters IV and the rest of the deficit orally is an alternative when the expense of IV fluids is a concern.
 - Rapid volume expansion with IV fluids may improve perfusion of the gut and increase absorption of oral fluids/electrolytes.
 - Once dehydration has been corrected in calves with IV fluids, oral fluids can be used to provide maintenance needs.
- Transfaunation is the administration of rumen fluid from a healthy ruminant to one whose rumen environment has been altered.
 - Providing a healthy population of rumen microbes will often improve appetite and feed consumption.
 - Pelleted feed soaked in warm water can also be included to improve the rumen environment and provide some energy.
- Hypertonic (7.2%) saline can be used in conjunction with oral fluid therapy.
 - Hypertonic saline administered at 4 mls/kg IV over 3–5 minutes followed immediately by oral fluid therapy may increase absorption of orally administered fluids.
 - Hypertonic saline increases the osmolality of the plasma resulting in volume expansion by pulling water into the vascular space.

Note: Hypertonic saline must be combined with oral fluids or the dehydration will become worse.

CONTRAINDICATIONS

N/A

PRECAUTIONS

The response to therapy should be monitored so that necessary adjustments can be made.

POSSIBLE INTERACTIONS

- Bicarbonate-containing solutions should not be fed to calves that are still consuming milk because the bicarbonate will interfere with the formation of the milk clot in the abomasum, which may result in osmotic diarrhea by increasing the nutrients that reach the colon.
- Combining milk replacer with bicarbonate-containing solutions is safe because these products do not normally clot in the abomasum.
- If calves are consuming milk and need oral electrolytes, an electrolyte product containing acetate as a metabolizable base can be used. The acetate is an effective alkalizing agent but it will not interfere with the formation of the milk clot in the abomasum.
- Bicarbonate should not be mixed with solutions containing calcium because an insoluble precipitate will form.

ALTERNATIVE DRUGS

Antibiotics may be indicated depending on the concurrent disease processes.

FOLLOW-UP

PATIENT MONITORING

Diarrheic calves should respond to therapy within 24 hours. If depression remains, acidosis may still be present.

PREVENTION/AVOIDANCE

Ensuring adequate colostrum intake is the best way to minimize neonatal calf diarrhea.

POSSIBLE COMPLICATIONS

Complications are rare with appropriately applied oral fluid therapy but overhydration may result in increased central venous pressure and pulmonary edema.

REINDEER MANAGEMENT: OVERVIEW

BASICS

OVERVIEW

- Historically, more than 25 indigenous ethnic groups residing in the Eurasian circumpolar regions have participated in reindeer herding.
- Currently, the reindeer industry is a primary focus of the Koryak, Chukchi, Komi, Nenets, Yakut, Enets, Even, Evenk, Nganasan, Dolgan, and Sámi (see map at <http://miljo.npolar.no/temakart/pages/homeE.asp/>).
- There are approximately 1.5 million domesticated reindeer in Russia, 200,000 in Finland, 250,000 in Sweden, and 200,000 in Norway.
- Although less than 1% of the total meat consumed in Fennoscandia is reindeer, its production is a vital source of income to remote regions of this subarctic region.
- Although difficult to quantify, reindeer herding has important cultural value. Reindeer, aside from being an important source of food and revenue, typically play a central role in the traditions of the circumpolar indigenous herding groups.
- These cultures are of the few remaining indigenous cultures that have maintained their ability to live traditional lifestyles.

SYSTEMS AFFECTED

Production management

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Russia, Finland, Sweden, Norway, Greenland, Canada, and Alaska

SIGNALMENT

Species

- *Rangifer tarandus* is a circumpolar species consisting of seven subspecies formed through the isolation of populations during the ice age.
- Peary caribou (*R.t. pearyi*) and Svalbard reindeer (*R.t. platyrhyncus*) inhabit the high Arctic.
- Alaskan caribou (*R.t. granti*), barren ground caribou (*R.t. groenlandicus*), and Eurasian reindeer (*R.t. tarandus*) inhabit the taiga, woodland caribou (*R.t. caribou*) and woodland reindeer (*R.t. fennicus*) inhabit the Boreal forests.
- *Rangifer tarandus* are polygamous and highly sexual dimorphic with males being approximately twice the size of females.
- North American caribou have been utilized only through hunting.
- Eurasian reindeer were originally domesticated by indigenous people.
- Domesticated reindeer are highly gregarious and form large herds, particularly during migration and periods of insect harassment.

Breed Predilections

- Eurasian reindeer are smaller than caribou.
- Females reach maximum size at the age of 4–5 years, and senescence starts at the age of 7–8 years.
- Herders selectively remove old individuals.
- A single calf is typically produced every year. Calves are born in April-June, depending on the nutritional status of the female.
- Females in poor nutritional status delay calving.

- Birth weight is ~5 kg, males being 0.5 kg larger than females. Birth weight is positively associated with neonatal survival.
- Weaning ends in September/October (i.e., when the rut starts), but the calf may follow its mother for a year, but rarely longer.
- Calves following their mothers have easier access to food and are more likely to survive the winter.
- Male calves have higher mortality rates and are less likely to follow their mothers during the winter.

Mean Age and Range

N/A

Predominant Sex

- Females are ~60 kg and males 120 kg at their prime, although body weights vary markedly depending on range conditions
- Age of maturity is 1–3 years in females and 2–5 years in males. Poor nutritional conditions during early development may delay maturity. Conversely, exceptional conditions may result in early maturity (age 1) for females, and this premature reproduction effort can permanently stunt somatic growth.
- Females reach maximum size at the age of 4–5 years, and senescence starts at the age of 7–8 years.
- Herders selectively remove old individuals.

TREATMENT

DIET

- The most important food during winter is lichen (*Cladina* spp.).
- During summer, the diet is more variable, and includes vascular plants, grasses (graminoids), herbs, shrubs such as willow (salicaceae), and heathlike shrubs (ericoids) and trees.
- Inadequate harvesting and subsequent populations exceeding range-carrying capacity have led to degradation of the winter pastures in many areas.
- Many reindeer are thus fed with hay and commercial feed pellets during winter. This is particularly the case in Finland where the European Union subsidizes production of hay.

MISCELLANEOUS

Herding Systems

- Reindeer management has been exported in more recent times from Fennoscandia and Siberia to other regions and cultures including the Inuit in Alaska and the Greenland Eskimos.
- The most intensive and modernized management of domesticated reindeer is found among the Sámi people in Fennoscandia. There, herding is a cooperative operation based on year-round free range with seasonally defined ranges and migration routes, intensive use of mechanical transportation for herding (motorcycles, snow machines, helicopters), and supplemental feeding during poor range conditions.
- Reindeer are generally individually owned in most regions of Fennoscandia, but reindeer cooperatives with joint ownership are common in Finland, southern Norway, and most of Siberia.
- Reindeer husbandry requires access to extensive land areas and utilizes 35% of the land area in Finland and Sweden, and 40% in Norway.
- Management is organized into herding districts, with defined ranges and migration routes, carrying capacities, and governmental oversight.
- Coastal regions, with their moister climates, nutrient-rich graze, and lower intensity of flying, biting insects are used for summer range, while drier continental climates with dense lichen beds, and less snow and stable cold conditions during the winter months are used for winter range.
- Governmental restrictions regarding crossing geopolitical boundaries have tended to break up traditional, ecologically determined migration patterns and seasonal ranges.
- Historically, reindeer herders in Russia, Finland, Sweden, and Norway migrated freely over the national borders.

- During the nineteenth century, the Russian and Finnish borders were closed, and today severe restrictions exist on the movement of reindeer between pastures in Norway and Sweden. This has led to reduced availability of appropriate summer and winter pastures.
- Many Norwegian reindeer herds are forced to survive on winter pastures along the coast where heavy snowfall and icing prevent efficient foraging. This has been remedied to some extent by supplemental feeding during some of the winter months.
- Conversely, Finnish and Swedish reindeer lack access to nutrient-rich pastures along the coast during the summer and experience a very high burden of flying parasites such as nasal bot flies (*Cephenomyia trompe* Modeer) and warble fly (*Hypoderma tarandi* L.).

Economic Considerations

- An economic infrastructure developed around the reindeer industry early in the twentieth century when there was a shift toward a cash economy based on meat production.
- Historically, reindeer were utilized for clothing, milk production, transportation (sled and draft animals), and meat production.
- Today, meat production is the primary goal in reindeer husbandry and has become quite lucrative. Reindeer meat is considered a delicacy and an organically, free-range-raised meat, and commands a high price in European markets.
- The meat is not widely marketed in the United States or the rest of the world.
- More recently, with incorporation of modern technology into the husbandry techniques, it became necessary to produce adequate revenue to support the increased mechanization (e.g., snow machines, modern dwellings).
- The amount of time domesticated reindeer are in close contact with humans varies greatly among different management practices from only a few times a year when the calves are marked in the summer or early fall, and in the fall when animals are slaughtered, to almost year-round, with some periods of round-the-clock surveillance.
- Herders follow the reindeer on the migration from winter pastures in continental areas to summer pastures along the coast.
- Calves are marked to signal ownership by cutting away small parts of the ear (see <http://213.161.163.54/merker/hoved.aspx>) in complex patterns of markings. These marks are passed down from generation to generation.
- Families, or family groups, often share pastures and herd their reindeer together in cooperative style management operations.
- Predation**
- Wolverine (*Gulo gulo*), lynx (*Lynx lynx*), and golden eagle (*Aquila chrysaetos*) are important predators on reindeer.
- In some regions, bears can be significant predators.
- Wolf (*Canis lupus*) may be an important predator, but has effectively been removed by humans from most reindeer-herding areas.
- Red fox (*Vulpes vulpes*) may be an important predator on neonates.
- Neonates are particularly vulnerable to predators.
- Food limitation increases risk of predation.

REINDEER MANAGEMENT: POPULATION DYNAMICS

BASICS

OVERVIEW

- High-density herds (populations exceeding carrying capacity) have reduced fecundity and calf growth, and are more vulnerable to density independent factors (e.g., climatic events). Particularly calves, yearlings, and mature bulls (weakened by the rut) and old (> 10 yr) females, especially with worn teeth, are at risk of starvation.
- In the absence of overgrazing, excessive mortality, or heavy animal harvesting, reindeer herds grow until their populations crash (exceed carrying capacity) or move to new feeding regions.
- Reindeer with poor nutrition are more susceptible to parasites, disease, and metabolic deficiencies, which can increase winter losses of meat, hides, and antlers.
- Basic range-management practices in the form of a range-management plan can prevent overgrazing and subsequent starvation of overpopulated reindeer herds.

SYSTEMS AFFECTED

Production management

GENETICS

- Females reach maximum size at the age of 4–5 years, and senescence starts at the age of 7–8 years.
- Herders selectively remove old individuals.

MEDICATIONS

DRUGS OF CHOICE

Broad-spectrum anthelmintics (e.g., Ivermectin MSD—Ivomec 1%, Merck-Sharp & Dohme), GABA (γ -amino butyric acid) inhibitors are frequently used to combat nematodes and arthropods in reindeer.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

MISCELLANEOUS

Population Dynamics

- Sex ratio in domesticated herds is highly skewed toward females (i.e., 1:10–20) due to selective harvest.
- A skewed sex ratio increases the growth rate and potentially the productivity given the higher growth efficiency (per unit feed) of younger animals.
- Large variations in regional climate and harvesting strategies and intensity have led to profound variation in reindeer density, size, and productivity.
- Although somewhat of an oversimplification, summer range conditions are most important determinants for somatic growth, while winter range conditions are most critical for survival.
- Populations with access to winter pastures with little precipitation (snow), stable (cold) continental conditions, and thus good access to food have higher survival rates.
- Intensive harvesting is needed to regulate such populations to sustainable levels that are appropriate for the winter range.
- Populations with winter pastures in coastal areas are exposed to high precipitation levels, bringing deep snow alternating with rains and icing. Resultant ice crystals embedded in the lichen beds reduce the access and palatability, causing reindeer to wander constantly rather than graze with stability.
- High-density herds (populations exceeding carrying capacity) have reduced fecundity and calf growth and are more vulnerable to density independent factors (e.g., climatic events). Particularly calves, yearlings, and mature bulls (weakened by the rut) and old (> 10 yr) females, especially with worn teeth, are at risk of starvation.

Future Challenges

- Closing of national borders led to suboptimal use of pastures for reindeer in Fennoscandia, and international range-sharing agreements could lead to improved productivity.
- Increased pressure on reindeer pastures due to development of infrastructure for other activities such as mining, oil drilling, and power plants may permanently reduce the sustainability of reindeer herding activities.
- The recovery of predator populations, such as wolverine and lynx, has increased predation on reindeer in Fennoscandia.

- Reindeer density is in many regions above sustainable levels because reindeer management authorities have been unable to implement harvesting strategies that balance reindeer numbers to available pastures.

Parasites and Other Infectious Disease

- Reindeer, like all free-ranging, semidomesticated herd animals, are exposed to a wide variety of parasite species and infectious diseases. However, only a few species have substantive economic impact.
- Parasite burden is determined to a large extent on density-dependent factors; herds exceeding carrying capacity or not migrating seasonally to new ranges may experience greatest transmission pressure and highest burdens of parasites.
- Density-independent factors may play a role (e.g., weather conditions influence the ability of flying parasites to breed and infect their hosts).
- *Elaphostrongylus rangiferi* Mitskevich (Nematoda: Metastrongylidae) causes cerebrospinal and muscular nematodiasis and mortality in the reindeer of the Palearctic.
- *E. rangiferi* likely has the greatest economic impact; epizootics have resulted in up to 25% mortality in a single year in select herds of northern Norway.
- The oestrids, *Hypoderma tarandi* L. (warble fly), and *Cephenomyia trompe* Modeer (nasal bot fly), cause substantial harassment during the warmer summer months resulting in reduced feeding time due to insect avoidance.
- Finnish and Swedish reindeer lack access to nutrient-rich pastures along the coast during the summer and experience a very high burden of flying parasites such as nasal bot flies (*Cephenomyia trompe* Modeer) and warble fly (*Hypoderma tarandi* L.).
- *H. tarandi* L3 larvae damage the furs and thus have economic impacts.
- *C. trompe* can in rare instances cause mortality.
- Gastrointestinal nematodes (*Trichostrongylus*, *Ostertagia*, *Nematodirus*, *Marshallagia*, *Trichuris*, *Skrjabinema* species) have a detrimental impact on weight gain and somatic growth, but usually not a direct impact on survival.
- In North America and Siberia, brucellosis outbreaks in reindeer herds have caused serious morbidity and mortality and economic consequences.
- Brucellosis is a contagious, infectious, and communicable disease caused by bacteria of genus *Brucella*.
- Because brucellosis is zoonotic (causing undulant fever in humans), eradication through a vaccination program has been a major veterinary medicine focus in recent years.

RENAL AMYLOIDOSIS

BASICS

OVERVIEW

- Renal amyloidosis is an infrequent systemic disease characterized by chronic wasting and diarrhea.
- Amyloidosis results from the deposition of amyloid (insoluble protein fibrils) in various body tissues. In particular, the kidney seems to be the most common site.
- Proteinuria and a nephrotic syndrome develop in bovine amyloidosis patients.

PATHOPHYSIOLOGY

- Amyloidosis in cattle is classed as the reactive (AA) type, associated with chronic inflammatory disease in domestic animals and humans.
- Concurrent inflammatory disease has been found in some, but not all, cattle with amyloidosis.
- Serum amyloid A protein (SAA) synthesized in the liver is a precursor of amyloid A (AA) fibril in tissues. SAA increases dramatically in cases of trauma, neoplasia, and inflammatory disease (elevation of SAA is necessary for an animal to develop active amyloidosis).
- Elevation of SAA due to abnormal catabolism by the RE system may also increase AA fibril formation.
- AA fibrils, resistant to proteolysis, accumulate in tissues over time.
- Accumulation of amyloid in the glomerulus results in altered glomerular filtration, with a protein-losing nephropathy, development of hypoproteinemia, and decreased intravascular oncotic pressure.
- Diarrhea develops due to edema or amyloid deposition in the GI tract.
- Protein-losing nephropathy and diarrhea result in weight loss.
- Renal or pulmonary thrombosis may occur as a result of the loss of low-molecular weight anticoagulants through the compromised renal system.

SYSTEMS AFFECTED

- Renal, gastrointestinal, hepatobiliary, endocrine
- Amyloid is deposited in the kidney, intestine, liver, spleen, adrenal glands, and other tissues.

GENETICS

Unknown

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

The disease has been reported worldwide.

SIGNALMENT

Species

Although no age, breed, or sex predilection has been implicated, most reports describe the syndrome occurring in adult dairy cows.

Breed Predilections

N/A

Mean Age and Range

Unknown

Predominant Sex

No sex predilection has been reported.

SIGNS

- Chronic diarrhea, weight loss, and poor productivity in adult animals
- Hypoalbuminemia leading to ventral edema occurs commonly.
- Altered attitude and appetite may be present. This may be due to concurrent disease conditions.
- Renal enlargement is evident. The left kidney may be palpable and if so is generally not painful. Kidneys maintain their normal lobular structure.
- Urine develops a stable foam upon hitting the ground or during collection. This symptom is due to the high protein concentration found in the urine of affected animals.

CAUSES AND RISK FACTORS

Cattle with chronic inflammatory conditions such as traumatic reticuloperitonitis, metritis, mastitis, chronic pneumonia, and abscesses are at a higher risk for the development of renal amyloidosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diseases causing chronic diarrhea, weight loss, hypoproteinemia, and reduced productivity; these may include salmonellosis, lymphosarcoma, Johne's disease, bovine viral diarrhea, copper deficiency, parasitism, chronic renal disease, chronic liver disease, and glomerulonephritis.
- Besides amyloidosis, glomerulonephritis is the only other disease to cause prolonged proteinuria.

CBC/BIOCHEMISTRY/URINALYSIS

- Affected cattle consistently develop marked hypoalbuminemia and proteinuria.
- If advanced renal damage has occurred, urine creatinine and urea nitrogen may be elevated.
- If chronic active inflammatory disease is present, hyperfibrinogenemia and hyperglobulinemia may also occur.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Diagnosis of amyloidosis in the live animal requires a renal biopsy. Biopsies can also differentiate renal amyloidosis from glomerulonephritis.
- Polarized light microscopy and EM have been used to examine urine sediment for the presence of amyloid protein.

PATHOLOGIC FINDINGS

- Renal enlargement with yellow-tan discoloration is often present.
- Waxy appearance of the renal parenchyma on kidney cut surface is evident.
- Generalized edema due to hypoalbuminemia is usually present.
- Some cases may present with renal or pulmonary thrombosis.
- There may be evidence of inflammation in other systems.
- Histopathology reveals amyloid deposition in the glomerulus, interstitium, and tubule lumen.
- Renal tissue may be stained with Lugol's iodine. Lugol's iodine turns amyloid mahogany brown in color. Further staining with sulfuric acid produces a blue color.
- Congo red stains highlight amyloid for subsequent light microscopy.
- Electron microscopy identifies characteristic fibril appearance.

TREATMENT

- Lesions are irreversible. The prognosis for affected animals is poor.
- Amyloid protein is resilient so it persists in tissues even if underlying cause is treated successfully.

- Specific treatment in cattle has not been reported as effective.

REPEAT BREEDER MANAGEMENT

BASICS

DEFINITION

- “Repeat breeding” is defined as a failure of conception following three or more regularly spaced services in the absence of obvious abnormalities.
- This definition may need to be modified if the herd is using techniques of estrus/ovulation synchronization.
- A more restrictive definition includes only cows that fall within this description and have been inseminated correctly with good-quality semen.

PATHOPHYSIOLOGY

Any approach to dealing with repeat breeding should consider that this syndrome might be due to either conception failure or embryonic death before maternal recognition of pregnancy. These may be affected by several factors that can be grouped in four large categories:

1. Management/human factors: concerning mainly heat detection accuracy and proper timing and delivery of semen
2. Semen factors: particularly postthaw quality and intrinsic fertility (bull fertility)
3. Cow factors: primarily disorders that may contribute to failure of fertilization or failure of embryo survival
4. Environmental factors: particularly excessive heat and humidity

SYSTEMS AFFECTED

Reproductive

GENETICS

N/A

INCIDENCE/PREVALENCE

- Repeat breeding syndrome incidence varies from 5% to 20%. Several factors affect this incidence including herd size, age of the cows, season, and production.
- The economic loss due to repeat breeding is estimated at approximately \$170 per cow per annum.

GEOGRAPHIC DISTRIBUTION

Potentially worldwide, depending on species and environment

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

Reproductively mature females

Predominant Sex

Females

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of repeat breeding requires a thorough analysis of reproductive health records, observation and

evaluation of personnel involved in breeding and examination of semen/bulls and affected cows.

- Record analysis will be possible only if a system is in place that allows investigating each factor and its interaction in the contribution to repeat breeding.

Rule Out Management/Human Factors

- History and retrospective analysis of conception rate by inseminator
- Retrospective analysis of conception rate by method of heat detection
- Evaluation of inseminator
- Retraining of inseminator
- Inseminator fatigue

Rule Out Semen Factors

- Retrospective analysis of bull conception rate
- Retrospective analysis by semen/tank batches
- Evaluation of semen tank management
- Evaluation of semen handling
- Evaluation of a semen sample: evaluation should include postthaw motility, acrosome integrity, and concentration. Help from a specialized laboratory may be required to complete this examination. Analysis results should be compared to parameters from the bull stud center.
- Breeding soundness evaluation of bulls if natural mating (see Beef Bull Management and Dairy Bull Management)

Rule Out Female Factors

Failure of Fertilization Failure of fertilization may be due to any factor that compromises gamete survival or transport to the site of fertilization and the process of fertilization. Factors include:

- *Defective oocytes*: estimated to be responsible for 3% to 8% of all causes of RB. Aged oocytes with poor fertilizing ability may be implicated in repeat breeding of individual animals. In herd situations, poor fertilizability of oocytes is generally the result of poor timing of insemination (too late). Quality of oocytes is affected if a cow experiences severe negative energy balance.
- *Oviductal anomalies*: estimated to be responsible for 6% to 15% of all causes of RB. Bilateral congenital (segmental aplasia, hydrosalpinx) or acquired (salpingitis, pyosalpinx, perisalpingitis) conditions of the uterine tube or bursa (hydrobursitis, ovariobursal adhesions) will interfere with gamete transport and prevent fertilization. Diagnosis requires detailed examination of the reproductive tract. Ultrasonography per rectum and technique to verify uterine tube patency may be required. Estimated to be responsible for 3% to 8% of all causes of RB
- *Abnormalities of the uterus*: the most common cause of fertilization failure is endometritis, which compromises sperm viability. Diagnosis of endometritis requires careful examination during estrus; uterine cytology and culture may help in diagnosis of endometritis. Immunologic reaction against semen may be a significant factor in some cows.
- *Abnormalities of the cervix*: cervical malformations such as cervical adhesion, double cervix or double external os of the cervix, cervicitis and pericervical adhesions/abscesses may be a cause of fertilization failure in individual cases but rarely is a herd problem. In some breeds (i.e., Santa Gertrudis), cervical morphology may be an important factor in poor conception rate. These disorders present as a difficulty to bypass the cervix and deposit semen into the uterus.
- *Hormonal imbalances*: excessive hormonal treatment (estrogens, progestogens) prior to ovulation or after insemination may compromise semen transport. Synchronization using MGA results in poor fertility of the induced heat. Improper timing or dosage of estrogens and GnRH used in some synchronization protocols may lead to poor timing between insemination and ovulation. In dairy heifers, repeat breeding has been associated with prolonged duration of estrus, delayed LH peak, prolonged lifespan of preovulatory follicle, late postovulatory rise in plasma progesterone, and the tendency for periovulatory suprabasal progesterone levels. Recent studies have shown that hormonal imbalance also may affect expression of epidermal growth factors in the uterus, which are important for embryonic development.

Early Embryonic Death

- Cows that experience early embryonic death before embryouterine signaling (day 16 of the cycle) will have a normal cycle length and would manifest as a repeat breeder syndrome.
- Embryo loss before day 16 is estimated at 40% to 50% of all conceptions.
- Early embryonic death can result from poor quality embryos originating from poorly timed insemination (aged oocytes), older cows, poor oviductal or uterine environment due to inflammation or hormonal imbalances, and genetics.

• In dairy herds, one of the most important causes for embryonic death is elevated ambient temperature and humidity. Infectious Disease Infectious diseases may be implicated in increased repeat breeding in a herd. Most of these agents predispose to RB due to inflammatory changes to the ovaries; ovarian bursa (viruses); and/or the uterus, cervix, and vagina. These diseases include:

- *Brucella abortus*
- *Mycobacterium tuberculosis*
- BVDV
- IBR
- *Ureaplasma diversum*
- *Mycoplasma bovis*
- *Hemophilus somnus*
- *Leptospira interrogans*
- *Trichomonas foetus*
- *Campylobacter fetus* ssp. *venerealis*

TREATMENT

- A strict case definition of repeat breeding should be established on a herd basis.
- Herd reproductive performance records should be analyzed regularly and the incidence of repeat breeders reported.
- Analysis of records should take into account human, bull/semen, environment, and cow factors.
- Address human/management factors:
 - Improve heat detection efficiency and accuracy
 - Use fixed-time insemination
 - Periodic retraining of inseminators
- Address cow factors:
 - Individual cases should be examined thoroughly: ultrasonography of the reproductive tract and uterine cytology may add to the accuracy of diagnosis.
 - Eliminate individual causes (congenital or acquired nontreatable conditions).
 - Determine causes of uterine infection and set up protocol for prevention
 - Early identification and treatment of uterine infection
 - Reduce ovulation failure/ovulation problems by the implementation of a ovulation synchronization protocol or systematic injections of GnRH at the time of insemination in RB cows.
 - Improve embryo survival by administration of hCG or GnRH to create accessory corpora lutea and supplemental progesterone (CIDR) 6 days after insemination.
 - Administration of 500 mg BST has been shown to improve embryo survival.
- Address semen/bull factors:
 - Use semen from high-fertility bulls.
 - Use a double insemination regime.
 - Use deep horn insemination (if technician is well trained).
 - Perform breeding soundness evaluation on bulls.
 - Use clean-up bulls only on cows that are known not to have an infectious cause of infertility.
- Address environmental factors:
 - Use cooling system during summer.
 - Decrease incidence of uterine infection by improving calving condition.
 - Improve heat detection by addressing problems such as crowding and floor-surface issues.

REPRODUCTIVE TUMORS

BASICS

DEFINITION

Neoplastic changes can affect mainly the ovary, uterus, and cervix. They are relatively rare in ruminants. Reproductive tract tumors are most commonly found in pet goats. Reproductive tumors in the male ruminant involve primarily the testicles.

PATHOPHYSIOLOGY

- Neoplasia of the reproductive organs are accompanied by a wide variety of clinical signs.
- The most determinant factors in the type of clinical signs seen are the tissue affected, the nature of the tumor, and the location. Tumors may originate from the reproductive tract or from another system.
- Ovarian tumors, particularly sex-cord tumors, are accompanied by several behavioral and phenotypic changes due to the hormone secreted. Testosterone-secreting tumors are accompanied by virilization (increased size and thickness of the head and neck) and malelike behavior. Erratic cycles may be observed with some ovarian tumors.
- Uterine and cervical tumors are generally asymptomatic or accompanied by frequent, intermittent, or continuous mucus or mucohemorrhagic discharge. Anestrus or erratic cycles may be observed with some ovarian tumors.
- Malignant tumors may affect several other organs (liver, kidney, lungs) leading to the development of a host of other clinical syndromes (weight loss, dysuria, respiratory problems, etc.).

FOLLOW-UP

MISCELLANEOUS

Reproductive Neoplasia in the Female

General considerations:

- Symptoms depend on the nature and site of the tumor and malignancy
- Always look for metastasis particularly in small ruminants with uterine tumors (chest radiographs)
- Tumors may be encountered at any age; however, uterine and cervical tumors seem to be more prevalent in older animals
- In practice, pet goats seem to be the species most frequently diagnosed with reproductive tumors
- Reproductive tumors in the female should be suspected in the presence of:
 - Abnormal palpable masses in or around the ovaries, uterus or cervix
 - Vaginal discharge (bloody or mucoid)
 - Irregular cycles
 - Stranguria, straining
 - Abnormal ultrasonographic appearance of the ovaries, uterus or cervix
 - Repeat breeding

Diagnosis

Differential Diagnosis

- Other causes of ovarian masses: adhesions, large cysts
- Other cause of uterine masses: uteroperitoneal adhesions, maceration, mummification, tuberculosis
- Other causes of cervical masses: cervicitis, abnormal cervical conformation, double cervix, cone/funnel-shaped cervix

CBC/Biochemistry/Urinalysis

N/A

Other Laboratory Tests

Examination of the female with suspected reproductive tumor:

- Laparoscopy
- Endocrinology: steroid hormone profiles and inhibin may be of value for the diagnosis of ovarian tumors. Inhibin and testosterone or estrogen are high in the case of granulosa cell tumors.
- Cervical and uterine biopsy
- Fine needle aspirate if the mass is easily accessible (vaginal or cervical)

Imaging

- Transrectal ultrasonography
- Transcutaneous abdominal ultrasonography in sheep, goats, and alpacas
- Exploratory laparotomy: this is particularly useful in the bovine where laparoscopy is generally difficult. This could also be utilized in camelids of value.

Other Diagnostic Procedures

- Transrectal palpation of all genital organs and pelvic area. Serial palpation may be required to monitor the progress of the lesion.
- Transabdominal palpation/ballottement may be helpful in detecting large uterine and ovarian masses in sheep and goats.

Treatment

- Benign ovarian neoplasm can be treated by surgical ablation (ovariectomy) of the affected ovary.
- Uterine masses require hysterectomy—indicated mainly in companion animals (alpacas or goats).
- Histopathological findings determine the extent of medical management following surgery.

Specific Reproductive Tumors in the Female

Ovarian Neoplasm Ovarian tumors are generally classified as epithelial, germ cell, sex-cord, or mesenchymal of origin.

Epithelial Tumors

- Include papillary adenoma or carcinoma, cystadenoma, cystadenocarcinoma, and adenocanthoma
- Papillary adenoma or adenocarcinoma are very rare and arise from the surface epithelium, the subsurface epithelial structures, or rete ovarii.
- Cystadenoma arise from epoophoron and/or rete ovarii. They are large single-cavity cystic structures.
- Cystadenocarcinoma has been reported in the bovine with metastasis to the peritoneum and iliac lymph nodes, kidney, and other organs; may have been a malignant granulosa cell tumor.
- Adenocanthoma (carcinoma with squamous metaplasia) has been reported in the bovine.

Germ Cell Tumors

- Dysgerminoma: reported in the cow as firm, spherical, red-gray mass, 15 cm in size, which can metastasize. Hyperplasia of the endometrium due to hyperestrogenism
- Teratomas arise from all three germinal layers with tissue representing any organ except the ovary or testis. Teratomas of different sizes and ectopic tissue content (e.g., cartilage, hair, bone, teeth, etc.) have been reported in the ewe, bovine, goat, llama, alpaca, and camel.
- Bovine cystic ovarian teratomas (dermoid cysts) have been reported in zebu cattle and water buffalo. Cysts vary in size. Ovaries range in size from 5.7 to 45 kg. Metastasis has been described.

Sex-Cord Stromal Tumors

- The most common sex-cord stromal tumor is the granulosa cell tumor. Other sex-cord tumors include thecoma (theca cell tumor, firm white/yellow/orange tumors reported in cattle) and luteoma (interstitial cell tumor, smooth slightly lobulated, orange cut surface, high progesterone).
- Granulosa cell tumor:
 - Nymphomania, virilism, or asymptomatic masculinization of the head and neck
 - Cows have large multilobulated masses up to 40 kg; has been reported in newborn and nursing calves. Majority are reported at 2 to 3 years of age.
 - Male behavior, udder development
 - Ovary enlarged, contralateral ovary small
 - Generally unilateral
 - Very few are malignant
 - High testosterone, estrogen, or both; high inhibin
 - GCT have been reported in goats, sheep, and camelids

Mesenchymal Tumors

- Hemangioma
- Leiomyoma
- Fibroma
- Lymphoma (lymphosarcoma)

Uterine Neoplasm

Epithelial Tumors

- Adenoma: polyps of the endometrium are considered hyperplastic and are rare.
- Adenocarcinomas have been reported in cows (2–14 years of age), goats (7 years or older), ewes, and camelids.
 - Animals with uterine adenocarcinoma may present with several clinical signs such as infertility, bloody discharge,

palpable abnormality, listlessness, respiratory syndrome, stranguria.

- Metastasis to lymph nodes, peritoneum, lungs, and other organs may be present.
- Lesions start in the endometrium and progress into the myometrium.
- Palpation finding, indentation of the myometrium
- Diagnosis: ultrasonography, biopsy, or exploratory laparotomy

Mesenchymal Tumors

- Fibroma: rare, hard, white, spherical neoplasm of the uterine wall
- Fibrosarcoma: extremely rare
- Leiomyoma: benign, firm, tan, nodular; generally affect the myometrium
- Leiomyosarcoma: reported in the cow and goat but are extremely rare
- Uterine lymphosarcoma: cattle—multiple irregular-shaped, soft masses

Cervical Neoplasia

- Cervical tumors are primarily of epithelial nature and include adenocarcinoma and squamous cell carcinoma. These tumors have been reported in the bovine and caprine.
- Cervical adenocarcinomas are relatively common in older goats and should be differentiated from cervical hyperplasia. Metastasis to other organs is possible in the case of adenocarcinoma.
- Mesenchymal tumors such as leiomyoma are generally associated with the uterus and vagina.

Vaginal and Vulvar Neoplasia

- Papilloma and squamous cell carcinoma occur predominantly in cattle, goats, and sheep.
- Risk factors for squamous cell carcinoma include surgical removal of perineal skin folds to reduce myiasis, tail-docking for ewes, and the lack of pigmentation on the vulva in cows, which increases exposure or sensitivity to ultraviolet radiation.
- These lesions can become ulcerated, necrotic covered by exudates and blood.
- Fibropapillomas are firm, elevated, white or pink masses, smooth or cauliflowerlike in texture, and are transmissible tumors in heifers.

Reproductive Neoplasia in the Male

General considerations:

- Tumors of the reproductive tract are rare with the exception a few obvious ones such as penile fibropapilloma in the bull.
- Reproductive tumors in the male should be suspected in presence of:
 - Deterioration of semen quality in the absence of a detectable inflammatory, traumatic, degenerative, or environmental cause
 - Progressive increased size of the testis
 - Preputial bleeding or presence of proliferative lesions on the penis surface

Diagnosis

Examination of the male with suspected reproductive tumor:

- Semen evaluation
- Testicular measurement and palpation
- Testicular ultrasonography
- Penile exteriorization and examination
- Testicular biopsy

Differential Diagnosis

- Other causes of scrotal or testicular enlargement
 - Testicular hematoma, abscesses
 - Orchitis
 - Inguinal hernia
- Other causes of preputial bleeding or phimosis
 - Preputial/penile laceration
 - Preputial abscess or adhesions

Treatment

- Testicular neoplasm requires unilateral castration and monitoring for semen quality and signs of metastasis.
- Fibropapillomas are best removed surgically by electrocauterization or ablation.
- Prevention of penile fibropapilloma may be achieved by use of autovaccine.

Specific Reproductive Tumors in the Male

Testis

- The most common testicular neoplasia in domestic animals includes seminomas, sustentacular cell tumors (tubular adenoma, tubular adenocarcinoma, Sertoli cell tumor), and interstitial cell tumors (Leydig cell tumors).
- Interstitial cell tumors are generally characterized by poor semen quality, large volume of ejaculate with low motility, and poor concentration.
- Seminomas have been reported in male alpacas, bulls, bucks, and rams. The affected testicle is generally enlarged. Effects on semen quality are variable.
- Sertoli cell tumors have been reported in bulls and rams. The affected testicle is enlarged, and semen quality may be normal or slightly affected. These tumors are pale gray and firm with irregular surface.

Penis

- Fibropapilloma is the most common penile tumor. It is primarily seen in young bulls. It is due to the fibropapilloma virus.
- Treatment consists of surgical excision.
- This tumor can be prevented by use of autovaccine.

ASSOCIATED CONDITIONS

See Pathophysiology above

AGE-RELATED FACTORS

- Adenocarcinomas have been reported in cows (2–14 years of age), goats (7 years or older), ewes, and camelids.
- Granulosa cell tumor: cows have large multilobulated masses; has been reported in newborn and nursing calves. Majority are reported at 2–3 years of age.
- Cervical adenocarcinomas are relatively common in older goats.
- Tumors may be encountered at any age; however, uterine and cervical tumors seem to be more prevalent in older animals.

RESPIRATORY PHARMACOLOGY

BASICS

OVERVIEW

- Respiratory diseases of cattle are usually best described as “syndromes” involving one or more infectious organisms and environmental stressors in a compromised animal.
- Bovine respiratory disease complex (BRD) is used to describe the syndrome in older calves and adult cattle, while enzootic pneumonia is the syndrome in young calves.
- Also known as shipping fever, BRD is the primary cause of illness and death in feedlot cattle.
- *Mannheimia hemolytica*, *Pasteurella multocida*, *Histophilus somni* are gram-negative bacteria considered the primary causes of BRD, in conjunction with a number of viral infections.
- *Arcanobacterium pyogenes* (gram-positive anaerobe), gram-negative enteric bacteria, anaerobes, and *Mycoplasma* are secondary pathogens involved in chronic cases.
- To be successful, antimicrobial therapy needs to be given early in the course of the disease and should target the appropriate pathogen(s).
- Anti-inflammatory therapy can improve clinical signs and reduce pathology.

PATHOPHYSIOLOGY

- The numerous pathogens involved are ubiquitous in cattle and are often part of the normal flora of the nasopharynx.
- When a group of cattle is exposed to various stressors, such as long shipping distances, transit shrinkage, and commingling, they are at risk of developing BRD, particularly if the cattle's immune systems are naïve.
- During stressful events, deficient immune defenses allow proliferation of the virulent flora and subsequent infection of the lower respiratory tract.
- Due to the release of endotoxin and leukotoxin from the primary bacterial pathogens, severe bronchopneumonia may develop.

SYSTEMS AFFECTED

Respiratory tract

GENETICS

N/A

INCIDENCE/PREVALENCE

- Up to 81% of feedlots use injectable antimicrobials for high-risk calves (metaphylaxis).
- Approximately 10% of cattle entering feedlots are receiving injectable antimicrobials upon arrival.
- Of cattle in feedlots, 20% are treated with an injectable antimicrobial for BRD. It costs producers approximately \$13/head (U.S. dollars) for treatment.
- Over 80% of feedlots use antimicrobials in the feed or water of cattle to prevent disease and improve performance. Lung concentrations attained are below the MIC values of BRD pathogens.

MEDICATIONS

DRUGS OF CHOICE

Antimicrobials

See also [Tables 1](#) and [2](#).

- To be effective, antimicrobial therapy needs to be given early in the course of the disease, reach the site of infection, and target the appropriate pathogens.
- Approved drugs for the treatment of BRD vary in their pharmacokinetics and pharmacodynamics. Values for volume of distribution (Vd) indicate drug penetration into tissues, and the elimination half-life (T_{1/2}) is a measure of drug persistence for action and slaughter withdrawal time.
- Antimicrobial action is classified as concentration-dependent or time-dependent.
- Efficacy of concentration-dependent antimicrobials is associated with achieving drug concentrations that are eight to ten times the minimal inhibitory concentration (MIC) of the pathogen. Efficacy of time-dependent antimicrobials is associated with keeping drug concentrations above the pathogen's MIC for at least 50% of the dosing interval.
- Metaphylaxis and first pull therapy should target the gram-negative respiratory pathogens. All of the antimicrobials approved for BRD initially have good activity against *Mannheimia hemolytica*, *Pasteurella multocida*, and *Histophilus somni*. In relapse cases, antimicrobial resistance of the primary pathogens and opportunistic infections with *Arcanobacterium pyogenes* (gram-positive anaerobe), gram-negative enterics, anaerobes, and *Mycoplasma* should be considered. Activity against these pathogens varies considerably among the approved products.
- Even appropriate therapy against the opportunists may fail, as advanced disease prevents effective drug concentrations from reaching the site of infection. In vitro susceptibility of *Mycoplasma* species poorly correlates with clinical efficacy.
- Single-dose therapy with long-acting antimicrobials decreases animal stress from handling and reduces labor costs. Other considerations in antimicrobial selection include cost, route of administration, effect on carcass quality, and length of withdrawal time.
- First-line treatment of calves with clinical signs of BRD in feedlots is with enrofloxacin, danofloxacin, florfenicol, tilmicosin, a long-acting oxytetracycline, or a ceftiofur formulation. Ceftiofur sodium or ceftiofur hydrochloride are used in cattle close to market weight because of their zero and 48-hour withdrawals, respectively. Approval is currently being sought for tulathromycin, a very long-acting macrolide antimicrobial for SC treatment of BRD.
- Although approved for BRD, spectinomycin, erythromycin, tylosin, penicillin, sulfonamides, ampicillin, and amoxicillin are less commonly used due to issues including requirement for repeated administration, less-desirable pharmacokinetics, lower efficacy, and carcass damage at injection sites.

Anti-inflammatory Drugs

- Corticosteroids may reduce inflammation in calves with necrotic laryngitis and or tracheal edema syndrome. Single doses of a corticosteroid are unlikely to cause significant immunosuppression. Recommended doses include 5–20 mg of dexamethasone IM or IV, 10–20 mg of isoflupredone IM, or 1.25–5 mg of flumethasone IM (approved in Canada).
- Nonsteroidal anti-inflammatory drugs reduce fever and endotoxin-induced inflammation in cattle with BRD. Flunixin meglumine is approved for use in cattle with BRD at 1.1–2.2 mg/kg IV either as a single dose or divided into two doses at 12-hour intervals. The U.S. withdrawal time is 4 days for meat and 36 hours for milk; the Canadian withdrawal time is 6 days for meat. Ketoprofen is approved in Canada at 3 mg/kg IM q 24 hr with zero milk and 24-hour meat withdrawal times.

CONTRAINDICATIONS

- AMDUCA regulations and appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Fluoroquinolones must not be used in an extralabel manner in the United States.

- Contact a U.S. (1-888-873-2723) or Canadian (1-866-243-2723) gFARAD office for withdrawal recommendations for extralabel drug use.
- Deep nasal swab cultures are predictive of bacterial isolates from the lungs of cattle with acute BRD.
- Avoid sampling from dead animals, as the in vitro susceptibility of the isolated pathogens from treatment failures will not represent the bacterial population as a whole.
- Treated cattle need to be closely monitored for response to therapy. Typically, if clinical improvement and normalization of body temperature does not occur within 3 days of therapy, an alternative therapy is used.
- Avoid overtreating chronic animals, as response is poor and treatment is uneconomical.

Table 1

Commonly Used Antimicrobials for Metaphylaxis and Treatment of BRD					
Antimicrobial	Action	Vd	T1/2	Route of Administration	Slaughter Withdrawal
Ceftiofur Sodium or hydrochloride	Time-dependent	Low	Short	IM, SC	Sodium: zero Hydrochloride: 2 days
Ceftiofur crystalline free acid	Time-dependent	Low	Long	SC in the ear	Zero
Danofloxacin	Concentration-dependent	High	Moderate	SC	4 days
Enrofloxacin	Concentration-dependent	High	Moderate	SC	28 days
Florfenicol	Time-dependent	Moderate	Long	SC, IM	IM: 28 days SC: 38 days
Oxytetracycline (long-acting)	Time-dependent	Moderate	Long	SC, IM	28 days
Tilmicosin	Time-dependent	Very high	Very long	SC	28 days

Table 2

Relative In Vitro Antimicrobial Activity						
	Ceftiofur	Danofloxacin	Enrofloxacin	Florfenicol	Oxytetracycline	Tilmicosin
Gram – respiratory	+++	+++	+++	+++	++	+++
Gram – enterics	++	+++	+++	+	+	–
Gram +	+++	+	+	+++	++	+++

RETAINED PLACENTA

BASICS

DEFINITION

- Retained placenta (RP) is failure to pass the placenta (fetal membranes) within 24 hours after parturition.
- Although various authors define RP at 6, 12, or 24 h, among cows that passed the placenta within 24 h, 77% did so within 6 h and 94% did so by 12 h after calving. The 24 h definition is most practical for monitoring in the field.

PATHOPHYSIOLOGY

- The anatomy of normal placental attachment is that cotyledon (fetal) villi attach into crypts in caruncles (maternal); cotyledons may also form pouches over caruncles in forming placentomes, of which there are approximately one hundred in the cow.
- The exact mechanism by which detachment occurs normally is not completely known. It appears that critical biochemical changes occur at the uterine-placental interface in the hours to day before parturition. However, decreased neutrophil function occurs 1 to 2 weeks before calving in cows that go on to have RP.
- The key element in RP is failure of detachment of the placentome. Specifically, there appears to be a failure of proteolysis of the cotyledon and, in particular, a failure of collagenolysis to release the cotyledon from the caruncle. This is supported by experimental evidence that injection of collagenase into the umbilical artery within the uterus (after RP occurred) or into the uterine artery during cesarean section was associated with detachment of the placenta within hours.
- It is very likely that neutrophils play a key role in breaking down the placental attachment, and prepartum immunosuppression, specifically impairment of neutrophil function, is a substantial component of the cause of RP.
- Conversely, a lack of uterine contractions is not part of the pathogenesis of RP. In fact, uterine contractions are normal to increased after parturition in cows with RP.
- In RP, detachment occurs around day 6–10 due to necrosis of the caruncle. While the RP is present in the uterus, partial necrosis contributes to bacterial growth, which along with ongoing metabolic activity by the placental tissue results in inflammation of the uterus, which may progress to clinical metritis.

SYSTEMS AFFECTED

Reproductive

GENETICS

No specific genetic predisposition, however, there is some evidence that compatibility between mother and calf of the major histocompatibility complex (MHC) class I is associated with increased risk of RP. Given that immune function is critical to normal placental detachment, it is likely that molecular genetics does have role in RP, but more research is needed.

INCIDENCE/PREVALENCE

In a 1998 summary of 50 citations, the median lactational incidence risk was 8.6%, with a range of 1.3% to 39.2% of lactations affected.

GEOGRAPHIC DISTRIBUTION

Worldwide among dairy cattle. The reported incidence is highly variable, but RP appears to be more common in North America (typical incidence of 8%–10%, up to 14%) than in Scandinavia, the UK, and New Zealand (typical incidence of 1%–3%). However, there may be reporting biases inherent in the sources of data for the published figures.

SIGNALMENT

Species

Bovine: common in dairy cattle, less so in beef cattle; also occurs uncommonly in sheep and goats

Breed Predilections

No clear associations

Mean Age and Range

Immediately after calving, therefore > 2 years old

Predominant Sex

Females only

SIGNS

Presence of some or the entire placenta in the uterus > 24 h after parturition; commonly obvious on inspection from a distance, with up to 1 m of the placenta hanging downward from the vulva. Within 1–3 days, a fetid odor and/or fetid red-brown discharge from the vulva are likely to be present.

HISTORICAL FINDINGS

Calving within the last week

PHYSICAL EXAMINATION FINDINGS

In some cases, inspection or palpation per vagina is necessary to confirm the presence of placental tissue and rule out a retained fetus.

CAUSES

Failure of detachment of the placentome, at least in large part due to impaired neutrophil function in the week or so before calving, which in turn is associated with excessive or maladaptative negative energy balance and suboptimum availability of selenium, vitamin E, and other nutrients.

RISK FACTORS

Abortion, twin birth, induced parturition, dystocia, cesarean section, stillborn calf, and milk fever are all associated with increased risk of RP. Although milk fever is associated with RP, hypocalcemia is not directly causal. Animals with elevated serum nonesterified fatty acids (NEFA ≥ 0.5 mEq/L) and/or suboptimal vitamin E status in the last week prepartum (serum α -tocopherol:cholesterol ratio $< 2.5 \times 10^{-3}$) are more likely to have RP. Lower prepartum serum cholesterol concentration has also been associated with increased risk of RP.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Diagnosis is straightforward. If fever ($T > 39.5^{\circ}\text{C}$) is present together with RP (in the absence of other causes), this may be considered a case of metritis, particularly if dullness, decreased milk production or appetite, anorexia, or signs of toxemia (dehydration, elevated heart rate, diarrhea, weakness, cold extremities) are also present.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Generally, external inspection is sufficient. Palpation of the uterus per rectum or per vagina may be performed to confirm the diagnosis of RP. As involution proceeds and the cervix closes, it is not recommended to exert force to palpate beyond the cervix.

PATHOLOGIC FINDINGS

Animals with RP have necrotic placental tissue attached at the caruncles, abundant mixed bacterial growth in the uterine lumen, and variable severity of inflammation of the layers of the uterus.

TREATMENT

APPROPRIATE HEALTH CARE

Outpatient

NURSING CARE

Animals with RP will plausibly benefit from extra effort to provide easy access to feed (60–90 cm linear bunk space per cow) and lying space (at least 9.3 m² [100 sq ft] of bedded pack space or < 100% stocking density in freestalls), as well as unrestricted access to water and heat abatement measures if ambient temperature is > 27°C. However, all transition cows may benefit from such measures.

ACTIVITY

As usual

DIET

As usual (see Prevention below)

CLIENT EDUCATION

See Prevention below.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

- Many treatments for RP have been reported or advocated, including systemic and IU antibiotics, prostaglandin F₂ α , oxytocin, and estradiol. It is important to clearly establish what the objective of treatment is. Although there are some reports of benefits of PGF or oxytocin, especially within 1 hour after calving, the data are limited and contradictory. There are persistent anecdotes in circulation, and some controversy in the scientific literature, but these arguments are not based on data from field studies of naturally occurring cases. On balance, there is no strong evidence that any of the suggested treatments hasten the passage of the RP, reduce the risk of displaced abomasum (DA), or improve subsequent reproductive performance.
- Several studies indicate that approximately half of cows (up to 80% in a few studies) with untreated RP will have a temperature > 39.5°C on at least 1 day. It is not clear if all of these require systemic antibiotic treatment. At a minimum, it appears that approximately half of cows with RP do not require antibiotic treatment because they never become febrile. Therefore, automatic treatment of all RP cows with antibiotics is questionable.
- Several studies indicate that daily infusions of 5-oxotetracycline IU for as long as the RP is in place (typically 4–5 d) reduced the incidence of fever from approximately 50% of cows with RP to approximately 30% of affected cows. However, in these studies, there was no reduction in associated diseases (DA, ketosis), and no improvement in reproductive performance associated with this aggressive use of IU antibiotics. This dose of oxytetracycline IU resulted in widely variable concentrations and duration of detectable residues in milk, with a mean of 52 hours of residue > 200 ppb. Therefore, the benefit (if any) of such an approach is unclear.
- Historically, manual removal of RP by manipulation and traction was practiced. There is no evidence that this practice produces beneficial results, and there is some evidence that it exacerbates damage to the endometrium, increases the risk of toxemia, and may delay return to cyclicity. Removal of an already detached placenta at 3–7 d postpartum using no more than a few pounds of pressure is permissible; otherwise, manual removal is contraindicated.
- Estradiol cypionate (ECP) (4 mg IM, once at 1 d postpartum) in cows with RP did not reduce the incidence of fever with fetid discharge within 7 or 30 DIM, but significantly prolonged time to pregnancy relative to no treatment in cows with RP. Similarly, in two other studies, ECP (4 mg IM once 24–36 h postpartum) to all cows, or high-risk cows (with clinical hypocalcemia, RP, twins, dystocia, or stillborn calf) failed to reduce the incidence of fetid discharge (with or without fever).
- Ceftiofur HCl (2.2 mg/kg IM q 24 for 5 d) administered starting at 1 DIM to cows with RP without regard to body temperature significantly reduced the incidence of fever with fetid discharge, with no effect on time to pregnancy. In a separate study, administration of ceftiofur to multiparous cows at high risk for metritis (see Pathophysiology and Risk Factors above) in the first 3 DIM when fever was detected reduced the incidence of subsequent fetid discharge. In a third study, ceftiofur (1.1 mg/kg IM q 24 for 5 d) in cows with RP and fever was as effective (67% absence of fever by 10 DIM) as a combination of systemic and IU ampicillin and manual removal of the placenta; there was no difference in reproductive performance between the two treatments. There are no trials published in which cows with RP and fever (with or without fetid discharge) were left untreated, even for 1–2 d. Therefore, it is unclear what the health or economic

benefits are of treating all cows with RP, or even all febrile cows with RP, with systemic antibiotics.

DRUGS OF CHOICE

Subject to the caveats discussed above:

- Ceftiofur (Na- or -HCl)—1–2 mg/kg IM q 24 h for 3 d; up to maximum of 5 d if clinically improving but not resolved (WD = 0 milk, 3 d meat)
- Procaine penicillin G—21,000 IU/kg IM q 24 h for 3 d (WD = 4 d milk; 10 d meat [Canadian label])

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

None known

ALTERNATIVE DRUGS

Little or no evidence to support other treatments

FOLLOW-UP

PATIENT MONITORING

- Cows with RP should be inspected daily until the placenta is passed to detect progression to metritis. Observation of the cow's attitude, appetite (if possible), and daily milk production is likely a useful screening test.
- Measurement of rectal temperature is indicated in cows that are dull, inappetent, producing less milk than expected, or declining in milk production. Some authors advocate daily measurement of temperature in all cows with RP for 10 d postpartum. More large-scale field studies are needed to determine if this approach results in early detection and mitigation of metritis, avoidance of other related diseases (e.g., displaced abomasum), and/or improved reproductive performance, or if this approach leads to medically or economically unnecessary treatment.

PREVENTION/AVOIDANCE

- Because the cause of RP is multifactorial, it is important to recognize that no one preventive measure will be universally effective. The principle for prevention is to optimize peripartum immune function.
- In general, best management and nutritional practices (e.g., transition diet to meet or exceed National Research Council [2001] requirements for > 3 weeks prepartum with average DMI > 12 kg/cow/day, > 60 cm manger space/cow, calving at body condition score of 3.5 out of 5, lack of crowding, heat abatement measures above 27°C, free access to clean water) will plausibly help to prevent RP.
- In particular, the prepartum diet should include 0.3-ppm selenium and 1000–2000 IU/cow/d of vitamin E. Among animals with suboptimum circulating vitamin E in the last week prepartum (serum α -tocopherol: cholesterol ratio < 2.5×10^{-3}), injection of 3000 IU α -tocopherol SC or IM 1 week before expected calving reduced the risk of RP. Unfortunately, there is no simple way to identify individuals or herds that may benefit from this treatment. In two studies, peripartum oral administration of calcium (one to three treatments of 60 g Ca within a 24 hour period around calving) did not reduce the incidence of RP.
- One economic analysis estimated that at a herd incidence of 7%, the economic loss was minimal. Therefore, decisions about preventive interventions should consider the magnitude of the problem as well as the evidence for the expected costs and benefits of proposed measures.

POSSIBLE COMPLICATIONS

Metritis, endometritis, ketosis, DA, mastitis, increased time to pregnancy (days open), and decreased probability of pregnancy/increased risk of culling

EXPECTED COURSE AND PROGNOSIS

- It is difficult to generalize about the expected impact of RP, which will range from none (other than an aesthetically unappealing condition for 1 week), to impaired reproductive performance, or progression to severe metritis and toxemia. Just as the occurrence of RP depends on immune function, so does the course once the condition has occurred.
- The ability of the uterine immune system to respond to RP, inflammation, and increased bacterial challenge determines

whether the cow will go on to suffer metritis or impaired reproductive performance.

- RP is a risk factor for metritis, displaced abomasum, and endometritis. Approximately half of untreated cows with RP will become febrile ($T > 39.5^{\circ}\text{C}$) at least once while the RP is present. Conversely, many of cows with RP do not have any clinical complications, even if untreated.
- Although many studies report negative impacts of RP on reproductive outcomes, the results are variable. The best analyses estimate that affected cows become pregnant approximately 15% more slowly (i.e., hazard ratio for pregnancy = 0.85) than unaffected cows (e.g., reduction in 21-day pregnancy rate from 15% to 12.8%).
- It is not clear whether impaired reproductive performance is directly attributable to RP, or (more likely) if only metritis or clinical and/or subclinical endometritis result.
- There are some reports of short-term reductions in milk yield associated with RP, but meaningful loss of production appears to be confined to those individuals that progress to clinical metritis. Likewise, RP itself appears not to increase culling risk.

RIFT VALLEY FEVER

BASICS

DEFINITION

- Rift Valley fever (RVF) is an acute viral disease that severely affects sheep, cattle, and goats.
- It causes very high rates of abortion and death in neonates and necrotic hepatitis.
- There is a great economic impact from this disease due to the large losses of young animals.

PATHOPHYSIOLOGY

- RVF is caused by a phlebovirus (family Bunyaviridae). The virus replicates mainly in the liver and spleen, however, the brain can also be affected.
- Lesions seen are a direct effect of the lytic nature of the virus.

SYSTEMS AFFECTED

- Reproductive—abortion, neonatal death
- Gastrointestinal—severe hepatic necrosis

GENETICS

N/A

INCIDENCE/PREVALENCE

- Outbreaks of RVF tend to occur in a cyclic pattern every 5 to 20 years and are usually associated with abnormally heavy rainfalls and persistent flooding.
- The incidence of RVF peaks in late summer, disappearing after the first frost.
- In warmer climates, where insect vectors are present continuously, seasonality is usually not seen.
- Abortion rate in ruminants can be very high. It can reach 70–100% in lambs or kids but drops to 20% in those that are over 2 weeks old.
- Mortality in adult sheep and goats ranges from 20% to 30%.
- In cattle, abortions can also reach 100%, but range from 10% to 70% in calves.
- In adults, mortality may be near 10%.

GEOGRAPHIC DISTRIBUTION

RVF is endemic throughout most of Africa. Prior to 1977, the disease occurred only in Africa; however, recent outbreaks and spread of the disease have occurred in Saudi Arabia, Yemen, and Egypt. Rift Valley fever has not occurred in the United States.

SIGNALMENT

Species

- RVF has been found to infect many species of animals, however, the most commonly affected are sheep, goats, and cattle. They are also the primary amplifier of the virus.
- Dogs are also highly susceptible, while horses and pigs are resistant to the virus.

Breed Predilections

N/A

Mean Age and Range

- All ages can be affected, but the greatest mortality is seen in fetal or newborn animals.
- Susceptibility decreases with age.

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

- The incubation period for RVF is 12–36 hours.
- Neonates usually die within 2 days.
- Older animals may die acutely or develop an inapparent infection. Viremia is typically 1–3 days but can be as long as 10 days.

HISTORICAL FINDINGS

- RVF should be considered when high abortion rates or high mortality rates occur in young ruminants, following abnormally heavy rains and high numbers of mosquitoes.
- Additionally, there is rapid spread of the disease and flulike illness in humans.

PHYSICAL EXAMINATION FINDINGS

- Abortion in adult sheep and goats is the most common sign of RVF.
- It can occur at any stage of gestation.
- The fetus will have an autolyzed appearance with signs of hepatic necrosis. Placental lesions are not typically seen.
- Lambs and kids may have high fever (105.8°F; 41°C), listlessness, anorexia, and abdominal pain. Adult animals typically have inapparent infection.
- Clinical signs most commonly seen include fever, mucopurulent nasal discharge, and possibly vomiting.
- In cattle, icterus and abortions are the most common signs seen. Calves may show fever, depression, and acute death.
- Adult animals usually have inapparent disease, but clinical signs include fever, weakness, anorexia, ptialism, and fetid diarrhea.

CAUSES

- The reservoir for RVF is mosquitoes, particularly *Aedes* species.
- The virus is transovarially transmitted to the eggs, which can lay dormant for many years in the dry soil of grasslands areas.
- Following heavy rainfalls, the pooling water gives the eggs a proper environment to hatch. These newly hatched infected mosquitoes then seek a feeding source (human or animal).
- Once a ruminant is infected, it serves as an amplifying host. Secondary arthropod vectors (e.g., *Culex* and *Anopheles* mosquitoes) can become infected from the ruminant, and rapidly spread the disease.
- Biting flies, such as midges, phlebotomids, stomoxids, and simuliids, are potential mechanical vectors, but this is thought to be a minimal route of transmission.

RISK FACTORS

- Risk factors for RVF include exposure of ruminants to competent arthropod vectors during pregnancy.
- Other routes of viral transmission include direct contact or aerosolization of body fluids or tissues of infected animals, particularly parturient material.

DIAGNOSIS

Diagnosis is based on histopathology and demonstration of viral antigen or antibody.

DIFFERENTIAL DIAGNOSIS

Differentials include diseases with relatively high rates of abortion or neonatal deaths accompanied by hepatic necrosis:

- Wesselsbron
- Vibriosis (*Campylobacter fetus*)
- Ephemeral fever
- Brucellosis
- Ovine enzootic abortion
- Listeriosis
- Toxoplasmosis
- Enterotoxemia of sheep
- Trichomoniasis

- Nairobi sheep disease

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- The virus can be readily isolated from tissues of aborted fetuses and the blood of infected animals.
- Viral antigen tests include immunodiffusion, complement fixation, or immunofluorescence. The virus can also be isolated from inoculation tests (i.e., mice or cell culture).
- Serological tests can be used to detect antibody against RVF virus and are useful for epidemiologic studies but of limited value for diagnosis, due to cross-reaction with other phleboviruses.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Although histopathologic liver lesions are pathognomonic, laboratory confirmation should be done.
- Specimens should include heparinized blood and serum from live animals.
- Tissue samples should include liver, spleen, kidney, lymph nodes, and brain of an aborted fetus.
- Reverse transcriptase PCR (RT-PCR) for diagnosis of Rift Valley fever (RVF) is available.
- Indirect enzyme-linked immunosorbent assay (ELISA) for the detection of antibody against Rift Valley fever virus in domestic and wild ruminant sera is available.

PATHOLOGIC FINDINGS

- Hepatic necrosis is the most common postmortem lesion found in sheep, cattle, and goats. This can be quite extensive in fetal and neonatal animals. The liver is greatly enlarged, yellow, friable, and will have multifocal small, gray-white foci.
- The wall of the gallbladder is commonly hemorrhagic and edematous.
- Petechial hemorrhages may also be very prominent and found on cutaneous or serosal surfaces.
- Aborted fetuses will have an autolyzed appearance.
- The contents of the abomasum and small intestine of newborns will be chocolate brown.
- Histopathologic liver lesions are pathognomonic for RVF. Severe lytic necrosis with dense aggregates of cellular and nuclear debris, fibrin, and inflammatory cells can be found in the liver parenchyma of aborted fetuses or affected neonates.
- Eosinophilic rod-shaped intranuclear inclusion bodies may also be seen in over half the cases.

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Sanitation and vector control should be attempted but do not usually control the spread of the disease.
- Carcasses should be buried or burned.
- Although immunization of sheep, goats, and cattle is the most effective method of controlling the disease, the current vaccine can be abortogenic and teratogenic but is usually less than the effect from the disease. There is no vaccine currently available in the United States for RVF.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Affected neonates typically die within 2 days.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Abortion in adult sheep and goats
- Lambs and kids may have high fever (105.8°F; 41°C), listlessness, anorexia, and abdominal pain. Adult animals typically have inapparent infection.
- In cattle, icterus and abortions are the most common signs seen. Calves may show fever, depression, and acute death.
- Adult animals usually have inapparent disease, but clinical signs include fever, weakness, anorexia, ptialism, and fetid diarrhea.

AGE-RELATED FACTORS

- The greatest mortality rates are seen in fetuses or young neonates of sheep, goats, and cattle.
- Susceptibility decreases with age.

ZOONOTIC POTENTIAL

- Humans are highly susceptible to infection by mosquitoes or by exposure to aerosols when handling infected animal tissues during assisted parturition, necropsy of aborted fetuses, slaughter, or laboratory procedures.
- Humans also develop a high enough viremia to be a source of infection for mosquitoes.

- Following an incubation period of 4–7 days, flulike signs (fever, weakness, myalgia, headache, nausea) and photophobia may develop.
- Recovery generally occurs after 4–7 days. Rarely, the disease may cause hemorrhagic fever, encephalitis, or retinopathies.
- The greatest risk for RVF is for travelers to endemic African countries. Avoidance of exposure to arthropod vectors should be implemented.
- Diagnostic laboratory infections can be common; personnel should use biosafety level 3 procedures.
- Personal protection equipment (i.e., gloves, coveralls, boots, and face masks) should be worn when in contact with infected animals.
- Vaccination is available for those at risk of exposure.
- To date, no person-to-person transmission has been documented.

PREGNANCY

- RVF causes abortion and neonatal death in sheep, goats, and cattle.
- Abortion rate in ruminants can be very high. It can be 70–100% in lambs or kids but drops to 20% in those that are over 2 weeks old.

RUMINANT SPECIES AFFECTED

Sheep, goats, and cattle

BIOSECURITY

- RVF has a limited endemic region. If cases or outbreaks are suspected outside of this region, proper veterinary authorities should be contacted immediately.
- RVF is an OIE List A Exotic disease, which requires mandatory reporting.

PRODUCTION MANAGEMENT

- Management steps for the prevention of RVF include implementation of vector (mosquitoes) control and moving animals to higher altitudes (i.e., less flood plain areas).
- Additionally, vaccination in endemic areas prior to breeding season may be beneficial.

Author: Glenda Dvorak

RINDERPEST

BASICS

OVERVIEW

- Rinderpest is one of the most feared viral diseases of cattle.
- It is estimated that this disease caused the death of over 200 million cattle in Europe in the 18th century and 2.5 million cattle in the last Great African Pandemic in the 1890s. This disease was instrumental in the formation of veterinary schools throughout Europe.
- Rinderpest is a viral disease caused by a morbillivirus that is closely related to peste des petits ruminants (PPR), canine distemper, and measles.
- There is only one serotype but many strains of the virus that vary in virulence.
- Affected animals develop a high fever, depression, anorexia, and diarrhea. Death usually follows.
- Ulceration of the oral mucosa and a necrotizing enteritis are common gross necropsy findings.
- The disease is spread by direct contact with oculonasal fluids and feces. However, the virus can be identified in all tissues.
- Currently, rinderpest is believed to be present only in eastern Africa (Somalia) and Pakistan. The disease is targeted for eradication by 2010.

SIGNALMENT

- In endemic areas, rinderpest is mild and self-limiting; however, when the virus is introduced into naïve animals, the virus seems to change in virulence and a severe disease is presented clinically.
- All cloven-hoofed animals are susceptible to infection with European breeds of cattle (*Bos taurus*), Asian water buffalo (*Bubalus bubalis*), and the yak (*Bos grunniens*) most susceptible. Zebu cattle (*Bos indicus*) are more resistant. Swine are susceptible to the virus.
- Most African wildlife are susceptible to the virus with the Cape buffalo being very sensitive to the virus.

SIGNS

- Rinderpest may present as an acute or subacute disease. Incubation period is between 7 and 14 days.
- Animals develop a high fever, 104°F to 107°F (40 to 42.2°C), and become depressed with anorexia. Milk production is severely curtailed.
- Mucous membranes of the mouth and conjunctiva become congested. The muzzle usually becomes dry, crusty, and ulcerated.
- Animals occasionally become constipated early in the course of the disease, and this is followed by abundant, runny diarrhea that may contain mucus, fibrin, and/or blood.
- Small pinpoint areas of necrosis or shallow erosions are usually first noted on the lips and gums and later on the tongue, dental pad, and plate.
- Vesicles may develop on the tongue.
- As the disease progresses, the animals become dehydrated, weak, and prostrate. Death often follows.

CAUSES AND RISK FACTORS

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bovine viral diarrhea–mucosal disease (BVD-MD): naïve animals have fever and diarrhea, and develop ulcers in oral cavity and esophagus. Necrosis of intestinal gut associated lymphoid tissue (Peyer’s patches) can be seen. BVD can be identified by PCR probes on whole blood and spleen. Persistently infected animals can be identified by immunohistochemistry of skin biopsies and ELISA techniques on sera.
- Malignant catarrhal fever (MCF): common finding in affected animals is severe erosion of the nasal mucosa, oral ulcerations, severe corneal edema, and conjunctivitis.
- Infectious bovine rhinotracheitis (IBR): animals develop severe upper respiratory disease with ulceration of the tracheal and nasal mucosa. Occasional ulceration of the oral mucosa and esophagus is noted.
- Foot-and-mouth disease (FMD): animals develop vesicles and ulcers on the lips, oral mucosa, tongue, teats, interdigital space, and/or coronary band.
- Bluetongue: animals (mostly sheep) can develop oral ulcers in the mouth with edema and ulcers of the muzzle. Laminitis can occur.
- Bovine papillary stomatitis: single or coalescing proliferative lesions on the palate and tongue often characterize bovine papillary stomatitis.
- Contagious ecthyma (orf): animals develop prominent proliferative growths on the lips, oral mucosa (primarily gums and dental pad), and teats (primarily in sheep) that are easily ulcerated and bleed.
- Peste des petits ruminants (PPR): this disease is primarily a disease of sheep and goats and is closely related to rinderpest. Clinically, animals present with ulceration of the oral mucosa, conjunctivitis, diarrhea, and pneumonia.

CBC/BIOCHEMISTRY/URINALYSIS

A severe leukocytopenia is observed, which may last for several weeks.

OTHER LABORATORY TESTS

N/A

DIAGNOSTIC PROCEDURES

- Rinderpest is a reportable disease in most countries. Animals suspected of having this disease must be reported to state and federal veterinary officials to insure that the disease is eradicated from the region.
- Complete ELISA, virus neutralization, complement fixation, and agar gel immunodiffusion techniques are useful serological tests commonly used to detect exposure to the virus.
- Virus isolation is best completed on freshly dead or killed animals. Submission of spleen, lymph nodes, tonsil, and necrotic gum or oral mucosa should be submitted in a sterile sample container.
- Whole blood preserved in EDTA or heparin can be submitted also.
- Ocular and nasal secretions during early stages of the disease contain abundant virus. These secretions can be submitted in virus isolation media.
- Blood and tissues should be sent on cold packs, not with dry ice, to the designated veterinary diagnostic laboratory for evaluation.

PATHOLOGIC FINDINGS

GROSS FINDINGS

- Lesions include small shallow ulcers on the lips, tongue, palate, esophagus, and rumen. Erosions may also be present in the vulva, vagina, and prepuce.
- The abomasum is congested and occasionally hemorrhagic. Lesions commonly observed in the intestines are necrosis of the gut associated lymphoid tissues (Peyer’s patches), ulceration of the colon and rectum, and hemorrhage (zebra-striping) of the rectum and distal colon. The lymph nodes are often swollen and edematous. Petechial and ecchymotic hemorrhage and necrosis of the gallbladder are also occasionally seen in diseased animals.
- The lungs may also be emphysematous and congested with a mild interstitial pneumonia.

HISTOPATHOLOGIC FINDINGS

- Necrosis of the mucosal epithelium of the oral, esophageal, and ruminal mucosa is severe with multinucleated syncytial cells present in the epithelium. Intranuclear and intracytoplasmic inclusions may be present in the syncytial cells.
- Lymph nodes, spleen, and gut associated lymphoid tissue (Peyer’s patches) have severe lymphoid necrosis with occasional syncytial cells present. Intranuclear and intracytoplasmic inclusions may be identified occasionally in syncytial cells and some degenerate and necrotic lymphocytes.
- The small and large intestine have necrosis of the crypts with flattening of the villi.

- Occasional syncytial cells can be noted in the glandular crypts.
- Intracytoplasmic and intranuclear inclusions can occasionally be observed in the tissues.

TREATMENT

- Since this disease is scheduled for eradication by OIE, euthanasia of affected animals is usually recommended to prevent further spread of the disease; however, if one is to treat affected animals, intensive supportive care is needed to keep the animal hydrated from the severe fluid loss due to diarrhea.
- Antipyretics (e.g., aspirin, flunixin meglumine) may be useful for decreasing the animal's fever and assist in making the animal feel better so it will eat and drink.

MEDICATIONS

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

POSSIBLE INTERACTIONS

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- The virus is primarily spread by direct contact with infected animals (oculonasal fluid and feces). Quarantine and prohibiting animal movement in infected areas can stop the spread of the disease to other susceptible herds.
- No carrier state has been observed in infected cattle that have recovered from the disease.
- In an outbreak or in an endemic area, vaccination of susceptible animals is a possible means of stopping the spread of the disease. Both modified live and killed vaccines are available for use in some areas of the world.
- Thorough cleaning and disinfection of an infected facility and allowing the facility to remain idle without animals present (usually 30 days) before repopulating the facility with new naïve animals is critical to prevent reinfection.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Depending on the strain of rinderpest virus, morbidity can be greater than 90% and mortality can be very high (greater than 90%, particularly for European breeds of cattle, yak, and Asian water buffalo).

MISCELLANEOUS

ASSOCIATED CONDITIONS

As the disease progresses, the animals become dehydrated, weak and prostrate. Death often follows.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

All cloven-hoofed animals are susceptible to infection with European breeds of cattle (*Bos taurus*), Asian water buffalo (*Bubalus bubalis*), and the yak (*Bos grunniens*) most susceptible. Zebu cattle (*Bos indicus*) are more resistant. Swine are susceptible to the virus.

BIOSECURITY

- The virus is fairly fragile and is sensitive to heat and light. Decomposition of an infected carcass quickly kills the virus.
- The virus is primarily spread by direct contact with infected animals (oculonasal fluid and feces). Quarantine and prohibiting animal movement in infected areas can stop the spread of the disease to other susceptible herds.
- No carrier state has been observed in infected cattle that have recovered from the disease.
- In an outbreak or in an endemic area, vaccination of susceptible animals is a possible means of stopping the spread of the disease. Both modified live and killed vaccines are available for use in some areas of the world.

RINGWOMB

BASICS

DEFINITION

Nondilation of the cervix that results in prolonged lambing (kidding), weak-born or dead lambs (kids), and cervical trauma or secondary infections in the ewe (doe). Mortality is often high in dam and offspring, even with veterinary intervention.

PATHOPHYSIOLOGY

- Complex interactions between fetal and maternal neural, endocrine, and paracrine systems lead to the efficient delivery of normal lambs or kids.
- Increased levels of fetal plasma cortisol result in an increase in estrogen and a decrease in progesterone in maternal plasma and an increase in maternal uterine prostaglandin production. These changes lead to the induction of normal delivery including efficient and coordinated myometrial contractions, dilation of the cervix, delivery of the fetus, and expulsion of the placenta.
- The exact mechanism by which estrogen and other hormonal factors regulate cervical ripening and dilation is not completely known.
- Failure of the cervix to dilate is referred to as ringwomb. For a complete review of endocrine and paracrine regulation of preterm and birth processes, see Challis et al. (2000) in Suggested Reading below.

SYSTEMS AFFECTED

Reproductive, nondilation of the cervix

GENETICS

A clear genetic linkage has not been determined; however, there is anecdotal evidence that suggests that certain bloodlines within a particular breed may have an increased incidence of ringwomb.

INCIDENCE/PREVALANCE

Incidence is usually higher in maiden dams; however, older animals may also present with ringwomb. The number of cases within a given flock/herd can vary dramatically from year to year. Predisposing factors are not well established.

GEOGRAPHIC DISTRIBUTION

Ringwomb is apparently common in most regions of the world, although complete data on distribution with emphasis on individual species have not been reported.

SIGNALMENT

Species

Ovine, caprine, bovine

Breed Predilections

None confirmed

Mean Age and Range

All ages are affected; first or second parity dams are most commonly affected.

Predominant Sex

Female

SIGNS

GENERAL COMMENTS

- Affected ewes and does may go undetected until the fetuses have died from hypoxia, and the ewe is suffering systemic effects from uterine toxemia.
- Often the first indication of ringwomb is the presentation of fetal membrane through the vagina without concurrent evidence of active labor. The ewe may act restless or appear normal.

- Similar signs are observed in does, although vocalization may be more prominent.

PHYSICAL EXAMINATION FINDINGS

- The cervix is not sufficiently dilated to allow expulsion of the fetus. Often, only a finger may be inserted through the cervical os on vaginal examination.
- Status of the fetus should be determined by stimulating fetal movement if possible. Oftentimes the presence of a malodorous discharge will confirm the demise of the lamb and impending metritis and septicemia in the ewe.

CAUSES

Nondilation of the cervix

RISK FACTORS

- Risk factors are not well understood.
- There is limited evidence of unknown genetic factors that may predispose to ringwomb.
- Infectious causes including *Chlamydophila ovis* have been implicated; however, many flocks have problems with enzootic abortion and report no significant problems with ringwomb.
- Factors that have been considered in the past but are not supported scientifically include trace mineral deficiencies, exogenous estrogen in feedstuffs, or simple malpresentation of the fetus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dystocia, uterine torsion, early dilation syndrome

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Vaginal examination readily confirms nondilation of the cervix.

PATHOLOGIC FINDINGS

Often, postmortem examinations are not performed. If performed, gross examination reveals term or near-term fetuses that are fresh or variably autolyzed. The cervix is usually only slightly dilated to allow expulsion of minimal fetal membranes.

TREATMENT

APPROPRIATE HEALTH CARE

- If fetuses are alive, a cesarean section is the most reliable way to achieve a positive outcome for the dam and offspring.
- Hormonal therapy with estrogen may help dilate the cervix, although the response is variable and often delayed.
- Oxytocin may stimulate uterine contractions but if the cervix is not dilated, contractions will be not be productive and will result in uterine tearing.
- Producers will often attempt to manually dilate the cervix with digital pressure. If care is taken, and the cervix is slowly dilated (30 minutes or more) with minimal tearing, live lambs or kids may deliver. More often, this procedure results in delayed delivery with dead fetuses and trauma to the dam's cervix that results in the need to treat aggressively for secondary bacterial infection of the cervix and uterus.

NURSING CARE

N/A

CLIENT EDUCATION

- All the risk factors for ringwomb are not known.
- If manual dilation is attempted, the ewe may need to be culled if significant trauma has occurred to the uterus or cervix. If the producer has examined the dam prior to veterinary intervention, it is an appropriate time to provide education on the zoonotic risks associated with lambing ewes.

MEDICATIONS

DRUGS OF CHOICE

- Broad-spectrum antibiotics are usually needed as follow-up therapy after manual dilation.
- Estrogen products have been recommended to assist in cervical dilation; however, the effects are minimal and the response is often delayed.
- Oxytocin, 30–50 IU administered IM, will stimulate uterine contractions; however, the cervix is usually not dilated and the uterus may tear or rupture.
- Calcium preparations have been administered as a preventive approach if hypocalcemia is suspected; however, a link between low blood calcium and ringwomb has not been established.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Goats are extremely sensitive to the effects of lidocaine. Care must be utilized when using this drug.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Affected dams will usually recover if trauma to the cervix is minimized. These individuals will usually conceive and deliver offspring in subsequent pregnancies.
- Secondary infection is usually responsive to antibiotics.
- If trauma to the cervix is severe or the dam is toxic and the fetuses are dead at the time of presentation, the prognosis is poor.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

All ages are affected; first or second parity dams are most commonly affected.

ZOONOTIC POTENTIAL

Any assisted delivery in the ewe and doe has the potential to transmit several zoonotic pathogens including *Chlamydophila abortus*, *Campylobacter jejuni*, and *Coxiella burnetti*. Appropriate safety precautions should be observed.

PREGNANCY

Ringwomb is a condition of parturition. If unresolved quickly, the fetal survival is compromised.

RUMINANT SPECIES AFFECTED

Ovine, caprine, occasionally bovine

RODENTICIDE TOXICITY: 1080 AND 1081

BASICS

OVERVIEW

- The chemical agents 1080 (sodium monofluoroacetate) and 1081 (sodium fluoroacetamide) were developed as rodenticides and insecticides.
- They are commonly mixed with bread, carrots, bran, and other baits, and treated with black dye (in the United States)
- The product is used only in restricted commercial applications; only certified, insured exterminators can purchase it. In New Zealand, it has broader use.
- Colorless, odorless, tasteless, water soluble
- Highly toxic, at 0.1–8.0 mg/kg to all animals, LD50 mg/kg is 0.39 in cattle, 0.22 in calves
- Poisoning by ingestion of killed rodents, or direct exposure to compound, via the GI and respiratory tracts, abraded, but not intact skin.

PATHOPHYSIOLOGY

- The compound is metabolized to fluorocitrate; the increased citrate decreases cell respiration by blocking the TCA cycle, leading to lactic acidosis, and CNS effects.
- Effects include the overstimulation of the CNS resulting in death by convulsions. This is a common finding in sheep and goats. Also, the alteration of cardiac function leading to myocardial depression, cardiac arrhythmias, ventricular fibrillation, and circulatory collapse.

Species

- All species are potentially affected.
- Sheep and goats more often show neurological signs.

SIGNALMENT

Characterized by a “lag phase” of 30 minutes to 2 hours after ingestion before nervousness and restlessness ensue. Symptoms are generally acute with a rapid violent course.

SIGNS

- About a 30 minute lag phase after ingestion then restlessness and nervousness
- Marked depression and weakness, animals become prostrate, with rapid weak pulse, ventricular fibrillation. Death is by cardiac failure.
- Animals die within hours after symptoms first appear; few animals recover.
- Moaning and teeth grinding may be found with no signs of physical struggle.
- Terminal convulsive seizures, rapid onset with the limbs in fixed rigidity.

CAUSES AND RISK FACTORS

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Strychnine, chlorinated hydrocarbons, lead poisoning, plant alkaloid toxicity, nicotine, taxine (Japanese yew), circutoxin (water hemlock)

CBC/BIOCHEMISTRY/URINALYSIS

Hyperglycemia may be evident.

OTHER LABORATORY TESTS

- Samples included for chemistry evaluation. Primary samples include baits, stomach contents, and liver
- Kidney samples yield high citrate levels.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

History, clinical signs, necropsy findings; rule out other convulsing conditions.

PATHOLOGIC FINDINGS

GROSS FINDINGS

Generalized cyanosis of the mucous membranes and other tissues, liver and kidneys dark and extremely congested, subepicardial hemorrhages evident, heart failure in diastole, diffuse visceral hemorrhages (especially in cattle)

HISTOPATHOLOGICAL FINDINGS

Cerebral edema, lymphocytic infiltration of the CNS

TREATMENT

No specific antidote

MEDICATIONS

DRUGS OF CHOICE

- Barbiturates are used with caution
- Ca^{++} gluconate may be used to combat convulsions and hypocalcemia.
- Gastric lavage and adsorbents such as activated charcoal 0.5 g/kg may be helpful if early in the toxemia.
- Glyceryl monoacetate (monacetin) may be used as a competitive antagonist of fluoroacetate. The dose of 0.25 ml/lb (0.55ml/kg) IM or IV in 5 parts sterile isotonic saline every 30 minutes for several hours is suggested by some practitioners.
- Oral administration of 8.8 ml/kg each of 50% ethyl alcohol and 5% acetic acid may be substituted for monacetin if the product is unavailable

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

Author: Greg Stonner

RODENTICIDE TOXICITY: ANTICOAGULANTS

BASICS

OVERVIEW

- Anticoagulant rodenticides are structurally related to coumarin, a compound that causes a prothrombin deficiency, leading to bleeding. Many anticoagulant rodenticides include sulfonamides in the bait, and are utilized to inhibit vitamin K synthesis.
- The original compound, warfarin, was developed after observing that cattle that consumed moldy sweet clover had increased incidences of bleeding.
- Common rodenticides used by professional exterminators and laymen include first and second generation products.
- Toxicity occurs when ruminants (and other mammals and birds) are exposed to rodenticide preparations incorporated into grains and pellets that are palatable to livestock, as in feed barns where they are placed as a deterrent to rodent infestation.
- Signs are not seen for 3–5 days after ingestion.
- A massive single exposure or repeated low dosages may cause poisoning. Repeated doses of 200 mg/kg are toxic.

PATHOPHYSIOLOGY

- Mechanism of action—coumarin anticoagulants competitively inhibit vitamin K by interfering with the conversion of inactive to active vitamin K. This in turn decreases the synthesis of active prothrombin and the conversion of prothrombin to thrombin, essential in the clotting cascade.
- Causes the depression of vitamin K–dependent clotting factors IX of the intrinsic pathway, VII of the extrinsic pathway, and II and X of the common pathway
- Decreased platelet adhesion (but not platelet numbers directly) causes defects in blood coagulation, apparent 2–5 days after ingestion. This latent period can vary according to the type of anticoagulant present, species, dose, and activity during which the clotting factors are used up. Brodifacoum can be present in the plasma for up to 24 days.
- There is no direct hepatotoxicity.

SYSTEMS AFFECTED

Hemolymphatic, reproductive

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Worldwide distribution

SIGNALMENT

Most cases are seen in feed-barn situations, where anticoagulant is left as rodent bait.

Species

All ruminants and camelids, as well as other mammals, birds and rodents

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

Anticoagulants

- Warfarin, the most well known, and other first generation products are less used because of resistance of rodents to their effects. These are multiple-use poisons, requiring frequent feedings, which reduces their toxicity.
 - Warfarin (final)
 - Pindone (Pival, Pivalyn)
 - Coumafuryl
 - Coumachlor
 - Isovaleryl indandione
- Second generation anticoagulants are highly toxic after a single feeding and include:
 - Bromadiolone (Maki, Contrac)
 - Brodifacoum (Talon, Havoc, d-Con)
- Intermediate anticoagulants require fewer feedings than the first generation chemicals, thus are more toxic than first generation products.
 - Chlorophacinone
 - Diphacinone (Ramik, Ditrac)

SIGNS

- Signs of hemorrhage manifest clinical signs. The onset may appear to be acute, with animals found dead with no previous signs of illness. It can lead to excessive bleeding with routine procedures such as dehorning or castration, or in the presence of wounds or injection sites.
- Bloody diarrhea is the main sign in sheep. Hematomas develop in areas that get jostled, as in tough feeding.
- Early embryonic loss and abortions can additionally be seen with sweet clover poisoning.
- Other signs include anemia, weakness, pale, icteric mucous membranes, eye hemorrhages, dyspnea, hematemesis, epistaxis, melena, blood-tinged froth around the nose and mouth, irregular weak heartbeat, swollen tender joints. If hemorrhage involves the brain, spinal cord—paresis, ataxia, convulsions, and acute death.

CAUSES AND RISK FACTORS

- Toxicity can be influenced by several factors. A high dietary fat intake or prolonged oral antibiotic therapy can increase susceptibility to anticoagulants. Liver disease compounds the affect of vitamin K inhibition by the subsequent decreased prothrombin production.
- Anticoagulants are protein bound for the most part, but it is the unbound portion that is toxic. Protein-bound drugs essentially increase the toxicity by competing for protein binding sites, freeing anticoagulants. Phenylbutazone, sulfonamides, adrenocorticosteroids, and phenobarbital can cause this.

DIAGNOSIS

Based on history, clinical signs, clinical pathology, and response to treatment of vitamin K 1.

DIFFERENTIAL DIAGNOSIS

- Blackleg, pasturellosis, brackenfern poisoning, and aplastic anemia
- Sweet clover poisoning
- Hepatic toxicants, such as aflatoxicosis (detection in feed, histopathological lesions)
- Causes of thrombocytopenia
- Causes of anemia, bleeding
- Causes of early embryonic death and abortion

CBC/BIOCHEMISTRY/URINALYSIS

- PCV variable, leukocytes and differential normal
- Bleeding time variable, ACT, PT, APTT elevated
- Fibrinogen, fibrin degradation products, platelets normal

OTHER LABORATORY TESTS

- Plasma anticoagulants from live animals

- Anticoagulant levels from necropsy of the liver, GI contents, and unclothed blood

IMAGING

N/A

PATHOLOGIC FINDINGS

- Gross—petechiations, ecchymosis of mucous membranes, free blood in thoracic cavity and/or abdomen, GI hemorrhages
- Histopathological findings—N/A

TREATMENT

- Minimize trauma
- Oxygen therapy
- Whole blood transfusions

MEDICATIONS

DRUGS OF CHOICE

- Vitamin K 1: Controversial use intravenously, has caused anaphylactoid reactions, and IM injections can aggregate bleeding. The dose varies 15–75 mg/kg. Used as a 5% suspension in 5% dextrose. Begins to work in 30 minutes, full effects in several hours.
- IM dose 0.5–2.5 mg/kg
- Oral vitamin K1 is not practical for large ruminants, but dose is 2.5–5.0 mg/kg
- Clotting factor synthesis requires 6–12 hours.
- Duration of treatment depends on the specific compound: warfarin with the shortest half-life at 13.3 hours, brodifacoum 24 days; continue for 3–4 weeks of therapy.
- Whole blood transfusions where practical
- Iron preparations

CONTRAINDICATIONS

- Concurrent use of protein-binding drugs can increase toxicity—phenylbutazone, sulfonamides, adrenocorticosteroids.
- Vitamin K 3 as a feed additive is ineffective.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Monitor CBC, PCV, ACT, PT, APTT

PREVENTION/AVOIDANCE

Avoid contaminated sweet clover, treated grain in feed barns.

POSSIBLE COMPLICATIONS

- Secondary pneumonia
- Death

EXPECTED COURSE AND PROGNOSIS

If sufficient and prolonged treatment can be continued, prognosis is good. The difficulty is early diagnosis and being able to keep sufficient levels of vitamin K 1 systemically for 2–3 weeks, if the more common, longer acting brodifacoums are involved. Concurrent liver disease complicates treatment and worsens prognosis.

RODENTICIDE TOXICITY: ANTU

BASICS

OVERVIEW

- ANTU is alpha-naphthylthiourea.
- Used exclusively as a rodenticide. Comes as a gray powder, insoluble in water
- Prepared in sausage or bread as bait in 1%–3% concentration
- Causes gastric irritation and increased capillary permeability in the lungs when absorbed.
- Its use has been curtailed, replaced by more effective anticoagulant products.
- Ruminants tend to be resistant.

PATHOPHYSIOLOGY

Causes the increased permeability of pulmonary capillaries, leading to pulmonary edema and pleural effusion.

SYSTEMS AFFECTED

Cardiopulmonary

GENETICS

RODENTICIDE TOXICITY: BROMETHALIN

BASICS

OVERVIEW

- Hundreds of rodenticides are available worldwide.
- Many of these rodenticides were introduced because of their anticipated safety in relation to nontarget species; unfortunately, this has not been the case. Veterinarians must attempt to identify the specific rodenticide involved in poisoning cases.
- Packaged as pelleted, grain-based bait, containing 0.01% (100 ppm) of substance impregnated with green, water-soluble dye.
- The most commonly reported toxicosis in the United States are those caused by anticoagulant rodenticides, bromethalin, cholecalciferol, strychnine, and zinc phosphide.
- Neurotoxin that acts by decreasing Na/K ATPase activity, uncoupling oxidative phosphorylation in the CNS. This allows CSF pressure increases, placing pressure on nerve axons, resulting in decreases in nerve impulse conduction, paralysis, and death.
- At > 5 mg/kg BW ingestion, acutely see hyperexcitability, severe muscle tremors, running fits, grand mal seizures, hind limb hyperreflexia, depression, death about 10 hours after ingestion.
- Chronic effects may appear 24–86 hours after ingestion, characterized by tremors, depression, ataxia, vomiting, and lateral recumbency. These may be reversible if exposure to bromethalin is discontinued.
- The minimum toxic dose is 5 mg/kg body weight. Doses in excess of the LD50 (2 mg/kg in rats) will cause death within 8–12 hours and it is preceded by one to three episodes of clonic convulsions with death usually due to respiratory arrest.
- Brand name products—Vengeance, Assault, Trounce.

SYSTEMS AFFECTED

Potentially all, depending on condition

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Potentially worldwide, depending on species and environment

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

Develop a toxic syndrome characterized by ataxia, focal motor seizures, decerebrate posture, decreased conscious proprioception, recumbency, depression, and semicomatose

DIAGNOSIS

- History of ingestion
- Should be considered when see cerebral edema or posterior paralysis
- Chemical analysis of stomach contents, bait, kidney, fat, liver, brain tissue, and necropsy

DIFFERENTIAL DIAGNOSIS

Alcohol intoxication, ethylene glycol, salt poisoning, botulism, rabies

OTHER DIAGNOSTIC PROCEDURES

- Identification of the desmethyl metabolite was demonstrated in the blood and liver of treated animals by comparison of chromatographic retention times to a reference standard, but direct mass spectral identification was unsuccessful in part due to the low dose that could be administered.
- Bromethalin can be detected in kidney, liver, fat, and brain tissues, using gas chromatography with electron capture detection. Photodegradation of extracted bromethalin may limit accurate quantification of tissue residues.
- Identification of the desmethyl metabolite may be demonstrated in the blood and liver of animals by comparison of chromatographic retention times to a reference standard. Direct mass spectral identification is unsuccessful.

PATHOLOGIC FINDINGS

Histopathology

- Diffuse white matter spongiosis with intramyelinic vacuolation. Histopathology of the brain and spinal cord of cats revealed a spongy degeneration of the white matter, which was shown upon ultramicroscopic examination to be intramyelinic edema. No inflammation or cellular destruction of neuronal tissue was noted. LD50 values ranged from 1.8 mg/kg in the cat to approximately 13 mg/kg in rabbits.
- Spongy change (edema characterized by the formation of vacuoles in extracellular spaces and myelin lamellae), hypertrophied fibrous astrocytes, and hypertrophied oligodendrocytes were observed in the white matter of the cerebrum, cerebellum, brain stem, spinal cord, and optic nerve of all bromethalin-dosed cats. Spongy change occasionally extended into contiguous cerebellar Purkinje cell layer and cerebral cortical gray matter. Ultrastructural findings included separation of myelin lamellae at the interperiod lines with the formation of intramyelinic vacuoles (intramyelinic edema), rupture, and coalescence of intramyelinic vacuoles into larger extracellular spaces (spongy change), and pronounced cytosolic edema of astrocytes and oligodendroglial cells.
- LD50 values ranged from 1.8 mg/kg in the cat to approximately 13 mg/kg in rabbits. The only apparent nonsusceptible species was the guinea pig, which could tolerate doses in excess of 1000 mg/kg without effect.

TREATMENT

- Decrease the absorption of toxin and decrease cerebral edema.
- Use mannitol and corticosteroids to decrease cerebral edema.
- Super-activated charcoal repeated because of enterohepatic recycling of bromethalin.
- Treatments may not reverse symptoms.
- Therapeutic success in these poisonings is often more dependent upon symptomatic and supportive care rather than the use of antidotal therapy.

MEDICATIONS

DRUGS OF CHOICE

- Mannitol and corticosteroids to decrease cerebral edema
- Super-activated charcoal repeated because of enterohepatic recycling of bromethalin

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

Author: Greg Stoner

RODENTICIDE TOXICITY: CHOLECALCIFEROLS

BASICS

OVERVIEW

- Vitamin D rodenticide causing hypercalcemia by toxic intestinal absorption of calcium, bone resorption, and increased renal retention of calcium. The ingestion of cholecalciferol-containing rodenticide leads to renal failure, cardiac abnormalities, hypertension, central depression, and GI upset.
- Half-life of up to 30 days, duration of several weeks
- Rodents die within 2 days of ingestion.
- Exposure by ingestion of treated feed contaminated with the rodenticide, also by plants such as day jessamine (*Cestrum diurnum*).
- Included in vitamin D-containing vitamins added to cattle rations and given to decrease the occurrence of milk fever.
- Hypercalcemia occurs 12–24 hours postingestion, with concurrent hyperphosphatemia.
- Types of products include Qunintox, Rampage, OrthoMouse B Gone, Ortho Rat B Gone.

Species

All ruminant species can be affected.

SIGNALMENT

SIGNS

- Anorexia, lethargy, depression, polyuria, polydipsia
- As calcium levels rise, clinical signs become more severe as decreased excitability of GI smooth muscle, resulting in anorexia and diarrhea.
- Hematemesis, bloody diarrhea because of dystrophic calcification of the GI tract
- Severe muscle twitching, seizures, stupor
- Loss of renal concentrating ability, mineralization of the kidneys and progressive renal insufficiency
- ECG changes—ventricular fibrillation, hypertension, anorexia, diarrhea, depression, seizures, weakness

CAUSES AND RISK FACTORS

Feed mixing errors, oversupplementation of vitamin D, consumption of rodenticide

DIAGNOSIS

- Based on history of ingestion, clinical signs, hypercalcemia, > 16 mg/dl in the serum is not uncommon
- Gross lesions are associated with hypercalcemia. Pitted mottled kidneys, diffuse hemorrhage of the GI tract, roughened raised plaques on the great vessels and on the surface of the lung and abdominal viscera.

DIFFERENTIAL DIAGNOSIS

- Anticoagulant rodenticide toxicosis
- Neoplasia
- Ingestion of calcinogenic plants—*Solanum*, *Cestrum*, *Trisetum*
- Overdose vitamin D supplements

CBC/BIOCHEMISTRY/URINALYSIS

- Hypercalcemia > 11 mg/dl adult
- Hyperphosphatemia before hypercalcemia
- Azotemia, hyperproteinemia, proteinuria, glycosuria, urine specific gravity 1.002–1.006

- Increased 25-hydroxy, 1,25-hydroxycholecalciferol concentrations

OTHER LABORATORY TESTS

Cardiac arrhythmias

IMAGING

Calcification of tissues can be seen in ultrasound/radiology.

DIAGNOSTIC PROCEDURES

PATHOLOGIC FINDINGS

GROSS FINDINGS

Mineralization of kidneys, dystrophic calcification of GI tract

HISTOPATHOLOGICAL FINDINGS

Histopathological examinations revealed diffuse metastatic mineralization throughout the body, particularly involving the lung, kidney, atria, and stomach.

TREATMENT

- The treatment object is to decrease calcium levels in serum—0.9% sodium chloride solution and furosemide (5 mg/kg IV).
- Activated charcoal 2–8 g/kg BW
- Corticosteroids at 1–2 mg/kg prednisolone BID continued for 2–4 weeks.
- Na bicarb to alkalinize—shifts active calcium to an inactive, unionized form
- If ingestion within 2–4 hours, activated charcoal
- Low-calcium diet
- Monitor BUN/creatinine
- Treatment continued for 2 weeks or more

MEDICATIONS

DRUGS OF CHOICE

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Renal and cardiac functions

PREVENTION/AVOIDANCE

Avoid feed-mixing errors, oversupplementation of vitamin D, and the consumption of rodenticide.

POSSIBLE COMPLICATIONS

Renal and cardiac failure

EXPECTED COURSE AND PROGNOSIS

Good prognosis if treatment started within 4 hours of ingestion and calcium remains normal 72 hours after stopping treatment

Author: Greg Stoner

RODENTICIDE TOXICITY: ZINC PHOSPHIDES

BASICS

OVERVIEW

- These products are available for rodent control, specifically mice, ground squirrels, rats, and moles. Product is put in bits of bread, in bran mash, soaked wheat, damp rolled oats, sugar at 2.5% concentration.
- Comes as a grayish black powder, insoluble in water, has faint phosphine or acetylene odor
- Causes GI irritation, cardiovascular collapse, and seizing
- Sold under the names of Zinc Phosphide, MousCon, KilRat, Rumetan
- Toxicity persists for about 2 weeks under average exposure.
- Ruminants are particularly susceptible.
- The toxicity of zinc phosphides is due to the release of phosphine gas in the presence of an acid pH in the stomach. Both the phosphine and intact zinc phosphide are absorbed from the GI tract. The gas causes a direct irritation of the GI tract along with cardiovascular collapse. Intact phosphine causes renal and hepatic damage.
- Toxic dose is 20–40 mg/kg BW, and onset is rapid on a full stomach.

SIGNALMENT

All species of ruminants, especially feedlot cattle

Species

Ruminants especially affected

SIGNS

- Rapid toxemia, occurs 15 minutes to 4 hours after ingestion; can be delayed up to 24–48 hours; death from large doses in 3–5 hours
- Anorexia, weakness, recumbency; rapid, deep respiration, which is wheezy and stertorous, to terminal hypoxia of gasping and struggling
- Ruminal tympany
- Convulsions, aimless running and howling, followed by depression, dyspnea, and convulsions
- Phosphine or acetylene odor to breath, stomach contents

CAUSES AND RISK FACTORS

DIAGNOSIS

Made by history of exposure, accompanied by rapid death, characterized by dyspnea, pulmonary edema, and visceral congestion

DIFFERENTIAL DIAGNOSIS

Strychnine, fluoroacetate poisoning

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY

- Chemical detection of phosphine gas in stomach contents. Because the gas dissipates rapidly in air, collected sample of stomach contents should be placed in an airtight container and frozen immediately.
- Elevated zinc levels in blood, liver, and kidney

IMAGING

N/A

DIAGNOSTIC PROCEDURES

PATHOLOGIC FINDINGS

GROSS FINDINGS

- Marked congestion of lungs with interlobar edema
- Pleural effusion, subpleural hemorrhages
- Liver and kidney extremely congested acutely
- Subacute, pale yellow mottling of liver
- Stomach contents characteristic odor of acetylene

HISTOPATHOLOGICAL FINDINGS

- Hepatic cloudy swelling, fatty change
- Congestion of liver and kidney
- Renal tubular degeneration, hyaline change, and necrosis

TREATMENT

- Symptomatic only—antacids, activated charcoal, gastric lavage
- Calcium gluconate, sodium bicarbonate (cattle 2–4 L 5%) PO to neutralize stomach acid
- Sodium thiosulfate, lipotropic agents, dextrose can be used for liver injury.

ROTAVIRUS

BASICS

OVERVIEW

- Most common cause of neonatal ruminant diarrhea
- Causative agent—a rotavirus
- There are several serogroups of rotaviruses: A is more common in calves and B (pararotavirus) is more common in kids and lambs.
- Pathogenicity is related to serotype and load of exposure, level of immunity to the virus, concurrent infection with other neonatal pathogens, and stress.
- Most infections are concurrent with other neonatal pathogens.
- Virus may survive for 9 months in the environment.
- Virus is ubiquitous with seroprevalence in the adult herd of 80%–90%.

PATHOPHYSIOLOGY

- The virus is acquired through the ingestion of feces-contaminated material.
- Absorptive epithelial cells lining the distal portions of the villi are infected.
- Epithelial cells of the proximal small intestine are infected first with the infection moving distally to the middle and distal portions of the small intestine.
- Infected cells contain large numbers of virus particles and are desquamated into the lumen.
- The villi become shortened due to exfoliation of the epithelial cells resulting in the loss of digestive enzymes contained within the glycocalyx and decreased absorptive capacity of the villi.
- The loss of epithelial cells results in a maldigestive- as well as a malabsorptive-type diarrhea. Undigested carbohydrates undergo bacterial fermentation resulting in an increase in osmotic pressure and water being drawn into the intestinal lumen. The crypt cells are not affected and continue to secrete fluid resulting in net secretion exceeding absorptive capacity.
- Diarrhea results due to increased osmotic pressure and decreased absorption. The physical loss of the epithelial cells results in increased susceptibility to other pathogens because of loss of the villous integrity and decreased secretion of lactoferrin and lysozymes.
- Damage predisposes the attachment of ETEC and attaching and effacing *E. coli* to the intestinal villi. The loss of electrolytes, bicarbonate, and water leads to dehydration and metabolic acidosis.

SYSTEMS AFFECTED

Gastrointestinal

GENETICS

N/A

INCIDENCE/PREVALENCE

- Prevalence of rotavirus infections ranges from 50% to 100% with a large variation in mortality.
- Depending on immunity, calves may appear normal except for a mild diarrhea. Farmers often report that this “normal” diarrhea is due to the cow producing too much milk.

SIGNALMENT

SPECIES

Bovine, caprine, and ovine

Breed Predilections

N/A

Mean Age and Range

- Most infections occur within the first week of life.
- Range—1 day to 3 weeks

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

- Clinical signs will vary from mild to severe diarrhea. In the case of uncomplicated disease, diarrhea may exist for 1 to 2 days.
- In cases of secondary bacterial infection, diarrhea may last from 3 to 5 days.

HISTORICAL FINDINGS

- Sudden onset of diarrhea that spreads rapidly through the neonatal population
- A few cases may have been noticed initially but the frequency of cases increases as the calving season progresses.
- Increased number of cases is observed following periods of stress such as a snowstorm or cold, wet weather.
- Individuals may develop diarrhea at the same day of age.

PHYSICAL EXAMINATION

- Mild to severe watery, yellow diarrhea; color, consistency, and composition will vary with coexisting infections.
- Dehydration and depression with degrees of inappetence or reluctance to nurse
- Some animals may be weak to the point of recumbency.

CAUSES

- Rotavirus serogroup A most common in calves
- Rotavirus serogroup B, pararotavirus in small ruminants

RISK FACTORS

- Inadequate colostral transfer of immunoglobulins resulting in agammaglobulinemia or hypogammaglobulinemia
- Lack of local colostral immunity in the case of neonates fed milk replacers
- Lack of specific antibodies against the infective serogroup or type of rotavirus in colostrum
- Birthing areas contaminated with fecal material containing rotavirus
- Neonatal housing in which buildup of pathogen load occurs
- Neonates housed or maintained in a cold, wet environment.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *E. coli*, coronavirus, cryptosporidia, *Salmonella* spp., *Clostridium perfringens* type C are disease agents that cause diarrhea during the first 3 weeks of life.
- Nutritional causes of diarrhea may be differentiated from rotaviral diarrhea if history contains a dietary change or identification of nutritional deficiencies or excesses.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC: hemoconcentration, increased plasma proteins
- Serum chemistry: metabolic acidosis with low plasma bicarbonate; glucose and electrolyte values will be low depending on severity of diarrhea.

OTHER LABORATORY TESTS

- Feces should be collected as soon as diarrhea is noted because exfoliation of virus-laden enterocytes is short-lived and occurs early in the disease process.
- Feces can be submitted for electron microscopy and identification of virus. A few drops of formalin can be added to 10 cc of feces.
- Feces can be submitted for ELISA and latex agglutination tests for detection of viral antigens.
- Fresh sections of the small intestine, preferably midileum, tied at the cut ends to contain intestinal contents can be

submitted on cold packs for fluorescent antibody testing. An in-house ELISA can be used to detect viral antigens of serogroup A in feces (Rotazyme II kit, Abbott Laboratories, Abbott Park, Ill).

PATHOLOGIC FINDINGS

- No gross lesions except for increased fluid contents throughout the intestinal tract.
- Histopathology: intestinal villi are shortened.

TREATMENT

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

- Fluid therapy is needed to correct dehydration, circulatory impairment, and electrolyte and metabolic imbalances.
- Fluid deficit should be calculated as well as maintenance requirement, 80–100 ml/kg, to determine volume of fluids needed during a 24-hour period.
- Fluid may be administered orally or intravenously. Commercial oral electrolyte solutions containing glucose and an alkalizing agent are recommended if the neonate is still nursing. Although oral electrolytes are less likely to be absorbed due to enterocyte pathology, not all enterocytes are affected so some absorption may occur.
- Neonates without a suckle response need IV fluids. IV administration of lactated Ringer's solution is adequate.
- With severe acidosis, isotonic sodium bicarbonate solution (1.3%, 13 of sodium bicarbonate to 100 of distilled water) may be utilized.
- Dextrose solutions (2.5%–5%) are indicated in cases of hypoglycemia. With hypoglycemia and an unknown electrolyte and acid-base status, a 2.5% dextrose and 0.45% saline solution has been recommended.

ACTIVITY

N/A

DIET

- Neonates with a suckle response should be left with the dam and allowed to nurse.
- Animals being reared artificially should remain on their diet or switched to whole milk or colostrum. If the diarrhea becomes worse or the calf becomes depressed, removal from the dam or milk is warranted.
- In case of hand-fed neonates that are depressed and not interested in suckling or neonates not nursing the dam, neonates should receive a high-energy electrolyte solution at a rate of 10% of body weight divided into a minimum of four feedings. Once neonates are suckling, feed milk at 5% of body weight in four feedings a day. Increase amount per feeding gradually so calf is back on full feed within 2 to 3 days.
- Oral electrolytes containing an alkalizing agent, other than acetate, should not be fed when calves are receiving milk as milk digestion may be disrupted.

CLIENT EDUCATION

- Neonates should be kept dry and in a draft-free environment.
- Animals should be moved and fed in such a way as to reduce the buildup of mud and fecal material in the neonate's environment.
- Diarrheic animals should be isolated from healthy neonates as they are sources for large numbers of pathogens.

MEDICATIONS

DRUGS OF CHOICE

- Broad-spectrum antibiotics may be considered because of the potential for mixed infections as well as the loss of mucosal integrity.
- In the case of a true viral infection, antibiotics are not warranted.
- Oral amoxicillin trihydrate 10 mg/kg PO q 12 h for nonruminating calves, 20-day slaughter withdrawal (extralabel in small

ruminants). Amoxicillin trihydrate-clavulanate potassium 12.5 mg combined drug/kg PO q 12 h for 3 days (extralabel usage).

- Parenteral ceftiofur 2.2 mg/kg IM/SC q 24 h for 3 days (extralabel usage).
- Drug withdrawal times must be determined and maintained in the treated animal.
- Plasma transfusion: Although not specific for rotaviral infections, in cases of failure of passive transfer and depending on value of the animal, plasma transfusion may be warranted.

CONTRAINDICATIONS

- Do not use kaolin and pectin as this may increase electrolyte loss.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Monitor attitude, suckling response and appetite, fecal color and consistency, and hydration status every 6–12 hours.
- Monitor age cohorts for signs of diarrhea.

POSSIBLE COMPLICATIONS

Hypovolemic shock

PREVENTION/AVOIDANCE

- Reduce viral exposure by calving in clean maternity areas and moving to a clean area after birth.
- Those handling sick neonates should practice biosecurity measures to reduce exposure to healthy neonates; wash hands and disinfect boots, maintain clothes free of fecal material.
- Vaccination of dams prepartum according to manufacturers' recommendations with a rotaviral vaccine may increase colostral antibody. Effectiveness will be dependent on field virus serogroup and type and that contained in the vaccine.
- Oral vaccination of neonate with a modified live oral vaccine will produce IgA and IgM. This vaccine is cumbersome for management as it is to be given prior to colostrum consumption and colostrum must be withheld after vaccination. This may increase the opportunity for bacterial infections and failure of passive transfer.
- Eliminate areas of fecal buildup.
- Keep environment dry and draft free.

EXPECTED COURSE AND PROGNOSIS

- In uncomplicated infections, diarrhea is present for 1 to 2 days.
- Prognosis is good, as this infection tends to be self-limiting and generally requires minor supportive care.
- Duration of diarrhea may be 3 to 5 days with secondary bacterial infections.
- Prognosis is dependent on the degree of pathology produced by the secondary bacteria.
- Prognosis is good to fair with supportive care.

MISCELLANEOUS

AGE-RELATED FACTORS

- Most cases less than a week of age
- Range: 1 day to 3 weeks

ZOONOTIC POTENTIAL

- Isolates from neonatal ruminants have not been infective to humans.
- Some human isolates have been found to be infective for calves.

RUMINANT SPECIES AFFECTED

Bovine, caprine, ovine

SYNONYMS

RUMEN DYSFUNCTION: ALKALOSIS

BASICS

OVERVIEW

Form of gastrointestinal indigestion resulting from rumen inactivity or toxic ingestion

SIGNALMENT

- Any age ruminating animal
- Generally adults

SIGNS

- Forestomach dysfunction
- Bloat
- Decreased appetite
- Rumen hypomotility
- Signs of abdominal pain
- Vomiting
- Signs of urea toxicosis
- CNS excitation
- Diarrhea
- General rumen dysfunction: Rumen fluid pH 7.5–8.5; strong odor of ammonia
- Incoordination
- Muscle tremors
- Rapid deterioration and death
- Tachypnea
- Weakness

CAUSES AND RISK FACTORS

- Mild alkalosis (Rumen pH 7.0–7.5)
 - Prolonged anorexia
 - Microfloral inactivity
 - Poorly digestible roughage
 - Some cases of simple indigestion
 - Pathogenesis: animal continues to produce and swallow alkaline saliva, while low rate of rumen fermentation produces insufficient acid to neutralize saliva.
 - Absorption of VFAs, especially acetate, across rumen wall is associated with bicarbonate generation in the rumen fluid. Acetate is the primary VFA generated from roughage.
 - Generation and absorption of VFAs continues, although at a low rate, further contributing to the alkaline state of the rumen.
- Severe alkalosis (rumen pH > 7.5)
 - Overfeeding/accidental overingestion of NPN sources: Urea, biuret, ammonium phosphate, ammonium-salt-containing fertilizers

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other forms of indigestion:

- Lactic acidosis
- Simple indigestion
- Vagal indigestion
- Other systemic or primary disease-causing anorexia

CBC/BIOCHEMISTRY/URINALYSIS

- Consistent with dehydration: Increases in hematocrit, BUN, creatinine, total protein
- Stress leukocytosis
- Hypokalemia
- Hypocalcemia
- Alkalemia

OTHER LABORATORY TESTS

Rumen fluid analysis:

- Alkaline pH
- Poor microbial activity under light microscopy

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Ruminocentesis/orogastric tubing for rumen fluid analysis (see Other Laboratory Tests above)

GROSS FINDINGS

- If fresh, rumen fluid pH of 7.5–8.5
- Rumen contents may have distinct odor of ammonia if NPN overfeeding is the cause

HISTOPATHOLOGICAL FINDINGS

TREATMENT

- Identify and manage primary disease.
- Correct acid-base and electrolyte aberrations with appropriate fluid therapy: Potassium and calcium will likely be low.
- Establish normal rumen volume.
 - Increase volume with transfaunation of 8–16 L and balanced oral electrolytes.
 - Decrease volume by removing abnormal rumen contents by siphon or rumenotomy.
 - Resolve rumen impaction.
- May provide acetic acid 4–10 L PO

MEDICATIONS

DRUGS

Supplement with parenteral or oral vitamins and minerals—particularly B vitamins

CONTRAINDICATIONS

Do not administer magnesium hydroxide if rumen alkalosis is present.

FOLLOW-UP

PATIENT MONITORING

- Monitor patient for return to appetite and normal rumen motility.
- May require repeat transfaunations

PREVENTION/AVOIDANCE

Good feed management:

- Provision of quality digestible feedstuffs
- Proper dosing of NPN sources
- Securing fertilizers

POSSIBLE COMPLICATIONS

Rumen putrefaction:

- High rumen pH and repeated inoculation with abnormal bacteria such as coliforms and *Proteus* spp. leads to putrefactive decomposition of feeds.
- Sources of putrefactive bacteria: spoiled or feces-contaminated feed

EXPECTED COURSE AND PROGNOSIS

- If mild case is caused by poor quality roughage, it may be easily corrected with transfaunation and gradual provision of good quality feeds.
- If severe alkalosis is caused by intoxication, rumenotomy or other rumen evacuation method may be required, along with rumen fluid replacement and supportive care: poor prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Rumen putrefaction

RUPTURED PREPUBIC TENDON

BASICS

OVERVIEW

- A ruptured prepubic tendon (RPT), which is a life threatening complication of pregnancy, affects the bovine and ovine species.
- It involves tearing of the elastic tendons that attach the abdominal muscles to the pelvic bone.
- The prepubic tendon and its associated musculature help hold the pelvis in position.
- Once it ruptures it reduces the amount of support available for the gravid uterus, resulting in signs affecting the musculoskeletal, reproductive, and gastrointestinal systems.

SIGNALMENT

- A rare condition of ruminants
- Most reported cases involve older animals that are either late in gestation or have a prolonged gestation.

SIGNS

- An extremely sagging pendulous abdomen.
- A severely painful edema of the lower abdominal cavity extending from the udder to the xiphoid cartilage.
- The pelvic bone, tail head, and ischial tuberosities appear abnormally tilted due to the loss of their cranial tension.
- Generalized depression and discomfort with a reluctance to move.
- Pain associated signs like a stretched stance, tachycardia, tachypnea, and intermittent colic.
- With a sudden and complete rupture, shock, collapse, and death may result.

CAUSES AND RISK FACTORS

- A prolonged gestation
- An extremely gravid uterus from a pathological pregnancy like twins or fetal membrane dropsy.
- Trauma to the prepubic area
- Newborn survival may be questionable due to a reduction in blood supply from stretching or twisting of the umbilical cord.
- A possibility for bowel entrapment

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Severe ventral edema
- Rupture of abdominal musculature leading to a ventral hernia
- Intramuscular or subcutaneous hematoma

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

- Abdominal ultrasound will reveal extensive fluid.
- The location and size of a ventral hernia may be established with abdominal ultrasound.

DIAGNOSTIC PROCEDURES

- Rectal palpation is typically unrewarding.
- Palpation of the ventral abdominal wall will reveal edema and a pain response.

TREATMENT

- Immediate veterinary attention required.
- Deliver the fetus by cesarean section or induce parturition if near term.
- Fetal maturity needs to be considered for parturition induction.
- Adequate mammary gland development, good-quality colostrum, and a relaxed cervix indicate fetal maturity.
- Induced parturition requires close observation since the animal will lack the ability to produce adequate abdominal pressure for fetal expulsion.
- If fetus is not near term and the rupture is gradual, alternative therapy will be required.
- Restrict activity to a small pen or box stall.
- An abdominal sling consisting of a strong bandage may provide some support for the gravid uterus.
- The abdominal sling needs to be well padded over the backline to prevent pressure necrosis.
- Laxatives and a high-concentrate diet may decrease the amount of bowel contents and the exertion associated with defecation.
- If supportive therapy fails, abortion induction may be needed.
- Surgical repair of a RPT is impossible.
- Euthanasia of the animal may be necessary if there are associated complications like bowel entrapment.

MEDICATIONS

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

- Closely monitor for further development of discomfort.
- Watch for signs of bowel entrapment.
- Newborn may have difficulty nursing due to the extensive abdominal edema.

PREVENTION/AVOIDANCE

- Do not rebreed due to the likelihood that the condition will reoccur during the next pregnancy.
- Promote embryo transfer if further offspring are wanted from the animal.

POSSIBLE COMPLICATIONS

Bowel entrapment.

EXPECTED COURSE AND PROGNOSIS

Regardless of treatment method, the fetus and mother may be lost depending on the extent of the condition.

MISCELLANEOUS

ASSOCIATED CONDITIONS

A ventral hernia may be an associated condition of a RPT.

AGE-RELATED FACTORS

Older, multiparous females are predisposed for a RPT.

ZOONOTIC POTENTIAL

N/A

RYEGRASS STAGGERS—LOLITREM B

BASICS

OVERVIEW

- Ryegrass staggers is caused primarily by an endophyte fungus *Acremonium lolii*, which lives in the lower leaves and stems of infected ryegrass, *Lolium perenne*. If the ryegrass is infected with the fungus, it produces lolitrem B, which causes transient tremors in cattle and sheep after ingestion.
- Lolitrem B is an indole diterpine alkaloid that interferes with neuronal transmission in the cerebral cortex of affected animals.
- It is likely that ryegrass staggers is due to many other toxins and toxigenic organisms, often referred to as corynetoxins.
- *Penicillium janthinellum* Biourge, also a fungus, is found on ryegrass pasture and produces janithitrems, a tremorgenic toxin that, when irradiated with long wave ultraviolet light, fluoresces a blue color.
- There is also a bacterial agent, *Clavibacter toxicus*, which produces annual ryegrass toxicity (ARGT) in Australia.
- Dallisgrass, *Paspalum dilatatum*, may be present in the ryegrass pasture, and may be infested with an ergotlike fungus, *Claviceps paspali*.
- Signs of ryegrass staggers can take up to 7 days to manifest and, although there is a high morbidity (50%–90%), the mortality is quite low (0%–5%).
- Effects are usually transient and disappear within 2 weeks of removal of affected forage. There is a nearly complete recovery.

SYSTEMS AFFECTED

Neurologic, production management

GENETICS

Individual susceptibility varies and is heritable.

INCIDENCE/PREVALENCE

Mortality from annual ryegrass toxicity is commonly 40%–50%.

GEOGRAPHIC DISTRIBUTION

Worldwide, where ryegrass is grown.

SIGNALMENT

Animals that are most commonly affected graze on ryegrass pastures in the late summer to fall months.

SIGNS

Animals appear normal at rest, with an occasional fine tremor, but with stimulation, they exhibit a stiff, spastic gait, hypermetria, head nodding, and ataxia. They often fall onto their chest and exhibit opisthotonus and titanic seizures. The animals then recover, but can repeat these signs with stimulation again. The signs are more severe with heat stress. Most deaths are accidental due to drowning when they fall into bodies of water or due to the inability to eat or drink.

CAUSES AND RISK FACTORS

- The risk factor seems to be heritable.
- There is also an increased risk with ryegrass pasture grazing in the late summer to fall months.

DIAGNOSIS

Diagnosis is by clinical signs and microscopic identification of the tremorgenic substrate endophyte in the ryegrass sheaths.

DIFFERENTIAL DIAGNOSIS

- Perennial ryegrass
- Phalaris
- Ergots of paspalum and other grasses
- Polioencephalomalacia
- Enterotoxemia

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Chromatography for lolitrem
- Bioassay on vomitus or urine for lolitrem
- Check for fluorescence of janthitrem.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Microscopic identification of the endophyte hyphae within the ryegrass sheaths.
- Bacterium in seed heads is detected and quantified by ELISA.

PATHOLOGIC FINDINGS

GROSS FINDINGS

N/A

HISTOPATHOLOGICAL FINDINGS

- None recognized in acute cases.
- Cerebellar Purkinje cell degeneration and necrosis in long-standing or severe cases.

TREATMENT

- Removing animals from the affected feed and letting them rest will allow for recovery in 3–7 days.
- It is usually impractical to treat because handling exacerbates the signs.
- In severe cases, you could administer anesthesia to help alleviate the seizures and administer activated charcoal and saline cathartics orally.

MEDICATIONS

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Keep the animal quiet and restful while providing fluids to prevent dehydration.

PREVENTION/AVOIDANCE

- Prevention is primarily by grazing management. Don't overgraze pastures, especially in the dangerous season, as the toxic endophyte is on the lower leaf sheaths.
- Encourage the growth of other grasses.
- Use ryegrass seed that is endophyte free or has been stored for 18 to 24 months.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Most animals recover nearly completely within 2 weeks of removal of the affected feed.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

The alkaloids do not accumulate in fat or muscle so residues are not considered a problem.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected.

BIOSECURITY

- Isolation and quarantine of new stock entering the herd/flock.
- Treat and or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT

Burning annual ryegrass pastures destroys most of the galls colonized by bacteria. This will minimize the risk of subsequent toxicity.

SYNONYMS

Rye grass staggers

SALMONELLOSIS

BASICS

DEFINITION

Salmonellosis refers to the clinical symptoms that result from a bacterial infection with a serotype of *Salmonella*.

OVERVIEW

- *Salmonella* infections are the second most economically important bacterial disease affecting the gastrointestinal system in ruminants.
- The severity of the disease is dependent on the serovar involved in the infection and the immune status of the animal.
- Infections in young animals are most often a result of contaminated environments.
- Outbreaks in adults are associated with stress and exposure to a virulent serovar.

Causative Agent

- One of the 2002 serovars of *Salmonella* spp.
- *Salmonella typhimurium* is the most common serovar isolated from ruminants, but all serovars are potentially capable of causing disease.
- *Salmonella dublin* is host adapted to cattle and *S. Arizona* and *abortus ovis* (uncommon in North America) to sheep.

PATHOPHYSIOLOGY

- *Salmonella* are generally acquired through the fecal oral route.
- Carrier cows may secrete organisms directly into milk, especially *S. dublin*.
- Young calves are susceptible to infection because the organism can easily pass through the rumen and the abomasum. There are no volatile fatty acids in the rumen to kill the bacteria nor is the abomasal pH low enough to kill the organism.
- The organism attaches, via adhesins, to mucosal cells of the ileum, cecum, and colon. The organism then invades epithelial cells, spreading through the mucosa to lymphoid tissue and into the blood stream.
- Various virulence and host factors determine the extent of damage and invasiveness of the organism.
- The organism secretes exotoxins that stimulate fluid secretions and damage host cells. In addition, lipopolysaccharide (LPS) is released during replication and death. These LPSs stimulate the inflammatory cascade leading to tissue damage, cardiovascular collapse, and signs of toxemia.
- Diarrhea results from increased cellular secretions, malabsorption, and maldigestion due to mucosal damage and the inflammatory response.

SYSTEMS AFFECTED

Gastrointestinal, hepatic, musculoskeletal, renal, nervous, respiratory, and cardiovascular

GENETICS

N/A

INCIDENCE/PREVALENCE

- As farm size and concentration of animals have increased, so has the incidence of disease.
- Once an outbreak has occurred on a farm, the environmental prevalence of the organisms may be high, but the incidence of clinical disease is actually low.
- The farm prevalence of *Salmonella* was determined to be 11.2% for cow-calf operations and 30% for dairy operations based on the National Animal Health Monitoring System.

SIGNALMENT

Species

Bovine, caprine, and ovine

Breed Predilections

N/A

Mean Age and Range

- Most infections occur from 14 days to 2 months of age.
- All animals, regardless of age, are at risk of developing salmonellosis.

PREDOMINANT SEX

N/A

SIGNS

GENERAL COMMENTS

- The disease may have three different presentations, including peracute, acute, and chronic.
- Acute infections may result in a chronic state.
- Depending on the virulence of the specific serotype and immune status of the host, the organism may be contained within the intestinal tract or invade the circulatory system resulting in multiple organ pathology.
- Clinical signs are often associated with the release of endotoxins and the development of endotoxemia.
- Animals may be convalescent carriers up to 6 months.

HISTORICAL FINDINGS

- Salmonellosis in animals older than 3 months of age is often associated with the introduction of a carrier animal into the herd as well as recent exposure to new water or feed sources.
- Periods of stress such as grouping of animals, late pregnancy, parturition, transport, feed or water deprivation, surgery, or antibiotic usage are often associated with cases or outbreaks.

PHYSICAL EXAMINATION FINDINGS

Peracute

- May observe anorexia, depression, right-sided abdominal distension, and dehydration prior to sudden death
- Signs of overwhelming septicemia, meningitis, opisthotonus, and convulsions may be observed.
- Signs of diarrhea and colic are not common consistent findings.

Acute

- Most frequently encountered state
- Animals exhibit enteritis, fever, anorexia, depression, and dehydration.
- Feces initially are watery in nature becoming voluminous with a foul odor and may contain shreds of mucosa, casts, and frank blood.
- Animals are severely dehydrated, have sunken eyes, and may be too weak to stand.
- Body temperature initially is elevated but decreases and may be subnormal in the terminal stages of the disease.
- Calves infected with *S. dublin* are unthrifty in appearance, weak, and anorectic, and die acutely.
- Many of these calves will develop meningoencephalitis, polyarthritis, osteomyelitis, and pneumonia.
- Adult animals exhibit fever, anorexia, diarrhea, and dehydration, and pregnant animals often abort.
- Heat stress exacerbates clinical signs.

Chronic Infections

- Occurs in older animals 6–8 weeks of age.
- These animals fail to thrive, stools may be puddinglike to diarrheic.
- The animal's body temperature may be normal to slightly elevated; animals have poor hair coats and are undersized.

CAUSES

- The most frequently isolated serotypes from cattle include *Salmonella enterica* Typhimurium, Montevideo, Dublin, Newport, and Uganda.
- *Salmonella enterica* Typhimurium, Dublin, and Arizona are frequently isolated serotypes of sheep and goats.

RISK FACTORS

- Inadequate colostral transfer of immunoglobulins resulting in agammaglobulinemia or hypogammaglobulinemia.
- Birthing areas contaminated with fecal material containing *Salmonella* spp.
- Crowding and poor sanitation increases pathogen concentration and decreases host immunity.
- Use of common feeding/manure moving implements and improper cleaning between uses.

- Late gestation, parturition, and induction of lactation are physiological stressors.
- Factors that reduce immunity or cause alterations in microbial gut flora—transportation, concurrent disease, anesthesia, surgery, feed changes, antimicrobial therapy, and withholding food and water.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diarrhea may result from a variety of infectious agents as well as nutritional causes.
- *Clostridium perfringens* type C and *E. coli* occur during the first week of life.
- *Cryptosporidia*, rotavirus, and coronavirus are disease agents that cause diarrhea during the first 3 weeks of life.
- Salmonellosis develops after 2 weeks of age and is usually associated with a fever; the other agents generally are not associated with a fever.
- Differential diagnosis in animals older than 1 month of age are dietary changes, indigestion, lactic acidosis, toxicosis, BVD, and winter dysentery.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC—Hemoconcentration: a slight anemia may exist but is masked by dehydration. A degenerative left shift with neutropenia and band neutrophilia is commonly observed. Plasma proteins are increased initially due to dehydration; however, plasma protein levels decrease due to decreased albumin levels as a result of malnutrition and protein losing enteropathy.
- Serum chemistry—Metabolic acidosis with low plasma bicarbonate. Cattle with nonfatal diarrhea do not develop significant acidosis. Electrolyte values will be low depending on severity of diarrhea. Levels may appear normal but are deficient on a whole body basis. BUN and creatinine levels are increased due to prerenal azotemia and acute nephrosis due to septicemia and endotoxemia.
- Urinalysis—Depending on state of dehydration, urine will be concentrated resulting in an increased specific gravity.

OTHER LABORATORY TESTS

- Isolation of the organism from feces in live animals and bone marrow and lymph nodes in dead animals along with clinical signs consistent with salmonellosis is confirmatory.
- Samples should be collected and placed in Cary Blair Transport Media for shipment to the lab.
- Fecal PCR can be performed.

PATHOLOGIC FINDINGS

Peracute Infections

- Result in nonspecific gross lesions
- Petechial hemorrhages on the serosal surfaces of the intestine and in epicardium
- The lungs are congested.
- Intestines are distended with fluid and mucosal hemorrhage and necrosis is variable.

Acute Infections

May result in the following gross changes: the abdominal cavity contains increased peritoneal fluid and may contain fibrin tags; the intestines are congested and distended with fluid containing a mixture of mucus and fluid feces along with frank blood, blood clots, pieces of sloughed mucosa, fibrin, and mucosal casts; the spleen is enlarged and the liver swollen; lymph nodes are edematous and hemorrhagic; lungs may be congested with evidence of pneumonia.

Chronic Infections

- Result in thickened intestines with evidence of catarrhal enteritis in the distal small intestine, cecum, and colon
- The mesenteric lymph nodes are hyperplastic and the gallbladder may be thickened containing fibrin.
- Chronic infections associated with *Salmonella enterica* Dublin are exhibited by arthritis, osteomyelitis, and meningitis along with pneumonia.

TREATMENT

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

- Fluid therapy is needed to correct dehydration, circulatory impairment, and electrolyte and metabolic imbalances. Fluid deficit should be calculated as well as maintenance requirement, 80–100 ml/kg, to determine volume of fluids needed during a 24-hour period.
- Fluid may be administered orally or intravenously. Commercial oral electrolyte solutions containing glucose and an alkalizing agent are recommended if the neonate is still nursing.
- Although oral electrolytes are less likely to be absorbed due to enterocyte pathology, not all enterocytes are affected so some absorption may occur. Neonates without a suckle response need IV fluids. IV administration of lactated Ringer's solution is adequate.
- With severe acidosis, isotonic sodium bicarbonate solution (1.3%, 13 of sodium bicarbonate to 1L of distilled water) may be used. Dextrose solutions (2.5%–5%) are indicated in cases of hypoglycemia.
- With hypoglycemia and an unknown electrolyte and acid-base status, a 2.5% dextrose and 0.45% saline solution has been recommended.

ACTIVITY

N/A

DIET

- Neonates with a suckle response should be left with the dam and allowed to nurse.
- Animals being reared artificially should remain on their diet or switch to whole milk or colostrum. If the diarrhea becomes worse or the calf becomes depressed, removal from the dam or milk is warranted.
- In the case of hand-fed neonates that are depressed and not interested in sucking or neonates not nursing the dam, neonates should receive a high-energy electrolyte solution at a rate of 10% of body weight divided into a minimum of 4 feedings.
- Ruminating animals should be provided a forage-based diet.
- Force feeding alfalfa meal and electrolytes in a water solution to inappetent animals is helpful.

CLIENT EDUCATION

- Clients should be made aware of the potential for fecal shedding of *Salmonella* organisms by both clinically ill as well as convalescent animals into the environment.
- Isolation and biosecurity procedures should be developed to keep organisms from spreading throughout the environment.
- Potential for zoonotic spread should be addressed.

MEDICATIONS

DRUGS OF CHOICE

- Florfenicol 20 mg/kg IM every 48 hours (extralabel usage)
- Ceftiofur 2.2 mg/kg IM/SC bid for 4–7 days (extralabel usage)
- Flunixin meglumine 0.5 mg/kg IV BID first day, then SID (extralabel usage)

CONTRAINDICATIONS

- Do not use kaolin and pectin as use may increase electrolyte loss.
- Do not use hypertonic saline.
- Do not use flunixin if renal disease is evident.
- Meat and milk withhold times must be maintained at all times.

FOLLOW-UP

PATIENT MONITORING

Monitor attitude, suckling response and/or appetite, fecal color and consistency, and hydration status

PREVENTION/AVOIDANCE

- Cleanliness is the basis of prevention. Clean and disinfect animal holding facilities between groups of animals.
- Do not overcrowd animals.
- Equipment should be cleaned and disinfected with iodine, chlorine, or phenolic compounds. Drying and exposure to sunlight increases die-off.
- Reduce manure buildup.
- Control bird and rodent populations as both may carry *Salmonella* organisms.
- Avoid runoff ponds for water sources.
- Vaccination with a LPS core antigen vaccine will not prevent infection but will reduce clinical signs.
- Quarantine new additions for 30 days.
- Those handling sick animals should practice biosecurity measures to reduce exposure to healthy animals, wash hands and disinfect boots, maintain clothes free of fecal material.

POSSIBLE COMPLICATIONS

- Endotoxic shock and death
- Retained placenta and metritis in animals that abort

EXPECTED COURSE AND PROGNOSIS

- Prognosis is dependent on the virulence of the serovar and the host's immune status.
- Animals will have diarrhea or loose stools for approximately a week.
- Poor weight gains can be expected for 2 to 3 weeks after clinical signs resolve.
- Some acute infections will become chronic infections.
- Animals may shed the organism in feces for up to 6 months postrecovery.
- Because the organism can survive for months in the environment, outbreaks may reoccur during periods of animal stress.
- Most outbreaks last 2 weeks, unless the infection becomes endemic, in which case, animals brought into the environment may develop signs over an extended time period.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Acute infections may result in a chronic state.
- Depending on the virulence of the specific serotype and immune status of the host, the organism may be contained within the intestinal tract or invade the circulatory system resulting in multiple organ pathology.
- Clinical signs are often associated with the release of endotoxins and the development of endotoxemia.

AGE-RELATED FACTORS

- Most cases are 2 weeks to 2 months of age.
- All ages are susceptible.
- Infections in young animals are most often a result of contaminated environments.
- Outbreaks in adults are associated with stress and exposure to a virulent serovar.

ZOONOTIC POTENTIAL

- During outbreaks within animal populations, it is common for animal caregivers to become infected and develop clinical signs.
- Serotypes of concern with multiple drug resistance are *S. typhimurium* and emerging *S. enterica* Serotype Newport.

- The CDC estimates that there are 1.4 million nontyphoidal salmonella infections in the United States, resulting in 168,000 physician office visits per year, 15,000 hospitalizations, and 400 deaths annually. These estimates indicate that salmonellosis presents a major ongoing burden to public health.

RUMINANT SPECIES AFFECTED

Bovine, caprine, and ovine

BIOSECURITY

- Separation by animal age
- Limiting fecal exposure among classes of animals through good feeding hygiene (e.g., cleaning and sanitizing feeding equipment)
- Limiting contact between ill or infected animals and healthy animals
- Addition of new animals in the herd only after consideration of biosecurity risks
- Minimizing the potential introduction of agents via visitors or fomites through access restriction, and cleaning/disinfecting boots and equipment
- When cleaning stalls using flush water, remove animals prior to flush procedure.
- Avoidance of contaminated feed sources
- Limiting human contact with ill animals and appropriate hygiene

SALT

BASICS

OVERVIEW

- “Salt” is composed of sodium chloride in a one to one molar ratio. In pure form, sodium chloride is a crystalline substance commonly incorporated into “licks” of various size and combinations with trace minerals.
- Both sodium and chloride are required for normal physiological function. Sodium is required for maintaining osmotic balance, acid/base balance, active transport of certain nutrients, and glucose uptake. Chloride is required for gastric HCl, enzyme activation, regulation of blood pH, and respiration.
- Problems associated with salt include either depletion of circulating sodium and chloride, or excessive salt intake.
- Salt intake recommendations vary with species and level/type of production within species. It is suggested that the reader consult species-specific National Research Council publications for requirements.

SYSTEMS AFFECTED

- Hemic/lymphatic/immune
- Hepatobiliary
- Cardiovascular
- Central nervous system
- Respiratory
- Renal/urologic
- Gastrointestinal

GENETICS

Genetic and species differences are reflected in salt needs on an individual animal basis.

Mean Age and Range

All ages of animals are affected.

Predominant Sex

No sex predilection

SIGNS

Salt Excess

- Generally manifested by sodium excess
- Sodium excess will cause increased body water to maintain an isotonic environment. Increased body water will expand the extracellular fluid volume, resulting in generalized edema and hypertension.
- “Salt intoxication” can occur if salt-restricted animals are allowed immediate access to salt for ad libitum consumption. Unlimited access to drinking water should minimize adverse effects of high salt intake; however, salt intake should be gradually increased in previously salt-deprived animals.

- Excessive salt intake with inadequate water intake will result in sodium intoxication. Cortical edema, as well as eosinophilic meningoencephalitis in swine, is associated with sodium intoxication.
- Signs include severe nervous symptoms characterized by staggering, circling, blindness, head-pressing, and collapse.
- Sodium levels of > 2000 ppm is supportive of sodium toxicosis.

Salt Deficiency

- Associated with sodium depletion
- Sodium depletion is generally associated with loss of circulating sodium, and not necessarily to low sodium intake. Low sodium intake in domestic animals is the result of poor livestock management because salt is inexpensive.
- Sodium loss in milk in cows consuming a low-salt diet can induce sodium depletion. Mastitis will exacerbate sodium depletion in milk.
- Conditions associated with fluid loss (diarrhea, lactation, sweating, vomiting) will increase the rate of sodium loss. Renal disease can increase sodium loss.
- Salt deprivation can lead to hyperphagia, inducing digestive problems. Animals also will consume nonfeed materials, such as dirt, wood, etc.
- Salt deficient animals are unthrifty and manifest poor growth, male infertility, and delayed female maturity.
- Ruminants consuming primarily forages should be provided with supplementary salt because of the high potassium to sodium ratio common in grass and other forages.

DIAGNOSIS

PATHOLOGIC FINDINGS

Gross pathology:

- Salt intoxication: marked congestion and edema of the brain and meninges, as well as petechiae and ecchymoses within the grey and white matter of the cerebrum, cerebellum, and brain stem, and moderate to severe congestion of the abomasal mucosa.
- Sodium chloride poisoning has been classified as acute/direct salt poisoning where there has been ingestion of excessive salt in feed or drinking water or as delayed/indirect when there has been a restriction in water intake with or without ingestion of excessive salt.
- Hyponatremia with resultant brain edema and neurological disease has also been induced in calves by injudicious use of sodium bicarbonate and oral electrolyte solutions during treatment of diarrhea with dehydration and acidosis.

TREATMENT

CLIENT EDUCATION

Conditions associated with severe nonregenerative anemia or pancytopenia generally carry a guarded to poor prognosis and may require long-term therapy without complete resolution.

SARCOCYSTOSIS

BASICS

DEFINITION

Infestation with protozoan species of the genus *Sarcocystis*. The condition is also known as sarcosporidiosis.

PATHOPHYSIOLOGY

- *Sarcocystis* spp. have a two-host cycle involving a final host and an intermediate host.
- The final host is a predator, which ingests muscle tissue of the intermediate host that contains *Sarcocystis* cysts (sarcocysts). After about 1 week, the final host begins shedding infective sporocysts in its feces for several months.
- The intermediate host is a prey species, which ingests the infective sporocysts during grazing or drinking and then releases sporozoites that develop into schizonts in the vascular endothelium. Merozoites develop from these and give rise to another generation of schizonts in the vascular endothelium. The last generation gives rise to schizonts, which encyst in muscle and other soft tissues to form the sarcocysts. In 2 to 3 months, infective zooites develop within the sarcocysts.
- Clinical disease in the intermediate host may occur at two stages in the developmental cycle.
 - First stage at 3 to 5 weeks after the initial infection; can last for 6 to 8 weeks. This stage corresponds with the formation of endothelial schizonts with fever, petechiation of mucous membranes, edema, icterus, and macrocytic hypochromic anemia.
 - Second stage corresponds to the entry of schizonts into muscle tissue where extensive fiber degeneration and enzyme release can occur. The enlargement of the cysts in massive infestations can cause muscle pain and lameness. After about 100 days, maturation of the cysts occurs, and tissue reactions subside along with clinical signs.
- This recovery from clinical disease may explain the past impression that sarcosystosis was an innocuous condition. In cattle, *S. cruzi* seems to be the only one capable of causing significant clinical disease. In sheep, *S. tenella* can be very pathogenic to lambs.

SYSTEMS AFFECTED

- Production management; potentially all, depending on condition
- Vascular endothelium
- Skeletal and cardiac muscle
- Possibly CNS tissue in lambs
- Reproductive system—abortions, stillbirths.
- Lymphadenitis

GENETICS

None

INCIDENCE/PREVALENCE

- Worldwide prevalence of *Sarcocystis* in ruminants is very high, approaching 100% in many areas.
- The prevalence of intestinal infection in humans worldwide is thought to be between 6% and 10%.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

- Specific final/intermediate host relationships exist for each species of *Sarcocystis*.
- Some examples include: Dog/cattle—*S. cruzi*; Cat/cattle—*S. hirsuta*; Human/cattle—*S. hominis*; Dog/sheep and goat—*S. capracanis*, *S. hircicanis*; Cat/sheep—*S. tenella*, *S. gigantea*, *S. medusiformis*; Cat/goat—*S. moulei*.
- Other species which serve as hosts include water buffalo, wild ruminants, camels, horses, pigs, rodents, raccoons, birds,

and reptiles.

- *S. cruzi* is the only species that causes clinical disease in cattle.
- *S. tenella* can be very pathogenic in lambs.
- *S. gigantea* in sheep affect the esophagus; sarcocysts are large enough to be seen visually.
- No species have been determined as pathogenic to goats.
- There are numerous *Sarcocystis* spp. that affect deer and involve canids in their cycle.

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Intermediate hosts (ruminant species) grazing on soil/pasture contaminated by sporocysts shed by the final hosts (dogs and cats primarily, humans may be involved)
- Feeding on raw tissues of infected ruminants by dogs, cats, or humans

PHYSICAL EXAMINATION FINDINGS

- Usually asymptomatic
- In severe cases—fever, anorexia, cachexia, decreased milk production, diarrhea, muscle spasms, anemia, sloughing of tip of tail, hyperexcitability, weakness, late-term abortion, CNS signs, prostration, or death have been observed.
- The severity of disease may be modified by the strength of the host's immune system.

CAUSES

Sarcocystis spp.

RISK FACTORS

Dogs, cats, or humans feeding on uncooked tissues of ruminants infected with *Sarcocystis* spp. subsequently reexposing ruminants to sporocysts via their feces.

DIAGNOSIS

- Usually an incidental discovery at slaughter
- PCR-RFLP resolved by agarose gel electrophoresis
- Monoclonal antibody to *T. saginata* and avidin-biotin complex immunohistochemistry

DIFFERENTIAL DIAGNOSIS

In severe cases, consider GI parasitism, toxicity, brucellosis, leptospirosis, enzootic bovine abortion, other causes of abortion, white muscle disease, and CNS diseases (rabies, bovine spongiform encephalopathy, and scrapie).

PATHOLOGIC FINDINGS

- Only *S. gigantea*, found in sheep, form sarcocysts that are visible grossly in tissues. These are seen in the esophagus. Others are microscopic and can be detected in the esophagus, diaphragm, heart, and other muscle.
- Lesions from *S. cruzi* in cattle may be visible in massive infestations and can lead to carcass condemnation at slaughter.
- Trichinostomy or enzyme digestion techniques may be needed to visualize the sarcocysts.
- Severely affected animals may appear cachectic or have hemorrhage of the visceral and myocardial serosa.

TREATMENT

Therapeutic treatment is ineffective.

MEDICATIONS

- Not generally practiced
- Experimentally, amprolium at 100 mg/kg body weight fed once daily prophylactically for 30 days seemed to reduce the severity of illness in sheep and calves. Other references put the dose at 5–10 mg/kg orally for the prevention or treatment of other coccidia. Except for calves, this is extralabel use. Do not use in animals producing milk for human consumption. Meat withdrawal time is 24 hours after last treatment. Do not use in calves to be processed for veal.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PREVENTION/AVOIDANCE

- Prevention by keeping dogs and cats from eating raw tissues of ruminants and contaminating feed and pasture with sporocyst-infected feces is important.
- Freezing of meat reduces the number of viable cysts.
- Prevent contamination of ruminant feed and environment by dog, cat, and human feces.

POSSIBLE COMPLICATIONS

EXPECTED COURSE AND PROGNOSIS

- Cattle—only *S. cruzi* has potential to cause significant disease, and can range from muscle pain to abortions to death. Full recovery is seen after 100 days when cysts mature. Sarcocysts will remain in the muscle and can result in carcass condemnation at slaughter.
- Sheep—*S. tenella* has been associated with high morbidity and mortality in lambs

MISCELLANEOUS

ASSOCIATED CONDITIONS

Other intestinal parasites

AGE-RELATED FACTORS

Clinical disease is seen primarily in calves, lambs, and kids, although adults may also be affected.

ZOONOTIC POTENTIAL

- *S. bovis*—Humans are the primary host, and generally no clinically significant disease has been documented in humans or cattle in natural infections.
- In experimental infections, some humans experienced transient abdominal pain and diarrhea 10–14 days after exposure, and shed sporocysts in their feces for 5–12 days.
- In other *Sarcocystis* spp., rare cases of muscular weakness and pain, periarteritis and subcutaneous tumefaction have been observed, indicating humans can potentially serve as the intermediate host as well. But a causal association has not been established. Immunosuppressed individuals may be at increased risk of clinical disease. It is thought that nearly half of the muscular cysts worldwide in bovines and swine are caused by *S. bovis* and *S. suis*.
- The prevalence of intestinal infection in humans worldwide is thought to be between 6% and 10%.

PREGNANCY

Severe infestation can result in stillbirths and abortion in cattle.

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected

Author: Edward L. Powers

SCRAPIE

BASICS

OVERVIEW

- Scrapie is a progressive, degenerative, nonfebrile disease of sheep and, less commonly, goats and is the oldest known agent in the family of transmissible spongiform encephalopathies (TSEs).
- Additional TSEs include chronic wasting disease (CWD) in cervids, transmissible mink encephalopathy, feline spongiform encephalopathy, bovine spongiform encephalopathy (BSE), and Creutzfeld-Jakob disease (CJD) in humans.
- Contamination of the environment and oral exposure with placenta and fetal fluids from infected sheep is thought to be the most likely source for horizontal and vertical transmission of scrapie.
- Milk, saliva, urine, colostrum, and feces have not been demonstrated to transmit disease.
- Scrapie has a long incubation period and clinical signs commonly appear in adult sheep 2.5 years of age and older. Clinical signs can be localized to damage within the brain stem.
- There is currently no approved definitive antemortem diagnostic test for scrapie. Immunohistochemistry (IHC) staining of the obex, retropharyngeal lymph node, and tonsil is the current gold standard for postmortem testing.
- Genetic analysis, or genotyping, of codons 136, 154, and 171 has become an effective tool to determine susceptible sheep within a flock.
- It is estimated that scrapie cost the U.S. sheep industry \$20 million a year in lost productivity and potential export markets.
- Scrapie has never been linked to disease in humans who consume sheep muscle.

PATHOPHYSIOLOGY

- The infectious agent of scrapie is a prion, a misfolded glycoprotein of the cell membrane, of which there are more than 15 strains. The misfolded prion protein is resistant to degradation by normal host protease.
- Accumulation of the protease-resistant prion (PrP) in the brain stem causes vacuolation of the grey matter neuropil and has a “spongy” appearance on H&E preparations.

SYSTEMS AFFECTED

CNS

GENETICS

- Genetic analysis, or genotyping, of codons 136, 154, and 171, has become an effective tool to determine susceptible sheep within a flock.
- Scrapie is primarily a disease of Suffolk sheep in the United States. The disease is found in the Suffolk, Cheviot, Swaledale, Bleu du Maine, Herdwick, Poll Dorset, Shetland, and Soay breeds in the UK, Texel breed in The Netherlands, Suffolk and Corriedale breeds in Japan, Romanov and Lacune breeds in France, Rygja breed in Norway, and Icelandic breed in Iceland.
- Genetic resistance to scrapie depends not only on the prion genotype of the sheep but also on the strain of scrapie present.
- Genotypes found to be resistant to one strain of scrapie have been shown to be susceptible to another strain. It appears that there are differences between the United States and Europe in the strains of scrapie that are present.
- Codon 136: Sheep homozygous for alanine (AA) have been shown to be more resistant to scrapie than sheep homozygous for valine (VV) or heterozygous (AV) in European studies.
- Codon 154: Of the three important codons, amino acid changes at 154 appear to have a slightly less dramatic effect on scrapie susceptibility than do the other two, and the susceptible genotypes are not consistent across studies.
- Codon 171: Amino acid changes at codon 171 have a large effect on scrapie susceptibility in sheep in both Europe and the United States. Virtually no sheep homozygous for arginine (RR) have been identified with scrapie.

INCIDENCE/PREVALENCE

- Beginning April 1, 2002, through March 31, 2003, the overall weighted national prevalence of scrapie in 12,491 sheep greater than 1 year of age was 0.20%. States within the eastern half and north central United States have a higher prevalence than the western states.
- Scrapie was first diagnosed in the United States in 1947 in a flock of Suffolk sheep in Michigan.
- From 1947 through July 2001 in the United States, scrapie had been diagnosed in over 1000 flocks, and approximately 1600 individual cases of natural ovine scrapie and 7 individual cases of natural caprine scrapie have been found.
- Relative to most other goat and sheep diseases, the incidence of scrapie is low.

GEOGRAPHIC DISTRIBUTION

Potentially worldwide

SIGNALMENT

Black-faced sheep are significantly more likely to test positive for scrapie than white- or mottle-faced sheep. The Suffolk breed is most commonly diagnosed with scrapie.

Species

Sheep and goats

Breed Predilections

In 1998, the USDA found the breed distribution in the United States was 87% Suffolk, 6% Hampshire, and 7% other breeds (Border Leicester, Cheviot, North Country Cheviot, Corriedale, Cotswold, Dorset, Finnsheep, Merino, Montadale, Rambouillet, Shropshire, and Southdown) and crosses.

Mean Age and Range

Scrapie is commonly diagnosed in sheep between 3 and 5 years of age and is rarely diagnosed in sheep less than 18 months of age.

Predominant Sex

N/A

SIGNS

- Clinical signs include sudden onset of behavioral changes, development of an unstable gait or other locomotion disorders, neurological deficits localized to the brain stem, and generalized wasting without a loss of appetite.
- A small percentage of sheep smack their lips and develop the pruritic form ("scrapie") characterized by a loss of wool around the tail, lateral neck and body, and elbow.
- Recumbency, seizing, difficulty swallowing, and blindness are common clinical signs in the latter stages of disease.

PHYSICAL EXAMINATION FINDINGS

- Signs of scrapie vary widely among individual animals and develop very slowly.
- Due to damage to nerve cells, affected animals usually show behavioral changes, tremor (especially of head and neck), pruritus, and locomotor incoordination that progresses to recumbency and death.
- Early signs include subtle changes in behavior or temperament. Scratching and rubbing against fixed objects, apparently to relieve itching, may follow these changes.
- Other signs are loss of coordination, weight loss despite retention of appetite, biting of feet and limbs, lip smacking, and gait abnormalities, including high stepping of the forelegs, hopping like a rabbit, and swaying of the back end.
- An infected animal may appear normal if left undisturbed at rest.
- When stimulated by a sudden noise, excessive movement, or the stress of handling, the animal may tremble or fall down in a convulsion-like state.

CAUSES AND RISK FACTORS

- Scrapie is thought to be spread most often from ewe to offspring and to other lambs in contemporary lambing groups through contact of lambs with the placenta and placental fluids of infected ewes.
- Lateral transmission from infected rams to ewes and lambs, from infected ewes to other ewes, and from an infected environment to adult animals is not thought to be a major route of transmission; however, there are documented cases of scrapie where such routes of transmission are thought to have occurred.
- Contamination of the environment and oral exposure with placenta and fetal fluids from infected sheep is thought to be the most likely source for horizontal and vertical transmission of scrapie. Milk, saliva, urine, colostrum, and feces have not been demonstrated to transmit disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Neurological Signs: Sheep

- Brain abscess (caseous lymphadenitis—CLA/*Actinobacillus*)
- *Clostridium perfringens* type C
- Cobalt deficiency
- Copper deficiency
- Hypocalcemia
- Hypomagnesemia
- Inner ear infection
- Listeriosis
- Louping-ill
- Mycotoxins
- *Parelaphostrongylus* (meningeal worm migration)
- Polioencephalomalacia/thiamine deficiency
- Pregnancy toxemia
- Rabies
- Swayback
- Tetanus
- Tick paralysis
- Uremia
- Vitamin A deficiency

Neurological Signs: Goats

- Bacterial: botulism brain abscess, inner ear infection, *Listeria* infection, meningoencephalitis, tetanus
- Congenital: hydranencephaly, hydrocephalus, progressive paresis
- Nutritional/metabolic: cobalt deficiency, enzootic ataxia/swayback/copper deficiency hypovitaminosis A, polioencephalomalacia/thiamine deficiency, pregnancy toxemia uremia
- Parasitic: *Parelaphostrongylus tenuis*, tick paralysis
- Toxic ingestion
- Pyrethrin/organophosphates
- Salt toxicity
- Trauma
- Viral/prion: border disease, borna disease, caprine arthritis encephalitis virus (CAE), louping-ill, maedi visna, pseudorabies, rabies

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Diagnostic testing

- Conclusive diagnosis of scrapie is by detection of accumulated protease resistant prion, PrP, by immunohistochemistry (IHC) staining of the obex, retropharyngeal lymph nodes, and tonsils of sacrificed sheep.
- Humoral or cell-mediated immunity in response to the exposure of misfolded prion is not a feature of scrapie and conclusive antemortem diagnosis by common serological methods is not possible.
- Biopsy and IHC staining of at least six lymphoid follicles from the third eyelid has been attempted as an antemortem test for scrapie, but is currently not an official antemortem diagnostic test.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Genetic testing

- Experiments have demonstrated that there is substantial genetic control over the incidence of disease.
- Identification of specific amino acid sequences at codons 136, 154, and 171 correlate with a sheep susceptibility to becoming infected with scrapie.
- Although there is a genetic variability within breeds, families, and individual sheep, codon 171 has become a reliable susceptibility indicator in the United States. Sheep that are homozygous arginine (RR) or heterozygous arginine/glutamine (QR) at codon 171 appear resistant to scrapie.
- Sheep homozygous glutamine (QQ) at codon 171 have demonstrated to be susceptible to scrapie.
- Susceptibility genetic sequences have been established for codons 136 and 154 but are less reliable than codon 171.

PATHOLOGIC FINDINGS

- The most diagnostic lesion is the presence of bilaterally symmetrical neuronal vacuolation; microcystic vacuolation (spongiform change) of the grey matter neuropil.
- Hypertrophy of astrocytes often accompanies vacuolation.
- Cerebral amyloidosis is an inconstant histological feature of scrapie.
- Brain extracts contain an abundance of characteristic abnormal fibrils (SAF), which are readily identified by negative-stain EM.

TREATMENT

There is no known treatment for scrapie.

Control

- Sacrificing and testing sheep with clinical signs, in addition to genetic testing susceptible sheep, is the current control method.
- The selection of breeding rams with resistant gene profiles to perpetuate resistant genes is also advised.
- Lambing in a clean environment and removing fetal membranes and contaminated bedding to prevent additional exposure will also reduce exposure and disease risk.
- Sheep and goat identification program in the United States: Sheep and goat classes that require tagging:
 1. All sheep 18 months of age or older
 2. All breeding sheep regardless of age
 3. Sexually intact show or exhibition sheep and goats
 4. All goats 18 months of age or older that are or have been commingled with sheep
 5. All breeding goats that are or have been commingled with sheep.

SEGMENTAL APLASIA/HYPOPLASIA OF THE WOLFFIAN DUCT SYSTEM

BASICS

DEFINITION

In this context, segmental aplasia usually refers to lack of development of part of one or more of those structures (epididymis, vas deferens) that are derived from the embryonic mesonephric, or Wolffian, duct system.

OVERVIEW

- Affected structures may include the epididymis, vas deferens, and ampulla. The vesicular gland on the affected side may also be underdeveloped.
- The most frequently affected areas are the body and tail of the epididymis.

PATHOPHYSIOLOGY

SYSTEMS AFFECTED

Reproductive

GENETICS

- Numerical chromosomal aberrations (e.g., XXY) have been identified as a risk factor.
- In addition, European work suggests that a hereditary form exists.

INCIDENCE/PREVALENCE

In Europe, the prevalence has been estimated as being between 0.59% and 1.18% in young calves, 1% in normal bulls, and 5% in infertile bulls.

GEOGRAPHIC DISTRIBUTION

Worldwide distribution

SIGNALMENT

- More commonly unilateral and on the RHS
- In unilateral cases, the bull is usually fertile, even though semen from only one testicle is available for fertilization.

Species

Although segmental aplasia can occur in all species, it is particularly well described in the bull.

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

Male

SIGNS

Whether classified as aplasia or hypoplasia, complete occlusion usually occurs of the affected region, precluding passage of sperm on the affected side.

CAUSES AND RISK FACTORS

DIAGNOSIS

- Diagnosis can be difficult, and usually entails careful palpation of those structures derived from the Wolffian duct

system.

- The testicle on the affected side(s) is often developed normally.
- If occlusion is in the upper body or head of the epididymis, fluid backpressure may cause testicular swelling and subsequent degeneration.
- If the lesion is more distal to the testicle, fluids may be absorbed within the epididymis.
- Palpation of a very small or absent, epididymal tail is suggestive of the condition. The epididymal head may be enlarged due to distension with semen. If the defect is located in the vas deferens, the epididymal tail may be enlarged.

DIFFERENTIAL DIAGNOSIS

- Small cystic structures derived from the embryonic duct systems (either Wolffian or Muellerian), which can occur adjacent to the ampullae and vas deferentia, paradidymis
- Spermiostasis, sperm granuloma, epididymitis, epididymal neoplasia (rare in the bull)
- Orchitis, testicular degeneration

SELENIUM TOXICITY

BASICS

OVERVIEW

- The identification of physiologically important roles of selenium in immunity, reproduction, and productivity has led to an increased use of selenium in man and animals over the years, for both therapeutic and preventive purposes.
- Selenium (Se) is the only essential nutrient that does not have a GRAS (generally regarded as safe) status and so the FDA regulates Se supplementation in animals as if it were a drug.
- There is a narrow margin between selenium deficiency and selenium toxicosis in animals. Selenium toxicosis has been reported either naturally, by consumption of selenium-accumulator plants, or by human errors, due to oversupplementation of selenium in the diet and/or accidental overdosing.
- Organic forms of selenium such as selenomethionine and Se-methyl selenocysteine are the major selenium-containing compounds found in the plants/hay, whereas an inorganic form of selenium such as sodium selenite is the common supplemental/dosing form.
- Acute selenosis may occur at oral doses ≥ 2.2 mg Se/kg BW.
- Chronic selenosis has been reported to occur in animals fed $> 5\text{--}40$ ppm Se in feed.
- The toxic effects of the organic and inorganic forms of selenium are similar but, in most cases, the toxic dose of the inorganic form is greater than the organic form.
- Clinical signs involve respiratory, cardiovascular, hematologic, and gastrointestinal systems.
- Bovines are more susceptible than ovines.
- Fetus can concentrate Se in liver at concentrations up to three times higher than in the dam.
- Chronic selenosis or “alkali disease” causes hoof deformities and hair loss. The term “blind staggers” is a misnomer for selenium toxicosis.

PATHOPHYSIOLOGY

- Replacement of sulfur with selenium in the amino acids weakens keratin and causes disruption of hair, hoof, and horn integrity due to loss of the disulfide bonds. Se also causes abnormal maturation of the keratinocytes in the stratum spinosum. This may be followed by degeneration and necrosis. Alopecia results from atrophy of primary hair follicles.
- In the hoof, cells on the coronary papillae produce dyskeratotic debris that accumulates in the horn tubules and distorts the normal architecture of the hoof wall.
- Cytotoxic effects of Se are the result of denaturation of critical protein thiols. Selenite and SeCys react with tissue thiols to produce ROS.

SYSTEMS AFFECTED

Cardiovascular

- Tachycardia
- Atrophy and dilatation of heart with multifocal myocardial necrosis or hydropic degeneration
- Endocarditis or myocarditis with focal hemorrhages

Gastrointestinal

- Diarrhea
- Mild gastroenteritis

Hemic/Lymphatic/Immune

- Selenium has been reported to decrease erythrocytic volume by reducing the hemoglobin synthesis and may result in anemia.
- Variable necrosis and/or atrophy of lymphoid tissue

- Reduced immune response

Hepatobiliary

- Congested and swollen liver
- Vacuolation of hepatocytes
- Cirrhosis/fibrosis

Musculoskeletal

- Ataxia
- Mild hyaline or granular degeneration of the muscle fibers

Nervous

- Depression
- Polioencephalomalacia

Renal/Urologic

- Hemoglobinuria
- Glomerulonephritis
- Parenchymatous and tubular degeneration with casts

Reproductive

- Infertility
- Abortions, stillbirths
- Hypoplasia of reproductive organs has been observed in lambs from seleniferous areas.

Respiratory

- Dyspnea
- Pulmonary edema (marked interlobular edema), hydrothorax and focal hemorrhages
- Pulmonary alveolar vasculitis
- Accumulation of serosanguinous fluid and foam in the trachea, bronchi, and bronchioles.

Skin

Structural abnormalities of hair, hoof, and horn

GENETICS

N/A

INCIDENCE/PREVALENCE

- Seleniferous areas with alkaline soil
- Sporadic incidences resulting from accidental overdoses

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

- Young animals are more susceptible to selenosis as a result of the underdeveloped rumen. Ruminal microflora is known to reduce bioavailable forms of selenium to unavailable, elemental forms.
- No breed or sex predilections have been described in the literature.

SIGNS

Acute Effects

- Clinical signs generally include anorexia, depression, reluctance to move, and respiratory distress. Grinding of teeth, diarrhea, bloat, and abdominal pain may also be seen.
- Heart rate and respiration rate are high and the pulse may be weak. Fever, polyuria, and hemolytic anemia have been reported in some cases.
- Death usually occurs within 12–48 hours of acute exposure, otherwise the animal usually recovers.
- Once clinical signs such as dyspnea and ataxia appear, the animals succumb within the hour.
- A garlicky smell to the breath is usually present, especially during first 16 hours postexposure.
- Bovine—orally, 11 mg Se/kg BW as selenite resulted in dyspnea, garlicky breath, and death within 2 days.
- Sheep—Blood-tinged frothy mucus may appear at the mouth and nostrils, progressing to prostration and death. Diarrhea

and peracute death have been reported in the absence of any other clinical signs. Congestion in the brain and swollen mesenteric lymph nodes are also observed in some animals. Using sodium selenite, an oral LD-50 of 1.9 mg Se/kg BW has been reported.

Table 1

Comparative Selenium Toxicosis in Cattle and Sheep		
	Se as sodium selenite (inorganic) (orally)	Se as selenomethionine (organic) (orally)
Cattle	<ul style="list-style-type: none"> • 7 mg Se/kg BW—no effect • 10.1 mg Se/kg BW—anorexia and low milk production for 5 days • 9–11 mg Se/kg BW—anorexia, dyspnea, garlicky breath, followed by death within 2 days • Oral MLD at 9.9–11 mg Se/kg BW • 15 ppm Se in diet for 231 days—decreased weight gain, sore foot, cracked hooves, excitability in 1 of 5 heifers 	<ul style="list-style-type: none"> • 2.2 mg Se/kg/day (<i>A. pectinatus</i>) for 6–16 days caused blind staggers in steers. • 3.4 mg Se/kg/day (<i>A. bisulcatus</i>) for 7 days caused blind staggers in steers. • 25 ppm Se (<i>Astragalus</i> hay) for 46 days caused joint stiffening and cracking of hooves in 4 weeks. By the end of 4 months, sloughing of the hoof started. • 9 out of 11 bullocks showed stiffness and lameness in all four legs, pale mucosa, and slow but gradual sloughing of the hoof. Mean concentrations of Se in the herbage was 37 ppm.
Sheep	<ul style="list-style-type: none"> • 6.4 mg Se/kg BW—pulmonary cong., 95% mortality in 15 days • 1.7 mg Se/kg BW—35% mortality within 12–16 hr • 2.2 mg Se/kg BW—35% mortality within 12–48 hr • Hyperpnoea, salivary frothing, hydrothorax, pulmonary edema, hepatic and renal degeneration • 1 mg Se/kg BW—no weight loss in 72 days • 0.5–1 mg Se/kg BW—several deaths between 78–178 days • Oral LD₅₀—1.9 mg Se/kg BW 	

Chronic Effects (Alkali Disease/Bob-Tail Disease)

- Chronic selenium poisoning is more common than acute poisoning due to the typical exposure rates. Also, the ingested selenium bioaccumulates, thus causing adversities over longer periods of time.
- Chronic selenosis is associated with depression, weakness, emaciation, anemia, hair loss/alopecia, swelling of coronary band, and hoof deformities that may result in separation and sloughing of the hoof wall.
- Reproductive performance may be reduced without showing clinical signs at concentrations ranging from 5 to 10 ppm Se in the total diet. Some of these adverse effects on reproduction are considered to be caused by the interference with absorption and retention of copper that results in copper deficiency.
- Blind staggers has been described in cattle and sheep but its causal link with selenium intoxication is weak.
- Bovine—even in the absence of clinical alkali disease in cattle, elevated Se concentrations may adversely affect both pregnancy and the bovine immune response. Se administered as sodium selenite at 25 ppm (0.6–1 mg Se/kg BW) for 1 month or 15 ppm (0.4–0.6 mg Se/kg BW) for 6 months caused chronic selenosis.
- Sheep—chronic selenosis may result in death—without observing clinical signs. Unlike other species, wool loss and hoof lesions are not commonly identified in sheep, although the wool production is known to decrease. Sheep fed diets containing 0.5–1 mg Se/kg BW (about 17–33 ppm in the diet) reportedly was lethal when exposed for 2 1/2–6 months. Unlike other ruminant species, hair loss and hoof lesions are not commonly seen in sheep. Please see [Table 1](#).

RISK FACTORS

- Vitamin E—deficient animals are more susceptible to acute selenosis.
- Se toxicosis has been reported to increase with concomitant cobalt deficiency.
- Signs of Se deficiency resemble those of selenium toxicosis.
- Primary selenium accumulators such as *Astragalus*, *Machaeranthera*, *Xylorhiza*, and *Haplopappus* spp. can contain > 1000 ppm selenium. Secondary accumulators such as *Aster*, *Atriplex*, *Grindelia*, *Gutierrezia*, and *Casteilleja* spp. can also contain toxic amounts of selenium, are usually unpalatable, and are the last choice for animals. The commonly used forage species are nonaccumulators.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Pneumonia, cardiotoxic plant exposure, ionophore overdose, thallium toxicosis, Vitamin E and selenium deficiency, and endotoxemia

CBC/BIOCHEMISTRY/URINALYSIS

- CBC, serum biochemistry, and urinalysis results are usually unremarkable in acute cases.
- In chronic exposure, the liver enzymes may be elevated as a result of the liver damage.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- For most ruminants, normal Se in blood (0.08–0.5 ppm) and liver (0.25–1.0 ppm)
- In acute cases, the liver selenium may range from 15–30 ppm or above.
- In chronic cases, liver selenium may range from 2–7 ppm and the hair/hoof Se may range from 1.5 ppm up to 45 ppm. Blood Se and blood GSH-Px activity has also been used for diagnostic purpose.

PATHOLOGIC FINDINGS

Acute Selenosis

- Gross lesions include edematous, congested, and/or hemorrhagic lungs. Bloody froth may be seen in the airways. Congestion and hemorrhages are also observed in the liver, kidneys, and GIT. Petechiations of the epicardium may also be seen with or without edema.
- Histopathology reveals endocarditis, myocarditis, and myocardial necrosis. Hydropic degeneration of myocardium is seen along with petechial hemorrhages. Focal areas of necrosis are seen in the liver with occasional vacuolation of the hepatocytes. In kidneys, parenchymous and tubular degeneration with casts is a common finding. Histologic lesions are minimal if the clinical course is brief. Mild hyaline or granular degeneration of skeletal muscle fibers may be present. Variable necrosis of the lymphoid cells may also be present.

Chronic Selenosis

- Gross lesions include edematous and congested lungs, atrophied and cirrhotic liver with discoloration, enlargement of spleen and pancreas, anemia, atrophy of lymphoid tissue, atrophy and dilation of the heart, and erosion of articular surfaces.
- Histopathology indicates congestion and thickening of the alveolar walls in the lungs, hepatic fibrosis, myocardial degeneration, glomerulonephritis, and mild gastroenteritis. Areas primarily affected in the CNS include ventral horns of the cervical and lumbar vertebral segments, with lesser damage in brain stem nuclei. The microscopic appearance of the affected spinal cord includes vacuolation of the neuropils and sometimes within the cytoplasm of the neurons. Neuronal chromatolysis, axonal swelling, multifocal hemorrhage, and endothelial cell swelling and proliferation are also usually present. The white matter has minimal changes.

TREATMENT

No proven therapy for acute selenium toxicity

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

- Supportive therapy
- Mechanical support for legs with hoof abnormalities until recovery

ACTIVITY

Avoid exercise/stress.

DIET

- Increase protein and carbohydrate in diet.

- Increase sulfur in the diet.
- 40-ppm arsenic salt or 50–100 ppm arsanilic acid has provided benefit to calves. Arsenic compounds can increase the biliary excretion of selenium.
- 4–5 g naphthalene daily for 5 days has been successfully used in the past in mature cattle.

CLIENT EDUCATION

N/A

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- No specific drug/antidote available.
- Analgesics and NSAIDs may be used for pain relief.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Avoid excess/further selenium exposure.
- Keep the total dietary concentrations within the recommended limits.
- Prevent animals accessing seleniferous plants.
- Check for the selenium status in the blood.
- Avoid selenium supplementation in seleniferous areas.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Guarded prognosis with acute selenosis
- Prolonged recovery with chronic selenosis

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Blind staggers (misnomer)
- Polioencephalomalacia

AGE-RELATED FACTORS

Preruminants and young ruminants are considered to be more susceptible to selenosis because of the nondeveloped rumen that significantly reduces the amount of bioavailable selenium to nonbioavailable form.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

- Abortions, stillbirths, or weak/lethargic calves
- No teratogenic effects described

RUMINANT SPECIES AFFECTED

All ruminant species should be considered susceptible.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Analysis of selenium in feed or whole blood for regular monitoring of the overall status

SYNONYMS

Alkali disease

Bobtail disease

SEE ALSO

SELF-MUTILATION

BASICS

OVERVIEW

- Self-inflicted bodily injury such as licking, chewing, or biting at tail, mammary, or limbs, or rubbing against objects until injury occurs.
- Behavioral abnormalities can be a result of central nervous system disorders affecting the cerebrum.
- Behavioral problems can also result from environment conditions such as stress or boredom.

SIGNALMENT

Any species and age can be affected.

SIGNS

- Hair loss
- Dermatitis with possible secondary bacterial infections of epidermis and dermis
- Weight loss due to decrease in feeding associated with obsessive behaviors
- May find blood or clumps of hair on gates or other inanimate objects the animal is rubbing against.
- Traumatized mammary gland

CAUSES AND RISK FACTORS

- Underlying medical problems such as dermatological conditions or parasitic infections
- Behavioral abnormalities can be a result of central nervous system disorders affecting the cerebrum.
- Behavioral problems can also result from environmental conditions such as stress or boredom.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Skin diseases with alopecia and/or dermatitis
 - Pruritis or pain
 - Ectoparasites, dermatophytosis, primary or secondary pyoderma
 - Atopy, food or contact allergies, insect hypersensitivity
 - Reactions to previously administered medications
 - Friction due to poorly fitted halters or stanchions
- Neurologic diseases such as
 - Pseudorabies (Aujeszky's disease, mad itch)—viral infection results in intense pruritis at point of dermatological infection.
 - Transmissible spongiform encephalopathies (TSEs) such as scrapie in sheep can result in extreme pruritis of the trunk.
 - Rabies can result in any form of behavioral abnormality.
- Behavioral disorders: obsessive-compulsive disorders
- Nutritional deficiencies and metabolic or endocrine disease can affect skin and hair coat.

CBC/BIOCHEMISTRY/URINALYSIS

Depends on underlying cause, medical or behavioral

OTHER LABORATORY TESTS

Depends on underlying cause

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Accurate and complete history is essential to ascertain medical or behavioral causes of self-mutilation
- Whether lesions are localized or generalized, this is often useful in diagnosing parasitic infections that have characteristic distribution of self-mutilation lesions.
- Determine whether multiple animals in the herd or flock are affected or if it is an individual animal problem. Behavioral or allergic problems are more typically individual problems. Neurologic disorders can be either an individual or an infectious problem.
- Physical examination may indicate primary cutaneous changes such as wheals, nodules, or pustules that would not be present if lesions were due solely to self-mutilation.
- Skin scrapings
- Fungal cultures
- Biopsy for histopathologic exam or direct immunofluorescence testing
- Bacterial culture and sensitivity: may only confirm secondary infection without determining underlying disease cause
- Blood serum chemistry and complete blood count
- +/- CSF tap
- +/- Intradermal skin testing

PATHOLOGIC FINDINGS

GROSS FINDINGS

Can include alopecia, dermatitis, and possible secondary pyoderma

HISTOPATHOLOGICAL FINDINGS

Depends on underlying cause

TREATMENT

- Parasitic conditions require appropriate ectoparasite or anthelmintic treatment. Environmental control of parasites is also necessary.
- Neurologic conditions require specific treatment based on the underlying condition.
- Behavioral conditions often require environmental management changes to reduce stress or relieve boredom. Antianxiety medications may be needed in conjunction with behavior modification.
- Evaluate ration for nutritional deficiencies.
- Consider exotic diseases and rabies prior to treatment regime.

MEDICATIONS

Depends on underlying cause

CONTRAINDICATIONS

N/A

FOLLOW-UP

PATIENT MONITORING

Monitor for progression of disease and for secondary infections caused by self-mutilation.

PREVENTION/AVOIDANCE

- Provide housing with adequate space and access to feeders and water for all animals to prevent disease and reduce stress that can lead to behavioral problems.
- Provide adequate space for movement and environmental enrichment to avoid behavioral problems due to boredom.
- Feeders should be above ground to reduce risk of parasitic infestations.
- Provide adequate bedding and clean buildings and yard regularly.
- Keep newly purchased animals isolated from the rest of the herd or flock for 30 days to evaluate for disease.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Parasitic conditions respond well to appropriate treatment but may require ongoing environmental and medical management.
- Allergic or immune conditions respond to therapy depending on individual condition.
- Neurologic conditions are often progressive and may be fatal.
- Behavioral conditions can respond to environmental enrichment or reduction of stress in environmental management.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Behavioral disorders can occur at any age, but can start very early in life such as abnormal suckling behaviors in orphaned calves.
- Other problems arise at or near the time of social maturity when stress is increased and dominance hierarchy is being established.
- Ewes and does may self-suckle if they abort late in pregnancy or due to extreme stress in environment.
- After sexual maturity, rams or bulls may develop obsessive-compulsive behavior of masturbation.

ZOONOTIC POTENTIAL

Depends on underlying medical condition

SEMINAL VESICULITIS

BASICS

OVERVIEW

- The paired vesicular glands are the major accessory sex glands in the bull, buck, and ram.
- The vesicular glands are absent in camelids.
- The vesicular glands contribute volume, nutrients, and buffers to the ejaculate but these contributions are not absolutely essential for fertility.
- The vesicular glands have a lobar structure and are found on the floor of the cranial pelvic cavity. Normal glands in the bull are about 2–4 cm wide and 10–15 cm long.
- Seminal vesiculitis is an inflammation of either or both vesicular glands.
- The condition is most commonly described in the bull but this may be due to the accessibility of the pelvic organs in the bull to palpation per rectum as compared to the buck and ram.

PATHOPHYSIOLOGY

- Bacteria are the most commonly incriminated infectious etiological agents but viral, chlamydial, fungal, and protozoal agents have been isolated.
- The precise mechanism of infection and pathology is not known and ascending, descending, or hematogenous routes of infection are all considered possibilities.
- Primary infections elsewhere in the body, especially chronic ones, may cause seminal vesiculitis by the hematogenous route.
- Urogenital anomalies may contribute to malfunctioning of the vesicular gland openings on the colliculus seminalis and increase the risk of seminal vesiculitis.
- Retrograde ejaculation or urine reflux into the vesicular gland may predispose to infection or cause a sterile inflammation of the glands.
- Bilateral and unilateral involvement of glands is equally likely.
- In ruminants, seminal vesiculitis is often found as part of a seminal vesiculitis syndrome with concurrent orchitis, epididymitis, ampulitis, bulbourethral adenitis, or prostatitis.

SYSTEMS AFFECTED

Reproductive

GENETICS

No known genetic influence or breed distribution

INCIDENCE/PREVALENCE

- The prevalence has been reported to be between 1% and 10% in bulls.
- The prevalence is significantly higher in young, peripubertal bulls intensively housed and fed high-energy diets. Within peripubertal bulls, the prevalence may reach 10%–30%.
- The prevalence is also higher in aged bulls (> 9 years).
- Clinical diagnostic criteria may significantly underestimate the true disease prevalence, especially in small ruminants where physical examination of the pelvic accessory sex glands is difficult to accomplish and is not routinely done.

GEOGRAPHICAL DISTRIBUTION

Worldwide distribution

SIGNALMENT

Species

- Most commonly found in bulls but does affect rams and bucks as well.

- *Bos taurus* and *Bos indicus* bulls are equally affected.

Breed Predilections

None known

Mean Age and Range

Most commonly found in peripubertal bulls (10–15 months) and older bulls (> 9 years).

Predominant Sex

Males only

SIGNS

GENERAL COMMENTS

Clinical signs are often completely lacking.

HISTORICAL FINDINGS

- Breeding bulls may have a history of sterility or subfertility but often have acceptable levels of fertility.
- AI sires may have a history of producing semen with poor motility and postthaw viability along with the presence of white blood cells in the ejaculate.

PHYSICAL EXAMINATION FINDINGS

- Unilateral or bilateral enlargement of the glands and loss of lobulations on palpation per rectum are the most common findings.
- In chronic cases, abscess formation and adhesions to adjacent abdominal or pelvic structures may occur.
- Rarely, bulls may show signs of abdominal pain, pain during mounting and thrusting, or when they are collected by electroejaculation.
- Most physical exam findings are normal.
- The finding of infectious or inflammatory lesions anywhere in the genital tract of male ruminants should suggest the possibility of a concurrent seminal vesiculitis.

CAUSES

- Seminal vesiculitis has been attributed to a variety of infectious and noninfectious causes.
- *Mycobacterium tuberculosis*, *M. avium* ss *paratuberculosis*, *Brucella abortus*, *B. ovis*, and *B. melitensis* are potential agents of special concern either for their zoonotic potential or local reporting requirements or both.
- In areas free of brucellosis, *Arcanobacterium pyogenes* is the bacteria most commonly isolated from clinical cases.
- *Streptococcus* spp., *Staphylococcus* spp., *Pseudomonas aeruginosa*, *E. coli*, *Tritrichomonas foetus*, *Chlamydia* spp., *Ureaplasma* spp., *Mycoplasma* spp., and *Haemophilus* spp. have all been reported to cause seminal vesiculitis in bulls.
- A wide variety of bacteria have been isolated from cases of ovine epididymitis and should be considered potential causes of seminal vesiculitis in this species as well.
- Bovine herpesvirus-1 and other viruses have been incriminated as causes of vesiculitis.
- Sperm entering the gland during ejaculation may initiate an autoimmune reaction and subsequent vesiculitis.

RISK FACTORS

- Infections at other body sites (e.g., orchitis, epididymitis, urethritis, rumenitis, pneumonia, omphalophlebitis, or traumatic reticulopericarditis) or congenital anomalies of the urogenital system (e.g., uterus masculinus or malformation of the colliculus seminalis) may predispose to developing seminal vesiculitis.
- High-density housing systems and high-concentrate diets commonly found in bull test stations appear to increase the risk of vesiculitis as well.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differential diagnoses for enlargement or asymmetry of the vesicular glands are segmental aplasia, hypoplasia, or accessory vesicular glands.
- The presence of a dilated or infected uterus masculinus may mimic seminal vesiculitis.
- Differentials for white blood cells in the semen include infections or inflammation anywhere along the urogenital tract

including the prepuce and penis.

- Urinary calculi should be considered, especially in rams and bucks.
- Primary infectious diseases of special concern in cases of seminal vesiculitis include brucellosis, tuberculosis, and paratuberculosis.

CBC/BIOCHEMISTRY/URINALYSIS

- The CBC will usually be normal.
- Certain semen biochemistry values are altered but these have limited clinical relevance.
- Urinalysis may be normal or show an elevated white blood cell count.

OTHER LABORATORY TESTS

- Semen evaluation may reveal an elevated pH, lower sperm motility, increased catalase activity, and lower fructose concentration.
- Leukocytes are not normally seen in ruminant ejaculates but are generally present in seminal vesiculitis. Neutrophils are most commonly seen, but lymphocytes may predominate in some cases.
- Many bulls with seminal vesiculitis have semen quality problems, typically sperm with poor motility or morphologic abnormalities are found.
- Changes in sperm morphology may actually be the result of a concurrent orchitis or epididymitis as part of the seminal vesiculitis syndrome, rather than the direct result of seminal vesiculitis.

IMAGING

- Transrectal ultrasonography is useful for imaging the vesicular glands.
- A 5 MHz transrectal probe with a rigid extension can be used for pelvic examination in small ruminants.
- Affected glands are larger and may have a more or less echoic parenchyma with a relatively hyperechoic appearance to the stromal and ductular network.
- Abscessed glands will show a loss of normal lobar architecture with globoid areas of variable echo-density.

DIAGNOSTIC PROCEDURES

- Culture and antibiotic sensitivity testing are used to confirm cases with a bacterial etiology and to select appropriate treatment.
- Quantitative culture of an ejaculate collected by artificial vagina or electroejaculation may suffice if large numbers of the infectious agent are being secreted in the ejaculate but contamination with urethral, penile, and preputial microflora is unavoidable and may confuse the diagnosis.
- Noncontaminated samples require that the bull be sedated, and the penis be exposed, disinfected, and catheterized followed by transrectal massage of the vesicular glands and collection of fluid.
- Aerobic, anaerobic, and special (e.g., *Mycoplasma*, *Ureaplasma*, *T. fetus*, and fungi) cultures should be performed.
- Routine semen evaluation will usually show hypercoagulation of sperm cells and Diff-Quick staining of semen will confirm pyospermia.

PATHOLOGIC FINDINGS

GROSS FINDINGS

Gross findings are consistent with the physical examination findings.

HISTOPATHOLOGICAL FINDINGS

- The lesions consist of variable leukocytic infiltration of the interstitial and alveolar areas (microabscessation) along with fibrotic and other degenerative changes throughout the glands.
- Sperm cells are frequently seen in the ductular or alveolar regions of the gland.

TREATMENT

APPROPRIATE HEALTH CARE

- Medical treatment with antibiotics, local injection of sclerotic agents, and surgical removal of the affected glands have all been attempted but with limited success.
- Medical treatment is usually done on the farm or at the AI center.

- Surgical treatment consists of unilateral or bilateral vesiculectomy and usually requires hospitalization.
- Given the prolonged duration of medical therapy and the length of time required for postoperative recovery, the bull will usually be lost for at least the current breeding season.

NURSING CARE

N/A

ACTIVITY

Sexual rest is recommended during medical therapy and for at least 6 weeks after surgical therapy.

DIET

N/A

CLIENT EDUCATION

It is imperative that clients understand that there is a guarded to poor prognosis for recovery, therefore, only very valuable bulls should be considered candidates for treatment.

SURGICAL CONSIDERATIONS

- Surgery is performed on the standing bull so restraint of the patient is critical.
- Both a perirectal ischiorectal fossa and a ventral pararectal approach to vesiculectomy are described.

MEDICATIONS

DRUGS OF CHOICE

- Antibiotics based on culture and sensitivity for a minimum of 2–4 weeks and potentially for as long as 6–8 weeks
- Penicillins are appropriate for cases caused by *A. pyogenes*.
- Rifampin, isoniazid, erythromycin, and trimethoprim have been used with some success.
- Nonsteroidal anti-inflammatory agents may improve the response to antibiotics in acute cases and reduce the risk of adhesions.

CONTRAINDICATIONS

N/A

PRECAUTIONS

No drugs available in the United States are labeled for treatment of seminal vesiculitis, so all therapies represent extralabel drug use and require a determination of appropriate withdrawal times before slaughter.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

- Repeat a BSE every 6 weeks for up to 6 months.
- Examine the semen carefully for the presence of pyospermia.

PREVENTION/AVOIDANCE

Avoid crowded and unsanitary conditions that may increase the general risk of infectious diseases, especially those caused by *A. pyogenes*.

POSSIBLE COMPLICATIONS

Postsurgical abscess formation and peritonitis

EXPECTED COURSE AND PROGNOSIS

Guarded to poor prognosis and recovery is often temporary so semen from valuable bulls should be collected and frozen as

soon as it receives a normal evaluation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Seminal vesiculitis can occur in association with primary infections in other organs or as part of the seminal vesiculitis syndrome.

AGE-RELATED FACTORS

- Spontaneous recovery is probably the rule for most young bulls affected with seminal vesiculitis, and treatment of these bulls will often seem to be successful.
- Older bulls are less likely to respond favorably to treatment and have a more guarded prognosis for recovery.

ZOONOTIC POTENTIAL

Brucellosis and tuberculosis can cause seminal vesiculitis in ruminants.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Cattle, sheep, goats

BIOSECURITY

- All males to be used as breeding animals should be subject to the same parasite control and vaccination procedures as the females in the flock or herd except that bulls should not be routinely vaccinated for brucellosis.
- Bulls or bull calves destined for sale to AI centers should not be vaccinated for any diseases unless specifically requested by the facility.
- All breeding males entering a herd or flock should undergo a breeding soundness examination and an appropriate period of quarantine followed by reexamination.

PRODUCTION MANAGEMENT

- Animals affected with seminal vesiculitis have the potential to reduce the reproductive efficiency of food and fiber production systems.
- This reduction occurs most often as a result of the decreased fertility of the affected males but may also involve disease transmission to the females.
- Males with evidence of subfertility or infectious or hereditary diseases should be eliminated from the breeding population.

SENNA (CASSIA SPP.)

BASICS

OVERVIEW

- Annual or perennial herbs or shrubs that cause musculoskeletal problems in ruminants
- These plants are members of the Fabaceae (legume) family.
- Approximately 240 species exist and are found primarily in tropical and warm temperate climates of the world.
- *Senna occidentalis* (common names: senna, coffee senna, coffee weed) and *Senna obtusifolia* (sickle pod, coffee bean, coffee weed) are the two most common species in North America.
- Other common species
 - *S. roemeriana* (twin-leaf senna)
 - *S. fasciculata* (showy partridge senna)
 - *S. lindheimeriana* (lindheimer senna)
 - *S. nictitans* (wild sensitive plant)
- *S. occidentalis* is often found along roadsides and waste places. It prefers partial shade.
- *S. obtusifolia* is commonly a problem in cultivated areas such as cornfields, and prefers sandy soil.
- The sennas are up to 6–8 feet in height, woody and erect.
- They possess alternate, pinnate compound leaves with 4–8 pairs of leaflets or more.
- Flowers are yellow, 1–2 cm.
- Pods on *S. obtusifolia* are sickle shaped, almost four sided, 10–20 cm in length with the ends pointing downward.
- *S. occidentalis* has pods that are more flattened, straighter, and shorter with the ends pointing upward. Seeds are dark brown.
- The plants may contaminate grains, silage, green chop, and hay.
- Ruminants can also become intoxicated by eating the plant in the field, although it is generally not palatable.
- The toxins affect the gastrointestinal tract and skeletal muscles.
- When cattle consume approximately 0.5% body weight of seeds, severe muscle degeneration has occurred.
- Feed containing 10% seeds from *S. occidentalis* will cause disease.
- A 0.2% body weight of green plant consumed daily over 5–7 days or overnight fill on *S. occidentalis* will produce toxicity.

SIGNALMENT

- All ruminants are susceptible, although cattle are most commonly poisoned. Other animals poisoned include horses, pigs, rabbits, and chickens.
- *S. roemeriana* (two-leaved senna) is more common in the western United States and is more likely a problem in the spring.
- Disease associated with *Senna* spp. is usually limited to a few animals unless plants are inadvertently fed in contaminated silage, hay, etc.

SIGNS

- Diarrhea, moderate to severe and shortly after consumption, is usually the first observed sign.
- Progressive muscular weakness indicated by tremors in rear limbs, ataxia, weakness, and eventual inability to rise occurs later in the course of the toxicity.
- Animals are generally afebrile.
- Cattle are often referred to as “bright-eyed downers” as they will sometimes continue to eat, drink, and remain alert. In contrast, other affected animals become lethargic and anorectic.

- The urine becomes dark (myoglobinuria) as muscle degeneration progresses.
- Most animals do not survive once recumbency occurs; death usually occurs within 1–7 days.

CAUSES AND RISK FACTORS

- Anthraquinones are the toxic principles in *Senna*.
- Obtusin, emodin, and obtusifolin toxins are common, but numerous others exist.
- All parts of the plants are toxic. Mature plants are more toxic than younger specimens. Seeds contain the highest concentration of anthraquinones.
- *Senna* spp. are not generally very palatable and are more likely consumed in the late summer and fall when other food sources become scarce.
- Plants are more commonly eaten after the first frost when they are wilted, possibly making them more palatable.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- White muscle disease is associated with deficiencies of vitamin E and selenium.
- Many other causes of “downer” animals

CBC/BIOCHEMISTRY/URINALYSIS

- Myoglobinuria may be mistaken for hemoglobinuria (hemoglobin is visible in plasma, whereas myoglobin is not).
- AST is elevated (10x).
- CK is elevated (10–1000x).
- The elevation in AST and CK reflects acute muscle degeneration.

OTHER LABORATORY TESTS

Evidence of plant consumption

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

- Severe muscle necrosis occurs.
- Pale discoloration and streaking of skeletal muscles may be seen, especially in the quadriceps femoris, semimembranosis, and semitendinosus.
- Hyperemia of the stomach and small intestinal mucosa
- The heart may contain pale streaking and hemorrhages.
- Mild centrilobular hepatic necrosis

TREATMENT

- Primarily supportive treatment of symptoms as there is no specific therapy available.
- Prevent further access to plants and feed a balanced ration.
- Intravenous fluids may help renal function if myoglobinuria is present.
- The use of vitamin E and selenium is contraindicated, as their use will increase myodegeneration and mortality.
- Treatment is usually unrewarding after recumbency develops.

MEDICATIONS

DRUGS OF CHOICE

Activated charcoal dosed at 5 g/kg body weight PO in a water slurry (1 g of activated charcoal in 5 ml water)

CONTRAINDICATIONS

Vitamin E and selenium

**FOLLOW-UP****PATIENT MONITORING**

N/A

PREVENTION/AVOIDANCE

- Prevent animal access to *Senna* spp.
- Maintain appropriate level of nutrition.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Clinical course may last up to 7–10 days.
- Once recumbency occurs, few animals recover.

SHEEP AND GOAT POX

BASICS

OVERVIEW

- Sheep and goat pox is caused by a capripoxvirus that is closely related to the virus that causes lumpy skin disease in cattle.
- Sheep and goat pox is endemic in Africa, the Middle East, India, and most of Asia.
- The disease is characterized by fever and generalized pox lesions on the skin and mucous membranes. A severe bronchopneumonia can also be noted in infected animals.
- The disease is transmitted by direct contact with dried scabs, contaminated fomites, and aerosols from sick animals.
- Sheep and goat pox has not been detected in wild ungulate populations.

SYSTEMS AFFECTED

Production management; potentially all depending on condition

GENETICS

N/A

INCIDENCE/PREVALENCE

In areas where the disease is not present, susceptible adult animals can have a mortality of up to 50%, and lambs and kids can have a mortality of up to 100%.

GEOGRAPHIC DISTRIBUTION

Sheep and goat pox is endemic in Africa, the Middle East, India, and most of Asia.

SIGNALMENT

Species

Sheep and goats

Breed Predispositions

N/A

Mean Age and Range

- Adult sheep and goats tend to have a lower mortality than lambs and kids.
- Naïve adult animals may develop a severe condition with high death losses (may approach 50%).
- Lambs and kids are usually the most severely affected with death losses approaching 95%.
- Animals under 1 month of age usually have a mortality of 100%.

Predominant Sex

N/A

SIGNS

- Depending on the susceptibility of the animal, clinical disease may range from mild to severe.
- Incubation period ranges from 4 to 14 days with the course of the disease lasting up to 6 weeks with various stages of the pox lesions seen at the same time. Complete recovery may take up to 3 months.
- Animals first develop fever, 104–106°F (40–41°C), and become depressed. Increased lacrimation with conjunctivitis and rhinitis are often noted.
- Pox lesions are soon noted in haired and hairless areas of the body. Swelling of the muzzle, nares, and lips is usually noted first. As the disease progresses, characteristic pox lesions develop on the muzzle, nares, lips, eyelids, perineum, scrotum, axillary and inguinal regions, and udder.
- Lesions first appear as circular, raised, erythematous areas (macula). The lesions progress to circular, raised, blanched regions with a central region of fluid (papule). The papules eventually rupture leaving circular umbilicated lesions that scab

over and slowly heal. The associated dermis is often thickened, hard, and edematous.

- Pox lesions often leave deep scars after the lesions heal.
- Pneumonia is often noted with severe labored breathing. Secondary bacterial infections are a common sequela. The animals usually have a persistent cough and are emaciated.
- As the disease progresses, the lesions scab over forming deep, slow-healing ulcers in the skin.

CAUSES AND RISK FACTORS:

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bluetongue: animals develop a high fever and depression and have swollen lips and muzzle. Conjunctivitis with discharge is often noted. Animals often become lame due to a coronitis. Abortions, deformed fetuses, and deformed newborns are common with intrauterine infections.
- Contagious ecthyma (orf): proliferative pox lesions are seen on lips, dental pad, nares, and eyelids in affected young lambs and kids. Adult nursing females may have proliferative pox lesions on the lips, gums, dental pad, and udder.
- Photosensitization: nonpigmented regions of the body may be inflamed with necrosis, edema, and scabbing of the affected epithelium particularly of the lips, muzzle, eyelids, and face.
- Insect bites: localized regions of circular swelling and erythema in the area of the insect bites are usually very pruritic. Mucous membranes are rarely involved.
- *Dermatophilus congolensis* (streptothricosis): superficial scabbing of the skin is noted with intact skin seen underneath the scabs. Lesions are commonly observed in the skin of the neck, axillary and inguinal regions, and perineum.
- Psoroptic mange: scabs and alopecia are due to intense itching of affected areas. Intense itching is not observed with sheep or goat pox.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY FINDINGS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Virus is often isolated from scabs or vesicle fluid.
- Electron microscopy is often used to identify typical brick-shaped poxvirus particles.

PATHOLOGIC FINDINGS

GROSS FINDINGS

- The dermis and epidermis are thickened and edematous. Lymph nodes draining these areas are often swollen and edematous.
- Pox lesions (circumscribed macules, papules, vesicles, and deep circular ulcerated lesions with scabs in later resolving cases) are noted on the muzzle, nares, hairless areas of the axillary and inguinal regions, vulva, prepuce, udder, teats, eyelids, sclera, lips, oral cavity, esophagus, and rumen.
- Lung lesions are randomly distributed throughout the lungs due to hematogenous spread of the virus. The lesions are discrete, hard, grey-white to hemorrhagic nodules that are easily identified in the lungs. The pulmonary parenchyma adjacent to these areas often becomes atelectic due to the affected bronchiole constriction.
- Secondary bacterial pneumonias are often sequela to the infection.

HISTOPATHOLOGIC FINDINGS

- Histologically in the skin, there is acanthosis of the epidermis, with ballooning degeneration of keratinocytes. Necrosis and microvesiculation of the stratum spinosum occurs as the lesion progresses.
- Eosinophilic intracytoplasmic inclusion bodies are noted in the swollen keratinocytes. The dermis is edematous with

some hemorrhage and neutrophilic infiltrates.

- Macrophages accumulate in the affected dermis with some becoming enlarged and swollen with eosinophilic intracytoplasmic inclusion bodies and large vacuolated nuclei with marginated chromatin (cellules claveleuses or sheep pox cells). As the disease progresses, a severe necrotizing vasculitis develops in the affected dermis affecting arterioles and venules with thrombosis of affected blood vessels.
- Necrosis of the affected dermis and epidermis follows.
- Lung lesions are characterized by a proliferative bronchopneumonia with hyperplasia and necrosis of the bronchiolar epithelium. The alveolar septal walls and associated peribronchiolar connective tissue are thickened by edema and hemorrhage. Some type II pneumocyte hyperplasia is noted in alveoli. Variable numbers of macrophages and neutrophils are present in the affected areas with scattered “sheep pox cells” present.
- Eosinophilic intracytoplasmic inclusions can be present in the “sheep pox cells” and type II pneumocytes.
- Mononuclear infiltrates containing sheep pox cells can be noted in the heart, kidney, adrenal glands, liver, thyroid, and pancreas.

TREATMENT

- Since this is a reportable disease in many parts of the world, one should consult with regulatory veterinarians prior to undertaking treatment.
- Treating affected animals is difficult. The administration of an antipyretic drug to make the animal feel better so it will eat and drink is important. Treating the animal with antibiotics for secondary bacterial skin or pulmonary disease may be helpful to the survival of the affected animals.

MEDICATIONS

N/A

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food- producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

N/A

POSSIBLE COMPLICATIONS

Secondary bacterial infections in the skin and lung are possible.

EXPECTED COURSE AND PROGNOSIS

- Animals living in endemic areas usually have some innate immunity.
- In areas where the disease is not present, susceptible adult animals can have a mortality of up to 50%, and lambs and kids can have a mortality of up to 100%.

MISCELLANEOUS

ASSOCIATED CONDITIONS

AGE-RELATED FACTORS

- Lambs and kids are usually the most severely affected with death losses approaching 95%.
- Animals under 1 month of age usually have a mortality of 100%.

ZOONOTIC POTENTIAL

Several suspected human cases of goat pox have been described; however, no virus was isolated from these individuals.

PREGNANCY

N/A

BIOSECURITY

- Quarantine new stock entering the herd/flock.
- Treat and/or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT

The disease is transmitted by direct contact with dried scabs, contaminated fomites, and aerosols from sick animals.

SEE ALSO

- Bluetongue
- Contagious ecthyma (orf)
- *Dermatophilus congolensis* (streptothricosis)
- Insect bites

SHEEP KEDS

BASICS

OVERVIEW

- Pruritic external parasitic skin disease of goats and sheep found in temperate countries and in cooler highlands of the tropics.
- Infestation is caused by *Melophagus ovinus*, a flat, brown wingless sucking insect approximately 4–7 mm in length.

PATHOPHYSIOLOGY

- Keds spend entire life on the host and live less than 1 week off the host.
- Adult females live 100–120 days (4–5 months) and lay about ten keds (10–15 larvae) during this time.
- Larvae are attached to the hairs and wool and pupate within 6–12 hours and mature within 22 days.
- Pupae develop between 25–34°C; optimum temperature is 30°C.
- Ambient temperature affects life cycle, hence their absence in hot, humid areas.
- Keds feed by piercing skin with mouthparts and sucking blood.
- Transmission is via direct contact.
- The ked may transmit *Trypanosoma melophagium* and *Rickettsia melophagi*, harmless blood parasites of sheep.

SYSTEMS AFFECTED

Production management, skin

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on species and environment

SIGNALMENT

- Seen in goats and sheep worldwide
- No age, sex, or breed predilection

SIGNS

- Parasite is found most commonly on neck, shoulders, flanks, rump, and anterior thorax, abdomen, but *not* on dorsum
- Ked bites are pruritic and cause sheep/goats to be restless, bite, scratch, kick, and rub resulting in alopecia, excoriations, and/or broken wool.
- Ked excrement stains wool, which increases cost of processing wool.
- Heavy infestations can result in anemia, weight loss, decreased milk production, secondary infections.
- Hide and wool damage due to continuous scratching and biting by sheep
- Although keds are bloodsucking parasites, they rarely cause anemia unless there is a very heavy infestation. Large numbers of feeding keds gradually exsanguinate the host and cause variable degrees of anemia
- In infected flocks, all individuals are continuously parasitized, but few if any sheep die from uncomplicated ked infestation.

CAUSES AND RISK FACTORS

- A seasonal pattern of infestation occurs. Keds are sensitive to hot, dry weather and numbers decrease markedly in summer. Populations increase slowly over autumn and winter.
- Most common in fall and winter
- Numbers increase during fall and winter because ambient temperature is optimum for reproduction.

- Overcrowding or flocking of animals for shearing increases risk of transmission/infestation.
- Can spread rapidly in spring when sheep are housed together for shearing
- Spring shearing removes many of the keds and extremely high temperatures during the summer months keep the ked population low.
- Keds can live off the hosts for up to 2 weeks in moist mild conditions, but most die within 3–4 days and do not play a role in reinfestation of sheep.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other pruritic skin diseases including *Sarcoptes*, *Psoroptes*, *Chorioptes*, and *Psorergates* spp. mites, lice, trombiculidiasis, forage mites

CBC/BIOCHEMISTRY/URINALYSIS

Anemia in heavily infested animals

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Finding sheep keds on physical examination
- Adults are red brown in color and have a broad head and stout piercing mouthparts.
- Diagnosis is usually obvious; handheld magnifying lens may aid in locating parasite.
- Because of their size and color, both adult and pupal keds on lambs and shorn sheep are conspicuous to the naked eye, but on woolled sheep they are concealed within the fleece and their quantitation requires close inspection between parted fibers.
- Topographically, they concentrate on skin of the neck, sides, abdomen, and rump.

TREATMENT

- Shear wool to remove adults and larvae, especially before lambing.
- Treat sheep after shearing with an insecticide that has residual activity of at least 3 weeks; this will kill emerging pupae.
- Most treatments for lice are effective for sheep keds.
- Whole body vat dipping kills adults but not pupated larvae.
- Spraying, jetting, or shower dipping is most effective in sheared or short-haired animals.
- Spot-on or pour-on treatments are most effective
- If an insecticide with residual activity of > 3 weeks is not used, it will be necessary to repeat treatment several times at 14- to 21-day intervals to kill larvae.

MEDICATIONS

DRUGS OF CHOICE

- Topical (spray, dusts, and pour-ons) and systemic parasitocidal agents effective against lice are effective against keds. To insure proper meat and milk drug withdrawal times, consult FARAD.
- Many drugs licensed for use in dairy or beef cattle are not licensed for use in sheep or goats or in all countries. Effective drugs in cattle include:

- Injectable drugs: ivermectin or doramectin (200 µg/kg body weight)
- Pour-ons: permethrins, ivermectin, epinomectin, amitraz, doramectin, moxidectin
- Diazinon used as a pour-on removed all keds and prevented reestablishment for 9 weeks.
- Amitraz will kill adult keds but has little residual action and therefore is usually combined with another compound to provide sufficient residual action to eliminate infections.
- Coumaphos or malathion liquid for spray or dip application
- Keds are particularly susceptible to organophosphates and most of those used to eliminate lice will also remove keds. Many preparations can also be used in higher dose rates in pour-on applications. Consult labeled instructions prior to treatment.
- Deltamethrin, cyhalothrin, and cypermethrin are effective.
- Cyfluthrin 2 mg/kg pour-on in sheep also eradicates keds and protects for 50 days.

CONTRAINDICATIONS

- Topical sprays and/or dusts represent an environmental risk to people and other nontarget species such as birds, amphibians, and fish, and should be used with appropriate care.
- Care should be taken when disposing of containers and/or topical solutions (i.e., large volumes of dip) to avoid groundwater contamination or runoff. Follow labeled disposal instructions.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Rapid resolution of pruritus should occur shortly after therapy
- Lack of response to treatment may occur if sheep are not sheared and/or if all in contact animals are not treated.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Keds can transmit bluetongue virus.
- Secondary bacterial infections may need to be treated and/or wounds may need to be protected against myiasis.

ZOONOTIC POTENTIAL

N/A

RUMINANT SPECIES AFFECTED

Sheep and goats

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Infestations may result in decreased milk and meat production.
- Infestations may result in damage to the wool and hide resulting in decreased grading.
- Staining of the wool by the keds' feces reduces its value and gives it a musty odor. Heavy infestations cause skin blemishes, which are costly to the leather industry.
- Infected purchased sheep should be treated several times during the quarantine period. Death of the parasites should be verified before the quarantined animals are released into the flock/herd.

SYNONYMS

Sheep ticks

SILAGE DISEASE

BASICS

OVERVIEW

- Silage is the process of sealing grass and other forages in anaerobic conditions and allowing fermentation to occur. The water-soluble plant carbohydrates are converted to organic acids (especially lactic acid) by anaerobic bacteria. Proteins degrade to amino acids and other nitrogenous compounds. Ensiled feeds remain stable for years, provided that anaerobic conditions are maintained.
- Silage is most often fed to dairy cows or used in feed lots.
- There are three potential hazards from silage: (1) infectious, (2) chemical, (3) metabolic disorders from excess acidity, poor-quality silage, unpalatability, etc.
- The phrase “silage disease” most often refers to listeriosis.
- Potential economic losses from decreased productivity, illness, or death caused by poor-quality or damaged feeds can be significant.

SYSTEMS AFFECTED

Potentially all, depending on the disorder

GENETICS

N/A

INCIDENCE/PREVALENCE

- Can occur anytime, depending on etiology
- In some instances, silage is mostly fed in winter and spring.

GEOGRAPHIC DISTRIBUTION

Potentially worldwide. In some parts of Europe, silage production is prohibited or discouraged because of the risk of zoonotic diseases like listeriosis.

SIGNALMENT

Species

Most frequently cattle, although possible in any species fed silage

Breed Predilections

N/A

Predominant Sex

N/A

SIGNS

Clinical signs vary depending on etiology.

Sources

- Spoiled silage
- Elevated pH (not enough acidity)
- Improper ensilage
- Oxidative damage
- Contaminated silage (bacteria, mycotoxins, carcasses, toxins such as lead or fertilizers)
- Ammoniated high-quality forage

CAUSES AND RISK FACTORS

- Temperature, moisture content, and oxygen are important components in allowing the growth of microbes or molds. A change in optimum conditions allows deterioration of the silage. Feed deterioration allows the loss of dry matter and

reduces simple carbohydrate content and loss of fat-soluble vitamins. Proteins can bind to carbohydrates forming an undigestible complex. Mycotoxins may be produced.

- Silage should be observed visually for changes in color (especially dark brown to black). Silage generally has a sweetly acidic smell or an acetone odor. If the odor changes, especially if musty, sour, or burnt caramel odor, damage has probably occurred.
- Normal fermentation temperature typically results in a 20°F rise in temperature. After oxygen is used, the temperature will fall to near-ambient temperatures. Temperatures above 95°F (35°C) should be avoided to reduce dry matter and energy losses.

DIAGNOSIS

History

Questions should include:

- How many animals are affected (ill or died)?
- What is the age of affected animals?
- What is the current feeding program?
- When was silage produced, and what forages were included?
- How long has the silage been fed to affected animals?
- Has a diagnosis been made, and is silage a potential source of contamination?

Animal Diagnostic Samples

- Standard samples should be included as part of a complete workup.
- Blood
 - Whole blood–EDTA (5–10 ml per animal)
 - Serum–5–10 ml per animal
- Urine
 - 50–100 ml
 - Store in an airtight bottle with a tight lid.
- Ingesta/feces–up to 500 g
- Consult the local diagnostic laboratory
 - Provide clinical history, signs, and signalment so that the laboratory may provide suggestions for additional samples or recommended tests.
 - The diagnostic lab will provide their recommendations for sample sizes, containers, and shipping preferences.

Feed Sample and Submission

- 500 g or more of a composite sample within a lot
- Each lot should be tested separately.
- Multiple grab samples from each lot should be obtained, increasing the chance of identifying the problem.
- Silage should be frozen.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Metabolic
 - Acidosis (often subclinical)
 - Decreased production (due to poor-quality feed or poor palatability)
- Infectious
 - *Listeria monocytogenes*

- *E. coli* and other coliform bacteria
- *Clostridia* spp.
- *Cryptosporidium parvum*
- Mycotoxins, especially from *Aspergillus fumigatus*, *Actinomyces*, *Penicillium*, and *Fusarium* species
- Chemical
 - Contamination with lead or other heavy metals (especially if industrial manufacturing is nearby)
 - Respiratory disease (similar to silo-filler's disease in humans) can occur if cattle are confined immediately adjacent to the silo.
 - Bovine bonkers (ammoniated high-quality forage)
 - Contamination with other potential toxins including fertilizers, insecticides, rodenticides, etc
 - Contamination with carcasses of other animals, providing a potential source of botulism
 - Phytoestrogens and other plant toxins can survive ensilage.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Significant zoonotic potential exists.
- Infectious potential from diseases like listeriosis
- Contamination of milk with mycotoxins such as aflatoxin M1 metabolites.
- Several of these diseases are zoonotic. Care must be taken in the collection of laboratory samples and the diagnosis/treatment of affected animals.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

- Potentially all ruminant species can be affected.
- Most frequently cattle, although possible in any species fed silage.

BIOSECURITY

Reasonable precautions should be taken to prevent unauthorized personnel from access to feeds or cattle because deliberate contamination of silage could occur.

PRODUCTION MANAGEMENT

See Causes and Risk Factors and Animal Diagnostic factors above.

SNAKEBITE

BASICS

OVERVIEW

- Pit vipers account for a majority of venomous snakebites in North America.
- Named for the temperature-sensitive pit organ between the eye and the nostril, they include rattlesnakes (*Crotalus* spp.), cottonmouths (water moccasins), and copperheads (*Agkistrodon* spp.), and pygmy rattlesnakes and massasaugas (*Sistrurus* spp.). They are identified by a triangular head, elliptical pupils, keeled scales, and the presence of tail rattles in adults. Young rattlesnakes have a blunt tip on the tail until it is broken off.
- These snakes are aggressive and inject a neurotoxic or hemotoxic venom designed to incapacitate or predigest its victim with a small, potent dose. Venom is delivered through hinged, hollow, retractable, fangs, in a rapid, stabbing motion.
- Coral snakes (*Micruroides euryxanthus* and *Micrurus* spp.) are nocturnal, nonaggressive, and rarely responsible for venomous bites to farm animals. They bite with short fixed fangs and hold on, delivering a neurotoxic venom by chewing.
- Envenomation in all victims is potentially fatal and a medical emergency.

PATHOPHYSIOLOGY

- The composition and mechanism of action of the various components of snake venoms continues to be elucidated.
- Venoms have generally been classified as hemotoxic or neurotoxic depending on predominant physiological effects.
- Hemotoxic venom contains enzymatic proteins that aid in tissue degradation and digestion (metalloproteases, hyaluronidase, collagenase); affect hemostasis (plasminlike protease, thrombinlike protease, kallikreinlike protease); hydrolyze second messengers like cAMP (phosphodiesterases) and potent, nonenzymatic polypeptides, resulting in pain, massive swelling, tissue necrosis, and abnormalities in coagulation.
- Neurotoxic venom produces significantly less local tissue destruction and pain, but has profound effects on both pre- and postsynaptic skeletal muscle and nonskeletal muscle neuromuscular junction sites including muscarinic and neuronal receptors, and K^+ , Na^+ , and Ca^{2+} ion channels. Phospholipase A_2 causes membrane disruption and mediates many of the neurotoxic and cardiotoxic biochemical changes. Numbness, muscle fasciculations, paralysis, and respiratory collapse result.

SYSTEMS AFFECTED

- Cardiovascular—tachycardia, cardiac arrhythmias, edema, shock, death
- Endocrine/metabolic—pyrexia,
- Hemic/lymphatic/immune—hemoconcentration, hypoalbuminemia, thrombocytopenia, enlarged regional lymph nodes, leukocytosis, lymphangitis
- Hepatobiliary
- Musculoskeletal—weakness, muscle fasciculation, rhabdomyolysis, tissue necrosis
- Nervous—pain, paresis, respiratory depression, anxiousness or depression, paralysis
- Ophthalmic—epiphora
- Renal/urologic—hematuria, proteinuria, renal failure
- Reproductive
- Respiratory—inspiratory dyspnea, epistaxis, asphyxiation if swelling occludes nasal passage or larynx, respiratory failure due to paralysis
- Skin/exocrine—sweating

GENETICS

None

INCIDENCE/PREVALENCE

Unknown in large animals

GEOGRAPHIC DISTRIBUTION

Pit vipers are widely distributed throughout the United States (except Alaska, Hawaii, and Maine). They survive in parts of Canada, Mexico, South America, and Australia. Coral snakes inhabit the southern United States from Arizona to Florida; worldwide in the tropics.

SIGNALMENT

Breed Predilections

None

Mean Age and Range

None

Predominant Sex

None

SIGNS

HISTORICAL FINDINGS

Usually one animal is affected at a time but several may be affected over the course of a season.

PHYSICAL EXAMINATION FINDINGS

Rapid, regional swelling with severe pain, edema, ecchymosis, petechiation, bleeding puncture wounds may or may not be apparent, tissue necrosis, inspiratory dyspnea, and epistaxis (especially if bite is near muzzle), increased salivation, dysphagia, anorexia, lethargy, weakness, reluctance to move, muscle fasciculations, tachycardia, cardiac arrhythmias, shock, numbness, paresis, paralysis, respiratory collapse, and CNS signs

CAUSES

Snakebite with envenomation

RISK FACTORS

Snake

Size, age, nutritional status, and species of snake (aggressive species are more likely to strike), amount of venom injected (25% of bites are “dry” with no injection of venom), and the toxicity of the venom, which will vary between species (rattlesnakes > water moccasins > copperheads), within species, and within the same individual snake as it ages or as the size of its prey changes

Victim

Depth of bite and location (tongue, muzzle, face, body wall, or directly into a large vessel pose the greatest risk), age and size of victim (younger and smaller animals are more likely to sustain bites resulting in fatality), preexisting health conditions that affect cardiovascular, respiratory, renal, or hematological physiology or preexisting conditions that compromise immune response, victim's susceptibility to venom, time to medical treatment (animals often survive the initial bite to succumb to infection later due to delayed discovery and treatment), and activity after bite (activity increases the distribution of venom).

Location/Habitat/Time of Year

Animals that crowd into shaded areas in hot summer months especially adjacent to watering holes, woodpiles, rocky outcroppings, overgrazed pastures, during drought, April-October when snakes are active

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Trauma, insect envenomation, abscessation, lizard bite

CBC/BIOCHEMISTRY/URINALYSIS

- Hemoconcentration, thrombocytopenia, leukocytosis, echinocytosis
- Elevated CPK
- Myoglobinuria, hematuria, proteinuria, glucosuria

OTHER LABORATORY TESTS

- Serial coagulation profiles, fibrinogen

- Serum antibodies to venom
- Detection of venom in serum

IMAGING

Ultrasonography or radiography may rule out traumatic injury or puncture.

DIAGNOSTIC PROCEDURES

- Marking the leading edge of the swelling along with circumferential measurements of limb or muzzle may give an indication of progression.
- ECG

PATHOLOGIC FINDINGS

GROSS FINDINGS

Variable: swelling, serous exudation, tissue necrosis, and/or sloughing; hemorrhage, especially at bite site; passive congestion of all organs; hemorrhagic icterus

HISTOPATHOLOGICAL FINDINGS

Highly variable

TREATMENT

- Maintain patent airway by preplacing nasal tubing prior to occlusion or by tracheostomy if necessary, IV fluid support (LRS or 0.9% NaCl solution) for hypotensive cases.
- Keep animal calm, restrict movement, gently wash wound to remove topical debris, do not infuse fluids into wound.

APPROPRIATE HEALTH CARE

NURSING CARE

Wound care and debridement as necessary

ACTIVITY

Restrict activity and movement

DIET

Food and water should be readily accessible and feed should be easy to swallow.

CLIENT EDUCATION

SURGICAL CONSIDERATION

N/A

MEDICATIONS

DRUGS OF CHOICE

- Antivenin is the treatment of choice. Recommendations for human bite victims are for treatment with multiple vials, but one to two vials may be sufficient to improve outcome in animals.
- Administration of antivenin as early as possible after envenomation may preclude the need for treatment with additional vials later.

Antivenin

- Antivenin; CroFab Crotalidae Polyvalent Immune Fab (Ovine) (Protherics Inc., Nashville, TN 37212) is composed of four antivenins—*Crotalus atrox* (western diamondback rattlesnake), *Crotalus adamanteus* (eastern diamond rattlesnake), *Crotalus scutulatus* (Mojave rattlesnake), and *Agkistrodon piscivorus* (cottonmouth or water moccasin). A study in dogs has been conducted with good results utilizing 1–2 vials of antivenin.
- Antivenin (Crotalidae) Polyvalent (ACP) equine origin (Wyeth Laboratories Marietta, PA 17547) is the only antivenin product labeled for use in animals. It is composed of antivenins from *Crotalus adamanteus* (eastern diamond rattlesnake), *C. atrox* (western diamond rattlesnake), *C. durissus terrificus* (tropical rattlesnake), and *Bothrops atrox* (fer-de-lance).
- Antivenin (*Micrurus fulvius*) equine origin (Wyeth Laboratories Marietta, PA 17547) will neutralize the venom of

Micrurus fulvius tenere (Texas coral snake) but will not neutralize venom of *Micruroides euryxanthus* (Arizona or Sonoran coral snake).

- Current use in animals is extralabel.
- Be prepared to treat for allergic reaction.

Other Treatments

- Treatment with broad-spectrum antibiotics
- Nonsteroidal anti-inflammatory medication for pain
- Revaccinate with tetanus and clostridium toxoids

CONTRAINDICATIONS

PRECAUTIONS

- Use caution when handling a dead snake. Reflex bites have occurred.
- Treatments previously utilized that have been shown to be either ineffective or detrimental include incision, suction, the infusion of fluids into wound area in an attempt to dilute toxin, the application of hot or cold compresses, tourniquets, or electric shock.
- Corticosteroids in treatment of venomous snakebite have been widely used in veterinary medicine, but their effectiveness and continued use is controversial.
- Corticosteroids delay healing and may interfere with the effects of antivenin. No studies have demonstrated an increased survival rate with use of corticosteroids. Use for treatment of allergic reaction associated with antivenin treatment.
- Colloids may increase risk of bleeding diathesis, complicate interpretation of coagulation profiles, or cause anaphylaxis. Use with caution.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered.

POSSIBLE INTERACTIONS

Corticosteroids may interfere with antivenin.

ALTERNATIVE DRUGS

FOLLOW-UP

PATIENT MONITORING

- Serial monitoring of coagulation profiles, complete blood count and blood chemistry, urinalysis, and cardiac parameters should be performed as often as warranted by the clinical condition, especially in the first 48 hours.
- Tissue destruction may not peak for several days. Swelling resolves in 3–7 days in most cases that survive.
- Recurrent coagulopathy may occur 1–2 weeks after administration of antivenin due to the shorter persistence of antivenin in the blood as compared to venom.

PREVENTION/AVOIDANCE

POSSIBLE COMPLICATIONS

EXPECTED COURSE AND PROGNOSIS

- Most adult animals survive if found in time to prevent respiratory collapse.
- Mortality is more common in younger, smaller animals.
- Systemic neurological signs and severe tissue necrosis may result in permanent deficits.

MISCELLANEOUS

ASSOCIATED CONDITIONS

AGE-RELATED FACTORS

Young animals are more at risk due to their inquisitive nature. A bite with envenomation is more likely to result in mortality due to smaller body size.

ZOONOTIC POTENTIAL

Wear gloves to protect hands with skin abrasion when treating wounds.

PREGNANCY

Fetal death as a result of venomous snakebite has been reported in humans.

The safety of antivenin treatment during pregnancy in animals has not been established.

RUMINANT SPECIES AFFECTED

All species are susceptible.

SOLE LESIONS IN DAIRY CATTLE

BASICS

OVERVIEW

- Lameness is common in dairy cows, with most lesions affecting the sole.
- The most significant lesions of the sole are *white line abscesses* and *sole ulcers*
- An initial insult to the corium primarily affects the laminar region and that corium damage increases with the resulting alteration in the physical forces on the sole.
- The risk of sole lesions is related to stage of lactation, individual cow factors, and farm characteristics. Claw disorders associated with chronic subclinical laminitis are primary causes of lameness in most herds.
- Ninety percent or more of lameness in dairy cattle involves the foot. Of that involving the foot, most involves rear feet, particularly the lateral claw.
- Cows most at risk of sole lesions are those with low body condition scores, first lactation cows in early lactation and second + lactation cows in mid- to late lactation.
- Farms most at risk are those with high steps or stall curbs, long standing times during milking, automatic alley scrapers, and flooring imperfections (e.g., holes in concrete).

SYSTEMS AFFECTED

Musculoskeletal

GENETICS

N/A

INCIDENCE/PREVALENCE

- Surveys have suggested that the incidence may be as high as 55 cases per 100 cows per year.
- Another survey estimated an incidence rate of 30 cases/100 cows/year, a fatality rate of 2%, an increase in days open of 28 days, and costs for treatment and additional labor of \$23/case, estimating a cost of \$9000/100 cows/year.

GEOGRAPHIC DISTRIBUTION

Worldwide depending on the environment

SIGNALMENT

Although white line abscesses can be seen in any bovine, they are most common in the lactating dairy cow. Sole ulcers are seen almost exclusively in housed, lactating dairy cattle.

Species

Dairy cattle

Breed Predispositions

Dairy breeds

Mean Age and Range

Adult dairy cattle

Predominant Sex

Lactating dairy females

SIGNS

- Cows with a white line abscess typically present with severe acute lameness. Close examination of the foot will demonstrate the presence of heat within the affected digit.
- The site of the abscess can normally be determined by using equine hoof testers around the periphery of the abaxial wall. Using a hoof knife, the sole should be cleaned and a thin layer of horn removed. The key sign to identify is a dark mark within the white line at the site identified with the hoof testers. This is most likely the site at which the abscess formed.

- Cows with sole ulcers typically suffer from low-grade lameness for a period of time that slowly progresses to a severe lameness over a period of weeks. Depending on the severity of the lesion, the foot may appear normal or grossly swollen.
- Lesions are most commonly seen in the lateral hind claw. The sole of the claw may appear normal on initial examination, however, using hoof testers an area of pain is typically identified approximately two-thirds of the way back from the toe and toward the axial wall.
- As the sole is trimmed with a knife, it is common to find evidence of old hemorrhage within the horn of the sole at this site. Eventually, a portion of horn will be removed to reveal a full thickness defect of the sole with granulation tissue protruding from the underlying corium.
- In severe cases, bacteria may enter through the defect resulting in cellulitis that may spread to involve the navicular bursa, heel bulb, deep digital flexor tendon, or the distal interphalangeal joint.

CAUSES AND RISK FACTORS

- The fibrous junction between the sole and wall horn, colloquially known as the “white line,” is the weakest portion of the sole. Even in a normal animal, it is common to see a small amount of debris impacted into this area.
- Dairy cattle are prone to a subclinical laminitis-like syndrome as a result of being fed diets rich in easily fermentable carbohydrate and low in long-stem fiber.
- Alterations in the internal structure of the hoof may result in separation and weakness of the white line. Areas of hemorrhage may also be visible within the horn in the region of the white line. Weakening of the white line allows debris to become impacted into the area. Should contaminated debris breach the white line and reach the corium, an abscess will form. Such abscesses cause extreme pain as they enlarge due to the great pressures developed between the base of the pedal bone and the hoof capsule, neither of which are flexible.
- Unlike horses where the abscess has a tendency to enlarge and track up the wall of the hoof and burst out at the coronary band, abscesses in cattle commonly tract caudally below the sole and burst out in the region of the heel.
- The same subclinical laminitis syndrome described above can result in a weakening of the attachments between the laminae of the wall and sinking of the pedal bone within the hoof capsule. This results in the ventral surface of the pedal bone compressing the corium of the sole against the horn of the sole. This compression appears to be most marked in the region of the flexor process of P3.
- In addition to changes within the hoof, there are important changes seen in the morphology of the dairy cow’s hoof. In the hind limb, the lateral claw is under asymmetrical stress when compared to the medial claw. This overloading of the lateral claw tends to result in hypertrophy of the sole horn, which further overloads the claw.
- In most dairy cows, overgrowth of the claw is characterized by a disproportionate overgrowth of the toe. This, combined with the commonly seen erosion of the heel horn, results in weight bearing by the claw being transferred from the toe back toward the heel region.
- When all these factors are combined, it is apparent that the heel region of the lateral hind claw is under a great deal of stress. As P3 sinks within the hoof capsule, the corium is compressed between the flexor process and the sole. This initially results in hemorrhage. The blood is incorporated into the horn and may be seen in the sole as bruising. As the condition progresses, the corium undergoes pressure necrosis and horn formation in the area is halted. This results in a defect in the sole that grows from the inside to the external environment. When the defect is full thickness, a sole ulcer has formed exposing the corium, causing pain and providing a portal for bacterial entry to the deep structures of the hoof.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other causes of acute lameness in dairy cattle include:

- Digital dermatitis
- Lacerations
- Foreign bodies
- Fractures
- Foot rot: this condition may be easily distinguished from the above by close examination of the foot.
- Abscesses may on occasion be due to penetration of the sole by a sharp foreign object, but this is comparatively rare

compared to white line disease.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Radiology of the distal limb may be of benefit in cases where there is concern that infection may have spread to either the navicular bursa or the distal interphalangeal joint.

DIAGNOSTIC PROCEDURES

- Lesions are diagnosed on the basis of the characteristic clinical signs. All that is necessary is close examination of the foot.
- In cases where the infection has spread to the deep tissues of the foot, it is common to identify that the foot is grossly swollen. The swelling seen in such cases may be distinguished from simple foot rot on the basis that the swelling is asymmetrical and centered on one claw.
- The swelling is typically found in either the heel region or around the cranio-lateral aspect of the coronary band.

TREATMENT

- White line abscesses require drainage to provide pain relief and promote healing of the lesion. Having identified the suspected site of the abscess, a hoof knife should be used to resect the wall horn and to follow the lesion to the corium and drain the abscess. Once the abscess is open, the extent of the abscess should be determined using a blunt probe. The entire defect should be opened and all underrun horn removed.
- Care should be taken to avoid leaving any jagged or underrun edges, which would allow foreign material to impact in the lesion.
- When dealing with a sole ulcer, it is important to first trim the foot to normalize weight bearing between the medial and lateral claws as well as adjusting the plane of the sole to prevent excessive weight bearing in the heel region. Finally, the axial aspect of the sole should be hollowed out to prevent any weight bearing in the region of the flexor process.
- The area of the sole ulcer should be trimmed with great care to remove any underrun horn tissue.
- Bandaging the lesion left by an abscess or sole ulcer is of no value as the dressing simply becomes contaminated with fecal material. The lesions should be left open to heal.
- Animals will benefit from the application of an orthopedic block (Technovit or similar) to the opposite claw. This will minimize weight bearing by the affected claw promoting healing, and will also elevate the lesion from the contaminated floor surface when the animal is walking.

MEDICATIONS

- Antibiotics are not indicated in the treatment of simple uncomplicated abscesses or sole ulcers. They are indicated only when infection has spread to the deeper structures of the foot.
- Some clinicians may elect to use NSAIDs to provide analgesia in severe cases (e.g., ketoprofen 3 mg/kg).

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- The majority of animals will show immediate relief after trimming of the lesion and application of an orthopedic block.

- Animals that remain significantly lame after 1 week should be reexamined.
- Orthopedic blocks should always be removed within 7 weeks of application. At this time, it is also appropriate to perform a minor hoof trim to encourage complete resolution of the lesion.

PREVENTION/AVOIDANCE

- Attention should be paid to the dairy cow ration to ensure that it always contains sufficient long-stem fiber to prevent ruminal acidosis.
- Dairy cows should have their feet trimmed on a regular basis to prevent overloading of the lateral hind claw.
- Attention should be paid to the design of the dairy barn to ensure that cows can always lay down in comfort. Cows at pasture typically lay down for two-thirds of the day. When the animal is recumbent, the feet do not bear weight and therefore the diseases cannot develop.

EXPECTED COURSE AND PROGNOSIS

- Simple uncomplicated white line abscesses typically resolve without complication in 4–6 weeks.
- Simple sole ulcers typically take longer to fully resolve but should heal within 2 months.
- The prognosis for infections that involve the deep structures of the hoof is always guarded. Since many of these cases typically present late in the disease course, the infection is well established and there is already significant pathology.
- Aggressive antibiotic therapy is warranted but rarely successful.
- A number of surgical procedures have been described to salvage the claw, but due to the expense involved, many clinicians opt to amputate the affected digit and salvage the cow in that manner.
- Studies have shown that the life expectancy for a dairy cow following amputation of a digit is less than 1 year.

MISCELLANEOUS

ASSOCIATED CONDITIONS

SQUAMOUS CELL CARCINOMA

BASICS

DEFINITION

SCC is a malignant tumor of epidermal cells that exhibit differentiation to keratinocytes.

PATHOPHYSIOLOGY

- Multiple factors have been implicated in the development of SCC in ruminants:
 - Exposure to ultraviolet light resulting in DNA damage
 - Papillomavirus infection causing precursor lesions that then undergo neoplastic transformation
 - Exposure to carcinogens in bracken fern can result in malignant transformation of papillomas of the upper gastrointestinal tract and bladder.
 - Immunosuppression by bracken fern can prevent rejection of early neoplastic lesions.
- Lack of pigmentation in the periocular tissues in the corneoscleral region greatly increases the risk of developing ophthalmic SCC in cattle exposed to high levels of UV light.
- There is a significant association between all measures of exposure to solar radiation and the development of OSCC.
- Twenty-six of 41 OSCCs (63.4%) showed abnormal expression of p53, a tumor suppressor gene.
- Some SCCs are thought to progress from plaques, papillomas, or carcinoma in situ.
- Some neoplastic lesions appear independently, without precursor lesions.
- Invasive OSCC of the palpebrae and medial canthus metastasize more commonly than do OSCC arising from the globe.
- OSCC can result in significant financial loss to the herdsman due to condemnation of the carcass at slaughter and premature loss of breeding stock.
- Cutaneous SCC may occur as a result of BPV infection and chronic sun exposure.

SYSTEMS AFFECTED

- Ophthalmic (OSCC)
- Skin
- Gastrointestinal
- Renal/urologic

GENETICS

- The high incidence of OSCC in Hereford and Hereford-cross cattle resulted in long belief in a heritable component.
- More recent studies have demonstrated that the relationship between tumor development and breed is actually the result of a strong association between lid and corneoscleral pigmentation, which are heritable traits, and the development of OSCC.

INCIDENCE/PREVALANCE

- When recording incidence, typically preneoplastic and early neoplastic lesions (plaques, papillomas and carcinoma in situ) are included in the affected group.
- Within the Hereford breed of cattle in the United States, estimates of the incidence of OSCC have ranged from 0.8% to 5%.
- In Australia, the incidence of ocular tumors within some Hereford cattle herds has ranged as high as 10–20%.
- In the Netherlands, the incidence of OSCC is estimated at 0.04%.
- Observation of five herds of Simmental cattle in Zimbabwe demonstrated an incidence of OSCC of 36–53% in cattle over 7 years of age.
- The incidence of OSCC increases with age.
- Bladder SCC is very rare except in endemic areas, where the incidence of bladder neoplasia may range from 15 to 25%.

- Cows with bladder SCC may have more than one type of tumor in their bladder.

GEOGRAPHIC DISTRIBUTION

- Most OSCC in the United States occurs in the South and Southwest—development of OSCC is associated with increase in altitude and mean annual hours of sunlight and with decreases in latitude.
- Australia and some regions in Africa also experience a significant number of cattle afflicted with OSCC.
- SCC of the upper intestinal tract and bladder are most common in regions where the cofactor for tumor development, bracken fern, exists along with infection of the cattle with BPV-4.
- This combination of factors resulting in SCC of the upper intestinal tract was initially reported in Scotland, but additional reports from Europe, Africa, and South America have been published.
- SCC of the muzzle, ears, and perineal region of sheep is a significant problem in Australia.

SIGNALMENT

Species

- SCC of all types is seen primarily in cattle, but has been reported in sheep.
- SCC is rare in goats.

Breed Predilection

- In the United States, Hereford and Hereford-cross cattle are most likely to be affected with OSCC.
- Other breeds in which OSCC is reported include Simmental, Holstein Friesians, and rarely in other breeds.
- Sheep develop SCC in regions that are not covered by wool and are not pigmented.

Mean Age and Range

- The mean age of cattle with OSCC is 7–8 years, with a decreasing mean age in areas of highest ultraviolet light exposure.
- OSCC has been seen in cattle as young as 3 years of age, and there is a 2% increase in the risk of affliction with OSCC for each additional month of age.
- SCC of the upper intestinal tract and bladder is typically found in cattle between 6 and 12 years of age.

Predominant Sex

- Although most afflicted cattle are cows, that simply reflects the fact that most herds are made up primarily of cows, and bulls are kept in fewer numbers.
- The same is true of ewes and rams.

SIGNS

- OSCC: mass can be flat white plaques, papillomas with raised surfaces, and SCC can be an irregular, pinkish mass; can present with secondary conjunctivitis.
- SCC of the upper intestinal tract can result in bloat, regurgitation of ruminal contents, or pain and difficulty on swallowing.
- As SCC of the intestinal tract progresses, there is loss of condition and abdominal pain.
- SCC of the bladder is typically associated with hematuria.
- Clinical signs associated with distant metastasis are rarely seen.

HISTORICAL FINDINGS

- OSCC: ocular discharge
- SCC of the upper intestinal tract: weight loss, difficulty eating, regurgitation of ruminal contents

PHYSICAL EXAMINATION FINDINGS

- OSCC: precursor lesions can be flat white plaques or papillomas with raised, textured surfaces, and SCC can be an irregular, nodular, pinkish mass, possibly invading the normal tissues.
- OSCC: most common site is the limbus, followed by the eyelids, nictitating membrane, and medial canthus
- OSCC: parotid lymph node may be enlarged
- SCC of the upper intestinal tract: bloat, regurgitation, loss of condition, painful abdomen
- Cutaneous SCC: horny outgrowths of skin or scales that are painful on manipulation, occurring on unpigmented or lightly pigmented skin in the sacral region, dorsum, and escutcheon.

CAUSES

Ophthalmic and Skin

- Exposure to ultraviolet light

- Lack of pigmentation
- Infection with bovine papillomavirus

Upper Gastrointestinal Tract and Bladder

- Infection with BPV-4 and/or BPV-2
- Ingestion of bracken fern or other carcinogenic and immunomodulatory compounds
- Trauma

RISK FACTORS

- Lack of periocular pigmentation and corneoscleral pigmentation
- High levels of exposure to UV light
- Increased nutritional intake (OSCC)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Papillomas
- Keratoacanthomas
- Carcinoma in situ
- Dermoid cyst
- Follicular hyperplasia of the third eyelid

CBC/BIOCHEMISTRY/URINALYSIS

OSCC and SCC of the Upper Intestinal Tract

N/A

SCC of the Bladder

- Anemia
- Hematuria

OTHER LABORATORY TESTS

N/A

IMAGING

- Radiographs of the chest are indicated prior to final prognosis and possible surgical intervention.
- Wide surgical excision of an invasive OSCC in a valuable animal is indicated if radiographs are negative for metastasis.
- Ultrasound of the abdomen and neck region may help in the diagnosis of upper intestinal SCC or in the diagnosis of a bladder tumor.

DIAGNOSTIC PROCEDURES

OSCC

- In valuable animals, a biopsy or scraping of an ocular lesion may confirm a clinical impression of OSCC.
- Cytologic diagnosis agrees with histopathologic diagnosis 85–90% of the time.

PATHOLOGIC FINDINGS

OSCC

- Invasion into the normal tissues, including bone and along the optic nerve may be seen.
- Metastasis to the ipsilateral parotid and lateral retropharyngeal lymph nodes may be seen.
- Five percent of cattle with OSCC have lung metastasis at slaughter.
- Histopathology of OSCC included epidermal hyperplasia, hyperkeratosis, parakeratosis, acanthosis, accentuation of the epidermal rete, and keratinocyte dysplasia. Extending into the dermis are cords and islands of neoplastic cells demonstrating a variable degree of epithelial differentiation, sometimes including “keratin pearls.”

SCC of the Skin, Upper Gastrointestinal Tract and Bladder

- Individuals affected with upper GI SCC may have multiple papillomas of the oral cavity and throughout the upper and lower GI tract.

- Histopathologic findings are similar to those described above.

TREATMENT

APPROPRIATE HEALTH CARE

- Early detection of OSCC is important in order for treatment to be effective.
- Up to 75% of small lesions (<5mm in diameter) will regress spontaneously.
- Multiple treatment modalities can be used successfully on early lesions.
- Treatment of OSCC with hyperthermia (raising the temperature in the tumor to 50°C for 30 sec/cm² of tumor surface), resulted in complete regression in 90.7% of tumors treated, and this regression lasted at least for 5.5 months in all animals, and for a year in the cattle available for monitoring at that time.
- Radiation therapy, administered with implants of gamma-emitters such as cobalt-60, gold-198, or cesium-137, has been quite effective at controlling OSCC, however, these methods are quite costly and not widely available.
- Cryosurgery, utilizing two freeze/thaw cycles (freezing to -25°C, allowing a thaw and repeating) has been reported to result in a 97% complete regression rate.
- A study with more complete follow-up demonstrated that approximately 71% of lesions treated with cryosurgery had complete regression without recurrence with follow-up data for up to 3.5 years.
- Almost 6% of lesions in this study recurred after initial regression, and 17.6% did not respond to cryosurgery.
- Immunotherapy has been investigated for the treatment of OSCC, but has limited efficacy.
- No effective treatments exist for SCC of the upper gastrointestinal tract and bladder.

NURSING CARE

N/A

ACTIVITY

N/A

DIET

- A high level of nutrition has been correlated with increased risk of developing OSCC.
- The ingestion of bracken fern is a critical cofactor to the development of upper gastrointestinal tract SCC and bladder tumors and should be avoided.

CLIENT EDUCATION

- Lesions may recur locally so treated animals should be examined periodically (every 3 to 4 months) for evidence of recurrence.
- Cryosurgery or hyperthermia can result in hair loss at the treated site.

SURGICAL CONSIDERATIONS

- Surgical removal of OSCC and precursor lesions is only moderately successful in controlling the disease with recurrence rates of 37–48% reported.
- En bloc excision of the tumor and regional lymph nodes can be performed to salvage valuable animals, but is not cost effective in most instances.

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

All cattle should be examined on a regular basis for OSCC, at least three times a year (including once in the summer months) during routine maintenance health treatments.

PREVENTION/AVOIDANCE

- Breeding cattle for pigmentation in the periocular tissues as well as for pigmentation of the corneoscleral junction will decrease the incidence of OSCC.
- Routine evaluation of all eyes, with cryosurgery or surgical removal of lesions that are enlarging and greater than 5 mm in diameter, greatly decreases the development of lesions that would result in financial loss to the herdsman (through carcass condemnation and premature loss of breeding stock).

POSSIBLE COMPLICATIONS

- Premature loss of breeding cows
- Carcass condemnation at slaughter due to metastasis or multiple SCC

EXPECTED COURSE AND PROGNOSIS

- Untreated, OSCC will invade normal tissues (including, potentially, the CNS) and ultimately metastasize to the regional lymph nodes and lungs. Extensive disease can result in carcass condemnation and thus financial loss.
- With surgical excision (enucleation or mass resection), local recurrence is common (37% in one report), but may allow salvage of the animal for slaughter.
- Cryosurgery, with a two-freeze cycle, will result in a 77–97% complete response rate. Approximately 71% of responding tumors did not recur in one study following cryosurgery.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Infection with bovine papilloma viruses is thought to cause the initial precancerous lesion.

AGE-RELATED FACTORS

OSCC are typically diagnosed in animals greater than 4 years of age.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Cattle are most frequently affected, SCC is also seen in sheep, but is rare in goats.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Routine evaluation of all eyes in a herd allows early detection and treatment of lesions that may be early SCC or premalignant changes in the epithelium.

ST. JOHN'S WORT TOXICITY

BASICS

OVERVIEW

- St. John's wort is an erect perennial herb that stands 1–3 feet tall. Its leaves are opposite, dotted, with many yellow flowers.
- Hypericin is the active ingredient. It's a red florescent pigment found in a semisolid state in the black dots that are scattered over the surface of the leaves, stems, and petals and is present in the plants at all times.
- Hypericin is a naturally occurring naphthodianthrone derivative in the plant species *Hypericum perforatum*. The hypericin concentration in the plant may vary depending on the place of growth, state of plant material, and part of the plant—whole herb concentration 0.00095%–0.466% and flowers up to 0.086%.
- The hypericin concentration in a broadleaf biotype varies from a winter minimum of less than 100 ppm to a summer maximum approaching 3000 ppm. In contrast, the narrow-leaf biotype increases from similar winter values to summer maxima approaching 5000 ppm.
- Consumption causes primary photosensitization, which leads to increased sensitivity of the skin to subsequent light exposure.
- There appears to be an absolute requirement for exposure to bright sunlight before any effects of hypericum will develop.
- St. John's wort is found in dry soil, roadsides, and pasture ranges.

PATHOPHYSIOLOGY

- The mechanism of action is unresolved.
- One study suggested that hypericin was an inhibitor of rat brain mitochondrial monoamine oxidase (MAO).
- Serotonin receptors may be involved in the pharmacological action of hypericum extracts.
- Another study found that hypericum extract inhibits serotonin uptake by rat synaptosomes derived from rat embryo neurons. Other investigators reported that serotonin receptor expression in neuroblastoma cells was reduced by hypericum extracts.
- When animals ingest the plant, the hypericin is absorbed from the intestinal tract and goes into the circulation. Hypericin is a photodynamic agent able to cause cellular damage and sunburn.

SYSTEMS AFFECTED

Skin, gastrointestinal, cardiovascular, liver, renal

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Potentially worldwide, depending on species and environment

SIGNALMENT

- Cattle, sheep, horses, and goats
- Most common in sheep and cattle
- Potentially all ruminant species

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- Extreme hyperesthesia to touch and to contact with cold water
- Restlessness and discomfort. Animals tend to rub their ears, eyelids, and muzzle.
- Photophobia
- Hyperthermia when exposed to sunlight
- Diarrhea and tachycardia
- Exposure of the tongue to sunlight while licking can cause glossitis with ulceration and deep necrosis.
- Congested mucous membranes and hyperemia of exposed skin on tail and legs. Edema of eyelids and ears, exudation of serum from ears.
- Loss of eyelashes, corneal opacity, and blindness after 5–7 days with high levels of ingestion.
- Animals with pigmented skin and those that remain in subdued light suffer few effects.
- Hemolytic anemia
- Kidney and liver dysfunction may occur with severe exposure.

CAUSES AND RISK FACTORS

- Severity of effects increases with duration of exposure, but not with dose.
- A single dose of hypericum remains potentially effective for up to 4 days.
- Induces hepatic cytochrome P450 and approximately doubles its metabolic activity.
- Plasma concentration of concomitant medication using cytochrome P450 enzymes will be reduced.
- Rectal temperature rise in affected sheep is a reliable indicator of the early development of an adverse clinical effect.
- There appears to be an absolute requirement for exposure to bright sunlight before any effects of *H. perforatum* will develop.
- A single dose of *H. perforatum* remains potentially effective for up to 4 days.
- In a small group of Merino sheep tested, a tolerance level for *H. perforatum*, eaten at the flowering stage, of < 1% (plant wet weight) of body weight and a tolerance level for hypericin of < 2.65 mg per kg live weight were demonstrated.
- Sheep develop restlessness, photophobia, tachycardia, tachypnea, congested mucous membranes, diarrhea, and hyperthermia. Skin lesions include redness of the tail, eyelid edema, and auricular edema. One week later, salivation, perioral and periauricular alopecia, keratoconjunctivitis, corneal opacity, and blindness may be evident.
- Another study found the minimal dose of dried whole hypericum to cause symptoms to be 3 g/kg in calves weighing 100 to 120 kg. Calves that receive this dose and were exposed to sunlight developed pyrexia and tachypnea 3 to 4 hours later. The animals became restless, passed soft feces, and developed perinasal and perioral erythema. Calves receiving the same dose but not exposed to sunlight only developed soft feces. Calves receiving 5 g/kg developed similar but more severe symptoms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hepatogenous photosensitivity as a result of phylloerythrin accumulating in the blood. Phylloerythrins are formed from the anaerobic breakdown of chlorophyll by microorganisms in the forestomach of ruminants.
- Endogenous photosensitizing agent from aberrant metabolism of hemoglobin
- Antibiotic-associated photosensitization (sulfonamides and tetracyclines)
- Phenothiazine-induced photosensitization (Phenothiazine sulphoxide is the metabolite.)
- Plants that can cause sunburn either by contact or ingestion—vetches, various clovers, and buckwheat (*Fagopyrum* spp.)—have caused sunburn and skin scald in animals.

CBC/BIOCHEMISTRY/URINALYSIS

- Elevated serum BUN, Na, K, and bilirubin (total and direct) concentrations
- Lower than normal serum in Hb, RBC count, PCV, TP, glucose, cholesterol, triglycerides, and serum alkaline phosphatase concentrations
- Serum sorbitol dehydrogenase, GGT, concentrations within normal limits
- Transaminases, CPK, sodium, and potassium increase and the BUN may increase up to ninefold. Glucose and hemoglobin decrease, while WBC level does not change.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

N/A

TREATMENT

- Remove animal from source.
- Animals should be given full shade or preferably housed and allowed out to graze only during darkness.
- Corticosteroids given parenterally in the early stages may be useful.
- Secondary skin infections and suppuration should be treated with a topical broad-spectrum antibiotic.
- Fly-strike should be prevented.
- Emergency evacuation of the gastrointestinal tract is not required since the toxin takes several days to build up in the body and cause signs.

MEDICATIONS

- 1.1 mg/kg/day prednisone or prednisolone PO for 10 days
- Depending on the severity of the lesions, antibiotics and anti-inflammatory medications may be indicated.

CONTRAINDICATIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Weed management—mowing and hand removal
- Animals will avoid St. John's wort if more palatable forage is available.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Condition seldom causes death and soon clears once the plant source is removed.
- The prognosis and the eventual productivity of the animal are related to the site and severity of the primary lesion and to the degree of resolution.

STARVATION/MALNUTRITION

BASICS

DEFINITION

Starvation is the inability to obtain food or the unavailability of food for an extended period of time or insufficient energy intake, commonly seen during periods of drought.

PATHOPHYSIOLOGY

- Many physiological changes occur as the animal attempts to satisfy its energy requirements. At the cellular level, catabolism continues to supply the substrates required for anabolism and vital functions. Reserve stores of nutrients are utilized to compensate for the lack of nutritional intake.
- The most readily usable material, glycogen, is utilized first primarily from liver stores and is exhausted in a few hours. Next, stored fat from various subcutaneous deposits (near the kidney, mesentery, and omentum) is utilized. Following this use, fat deposits in the parenchymal organs are utilized, followed by fat deposits in the bone marrow. The final source of energy available to the animal is cell cytoplasm, which is primarily protein.
- Ketosis is commonly seen in starvation.
- Nitrogen excretion rises due to the protein catabolism. The animal eventually reaches a point where it dies because of insufficient blood glucose necessary for brain function and hypoglycemic shock occurs.
- At the microbial level, inadequate food intake, especially in ruminants, results in a rapid decrease in the number of bacteria and protozoa and in the level of volatile fatty acids present in the rumen.
- Nearly 70% of the energy available to ruminants is from these fatty acids, thus causing a significant further impact on energy availability.
- Decreasing the microbial populations also diminishes the animal's ability to digest fiber.
- Prolonged food deprivation is known to cause a fall in the core body temperature.

SYSTEMS AFFECTED

Musculoskeletal, hepatic, immune and production management; potentially all depending on initiating events

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

- Adult ruminants are able to store large amounts of nutrients and fat within their body tissues. These mature animals will utilize higher proportions of fat than protein, especially in the early stages of starvation. In contrast, young animals will utilize higher proportions of protein than fat. They have smaller fat reserves because of higher nutritional demands for growth, smaller body size, and social interactions within their environment.
- In the wild, starvation tends to occur more frequently in the winter and early spring months due to food availability and weather demands on energy utilization.

Species

All ruminant species

Breed Predilections

N/A

Mean Age and Range

- Young, yearling, and old animals are most susceptible to starvation because they enter the season with the smallest fat stores, highest nutritional demands, greatest heat loss, and lowest positions in the social environment.
- Young animals and pregnant or lactating animals have much higher energy and protein requirements than do dry stock, and are therefore most susceptible to the effects of malnutrition. These animals will need to be fed separately to ensure that their requirements are met.

Predominant Sex

N/A

SIGNS

PHYSICAL EXAMINATION FINDINGS

- Attitude—lethargic, unsteady, listless, unafraid of humans
- External findings—dehydration, rough hair coat, thin body condition, muscle atrophy (prominent ribs, vertebrae, shoulders and pelvis)

HISTORICAL FINDINGS

Knowledge of food unavailability or shortage; wild animals seen by humans more frequently (stray into developed areas); significant loss in body weight (may be near 20%–30%).

CAUSE AND RISK FACTORS

- Inability to ingest, digest, absorb, or utilize food
- Injury, poor teeth, parasitism, disease, foreign bodies, neoplasia, increased motility of the digestive tract
- Inadequate supply of food
- Insufficient energy intake
- Extreme parasitism
- Environmental conditions
- Cold weather, deep snow, increased energy demands (pregnancy), snow-covered food, drought, overpopulation, predator stress
- Social conditions within the flock/herd

Feed-Related Illnesses Occurring During Drought/Starvation

- Malnutrition and starvation
- Metabolic disease
- Mineral deficiencies and imbalances
- Hypocalcemia
- Hypomagnesemia
- Reduced fertility: cow fertility, bull fertility
- Grain toxemia/acidosis: Any factor that causes variation in intake (e.g., inclement weather or palatability of feed) or changes in the availability of the carbohydrate (e.g., a change in grain type or grain processing) may cause digestive upsets at any time, not just in the period of grain introduction.
- Clostridial diseases: Spores of clostridial bacteria are present in soil and are ingested when animals ingest soil when grazing close to the ground.
- Laminitis
- Urea poisoning
- Urinary calculi
- Vitamin A deficiency
- Plant poisoning: hungry animals may consume plants, including shrubs and trees, which they would normally avoid.
- Blue-green algae: blooms of blue-green algae are more likely to appear in warmer months during drought.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Malnutrition, parasitism, neoplasia

CBC/BIOCHEMISTRY/URINALYSIS

Chemistry

Hypoproteinemia, hypoglycemia, hypocalcemia, high anion gap, increased AST, SDH, and CK

Urinalysis

Proteinuria, ketonuria

OTHER LABORATORY TESTS

- Starvation is best diagnosed by gross examination or necropsy.
- A gross determination is based on examining the presence or lack of adipose tissue in the various subcutaneous and visceral locations.
- Femur or mandibular bone marrow fat analysis can be grossly examined in older animals. Some labs offer a femur marrow compression method, either-extract method, kidney fat index, and wet weight-dry weight method.
- Laboratory tests offer little additional information than can be derived from gross examination.

IMAGING

NA

DIAGNOSTIC PROCEDURES

PATHOLOGIC FINDINGS

- Pathological changes which occur in a starved ruminant are many and varied. The most striking change is the lack of fat in the subcutaneous, visceral, and bone marrow locations.
- Muscle atrophy is generally significant. Serosal atrophy is common. The organs are generally smaller than normal.
- The digestive tract is generally void of any material and is often shrunk. The gallbladder is generally distended and bile straining may be present. Rumen ulcers may be present and rumen materials are scant and dry. Villus atrophy may be seen in the rumen.
- Femur marrow will be red or yellow in color, transparent and gelatinous.

TREATMENT

- Generally ruminants will not eat large quantities of food when sudden access to unlimited food occurs.
- If food is not provided until late stages of starvation, the animal will likely die. It takes up to 2 weeks for a ruminant to adjust to the new diet and change into a positive energy balance.
- Care must be given to provide a high quality palatable feed containing readily available carbohydrates, roughage, minerals, and vitamins.
- The animal is prone to acidosis if a sudden shift of microbial population occurs and the only feed provided is high in carbohydrates.
- Treat preexisting health conditions.
- Factors that must be corrected, in order of importance, are:
 - Deficiency of energy
 - Deficiency of rumen-digestible protein (or alternative nitrogen and sulfur equivalent) required by rumen bacteria to produce energy and protein from low-quality feed
 - Deficiency of high-quality protein required for growth, pregnancy, and lactation
 - Deficiency of other minerals, particularly phosphorus, calcium, and magnesium
 - Deficiency of vitamins associated with the lack of fresh green feed, particularly vitamins A, D, and E.

MEDICATIONS

Directed at specific causes of starvation (e.g., parasitism, poor dentition, chronic disease)

DRUGS OF CHOICE

Directed at specific treatments of underlying disease conditions if present

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Ketosis is commonly seen in starvation.
- Decreasing the microbial populations also diminishes the animal's ability to digest fiber.
- Prolonged food deprivation is known to cause a fall in the core body temperature.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY

It is common for pregnant animals to abort or absorb their fetus during times of starvation. A fetus that survives will often be small and have an increased chance for mortality. Dams will often not allow nursing or abandon their young.

RUMINANT SPECIES AFFECTED

All ruminant species

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Feed Management

- Once pasture is inadequate, cattle should be confined and fed. Confined cattle need significantly less energy for maintenance than do those that are left in the paddock to wander in search of feed.
- The pastures should be left in a condition where they can recover quickly when the drought breaks.
- Any change in feed (especially grain) should be introduced gradually—failure to do this is probably the major cause of illness seen in drought/starvation.

Author: Angela M. Daniels

STIFLE INJURIES

BASICS

OVERVIEW

- Ligamentous injuries affecting the cranial and caudal cruciate ligaments, medial and lateral menisci, collateral ligaments, and the patella and its associated ligaments.
- Affected cattle are acutely lame.
- Cattle that recover from initial injuries often develop chronic osteoarthritis.

SIGNALMENT

- Ligamentous injuries of the stifle have been reported in both beef and dairy cattle.
- In female dairy animals, the condition has been reported in cattle as young as 11 months and as old as 14 years.
- The disease is most common in large-framed, young adult (3- to 6-year-old) beef animals with exceptional genetic potential for rapid weight gain and excessively straight conformation of the stifle and hock. This observation may reflect an actual increased risk or, alternatively, a biased population being presented for diagnosis and treatment.

SIGNS

- Physical examination is the most useful method to diagnosis stifle injuries in cattle.
- Affected cattle are acutely lame.
- The severity of the lameness is directly related to the severity of injury, the specific structures damaged, and the joint laxity induced by these injuries.
- The majority of gait abnormalities generally subsides in the 6 to 12 weeks after the initial injury; however, most cattle will have a visible residual lameness. At this point, clinical signs will remain static for a variable interval. This period of static clinical signs varies from 3 months to 1 year. Thereafter, affected cattle begin to become progressively lamer.
- Most affected cattle are recognized as having intractable lameness resulting in euthanasia within 2 years following the first recognition of lameness. Consequently, the severity of clinical signs varies greatly depending on the elapsed time since the injury.
- Cattle with ligamentous injuries of the stifle usually walk with a characteristic gait.
- Cattle with stifle injuries are reluctant to bear weight on the affected limb.
- At a walk, the stifle and tarsus joints are relatively fixed. Cattle advance their limb by first abducting the pelvic limb and then swinging it lateral, forward, and then medial. This altered gait appears to avoid the pain caused by repetitive cycles of stifle flexion and extension.
- When cattle walk, weight appears to be shifted onto the toe and off the heels of the affected limb. In many cases, the heels are visibly elevated and do not contact the ground at a walk.
- Hoof lameness localized in the heel is readily confused with stifle injuries. Consequently, close examination of the hoof is necessary to rule out these conditions.
- The stifle should be palpated for heat, swelling and distension of the joint. In acutely lame cattle, swelling often gravitates ventrally through the subcutaneous tissues. On superficial examination, the tarsus may appear swollen.
- Tarsal enlargement and the patient's unwillingness to flex or extend either the tarsus or stifle often make diseases of the tarsus a tempting, although incorrect, diagnosis.
- A series of limb manipulations should be performed on all cattle suspected of having ligamentous stifle injuries. These procedures are all designed to detect abnormal laxity.
- Laxity, instability, and forced movement typically produce a sudden popping sensation, an audible click or snap, and in long-standing cases, a grating sensation.
- Determination of the specific damaged structures is usually not possible solely on the basis of clinical examination.
- Given that the prognosis and treatment are similar for most cases of traumatic stifle disease, more anatomically specific

diagnoses may be neither necessary nor desirable.

- It should be noted that joint instability is most easily detected in the first month after the initial injury and may become difficult to detect if the interval from injury to examination spans several months.

Stifle Examination Technique

- The affected animal should be restrained in a head gait with free access to the affected side of the cow. Ideally, the head gate should be positioned such that the unaffected side of the cow is next to a solid wall.
- Initially, the examiner should perform a drawer sign examination. The examiner stands behind the cow or bull and places a shoulder firmly against the semimembranosus and semitendinosus muscles.
- The proximal tibia is grasped with both hands and pulled caudally, while the distal femur is forced forward using the examiner's shoulder.
- Rotational instability is initially assessed in the standing animal by grasping the tuber calcis with one hand and the proximal tibia or stifle with the other hand. The limb is twisted both clockwise and counter-clockwise.
- After completion of these examinations, the affected limb is manually lifted and flexed. The examiner stands next to the cow facing caudal. The tarsus and stifle run through a full range of flexion and extension.
- The leg is held in flexion with one hand and rotational force is placed on the hock and stifle using the opposite hand. The leg is extended and the hoof is manually abducted to assess medial and lateral joint instability.

CAUSES

- The primary cause of stifle injuries appears to be trauma. However, degenerative changes in the ligamentous structure of the stifle may precipitate a catastrophic event leading to clinical disease.
- Excessively straight stifle conformation has been linked to degenerative changes in the ligamentous structures of the stifle.

RISK FACTORS

- In addition to the risk factors outlined under signalment, excessive or violent physical activity may precipitate traumatic injuries to the stifle.
- Injuries are often observed in athletic young bulls of high libido near the end of the breeding season and injuries are often observed in cows coincidental with estrus.
- Mixing groups of cattle or adding single cows to preexisting herds or groups will often precipitate social dominance behavior that leads to traumatic injuries. This is particularly the case when unaccustomed bulls are placed together in small pens or pastures.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differential diagnoses include femoral and tibial fractures, luxations of the hip, infectious polyarthritis, osteochondrosis, and hoof lamenesses.
- Physical examination and radiographs can rule out femoral and tibial fractures.
- Luxations of the coxofemoral joint are ruled out by physical examination.
- Polyarthritis typically presents as a shifting limb lameness with multiple joints involved. Additionally, arthrocentesis will reveal characteristic inflammatory responses.
- Hoof lameness is generally ruled out by physical examination and hoof trimming.

IMAGING

Ancillary diagnostic procedures:

- Radiography may be used to confirm luxation of the stifle joint; however, this procedure is not recommended in most cases. Most food-animal practitioners lack both the resources to produce quality stifle films and the experience interpreting these films. Additionally, quality stifle films in cattle usually require general anesthesia.
- This procedure is probably not justifiable based on costs and benefits unless surgical intervention is contemplated in a valuable animal.
- Definitive and anatomically specific diagnosis of stifle injuries generally requires arthrotomy or arthroscopy.
- These approaches are rarely undertaken due to the costs associated with general anesthesia, the difficulty of the

procedures, the relative inexperience of most surgeons with bovine stifle surgery, and the lack of controlled clinical trials documenting improved outcome associated with surgical intervention.

TREATMENT

- In cattle that are unable to stand, immediate euthanasia is a reasonable decision.
- In most circumstances, conservative management will be the optimal course of treatment.
- If treatment is attempted, affected cattle are confined in a small dirt-floored stall for 4 to 6 months, permitting scarring and fibrosis to stabilize the stifle joint.
- Many cattle will demonstrate dramatic improvement in their gait. Cattle with dramatic and persistent laxity of the stifle tend to respond poorly to stall rest.
- Cattle that respond well to stall rest will typically begin to become progressively lamer within a year of the initial diagnosis and this deterioration appears to be caused by osteoarthritis.
- Some practitioners have advocated that the affected limb should be placed in a Thomas or Walker splint apparatus.
- A number of surgical approaches have been used in an attempt to stabilize the stifle and prevent chronic arthritis. These approaches may be considered in valuable cattle with exceptional genetic merit.
- One study reported approximately a 50% one-year survival and function rate in cattle following surgical intervention, with some cattle remaining functional as long as 4 years postsurgery. However, it should be noted that this data set was restricted to female dairy cattle. One would anticipate less favorable responses in bulls due to their relatively larger size. No controlled clinical trial has compared response to conservative medical and surgical treatment of stifle injuries.
- Surgical intervention is probably not appropriate in most general food-animal practices, and the practitioner would be well advised to refer such cases.

FOLLOW-UP

- Bulls that respond to either medical or surgical intervention are poor candidates for natural service.
- Most bulls are unable to complete a single breeding season. Likewise natural service appears to carry an inordinate risk for cows that initially appear to recover from stifle injuries.
- Valuable breed bulls should be housed alone in a dirt lot and have semen collected for use in artificial insemination after their recovery from surgery or the recommended 6-month course of stall rest.
- Recovered cows of exceptional value should be used as embryo transfer donors.

MISCELLANEOUS

It should be noted that few clinical reports have attempted to describe the clinical course and response to treatment in cattle with stifle injuries. The limited reports available may not be representative of the disease presented to the private practitioner.

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- The individual most commonly affected is a young adult beef bull.
- Injuries are often observed in athletic young bulls of high libido near the end of the breeding season and injuries are often observed in cows coincidental with estrus.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Recovered cows of exceptional value should be used as embryo transfer donors.

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Mixing groups of cattle or adding single cows to preexisting herds or groups often precipitates social dominance behavior that leads to traumatic injuries. This is particularly the case when unaccustomed bulls are placed together in small pens or pastures.

STRONGYLOIDES

BASICS

OVERVIEW

- Order Rhabditida include three genera that parasitize animals
 - *Rhabditis* (*Pelodera*) *strongyloides*
 - *Halicephalobus* (*Micronema*)
 - *Strongyloides*
- *Rhabditis* (*Pelodera*) *strongyloides*
 - Free-living parasite that inhabits decaying organic debris
 - Produces pruritic, hyperemic dermatitis in cattle, horses, swine, dogs, and rodents; organism penetrates skin when animals contact dirty bedding or contaminated environment.
 - Dermatitis includes marked alopecia on neck and flank with flaking, thickening, and wrinkling of skin, pruritus, irritation, and exudation of serum in severe cases. Pustules containing thick, yellow, caseous material, and worms present on ventral abdomen and udder.
 - *Rhabditis bovis* in cattle in the tropics causes otitis externa and chronic wasting.
 - Easily found on skin scrapings, may also diagnose by skin biopsy or detection of organism in bedding (upper layers)
 - Remove soiled bedding and keep bedding clean and dry.
 - Spontaneous recovery may occur if remove source and change management.
 - Treat with ivermectin, avermectins, local application of parasiticide, or topical treatment (ear) and symptomatic treatment.
- *Halicephalobus* (*Micronema*) are highly pathogenic for horses and humans; one report of *M. deletrix* in the skin of a bull's scrotum
- *Strongyloides*: All domestic animals and many wild mammals and birds have a species of *Strongyloides*.
 - *Strongyloides papillosus* affects ruminants.
 - Worldwide distribution, particularly in warm, humid areas
 - *Strongyloides* infections are common, usually mild or moderate, and asymptomatic in ruminants.
 - Neonates and suckling calves, kids, and lambs are most commonly clinically infected.
 - Transmammary transmission to neonates
 - Initially considered as a commensal organism. Recent studies indicate that even light infections may cause substantial disease in susceptible young, especially kids.
 - Probably most common worm to infect goats with most goats having a few of these worms most of the time
 - Clinical signs related to skin penetration (dermatitis, lameness), intestinal infection (diarrhea), and migration of immature forms through lungs (coughing, tachypnea) are variable depending on species, age, and immunity of animal and on parasite load.

***Strongyloides* Infection**

Pathophysiology

Life Cycle

- Unique because it has alternate free-living and parasitic generations
- Parasitic female is embedded in the intestinal tract mucosa, primarily the upper small intestine.
- Eggs laid here develop rapidly and are embryonated when they are passed out with the feces.
- On pasture, eggs hatch quickly into infective larvae or become free-living males or females that can produce infective larvae.

- Larvae molt to infective third-stage larvae within 24 to 48 hours.
- Grazing host ingests infective larvae or infective larvae penetrate skin (usually between hooves) of host.
 - In older animals, larvae accumulate in the subcutaneous tissues and migrate to the mammary gland when lactation starts so neonates are infected via the milk, and egg-laying females may be present in the intestine from about 1 week after birth.
 - Infective larvae that penetrate the skin of young animals travel via the blood to lungs where they break into alveoli.
- Larvae migrate up airways or are coughed up the trachea into the pharynx and swallowed.
- Develop into mature females in 2 to 3 weeks after ingestion; prepatent period in sheep is 1–2 weeks
- Major mode of transmission is transmammary (colostrum, milk) and less often is by skin penetration (especially toes, ventrum) or ingestion.

Life Cycle Unique Characteristics

- *Strongyloides* spp. have alternating free-living and parasitic generations.
- Free-living life cycle has males and females.
- Parasitic life cycle contains parthenogenic females; males are not involved in the parasitic phase of the cycle.
- Parasitic (filariform) female produces eggs by mitotic parthenogenesis.
 - Homogonic rhabditiform larvae hatch from these eggs.
 - In external environment, larvae develop via molts to either infective filariform larvae or to free-living males and females.
 - Infective filariform larvae, after entering host, molts into parasitic females.
- Free-living rhabditiform males and females mate to produce heterogonic rhabditiformic larvae that generally only develop into infective filariform larvae.

SIGNALMENT

- Seen worldwide
- Infects young calves (particularly dairy stock), young and weaned kids, lambs
- No sex predilection
- Adult ruminants carry a degree of immunity to the intestinal form of the parasite

SIGNS

Natural Infections

- Intermittent diarrhea
- Blood and mucus in feces
- Loss of appetite
- Weight loss
- Coughing as immature forms migrate to air passages
- Penetration of worm through skin of feet (interdigital)
 - Lameness
 - Stamping of feet
 - Biting at or rubbing of feet and legs
 - Increased susceptibility to foot rot
- In sheep and lambs
 - Initial skin invasion by *S. papillosus* larvae may not induce any inflammation but subsequent exposure causes a pustular, erythematous dermatitis.
 - Lamb: dermatitis, pulmonary hemorrhage, and enteritis
- Localized dermatitis on feet or dependent regions of body is caused by an immune reaction to migrating larvae.
- Adults seldom show ill effects of parasite burden unless stressed, diseased, or exposed to heavy infestation.
 - Bulls—balanoposthitis
 - Sheep—heavy load may cause unthriftiness, diarrhea, weight loss, slow growth.
 - In goats with heavy overload stress or debilitated condition, *S. papillosus* may cause diarrhea, hypophagia, weight loss, and moderate anemia ± presence of tiny white worms in feces. Reinfection results in bouts of coughing.

Experimental Infections in Kids

- Death in some kids after as few as three exposures (2000–5000 larvae per exposure); death within 9 to 30 days after receiving 75, 000 larvae
- Kids 6 weeks to 6 months more susceptible than those 6 to 12 months old
- Clinical signs varied
 - Dehydration, inappetence, diarrhea, weight loss, weakness, afreble
 - Anemia, respiratory distress
 - Nervous signs
 - Sudden death from hepatic rupture in some kids

Experimental Infections in Lambs

Inoculation of live parthenogenetic females into duodenum of lambs induced sinus tachycardia and cardiac arrest.

Experimental Infections in Calves

- Pallor and coughing
- Heavy infection induced variety of cardiac arrhythmias
- Sudden death due to cardiac arrest

CAUSES AND RISK FACTORS

- Most common when animal kept in wet, dirty environment
- Dirty bedding
- Parasitized dams at time of parturition are greatest source of *Strongyloides* for neonates.

DIAGNOSIS

- Suspect in young animals with consistent history and clinical signs
- Adult (3–6 mm) in small intestine (sheep)
- Direct fecal smear or Baermann procedure to observe larvae
- Day-to-day variation in larval numbers makes diagnosis difficult.
- Fecal flotation
 - Small, clear, colorless, thin-shelled, oval embryonated egg (40–60 × 20–25 μm)
 - Free-living adults frequently develop in cultures of feces from *Strongyloides* -infected animals.
- Female is not highly prolific; does not produce a large number of eggs. In goats: a dozen or more eggs in sample represents a large load of worms.
- Skin biopsy: pustular dermatitis characterized by edema, inflammatory infiltration (neutrophils, eosinophils, lymphocytes, and giant cells), and destruction of the larvae.
- Necropsy
 - Adults in scraping of intestinal mucosa
 - Immature worms recovered from minced tissue placed in a Baermann isolation device
 - Catarrhal enteritis with petechiae and ecchymoses, especially in the duodenum and jejunum.
- Serodiagnosis with ELISA (serum) may be useful.

DIFFERENTIAL DIAGNOSIS

- A contact dermatitis or irritation from dirty wet bedding
- Infectious and noninfectious causes of diarrhea
- Foot rot
- *Pelodera* dermatitis
- Trombiculidiasis
- Hookworm dermatitis
- Chorioptic mange
- Dermatophytosis

CBC/BIOCHEMISTRY/URINALYSIS

Anemia in heavily infested animals

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Fecal flotation
- Skin biopsy

TREATMENT

- Eliminate moist, warm habitats for the larvae.
 - Remove contaminated bedding
 - Keep bedding clean and dry
- Dewormer should be approved for species and gestational and lactation status of animal in which it is to be used.
- Treatment frequency may be reduced by rotating pasture.
- Recommended withdrawal times for milk and meat must be observed.
- Ivermectin and doramectin have been recommended to treat adult worms in cattle, goats, and sheep; treatment may need to be repeated.
- Use dewormer to which nematodes on premises are susceptible. Parasite resistance is increasingly becoming a problem.
- If resistance to specific dewormers is suspected, check by doing fecal egg counts from representative animals before and after deworming.
- Rotational use of dewormer to avoid resistance development
- Use a strategic deworming program: deworm animals when the total worm population is in the host not on the ground (pasture).

MEDICATIONS

DRUGS OF CHOICE

- Appropriate drug(s) to be used will depend on susceptibility and resistance patterns found in animal groups to be treated.
- Breed, age, pregnancy, and lactation status will also influence choice of anthelmintic to be used. Milk and meat withdrawal times must be observed.
 - Ivermectin: goat and sheep 0.2–0.3 mg/kg PO
 - Eprinomectrin: goat and sheep 0.5 mg/kg PO
 - Moxidectin: goat 0.5 mg/kg PO
 - Fenbendazole: goat and sheep 5–10 mg/kg PO (may need up to 20 mg/kg PO to control nematode parasites)
 - Oxfendazole: goat 10 mg/kg PO; sheep 5–10 mg/kg PO
 - Levamisole: goat 8 mg/kg PO (may need up to 12 mg/kg PO)
 - Febantel: goats and sheep 5 mg/kg PO

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Threadworms are not of great economic importance in the United States.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Secondary mild bacterial bronchopneumonia

ZOONOTIC POTENTIAL

- Cutaneous larva migrans
 - Most commonly due to dog and cat hookworms
 - Less commonly due to animal roundworms including *Strongyloides papillosus*, *S. myopotami*, *S. westeri*
- *Strongyloides stercoralis* affects humans.

RUMINANT SPECIES AFFECTED

Goats, cattle, sheep, wildlife ruminants

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Routine deworming of dams in late gestation to decrease transmammary transmission to newborn
- Early deworming of newborns of affected but untreated dams
- Provide clean, dry environment with adequate clean bedding in stalls and rest areas.
- Pasture management to reduce hosts' exposure to parasites
- Selection for parasite resistance and culling of animals with chronic, heavy parasite loads may decrease parasite problem in herd or flock.
- Avoid bringing in resistant parasites by isolating new goats until they have been dewormed.
- Infestations may result in decreased milk and meat production.
- Severe infestations in young animals may lead to poor weight, stunting, or death.
- Pruritic dermatitis may result in damage to the wool and hide.

STRYCHNINE POISONING

BASICS

OVERVIEW

- Strychnine is an alkaloid derived from *Strychnos nux-vomica*, a tree native to India. Used primarily as a pesticide for rat, gopher, mole, and coyote control. Commercial forms are sold as powder, pellets, or treated seeds, dyed bright green or red. Contains 0.3%–0.5% strychnine
- Not absorbed until it reaches the intestine
- Highly toxic to ruminants orally at 0.5 mg/kg
- Mechanism of action—blocks glycine, the transmitter for inhibitory cells (Renshaw cells) of the spinal cord
- Direct effects on the CNS by antagonizing spinal inhibition in the spinal cord and medulla. This allows the uncontrolled and diffuse reflex activity. All striated muscle groups are affected, extensors predominate. Produces symmetrical and generalized rigidity and tonic seizures.
- There are no gross or microscopic lesions seen.

SIGNALMENT

Affects all ruminant species of any age

SIGNS

- Appear 10 minutes to 2 hours postingestion
- Nervousness, tenseness, stiffness; rigid cervical musculature, neck arched, ears erect, lips pulled back from teeth, and tense abdomen
- Violent tetanic seizures appear spontaneously or initiated by stimuli such as touch, sound, and sudden bright light
- Extensor rigidity, sawhorse stance
- Convulsions increase in frequency and duration
- Eyes dilated, cyanotic mucous membranes (from anoxia)
- If untreated, the whole syndrome can last 1–2 hours until death. The lethal dose is eliminated in 24–48 hours, so treatment is required during this period.

CAUSES AND RISK FACTORS

DIAGNOSIS

Based on history of ingestion, clinical signs, and lack of gross lesions

DIFFERENTIAL DIAGNOSIS

- Chlorinated hydrocarbon toxicity
- Zinc phosphate toxicity
- Lead toxicity
- Hypocalcemia
- Metaldehyde
- Organophosphate or carbamates
- 1080 toxicity
- Causes of acute, massive hepatic necrosis

CBC/BIOCHEMISTRY/URINALYSIS

Urine is a good diagnostic sample. Strychnine is readily absorbed from GI tract and excreted in urine.

OTHER LABORATORY TESTS

- Stomach contents are a common source of diagnosis.
- Postmortem, samples of liver, kidney, urine, and CNS will help yield a diagnosis.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

PATHOLOGIC FINDINGS

- Rigor mortis rapid after death
- Subsequent relaxation follows more rapidly than normal.
- Cyanosis, petechial and ecchymotic hemorrhages, and traumatic lesions are evidence of a violent and hypoxic state.

TREATMENT

MEDICATIONS

DRUGS OF CHOICE

- Prevent asphyxia and maintain relaxation for 24–48 hours using pentobarbital, methocarbamol at 150 mg/kg IV, diazepam, glyceryl guaiacolate at 110 mg/kg IV.
- Gastric lavage
- Diuresis with 5% mannitol in 0.9% NaCl at 6.6 ml/kg
- If not acidotic, administer NH_3Cl at 132 mg/kg orally to increase urinary elimination.

CONTRAINDICATIONS

- Monitor serum pH.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Acute rapid onset—prognosis is poor if untreated.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Violent tetanic seizures
- Extensor rigidity
- Convulsions

SUBCUTANEOUS EMPHYSEMA

BASICS

DEFINITION

Subcutaneous emphysema is the accumulation of gases under the skin and between tissue planes.

PATHOPHYSIOLOGY

- A transtracheal aspirate site may allow air to penetrate under the skin, usually accumulating around the trachea but occasionally extending further.
- Air may also extend subcutaneously by migrating from the site of a skin wound, fractured nasal bone or rib, or from pulmonary emphysema secondary to severe pneumonia.
- The introduction of anaerobic bacteria or their spores, especially clostridial organisms, under the skin by needle puncture or unsanitary surgical procedures or by a wound can result in elaboration of gases by the bacteria during their growth phase, with subcutaneous emphysema resulting.

SYSTEMS AFFECTED

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

All ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Previous needle punctures (e.g., from administering vaccines or medications).
- Animals not vaccinated against clostridial agents
- Previous thoracic trauma with fractured ribs
- Pneumonia during parturition, especially in sheep and goats, when lung parenchyma may rupture into the mediastinum due to increased intrathoracic pressure during parturition.

PHYSICAL EXAMINATION FINDINGS

Creptance can be palpated over affected areas of the body. If clostridial infection is the insidious cause of the subcutaneous emphysema, will see signs of myonecrosis (e.g., cool insensitive skin, malodorous serosanguinous fluid discharge from wounds), and the animal will be depressed, reluctant to move, and possibly febrile.

CAUSES AND RISK FACTORS

- Causes include air migration from a transtracheal aspirate site along tissue planes, and gases produced by clostridial

organisms, particularly *Clostridium chauvoei*, *Cl. septicum*, *Cl. sordelli*, *Cl. novyi* type B, *Cl. perfringens* type A, and *Cl. carnis*.

- Risk factors include needle punctures without prior aseptic preparation of the skin surface, repeated use of the same needles between different animals, and lack of prior vaccination against clostridia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Clostridial myonecrosis
- Cellulitis
- Hematoma
- Seroma

CBC/BIOCHEMISTRY/URINALYSIS

Hemoconcentration, a stress leukogram, and elevated muscle enzymes CK and AST if clostridial infection is the cause of the subcutaneous emphysema

OTHER LABORATORY TESTS

- Aspirate affected areas and examine fluid microscopically; culture fluid to aid in differential diagnosis.
- Biopsy/histopathology/culture of affected tissue.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

If clostridial infection is the cause of the subcutaneous emphysema, signs of tissue necrosis (e.g., swelling, autolysis, crepitus, serosanguinous fluid discharge from cut surfaces) will be evident.

TREATMENT

May need to surgically debride tissue and perform fenestrations or fasciotomies to allow gases to escape. This will create a more aerobic environment to slow proliferation of anaerobic bacteria if they are suspected as the cause of the subcutaneous emphysema.

ACTIVITY

Restrict movement to slow migration of gases along tissue planes.

DIET

May need supportive fluid therapy if clostridial infection is the cause of the subcutaneous emphysema.

CLIENT EDUCATION

- Importance of clostridial vaccination
- Extensive skin sloughing may result if clostridial infection is the cause of the subcutaneous emphysema.

MEDICATIONS

- Penicillins if clostridial infection is the suspected cause of the subcutaneous emphysema.
- NSAIDs to control pain and swelling, if clostridial infection is suspected.

DRUGS OF CHOICE

Penicillin 44,000 U/kg IV q. 2–4 hrs. for 1–5 days or until animal stable, then q. 12 hrs. IM until complete recovery.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

SWEET CLOVER POISONING

BASICS

OVERVIEW

- Sweet clover poisoning is from toxic ingestion of moldy hay where fungal metabolism of harmless natural coumarins in the plant, in the process of spoilage, produces toxic dicoumerol, a vitamin K inhibitor. These molds include *Penicillium* spp., *Mucor* spp., and *Aspergillus* spp.
- It affects *Melilotus* spp. of sweet clover.
- Any method of hay storage that allows molding of sweet clover promotes the likelihood of the formation of dicoumerol in the hay.
- Weathered large round bales, particularly the outer portion, has the highest levels of dicoumerol.
- Sweet clover plants are biennial legumes found throughout much of the United States and southern Canada along roadsides or in waste areas. In the northwestern United States, this plant is grown as a forage for livestock. These plants can produce a severe hemorrhagic disease in cattle that is less likely to occur in other ruminants.
- The stems arising from taproots are erect and reach a height of 3 to 6 feet. The leaves are composed of three leaflets with the apices rounded. The flowers are small and white (*Melilotus alba*) or yellow (*Melilotus officinalis*).

PATHOPHYSIOLOGY

- When the toxic hay or silage is consumed, hypoprothrombinemia results as dicoumerol combines with the proenzyme to prevent the formation of the active enzyme required for the synthesis of prothrombin.
- Fungal invasions in partially cured stems initiate the conversion of coumarin to dicoumarol, a potent anticoagulant. Dicoumerol is antagonistic to vitamin K and consequently blocks the synthesis of prothrombin and clotting factors VII, IX, and X. Vitamin K is necessary for the conversion of these clotting factors from their precursors in the liver.
- Prothrombin interferes with the synthesis of factor VII and other coagulation factors.
- The toxic agent crosses the placenta in pregnant animals and newborns may be affected at birth.
- Field investigations determined that 50–70 ppm is toxic.

Species

Sheep and cattle of all ages

SIGNALMENT

SIGNS

- Stiffness, lameness due to bleeding into muscles and joints
- Hematoma formation, epistaxis, GI bleeding
- Death can be sudden with massive hemorrhage after injury, surgery, parturition
- Abortions, stillbirths, weak calves

CAUSES AND RISK FACTORS

For sweet clover poisoning to occur, animals require a continuous consumption of contaminated sweet clover hay or silage.

DIAGNOSIS

- Based on history of consumption of sweet clover hay and silage over a long period of time, signs and lesions as well as a prolonged blood clotting time
- Demonstration of reduced prothrombin content in the plasma

DIFFERENTIAL DIAGNOSIS

Blackleg, pasteurellosis, braken fern poisoning, aplastic anemia, rodenticide poisoning (e.g., warfarin and brodifacoum), and rarely purpura hemorrhagica.

CBC/BIOCHEMISTRY/URINALYSIS

- Increased ACT, OSPT, APTT
- Prothrombin time in rabbits fed contaminated hay (prolonged from approximately 15 seconds to 100–200 seconds)
- Prolonged bleeding time
- Anemia
- Prolonged clotting time
- Platelets—normal

OTHER LABORATORY TESTS

- No quick chemical test for dicoumerol; absence of visible spoilage is insufficient evidence to disqualify diagnosis.
- Dicoumerol levels of 20–30 mg/kg in hay are usually required to cause poisoning in cattle.
- Liver dicoumerol concentration

IMAGING

N/A

DIAGNOSTIC PROCEDURES

PATHOLOGICAL FINDINGS

GROSS FINDINGS

Hemorrhage is characteristic necropsy finding, large accumulations of blood commonly found in subcutaneous and connective tissue.

TREATMENT

- Remove from source
- Try to avoid excessive movement or stress to the animals involved.

MEDICATIONS

- IV administration of 2–4 L of whole blood per 1000 lb (450 Kg) BW from an animal not fed sweet clover. Repeat as necessary.
- Vitamin K 1 (phytonadione) is more effective than vitamin K 3 given IM once at 1.1–3.3 mg/kg BW
- Vitamin K 3 is ineffective as a treatment.
- Remove sweet clover from ration 1 month prior to calving.

DRUGS OF CHOICE

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered.

FOLLOW-UP

PATIENT MONITORING

Recheck prothrombin time 1 week after initiation of treatment.

PREVENTION/AVOIDANCE

- Feed cultivars of sweet clover, low in coumarin; monitor feed.
- If sweet clover is present, make sure the hay is cured properly to avoid any moldy conditions.
- Avoid feeding sweet clover hay baled damp.

POSSIBLE COMPLICATIONS**EXPECTED COURSE AND PROGNOSIS**

- If anemia is severe, the prognosis would be guarded especially if animal is stressed. Prolonged prothrombin times may last 1 or more weeks.
- Milder cases respond well to treatment.
- Several weeks may be necessary for return to normal.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

- The disease manifests itself by prolonged hemorrhage. Anemia, depression, and bleeding from the nose or digestive tract are early signs of sweet clover poisoning.
- Hematomas from bruising may be prominent over body areas most subject to trauma.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

N/A

PREGNANCY

- Pregnant animals should not be fed hay or silage containing moldy sweet clover.
- Death can be sudden with massive hemorrhage after injury, surgery, parturition.
- Abortions, stillbirths, weak calves

RUMINANT SPECIES AFFECTED

Cattle; less likely sheep and other ruminants

SWEET POTATO TOXICITY

BASICS

OVERVIEW

- Respiratory distress syndrome caused by ingestion of pneumotoxin found in moldy sweet potatoes (*Ipomoea batatas*).
- Native range is pantropical but sweet potatoes are grown and distributed worldwide.
- Infected potatoes typically have a dry, black surface that extends inward.

PATHOPHYSIOLOGY

- In response to infection by the fungus *Fusarium solani*, or related species, sweet potatoes produce stress metabolites that the fungus then converts to ipomeanine.
- Within the host lung, ipomeanine is reduced to 4-ipomeanol, the toxic metabolite, via cytochrome P450 enzymes.
- This metabolite is highly reactive and binds to lung proteins, especially type I pneumocytes and epithelial cells.

SYSTEMS AFFECTED

Respiratory, production management

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Potentially worldwide in distribution.

SIGNALMENT

Species

- All ruminants
- Cattle most susceptible

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- Acute onset of respiratory distress including rapid open-mouthed labored breathing. In advanced stages, cattle stand with head extended and there may be foamy saliva and expiratory grunts.
- Tachycardia, lethargy, depression, anorexia, aggression when handled
- Symptoms may appear within 1 day of ingestion, death 2–5 days after ingestion due to anoxia. Mild cases usually recover without treatment.

CAUSES AND RISK FACTORS

Feeding of sweet potatoes infected with the mold *Fusarium solani* (*javanicum*) or *F. oxysporum*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- ARDS syndrome caused by purple mint (*Perilla frutescens*), kale, rape, grasses, and *F. semitectum* infection of legumes. Also, L-tryptophan/3-methylindole toxicity due to abrupt change in feed.
- Allergic alveolitis, bovine respiratory syncytial virus, paraquat/petroleum intoxication, parasitic bronchitis, shipping fever
- No history of dietary change from dry to lush feed, no exposure to mint, etc.

CBC/BIOCHEMISTRY/URINALYSIS

CBC and urinalysis within normal limits

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Analysis of feed samples for 4-ipomeanol
- Culture of sweet potatoes used as feed and identification of *Fusarium solani*

PATHOLOGIC FINDINGS

- Some variability depending on dose and time to death.
- Gross—lungs wet, red to purple, rubbery and distended, and do not collapse upon opening of chest cavity. Pulmonary edema and emphysema, foamy or gelatinous exudates
- Microscopic—alveolar edema and emphysema, interstitial emphysema, epithelialization (due to proliferation of type II pneumocytes), interstitial fibrosis, eosinophilic hyaline membranes, vascular congestion

TREATMENT

Minimize stress and animal movement. Benefit of treatment must be weighed against cost of stress and possible death.

MEDICATIONS

DRUGS OF CHOICE

- Supportive, typically ineffective
- Antiprostaglandin drugs such as flunixin meglumine may decrease inflammatory response; diuretics to reduce edema; antibiotics for prevention of bacterial pneumonia; corticosteroids.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

Remove contaminated feed. Avoid feeding spoiled sweet potatoes or feeding sweet potatoes in conditions that favor fungal growth in a range situation.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Case fatalities 25%–50%

MISCELLANEOUS

ASSOCIATED CONDITIONS

In survivors, there is some evidence of alveolar macrophage changes that may suppress defense against bacterial infection.

TEAT LACERATIONS

BASICS

OVERVIEW

- Teat lacerations are most often a result of step-on injury by the cow herself or an adjacent cow.
- Teat lacerations often involve crushing injury as well as a cut.
- Teat injuries often occur in contaminated environments, resulting in wound contamination.
- Improper healing of teat injuries can result in scar tissue formation, teat obstruction, teat fistulas, and ultimately loss of the quarter.
- Mastitis is a common sequela of teat laceration.
- The teat is composed of five layers: internal mucosa, submucosa, connective tissue and blood vessels, muscular layer (circular and longitudinal layers), and external squamous epithelium.
- The teat cistern is contained within the teat, the distal opening of which is the Rosette of Furstenberg, which leads to the streak canal and teat sphincter.

SIGNALMENT

- Female cattle in lactation
- Dairy cows more likely to be affected than beef cows
- Cows with large or pendulous udders more commonly affected
- Lactating dairy sheep and goats also can be affected.

SIGNS

- Teat swelling
- Teat bleeding
- Milk leakage through teat wall
- Pain
- Bloody milk
- Mastitis

CAUSES AND RISK FACTORS

- Self-trauma
- External trauma
- Pendulous or large udders

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Mastitis can cause swelling of the teat and/or discoloration, bloody milk without obvious external trauma.
- Teat spiders, webs, and scar tissue can cause swelling and obstruction, but do not have associated bleeding or laceration.
- Teat fistulas cause leaking milk, but without associated traumatized tissue.
- Gangrenous mastitis causes swelling, discoloration, and bleeding, but is progressive and often generalized.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- California Mastitis Test (CMT) may indicate increased somatic cell count if mastitis is present.
- Milk culture may show bacterial growth if mastitis is present secondary to laceration.

IMAGING

Ultrasound of teat may be helpful to differentiate laceration from other causes.

DIAGNOSTIC PROCEDURES

Theloscopy can be used to locate and differentiate lesions inside the teat.

PATHOLOGIC FINDINGS

N/A

TREATMENT

- Surgical repair is required.
- Surgical repair should be attempted immediately. Prognosis drops with time after injury, and is extremely poor at more than 12 hours postinjury.
- Teat must be thoroughly cleaned and evaluated for tissue viability, blood supply, extent of injury.
- An anesthetic ring block around the base of the teat, following sedation of the animal or restraint on a tilt table, is adequate for local anesthesia. Alternatively, a caudal epidural can be performed. A tourniquet may be placed around the base of the teat to reduce bleeding and milk flow into the lacerated area during repair.
- Surgical repair should be performed in three layers: mucosa in tight continuous pattern of 3-0 or 4-0 absorbable monofilament with knots on submucosal side, submucosal tissue in a continuous pattern of 3-0 or 4-0 absorbable monofilament, and skin in interrupted vertical mattress or simple interrupted pattern with 0 or 2-0 nonabsorbable monofilament.
- Milking by machine can begin at the next milking period after repair.
- If desired, drainage of the teat can be performed in a sterile manner using a teat tube. Care must be taken to avoid damaging the surgical repair. Machine milking should begin as soon as possible after repair.
- Tissue adhesives and glue result in a severe inflammatory reaction during healing, which is more likely to result in formation of teat fistulas.

MEDICATIONS

DRUGS OF CHOICE

- All cows should be treated prophylactically for mastitis using at least a single dose of an approved antibiotic at the time of surgery.
- Intramammary infusions are often not required, and may be damaging to the surgical repair
- Flunixin meglumine 1.1–2.2 mg/kg IV can be used at the time of repair, but is rarely necessary after the initial dose.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Incision should be monitored daily for signs of incision breakdown.
- Suture removal at 7–10 days after surgery

PREVENTION/AVOIDANCE

- Avoid overcrowding cows.
- Ensure good footing in cow areas.

- Cows with pendulous udders may require separate housing or culling.
- Ensure that free stalls are wide enough for easy rising.
- Monitor the length of the medial dew claw(s) as overgrowth can result in teat/udder injury.

POSSIBLE COMPLICATIONS

- Teat fistula formation can occur anywhere along the repair line. Fistulas should be allowed to heal for 3–4 weeks before surgical repair is attempted. Full-thickness repair should be performed again in the region of the fistula, following resection of the fistula.
- Mastitis is likely, and should be treated appropriately, avoiding intramammary infusions if possible.

EXPECTED COURSE AND PROGNOSIS

- Healing should be complete in 10–14 days.
- Prognosis is good with immediate repair, guarded with lacerations > 6 hours old, and poor with lacerations > 12 hours old.
- Prognosis is better with partial thickness lacerations than full thickness lacerations.

MISCELLANEOUS

ASSOCIATED CONDITIONS

TEAT LESIONS

BASICS

DEFINITION

- Teat lesions are the result of traumatic, infectious, chemical, neoplastic, environmental, or milking machine processes that injure teat skin, dermis, or mucosa resulting in lactation difficulties.
- Mastitis may result if there is penetration and compromise of the teat sinus or external sphincter.

PATHOPHYSIOLOGY

- Teat lesions damage the physiologic barriers of the teat skin, wall, and sphincter.
- Loss of barrier integrity can cause the teat and gland sinuses to leak milk or allow entry of pathogens into the mammary sinuses resulting in mastitis.
- Teat end lesions usually do not contribute to mastitis unless the lesions are severe.

SYSTEMS AFFECTED

Skin (as the specialized organ of milk delivery and innate immune barrier)

GENETICS

- Phenotypic traits associated with teat lesions include cylindrical teat shape (opposed to funnel-shaped), long teats, external sphincter shape (disc-shaped opposed to round), large and pendulous udders, teat placement and angle on the udder (allowing teats to be stepped on), and suspensory ligament breakdown.
- Slow milkers and high-producing animals also have higher incidences of teat lesions.

INCIDENCE/PREVALENCE

- Teat lesions are more common in animals with the characteristics mentioned above.
- Elevated incidence can be seen with infectious epidemics, abrupt milking system malfunction, or changes in milking practices.
- Higher prevalence may be seen with adverse environmental conditions (freezing cold, traumatic rough terrain, flies) and higher parity.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

- Teat injuries are problematic in lactating animals and more frequently affect high parity dairy breeds.
- They are more common in confined animals.

SIGNS

- Reluctance to be nursed or milked
- Teat erythema
- Swelling and edema
- Vesicles or papules
- Skin cracks
- Scab formation
- Bleeding or laceration
- Teat end hyperkeratosis or sphincter eversion
- Stamping of feet, brushing udder with hind legs
- In chronic cases, there is mammary gland atrophy.

CAUSES

Environmental

- Blunt trauma (stepped-on teats)
- Laceration (wire, brambles, other sharp objects)
- Cold (frostbitten and chapped teats)
- Photodermatitis (sunburn)
- Chemicals (defective or inappropriate teat dips or lime from floors or stalls)
- Milking machine trauma (overmilking and excessive vacuum pressure)
- Insects (teat atresia from *Haematobia irritans irritans*—the horn fly)

Infectious Agents

- Pseudocowpox
- Vesicular stomatitis
- Foot-and-mouth disease virus
- Bovine viral diarrhea
- Bovine malignant catarrhal fever
- Cowpox
- Bovine herpes virus 2
- Vaccinia virus
- Bovine papillomavirus

Corpora amylacea (CoA) Photosensitization Plants

- *Ammi majus* (bishop's weed, greater ammi)
- *Cooperia pedunculata* (rain lily)
- *Cymopterus watsonii* (spring parsley)
- *Fagopyrum esculentum* (buckwheat)
- *Heracleum mantegazzianum* (giant hog weed)
- *Hypericum perforatum* (St. John's wort)
- *Thamnosma texana* (Dutchman's breeches)
- *Brassica* spp. (kale)
- *Lantana camara* (lanata)
- *Senecio* spp. (ragwort)
- *Amsinckia* spp. (fiddleneck)
- *Panicum* spp. (millet)

Chemicals

- Phenothiazines
- Thiazides
- Acriflavines
- Rose Bengal
- Methylene blue
- Sulfonamides
- Tetracycline

Mycotoxins

- *Aspergillus* spp.
- *Fusarium* spp.
- *Anacystis* spp.
- *Pithomyces chartarum*

RISK FACTORS

See Genetics above, Incidence/Prevalence above, and Causes above.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Pseudocowpox, vesicular stomatitis, foot and mouth disease, bovine viral diarrhea, bovine malignant catarrhal fever, cowpox, bovine herpes virus 2, bovine papillomavirus, environmental causes (above), and photosensitization from ingestion of various plants, chemicals, or mycotoxins.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

Endoscopy and ultrasonography useful to assess cause and prognosis of milk flow hindrance

DIAGNOSTIC PROCEDURES

DIAGNOSIS

- Dependent upon visualization and palpation
- Milk culture prior to antibiotic treatment may be helpful to combat secondary mastitis.

PATHOLOGIC FINDINGS

GROSS LESIONS

- Include lacerations, swelling, hemorrhage, vesicles, papules, cracks, and teat end hyperkeratosis and/or sphincter eversion.
- In severe cases, there can be proliferative granulation tissue and keratin deposition with hyperkeratosis leading to lumen narrowing.
- Varying degrees of necrosis are common and bacterial agents or viral inclusions may be detected.

TREATMENT

APPROPRIATE HEALTH CARE

NURSING CARE

- Teats should be kept clean and bandaged if possible, or covered with an appropriate dip, ointment, or teat sealer.
- Milking should be done with a cannula in a fashion that is as aseptic as possible.
- Discontinued milking of affected teats will reduce milking-associated trauma.

ACTIVITY

House animals on clean, dry bedding and away from suckling calves and other sources of teat trauma.

DIET

N/A

CLIENT EDUCATION

- Severe acute teat end lesions are serious injuries with resultant mixed-pathogen mastitis and granulation/canal stenosis.
- Aseptic technique, canal dilation, and appropriate antimicrobial withdrawal times will benefit the patient.

SURGICAL CONSIDERATIONS

Milking

- Discontinued milking of affected teats will speed healing by reducing manipulation-associated trauma.
- Culling may be considered in severe cases with refractory mastitis.

Lacerations

- Surgical correction is appropriate depending on the severity and posttrauma interval.
- Fresh lacerations (less than 12 hours) with adequate blood supply may be closed with two-layer everting mucosa and skin/muscle sutures.
- Older lacerations warrant cleansing and removal of the skin flap followed by second intention healing with granulation.
- Teats should be bandaged and milk retrieved with a cannula.

Chapped or Sunburned Teats

- Apply topical emollients approved for use in lactating cattle such as mineral oil, glycerin, or lanolin.
- Teats should be dried after milking.

Frostbite, Virus Infection, and Teat End Trauma

- Preventing mastitis while keeping the teat duct patent may require teat dilators, cannulas, and intramammary or parenteral antimicrobials.
- For teat end lesions caused by the above conditions, using teat dips containing antiseptics such as chlorhexidine, iodophors, and bleach can reduce secondary mastitis.
- Keep teats dry and cows comfortable.

MEDICATIONS

DRUGS OF CHOICE

Antibiotics

See The Environment and Mastitis chapter.

Teat Dips

- Iodophor solutions: 1% available iodine
- Hypochlorite solutions: 4% free chlorine
- Chlorhexidine solutions: 0.3%

Emollients

- Glycerin: 15%–30%
- Mineral oil
- Lanolin

CONTRAINDICATIONS

- See The Environment and Mastitis chapter.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Aseptic milking techniques will reduce the incidence of mastitis.
- Teat sphincter integrity should be monitored as inflammation subsides and possible granulation ensues.
- Monitoring body temperatures, milk secretion consistency, CMT testing, in addition to follow-up milk cultures is useful to gauge presence of mastitis.

PREVENTION/AVOIDANCE

- House cows in clean areas with ample space and protection from the elements.
- Practice sound milking hygiene techniques.
- Keep lots, pastures, and fences well maintained and free of debris.
- Use approved fly control.

- Genetically select for desirable udder and teat conformation.

POSSIBLE COMPLICATIONS

- Permanently damaged teat end(s) with resultant quarter loss and decreased milk production
- Mastitis
- Reduced milk intake in suckling offspring

EXPECTED COURSE AND PROGNOSIS

Common adverse sequelae of severe lesions are teat sphincter scarring and obstruction with integrity loss and resultant mastitis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Mastitis, contact dermatitis, loss of productivity

AGE-RELATED FACTORS

Teat lesions increase with parity

ZOONOTIC POTENTIAL

- Teat lesions have no zoonotic potential unless they are caused by cowpox or pseudocowpox virus.
- Gloves should be worn when dealing with suspect or infected animals.

PREGNANCY

N/A

Species Affected

Lactating ruminants including cows, buffalo, sheep, and goats.

TESTICULAR ANOMALIES

BASICS

DEFINITION

Common diseases/anomalies affecting the testicles include hypoplasia, varicocele, orchitis/epididymitis, testicular degeneration, and cryptorchidism.

PATHOPHYSIOLOGY

- Testicular hypoplasia is thought to be a heritable genetic condition.
- Varicocele is a dilatation of the blood vessels of the pampiniform plexus.
- Orchitis/epididymitis can be the result of many infectious processes.
- Testicular degeneration may be idiopathic or be secondary to other diseases that affect the thermoregulation of the testes.
- Cryptorchidism is the failure of one or both testes to descend into the scrotum.

SYSTEMS AFFECTED

- Sperm production and/or fertility will be reduced in most cases of testicular disease.
- Sperm production and/or fertility may not be reduced in cases of disease involving only one testicle.

GENETICS

Testicular hypoplasia and cryptorchidism are heritable traits and affected animals should not be used for breeding.

INCIDENCE/PREVALENCE

- Testicular hypoplasia is the most common testicular abnormality seen in young bulls. Incidence has been reported to range between 0.2% and 1.3%.
- Varicocele occurs sporadically in rams but is rare in other ruminant species.
- Orchitis/epididymitis is rare in bulls and much more common in rams than in bucks. An incidence of 0.45% has been reported in a study of young ranch beef bulls and an incidence of 0.12% has been reported in bulls maintained at an AI stud.
- Testicular degeneration is often secondary to some other form of testicular disease.
- Cryptorchidism is uncommon in bulls with a reported incidence of 0.1%. In goats, there is a higher incidence of cryptorchidism in intersexes.

GEOGRAPHIC DISTRIBUTION

Worldwide distribution

SIGNALMENT

- Testicular anomalies occur in males of all domesticated ruminant species.
- Congenital testicular hypoplasia occurs in young bulls, bucks, and rams.
- Orchitis/epididymitis can occur in males of any age.
- Testicular degeneration can occur in males of any age secondary to other testicular diseases. Age-related degeneration occurs earlier in bulls than in males of other species.
- Cryptorchidism is a congenital condition and is usually recognized in young animals.

SIGNS

- Testicular hypoplasia produces no evidence of illness. It is most often noticed at puberty when an animal undergoes a breeding soundness exam.
 - The scrotum and testes appear smaller than normal.
 - Sperm motility, percentage of normal sperm, and total sperm per ejaculate may be reduced in males with testicular hypoplasia.
 - Libido is not usually affected.

- Varicoceles may result in a nodular or lumpy appearance to the affected testicle or may produce an evident swelling in the neck of the scrotum. Semen quality may be decreased if the varicocele interferes with the normal thermoregulation of the testicles.
- Orchitis/epididymitis is usually unilateral and produces a warm, painful swelling of the affected testicle and scrotum.
 - If severe enough, the animal may present with systemic signs of illness.
 - Swelling associated with orchitis may be marked.
- Testicular degeneration may be difficult to differentiate from testicular hypoplasia if the previous testicular size of an animal is unknown.
 - Testicles may become smaller and more flaccid.
 - Calcification may occur secondary to fibrosis in age-related degeneration.
 - Semen quality may be reduced.
 - Degeneration may be secondary to many other testicular diseases and signs of other disease processes may be present.
- Cryptorchidism is usually clearly evident due to the absence of one or both testicles in the scrotum.
 - Semen production may be absent if both testicles are involved.
 - Normal masculine features and behavior will still be present.

CAUSES

- Testicular hypoplasia is a heritable genetic condition.
- Varicoceles may result from an insufficiency of veins draining the testes or from abnormal connective tissue surrounding the veins, which allows stasis of blood in the veins.
- Orchitis/epididymitis may result from hematogenous spread, extension from other parts of the reproductive or urinary systems, or from local penetrating trauma to the scrotum.
 - *Brucella abortus* and *A. pyogenes* are the most common causes of orchitis in bulls.
 - Coliform bacteria and *Pseudomonas* have been cultured from bucks with orchitis. *Brucella melatinis* and *Actinobacillus seminis* also can cause orchitis in bucks.
 - *Brucella ovis* is the primary cause of orchitis in rams.
 - Many other nonspecific bacteria have been isolated from cases of orchitis/epididymitis.
- Testicular degeneration may occur secondary to many testicular diseases.
 - Conditions such as fever, frostbite, orchitis, trauma, and excessive scrotal fat, which result in an alteration of the normal thermoregulation of the testicles, can result in degeneration.
 - Degeneration may occur secondary to a blockage of the excurrent duct system.
 - Age-related degeneration may occur in older animals.
- Cryptorchidism is a heritable genetic trait.

RISK FACTORS

- Using animals affected with testicular hypoplasia or cryptorchidism increases the occurrence of these problems.
- Exposure of breeding males to females carrying infectious agents such as *Brucella* species will increase the risk of orchitis/epididymitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Differential diagnoses for small scrotum and testicle size include testicular hypoplasia, testicular degeneration, and cryptorchidism.
- Differential diagnoses for a swollen scrotum or testicle include orchitis/epididymitis, varicocele, inguinal hernia, hydrocele, hematocele, and neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS

Severe cases of orchitis/epididymitis may produce evidence of infection and/or inflammation on a complete blood count.

OTHER LABORATORY TESTS

- Culture and sensitivity of seminal fluid may be useful in establishing the presence of infectious orchitis.

- Evaluation of a semen sample is useful in diagnosing diseases of the testicles.
 - Animals with testicular hypoplasia and testicular degeneration produce low numbers of sperm and a higher number of morphologically abnormal sperm.
 - Orchitis may reduce semen quality by directly destroying the affected tissue and by affecting thermoregulation of the remaining testicle.
 - Varicoceles may reduce semen quality by disrupting normal testicular thermoregulation.

IMAGING

- Ultrasound examination of abnormal testicles is a very useful diagnostic tool. The affected testicle can be compared to the opposite unaffected testicle or to a normal animal of similar age and condition.
- If available, thermography may be useful in diagnosing orchitis/epididymitis.

DIAGNOSTIC PROCEDURES

- Testicular hypoplasia is diagnosed by observation and palpation of the scrotum and testicles.
 - Measurement of scrotal circumference provides definitive diagnosis.
 - Scrotal circumference less than 30 cm in postpubertal bulls is diagnostic for hypoplasia.
 - Poor semen quality combined with small testicle size is supportive of hypoplasia.
- Varicoceles are diagnosed by palpation of the scrotum and testes (“bag of worms”). Ultrasound examination may be useful when evaluating varicoceles.
- Diagnosis of orchitis/epididymitis is based on observation and palpation of unilateral testicular swelling with heat and pain.
 - Ultrasound exam may be useful.
 - Culture of seminal fluid may be useful.
- Testicular degeneration is diagnosed based on a reduction in testicle size and a reduction in semen quality. If previous testicular size is unknown, differentiating between hypoplasia and degeneration may be difficult.
- Cryptorchidism is diagnosed based on observation and palpation of the scrotum and testes.
 - Ultrasound examination may be helpful in locating the retained testicle.
 - Measurement of testosterone levels and response to human chorionic gonadotropin is helpful in diagnosing bilateral cryptorchidism or unilateral cryptorchidism once the normal testicle has been removed.

PATHOLOGIC FINDINGS

- Histopathologic examination of hypoplastic testicles reveals hypoplastic tubules that have a small diameter, are lined by Sertoli cells and a few stem cells and spermatogonia, and have a thickened basement membrane surrounded by collagen deposits. The severity of the abnormalities depends on the degree of hypoplasia.
- The histopathologic appearance of cryptorchid testicles and testicular degeneration is similar to that of testicular hypoplasia.
- Orchitis produces varying degrees of inflammation, edema, and necrosis of the affected testicle.

TREATMENT

APPROPRIATE HEALTH CARE

N/A

NURSING CARE

Hydrotherapy with cool water may be beneficial in cases of orchitis/epididymitis.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

- Animals with testicular hypoplasia or cryptorchidism should not be used for breeding purposes.
- Salvage may be the best option for commercial animals with testicular disease.

SURGICAL CONSIDERATIONS

Surgical removal of the affected testicle is often the best treatment for unilateral orchitis/epididymitis, varicocele, hydrocele, hematocele, or neoplasia.

MEDICATIONS

DRUGS OF CHOICE

- Antibiotic therapy for orchitis/epididymitis should be based on culture and sensitivity of seminal fluid.
- Antibiotic therapy is often unrewarding.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Consideration should be given to withdrawal periods before antibiotic therapy is instituted.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Repeated (monthly) semen evaluations are needed to monitor the progression of degeneration or the response to therapy for orchitis.

PREVENTION/AVOIDANCE

The presence of asymptomatic carriers in the herd must be considered when dealing with infectious orchitis, especially in sheep.

POSSIBLE COMPLICATIONS

Infertility

EXPECTED COURSE AND PROGNOSIS

- After successful medical or surgical treatment of orchitis, semen production may return to normal with time, depending on the severity of damage to the remaining testicular tissue.
- Once testicular degeneration has occurred, treatment is usually unrewarding. The prognosis will depend on the degree of degeneration and the progression of the disease.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Testicular hypoplasia and cryptorchidism are usually diagnosed in young animals.
- Age-related testicular degeneration may be seen in all male ruminants, especially bulls.

ZOONOTIC POTENTIAL

- Infectious orchitis caused by *Brucella* species poses some zoonotic risk to humans.
- Animals diagnosed with infections caused by these organisms should be culled.
- Brucellosis is a reportable disease.

PREGNANCY

Abortion can occur with infected bulls.

RUMINANT SPECIES AFFECTED

Cattle, sheep, goats, yaks, camelids, cervidae

BIOSECURITY

Sound biosecurity measures should be used to prevent the introduction of infectious organisms such as *Brucella* species into a clean herd or flock.

PRODUCTION MANAGEMENT

- All bulls should receive a BSE prior to the breeding season.
- A BSE is particularly important in young bulls prior to their first breeding season.

THELAZIASIS

BASICS

DEFINITION

- Ophthalmic infestation with the nematode *Thelazia* spp. (eye worms)
- In ruminants, species of *Thelazia* include *T. gulosa*, *T. skrjabini*, *T. rhodesii*, and *T. californiensis*.
- Other species of *Thelazia* can infect sheep, goats, deer, buffalo, and dromedaries.

PATHOPHYSIOLOGY

- *Thelazia* spp. requires flies of the genus *Musca* as a necessary intermediate host.
- Adult female *Thelazia* can live in the lacrimal ducts of the nictitating membrane, in the conjunctival sacs, or under the eyelids and nictitating membranes. They discharge their larvae into ocular secretions. The fly ingests the first-stage larvae, which develop into infective third-stage in 15 to 30 days. These larvae are deposited on the eye of the host by the fly during feeding.
- Depending on the species of *Thelazia*, the larvae reach maturity in 2 to 6 weeks and begin releasing larvae ovoviviparously.
- Mechanical irritation and inflammation can lead to lesions involving the lacrimal glands and ducts, conjunctivitis, blepharitis, keratitis, and other corneal damage.
- It can also be nonsymptomatic. *T. rhodesii* is implicated in more severe cases in ruminants.

SYSTEMS AFFECTED

Ocular system, production management

GENETICS

None

INCIDENCE/PREVALENCE

Varies with geographic location. Studies have found a 17% prevalence of *T. rhodesii* in slaughterhouse examinations in the Philippines, and 15% prevalence of *T. californiensis* in hunter-killed mule deer in Wyoming and Utah.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

- *T. californians*: deer, jackrabbit, sheep, canids, felids, raccoon, bear, and humans in North America
- *T. rhodesii*: bovines, buffalo, goats, sheep, and deer in Europe, Africa, Middle East, and Asia
- *T. gulosa* and *T. skrjabini*: cattle in North America

SIGNS

HISTORICAL FINDINGS

Asymptomatic to chronic conjunctivitis and keratitis

PHYSICAL EXAMINATION FINDINGS

- Quite variable, from asymptomatic incidental discovery to severe symptoms
- Conjunctivitis, epiphora, blepharitis, and photophobia
- Keratitis possibly with ulceration, perforation, or scarring.
- Visible worms on surface of eye, under eyelids or nictitating membranes

CAUSES

Thelazia spp. ophthalmic infection

RISK FACTORS

Face flies in an area known to have *Thelazia* spp.

DIAGNOSIS

- Examination of conjunctival sacs and underlying nictitating membranes. Topical anesthesia may be helpful to the examination process.
- Microscopic examination of lacrimal fluids for larvae

DIFFERENTIAL DIAGNOSIS

- Chronic bacterial conjunctivitis
- Viral conjunctivitis/keratitis
- Corneal laceration
- Foreign body

PATHOLOGIC FINDINGS

May see the parasite emerging from the conjunctival sac or deposited on the skin/hair around the eye of moribund species

TREATMENT

- Manual removal of the parasite, utilizing topical anesthesia. *T. rhodesii* and *T. californiensis* are more superficial species facilitating manual removal.
- Several species of *Thelazia* are more invasive and require pharmaceutical intervention.

MEDICATIONS

- Ivermectin or doramectin at 200 micrograms per kilogram body weight given subcutaneously can be 99% to 100% effective for *T. rhodesii* in cattle.
- Levamisole at 5 mg per kg body weight in cattle may be effective as well.

POSSIBLE INTERACTIONS

Do not treat lactating animals producing milk for human consumption with ivermectin or doramectin. Meat withdrawal times: ivermectin and doramectin, 35 days; levamisole, 7 days.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Control of face flies
- Dry, open pastures and less intensely confined conditions help reduce fly numbers.

POSSIBLE COMPLICATIONS

Scarring of cornea or loss of eye secondary to perforation of cornea is possible in rare severe cases.

EXPECTED COURSE AND PROGNOSIS

Full recovery if ocular lesions are not too severe

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Corneal ulceration
- Mechanical irritation and inflammation can lead to lesions involving the lacrimal glands and ducts, conjunctivitis, blepharitis, keratitis, and other corneal damage.

AGE-RELATED FACTORS

None

ZOONOTIC POTENTIAL

T. californiensis—in humans, chronic conjunctivitis, poorly responsive to conventional treatment

THIRD COMPARTMENT ULCERS IN SOUTH AMERICAN CAMELIDS

BASICS

OVERVIEW

- Mucosal ulcerations in the third compartment of the camelid stomach (C3) are a common occurrence in sick and stressed camelids.
- The majority of ulcers occur in the distal fifth of C3. This is the only region of the camelid stomach that contains acid-secreting gastric glands, with an intraluminal pH of 1.4–2.0. Ulcers are most commonly reported at the lesser curvature of distal C3 and in the proximal duodenum.
- Ulcers have been reported in all of the regions of the camelid stomach, but are rare in C1, C2, and the proximal four-fifths of C3.
- Ulcers typically occur as focal, discrete mucosal lesions. Perforating ulcers are not uncommon.

SIGNALMENT

- Ulcers occur in both crias and adult camelids with approximately equal incidence.
- Some studies report a slightly higher incidence in breeding-age females, but no clear sex predilection has been proven.

SIGNS

- Nonspecific signs such as depression and anorexia are most frequently reported. Decreased borborygmi and compartmental contractions are also common.
- Colic, recumbency, and bruxism occur, but are less common.
- Temperature, pulse, and respiratory rate are within normal limits unless perforation and subsequent peritonitis have occurred.
- Melena and/or anemia as a result of bleeding ulcers are not reported.
- The presence of concurrent or multisystemic disease in animals with third compartment ulcers is a frequent complicating factor, making the detection of clinical signs specific to gastric ulceration extremely difficult.

PATHOPHYSIOLOGY

- The normal physiology of gastric-acid secretion and of mucosal protection in the camelid stomach has not been determined, and thus the pathogenesis of third compartment ulcers is poorly understood.
- Ulcers are most commonly seen in hospitalized camelids with another, concurrent disease. It is postulated that the stress of concurrent disease and/or hospitalization predisposes the camelid to ulcer formation. The mechanism by which this occurs is not defined, but may be linked to the inhibition of mucosal protective factors by increased levels of endogenous cortisol and/or catecholamines.
- A direct association between nonsteroidal anti-inflammatory agents and a higher incidence of gastric ulcers has not been documented in camelids.
- The incidence of third compartment ulcers and the prevalence of grain in camelid diets are both higher in camelids living in the United States than in South America, but no direct link has been proven.

RISK FACTORS

- Hospitalization, especially when unable to see/associate with another camelid
- Other systemic disease, traumatic injury, and/or orthopedic problems

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Third compartment ulcers are a diagnosis achieved by exclusion. Important rule-outs include:

- Gastrointestinal lesions (intestinal torsions, intussusceptions, and impactions, C1 stasis)
- Intra-abdominal abscesses
- Pancreatitis
- Peritonitis in the absence of a perforated ulcer
- Plant toxicities
- Urogenital tract lesions (uterine torsion, ruptured bladder, urolithiasis, cystitis/urethritis)

CBC/BIOCHEMISTRY/URINALYSIS

- No consistent findings.
- Leukocytosis due to neutrophilia, with or without a degenerative left shift, may be seen in perforated ulcers depending on the duration of the lesion.
- Hypoalbuminemia may also be observed in cases with perforation.
- Hyperglycemia, with serum glucose > 250 mg/dl, is often seen, but this is a common stress response in any sick/stressed camelid and is not pathognomonic for gastric ulcers.

IMAGING

- Radiography after administration of oral contrast medium is of little diagnostic value due to the delay in transit time through the stomach compartments.
- Unlike the horse, endoscopic evaluation of the third stomach compartment and duodenum is not possible in the camelid.
- Ultrasonographic evaluation of the abdomen may be helpful in locating intrabdominal abscesses or masses and/or evaluation for generalized peritonitis, but is usually not helpful in diagnosing nonperforated third compartment ulcers.

OTHER DIAGNOSTIC PROCEDURES

- Analysis of peritoneal fluid may be informative in cases of perforated ulcers, but is usually unremarkable in the absence of perforation. Perforated ulcers are often walled off, producing only a localized peritonitis.
- Fecal floatation for intestinal parasites should be performed, although a direct link between parasitism and ulcers has not been proven.
- Analysis of fluid obtained from C1 via passage of an orogastric tube can be attempted; an acidic pH or decrease in numbers of microbial flora can be suggestive of third compartment ulcers.

SYSTEMS AFFECTED

Gastrointestinal—distal third compartment of the stomach and/or proximal duodenum

GENETICS

No genetic predisposition appears to exist.

INCIDENCE/PREVALENCE

- More prevalent in hospitalized camelid population than in the general population; estimated at ~5% of hospitalized camelids
- More common in the United States than in native South American populations of camelids

TREATMENT/PREVENTION

- Because of the lack of a good antemortem diagnostic test, treatment is initiated in the absence of a definitive diagnosis.
- Treatment/resolution of the primary problem is most important.
- The pharmacokinetics and pharmacodynamics of the standard classes of gastroprotectants (histamine-2 antagonists, proton pump inhibitors, synthetic prostaglandin-E analogues, and nonspecific gastric mucosal protectants) have not been fully determined in camelids; the following drugs are most commonly used:
 - Omeprazole: 0.4–1.2mg/kg PO SID-BID
 - Sucralfate: 20 mg/kg PO QID
 - Misoprostol: 10 ug/kg PO (do not use in pregnant animals)
 - Ranitidine (0.75–1.5 mg/kg IV, IM, or SQ SID-TID) has been used in camelids, but recent evidence suggests that at this dosing regime, ranitidine is not effective at decreasing gastric acid secretion for any significant duration in the camelid.
 - Supportive care with oral or intravenous fluids is usually necessary in anorexic animals.
 - If available, transfaunation with bovine ruminal fluid or camelid C1 fluid may be beneficial in some cases of prolonged

anorexia.

- Since camelids are extremely social animals, the stress of hospitalization can be reduced by providing a companion camelid, such as a healthy herd mate. If such a companion is not available, an appropriately sized mirror in or near the stall of the affected animal can provide the illusion of a companion.
- Antiulcer prophylaxis is becoming standard for any sick/hospitalized camelid.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

ASSOCIATED CONDITIONS

Any cause of systemic illness, trauma, or stress

AGE-RELATED FACTORS

None

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Rule out pregnancy-related causes of abdominal pain, such as uterine torsion, before diagnosing third compartment ulcers in a pregnant female.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

To minimize the risks of third compartment ulcers in a camelid herd, action should be taken to minimize stress associated with weaning, transport, showing, etc.

SYNONYMS

TICK PARALYSIS

BASICS

OVERVIEW

- A lower motor neuron (LMN) paralysis resulting from the bite of female ticks of species including *Dermacentor* spp. and *Amblyomma* spp. in the United States and *Ixodes holocyclus* in Australia.
- The potential for inducing paralysis has been suspected in 64 species of ticks belonging to the *Ixodid* and *Argasid* genera.
- The tick injects a neurotoxin that causes progressive motor paralysis, respiratory depression, and death in animals that have no immunity to the toxin.

SYSTEMS AFFECTED

CNS, gastrointestinal, respiratory, cardiovascular, hematologic, and musculoskeletal

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

- Common in Australia, potentially worldwide
- Distribution patterns reflecting tick populations
- Exposure to environments favorable to tick infestations such as brushy, woody areas

SIGNALMENT

- Sheep, goats, cattle
- Other species such as dogs may be affected.

Breed Predilections

N/A

Mean Age and Range

All ages potentially are at risk.

Predominant Sex

Both sexes are equally affected.

SIGNS

- Initially, ataxia and weakness in hind limbs
- Progression to paralysis of hind limbs then ascending, symmetrical, flaccid tetraplegia
- Afebrile
- Hyporeflexia of the superficial and deep tendons
- Nystagmus
- Dyspnea, dysphagia, weak facial muscles
- Flaccid tail and anus
- Disease may progress further and cause respiratory muscle paralysis resulting in death.

CAUSES AND RISK FACTORS

- Exact pathology is not certain. Signs are caused by a protein neurotoxin possibly produced by the tick itself, by a microbial organism associated with the tick, or by a toxic metabolite resulting from the interaction of tick saliva with host tissue.
- There is a reduction of acetylcholine release and a resulting blockage of neurotransmission at neuromuscular junctions.

- Interference with presynaptic nerve terminal depolarization and acetyl choline release produces a neuromuscular blockade. This manifests primarily as an ascending flaccid paralysis varying from paraparesis to quadriplegia.
- Exposure to environments favorable to tick infestations such as brushy, woody areas
- Seasonal incidence may change in geographic regions where tick populations vary based on ambient temperatures.
- Antitoxic immunity can occur 2 weeks after primary tick exposure and lasts a few weeks. Immunity may be boosted in subsequent infestations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Botulism
- Acute polyradiculoneuritis

CBC/BIOCHEMISTRY/URINALYSIS

- Results are usually normal.
- Mild acidosis and dehydration develop. Other changes include increases in blood glucose and cholesterol, and a decrease in blood potassium.
- Increased serum levels of creatine kinase (CK) in tick paralysis caused by *D. andersoni* and *I. holocyclus*.
- Phosphate levels increased in later stages of paralysis caused by *I. holocyclus*.

OTHER LABORATORY TESTS

Severely affected animals may have a mild metabolic acidosis.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Examination for the presence of ticks on affected animals

PATHOLOGIC FINDINGS

GROSS FINDINGS

None specific to the disease, death occurs due to respiratory paralysis

HISTOPATHOLOGICAL FINDINGS

N/A

TREATMENT

- Timely removal of attached ticks, either manually or by using a suitable acaricide. It may be necessary to shave long-haired animals to effectively locate all ticks.
- Supportive therapy—monitor for respiratory paralysis and hypoxia.

MEDICATIONS

Acaricidal dips

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- Ectoparasite sprays or dips to kill ticks on the animals
- Environmental control to reduce tick populations is recommended.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Incubation period is usually 5–7 days.
- If ticks are removed, prognosis is good to excellent. Recovery usually occurs within 1 to 3 days.
- *Ixodes* tick paralysis—untreated animals die within 1 to 2 days.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

The same ticks can cause tick paralysis in humans. Animals with the disease cannot transmit the disease to humans.

TICKS AFFECTING SMALL RUMINANTS

BASICS

OVERVIEW

- The tick families Ixodidae and the Argasidae belong to the order Acarina of the class Arachnida.
- Some species of Ixodid ticks (hard ticks) and Argasid ticks (soft ticks) parasitize mammals.
- Ticks are temporarily parasitic; the larvae, nymphs, or adults only parasitize mammalian hosts to obtain a blood meal. Various tick species are classified as one-host, two-host, and three-host ticks.
- Free-living stages can survive for long periods without feeding.
- Ticks are cosmopolitan in their choice of mammalian host.
- Typically, small numbers of ticks have little direct effect on the host.
- Heavy infestation with engorged adults can remove physiologically significant amounts of blood from neonates.
- Some species of tick cause so-called tick paralysis.
- Many tick species are vectors of disease-causing microorganisms and viruses.
- Wounds from bites can become infected and predispose to cutaneous myiasis.
- The geographic distribution of ticks is limited by climate, particularly humidity, as free-living stages are susceptible to desiccation.

SYSTEMS AFFECTED

Production management, CNS, hematologic, skin, reproductive

CAUSES AND RISK FACTORS

There is a bewildering regional variety of different species of tick and tick-borne diseases; wherever possible, local experts should be consulted.

Ixodidae (Hard Ticks)

Amblyomma spp., *Boophilus* spp., *Dermacentor* spp., *Haemaphysalis* spp., *Hyalomma* spp., *Ixodes* spp., *Rhipicephalus* spp.

Argasidae (Soft Ticks)

Otobius spp.

DIAGNOSIS

See also specific diseases.

DIFFERENTIAL DIAGNOSES

Tick-borne/tick-associated diseases:

- Benign theileriosis of small ruminants (*Theileria ovis*)
- Dermatophilosis (*Dermatophilus congolensis*)
- European ehrlichiosis (*Ehrlichia phagocytophila*)
- European piroplasmosis of small ruminants (*Babesia motasi*)
- General toxicosis (salivary endotheliotrophic toxin)
- Heartwater (*Ehrlichia* [Cowdria] *ruminatum*)
- Louping-ill virus (Flaviviridae)
- Malignant theileriosis of small ruminants (*Theileria hirci*)
- Nairobi sheep disease virus and Ganjam virus (Bunyaviridae)
- Q-fever (*Coxiella burnetti*)
- Spirochaetosis (*Borrelia theileri*)
- Spotted fevers (*Rickettsia* spp.)
- Sweating sickness (salivary epitheliotrophic toxin)
- Tick paralysis (salivary neurotoxin-induced dose-dependent ascending paralysis)
- Tick pyaemia (*Staphylococcus aureus*)
- Tropical anaplasmosis of small ruminants (*Anaplasma ovis*)
- Tropical babesiosis of small ruminants (*Babesia ovis*)
- Tropical ehrlichiosis of small ruminants (*Ehrlichia ovina*)
- Tularemia (*Francisella tularensis*)

TOBACCO TOXICOSIS

BASICS

DEFINITION

Intoxication and/or adverse consequences after ingestion of plants of the genus *Nicotiana*. They are members of the nightshade family, Solanaceae.

PATHOPHYSIOLOGY

- Two primary toxic compounds are responsible for the adverse effects of tobacco ingestion: nicotine and anabasine.
- Nicotine—a potent pyridine alkaloid has poor palatability, but animals will eat it if forage is scarce. It can cause a direct contact irritation to gastrointestinal mucosa. Pharmacologically, it mimics acetylcholine at the autonomic ganglia and myoneural junction acting as a neuromuscular blocking agent.
- Anabasine—a piperidine-pyridine alkaloid is a teratogen.

SYSTEMS AFFECTED

Intestinal tract, nervous system, reproductive, musculoskeletal, production management

GENETICS

None

INCIDENCE/PREVALENCE

- Varies with geographic location
- *N. tabacum*—cultivated tobacco
- *N. trygonphylla*—wild or desert tobacco in the dry areas of southwest United States
- *N. attenuata*—wild or coyote tobacco also in the dry areas of southwest United States
- *N. glauca*—tree tobacco, an evergreen shrub of low elevation areas of Arizona and California

GEOGRAPHIC DISTRIBUTION

Worldwide; southwestern United States and anywhere tobacco is cultivated.

SIGNALMENT

Species

- Potentially any animal can be affected.
- Among domestic ruminants, cattle, sheep, and goats have had documented cases.

SIGNS

.

HISTORICAL FINDINGS

Access to *Nicotiana* spp. where forage is poor, pasturing on land where tobacco is cultivated, and ingestion of tobacco products or tobacco-tainted water.

PHYSICAL EXAMINATION FINDINGS

Neurological Symptoms

Salivation, vomiting, diarrhea, excitement, increased respiratory rate, twitching, trembling, stiff and uncoordinated gait leading to respiratory paralysis, weakness, bloat, blindness, collapse, and death

Teratogenic Effects

Calves exhibit arthrogryposis of the forelimbs and spondylolisthesis identical to that seen in lupine toxicity. In sheep, carpal flexure and cleft palate can be seen.

DIAGNOSIS

History of potential exposure to *Nicotiana* spp. and compatible clinical signs

DIFFERENTIAL DIAGNOSIS

- Other toxic plant causes of sudden death: blue-green algae, cyanogenic plants, death camas, larkspur, laurels, lupine, milkweed, oleander, water hemlock
- Other causes of teratogens should be investigated such as bluebonnet, locoweed, poison hemlock

PATHOLOGIC FINDINGS

- In cases of sudden death, no specific lesions might be seen, except the finding of *Nicotiana* spp. in the digestive tract.
- *Pale mucous membranes, poorly oxygenated blood, myocardial hemorrhage, pulmonary hemorrhages, and cerebral congestion are occasionally seen.*
- Teratogenic lesions in calves or lambs as listed above might be seen.

TREATMENT

- No specific treatment except to prevent further ingestion
- Administering activated charcoal and cathartics might be helpful and intravenous fluids may be needed.
- If practical, artificial respiration and supplemental oxygen can be provided in extremely valuable livestock.

MEDICATIONS

No specific medications

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

PREVENTION/AVOIDANCE

Prevent access to and consumption of *Nicotiana* spp., especially in forage-scarce areas.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

If the animal survives acute toxicity, the prognosis is good.

TONGUE TRAUMA

BASICS

DEFINITION

Acute to chronic oral ulceration, necrosis, and/or bruising due to a viral (vesicular stomatitis, bluetongue, malignant catarrhal fever, rinderpest), trauma or irritant (chemical irritants, coarse plants/feed), oral foreign bodies, and abscesses (actinobacillosis, “Woody tongue”).

OVERVIEW

- Because of the tongue’s important role in feed prehension and the eating habits of ruminants, tongue trauma is often acutely evident (salivation, blood mixed with saliva, tongue extended from mouth, dysphasia).
- The incidence of tongue condemnation presumably associated with *Actinobacillosis* is reportedly increasing in slaughtered nonfed cattle.

PATHOPHYSIOLOGY

- Dependent upon inciting cause
- Actinobacillosis is a commensal organism of GI tract and therefore may colonize oral ulcerations.
- Feeding coarse, dry feeds containing stickers and plant awns may result in damage to oral mucosa and colonization of deeper tissues with organisms.
- Toxic plant ingestion (e.g., hay containing flower clusters of yellow bristle-grass)
- Cactus spines
- Oral foreign bodies such as wire may lacerate the tongue during prehension leading to hemorrhage and eventually infection.
- Surgical correction may involve glossectomy or partial glossectomy with consideration of the importance of the tongue to prehension of feed.

SYSTEMS AFFECTED

Production management, musculoskeletal, gastrointestinal; tongue, oral cavity, and head.

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

- Vesicular stomatitis in dairy cattle results in large ulcerations of tongue with lesions evident on teats and coronary bands.
- Bluetongue virus in susceptible sheep results in tongue and dental pad erosions along with other signs compatible with vasculitis.
- Malignant catarrhal fever (cattle) and rinderpest (cattle, sheep, and goats) generally manifest as erosive stomatitis not limited to the tongue.

Species

Potentially, all ruminant species

Breed Predilections

N/A

Mean Age and Range

Tongue trauma is more common in younger animals due to their predisposition to suckle on environmental objects (wire,

thorns, etc.).

Predominant Sex

N/A

SIGNS

Salivation, blood in saliva, dysphagia, reluctance to allow examination of head, anorexia, weight loss, dehydration, foul odor to breath, nasal discharge

RISK FACTORS

Early weaning, less than optimal housing conditions, salt- or water-seeking behavior (lack of salt/trace minerals or suitable source of clean water) resulting in consumption of irritant substances (chlorinated naphthalene).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Vesiculating viral diseases
- Oropharyngeal trauma
- Necrotic stomatitis.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Culture and sensitivity is indicated if an infective agent is suspected.

IMAGING

May be helpful with foreign body or fracture

OTHER DIAGNOSTIC PROCEDURES

TREATMENT

- Dependent on underlying management or disease factors
- Surgical correction may involve glossectomy or partial glossectomy.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

TOXIC GASES

BASICS

DEFINITION

- Gases associated with animal housing or production may be present in high enough concentrations to cause adverse clinical effects in animals, including death.
- Many of these toxic gases are produced during the decomposition of animal waste in anaerobic conditions provided by underfloor waste pits, deep litters, or manure pack, and include gases such as NH_3 , CO_2 , H_2S , and CH_4 .
- Other toxic gases include NO_2 , which is produced by the fermentation process of ensiled forages, sulfur oxides (such as SO_2 and SO_3), which are produced by industrial pollution, and CO , which is a by-product of incomplete combustion of hydrocarbon fuels.
- Exposure to toxic gases is primarily by the respiratory, dermal, and ocular route.
- Brief exposures to high concentrations of toxic gases are much more toxic and potentially fatal than low concentration exposures for longer periods.
- These gases may be lighter or heavier than air, and this plays an important role in determination of exposure.

PATHOPHYSIOLOGY

- NH_3 reacts with the moist mucous membranes of the eye and respiratory tract to form ammonium hydroxide (NH_4OH), which is caustic in nature. NH_3 also causes nonspecific stress and reduces resistance to infections. NH_3 is lighter than air, and has a characteristic odor detectable at about 5–10 ppm.
- CO_2 causes dyspnea and anoxia, if present at high concentrations. This effect is partly attributed to the replacement of oxygen from the environment. Normally, CO_2 is a colorless, odorless gas present in the air at concentrations of about 4000 ppm (0.4%).
- CO competes for binding sites on a variety of proteins, such as hemoglobin to form COHb . CO has a high affinity (>200 times that of oxygen) to bind with hemoglobin. Moreover, CO binds with the cytochrome oxidase system to reduce cellular utilization of oxygen, and thus tissues most sensitive to oxygen deprivation (e.g., brain and myocardium) are most sensitive to CO toxicity. This finally leads to systemic tissue hypoxia. CO is a colorless, odorless gas present in fresh air at around 0.02 ppm, and may be as high as 40 ppm in high-traffic areas.
- H_2S inhibits cytochrome oxidase enzymes by binding to the iron. This disrupts the electron transport chain and aerobic metabolism, leading to anoxic and direct damage to the cells of the brain. H_2S also has a direct paralytic effect on the carotid body leading to inhibition of respiration. Additionally, H_2S can combine with hemoglobin to form sulf-hemoglobin, which decreases oxygen transport in the blood. The H_2S gas has a characteristic “rotten egg” smell and is heavier than air. When inhaled, it also has an irritant effect on the respiratory tract. The odor threshold is 0.25–0.2 ppm, however, at higher concentrations (>50–150 ppm), hydrogen sulfide may block the detection of odor due to the paralyzing effect on the olfactory sensory apparatus. This gas may accumulate in manure pits and holding tanks in concentrations of over 1000 ppm.
- CH_4 concentrations of > 5%–15% by volume are considered explosive and under such conditions, electrical sparks can be detrimental. Otherwise CH_4 is a colorless, odorless gas that displaces oxygen in an enclosed environment and therefore produces asphyxiation.
- NO_2 combines with mucus and forms nitric acid, which is corrosive, thus causing adverse pulmonary and ocular effects. Most NO_2 forms within 2 weeks of storage of the forages in the silo for fermentation. NO_2 has a pungent, sweetish odor, and is a yellowish-brown gas with “bleachlike” smell (odor threshold is 0.1–0.2 ppm). It is visible only when concentrations reach a dangerous level (75–150 ppm). Concentrations as high as 1500 ppm may be reached within the first 2 days after filling the silo. NO_2 is heavier than air and can settle at the bottom of enclosed spaces.
- Sulfur oxides are readily converted to acids on contact with water, and produce a pronounced irritant effect on the

mucosa of the nasopharynx, respiratory tract, and conjunctiva. Bronchoconstriction may also occur. These gases are present in industry-polluted air and are irritating to the respiratory tract and eyes.

- Fire/smoke: CO and CO₂ intoxications are the leading cause of fire death in victims who die within 6 to 12 hours. Some of the other toxins produced in the process include:

- Acrolein from combustion of polyolefins and cellulotics
- Aldehydes from combustion of cellulose materials such as cotton, paper, and wood
- NH₃ from combustion of wool, silk, nylon, melamine
- HCl from combustion of polyvinylchloride, chlorinated acrylics, and retardant-treated materials
- H₂S from combustion of hair, wools, meats, and hides
- Nitrogen oxides from combustion of fabrics, cellulose nitrate, and celluloid
- These by-products may cause direct pulmonary irritation and inflammation of conjunctiva in eyes.
- HCN may be produced from combustion of wool, silk, polyacrylonitrile, acrylic fibers, nylon, polyurethane, paper. HCN is a rapidly fatal asphyxiant, which induces cellular hypoxia by formation of a stable complex with cytochrome oxidase. HF, SO₂, and free radicals produced in fires may also be a major contribution to fire toxicity.

SYSTEMS AFFECTED

- Respiratory—dyspnea, inflammation, edema, necrosis, fibrosis, and emphysema.
- Dermal—itching, erythema, and inflammation
- Eyes—irritation, lacrimation, and inflammation
- Cardiovascular—arrhythmia
- Neurologic—depression, staggering gait, disorientation, weakness, seizures, coma, and paralysis

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

SIGNALMENT

All species susceptible

SIGNS

- NH₃ causes tearing, shallow breathing, and nasal discharge. At higher concentrations, laryngospasm and coughing may be seen. Concentrations greater than 50–100 ppm NH₃ cause reduced growth rate and mucous membrane irritation, and at > 1000 ppm, airway and alveolar damage occurs.
- CO₂ at concentrations > 50,000 ppm (5%) may cause labored breathing in animals. Signs of anoxia—which include anxiety, staggering, coma, and death—may occur due to suffocation when air contains carbon dioxide at a concentration greater than 400,000 ppm (40%).
- CO causes drowsiness, lethargy, weakness, incoordination when COHb concentration in blood reaches about 30% (normal < 1%–3%). A more severe (>60% COHb) exposure may lead to dyspnea, coma, terminal clonic spasms, and acute death.
- H₂S causes eye and lung irritation at concentrations greater than 50–100 ppm in air. Characteristics of a fatal exposure are rapid “knock down,” respiratory depression, tremors, blurred vision, cyanosis, seizures, and tachycardia. Concentrations greater than 500–1000 ppm can be directly paralyzing on the respiratory center and neurotoxic, leading to hyperpnea, followed by apnea, and death.
- CH₄, at concentrations > 85%–90%, has been associated with asphyxiation. Signs of asphyxia are seen when atmospheric oxygen is displaced, leading to oxygen concentrations of less than 15%–16%.
- NO₂, at ambient concentrations > 50 ppm, can cause choking, coughing, and labored breathing. At > 50 ppm, bronchitis, pneumonia, and edema of the lungs may occur.
- Sulfur oxides can cause ocular irritation, salivation, laryngeal spasms, and emphysema at concentrations > 10–50 ppm.
- Fire/smoke cause a spectrum of clinical signs including eye irritation, behavioral dysfunction, anxiety, respiratory distress and hypoxia, narcosis to coma, burns, and trauma. Symptoms seen are often combined effects of irritants and asphyxiants.

CAUSES

- Accumulation of high nitrogenous waste (for NH_3)
- Heaters operated in poorly ventilated areas, and fire (for CO)
- Accumulation of protein/sulfur-containing organic matter and agitation of slurry (H_2S , CO_2 , NH_3 , CH_4)
- Industrial pollution (SO_2 , SO_3)
- Ensiled forages in silo produce NO_2 , which may move into adjoining risk areas.
- Animals in enclosed areas (CO_2 and CH_4)

RISK FACTORS

- Low temperature
- Overcrowding of animals
- Electrical failure
- Faulty furnaces and heaters
- Poor design/accidents
- Improper ventilation
- Poor waste management

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- CH_4
- CO
- CO_2
- H_2S
- HCN
- NH_3
- NO_2
- SO_2

CBC/BIOCHEMISTRY/URINALYSIS

Creatinine kinase may be high because of muscle ischemia and necrosis.

OTHER LABORATORY TESTS

- Blood gases (pCO_2 , pO_2)
- Color—bright red blood due to HCN or CO . Dark if methemoglobinemia is present.
- COHb in blood
- pH —low in cases with metabolic acidosis
- Blood/liver/muscle cyanide concentrations

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- History
- Field observations
- Clinical signs
- Check into “rapid tests” provided by the local fire department for analysis of toxic gases in the air.

PATHOLOGIC FINDINGS

Gross Findings

- Increased mucus secretion in the respiratory tract
- Bronchiolar constriction

- Pulmonary congestion and edema
- Bright red mucous membranes, and pink coloration to tissues and nonpigmented skin (cyanosis and CO)
- Greenish discoloration of gray matter, viscera, and bronchial secretions (H₂S)
- General congestion of tissues (resulting from hypoxia)

Histopathology

- Hyperplasia of the bronchiolar and alveolar epithelium
- Pulmonary congestion, edema, and emphysema
- Necrosis in brain and heart, consistent with hypoxia

TREATMENT

APPROPRIATE HEALTH CARE

- Restore adequate oxygen supply.
- Prevent any further exposure to the toxic gas.
- Corticosteroids—to alleviate the pulmonary edema and clinical signs
- Antibiotics—to control secondary bacterial pathogens
- Administer electrolyte and fluid therapy as needed.
- If methemoglobinemia is present, dose with methylene blue.
- Blood transfusion

MEDICATIONS

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

- Animals should not be allowed in the barn or near the silo for at least 48 hours after filling.
- Agitate manure or waste carefully

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

- Monitor cardiac, pulmonary, and neurologic functions
- Restrain animal from excessive stress and exercise.

PREVENTION/AVOIDANCE

- Provide good ventilation around the base of the silo during the fermentation process so that the gases will be carried away.
- Always keep at least one foot of space between the highest manure level and the slats. This protects the animals that lie on the slats and inhale the gases that will accumulate at the surface of the pit.
- Provide as much ventilation as possible in the pit and building during agitation of the waste. Although pits are agitated only a few times a year, most human and livestock deaths or illnesses occur at these times.
- Fire hazards management

POSSIBLE COMPLICATIONS

Secondary bacterial infections

EXPECTED COURSE AND PROGNOSIS

- Animals poisoned with toxic gases are often found dead.
- In animals that survive, the prognosis is fair if there is prompt treatment of clinical signs and no further exposure.

MISCELLANEOUS

ASSOCIATED CONDITIONS

NO₂ is associated with the “silo-fillers” disease in humans.

AGE-RELATED FACTORS

TOXOPLASMA ABORTION

BASICS

OVERVIEW

- Reproductive loss resulting from *Toxoplasma gondii* infection during pregnancy
- Toxoplasmosis occurs in a wide range of domestic and wild animals and birds.
- Cats are responsible for maintaining and spreading infection through a herd/flock.
 - Cats—definitive host (where parasite reproduces—i.e., host where sexual multiplication occurs)
 - Birds, rodents, and other mammals—intermediate hosts (asexual multiplication occurs)

Specifics

- *T. gondii*—protozoan parasite
 - Resides in the intestine of members of the cat family
 - Infected cats (usually kittens) shed *Toxoplasma* oocysts for about 2 weeks; then immunity develops
 - Some cats remain carriers and shed oocysts when stressed.
 - Major cause of abortion in ewes
 - Often occurs at flock level—10%–20+% of ewes abort
 - Level dependent upon host, parasite, and management interactions
 - Clinical disease limited to pregnant ewes
 - Syndromes include: abortion, mummification, fetal resorption, stillbirth, and reduced neonatal survival rate.
- Clinical syndromes are dependent upon previous exposure and immune status of the pregnant ewe as well as the gestation length at time of infection.
- Ingestion of infected cysts in muscle tissue
 - Cats—prey such as birds and rodents
 - Humans—raw or undercooked meat containing cysts (cooking to 70°C for 15 to 30 minutes destroys)
 - Ingestion of oocysts in infected cat feces (can remain infective for months)
 - Placental transfer—if in blood stream fetus may become infected
- Ewes infected by ingestion of feed, bedding, or pasture contaminated with infective cat feces; Outbreaks often involve grain used for a “litter box” or kittens born in hay storage areas.

PATHOPHYSIOLOGY

- Ewes ingest *T. gondii*—infected feed
- *T. gondii* invades gastrointestinal tract → migrates to lymph nodes → enters bloodstream → enters placenta
- Ewes asymptomatic when infected
- Two weeks after infection, organism invades placenta; symptoms are dependent on the stage of pregnancy.
 - Ewe open or infected as a lamb—immune; no clinical symptoms develop
 - Infected at 0 to 40 days gestation—fetal death and resorption; open ewe or rebreeds late
 - Infected at 40 to 120 days gestation—fetal death, abortion, and mummification common
 - Even though infected earlier, abortions usually occur during the last month of gestation.
 - Ewes infected long before symptoms of abortion occur, thus difficult to treat
 - Infected at 120 days to parturition—live births, weak lambs, high neonatal mortality
 - Mummified fetuses may accompany a live birth at term.

SYSTEMS AFFECTED

- Ewes—reproductive system

- Fetus—brain, liver, lungs

INCIDENCE/PREVALANCE

- Related to feeding management practices—odds of consuming infected feed or bedding material
- Most common in intensively managed flocks likely to use barn-stored feed during pregnancy
 - Winter-lambing flocks
 - Confinement and semiconfinement operations
 - Show, club lamb and small hobby flocks
- Less common in pasture-based, extensively managed grazing operations that feed little barn-stored dry feed during pregnancy—grass-based range flocks and larger commercial operations

GEOGRAPHIC DISTRIBUTION

- Occurs in most parts of the world where cats and sheep are found
- More likely to occur in farm-flock areas of the United States

RISK FACTORS

- Gestation—feeding hay or grain contaminated with cat feces (also bedding)
- Intensive management systems and smaller farm flocks feeding barn-stored hay or grain to pregnant ewes during pregnancy
- Feral and domestic cats raising kittens on premise—fecal contamination of hay or grain

DIAGNOSIS

Presumptive/on-the-farm: history and observations consistent with toxoplasmosis abortions

GROSS FINDINGS

- Mummified fetuses, cotyledon lesions—small, white, granular lesions on surface of cotyledon (better visualized by placing cotyledon in formalin solution)
- Intercotyledonary areas unaffected (grossly)
- Confirmation—laboratory examination of aborted lambs and placental membranes

HISTOPATHOLOGICAL FINDINGS

- Identification of the organism in fetal brain
- Focal necrotic lesions may be seen in the brain, liver, lungs, and fetal membranes
- Characteristic inflammation of the placenta

Serology

- Positive *Toxoplasma* titer from fetal thoracic fluid (good field tool for diagnosis as fetus is capable of mounting an immune response)
- Extremely high *Toxoplasma* titer in the serum of the dam (suggestive, but not as useful as titers on normal sheep may be positive)
- Paired serum samples for titer response more diagnostic

DIFFERENTIAL DIAGNOSIS

Other common causes of abortion and infertility in ewes:

- *Campylobacter* abortion (e.g., campylobacteriosis, vibriosis)
- *Chlamydia* abortion (EAE)
- Others less common—bluetongue, listeriosis, salmonella, border disease, leptospirosis, poisonous plants, medications, ram infertility

TREATMENT

- None—infection initiated long before clinical symptoms are recognized

- Isolate aborting ewes, remove aborted fetuses and placentas
- Some ewes will need to be treated for retained placenta and metritis.

MEDICATIONS

FOLLOW-UP

PREVENTION/AVOIDANCE

- Avoid feeding pregnant ewes the top layer of bales in barn-stored hay—most commonly infected by kitten feces
- Avoid feeding any pregnant ewe feed contaminated by cat feces.
- Feeding ionophore compounds such as monensin (15–20 mg/ewe/day) or lasalocid (35–40 mg/ewe/day) during gestation may help (not approved for this use and toxicity issues with other species)
- Spay, neuter, vaccinate, and keep cats healthy to prevent kittens and introduction of feral cats to premises.

EXPECTED COURSE AND PROGNOSIS

- Abortions continue to occur until all ewes infected during gestation either abort or produce live lambs.
- Exposed ewes develop immunity and should not abort in subsequent lambing seasons.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Retained placenta
- Metritis

AGE-RELATED FACTORS

Due to previous exposure and immunity—toxoplasma abortions may be restricted to one group of ewes related by age, housing, or feed source.

ZOOBOTIC POTENTIAL

- Pigs, sheep, goats, and humans are more susceptible to the disease; cattle and horses are less susceptible.
- Women of childbearing age and pregnant women should avoid contact with cat feces, contaminated feed, aborted fetuses, uterine discharge, placenta, and normal birthing procedures.
 - Women at risk and contemplating pregnancy should determine immune status (test for antibodies preferably before becoming pregnant).
 - Wear disposable gloves when handling aborted material.
- Pregnant women also should:
 - Avoid contact with cat feces (litter boxes)
 - Avoid working in soil or gardens contaminated by cats
 - Thoroughly cook meat
 - Wash hands after handling raw meat
- Avoid raw or undercooked meat containing cysts.
 - Little risk from properly cooked meat (70°C for 15 to 30 minutes)
 - Freezing to minus 4°F for 2 days also destroys cysts.

TRACHEAL COLLAPSE

BASICS

OVERVIEW

- Tracheal collapse is an uncommon respiratory condition in ruminants, generally with a traumatic etiology.
- Generally does not involve a stenosis of the trachea, but rather a dynamic dorsoventral collapse during inspiration; rarely may be a lateral collapse
- May result from hypotonic, pendulous dorsal membrane, and/or weak, poorly arched cartilage

SIGNALMENT

- Has been reported in beef and dairy calves of both sexes and various pure and crossbreeds
- Calves generally present at a few weeks of age if congenital condition or dystocia is the cause.
- If traumatic, may present at any age
- Has been reported in goats from 4 months to 9 years of age

SIGNS

- Intermittent or honking cough. Palpation or elevation of head may induce cough.
- Stridor or dyspnea with mild exercise; may have dyspnea at rest if collapse is severe.
- Stertor on inspiration; auscultation localizes to trachea.
- May have mild fever, especially if accompanied by pneumonia
- Tachycardia
- Tachypnea—prolonged inspiratory phase
- Cyanosis
- Mucosal hyperemia
- Physical exam may reveal evidence of other trauma, such as fractured ribs or sternbrae.
- Concomitant pneumonia
- Weight loss, reduced growth rate

CAUSES AND RISK FACTORS

- Condition may be congenital or acquired.
- Cause is a dynamic collapse of tracheal structures. Increase in negative pressure by animal during inspiration causes an abnormal thoracic trachea to further weaken and collapse.
- Trauma—most common cause in cattle
 - Commonly associated with fractured ribs and compression of the trachea at the thoracic inlet by bony callus formation
 - Calves often have history of being breech dystocias.
 - Roping injuries
- Congenital malformation of tracheal rings
- Genetic or nutritional weakness of cartilage
- Deficient innervation of trachealis muscle
- Ischemic lesions from endotracheal tube cuffs
- Posttracheostomy
- Primary pulmonary disease

DIAGNOSIS

See Gross Findings below for tracheal collapse classifications.

DIFFERENTIAL DIAGNOSIS

- Necrotic laryngitis
- Bronchopneumonia
- Foreign body
- Abscesses
- Actinobacillosis
- Hematoma
- Neoplasia

CBC/BIOCHEMISTRY/URINALYSIS

Abnormalities associated with stress or concomitant pneumonia

- Leukocytosis, neutrophilia, monocytosis, basophilia
- Elevated creatinine if dehydrated

OTHER LABORATORY TESTS

IMAGING

Radiography

- Survey radiographs may show dorsoventral collapse; lateral collapse may also occur.
- Collapse generally present at caudal cervical and cranial thoracic portions of the trachea near the thoracic inlet; may also indicate presence of fractured ribs

Fluoroscopy

May appreciate dynamic collapse

Endoscopy

- May be dangerous and stressful to animal
- Have oxygen available.

DIAGNOSTIC PROCEDURES

Physical Exam

- Auscultation localizes abnormal respiratory sounds to trachea.
- Palpation of trachea may induce collapse or reveal it.

GROSS FINDINGS

- Distortion of cartilage rings
- Pendulous dorsal membrane
- Tracheal collapse classifications
 - Class I: 25% reduction in diameter
 - Class II: 50% reduction in diameter, with pendulous membrane and relaxed cartilage
 - Class III: 75% reduction in functional diameter: dorsal membrane almost contacts ventral tracheal wall
 - Class IV: lumen almost obliterated
- Pneumonia

HISTOPATHOLOGICAL FINDINGS

Reports have shown no difference between collapsed and normal rings in one calf.

TREATMENT

- Confinement until slaughter with decreased activity

- Management of pneumonia
- Surgical reconstruction—consider anesthetic risk
- Internal and external prostheses

External Prosthesis

- Syringe barrels or syringe case rings, fenestrated and sterilized
- Placed around collapsed segment and trachea sutured out to rigid ring
- Coil spring: coiled around collapsed trachea and sutured in place
- Prosthesis should be removed 2–3 months postoperatively in order to allow unrestricted growth of the trachea

Other Procedures

- Plication of dorsal membrane; tracheal anastomosis; bisection of tracheal rings
- < 30% probability of favorable outcome with surgery
- If collapse is associated with rib fractures, surgery of trachea should include resection of rib callus

MEDICATIONS

DRUGS OF CHOICE

- Appropriate selection of antimicrobials to control primary or secondary pneumonia
- Antimicrobial therapy for 5–7 days postoperatively

CONTRAINDICATIONS

- Have supplemental oxygen available during examination and diagnostic procedures
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- Monitor for development or resolution of pneumonia
- Continue postoperative antibiotics for 5 to 7 days

PREVENTION/AVOIDANCE

POSSIBLE COMPLICATIONS

- Recollapse of corrected or adjacent segment of trachea
- Adjacent segments predisposed to collapse after surgical repair of primary segment due to increased forces on adjacent segment during inspiration
- Bronchopneumonia due to mechanical irritation, increased mucus production
- Patients are at a higher risk for lower airway diseases.
- Trachea out-growing prosthesis

EXPECTED COURSE AND PROGNOSIS

- If untreated, collapse may worsen and calf can become increasingly dyspneic until death.
- Trachea likely to out-grow prosthesis in a few months
- Retrospective report of surgical repair
- One calf subsequently produced two calves before dying of an unresolved abomasal volvulus
- One calf was normal at 11 months of age
- Two other calves died postoperatively 2 days and 4 months after surgery. Died of bronchopneumonia and recollapse, respectively

TRACHEAL EDEMA (“HONKER”) SYNDROME

BASICS

OVERVIEW

- Tracheal edema (“honker”) syndrome is a potentially life-threatening condition seen sporadically in feedlot cattle.
- Severe edema and hemorrhage of the dorsal wall of the trachea from the midcervical region to the tracheal bifurcation

PATHOPHYSIOLOGY

- The etiology of the syndrome is unknown.
- Causes may include viral or bacterial infection, trauma to the trachea from feed bunks, passive congestion and edema due to fat accumulation at the thoracic inlet, hypersensitivity, and mycotoxicosis.

SYSTEMS AFFECTED

Respiratory, production management, and musculoskeletal

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Canada and the United States; potentially worldwide

SIGNALMENT

- Only reported in feedlot cattle
- Typically seen during the last half of the feeding period.
- Seen more often in summer. Possible exacerbation due to heat and increased dust.

Species

Bovine

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

There appears to be no sexual predominance.

SIGNS

- Subclinical disease may exist. Tracheal lesions have been demonstrated at slaughter in cattle that did not have clinical signs.
- Typical signs include an acute onset of dyspnea with an increased inspiratory effort, coughing, and a loud, guttural stertor leading to the colloquial term “honker.”
- Symptoms can progress to open-mouth breathing with head and neck extended, cyanosis, belligerence, recumbency, and death.
- Some animals are found acutely dead with no premonitory signs.

CAUSES AND RISK FACTORS

- Clinical signs are seen predominantly in warm weather and are often brought on by increased movement or exercise.
- The etiology of the syndrome is unknown. Hypothetical causes include viral or bacterial infection, trauma to the trachea from feed bunks, passive congestion and edema due to fat accumulation at the thoracic inlet, hypersensitivity, and mycotoxicosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Necrotic laryngitis (calf diphtheria)—typically febrile, pain on laryngeal palpation, sometimes malodorous breath
- Pharyngeal trauma—recent history of being treated via balling gun, dose syringe, oral speculum, etc.
- Atypical interstitial pneumonia
- Miscellaneous uncommon conditions—laryngeal or tracheal foreign object, tumor, laryngeal paralysis

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

GROSS FINDINGS

Severe submucosal edema and hemorrhage of the dorsal trachea are seen from the midcervical trachea to the tracheal bifurcation. On cross section, the lumen of the trachea may be greater than 50% occluded.

HISTOPATHOLOGICAL FINDINGS

The tracheal mucosa is hyperemic and hyperplastic with focal erosions and loss of cilia. The submucosa is markedly thickened by hemorrhage and edema and infiltrated by white blood cells. The trachealis muscle is separated from the surrounding connective tissue by hemorrhage and edema with swelling and vacuolation of the myocytes.

TREATMENT

- Calm and minimal handling is imperative as asphyxiation and death can ensue if the animal becomes overly excited.
- The provision of shade and cooling with a water spray is helpful in hot weather.

MEDICATIONS

DRUGS OF CHOICE

- Corticosteroids—dexamethasone (0.04–0.22 mg/kg) (IM route of administration is preferred over IV due to decreased animal handling and stress)
- Broad-spectrum antibiotics—long-acting oxytetracycline (20 mg/kg SQ) or ceftiofur (1.1–2.2 mg/kg SQ for 3 days)

CONTRAINDICATIONS

Appropriate drug withdrawal time should be followed before slaughter.

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

Movement and exercise of cattle late in the feeding period should be avoided during warmer months and restricted to early morning hours when unavoidable.

POSSIBLE COMPLICATIONS

Poor response to therapy and relapse may require early slaughter or euthanasia.

EXPECTED COURSE AND PROGNOSIS

Prognosis for full recovery is poor to guarded as relapse often occurs.

TRANSFAUNATION

BASICS

OVERVIEW

- Transfaunation is an important tool in the medical management of acidotic, inappetent ruminants and pseudoruminants. Donor animals help readily provide the necessary amount, quality, and quantity of transfaunation fluid.
- Ciliate protozoa are commonly found in the rumen contents of both wild and domesticated ruminants as well as camelids.
- Ruminal species composition appears to reflect the type and composition of feed consumed by the animal as well as geographical distribution.
- Physiological/pathological status of the host is also important to microbial content. In animals that have undergone feed stress (e.g., starvation/acidosis), rumen ciliates may be eliminated. Normally 3–5 days of anorexia may cause death of rumen flora so transfaunation may become necessary.
- Apparent digestion in the rumen of organic matter and starch is higher when a large protozoal population is present. A large population of ciliates has been associated with increases in both rumen ammonia and plasma urea and has a stabilizing effect on ruminal pH. Effects of ciliate protozoa are related to animal performance.
- Compared with fauna-free ruminants, the presence of ciliate protozoa has been shown to result in a more stable ruminal fermentation, higher levels of ammonia, reduced numbers of bacteria, as well as changes in dry matter (%), liquid volume, and turnover rate of ruminal contents. Associated with these differences in the rumen are higher ruminal and total tract digestion of organic matter and fiber in faunated animals.
- Ciliate protozoa in the rumen include: *Entodinium* spp., *Polyplastron* spp., *Eudiplodinium* spp., *Epidinium* spp., and *Isotricha* spp.

MISCELLANEOUS

Quantity of Fluid Collection:

- Generally, an average bovine rumen contains between 30–70 liters of fluid depending upon age and breed characteristics.
- Collection volume should be somewhere between 0.5% and 3.0% of this fluid level. Lower collection levels will preclude any secondary rumen problems associated with the donor animal.
- The transfaunation fluid volume should be between 350 mL and 4.0 liters depending on species. It is important that the collected fluid be stored out of light, anaerobically, and at the cow's body temperature until use.
- 0.5–1L of camelid C1, or strained sheep, goat, or cow rumen contents is administered to camelids twice daily for 3 to 5 days.
- Prior to transfaunation, it is essential to correct rumen pH to the 6.5–6.8 range—use Mg hydroxide/oxide/carbonate for acidic rumen and vinegar or dilute acetic acid for alkaline rumen compensation.
- The disease status of the donor should be evaluated prior to use.

Time Between Collection and Transfaunation:

- Timing is very critical to the success of transfaunation. Generally, the fluid should be deposited into the recipient animal within 30 minutes postcollection.
- Two hours appears to be the limit to success if the collection is maintained in a strict anaerobic environment. At about the 2-hour time limit, the starch-digesting organisms have increased dramatically and the fiber-digesting microbes have decreased substantially.

Time of Day to Collect:

- The number of hours postfeeding of the donor animal usually determines the collection time. Collection timing is very important in emphasizing the type and number of organisms in the collection fluid.
- The recipient animal off feed is probably in rumen acidosis and therefore should be transfaunated from a donor cow 2 hours postprandial. Acidosis must be corrected prior to transfaunation.

Monitoring Fluid Quality:

- Monitoring the pH of both donor and recipient rumen liquor is as important a selection criterion as assessing microbe numbers.
- The ideal range is 5.8–6.2 for maximal microflora count. If the pH is below this ideal range, the microbial activity will be diminished. With a more highly acidic environment, starch-fermenting organisms will dominate over cellulytic microbes.
- Protozoa and fungi will also vary at lower pHs.

Transfaunation Procedure:

- When transfaunating, try not to disturb the donor animal's rumen mat or rumen mucosa. Generally it is best to insert a short stomach tube and pump out the necessary fluid.
- Recipient cows generally require 1000 ml of fluid twice daily for 2–4 days.
- Most transfaunation failures occur with inadequate donor fluid levels, not maintaining an anaerobic environment, concomitant use of antibiotics, inappropriate pH, and inadequate length of fluid treatment.
- Straining rumen fluid for large particulate matter is helpful with the tubing process.

TRAUMATIC RETICULOPERITONITIS

BASICS

OVERVIEW

- Traumatic reticuloperitonitis (TRP) is a common disease of cattle but rarely seen in small ruminants. The eating habits of cattle predispose them to the accidental swallowing of metal foreign objects that settle in the rumen/reticulum.
- The foreign object may penetrate the reticulum resulting in localized or generalized peritonitis, or only the wall of the reticulum may be involved and this may result in dysfunction due to interference with chemoreceptors or mechanoreceptors.
- The diaphragm, pericardium, and heart are located cranial to the reticulum and the liver is medial and dorsal. Any of these organs may be penetrated by the foreign body and become involved in the inflammatory process.

SYSTEMS AFFECTED

Gastrointestinal

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Potentially worldwide, depending on species and environment

SIGNALMENT

This disease is seen primarily in cattle consuming processed forages or concentrates. In at least one study, the risk of TRP decreased with increasing parity and was higher when cattle had feet and leg problems.

Species

Dairy and beef cattle; however, potentially all ruminant species can become affected.

Breed Predispositions

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- In the most severe form of TRP, affected cattle may present with a dramatic change in posture, standing with an arched back, total anorexia, and vocalizing with a grunting noise when forced to move or when urinating. A sudden decrease in milk production is commonly reported.
- Physical examination of these cattle is characterized by fever, decreased rumen contractions, and an unwillingness to flex ventrally when pinched over the withers. They may have tachycardia, and auscultation of the heart may reveal increased cardiac intensity or may be muffled due to bacterial contamination and subsequent inflammation of the pericardium.
- Sudden death has occurred as a result of laceration of a coronary blood vessel or puncture of the heart by the foreign body.
- More chronic cases present a diagnostic challenge due to signs that are subtle and vague. Affected cattle in early lactation may have mild ketosis secondary to their anorexia. Mild bloat and changes in fecal consistency are also common signs. Weight loss, roughened hair coat, and diffuse generalized lameness may be the only signs.

CAUSES AND RISK FACTORS

The indiscriminate eating habits of cattle are the most likely cause of this disease. Construction in and around their environment will also increase the risk. The care and upkeep of the machinery used to process and provide silage to the cattle also plays a role in risk management.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Abomasal ulcers, diaphragmatic hernia, endoparasitism, heart disease, hepatic abscesses, indigestion, laminitis, lymphosarcoma, or other neoplasia may all be confused with TRP. Clinical signs will assist with ruling out laminitis. Further physical examination findings via rectal palpation may assist in ruling out lymphosarcoma or other abdominal neoplasms.

CBC/BIOCHEMISTRY/URINALYSIS

- The white blood cell count and distribution, plasma proteins, and fibrinogen may be normal in the initial stages of TRP. Total plasma proteins of over 10 g/dl have been shown to have a positive predictive value of 76% for TRP in referral populations.
- Biochemical profiles are not of high value in diagnosing TRP, but may be of benefit in ruling out others on the differential diagnosis list.
- Urinalysis would not be of definitive value in this disease reflecting only the secondary ketosis that accompanies the anorexia commonly observed.

OTHER LABORATORY TESTS

Abdominocentesis is recommended and may be aided by ultrasonography to obtain fluid. Remember that in normal, nonpregnant, adult cattle the amount of abdominal fluid is small. All normal bovine peritoneal fluid clots upon exposure to air, so samples are placed in small EDTA tubes.

IMAGING

- Abdominal radiographs with the horizontal beam centered over the reticulodiaphragmatic region in an attempt to confirm the presence of metallic foreign bodies can be done with the cow in that standing position or cast into dorsal recumbency.
- One study in which standing radiographs were taken describes the sensitivity of the procedure in detecting TRP as 83%.
- Ultrasound diagnosis has been utilized as well.

TREATMENT

- Conservative treatment is most often attempted first and includes administration of a forestomach magnet, antibiotics, and confinement. Many cattle recover after this therapy with resumption of appetite and motility within 3 days. Those animals that do not recover in 3 days may require a rumenotomy to remove the foreign body in order to allow them to recover. This becomes an economic challenge for the producer and veterinary surgeon.
- Cattle with diffuse peritonitis have a poor prognosis for return to production or life. Treatment of peritonitis requires systemic antibiotics, possible drainage of the affected area, and surgical correction of the inciting cause.
- Those cattle that seem to recover in the short term may later develop forestomach outflow problems typical of vagal indigestion.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE COMPLICATIONS

N/A

FOLLOW-UP

PREVENTION/AVOIDANCE

- Most producers now have large magnets in place on feed-handling equipment that eliminates the delivery of sharp metal objects to cattle at the time of feeding. Also, many producers have gone away from upright silos for storage of their corn silage in favor of bunkers. This has eliminated another source of metal contamination of feedstuffs by eliminating the mechanical unloader necessary for old upright silos.
- Some producers will administer prophylactic magnets to all heifers at 6–8 months of age as another means of prevention of TRP.

EXPECTED COURSE AND PROGNOSIS

- Cattle with diffuse peritonitis have a poor prognosis for return to production or life.
- Those cattle that seem to recover in the short term may later develop forestomach outflow problems typical of vagal indigestion.

TREMETOL: WHITE SNAKEROOT AND RAYLESS GOLDENROD

BASICS

OVERVIEW

- White snakeroot is an opposite branching, dark green perennial, which grows 1–4 feet tall in damp, open areas of woods and shaded areas along streams.
- Stems are slender, round, and may be purplish.
- Leaves are 3–5 inches in length and have three distinct veins, coarsely toothed margins, and a sharp tip.
- Flowers are white and clustered in groups of 10 to 40 at the end of branches and bloom in late summer and fall.
- Roots are shallow and fibrous, and twist and turn giving the plant its name.
- The plant grows in moist areas bordering streams, woodlands, as well as wooded areas with rich basic soil. It may persist in open areas after clearing.
- The geographic distribution is mostly eastern North America and grows from the East Coast including Canada, west to Minnesota, and south to east Texas and the gulf coast.
- Intoxication requires ingestion of 0.5%–1.0% of body weight of green plant over 2–3 weeks.

PATHOPHYSIOLOGY

- Toxicity is most abundant in the foliage of the mature plant, is resistant to frost, and, although decreased, persists in the dried plant.
- The same toxins found in *Eupatorium rugosum* (white snakeroot) are also found in *Isocoma wrightii* (rayless goldenrod).
- The specific toxin has not been identified, but the unpurified form has been named tremetol.
- Effect of toxin requires microsomal activation and may explain different effects in different species.
- Intoxication is theorized to inhibit citrate synthase causing ketosis detectable by acetone smell of breath and urine.
- Intoxication in animals is often called trembles.
- Nursing young are clinically affected by high concentration in milk.
- Causes muscle damage and weakness
- Causes hepatic necrosis
- May cause photosensitization of small ruminants if animal survives acute disease
- The toxin is cleared in milk and may cause signs in offspring or humans if ingested.

SIGNALMENT

Seen most frequently in sheep and goats, but all species ingesting the plant are at risk.

SIGNS

- Disease usually seen in late fall or early winter
- Animals die soon after becoming recumbent.
- History of weight loss
- Ketosis causes acetone breath
- Afebrile
- Clinical signs different between species

Cattle and Sheep

- Reluctance to move
- Stiff movements or ataxia
- Severe trembles after exercise

- Depression
- Recumbency
- Sudden death
- Dyspnea, salivation, constipation, regurgitation may occasionally occur.
- Clinical signs may appear 3 days to 3 weeks after ingestion.

Goats

- Goats typically show signs of liver failure.
- Depression
- Weakness
- Head pressing
- Icterus
- Slight tremors with exercise
- Recumbency
- Sudden death
- Photosensitization if animal survives acute disease
- Clinical signs may appear 1–5 days after ingestion.

CAUSES AND RISK FACTORS

- Moving Naïve animals to contaminated pastures when there is inadequate forage (i.e., fall and winter)
- Lactating animals are more resistant due to rapid excretion of toxin in milk, putting nursing animals at high risk for clinical signs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Selenium deficiency
- Other causes of liver disease in small ruminants
- Gossypol intoxication
- Botulism in cattle
- Organophosphate intoxication
- CNS trauma
- Other tremorgenic toxicities

CBC/BIOCHEMISTRY/URINALYSIS

- Muscle enzymes (CK, LDH, ALP, AST) are elevated.
- Animals have ketoacidosis.
- May have myoglobinuria
- Goats may have elevations in bilirubin.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Evidence of plants in rumen
- Evidence of plant exposure

PATHOLOGIC FINDINGS

- Centrolobular hepatic degeneration and necrosis
- Skeletal muscle necrosis
- Cardiac abnormalities reported primarily in horses

- Extreme congestion of liver, kidney, abomasums, brain, and spinal cord
- Extreme fat degeneration of liver and kidney

TREATMENT

SYMPTOMATIC AND SUPPORTIVE CARE

- Correct any electrolyte and acid base abnormalities
- Ketosis is refractory to treatment

MEDICATIONS

DRUGS OF CHOICE

- Activated charcoal (AC) (2–5 g/kg PO in a water slurry)
- Evidence in other species of recycling through gastrointestinal system; repeat doses of AC may be beneficial.
- Laxatives

CONTRAINDICATIONS

- Any drug promoting hepatic microsomal enzymes is contraindicated.
- Any drug inhibiting hepatic microsomal enzymes may be helpful.
- Drug withdrawal times must be maintained.

FOLLOW-UP

PATIENT MONITORING

Monitor electrolytes

PREVENTION/AVOIDANCE

- Prevention of white snakeroot intoxication is possible—monitor pasture/hay for white snakeroot.
- Selective use of herbicides or manual removal of plants may help to diminish problem.

POSSIBLE COMPLICATIONS

.

EXPECTED COURSE AND PROGNOSIS

Animals exhibiting clinical signs have grave prognosis.

TRICHOMONIASIS (TRICHOMONOSIS)

BASICS

DEFINITION

- Trichomonosis, formerly called trichomoniasis, is a sexually transmitted disease that results in embryonic and fetal death (typically between 50 and 70 days in gestation, but occasionally up to the early third trimester), and is associated with postcoital pyometra.
- It is an insidious disease—neither the male nor the female shows overt signs, except that cows presumed to be pregnant will return to estrus after losing their pregnancies, often too late to rebreed them for that season.

PATHOPHYSIOLOGY

- *Tritrichomonas foetus* is an obligate venereal pathogen (i.e., it is transmitted only via coitus or unhygienic artificial insemination).
- The protozoan dwells on the surface of the epithelial covering of the bull's glans penis and the proximal prepuce.
- Specifically, it lives in the epithelial crypts of the squamous epithelium. As bulls age, the crypts deepen, providing a more favorable environment for the organism. *T. foetus* is readily transmitted to the female at mating.
- In the female, conception typically is not disrupted and, in many cases, the resulting embryo is not damaged for up to 7–9 weeks.
- Recent work using ELISA has shown that the local levels of *T. foetus* –specific immunoglobulin, especially IgA and IgG1, also peak at this time.
- Serum antibodies also exist, but at a very low level that is not detectable by ELISA. Hence, there is no practical serological test commercially available for diagnostic use. Infected females rid the reproductive tract of the organism, typically within 6 to 18 weeks, presumably via the action of the antibodies in the uterine lumen.
- The organism has been shown to release cytotoxins into the environment, although the in vivo significance of this is not known.

SYSTEMS AFFECTED

- Reproductive
- The organism is generally not invasive; it lives in the lumen of the vagina, uterus, and ovi-ducts of the female, and on the epithelial surface of the glans penis and prepuce of the male.
- It has been observed in deeper layers of the chorioallantois of aborted fetuses.

GENETICS

- There is no documented genetic basis for susceptibility to trichomonosis.
- The organism has been cultured from the prepuce of bulls of all breeds tested to date. *Bos indicus* bulls, with their longer prepuces, do not seem to be any more susceptible than *B. taurus* bulls.

INCIDENCE/PREVALENCE

- Trichomonosis exists wherever natural service is practiced, and has been diagnosed even in situations where unhygienic artificial insemination is practiced (e.g., where an inseminator performed serial manual vaginal examinations, using a common sleeve, just prior to inseminating).
- Because *T. foetus* can survive cryopreservation, it is also possible that contaminated semen could spread the infection, but this is highly unlikely if the semen is processed by a reputable company, using Certified Semen Standards (CSS).
- In the early 1990s, a survey of randomly selected herds estimated the prevalence of trichomonosis in California at 5% of all bulls and 16% of beef herds (at least one infected bull). As others have shown, there was a clear pattern of increased prevalence with increasing age of bulls.
- Bulls less than 4 years of age at the time of exposure to cows were significantly less likely to be infected, and infection of bulls less than 3 years old was rare. Similar results have been reported in Florida, with bull and herd prevalences of 6% and

30%, respectively.

SIGNALMENT

Species

Cattle

Breed Predilections

None

Mean Age and Range

- Older bulls (≥ 4 yrs) are more likely to become infected if exposed to an infected female at coitus.
- Once infected, they will remain so, probably for life.
- Younger bulls can mechanically transmit the organism, but generally do not become permanent carriers.
- Cows develop partial, short-lived immunity, but most would be susceptible the following breeding season.

SIGNS

- Trichomonosis is insidious. Neither the cow nor the bull is ever overtly ill, and a vaginal or preputial discharge is rarely seen.
- A very alert owner may notice that cows/heifers that were presumed pregnant begin returning to estrus near the end of the breeding season, or after the bulls are removed.

PHYSICAL EXAMINATION FINDINGS

- At the time of herd pregnancy examination, a herd recently infected with *T. foetus* will show a decreased overall pregnancy rate (reductions below 70% of normal are common), and the gestational ages of pregnancy in those cows that are pregnant will be highly variable.
- Approximately 5% of cows in an exposed herd may be diagnosed with pyometra at the time of pregnancy check.
- By transrectal palpation, this will present as a fluid-distended uterus with no positive signs of pregnancy, and a corpus luteum on one or both ovaries.
- This postcoital pyometra is a very important finding and should instigate actions to rule out trichomonosis.

CAUSES

- The flagellated protozoan *Trichomonas foetus*
- An immunopathological component is likely as well. This hypothesis is based on both in vivo and in vitro findings that peak mortality of concepti does not occur until there is peak IgG1 antibody in the uterine lumen, and that such antibodies are capable of redirecting the host response against host cells.
- It is also possible that cytotoxins elaborated by *T. foetus* can directly damage conceptus tissues.

RISK FACTORS

The major risk factors for bovine trichomonosis are:

- Use of natural service
- Use of older bulls
- Shared grazing (It has been well established that the use of shared grazing increases the risk of infection of any herd participating.)
- Failure to test bulls before the breeding season (Routine testing for the presence of *T. foetus* in bulls can easily be combined with pre-season breeding soundness examinations. Failure to do so increases the risk of undetected infection, especially if shared grazing is commonly practiced.)
- Lease of nonvirgin breeding stock
- Failure to vaccinate, given any of the risk factors above

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Poor nutrition, *Campylobacter fetus venerealis*
- Poor nutrition, especially energy deficiency in replacement heifers or late pregnant cows, can yield a herd pregnancy pattern in the next breeding season similar to a *T. foetus* –infected herd.

- Poor nutrition of heifers will delay onset of puberty, which will reduce the opportunities for heifers to become pregnant during a limited breeding season.
- Poor nutrition of third trimester pregnant beef cows will delay the postpartum return to cyclicity.
- Other infectious agents, including *Campylobacter fetus venerealis* can produce an almost identical epidemiological picture. Less commonly, *Haemophilus somnus*, *Chlamydophila* spp., and *Ureaplasma* are implicated in outbreaks of venereally transmitted infections leading to early conceptus death, but these generally are associated with detectable genital lesions in the female.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Bulls

- Collect preputial smegma by vigorously scraping/aspirating the fornix via a 22" infusion pipette attached to a sterile 12 cc syringe. Culture preputial smegma in a suitable medium, and identify *T. foetus* in the culture by daily microscopic examination at 200–400x, for up to 7 days.
- Suitable media include so-called Diamond's TYM medium, which has a short shelf life but is inexpensive and highly selective for *T. foetus*, or a longer-lived commercially available culture system (InPouch, Biomed Diagnostics, White City, OR).
- The organism is identified by its morphology (~ 8–12 microns by 15–20 microns, spindle-shaped, with three anterior flagellae, a recurrent flagellum down one side (also known as the "undulating membrane") and by its characteristic rolling, jerky motility. Because morphological assessment is subjective, some states are now requiring that all "positive" cultures be submitted to a laboratory certified to run a polymerase chain reaction (PCR) assay, for confirmation.
- Other trichomonads, including *Pentatrichomonas hominis* and *Tetratrichomonas* spp., have been identified in the preputial scrapings of bulls, especially young bulls. These non-*T. foetus* trichomonads are presumed to be nonpathogenic organisms of fecal origin.

Cows

- If pyometra is diagnosed at the time of herd pregnancy checks, pyometritic fluid can be an excellent source of *T. foetus*.
- If the examiner can pass an insemination pipette through the cervix, the pus that is aspirated can often be examined directly under the microscope for trichomonads, without culturing. It may be teeming with organisms. If not, the fluid may be cultured as for smegma.

IMAGING

Imaging is not often employed, but transrectal ultrasound exam may confirm palpation findings.

DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

Bull

- Virtually no inflammatory lesions are attributable to *T. foetus* infection.
- Using immunohistochemical staining techniques, it is possible to identify *T. foetus* and/or its surface antigen adhered to the surface of the preputial and penile squamous epithelium.

Cow

- Typically, in the 95% of cases where pyometra is not found, there are few if any gross lesions.
- Histologic lesions are not pathognomonic, and include a mild-to-moderate infiltration of neutrophils and eosinophils in the layer immediately below the endometrial surface epithelium (stratum compactum), and in the glandular portions (stratum spongiosum).
- After about 6–9 weeks of infection, many females will show aggregations of mononuclear cells in the stratum spongiosum that resemble lymphoid follicles.
- Minor erosions of the surface epithelium may be noted.

TREATMENT

Nonpharmacological

Females

The females in an infected beef herd should be divided into the following groups:

- A “safe in calf” group that is 5 months pregnant or more. These are very unlikely to still be infected or to lose their calves due to *T. foetus*.
- A “worry” group that is pregnant less than 5 months. These should be housed/pastured separately, and observed frequently for signs of abortion (elevated tails, sticky discharge on tail hairs, exposed fetal membranes, etc.).
- Nonpregnant cows and heifers. Ideally, these should be sold for slaughter. If this is not economically appropriate, then divide this group into two further groups:
 - Abnormal reproductive tract, based on palpation findings. Cull these immediately.
 - Normal reproductive tract. Keep these, vaccinate them according to label instructions, and rebreed them next season.

Bulls

- All bulls should be smegma cultured (see Follow-Up below) and infected animals should be culled.
- Many states require that such bulls be clearly identified and sold only for slaughter.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

The client must be made to understand that no treatments are both legal and efficacious (see Drugs of Choice section below). Risk factors should be made clear.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- There is no legal, efficacious treatment for infected animals. Several years ago, the substituted imidazoles (metronidazole, dimetridazole, ipronidazole) were successfully used in infected bulls, but this entire family of compounds was declared not only off-label but also illegal by the FDA.
- Practitioners who use any of these compounds in cattle may be subject to arrest and imprisonment.

CONTRAINDICATIONS

N/A

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

- Test all bulls immediately before next breeding season. Given the modest 80%–90% sensitivity of the culture test, consider multiple tests/bull (e.g., three tests at weekly intervals).
- Vaccinate all females twice at 1-month interval, just before bull exposure.
- Monitor pregnancy rate and loss, checking twice, once early after bull removal and once after 5 months' gestation.

- Replace any infected bull with a virgin bull.

MISCELLANEOUS

- A commercial vaccine is available prepared from killed whole cells.
- Efficacy in females was shown when 61% of vaccinated females calved while only 31% of controls calved following a very strong challenge by intravaginal instillation of millions of live *T. foetus*, immediately following mating to an infected bull.
- Recommendations for its use are controversial, but there is some benefit in vaccinating if any of the factors mentioned above under Risk Factors exist.
- The vaccine manufacturer makes no claim for efficacy in bulls.

TRYPANOSOMIASIS

BASICS

OVERVIEW

- Caused by protozoa of the genus *Trypanosoma* that live in the blood and body fluids of their hosts
- Results in anemia, emaciation of animals, and loss of condition
- Transmission is by vectors (tsetse flies—*Glossina morsitans*, *G. palpalis*, *G. fusca*, and vampire bats) and through mechanical vectors of the genus *Tabanus*. Hematogenous equipment, such as needles and surgical instruments, can also transmit trypanosomes.
- Ruminants are widely known to be active reservoirs.
- Infections with trypanosomes result in diseases such as nagana, surra, Chagas' disease, and African sleeping sickness.

PATHOPHYSIOLOGY

- The protozoa multiply in the blood, tissue, or body fluids of the vertebrate host and are transmitted between vertebrate hosts through the saliva of blood-sucking flies as they feed.
- At the site of inoculation, there is a local skin reaction called a chancre.
- From here the trypanosomes reach the blood stream directly or through the lymphatic system.
- Parasitemia becomes apparent 10–14 days after inoculation.
- Trypanosome's success lies in its ability to evade the host's immune system by altering the antigenic nature of its surface-coat glucoproteins.

SYSTEMS AFFECTED

- Cardiovascular: intense anemia and edema in chronic cases
- Gastrointestinal: weight loss and, in some cases, diarrhea
- Nervous: meningoencephalitis, progressive weakness, and ataxia
- Musculoskeletal: weakness and emaciation
- Lymphatic: lymphadenopathy
- Reproductive: infertility and abortion
- Ophthalmic: keratoconjunctivitis

GENETICS

N/A

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

Found in the subtropical and tropical areas of Africa, Asia, South and Central America

SIGNALMENT

Species

Cattle, sheep, goats, camels, llamas, and buffalo

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- There are no pathognomonic signs and the severity of the signs varies depending on the size of the inoculation dose, the species and strain of the trypanosomes, and breed and management of the host.
- Can present as an acute, subclinical, or chronic infection
- Acute: Anemia, intermittent fever, loss of condition, and abortion may be seen; decrease in milk production; some become inappetent with a stiff gait and die within a few weeks.
- Chronic: affected animals are anorexic, apathetic, and emaciated, and have ocular discharge and a dull coat. A marked jugular pulse develops, associated with pale mucous membranes and elevated respiratory and pulse rate. Although the animal continues to eat, it gradually loses weight and death occurs after several months due to heart failure.
- Subclinical: stress plays a prominent role in the disease process.

CAUSES AND RISK FACTORS

- Nagana or African trypanosomiasis: *Trypanosoma brucei*, *T. congolense*, *T. vivax*, and *T. simiae*—variety of animals affected. Transmitted cyclically by tsetse flies and mechanically by other biting flies
- Surra: *T. evansi*—horses and camels affected; transmitted mechanically by biting flies in Africa, Asia, South and Central America
- Found in subtropical and tropical locations; the risk factor is being exposed to vectors, such as tsetse flies, biting flies (tabanids), and vampire bats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute anthrax
- Anaplasmosis
- Babesiosis
- Theileriosis
- Hemorrhagic septicemia
- Gastrointestinal helminths (*Haemonchus*)
- Chronic malnutrition

CBC/BIOCHEMISTRY/URINALYSIS

- Decreased packed cell volume, erythrocyte count, and hemoglobin
- Leukopenia, neutropenia, lymphocytosis, and monocytosis
- Thrombocytopenia
- Metabolic acidosis

OTHER LABORATORY TESTS

Serology for other infectious diseases

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Microscopic examination (direct): wet mount of blood slides, thick and thin blood films stained with Giemsa, and stained lymph nodes
- Indirect method: antigen-detecting ELISA, indirect fluorescent antibody test
- Molecular test: species-specific DNA probes
- Subinoculation into experimental animals

PATHOLOGIC FINDINGS

Most findings are nonspecific but can include serous atrophy of fat, subcutaneous edema, emaciation, petechiation, and enlarged liver and spleen. The spleen may also be atrophied or normal in some cases depending on the severity of the disease. Other lesions include necrosis of the kidneys and heart muscle and a sore or chancre at the site of entry.

TREATMENT

- Supportive care
- Blood transfusion from known negative animals

MEDICATION

- Treating trypanosomiasis is expensive and not always successful. It is considered a foreign animal disease in the United States and should be reported immediately to authorities. In other countries, there are prophylactic treatments that have been used with some success.
- Diminazene aceturate (Berenil): 3.5–7 mg/kg body weight for *T. vivax* and *T. congolense*, well tolerated by ruminants, not so well by horses.
- Homidium bromide (ethidium) and homidium chloride (novidium) can be used at 1 mg/kg body weight for *T. vivax* and *T. congolense*.
- Isometamidium is another preferred drug to use against *T. vivax* and *T. congolense* in ruminants as a curative and prophylactic dose of 0.25–1 mg/kg body weight. Pyrimethidium bromide is less widely used against *T. vivax* and *T. congolense* as prophylactic at 2 mg/kg body weight.
- Suramin may also be used against *T. brucei* as a curative and prophylactic drug at 10 mg/kg body weight in horses and camels.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Because reinfection can occur, monitor weight, appetite, temperature, and PCV.

PREVENTION/AVOIDANCE

- Vector control is recommended.
- Trypano-tolerance: certain breeds of African cattle are considerably more resistant to African trypanosomiasis than others. The mechanisms of trypano-tolerance have been extensively studied and it has been established that it has a genetic basis.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Due to the potential for reinfection, prognosis varies depending on the severity of infection and how rapidly it was detected and treated.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Adult sheep between 1 and 4 years of age with 4 years of age being the norm; lambs are more susceptible to infection if exposed prior to 10 weeks of age.

ZOONOTIC POTENTIAL

- Chagas' disease: *T. cruzi*—occasionally pigs but mainly in dogs and humans susceptible; transmitted by sucking blood vectors in South and Central America and the southern parts of the United States.

- Human African trypanosomiasis in humans can be caused by *Trypanosoma brucei gambiense* (central and West Africa), which causes a latent chronic infection, and *Trypanosoma brucei rhodesiense* (southern and east Africa), which causes a more virulent acute infection.

PREGNANCY

African trypanosomiasis can be transmitted in utero from infected mothers resulting in abortion and perinatal death of the fetus.

RUMINANT SPECIES AFFECTED

Cattle, sheep, goats, camel, llamas, and buffalo

BIOSECURITY

Vector control is important although difficult in endemic areas.

PRODUCTION MANAGEMENT

Economic losses can arise from emaciated animals, mortalities, and the cost of vector-control programs.

TUBERCULOSIS: BOVINE

BASICS

OVERVIEW

- Bovine tuberculosis (bovine TB) is caused primarily by the bacterium *Mycobacterium bovis*.
- Bovine TB is a reportable disease in the United States (as well as many countries internationally) for which an ongoing national eradication program is in place. The disease is found in all parts of the world.
- Bovine TB primarily affects the respiratory tract and associated lymph nodes. Disseminated bovine TB can be found in other organ systems including the gastrointestinal tract, reproductive tract, mammary glands, and central nervous system.
- *Mycobacterium bovis* infections have been described in numerous domestic and wild animals including sheep, goats, horses, pigs, deer, antelope, dogs, cats, ferrets, camels, foxes, mink, badgers, rats, primates, llamas, kudus, elands, tapirs, elk, elephants, sitatungas, oryxes, addaxes, rhinoceroses, opossums, ground squirrels, otters, seals, hares, moles, raccoons, coyotes, lions, tigers, leopards, and lynx.
- Most species other than cattle are considered to be dead end hosts; however, some species can serve as reservoir hosts. Known reservoir hosts include brush-tailed opossums in New Zealand; badgers in the United Kingdom and Ireland; deer in the United States; bison in Canada; and greater kudu, common duiker, African buffalo, warthogs, and Kafue lechwe in Africa.
- Bovine TB can be transmitted either by the respiratory route or ingestion.
- *Mycobacterium bovis* is a zoonotic agent and is a significant public health concern.

SIGNALMENT

Bovine TB can affect all ages of cattle.

SIGNS

- Bovine tuberculosis is usually a chronic debilitating disease but can occasionally be acute and rapidly progressive.
- Early infections are often asymptomatic.
- In the late stages, common symptoms include progressive emaciation, a low-grade fluctuating fever, weakness, and inappetence.
- Animals with pulmonary involvement usually have a moist cough that is worse in the morning and during cold weather or exercise, and may have dyspnea or tachypnea.
- In some animals, the retropharyngeal or other lymph nodes enlarge and may rupture and drain.
- Greatly enlarged lymph nodes can obstruct blood vessels, airways, or the digestive tract. Airway obstruction can lead to severe dyspnea.
- If the digestive tract is involved, intermittent diarrhea and constipation may be seen. Lesions are sometimes found on the female genitalia but are rare on the male genitalia. In cats, skin lesions similar to those of feline leprosy may be seen.
- Mammary gland involvement typically results in induration and hypertrophy of the affected gland and enlargement of the supramammary lymph nodes.

CAUSES AND RISK FACTORS

- Bovine TB is caused primarily by the bacterium *Mycobacterium bovis*.
- *M. bovis* can survive for several months in the environment, particularly in cold, dark, and moist conditions.
- The major risk factor for infection with bovine TB is exposure to infected reservoirs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of chronic respiratory disease—*Mycoplasma bovis*, chronic lung abscesses, aspiration pneumonia
- Other causes of chronic weight loss and ill thrift—Johne's disease, parasitism, and bovine leukosis

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Caudal fold tuberculin test (CFT)—an intradermal skin test that is used as an initial screening test. In the United States, an accredited veterinarian must administer this test.
- Comparative cervical test (CCT)—an intradermal skin test used most commonly as a follow-up to the CFT test to differentiate immune responses to *Mycobacterium bovis* and *Mycobacterium avium*. In the United States, only a state or federal veterinarian can perform this test.
- *Mycobacterium bovis* gamma interferon assay—an assay used most commonly as a follow-up to the CFT test

GROSS FINDINGS

- The characteristic gross lesion seen in an animal infected with bovine TB is the presence of granulomatous tubercles within the body. A tubercle is a white nodule usually 1 mm to 2 cm in diameter.
- Tubercles may be localized to a single organ or disseminated through many organ systems.
- Bovine TB tubercles are most commonly found in the thoracic cavity and associated lymph nodes.

HISTOPATHOLOGICAL FINDINGS

- The lesion most commonly associated with bovine TB is a granuloma.
- Following acid-fast staining of suspect tissue, bacteria that take up stain, including *Mycobacterium bovis*, will appear as short red or pink rods when examined under a microscope.

TREATMENT

Bovine TB is a controlled disease. Animals diagnosed with the disease are humanely euthanized.

MEDICATIONS

N/A

CONTRAINDICATIONS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

Bovine TB is considered a herd disease; therefore, emphasis is placed on preventing the introduction of the disease into a farm. Biosecurity procedures should be put in place that prevent the introduction of cattle at high risk of having bovine TB and to prevent potential wildlife reservoirs, such as white-tailed deer, from having close contact with cattle, their feed or water.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Cattle infected with bovine TB are humanely destroyed. Farms where bovine TB-positive animals originate are considered infected and are subsequently quarantined. Disposition of these herds is decided upon by the regulatory authorities governing TB control in that area.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

Mycobacterium bovis is a zoonotic agent that historically was spread primarily thru the consumption of unpasteurized milk from infected cows. Other potential routes of zoonotic transmission include consumption of undercooked meat and close contact with infected cows. Pasteurization has helped eliminate many human infections, but each year, cases occur in people, primarily those consuming imported cheeses from countries that do not pasteurize their products.

PREGNANCY

In cattle with advanced bovine TB, fetal infection can occur resulting in calves being born infected with bovine TB.

RUMINANT SPECIES AFFECTED

Bovine; potentially all ruminants

TUBERCULOSIS: SMALL RUMINANTS

BASICS

OVERVIEW

- Tuberculosis is a disease of great historical significance in both humans and domestic animals. Goats and sheep are rarely infected, but when it occurs, *Mycobacterium bovis* is usually the causative agent. Recently, a new subspecies *Mycobacterium bovis* subsp. *caprae* has been found to infect goats in Europe.
- Compared to sheep, goats are quite susceptible to *M. bovis*. If they are infected, goats demonstrate clinical signs similar to cattle.
- Even though goats and sheep appear to have high resistance to infection with *M. bovis*, goats are thought to act as spreaders for other species.
- *M. tuberculosis*, the human infection, accounts for a small proportion of tuberculosis cases in animals.

PATHOPHYSIOLOGY

- The organism usually enters through the respiratory route, occasionally by ingestion.
- From the site of entry, the organism invades the local lymph nodes (bronchial, mediastinal, pharyngeal, mesenteric) where it causes necrosis surrounded by a granuloma containing mononuclear cells.
- Dissemination occurs to various organs and may result in diffuse miliary tuberculosis.

SYSTEMS AFFECTED

Production management, gastrointestinal, respiratory, and, occasionally, urogenital

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide depending on species and environment

SIGNALMENT

Species

- Potentially all ruminant species
- *Mycobacterium bovis* subsp. *caprae* has been isolated from cattle, wild boar and pigs.

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

- The disease is chronic and slowly progressive, which can gradually cause debilitation, emaciation, and depression.
- Bronchopneumonia is the most common form of the disease in livestock and it is manifested by cough and terminal dyspnea.
- Some goats have intestinal ulceration, diarrhea, and enlargement of the lymph nodes of the alimentary tract.
- Infection in sheep is rare—lesions in lymph nodes or the GI tract.

CAUSES AND RISK FACTORS

- Etiological agent is *Mycobacterium* spp.—gram-positive, acid-fast bacterial rods

- Risk factors—housing can predispose to the spread of disease. A crowded condition with inadequate ventilation increases the risk of transmission.
- The incidence may be as high as 70% for goats in an infected herd.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Progressive pneumonia
- Pulmonary adenomatosis
- Caseous lymphadenitis lesions

CBC/BIOCHEMISTRY/URINALYSIS

There are no specific clinical pathology data typical for this disease in small ruminants.

OTHER LABORATORY TESTS

- Caudal fold tuberculin test (CFT): measures the immune response to *Mycobacterium bovis* and can be performed only by an accredited veterinarian. The test is achieved by injecting 0.1 ml of USDA Purified Protein Derivative (PPD) tuberculin within the layers of skin of the caudal tail fold. The same veterinarian should read the test 72 hours after the inoculation and the site should be inspected for swelling or discoloration.
- Comparative cervical tuberculin test (CCT): is designed to determine if the response noted on the CFT is due to a *Mycobacterium bovis* or *Mycobacterium avium* infection. The test must be performed by an accredited state or federal veterinarian and it consists of an intradermal injection of a biologically balanced bovine PPD tuberculin and avian PPD tuberculin at separate sites in the cervical (neck) area. At 72 hours after the inoculation, the same veterinarian should measure the swelling of each injection site and plot them on a CCT scattergram.
- Identification of the organism in aspiration or biopsies of affected organs using acid-fast staining, histopathological examination, bacterial culture, or PCR.
- In one study, the sensitivity and specificity results were high for the comparative intradermal skin (CID) test (83.7%, 100%), the IFN-gamma assay (83.7%, 96%), and the anamnestic ELISA (88.6%, 95.8%). In contrast, they were comparatively low for the standard ELISA (54.9%, 88%). However, test results with the standard ELISA were positive in a group of goats with cavitating TB (100%). A combination of the CID test and the IFN-gamma assay offered the highest sensitivity, 95.8%, and also high specificity, 96%. In spite of this, the evidence that the serological tests were most sensitive for the detection of goats with severe lesions (100% positivity) suggested that a combination of CID test and anamnestic ELISA may be most useful as part of an eradication campaign against caprine TB.

IMAGING

Depending on the location of the suspected lesion, radiography and ultrasonography may demonstrate the presence of tubercles within the body and are used to evaluate the extent of the infection.

OTHER DIAGNOSTIC PROCEDURES

- Caudal fold tuberculin test
- Comparative cervical tuberculin test
- Necropsy
- Histopathology
- ELISA testing

PATHOLOGIC FINDINGS

- Tuberculosis granulomas—in any lymph nodes (especially in the bronchial, mediastinal, and mesenteric nodes) and in a variety of organs (particularly in the liver and lungs)
- Infected organs may be riddled with small miliary tubercles.
- Lungs—suppurative bronchopneumonia

TREATMENT

Since tuberculosis is a contagious disease of both animals and humans, the most effective and recommended way of handling this disease is by control and eradication (test and slaughter).

MEDICATIONS

N/A

FOLLOW-UP

PATIENT MONITORING

N/A

PREVENTION/AVOIDANCE

- All goats and sheep should be tested against tuberculosis.
- Reactors should be quarantined and identified and must be sent to an approved slaughter plant or euthanized under regulatory supervision.
- The origin of the reactors will be traced and these herds should be tested for tuberculosis.

POSSIBLE COMPLICATION

N/A

EXPECTED COURSE AND PROGNOSIS

As therapy is not an option, the prognosis is grave and a recommendation for euthanasia would be appropriate.

MISCELLANEOUS

ASSOCIATED CONDITIONS

From the site of entry, the organism invades the local lymph nodes (bronchial, mediastinal, pharyngeal, mesenteric) where it causes necrosis surrounded by a granuloma containing mononuclear cells.

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Tuberculosis is a zoonotic disease. Care must be taken in the collection of laboratory samples and the diagnosis of affected animals.
- Tuberculosis is a “historical disease” that is still endemic/enzootic throughout large regions of the world and highly zoonotic.
- *M. tuberculosis*, the human infection, accounts for a small proportion of tuberculosis cases in animals.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Small ruminants; potentially all ruminant species can be affected.

ULCERATIVE POSTHITIS

BASICS

OVERVIEW

- Synonyms: enzootic balanoposthitis, pizzle rot, sheath rot
- Ulcerative posthitis is an infectious urogenital disease of the external genitalia affecting both male and female small ruminants.
- It is caused by an aerobic, gram-positive, rod-shaped bacterium, *Corynebacterium renale*.
- These bacteria are a normal inhabitant of the skin and external genitalia of small ruminants and may be spread venereally.
- The bacteria can survive up to 6 months in wool and scabs; can survive freezing in exudates.
- *C. renale* proliferates on genital mucosa in the presence of urea, which increases in concentration in the urine of animals fed high protein and NPN diets.
- *C. renale* hydrolyses urea to ammonia, resulting in necrosis of surrounding tissue.

SIGNALMENT

- Male and female small ruminants may be affected.
- Males affected more commonly than females
- Most common in rams, Angora wethers, and pet wethers
- Most common breeds: Merinos and Angoras, due to dense wool
- Usually adult animals; animals under 6 months of age occasionally affected

SIGNS

- Rams, bucks, and wethers:
 - Moist ulcers at the mucocutaneous junction of prepuce early on
 - Followed by thin, brown, malodorous scab
 - Focal swelling of prepuce
 - Pain
 - Infection may spread inward, affecting entire length of prepuce.
 - Entire prepuce may be swollen and elongated.
 - Malodorous exudate consisting of necrotic tissue and urine present in the preputial orifice
 - Fibrinous or fibrous adhesions between penis and prepuce
 - Stenosis of preputial orifice
 - Dysuria (Vocalization during urination in goats; stricture of vermiform appendage may occur.)
 - Stilted gait
 - If chronic, weight loss
 - Bucks that transmit the bacteria may be asymptomatic.
- Does and ewes:
 - Ulcerative lesions of perineum and vulva
 - Vulvar swelling
 - Dysuria if urethral orifice affected by infection and inflammation
 - Fibrosis and contracture of vulva when long standing

CAUSES AND RISK FACTORS

- High protein level in diet
 - Generally when greater than 16 to 18%, but has been reported on 12% protein rations

- Legume pastures: thick fiber, wet grasses, venereal spread

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Herpesvirus and *Actinobacillus seminis* have also been reported to cause ulcerative posthitis lesions.
- Obstructive urolithiasis and/or urethral rupture
- Preputial trauma
- Ulcerative dermatosis—lesions present on sheath, vulva, legs, lips, eyes
 - Sheep—poxvirus
- Contagious ecthyma (orf)

CBC/BIOCHEMISTRY/URINALYSIS

If lesions causing urinary outflow obstruction: increased BUN, creatinine, and potassium

OTHER LABORATORY TESTS

- Culture and sensitivity can be helpful in the selection of appropriate antibiotic therapy.
- Gram stain

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Diagnosis generally based on physical examination and lesion characteristics
- May culture lesions
- Biopsy

GROSS FINDINGS

Ulceration and swelling of external genitalia

HISTOPATHOLOGICAL FINDINGS

- Lesions consistent with primary bacterial inflammation with mucosal ulceration
- If herpes etiology: acidophilic intranuclear inclusion bodies, chromatin margination in epithelial cells adjacent to ulcers

TREATMENT

- Isolate affected individuals
- Shear wool or hair around external genitalia to allow air flow
- Reduce protein or NPN levels in diet to less than 16%
- May effect a cure if alone if lesions are early
- Sheath irrigation with antiseptic solutions
- Surgery
 - Lesion debridement
 - Preputial resection to allow urine flow and possible return to breeding after infection cleared
 - Salvage procedure: aseptically make 2–4-cm incisions through ventral skin and into prepuce to allow drainage and lavage.

MEDICATIONS

DRUGS OF CHOICE

- Topical antibiotic application: avoid irritating or caustic solutions

- Systemic penicillin or tetracycline: treat until lesions are dry and inflammation reduced

CONTRAINDICATIONS

- Xylazine should not be used in an animal with suspected or known urinary obstruction; xylazine induces hyperglycemia and diuresis and may lead to urinary bladder rupture if the obstruction is not relieved.
- Avoid iodine-based preparations for sheath lavage in breeding animals as it encourages the formation of adhesions and granulation tissue.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

Patients must be closely monitored to ensure patency of urinary tract.

PREVENTION

- Reduce protein in feeding regimen to less than 16%: may feed grass hay to manage intake of high protein feeds
- Shear at times of high protein intake
- Isolate affected animals
- Increase water availability
- May include ammonium chloride in feed to reduce urine pH
- May include chlortetracycline in feeding regimen

POSSIBLE COMPLICATIONS

- Males
 - Loss of breeding soundness due to adhesion of penis to prepuce
 - Scarring of preputial orifice
 - Urethral obstruction
 - Urethritis
- Females
 - Loss of breeding soundness due to impaired vulvar conformation
 - Urine scalding

EXPECTED COURSE AND PROGNOSIS

- If recognized prior to fibrosis, may have a good chance of full recovery with appropriate medical and dietary management
- Internalized infection: return to breeding soundness unlikely

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Loss of breeding soundness due to adhesion of penis to prepuce
- Scarring of preputial orifice
- Urethral obstruction

AGE-RELATED FACTORS

- Generally rare in animals less than 6 months of age
- Generally a disease seen in adults

ZOONOTIC POTENTIAL

None

PREGNANCY

Fibrosis of vulva may be severe enough to cause dystocia.

RUMINANT SPECIES AFFECTED

- Small ruminants
- May be rarely seen in cattle

BIOSECURITY

- Isolation of affected individuals from herd or flock is indicated.
- Separate males and females
- Burn wool of affected animals

PRODUCTION MANAGEMENT

Shear animals at times of high protein intake

SEE ALSO

- Contagious ecthyma (orf)
- Obstructive urolithiasis
- Ulcerative dermatosis

ABBREVIATIONS

- BUN = blood urea nitrogen
- NPN = nonprotein nitrogen

UMBILICAL HERNIA

BASICS

OVERVIEW

- An umbilical hernia is a protrusion of abdominal contents through a defect in the body wall at the umbilicus. The hernial sac is covered with skin and subcutaneous tissue.
- Umbilical hernias are the most common congenital defect in cattle, and are commonly seen in llamas and alpacas. Although they are a recognized congenital defect in sheep and goats, they are generally considered to be rare.
- In cattle and small ruminants, a portion of the abomasum and/or greater omentum is commonly found within the hernial sac. Omentum is also found in umbilical hernias in South American camelids (SACs). The small intestine is rarely found in umbilical hernias in cattle. The greater omentum is less substantial in llamas; therefore, the small intestine is more commonly herniated in SACs than in cattle.
- Infection of umbilical remnants is common in calves with umbilical hernias, with as many as 45% of calves with umbilical hernias having evidence of associated infection.
- Concurrent infection is uncommon in small ruminants and SACs with umbilical hernias.
- Successful management of umbilical swellings depends upon accurately determining the contents of the swelling as well as determining how far the external problem extends internally.

SIGNALMENT

- Umbilical hernias occur most commonly in calves, lambs, kids, and crias as congenital defects. The vast majority are recognized in the first 3 months of life.
- Umbilical hernias occur in all breeds of cattle, although Holstein cows are at increased risk. Beef breeds, especially Hereford and Aberdeen Angus, are at lower risk. Breed predispositions have not been reported in sheep and goats.
- Both females and males are affected, although heifer calves are more commonly reported to be affected than bull calves.

SIGNS

- Umbilical hernias are usually recognized in the first few days or weeks of life as completely reducible swellings, with a discretely palpable circumferential hernial ring.
- The size of the body wall defect varies, with few umbilical hernias in calves under 6 months of age being larger than 10 cm. Similarly, the size of the hernial sac can vary depending on the contents.
- The hernial sac may contain omentum, abomasum, or less commonly intestine, although it is difficult to distinguish the specific contents by external palpation. In some cases, the contents will be adhered to the hernial sac. Reduction of large hernias may be easier with the animal in lateral or dorsal recumbency.
- Animals with uncomplicated hernias usually grow normally, have no abnormal findings associated with the hernia on physical examination or laboratory evaluation, and do not show signs of gastrointestinal dysfunction.
- Animals with abomasal or third compartment outflow obstruction or strangulation of intestines may have irreducible hernias and can be depressed, dehydrated, and possibly anorectic. Abomasal-umbilical fistula can occur resulting in drainage of abomasal contents from the hernial sac, which will result in depression, dehydration, and metabolic derangements.
- Animals with infection of umbilical structures concurrently with umbilical hernias may appear unthrifty, be smaller than animals of comparable age, drain purulent material from the umbilicus, or show signs of pollakiuria.

CAUSES AND RISK FACTORS

- Umbilical hernias are often found as congenital conditions, and they are considered to be heritable in cattle with dominant (with incomplete penetrance), recessive, and sporadic characteristics being proposed. In sheep, goats, llamas, and alpacas, a genetic cause has not been proven, but remains a possibility. It is considered likely in SACs. Females are generally not culled because of umbilical hernias. However, males to be used extensively for breeding should be free of congenital

defects, including umbilical hernias, because of the potential to perpetuate the trait. Most bull studs will not accept bull calves with umbilical hernias present or repaired.

- Infection of umbilical remnants is common in calves, and umbilical infection is a risk factor for the development of umbilical hernia. Umbilical infection may cause weakening of the abdominal wall or slowing of closure of the umbilicus, resulting in hernia formation.
- Another possible cause of umbilical hernia, particularly in small ruminants, is excessive traction on the umbilicus during delivery, resulting in tearing of the abdominal wall. This can lead to an open umbilical hernia with concurrent eventration of intestine through the umbilicus.
- Calves that are born via cesarian section are at greater risk for umbilical infections and umbilical hernias. The risk may be even greater if the umbilical vessels are cut rather than allowed to break as the calf is delivered.
- Calves that result from “splitting” embryos, in vitro fertilization, and cloning techniques tentatively and anecdotally are at greater risk for umbilical infections and umbilical hernias. This may be due, in part, to the greater likelihood that these calves are delivered via cesarian section, the tendency for these calves to have increased gestational lengths, or other factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of swelling in the umbilical area include umbilical abscess, infection of external umbilical cord remnants, urethral rupture in males, cellulitis, or hematoma.
- If the swelling is reducible and the hernial ring can easily be palpated, then the hernia is most likely uncomplicated. However, this is not always the case and in no way rules out the possibility that there may be infection internally in one or more remnants of the umbilical structures, internal organs in the hernial sac, adhesions of internal organs to the hernial sac, or other indications for further diagnostic workup or surgical exploration.
- Signs suggestive that the hernia is complicated by infection include: purulent discharge from the swelling, a scab or “soft spot” at the ventral aspect of the swelling suggesting that it has or is about to drain, inability to palpate the external umbilical vessel remnant, external umbilical vessel remnant palpably enlarged, heat or pain upon palpation, swelling is firm.
- Urine dripping from the swelling, especially evident when the animal is actually urinating, is suggestive that the umbilical problem is complicated by patent urachus. Pollakiuria, in the absence of urine dripping from the swelling, may suggest the presence of a nonpatent urachal remnant.
- An omphalocele is a congenital defect in the body wall at the umbilicus in which eviscerated abdominal organs are covered by amnion rather than skin. If recognized and treated expediently, a successful outcome is possible. Omphalocele is a developmental problem that is not known to be heritable.
- Infection of the internal umbilical structures should be considered as a differential in any young “poor doer” or “failure to thrive” case.

CBC/BIOCHEMISTRY/URINALYSIS

- Neutrophil-lymphocyte reversal / neutrophilia, hyperglobulinemia, and hyperfibrinogenemia are all suggestive that the umbilical swelling is complicated by infection. The absence of elevations in these parameters does not, however, rule out that the swelling may be complicated by infection.
- These values will be normal in animals with uncomplicated umbilical hernias.
- Elevation of packed cell volume and total protein can occur because of dehydration in animals with abomasal-umbilical fistulas, a rare condition that can occur after long-term incarceration of the abomasum in an umbilical hernia.
- Elevation of packed cell volume and total protein can also occur in animals with intestinal strangulation in an umbilical hernia.
- If an abscess is present in umbilical remnants or in the subcutaneous tissue in association with the hernia, total protein, globulin, and neutrophil levels may be increased, neutrophil:lymphocyte ratio may be reversed, and mild anemia may be present.

OTHER LABORATORY TESTS

- Other laboratory tests should also be normal in animals with uncomplicated umbilical hernias. However, if abomasal

outflow obstruction occurs or if abomasal-umbilical fistula develops after long-term incarceration of the abomasum in the hernial sac, the animal will develop hypochloremic, hypokalemic metabolic alkalosis as determined by serum blood gas analysis and electrolyte measurement.

- With intestinal strangulation, affected animals may eventually develop metabolic acidosis associated with dehydration.
- Bacterial culture and sensitivity should be performed in animals with concurrent infection of umbilical remnants.

IMAGING

- Ultrasonographic examination of affected animals provides information that alters the clinician's intervention with great enough frequency to recommend its use.
- Ultrasonographic examination may:
 - Help to detect or rule out the infection status of the internal umbilical remnants.
 - Help to further clarify the extent to which internal umbilical structures are distended / infected.
 - Help to determine which viscera are present in the hernia.
 - Aid in the determination of the best therapeutic approach to an irreducible hernia.
 - Aid in the determination of the best therapeutic approach to an umbilical abscess.

DIAGNOSTIC PROCEDURES

- External palpation of the umbilical region will define the hernial ring, the size of the hernia, the reducibility of the hernia, and possibly the contents. In uncomplicated cases, the hernia should be completely reducible and have a discrete circumferential hernial ring.
- Edema, cellulitis, heat or pain on palpation, or drainage are *not* present in an uncomplicated hernia.
- Gentle palpation in lateral or dorsal recumbency is helpful in determining reducibility and in identification of any enlarged internal umbilical remnants.

TREATMENT

CONSERVATIVE MANAGEMENT

- Small hernias, less than 4 cm, often close spontaneously in calves during the first 3–4 months of life. Larger hernias tend to enlarge in proportion to the growth of the animal, and the hernial sac tends to become more pendulous.
- Resolution of small hernias without intervention also occurs commonly in lambs and kids. Therefore, surgery is performed based on the value of the animal, the likelihood that the intestine will become strangulated, and/or failure of the hernia to resolve spontaneously.
- It is common for 1-cm umbilical defects to be present in crias for up to 1 month. Many of these will resolve spontaneously; however, larger defects are unlikely to resolve without intervention.

NONSURGICAL MANAGEMENT

Options for nonsurgical management for small, uncomplicated hernias in young animals include abdominal support bandages placed for 2–4 weeks (in females), hernial clamps or bands, daily irritation of the hernial ring by reduction and digital palpation, and injection of irritants around the hernial ring. Generally, these are selected for economic reasons and/or convenience.

SURGICAL CONSIDERATIONS

- Surgical correction is the treatment of choice in large hernias, hernias with concurrent infection of umbilical remnants, nonreducible hernias, and hernias with adhesion of abdominal contents to the hernial sac, or hernias that have not resolved with nonsurgical treatments.
- Hernias containing small intestine should be repaired surgically as soon as possible to prevent intestinal strangulation.
- Surgical exploration and repair is indicated when any one of the following is true:
 - There is reason to suspect infection in the internal umbilical remnants.
 - The size of the hernia defect in the body wall is large enough to necessitate surgical correction.
 - The animal is highly valued by the owner.
- There is controversy regarding how large a hernia must be before surgery is indicated. In general, uncomplicated hernias less than 5 cm diameter can be expected to close without any intervention (though a support wrap facilitates the closure—

see below).

- Hernias greater than 10 cm diameter should, if the animal has any reasonable value to the owner, be surgically repaired. Hernias between 5 and 10 cm diameter should be dealt with on a case-by-case basis and treated based upon suspected complicating factors (e.g., infection), the value of the animal, etc.
- Small, uncomplicated hernias may be treated by placing a circumferential bandage around the abdomen of the calf that maintains reduction of the hernia. The bandage is changed every 1 to 2 weeks until the hernia is healed. Bandaging is generally not possible in males.
- It is advantageous to:
 - Place the calf in dorsal recumbency during bandaging so that the hernia remains reduced during the procedure.
 - Glue a piece of plastic (a piece of a 500-mL calcium bottle and Kamar glue work well) that is larger than the hernial ring to the skin under the wrap.
 - Use adhesive elastic tape for the bandage.
- Techniques of hernial extirpation involving elastic bands or clamps are generally not recommended.
- Because concurrent infection is common, open herniorrhaphy is generally the recommended surgical procedure. This involves removal of the hernial sac, evaluation and removal of the internal umbilical remnants, and direct apposition of incised margins of the hernia. Although closed herniorrhaphy, in which the hernial sac is not removed, may prevent abdominal contamination during surgery, it does not allow removal of umbilical remnants, and often takes longer, is more traumatic, and may provide a less secure body wall closure.
- In animals with particularly large hernias, prosthetic mesh repair may be necessary, although very few hernias require mesh to appose. The use of mesh is not recommended in animals with concurrent umbilical infection.
- Surgical correction of uncomplicated umbilical hernias can be performed using sedation (xylazine) and local infiltration of anesthetic (lidocaine or bupivacaine). Local anesthetic should be diluted 1:4 with sterile saline and the volume minimized when used in sheep and goats to prevent lidocaine toxicity.
- General anesthesia, either injectable (such as xylazine, ketamine, guaifenesin infusion), or inhalant anesthesia (halothane or isoflurane), is preferred when concurrent infection of umbilical remnants is suspected.

MEDICATIONS

- Tetanus prophylaxis should be given before surgical treatment or before placement of clamps or bands.
- Prophylactic antibiotic administration is not needed in uncomplicated herniorrhaphy; however, because of the possibility of concurrent infection in calves, the use of preoperative antibiotics, such as penicillin, is common. Antibiotics are continued postoperatively if infection of umbilical remnants is identified at the time of surgery, with the choice of antibiotic being based on the results of culture and sensitivity when they become available.
- Although most animals do not demonstrate overt signs of pain after herniorrhaphy, analgesic medication (e.g., flunixin meglumine 0.5–1.0 mg/kg SID to BID) should be considered, starting before surgery and continuing for at least 24 hours after surgery.
- While the umbilicus can be the portal of entry for environmental bacteria that cause bacteremia, meningitis, joint-ill, etc., the bacteria involved in the vast majority of umbilical abscesses is *Arcanobacter pyogenes* (formerly *Actinomyces pyogenes*, even formerly *Corynebacterium pyogenes*). A small fraction of umbilical abscesses are infected with *E. coli* and other organisms cause the balance.
- Therefore, antimicrobial therapy should be chosen based upon:
 - Activity against *Arcanobacter pyogenes*.
 - Pharmacologically likely to penetrate an abscess.
 - Low but real possibility that other, including gram-negative, organisms may be involved.
- Antimicrobial therapy may not ultimately affect the outcome of a simple external umbilical abscess.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Goats are sensitive to the effects of lidocaine. Caution must be used to avoid toxicity. Local anesthetic should be diluted

1:4 with sterile saline and the volume minimized when used in sheep and goats to prevent lidocaine toxicity.

- Steroids should not be used in pregnant animals.

PRECAUTIONS

Holding a surgical candidate off all feed for 24 to 48 hours prior to and 24 hours after surgery greatly facilitates closure of large defects and decreases the likelihood of dehiscence.

FOLLOW-UP

- Activity in animals with umbilical hernias treated surgically should be restricted to stall confinement for a minimum of 2 weeks postoperatively. In animals with large hernias, restriction of activity should be longer, generally 4 weeks. In the rare instance when mesh repair is required, recommendations are for stall confinement for 4–8 weeks.
- Compliance with recommendations for restriction of activity is important but sometimes difficult. Inability to restrict activity may be associated with the development of postoperative incisional hernias.
- Hernia clamps or bands can dislodge and can result in acute evisceration of abdominal contents. Therefore, animals with clamps or bands should also have their activity restricted until healing is complete.
- Animals treated surgically or with clamps or bands should be evaluated in 2 weeks to remove sutures and evaluate the effectiveness of treatment.
- If abdominal bandages are used, they should be replaced as they loosen to ensure they continue to maintain reduction of the hernia.
- Surgery should be recommended in animals treated unsuccessfully with conservative treatments such as abdominal bandages.

PATIENT MONITORING

- All patients treated surgically should be monitored until recovery from anesthesia is complete, and the animal is able to stand without assistance.
- Surgical incisions should be monitored daily for swelling or discharge. Some swelling is normal, but should begin to decrease at about 4–5 days after surgery. Sudden swelling is likely indicative of incisional dehiscence and requires immediate evaluation and treatment.
- Discharge from the incision is not normal, and typically indicates infection in the subcutaneous tissue that should be treated with antibiotics based on bacterial culture and sensitivity and establishing drainage of the infected material by enlarging the opening in the skin after cleaning the site with an antiseptic solution such as povidone iodine or chlorhexidine.
- Hernial clamps or bands should be checked daily to be sure they remain securely attached. It is possible to incorporate intestine or abomasal wall in clamps or bands. Therefore, animals treated with clamps or bands should be monitored very closely in the first 24 hours for abdominal pain, obstruction, and other signs of gastrointestinal incarceration or dysfunction.

PREVENTION/AVOIDANCE

- In the event that multiple animals are affected on a given farm, it is indicated to pursue potential factors underlying the problem.
- Questions to be addressed include: Do the affected animals share common ancestors suggesting a genetic basis for the problem? Is the farm's protocol for ensuring adequate passive transfer of maternal antibodies appropriate and is it being followed? What are the conditions like in the maternity pen? What fraction of the cows actually calves in the maternity pen?

EXPECTED COURSE AND PROGNOSIS

- The prognosis for uncomplicated umbilical hernias repaired surgically is good to excellent. The most common complication is seroma formation at the incision, which will resolve without additional treatment.
- Small uncomplicated hernias also have a favorable prognosis for repair with hernial clamps or bands. The skin sloughs, and body wall defects generally heal in 7–14 days. Urine scalding of the skin often occurs in males treated with clamps or bands.
- Umbilical hernias associated with infection have a higher incidence of incisional complications, including infection and

incisional hernia, as well as peritonitis. However, with proper surgical technique, the prognosis is still favorable.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Infection of umbilical remnants, umbilical abscess

AGE-RELATED FACTORS

Umbilical hernias are most often congenital and are usually recognized in the first week to month of life. Acquired umbilical hernias also develop in calves and are generally recognized in the first 3 months of life.

UREA TOXICITY

BASICS

DEFINITION

- Urea is considered an economical source of crude protein (CP) in ruminant diets.
- Utilization of urea by the ruminant animal is initiated by its microbial hydrolysis to two ammonia (NH_3) molecules and one carbon dioxide molecule in the rumen environment. This step is accomplished by urease from specific bacterial species such as *Succinivibrio dextrinosolvens*, *Prevotella ruminicola*, and *Ruminococcus bromii*.
- In the rumen, the NH_3 produced from dietary proteins, urea, or other nonprotein nitrogen (NPN) sources is further utilized for synthesis of bacterial amino acids and bacterial proteins. Utilization of NH_3 for bacterial protein synthesis is dependent upon availability of highly fermentable carbohydrate sources such as dietary starch.
- Excess NH_3 is absorbed through the rumen wall and is transferred to the liver for conversion to urea before excretion in the urine.
- Depending on the CP level of the diet, a variable amount of urea is recycled back to the rumen. This is achieved mainly through saliva and to some extent through diffusion across the rumen wall. Urea recycling is intended to increase NH_3 concentrations in the rumen to meet N requirements of the rumen bacteria.
- When the liver's ability to detoxify NH_3 to urea is exceeded, blood NH_3 concentrations are increased to lethal levels (i.e., urea toxicity).
- Urea toxicity is defined as a condition that occurs when large amounts of urea are ingested.
- The dietary urea levels required to induce toxic symptoms as well as the blood NH_3 concentrations associated with toxicity vary considerably. The conditions that may protect ruminants from urea toxicity are also quite variable. However, urea administration with the diet is less toxic than when administered separately. Younger ruminants are found to be more susceptible to toxicity than older ones.
- In general, urea is used widely in ruminant diets and intakes exceeding 0.45 g urea/kg of body weight are known to decrease feed intake and milk production in dairy cows and can induce toxicity.
- The most accurate indicator of urea toxicity is blood NH_3 concentrations.
- Blood NH_3 is toxic to animal cells at low concentrations and is responsible for cell death. Additionally, NH_3 is carcinogenic.
- Urea toxicity symptoms occur at blood concentrations greater than 0.5 mg/100 mL and become more severe at higher levels.
- Urea-induced death usually occurs when blood NH_3 -N concentrations range from 2 to 4 mg/100 mL.

PATHOPHYSIOLOGY

- Following ingestion of large amounts of urea, a rapid release of NH_3 occurs.
- This increases the rumen pH to reach alkaline levels, which in turn supports high rates of NH_3 absorption through the rumen wall.
- Alkaline rumen environments (pH > 7.4), therefore, are considered the most important factor in inducing high blood NH_3 concentrations and toxicity.

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Elevated concentrations of rumen NH_3 and the subsequent high concentrations of NH_3 in peripheral blood are the key characteristics of urea toxicity.
- Complications due to increased blood NH_3 concentrations include alkalosis, rapid uptake of NH_3 by the brain, and central nervous system damage.
- Clinical signs are apparent within 20 to 30 min following ingestion of a toxic urea dose.
- Death occurs within 4 hours.
- The clinical signs include respiratory difficulties (e.g., rapid and/or labored breathing), nervousness, muscular tremors, incoordination, excessive salivation, loss of ability to stand, bloat (due to reduction in rumen motility), and occurrence of tetany. The main cause of death appears to be respiratory arrest.
- The clinical signs of urea toxicity have been categorized into the following three stages: (1) The stage of depression and fatigue is associated with blood NH_3 concentrations ranging from 0.5 to 1.0 mg/100 mL. (2) The beginning of the stage of convulsion is associated with blood NH_3 concentrations ranging from 1.2 to 1.9 mg/100 mL. (3) The end of the stage of convulsion is associated with blood NH_3 concentrations ranging from 4.0 to 7.0 mg/100 mL. Damage of the brain stem and paralysis of the respiration center are usually responsible for death.

CAUSES AND RISK FACTORS

- Inadequate mixing of urea or urea-containing supplements with the remaining dietary ingredients may result in consumption of large urea doses at one time and can dispose the animal to urea toxicity.
- Feeding urea to animals that are not adapted to dietary supplementation of NPN such as urea, NH_3 , and ammonium salts.
- Allowing free access to palatable sources of high-urea concentrates.
- Feeding poor-quality, forage-based diets.
- Use of urea in low-energy rations.
- Feeding urea-containing diets to cattle that are deprived of feed for extended periods of time (e.g., 24–48 hr)

TREATMENT

EARLY STAGES

- Oral administration of 5% acetic acid solution to neutralize excess rumen NH_3 . This treatment is effective in increasing potential survival of the animal if it is performed prior to the onset of tetany.
- Oral administration of cold water to slow the rate of urea hydrolysis to NH_3 and to dilute its concentration in the rumen.

LATE STAGES

Evacuating the rumen after a stab incision in the paralumbar fossa area.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PREVENTION/AVOIDANCE

- Gradual adaptation to urea feeding (e.g., feeding urea to dairy cows at 0.34 g/kg of body weight was achieved after a 6-week adaptation period without inducing negative effects on feed intake, blood composition, milk production, or milk composition).
- Feeding readily fermentable carbohydrate sources (e.g., starch and molasses) in amounts that enable rumen bacteria to capture the released NH_3 for bacterial protein synthesis
- Uniform mixing of urea with the remaining dietary ingredients
- Maintaining a regular feeding schedule
- Feeding urea at rates not exceeding 33% of dietary CP
- Feeding liquid urea supplements with phosphoric acid to maintain acidic rumen environments and to decrease the rate of NH_3 absorption
- Coating urea with fat supplements to decrease its rate of hydrolysis to NH_3
- Extrusion of urea with concentrates such as grains also decreases its rate of hydrolysis.
- Use of urease inhibitors to slow the release of NH_3 . These inhibitors include hydroxamic acids, especially caprylohydroxamic acid.
- Urea should not be added to diets that are already meeting the animal's CP requirements.
- The diet should contain sufficient amounts of calcium and phosphorus. The sulfur to N ratio in the diet also should not be less than 1:15. The diet should also contain sufficient amounts of trace minerals, especially cobalt and zinc.
- Feeding low-energy, high-fiber diets, especially poor-quality forages, should be avoided with urea feeding.

MISCELLANEOUS

UREAPLASMA

BASICS

OVERVIEW

- Ureaplasmas (formerly T-strain mycoplasmas) belong to the Mycoplasmataceae family of cell-wall deficient bacteria, which includes *Mycoplasma*.
- They are antigenetically diverse and species specific.
- *Ureaplasma diversum* is found only in cattle where it is a common inhabitant of respiratory and genital tracts.
- It has been implicated in a number of reproductive syndromes and it is assumed that it causes considerable loss under certain conditions, which have yet to be specified.
- The infective agent is *Ureaplasma diversum*.

INCIDENCE/PREVALENCE

- *U. diversum* is commonly isolated from the reproductive tract of apparently normal female cattle (60%–70%), particularly from the vulvar and vestibular regions.
- Breeding-age beef heifers tend to have the highest prevalence (70%–80%) while *U. diversum* has also been isolated from 1-month-old female calves (21%).
- It is also a common inhabitant of the bull reproductive tract (5– > 70%), particularly within the prepuce and distal urethra.
- The high prevalence rate of *U. diversum* in otherwise healthy cattle does not explain why problems occur under certain unspecified conditions, which are probably multifactorial.

GENETICS

Unknown

GEOGRAPHIC DISTRIBUTION

Unknown, potentially worldwide

SIGNALMENT

Species

All bovines are susceptible. *Ureaplasma diversum* is found only in cattle where it is a common inhabitant of respiratory and genital tracts.

Breed Predilections

N/A

Mean Age and Range

Breeding-age beef heifers tend to have the highest prevalence (70%–80%) while *U. diversum* has also been isolated from 1-month-old female calves (21%). Heifers appear to be particularly susceptible.

Predominant Sex

No sex predilection

Female

- *U. diversum* has been implicated in a number of reproductive tract disorders including granular vulvovaginitis, infertility, early embryonic loss, mid- to late-term abortion and birth of low-viability calves.
- Following experimental inoculation, granular vulvovaginitis resulted in 3–6 days followed by endometritis and salpingitis. *U. diversum* strains differ in pathogenicity as does female susceptibility.
- Heifers appear to be particularly susceptible.
- Although *U. diversum* may be cultured from prepubertal heifers, breeding activity appears to disseminate it more rapidly, suggesting that venereal transmission may occur.

- Clinical signs of granular vulvovaginitis caused by *U. diversum* include hyperemia of the vulval and vaginal mucosa, raised red to grey nodules, and, occasionally, a mild to marked mucopurulent discharge.

Male

U. diversum has been associated with granular balanoposthitis, and it has been suggested as a cause of seminal vesiculitis in bulls.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Granular venereal disease caused by other organisms, including IBR/IPV virus
- Infertility caused by vibriosis or trichomoniasis
- Other causes of mid- to late-term abortion
- Other causes of balanoposthitis in bulls

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- Culture is the method of choice.
- Samples should be taken carefully to avoid contamination.
- The organism is fragile with samples requiring careful handling (preferably frozen) and specific transport media (Stuart broth or Ames without charcoal).
- Not all labs have the appropriate infrastructure for culture and identification.

PATHOLOGIC FINDINGS

- *Ureaplasma diversum* causes a reddening of the inside of the bovine vulva.
- The development of tiny fleshy bumps, a condition called granular vulvitis, occurs. This can persist for more than a year in affected females.
- Abundant mucous discharge can appear 4 to 5 days postinfection, but is fairly short in its duration.
- The pathological cause of *U. diversum* repeat breeding cycle is not known.
- The organism may cause death of the embryo soon after conception.

TREATMENT

- Treatment in most bovine herds is not practical.
- Most cows become fertile again within two or three cycles.
- Aggressive treatment is not usually recommended.
- A vaccine is not available.
- Eliminating the organism from the sheath of bulls is difficult.

MEDICATIONS

DRUGS OF CHOICE

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PATIENT MONITORING

- As the organism progresses in a herd, first service conception rates can fall to as low as 28%.
- Eventually conception rates improve to 85% or 90% of normal.

PREVENTION/AVOIDANCE

- Attempts to induce vaccinal immunity to *U. diversum* have not been successful.
- Use of a guarded sheath for AI pipettes has been suggested as a way to reduce infection into the uterus.
- Use of tetracycline, both as a postinseminate infusion (24 h) or orally (1.1 mg/kg/day) for 30 days over the breeding period, has resulted in improved reproductive rates in affected herds.

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Breeding-age beef heifers tend to have the highest prevalence (70%–80%) while *U. diversum* has also been isolated from 1-month-old female calves (21%).

Author: Peter Chenoweth

UROLITHIASIS IN SMALL RUMINANTS

BASICS

OVERVIEW

- Obstructive urolithiasis is a frequent problem of sheep and goats most commonly occurring in males.
- Urinary calculi are formed proximally in the urinary tract and become lodged in the narrow urethra. It is a life-threatening situation and requires immediate attention.
- The composition of uroliths varies depending on diet and geography.
- Feedlot lambs and pet goats are most commonly affected.

PATHOPHYSIOLOGY

- The formation and composition of urinary calculi are dependent on geography and diet but are always composed of salts/minerals in an organic matrix (nidus) of proteinaceous material. Urine is normally highly saturated with mineral solutes. Multiple factors can cause these minerals to leave solution and precipitate in the urine.
- Complexes of phosphatic crystals are formed in situations of high-concentrate, low-roughage diet. Low dietary calcium to phosphorus ratios, high magnesium diets, and high phosphorus diets have all been implicated. The large amounts of phosphorus in a high grain diet overwhelm the salivary excretory mechanism and induce excretion by the renal system.
- In bucks, rams, and wethers, urethral calculi are most often found lodged in the urethral process, followed by the sigmoid flexure.
- Wethers are especially susceptible to obstruction at the urethral process due to the lack of testosterone effects on the urinary tract. At birth, the urethral process is attached to the preputial mucosa and gradually separates under the influence of testosterone.
- Additionally, testosterone increases urethral diameter.

SYSTEMS AFFECTED

- Renal/urologic: if a urine sample can be obtained, it may reveal hematuria, crystalluria, and proteinuria. Uncorrected urethral obstruction may lead to rupture of the bladder or urethra.
- Endocrine/metabolic: urethral obstruction may cause postrenal azotemia, hyperkalemia, or stress leukogram.
- Cardiovascular: tachycardia is often present. Additionally, hyperkalemia may cause cardiac arrhythmias.
- Skin/exocrine: scalding of the perineum and rear legs may be present. Rupture of the distal urethra may cause preputial and/or perineal edema.

GENETICS

The Texel sheep breed may be predisposed to increased renal excretion of phosphorus.

INCIDENCE/PREVALENCE

- Obstructive urolithiasis is well recognized in sheep wethers maintained in feedlot conditions and fed high-concentrate, low-forage diets.
- Wethers castrated at an early age are more susceptible due to a lack of testosterone driving development of the urethra and urethral process.

GEOGRAPHIC DISTRIBUTION

Silicate calculi are more commonly diagnosed in animals grazed on sandy soil, high in silica, conditions more frequently seen in the western parts of the United States and Canada.

SIGNALMENT

- Obstructive urolithiasis is most often seen in male sheep and goats both intact and castrated although castrated males are more likely affected (see Pathophysiology above).
- All ages are affected.

SIGNS

- Dysuria
- Stranguria
- Dribbling urine
- Vocalization
- Tail flagging
- Abdominal straining
- Abdominal pain (stretching, kicking at abdomen, flank watching)
- Abdominal distention
- Preputial/perineal edema
- Bruxism
- Anorexia, weakness, depression

CAUSES AND RISK FACTORS

- Ruminants fed high-grain diets are at increased risk.
- Additionally, dietary electrolyte imbalances, decreased water consumption/availability, and abnormal urine pH are risk factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

A hair ring present around the penis may cause signs of discomfort and dysuria similar to that seen with obstructive urolithiasis.

Hematuria

- Bladder polyps
- Bracken fern toxicity
- Cystitis
- Infarction of kidney
- Papilloma
- Pyelonephritis
- Trauma
- Urethritis

Dysuria

- Actinomyces
- Cystitis
- Mycoplasma
- Orf
- Photosensitivity
- Sacral fracture
- Spinal cord injury
- Trauma
- Ulcerative balanitis and vulvitis

CBC/BIOCHEMISTRY/URINALYSIS

- A complete blood count may reveal a stress leukogram, mild to severe azotemia depending on duration, and hyperkalemia.
- Crystalluria, proteinuria, and hematuria may be present on urinalysis.

OTHER LABORATORY TESTS

If bladder rupture is suspected, an abdominal fluid to serum creatinine ratio can be performed. The ratio should be < 2:1 and if greater suggests urine leakage into the abdomen.

IMAGING

- An enlarged bladder is often visualized on right-sided abdominal or transrectal ultrasound.
- Echogenic material in the bladder or kidneys is occasionally visualized, but lack of this finding does not rule out the diagnosis. A large amount of free fluid (ascites) may also be visualized in the abdomen if the abdominal portion of the urinary tract is ruptured due to unresolved obstruction.
- Abdominal radiography may allow visualization of the calculi depending on composition.
- Calcium oxalate and calcium carbonate crystals are radiopaque while struvite (magnesium ammonium phosphate), apatite, and silicate crystals are radiolucent. Therefore, lack of radiographic visualization does not rule out the presence of obstructive calculi.
- Infusion of contrast media retrograde through a urethral catheter may allow visualization of calculi; however, urethral rupture/fistula formation or bladder rupture can occur.

DIAGNOSTIC PROCEDURES

- Diagnosis is largely based on history and physical examination findings, supported by alterations in serum chemistry (azotemia, hyperkalemia).
- Urethrosopy has recently been recognized as a modality for diagnosing urethral obstruction in ruminants.
- The presence of urine in the abdomen or subcutaneous tissues is confirmation of obstruction of the urinary tract with secondary rupture.

PATHOLOGIC FINDINGS

- Dissection of the urinary tract will reveal single to multiple calculi lodged along the extent of the tract. The tissues will be hyperemic, hemorrhagic, or necrotic depending on duration of disease.
- Bladder or urethral rupture may be present as well as hydroureter and hydronephrosis.

TREATMENT

APPROPRIATE HEALTH CARE

Physical Examination

- The penis should be exteriorized and urethral process examined in all cases. This may be facilitated by sedation or lumbosacral epidural anesthesia.
- Sedation protocols include diazepam, at a dose range of 0.1–0.5 mg/kg IV, or acepromazine maleate 0.05–0.1 mg/kg IV.
- Acepromazine may promote relaxation of the retractor penis muscle.
- Lumbosacral epidural anesthesia can be performed to provide exteriorization of the penis by eliminating resistance by the retractor penis muscle. Lidocaine (2%) is used at a dose of 1 ml per 5 kg (not to exceed 15 ml).
- Once sedated and/or lumbosacral epidural has been given, the sheep or goat can be placed on its rump to allow easier extrusion of the penis. The penis is grasped through the skin at the base of the scrotum and forced cranially. Uroliths may be palpable in the urethra or urethral process (see Surgical Considerations below).

NURSING CARE

- Treatment should be aimed at supportive care and correcting the obstruction.
- In cases of bladder rupture, urine can be drained from the peritoneum to reduce the effects of uremia and correct electrolyte imbalances. Drainage should be performed slowly to reduce the risk of circulatory shock, and intravenous fluids should be given concurrently.
- Intravenous fluids should be given judiciously in cases of complete obstruction. Choice of fluid therapy should be based on electrolyte imbalances. Intravenous fluids containing potassium should be avoided if hyperkalemia is present.

ACTIVITY

N/A

DIET

A low-carbohydrate, high-roughage diet with a balanced mineral content is essential to prevent occurrence of calculi.

CLIENT EDUCATION

- Many small ruminant owners do not know the importance of feeding a low-carbohydrate diet. Small ruminants will

preferentially eat grain and owners should feed carbohydrates on a limited basis.

- Mineral supplementation should be done carefully, keeping with recommended ratios.

SURGICAL CONSIDERATIONS

Urethral Process Amputation

- If the obstruction is located in the urethral process, amputation may completely alleviate obstruction, as is the case in 37.5%–66% of cases.
- Amputation of the urethral process will not affect future breeding ability. This procedure does not prevent future obstruction if multiple calculi are present in the urinary tract.

Urethral Catheterization and Retrograde Flushing

- Catheterization of the bladder of a ruminant is difficult due to the sigmoid flexure and urethral recess. A catheter can be placed in the distal urethra while occluding the penis. Saline or a lidocaine-saline flush solution (one part lidocaine to three parts saline) is flushed retrograde through the catheter to lavage the calculi into the bladder.
- The disadvantages of this technique are that it is often unsuccessful, can cause trauma to the urethra if catheterization is overly aggressive, and, if successful, the calculus has been returned to the bladder for another chance to cause an obstruction.

Perineal Urethrostomy

- Perineal urethrostomy can be performed in the sedated animal with a lumbosacral epidural.
- Stricture, reduced reproductive ability, and reobstruction are common complications, and this option is best used as a temporary salvage procedure in animals intended for slaughter.

Tube Cystotomy

- Under general anesthesia, a laparotomy is performed placing an indwelling Foley catheter percutaneously into the bladder wall. The catheter is sutured in place to the abdominal wall enabling voiding of urine through the catheter. The bladder is lavaged to remove remaining calculi. The catheter is left in place to allow the urethra to heal and calculi to be expelled. Periodic challenging of urethral patency is performed until the urethral obstruction is resolved.
- This procedure is the best option for salvage of breeding function in intact males, but it does not prevent recurrence of obstruction.
- Tube cystotomy is the most expensive of the surgical options and is usually performed in pets and breeding animals.

Bladder Marsupialization

- A permanent bladder marsupialization can be performed in which the bladder is sutured to the ventral abdominal wall lateral to the prepuce through a laparotomy incision. This technique requires commitment by the owners as care and cleaning of the stoma are required for the life of the animal.
- Bladder marsupialization has the least chance of reobstruction by calculi but the stoma occasionally strictures and requires surgical modification.
- The breeding capabilities are questionable following this procedure.

MEDICATIONS

DRUGS OF CHOICE

- Sedation can be given for examination and manipulation of the penis and urethral process.
- Diazepam, at a dose range of 0.1–0.5 mg/kg IV or acepromazine maleate 0.05–0.1 mg/kg IV. Acepromazine may promote relaxation of the retractor penis muscle.
- Appropriate antimicrobial therapy should be instituted depending on the specifics of the individual case and route of therapy.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Lidocaine sensitivity is common in goats and should be considered prior to its utilization.

PRECAUTIONS

- Alpha-2 agonists (xylazine, detomidine) should not be used in cases of unresolved obstruction due to its diuretic effects.

- Neither diazepam nor acepromazine is approved for use in food animals. The meat withdrawal time for acepromazine maleate is 7 days. There are no withdrawal data for diazepam but a 30-day meat/milk withdrawal should be adequate. Consult with gFARAD.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Animals at risk to block should be monitored closely for signs to enable rapid treatment.

PREVENTION/AVOIDANCE

- Free access to water and modification of the diet are essential to prevent recurrence.
- Urine acidifiers can be used.

POSSIBLE COMPLICATIONS

Recurrence of obstruction and urethral stricture can be common complications.

EXPECTED COURSE AND PROGNOSIS

Prognosis depends on chronology and severity of obstruction as well as treatment method instituted.

UTERINE ANOMALIES

BASICS

DEFINITION

Uterine anomalies may be categorized as either genetic/congenital or pathophysiological.

SYSTEMS AFFECTED

Production management, reproductive

GENETICS

- There is evidence for a genetic basis for segmental aplasia of the reproductive tract in female cattle.
- Intersex is linked with the gene for polledness in dairy goats.

INCIDENCE/PREVALENCE

- In goats, freemartins are relatively frequently detected by chromosomal testing (6%).
- Intersex prevalence in goats may be relatively high (20%) in polled/polled matings.
- Hydroallantois, 85%–90%; hydroamnion, approximately 10% of bovine dropsical conditions.
- Freemartinism occurs in approximately 90%–95% of females born cotwin to a bull.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

In cattle, a condition encountered in white shorthorn heifers (“white heifer disease”) is often associated with segmental aplasia of the tubular portion of the reproductive tract.

Mean Age and Range

N/A

Predominant Sex

Female

DIAGNOSIS

See under specific anomaly below.

TREATMENT

See under specific anomaly below.

MEDICATIONS

See also under specific anomaly below.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals unless abortion is indicated.

FOLLOW-UP

MISCELLANEOUS

Genetic/Congenital Anomalies

This category includes arrested development of those structures derived from the embryonic Muellerian (or paramesonephric) duct system (i.e., oviducts, uterus, cervix, and cranial vagina). Problems caused by either defective or exaggerated fusion of the ducts are reported in most species. It is useful to classify defects on the basis of the underlying anatomic structure.

Segmental Aplasia of the Uterus

- Aplasia of one entire uterine horn is termed uterine unicornis. Alternatively, underdevelopment (hypoplasia) may occur of one or both uterine horns. Aplasia of a segment of uterine horn often occurs near the uterine body, and the blocked horn may become distended with uterine secretions (mucometra or hydrometra).
- Affected animals are infertile. In cattle, a condition encountered in white shorthorn heifers (white heifer disease) is often associated with segmental aplasia of the tubular portion of the reproductive tract (often with distension) plus an intact hymen or vaginal stenosis.
- Anatomic defects of the genital tract of female sheep are uncommon. In goats, intersexes containing an admixture of the Muellerian and Wolffian duct systems are relatively common, although most are male pseudohermaphrodites.
- Predisposing factors. There is evidence for a genetic basis for segmental aplasia of the reproductive tract in female cattle. In shorthorns, the condition is caused by a single, recessive, sex-linked gene linked to the gene for white color, occurring in approximately 10% of white shorthorn heifers. In Holsteins, arrested Muellerian duct development has been traced to a single, autosomal recessive gene.

Diagnosis

Infertility, history, palpation

Uterus Didelphys

- Failure of fusion of the Muellerian ducts can lead to a double cervix, or uterus didelphys (if the median wall of the Muellerian duct is persistent). This can result in delayed pregnancy if semen is deposited in the contralateral side; a problem with AI but not natural breeding. On palpation, the cervix is usually broader and flatter than normal.
- Affected females usually have little problem calving, although occasional obstruction might occur.

Freemartinism

- Freemartinism occurs in approximately 90%–95% of females born cotwin to a bull, and they are usually sterile. Here, the twins develop from different zygotes (dizygotic) with early fusion of the two chorioallantoic membranes resulting in suppression (variable hypoplasia or agenesis) of the female genitalia (oviducts, uterus, and anterior vagina), in conjunction with stimulated development of the Wolffian duct system.
- Freemartins usually have undeveloped, undifferentiated ovaries, an enlarged vulvar tuft, and a shortened, imperforate vagina. The affected female is often relatively small and steerlike, with undeveloped udder and teats. Bulls born cotwin to freemartins may also have fertility problems.
- Freemartinism is rare in sheep. In goats, freemartins are relatively frequently (6%) detected by chromosome confirmation of chimerism in intersexes, where it occurs in both horned and polled animals. Here, the external and internal genitalia are similar to those of polled intersexes, although with greater masculine emphasis.

Diagnosis

- History, infertility, external signs

- Insertion of a lubricated tubular device into the vagina of a freemartin heifer will allow only 7.5–10 cm of penetration compared with 5–7 inches in a “normal” heifer.
- Blood typing of twins reveals chimerism of blood types, providing an indicator of freemartinism.
- Chromosome analysis of freemartins reveals the coexistence of both male and female cells in blood and other hemopoietic tissues. In caprine freemartins, the proportion of male cells may be as low as 1%.

Hermaphroditism and Pseudohermaphroditism

- Hermaphroditism has been occasionally reported in cattle, usually associated with numerical chromosome disorders (XX/XY, XX/XXY) with no evidence that this condition is influenced by heredity.
- Intersexuality is not uncommon in goats (2%–10%) with male pseudohermaphroditism (sex-reversed genetic females) being most common. It is linked with the gene for polledness in dairy goats where the prevalence may be relatively high (20%) in polled/polled matings.
- Caprine male pseudohermaphrodites may vary in appearance from nearly normal females to nearly normal males, although most resemble females at birth. True hermaphroditism is seen occasionally in goats.

Pathophysiological Anomalies

Hydrops

- Hydroallantois and hydroamnion are the two most common causes of hydrops (or dropsy) in the bovine. These conditions are rarely encountered in sheep and goats.
- Prevalence
 - Hydroallantois, 85%–90%; hydroamnion, approximately 10% of bovine dropsical conditions.
 - Occasionally they can occur together.
- Predisposing factors
 - Hydroamnion is caused by a fetal failure of deglutition, and thus is often associated with fetal abnormalities (e.g., genetic conditions), caused by recessive autosomal genes resulting in defective fetuses (e.g., “bulldog” calves in Dexter cattle).
 - Hydroallantois is regarded as a uterine or placental disease (or both) and thus may be likely to recur.

Diagnosis

- Excessive abdominal enlargement in conjunction with pregnancy. Hydroamnion occurs more gradually (weeks or months) than does hydroallantois (5–20 days).
- On transrectal palpation, hydroallantois causes distension and pressure such that the fetus and cotyledons usually cannot be palpated; usually they can be palpated with hydroamnion.
- Allantoic fluid is watery, clear, and amber; amniotic fluid is syrupy and viscid.
- Differential diagnosis: edema of the chorioallantois, fetal anasarca, and fetal edema with ascites and hydrothorax

Treatment

- Varies with duration, severity, and the likelihood of success. In severe cases, prompt termination of the abnormal pregnancy is advised; removal of fluid only generally results in replenishment, which occurs much more rapidly with hydroallantois.
- In general, cesarean section is less successful than induced parturition.
- Abortion may be induced with prostaglandin, in conjunction with glucocorticoids. This is usually more successful with hydroamnion than with hydroallantois. Assistance with delivery is often necessary due to atony of the uterine wall.
- Fluid therapy is recommended due to the rapid loss of vast amounts of fluid associated with the process of delivery.

Prognosis

- With hydroamnion, an inherited cause should be considered as well as the strong possibility of a defective calf.
- Hydroallantois is more likely to recur. If advanced, sequelae may include rupture of the prepubic tendon or abdominal wall.
- Generally, the prognosis both for life and future fertility is poorer for individuals suffering from hydroallantois, than for those suffering from hydroamnion.

Hydrometra, Mucometra

- These conditions have been discussed above in relation to congenital abnormalities of the female tract.
- In does, hydrometra and/or mucometra can result in fluid accumulation that is expelled spontaneously (“cloudburst”) approximately 150 days following breeding.

- This condition occurs in conjunction with a CL, although membranes and fetus are not present.

UTERINE PROLAPSE

BASICS

OVERVIEW

- Uterine prolapse is a condition that affects all species; however, it occurs more often in multiparous cows.
- The protrusion of both uterine horns through the vulva is easily diagnosed and characterizes the uterine prolapse.
- Uterine prolapse usually occurs a few hours after parturition, but it can occur up to 5 or 6 days after calving.

INCIDENCE/PREVALENCE

The incidence of uterine prolapse is relatively low, ranging from 0.003% to 0.25%.

SIGNALMENT

Species

All species are at risk for the occurrence of uterine prolapse, but cows are at a higher risk.

Breed Predilections

It appears that Holstein cows are at higher risk for the occurrence of uterine prolapse.

Mean Age and Range

Primiparous cows as well as multiparous cows are at risk for uterine prolapse. However, multiparous cows are at higher risk due to a higher risk for hypocalcemia, a condition that predisposes cows to uterine prolapse.

SIGNS

- Immediately after prolapse occurs, the tissues are normal and there may be fetal membranes still attached to the endometrium and its caruncles. Within a few hours after the prolapse, the uterus becomes edematous and enlarged.
- Clinical signs that accompany uterine prolapse are straining, abdominal pain, restlessness, anorexia, and increased pulse and respiratory rate. Uterine prolapse in cows is frequently accompanied by hypocalcemia and, in the more severe cases, milk fever.
- Cows that present with hypocalcemia concurrent to uterine prolapse may be recumbent and have muscle fasciculation. Although unusual, the condition may progress to shock and death.

DIAGNOSIS

The diagnosis is obvious as the uterine horns can be identified protruding from the vulva.

DIFFERENTIAL DIAGNOSIS

- Vaginal prolapse
- Partial prolapse of the uterus

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

TREATMENT

- The correction of uterine prolapse can be performed with the cow standing or in sternum recumbency. It is recommended that 2% lidocaine be administered as an epidural anesthesia to avoid the continuous straining of the cow while the

veterinarian is attempting to replace the uterus. Administration of clenbuterol is reported to cause uterus relaxation, facilitating replacement of the uterus, reducing the need for epidural anesthesia. Clenbuterol is a prohibited drug in the United States.

- When attempting to reduce uterine prolapse in a recumbent cow, both hind limbs should be pulled posterior behind the animal so that she is resting on her stifles with the hind legs spread out. This positioning causes the pelvis to be slightly tilted downward and forward, leaving more room in the caudal abdominal cavity, favoring the replacement of the uterus.
- It is fundamental that when reducing a uterine prolapse the veterinarian and assistant be as clean as possible. Surgical scrub should be used to wash the entire uterine surface and remove fecal material, dirt, and fetal membranes if easily separated from the endometrium.
- Oxytocin should be used after the uterus is replaced to stimulate uterine contraction and involution. Cows that develop uterine prolapse are also at higher risk for hypocalcemia; treatments with calcium intravenous solutions should be considered.
- Antibiotic treatment is usually recommended after uterine prolapse is resolved to avoid the occurrence of metritis.
- In cases where replacement of the uterus is impossible or where the tissues are severely damaged, amputation may be indicated as a salvage option.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

MEDICATIONS

FOLLOW-UP

PATIENT MONITORING

Cows that develop uterine prolapse should be closely observed daily for 5 to 10 days postcalving. At any signs of fever, anorexia, or depression, cows should be examined and treated properly.

PREVENTION/AVOIDANCE

- Because cows are at higher risk of uterine prolapse when developing hypocalcemia, a balanced diet during the far-off and close-up periods should be offered to avoid such metabolic imbalance.
- Some studies have shown that cows that have stillborn calves are at higher risk for uterine prolapse, probably due to the longer period between initiation of parturition and assistance provided to the animal. Therefore, it is recommended that the calving area be well monitored at all times and that cows have the proper assistance as they show signs of dystocia or calving difficulties.

POSSIBLE COMPLICATIONS

- Fatalities are rare but can occur in the event of shock or rupture of a large uterine vessel.
- Cows that develop uterine prolapse are at higher risk for metritis and, consequently, are at higher risk for reproductive problems (e.g., increased calving-to-conception interval and calving interval). Due to reproductive problems, cows that present with uterine prolapse are at a higher risk for culling than their herd mates.

EXPECTED COURSE AND PROGNOSIS

The prognosis is usually good; however, it depends on the lag time between the occurrence of the uterine prolapse and replacement. The extent and magnitude of uterine lesions also determines the prognosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Hypocalcemia is a condition that predisposes cows to uterine prolapse due to the lack of contractility in uterine tissues.

AGE-RELATED FACTORS

Because hypocalcemia is more common in multiparous cows, it is expected that multiparous cows are at higher risk for uterine prolapse than primiparous cows.

RUMINANT SPECIES AFFECTED

All ruminant species may be affected.

PRODUCTION MANAGEMENT

Feeding well-balanced rations in the far-off and close-up periods is important to avoid the occurrence of hypocalcemia, decreasing the risk for uterine prolapse.

UTERINE TORSION

BASICS

OVERVIEW

- Uterine torsion is a relatively common cause of dystocia accounting for 5%–10% of dystocia events.
- Anticlockwise torsion of the uterus is more common than clockwise torsion.
- About 85%–90% of uterine torsion occurs around the time of parturition during the initial stages of labor.
- Factors such as increased fetal movements in the late first and early second stage of labor and uterine instability due to loose broad uterine ligament at the time of parturition predispose the occurrence of such dystocia. Fetal oversize is another factor that may predispose to uterine torsion.

INCIDENCE/PREVALENCE

Uterine torsion represents 5%–10% of the dystocia occurring in cattle.

SIGNALMENT

Species

Uterine torsion can occur in most bi-ungulates; cattle, sheep, goats, camelids, and cervidae

Breed Predispositions

N/A

Mean Age and Range

Although multiparous cows are believed to be at higher risk in developing uterine torsion due to decreased uterine and mesometrial tone, an epidemiological study has shown that the incidence of uterine torsion is similar between cows younger than 3 years, between 3 and 5 years, and cows older than 5 years of age.

SIGNS

Clinical Signs

- Cows with uterine torsion may present with signs of anorexia, depression, decreased milk production, and colic/abdominal pain (kicking the abdomen and treading on her hind limbs).
- The use of a speculum allows for the observation of the vaginal wall, which is rotating clock- or counterclockwise.
- Palpation per rectum usually allows for a definitive diagnosis. The uterus can be more toned than normal, the broad ligament is usually very tense, and the ovary is dislocated ventrally toward the torsion.

DIAGNOSIS

- Observation of the vagina with the use of a speculum for visual examination
- Palpation per rectum of the vagina, cervix, uterus, and broad ligament of the uterus

DIFFERENTIAL DIAGNOSIS

- Dystocia—fetal malposition in utero
- Colic

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

TREATMENT

MANUAL TREATMENT

- With the patient recumbent, rotate the animal in the same direction as the uterine torsion while one person holds the calf.
- Rotation of the calf in the opposite direction of the torsion by purchase of the elbow joint or shoulder of the calf. Before attempting the final push to correct the torsion, it is usual to do swing movements in the uterus.
- Rotation of the calf using a detorsion rod. One end of an obstetric chain is placed dorsally to the metacarpal/metatarsal joint of the calf. The chain is then passed through the loop of the detorsion rod and the free end of the obstetric chain is placed dorsally to the metacarpal/metatarsal joint of the calf. The detorsion rod is then twisted in the opposite direction of the uterine torsion.
- Manual approach in camelids is done prior to delivery. The cervical “star” is visualized and the animal is rotated in the direction opposite to the cervical displacement. It is not uncommon for three to four attempts to be made prior to success.

SURGICAL TREATMENT

- Laparotomy to correct the torsion of the uterus manually
- Laparotomy and cesarean section if the cow is in labor
- Laparotomy may be indicated in camelids secondary to manual detorsion failure.

MEDICATIONS

FOLLOW-UP

PATIENT MONITORING

- If the uterine torsion is corrected manually without the need for surgery, the prognosis is very good and little if any patient monitoring is required. It is suggested that patients be observed for at least 3 to 5 days postprocedure to evaluate appetite and to ensure that no fever develops.
- When the uterine torsion is corrected by a surgical procedure, with or without cesarean section, it should be recommended to the farm personnel that the animal be closely observed for 5 to 10 days. Rectal temperatures should be checked daily, and if signs of fever or loss of appetite appear, the animal should be treated immediately for such conditions.

PREVENTION/AVOIDANCE

- Adoption of good management practices is the only way to minimize the occurrence of this event.
- Pregnant animals should be well fed at all times and the feed bunk should never be empty. Feed bunk management is extremely important in its prevention.
- Far-off and close-up animals should be handled calmly at all times avoiding running.
- The condition is common in camelids and is generally associated with colic symptoms in pregnant llamas.

POSSIBLE COMPLICATIONS

- Uterine torsion usually does not have any further complications if the torsion is not severe and if the correction of the condition can be done manually without the need for surgery.
- The occurrence of uterine torsions that are beyond 360° can compromise uterine vascularization leading to hypoxia. The uterus can become devitalized and very friable. In such conditions, it is not uncommon for a cow that undergoes labor to rupture her uterus.
- Rarely, uterine torsion involves the alimentary tract or other abdominal organs; however, when this occurs there can be complications due to the compromised venous and arterial flow of blood from and to the organs.

EXPECTED COURSE AND PROGNOSIS

The prognosis is usually good; however, it depends on the extent of the torsion and the length of time between occurrence, diagnosis, and treatment.

MISCELLANEOUS

AGE-RELATED FACTORS

Multiparous cows may be theoretically at higher risk for uterine torsion due to decreased uterine and mesometrial tone.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Pregnancy may be terminated spontaneously after the occurrence of uterine torsion depending on the degree of torsion. Uterine torsions that are above 360° may cause the rupture of fetal membranes or compromise venous return to the uterus leading to the death of the calf.

RUMINANT SPECIES AFFECTED

Most bi-ungulates may be affected by this condition.

PRODUCTION MANAGEMENT

- Incidence of uterine torsion is low.
- Relative to the occurrence of other types of dystocia, uterine torsion has a prevalence of 5%–10%. This value may be overestimated because it usually requires veterinary assistance, and reporting bias may occur.

VACCINATION AND DEWORMING PROGRAMS FOR BEEF CATTLE

BASICS

DEFINITION

- Strategic vaccination and deworming programs are part of a total herd health management plan.
- Vaccination is a tool that can help prevent the occurrence of disease or reduce the severity of disease but it is not a substitute for poor management in other areas.
- A successful vaccination program depends on adequate nutrition, proper management and housing, and planning.
- Nutrition must be adequate for the immune system to function properly.
 - A vaccine prevents diseases by priming an animal's immune system to fight the disease.
 - The animal must be supplied with adequate protein and energy, as well as vitamins A and E, copper, selenium, and zinc for optimum immune system function.
- No vaccine is 100% protective in 100% of the animals. Some animals will have a less than maximal response to a vaccine and some animals may not respond at all.
- Vaccination is simply the act of inoculating an animal with a vaccine. It does not imply immunity.
- Immunization is the development of an immune response in response to a vaccine. It does not imply protection from disease.
- Strategic deworming improves animal health by preventing clinical parasitism, improves production by improving growth and efficiency, and reduces pasture contamination with infective larvae.
- *Ostertagia*, *Haemonchus*, and *trichostrongyles* are the most important gastrointestinal (GI) parasites of cattle. *Ostertagia* is the most economically important intestinal parasite of cattle.

PATHOPHYSIOLOGY

Types of immunity:

Passive Immunity

- Antibodies are obtained from some source other than the animal's immune system.
- Passive transfer of colostral antibodies is the most important form of passive immunity.
- Antibodies from passive immunity may interfere with the development of active immunity in response to a vaccination in young animals by "neutralizing" the vaccine.
- Other types of passive immunity include blood or plasma transfusions and antiserum products such as tetanus antitoxin.

Active Immunity

- Humoral, cell mediated, and secretory types
- Antibodies are produced by specific lymphocytes in response to exposure to an antigen or in response to a vaccination.
- Cell mediated immunity (CMI) develops when specialized lymphocytes are exposed to a specific organism and develop a "memory" for that organism. When exposed again, these cells attack and kill that organism or cells infected with that organism.
 - CMI is not as easily produced as humoral immunity and is rarely produced in response to a killed vaccine.
 - In most cases, an infectious organism has to replicate within an animal in order to produce CMI.
- Secretory immunity consists of antibodies produced in response to exposure or vaccination that do not circulate in the blood stream.
 - Antibodies are produced by cells lining the mucosal surfaces of various parts of the body.
 - Vaccines that can be administered in the same manner that natural exposure would occur tend to produce the best secretory immune response. An example would be an intranasal IBR vaccine.

Innate Immunity

- Innate immunity consists of natural defense mechanisms such as enzymes, tears, saliva, and gastric acids.
- These mechanisms destroy or mechanically remove infectious organisms before they can cause an infection.
- A failure of any one of these types of immunity predisposes an animal to disease.
- Proper vaccination can improve both passive and active immunity.
- Parasitism has many pathologic effects on an animal. The degree of the effect can range from minor infestations that have little significance to severe clinical parasitism resulting in death.
 - The most important GI parasites damage the mucosal lining of the abomasum and small intestine resulting in blood loss, reduced nutrient absorption, diarrhea, and edema.
 - Liver flukes may cause enough damage to result in clinical disease, but more often they predispose animals to other diseases or result in liver condemnations at slaughter. Liver damage caused by flukes is part of the pathophysiology of bacillary hemoglobinuria (*Clostridium haemolyticum*).
 - External parasites result in production losses from reduced growth and hide damage.

SYSTEMS AFFECTED

- The primary systems targeted in most vaccination programs include the respiratory, gastrointestinal, reproductive, and musculoskeletal systems.
- Reducing health problems through proper vaccination and parasite control can have an effect on virtually every system in the body.

GENETICS

Genetics play an important role in natural disease resistance including innate immunity and factors such as mothering ability, which affect passive immunity.

INCIDENCE/PREVALENCE

All cattle herds could benefit from some sort of planned vaccination and parasite control program.

GEOGRAPHIC DISTRIBUTION

Appropriate vaccination and parasite control programs must be customized to the specific herd and location for which they are being developed.

- Some vaccines may be appropriate in some areas but unnecessary in others depending on the occurrence of the disease in that area.
- Some geographic areas have parasite problems that other areas may not have. An example would be liver flukes.

SIGNALMENT

- All beef cattle, regardless of age and production status, should be incorporated into a vaccination and parasite control program.
- Different ages and classes of animals will require different protocols but all animals should be included in the program.

SIGNS

- The signs of vaccine failure depend on the body system affected by the disease. Signs may range from subclinical production losses to clinical disease and death.
- The signs of parasitism also depend on the system affected.
 - Signs associated with most external parasites are usually readily apparent.
 - Signs associated with internal parasites can range from subclinical production losses to clinical disease and death. The common signs associated with GI parasitism include ill thrift; dry, dull hair coat; weight loss; diarrhea; “bottle jaw”; and reduced production.

CAUSES

- The causes of vaccine failure are numerous.
 - Improper handling of vaccines
 - Improper timing of vaccination
 - Interference from maternal antibodies
 - Improper administration technique
 - Improper timing of booster vaccinations
 - Animals that are already sick or highly stressed

- Overwhelming disease challenge
- Nutritional deficiencies or other causes of poor health
- The causes of parasite control failure include improper dosing or administration technique, improper timing of administration, and drug resistance.

RISK FACTORS

Risk factors for vaccine failure include those factors listed above as causes of vaccine failure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

N/A

CBC/BIOCHEMISTRY/URINALYSIS

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Many infectious agents can cause disease and attempts should be made to establish a definitive diagnosis before implementing a vaccination protocol to combat a disease outbreak.
- Periodic fecal egg counts may help in the development and monitoring of parasite control programs.

PATHOLOGIC FINDINGS

N/A

TREATMENT

APPROPRIATE HEALTH CARE

Ensuring adequate colostral transfer of antibodies is much more important and effective than any vaccination program.

NURSING CARE

N/A

ACTIVITY

N/A

DIET

Animals must be provided a balanced diet that is adequate in vitamins and trace minerals to allow optimum immune system function.

CLIENT EDUCATION

- Clients must be educated on the proper administration of vaccines and parasite control products.
- Vaccines must be used according to the label directions.
- Vaccines should not be mixed in the same syringe unless directed by the label.
- Vaccines should be kept cool and out of direct sunlight. Keep vaccines in an ice chest or some other form of protection while in use.
- Only reconstitute the amount of vaccine that can be used in a 1 hour period. Do not try to store reconstituted MLV products; even if it is just for a few hours.
- Whenever possible, use products that can be administered subcutaneously.
- All injections, both subcutaneous and intramuscular, should be given in the neck to avoid damage to the more valuable parts of the carcass.

- Use clean injection equipment to administer vaccines.
 - Change needles every 5 to 10 head.
 - Never disinfect instruments that will be used for MLV products with chemical disinfectants. Residual disinfectant can destroy the effectiveness of MLV products.

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

Types of Vaccines

Killed Vaccines

- Require booster dose 2–3 weeks following initial dose. If booster is not properly administered, virtually no protective immunity occurs. Once an animal has received the initial two doses, a single yearly booster may be adequate.
- Provide a shorter duration of immunity
- Usually do not stimulate CMI
- May be the safest type to use in some situations

Modified-Live Vaccines

- Infectious agent is alive but altered so that it does not cause disease in healthy animals.
- Agent replicates within the animal and induces both humoral and cell-mediated immunity.
- Produce long-lasting immunity; may be lifelong in some cases
- Usually provide a greater immune response than killed products
- Some types may cause abortion in pregnant cows or disease in highly stressed animals.
- Some newer MLV products are labeled for use in pregnant cows and calves nursing pregnant cows as long as the vaccines are used according to the label.

Component Vaccines

Vaccines that contain only part of an infectious agent. These products induce immunity to a part of an infectious agent that is necessary for the agent to cause disease. Toxoids Vaccines that induce an immune response to certain toxins produced by bacteria.

Deworming Products

- Delivery method—many products are available with many different delivery methods: injectable; pour-on; molasses blocks, mineral mixes; crumbles; pastes; boluses; drenches
- Spectrum of activity
 - Refers to how many different parasites and which stages of the life cycle the product will control.
 - Many products are available that will kill external parasites, internal parasites, and hypobiotic larvae.
 - Some parasite problems may have to be addressed with specific products (e.g., flukes).
- Duration of activity: refers to the length of time a product will remain active in the animal
 - Products such as Valbazen, Safeguard/Panacur, and Synanthic are effective but short-lived: typically remain active for 2 to 3 days
 - Products such as Dectomax, Ivomec, Ivomec-Eprinex, and Cydectin have an extended duration of activity: typically remain active for 14 to 28 days.

Recommended Vaccination Programs

A successful vaccination program must be customized to each specific situation.

Young Calf Vaccines

- Passive immunity to clostridial diseases usually begins to decline around 2 to 3 months of age. Calves at this age should be given a clostridial bacterin/toxoid.
- Passive immunity to the common respiratory viruses (IBR, BVD, PI3, and BRSV) usually lasts for 4 to 5 months so calves at this age should be fairly well protected.

- Respiratory viral vaccines can be administered at this time if the herd has a history of respiratory disease in calves of this age.
- Intranasal vaccines are a good choice in young calves because passive immunity has less effect on these vaccines.

Prewaning Vaccines

- Ideally, calves should be vaccinated 2–4 weeks prior to weaning so that they have had time to develop an immune response and to help reduce the stress of weaning.
- At 2–4 weeks prior to weaning, calves should receive a respiratory virus vaccine and a clostridial booster.
 - MLV viral vaccines are preferable to killed products as long as they can be safely used according to label directions in nursing calves.
 - If a killed product is used, it must be boosted at weaning.
- Other vaccines to consider at this time include *Pasteurella* leukotoxoid vaccines, *Hemophilus somnus* and calf hood vaccination (Brucellosis) of potential replacement females. Some states require that females be official calf hood vaccinates in order to enter the state.

Weaning Vaccines

- MLV respiratory virus vaccines can be given at weaning without the risk of abortion in pregnant cows.
- Calves that received this type of vaccine at preweaning should not need another dose at weaning.
 - The advantage of giving a second dose at weaning is providing another opportunity for calves that did not respond to previous vaccinations to become immunized.
 - Calves that responded to previously administered vaccines usually do not develop greater immunity in response to a second dose.

Replacement Females

- At 1 year of age, replacement heifers should receive MLV respiratory virus vaccine with leptospirosis.
- *Campylobacter* (vibriosis) can be included if infertility due to vibriosis is a risk.

Adult Cows

- Adult cows should receive a five-way *Leptospira* bacterin once or twice yearly. Immunity produced by *Leptospira* vaccines is short-lived
- Cows that received MLV respiratory virus vaccine as heifers often develop lifelong immunity to these agents and do not need yearly boosters.
 - Yearly boosters can be given if the vaccination history is unknown or if the producer desires to increase the level of antibody provided in the colostrum.
 - If killed products were used in the replacement heifers, yearly boosters should be given.
- Cows can also be vaccinated with K-99 *E. coli* and rotavirus/coronavirus products to increase the level of passive immunity provided to the calf.
 - Pregnant replacements should be given two doses, 3 and 6 weeks prior to calving.
 - Previously vaccinated cows only need 1 dose, 3–4 weeks prior to calving.
 - Rotavirus/coronavirus products are available to give to newborn calves prior to the calf's nursing colostrum.
 - *Campylobacter* and trichomoniasis vaccines can be given yearly in at-risk herds.

Bulls

- Bulls should receive the same vaccinations used in the cow herd with some exceptions.
 - Bulls are not vaccinated for brucellosis.
 - The currently available trichomoniasis vaccine is not approved for use in bulls.
 - IBR virus from MLV products may recrudescence and be shed in semen.
 - Bulls should receive leptospirosis and campylobacteriosis vaccines in accordance with the cow herd.
- Other vaccines such as pinkeye and foot rot vaccines may be considered in problem herds.

Recommended Deworming Programs

- Deworming programs should be strategically designed to reduce the parasite burden within the animals and reduce pasture contamination.
- Deworming programs should be customized to meet the needs and management style of each producer.
- Producers should use broad-spectrum products that will kill several parasite species as well as hypobiotic larvae.

Deworming Twice Yearly

- Twice yearly deworming provides the most opportunity to reduce pasture contamination.
- Cows should be dewormed in the fall as they come off of summer pasture to reduce the number of parasites overwintering in the cows and reduce the additional drain on body condition caused by significant parasite burdens.
- These cows should be dewormed again in the spring prior to being turned out to grass. Deworming at this time removes parasites that overwintered in the cows and reduces pasture contamination in the spring.
- An alternative plan is to deworm cows prior to turn out on grass in the spring and again 8–9 weeks after turnout. If long-acting products are used, this program will greatly reduce pasture contamination for the first 11 to 12 weeks of the grazing season. Calves should also be dewormed 8–9 weeks into the grazing season to prevent pasture contamination.

Deworming Once Yearly

If cows can be dewormed only once per year due to management or other constraints, that deworming should be administered in the fall to reduce the parasite burden overwintering in the cows.

- Calves can be dewormed at preweaning or weaning. Deworming at preweaning reduces pasture contamination by the calves.
- Stocker cattle should be dewormed prior to being turned out to pasture and dewormed again 6–7 weeks into the grazing season.
- Feeder cattle should be dewormed once upon entry into the feedlot.

CONTRAINDICATIONS

- Some MLV viral vaccines can cause abortion if administered to pregnant cows or calves nursing pregnant cows. ALWAYS follow the label directions.
- Administering vaccines to animals that are already sick or heavily stressed often fails to produce an immune response and may further stress the immune system.
- Administering certain vaccines may complicate international shipment of animals or semen due to positive serologic tests. Consider the ultimate goals of the producer before administering vaccines.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Vaccines must be properly handled and administered in order to maximize the chances of developing a strong immune response.

POSSIBLE INTERACTIONS

- Vaccines should not be mixed in the same syringe with other products except as provided by the label.
- Equipment used to administer MLV products should not be cleaned with chemical disinfectants because these chemicals can reduce or eliminate the effectiveness of the vaccine.

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Patients should be monitored postvaccination for anaphylactic reactions.

PREVENTION/AVOIDANCE

POSSIBLE COMPLICATIONS

Anaphylaxis is possible with some vaccine products. If anaphylaxis occurs, epinephrine is the treatment of choice.

EXPECTED COURSE AND PROGNOSIS

N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

Young calves may not respond to vaccines due to the influence of passive immunity from colostral antibodies. Antibodies to clostridial diseases usually last until the calf is 2–3 months of age and antibodies to the respiratory viruses usually last until 5–6 months of age.

ZOONOTIC POTENTIAL

Care must be taken when administering brucellosis vaccination because injection of this product into humans will cause illness.

PREGNANCY

Care must be used when administering MLV products to pregnant cows. Always follow label directions.

RUMINANT SPECIES AFFECTED

Cattle

BIOSECURITY

Well-designed vaccination programs are an integral part of all biosecurity programs.

PRODUCTION MANAGEMENT

Provision of well-designed vaccination and parasite control programs is an integral part of any production management system.

Susceptibility and pathogenicity varies among host species.

INCIDENCE/PREVALENCE

Worldwide

GEOGRAPHIC DISTRIBUTION

Climate, topography, indigenous wildlife populations all determine which parasites will be of significance in a given area.

SIGNALMENT

Species

Susceptibility and pathogenicity varies among host species.

Breed Predilections

N/A

Mean Age and Range

Young animals more likely to suffer significant pathology.

Predominant Sex

N/A

SIGNS

- Anorexia, weight loss, slow growth rate, diarrhea, poor coat condition, cough or dyspnea (lungworm), anemia, and in severe cases death.
- For external parasites may also see a rough coat, pruritis, alopecia, scales, crusts, and skin thickening.

CAUSES

Include but are not limited to:

Internal Parasites

- Nematodes: *Dictyocaulus viviparus* (lungworm), *Ostertagia* spp., *Haemonchus* spp. (stomach worm), *Trichostrongylus* spp. (intestinal worm), *Parelaphostrongylus tenuis*, *Pneumostrongylus tenuis*, *Trichuris* spp. (whipworm), *Elaeophora schneideri*, *Setaria* spp. (abdominal worm)
- Cestodes: *Thysanosoma* spp., *Monezia* spp., *Echinococcus granulosus*, *Taenia hydatigena*
- Trematodes: *Fascioloides magna* and *Fascioloides hepatica* (liver flukes)
- Protozoal: Coccidia, cryptosporidia, *Toxoplasma gondii*, *Sarcocystis* spp.
- Arthropods: *Hypoderma tarandi*, *Hypoderma diana* (Warbles), *Cephenomyia* spp. (Bot fly)

External Parasites

Ticks, lice, mange, face flies, fire ants (*Solenopsis invicta*)

Blood Parasites

Babesia capreoli, *Babesia odocoeli*, *Anaplasma marginale*

RISK FACTORS

High-density stocking; malnutrition; harsh winter; introduction of new stock; recently captured wild or free-ranging animals; a warm, moist, environment; and contaminated pastures

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other infectious or metabolic disease, malnutrition

CBC/BIOCHEMISTRY/URINALYSIS

- CBC may show eosinophilia, anemia, or hypoproteinemia.
- Blood films may be used to diagnose hemoparasitism such as babesiosis.

OTHER LABORATORY TEST

CSF tap may show an inflammatory response if the CNS is involved.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Fecal float and direct examination, fecal egg counts, plasma pepsinogen levels (for abomasal parasitism), Baermann technique (for lungworm)

PATHOLOGIC FINDINGS

Depends upon parasite specified. Parasitic nodules in the abomasum and high worm count for abomasal parasites.

TREATMENT

APPROPRIATE HEALTH CARE

NURSING CARE

IV fluids, transfusion, and tube/bottle feeding may be necessary for severely debilitated calves.

ACTIVITY

N/A

DIET

N/A

CLIENT EDUCATION

Treat the herd as well as the infected individual.

MEDICATIONS

DRUGS OF CHOICE

- With the exception of ivermectin administered subcutaneously, there are no anthelmintics licensed for use in cervidae in the United States.
- Extralabel drug use in cervidae is permitted under specific guidelines, which require a valid veterinarian-client-patient relationship. This author does not endorse or guarantee the safety or efficacy of any of the following products when used in cervidae species.

Nematodes

Ivermectin (0.2 mg to 0.4 mg/kg SQ, 0.2 mg/kg PO, or 0.5 mg/kg topically), mebendazole (10 mg/kg PO X 3 days), oxfendazole (4.5 mg/kg PO), fenbendazole, albendazole, levamisole, thiabendazole, doramectin, and moxidectin

Cestodes

Benzimidazoles (cambendazole, oxfenbendazole, fenbendazole, albendazole)

Trematodes

Nitroxylin, closantel, clorsulon (with ivermectin), and triclabendazole (give as 24% drench at the rate of 50 mg/kg, repeat drench in 7 days), albendazole (give in feed at for 7 days), rafozanide.

Babesia

Imidocarb

Protozoan

- Coccidiosis: amprolium, sulfonamides, diclazuril
- Toxoplasmosis: sulfonamides

Ectoparasites

Ivermectin, permethrin, and amitraz

Flies

Warbles and nasal bots: ivermectin treatment must be done in the winter (between September and January for North American cervidae) in order to reach the larvae.

Withdrawal Times

- Ivermectin has a 56-day withdrawal period for reindeer.
- Drug withdrawal times must be determined and maintained for all food-producing species treated.

CONTRAINDICATIONS

Although ivermectin is safe for use during pregnancy, the stress of handling animals can induce abortion. Therefore, handling is not recommended during the last trimester of pregnancy.

PRECAUTIONS

- Withdrawal times and toxicities may vary greatly between species.
- Caution must be used when extrapolating doses and withdrawal times from data on other species.

POSSIBLE INTERACTIONS

Topical ivermectin products may cause local irritation, especially if biting insects are present.

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Monitor fecal egg counts, animal weights, and clinical condition.

PREVENTION/AVOIDANCE

- Avoid overcrowding and develop a deworming program based upon the geographic location, known parasites present, observed clinical signs, and the type of management employed (intensively managed farm vs. wildlife refuge).
- Move herd to a clean pasture in early summer.
- Avoid feeding raw cervidae meat to dogs.

POSSIBLE COMPLICATIONS

Decreased production, stunted growth, death

EXPECTED COURSE AND PROGNOSIS

N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS

AGE-RELATED FACTORS

ZOONOTIC POTENTIAL

Echinococcus spp.

PREGNANCY

Avoid using anthelmintics that are contraindicated in domestic ruminant species.

RUMINANT SPECIES AFFECTED

Depends upon the specific parasite.

BIOSECURITY

- Quarantine, preshipment and postshipment testing are a must.
- Prophylactic deworming of all new animals prior to herd entry is also helpful.
- Fencing must be of sufficient height to keep wild cervidae and other host species out.
- Double fencing may be required.
- Implement insect control measures where insect-borne parasitic diseases are a threat.

PRODUCTION MANAGEMENT

- Perform routine fecal exams on the herd and treat when fecal egg count is high or when clinical signs are observed. Since young animals can be a major source of infection, monthly fecal checks should be performed on calves greater than 2 months of age.
- Other general recommendations include routine deworming of pregnant hinds and calves and prewinter deworming of all stock. Deer may require deworming in the fall and spring. Deer grazing on heavily contaminated pastures may require treatment as often as every 3 weeks during the grazing season.
- Rotate pastures when possible. Deworm calves at weaning and move to clean pastures.
- When using medicated feeds, it is important to spread out the feed over a large amount of trough space so that the lowest animals in the herd's social hierarchy have access.
- Drenching and injectable routes of administration are preferable for large herds in order to ensure that all of the animals receive treatment.
- Implement insect control measures when insect vectors pose a threat. Implement pasture control measures where snails are acting as intermediate hosts.

VACCINATION AND DEWORMING: SHEEP

BASICS

OVERVIEW

Health programs should be individualized for each operation addressing

- Planned onset of lambing season
- Management system practiced (i.e., pasture-based, dry-lot, or combination)
- Economic issues—commercial or purebred
- Production goals
- Geographic locale and related disease prevalence issues

SYSTEMS AFFECTED

Production management, immune

GENETICS

Predominant Sex

N/A

MEDICATIONS

- Focus annual program on management issues associated with four phases of production cycle (See [Table 1](#)).
 - Prebreeding
 - Prelambing
 - Lambing
 - Preturnout
- *Clostridium perfringens* type C and D vaccine with/without tetanus toxoid
 - Only “routine” vaccine administered to sheep
 - Referred to as “overeating disease,” “CDT,” or “CD” vaccine

Additional Vaccine Comments

- Multivalent *Clostridium* spp. vaccines
- Not given routinely unless diseases prevalent in area or animals are shipped to areas where common

- May be useful if clostridium diseases are secondary to special management or parasite problems
- Caseous lymphadenitis vaccine (CLA or CL vaccine)
- Used routinely in some flocks to reduce incidence of CL
- “Soremouth” vaccine (“ecthyma,” “orf”)
- Live virus “scratch” vaccine: use caution and wear gloves when handling vaccine or lesions
- Causes ecthyma contagiosum in humans
- Vaccination causes disease: therefore not recommended if soremouth not present in flock
- Used mostly to prevent outbreaks affecting sales or lambs less than 3 weeks old
- “Blue tongue” vaccine
- Local use in endemic areas
- May affect serology for interstate/international shipment
- Rabies vaccine
- “Killed” vaccine available for endemic areas, but cost issue for sheep
- Bovine IBR-PI3 intranasal vaccine
- Used by some producers to prevent respiratory disease in show lambs (nonapproved use)

Additional Parasite Comments

- Prevent/postpone resistance issues by rotating anthelmintic families annually.
- Anthelmintic families (three major types) as determined by mechanism of action
- Benzamidazoles/probenzamidazoles: oxbendazole, fenbendazole, albendazole, oxfendazole
 - Resistance issues
 - Best options for tapeworm control
- Avermectins/milbamectins (macrocyclic lactones): ivermectin, doramectin, moxidectin
- Imidazothiazoles: levamisole
- Liver flukes: local problem no approved treatments available
- *Fasciola hepatica* (“common liver fluke”): clorsulon
- *Fascioloides magna* (“deer fluke” in Great Lakes Region): albendazole

PRECAUTIONS

- Extralabel use must be accompanied by a strict veterinarian - client - patient relationship (VCPR)
- *Albendazole should not be used during the first 45 days of pregnancy!* (teratogenic)

[Table 1](#)

Production Phase	Vaccination Issues	Parasite Issues
Prebreeding	<p><i>Immunize against abortion diseases:</i> Not suggested if a "closed-flock" with no history of infectious abortions Available products: 1. <i>Campylobacter fetus</i> subspecies <i>intestinalis</i> and <i>jejuni</i> (vibrio) vaccine First dose before breeding Second dose in midpregnancy Use only vaccines containing ovine isolates Bovine vaccine ineffective! 2. <i>Chlamydia psittaci</i> (also called enzootic abortion/EAE) vaccine First dose before breeding Second dose in midpregnancy Then booster yearly Geographic issue Toxoplasmosis vaccine unavailable in United States</p>	<p><i>Prior to breeding:</i> Review anthelmintic resistance records and treat with appropriate medication Approved: levamisole, ivermectin, albendazole Unapproved: doramectin, moxidectin oxfendazole, oxiabendazole, fenbendazole Move to a "clean" (worm-free) pasture after treatment Hay field regrowth Crop residue Cattle pasture or areas previously not pastured by sheep Use composite fecal float tests to detect efficacy and resistance issues with treatment/prevention program <i>Caution:</i> albendazole should not be used during the first 45 days of pregnancy!</p>
Prelambing	<p><i>Vaccination</i> Midpregnancy (60–90 days) booster abortion vaccines Booster clostridium vaccines 4 to 6 weeks prior to lambing • <i>C. perfringens</i> type C & D toxoid or CDT combination vaccine (if tetanus an issue) • Stimulates passive protection to newborn lambs via colostrum Other vaccines— <i>if warranted for area</i> • Multivalent <i>Clostridium</i> vaccines • <i>E. coli</i> vaccine • Foot rot vaccine • Caseous lymphadenitis vaccine</p>	<p><i>Parasite control</i> <i>Internal parasites:</i> prevent periparturient egg rise • Deworm as a group 2–4 weeks prior to lambing, or treat in lambing pens as lamb <i>External parasites:</i> after shearing, treat flock with pour-on for lice and keds If historical problems with coccidiosis, treat ewes with coccidiostat in feed, water or salt Reduces shedding of oocysts by carrier ewes • Medications: decoquinate, amprolium, oral sulfas, monensin</p>
Lambing	<p>If lambs <i>not pastured</i> with ewes and/or fed grain from birth (i.e., lambs fed concentrate early in life) • <i>C. perfringens</i> CD toxoid to prevent "overeating disease" in lambs on high-concentrate diets <i>If ewes were unvaccinated</i> • First vaccine when processing lambs at 2 to 3 days of age (labor issue) • Booster when lamb 25–30 days old <i>If ewes vaccinated</i> • First vaccine at 4–6 weeks old • Booster 2 weeks later <i>If lambs pastured with ewes</i> until weaning • <i>C. perfringens</i> CD toxoid usually not an issue until lambs weaned to grain diets • Then two doses <i>C. perfringens</i> CD toxoid prior to entering feedlot • When working lambs for deworming, etc.</p>	<p>Confinement, semiconfinement, or drop-lot lambing ewes • Treat ewes in lambing pens (jugs) as they lamb (if no prelambing treatment) • Pasture lambing ewes (no lambing pens) • Treat ewes as a group 2–4 weeks prior to lambing or entering lambing pasture • Time treatment to flock move to the lambing pasture • Often treated at shearing • Approved: levamisole, ivermectin, albendazole • Unapproved: doramectin, moxidectin oxfendazole, oxiabendazole, fenbendazole • Continue coccidiostat treatment in feed, water or salt to control oocyst contamination of lambing area and/or pasture.</p>
Preturmout	<p>If lambs <i>not pastured</i> with ewes (only dry ewes go to pasture) • Ewes— no special vaccines unless problem flocks • Foot rot vaccine—individual flock issue • Booster ewes prior to seasonal weather conducive to transmission (wet and warm) • <i>B. nodosus</i> vaccine utilized • <i>F. necrophorum</i> vaccine less common • Some flocks use both</p>	<p>If lambs <i>not pastured</i> with ewes (only dry ewes go to pasture) • Treat ewes before release to pasture Approved: levamisole, ivermectin, albendazole Unapproved: doramectin, moxidectin oxfendazole, oxiabendazole, fenbendazole • Release to "clean" pasture, if available <i>If lambs pastured with ewes</i> until weaning • Same as lambing • Lambing and preturmout recommendations coincide</p>
Special considerations for pastured lambs and ewes	<p><i>C. perfringens</i> vaccines not as important until lambs leave grass and arrive at feedlot <i>C. perfringens</i> type-D/CD toxoid routine on arrival at feedlot Booster second dose 2–4 weeks after arrival</p>	<p>Internal parasites major issue in pastured lambs • Treatment programs: location, weather, parasite dependent • Lamb treatment initiated when lambs 8–12 weeks old, followed by return to "clean pasture" • May need retreatment every 3 weeks if remain on contaminated pasture after treatment • Reduce pasture contamination: strategic treatment programs utilize serial treatments at 3 and 6 weeks after turn-out • Tapeworms also an issue in pastured lambs 8–12 weeks into the grazing season (due to grass mite intermediate host relationships)</p>

VACCINATION PROGRAMS ON DAIRIES

BASICS

DEFINITION

Vaccination is the intentional stimulation of a protective immune response by exposing an animal to a pathogen or the epitopes of the pathogen. Immunity is conferred by humeral antibodies or enhancing white blood cell function.

OVERVIEW

- Vaccination is a major part of prevention of infectious diseases on dairies.
- There are a few vaccines that are considered basic to the vaccine program on dairies in North America and there are many other vaccines that should be considered for a vaccine program based on the particular disease risks and management of individual farms.
- Vaccines should be chosen carefully because the process can bring both prevention of disease and risk for disease.
- The following principles must be adhered to for a vaccine to work well.
 - The vaccine must be stored and handled properly.
 - The vaccine must be administered to the appropriate animals at the right times using the correct route and dosage.
 - The animals must be in good health and in positive growth or energy balance.

SYSTEMS AFFECTED

Production management, immune

GENETICS

The Holstein breed appears to be highly susceptible to the effects of bacterial endotoxin.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

Epidemiology

- Vaccines must be given prior to exposure to the pathogen and the animal must have enough time to process the antigens and develop either humoral or cellular immunity.
- Accordingly, cattle should be vaccinated at least 2 weeks prior to risk periods with systemic vaccines. Temperature-sensitive IBR intranasal vaccines elicit local mucosal immunity and will be efficacious 48 hours after administration.
- Passively acquired immunity from colostrum may interfere with systemic vaccinations for varying periods after colostrum feeding. The effective half-life of maternal antibodies is dependent on the specific pathogen, the quantity of antibody in the colostrum, and the absorption of antibody through the GI mucosa in individual calves and the calf itself. Thus, maternal antibody may affect the efficacy of systemic vaccinations in calves for between 2 to 6 months after colostrum feeding at birth.
- Calves should always receive at least one systemic vaccination for the essential viral vaccines (IBR, BVD, BRSV) after 6 months of age. Intranasal vaccines are not affected by maternal antibody and should be expected to be efficacious as soon as the corticosteroids associated with calving have metabolized.
- The concept of herd immunity is important in dairy preventive medicine. Disease prevention and decreased case rate can be expected for most pathogens as long as the majority of animals in the population is effectively immunized.

Dairy Vaccinology

- A basic vaccine program on a dairy should include vaccinations for infectious bovine rhinotracheitis (IBR), bovine virus diarrhea types I and II (BVD), bovine respiratory syncytial virus (BRSV), and *Leptospira hardjo* and *L. pomona* bacterins.
- Other vaccines may be recommended depending on the management and problems on the dairy.

- Optional vaccines include: clostridial (malignant edema, redwater, and blackleg) bacterins, campylobacteriosis (vibrio) bacterins, *Moraxella bovis* (pinkeye) bacterins, *Neospora* killed protozoal vaccine and core-antigen J-5 gram negative bacterins (coliform mastitis). Rotavirus vaccines may be useful for protecting neonatal calves depending on the dairy.
- Some, but not all, states in the United States require vaccination of heifers with live RB 51 *Brucella abortus* vaccine.
- The viral pathogens can be administered either as modified-live virus (MLV) or killed vaccines.
- MLV vaccines are generally preferred because of the problem of compliance with boosting killed virus vaccines.
- Killed virus vaccines and bacterins must have a second dose within 2 to 4 weeks of the primary vaccination to develop an anamnestic response.

Dairy Vaccination Program

- A basic vaccination program for a dairy may include the following vaccines:
 - *Birth*: colostrum (Bull and heifer calves—maternal antibodies are necessary for mucosal and systemic immunity and the white blood cells in colostrum initiate the memory of the calf's immune system.)
 - *Three days of age*: temperature-sensitive intranasal IBR
 - *Before moving to group pens*: temperature-sensitive intranasal IBR or MLV IBR-BVD-BRSV with *Leptospira*
 - *Six months of age*: MLV IBR-BVD-BRSV with *Leptospira*
 - *Before breeding*: MLV IBR-BVD-BRSV with *Leptospira*
 - *At least 20 days postpartum*: MLV IBR-BVD-BRSV with *Leptospira*
 - *Or, during the dry period*: MLV IBR-BVD-BRSV with *Leptospira*
 - Other vaccines may be incorporated if the dairy experiences problems with specific pathogens and management cannot be changed to prevent disease. These vaccines include:
 - *J-5 gram-negative vaccines* to reduce the severity of coliform mastitis: one or two vaccinations prepartum and one vaccination 10–20 days in milk
 - *Neospora killed protozoal vaccine* to decrease abortions from neosporosis
 - *Leptospira borgpetersenii* serovar hardjo-bovis (type: *hardjo-bovis*) specific vaccine to prevent early abortions
 - *Rotavirus and coronavirus vaccine* to either dry cows or precolostrum calves to prevent diarrhea in calves
 - *Clostridial vaccines* to control malignant edema (*C. septicum* or *sordelli*), blackleg (*C. chauvoei*), or redwater (*C. haemolyticum*).

SIGNALMENT

Species Affected

Dairy cattle

Breed Predilections

The Holstein breed appears to be highly susceptible to the effects of bacterial endotoxin.

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

- Calves and cattle should always be in positive energy balance or growth when vaccinated.
- Avoid vaccinating heat-stressed cattle due to the increased risk of endotoxic reaction.

HISTORICAL FINDINGS

There should be clinical, laboratory, or other evidence of pathogens in the herd or region for which efficacious vaccines are available to recommend particular vaccines.

PHYSICAL EXAMINATION FINDINGS

N/A

CAUSES

N/A

RISK FACTORS

Typical risks that can be partially managed with vaccines on dairies include moving from individual calf hutches to group

pens, overcrowding, immunosuppressive periods such as transportation and parturition, and increased manure material on teats during milking.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

It is imperative to have knowledge of the infectious diseases the cattle on a farm will be exposed to at different times in the management cycle before recommending vaccine programs.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Monitoring selenium status in whole blood may be advised in some herds.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Submission of necropsy samples to determine pathogens on the farm is advised.

TREATMENT

CLIENT EDUCATION

- Clients must understand the importance of vaccine handling and timing of the vaccinations. All vaccines must be kept cold and out of the sunlight. Modified-live virus vaccines are inactivated quickly by ultraviolet light in sunlight and should be used within 1 hour of mixing with the diluent and kept out of sunlight.
- Vaccines should not be frozen; MLV vaccines are inactivated and attenuated by freeze-thaw cycles and cells can be ruptured and endotoxin released in bacterins.
- Bacterins must be boosted at the recommended intervals and clients choosing to use killed virus vaccines must understand the importance of the booster dose in the anamnestic response.

MEDICATIONS

DRUGS OF CHOICE

Epinephrine should be on hand in case of anaphylactic reaction after vaccination.

CONTRAINDICATIONS

- Do not administer corticosteroids within 1 week of vaccination.
- It is commonly recommended to not administer more than two gram-negative bacterins at the same time because of the risk of endotoxemia.
- Vaccination of animals in negative energy balance or weight loss may result in decreased efficacy and can potentially have negative effects through endotoxemia or reduced dry matter intake.

PRECAUTIONS

- Do not administer more than two gram-negative bacterins on the same day. Use only approved MLV vaccines in pregnant animals.
- Do not vaccinate cattle within 1 week after parturition to avoid the immunosuppressive complications of the corticosteroids associated with calving.

POSSIBLE INTERACTIONS

- Endotoxin in gram-negative and *Leptospira* bacteria can elicit a severe immune reaction mediated by lymphokines and cytokines. It is therefore recommended that no more than two gram-negative or *Leptospira* bacterins be used

simultaneously.

- Because high ambient temperature appears to increase the risk of endotoxemia, it is recommended to avoid vaccinating cattle during heat stress.
- Immunosuppressive drugs such as corticosteroids should not be given at or near vaccination.

ALTERNATE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Cattle should be observed for at least 2 hours postvaccination for signs of anaphylaxis.

PREVENTION/AVOIDANCE

N/A

EXPECTED COURSE AND PROGNOSIS

- Effective immunity can be expected within 2 weeks after systemic vaccinations.
- Bacterins must be boosted at the suggested times to achieve the desired anamnestic response.
- Mucosal immunity is developed within 48 hours after intranasal vaccination with temperature-sensitive IBR vaccines.

MISCELLANEOUS

PREVENTION

N/A

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

- Calves less than 1 week of age may not respond well to systemic vaccinations but will respond well to temperature-sensitive intranasal vaccines.
- Cellular immunity in the neonatal bovine appears to be decreased between 2 and 5 weeks of age and vaccination with systemic vaccines should be avoided during this period.
- Vaccine programs are generally targeted to bovines based on age. The goal of vaccinating calves is to decrease the case rate and severity of diarrhea and pneumonia, whereas older cattle are vaccinated to protect from abortifacients, mastitis, and pneumonia.

ZOONOTIC POTENTIAL

RB 51 and Strain 19 Brucella vaccines are live bacterial vaccines and are zoonotic pathogens.

PREGNANCY

- Bacterins and killed-virus vaccines are generally safe for pregnant cattle, although the endotoxins in bacterins can cause sufficient prostaglandin release during an endotoxic reaction to cause luteolysis and abortion.
- Only modified-live vaccines approved for use in pregnant cattle should be used during gestation.
- The first infection with IBR (wild type or vaccine strain) virus can result in infection of the ovary and subsequent luteolysis and abortion. Therefore, cattle should have been previously effectively vaccinated with MLV-IBR prior to MLV-IBR vaccination during pregnancy.

VAGAL INDIGESTION

BASICS

DEFINITION

- Vagal indigestion is a complex syndrome characterized by functional disturbances of the ruminant forestomachs.
- It is a syndrome with various causes, which result in rumen distension with gas and/or fluid.
- Contrary to the name, primary vagal nerve injury is rarely the cause of the syndrome.
- This syndrome is characterized and differentiated from other forms of indigestion by its slowly progressive onset and long duration.

PATHOPHYSIOLOGY

Syndrome composed of four categories of dysfunction:

Type I: Free Gas Bloat; Failure of Eructation

- Free gas bloat
 - Partial esophageal obstruction by foreign body
 - Extraesophageal compression
 - Lymphosarcoma, thyroid tumors
 - Chronic mediastinitis, abscesses
- Failure of eructation: inflammatory process adjacent to vagal nerve
 - Abscessation in cranial abdomen, peritonitis
 - Chronic pneumonia

Type II: Omasal Transport Failure

- Intraluminal reduction in omasal canal: placenta, bags
- Extramural masses that compress the omasal canal
 - Perireticular adhesions, localized peritonitis: traumatic reticuloperitonitis, perforating abomasal ulcers
 - Lymphosarcoma, papilloma, squamous cell carcinoma
 - Infarction
- Failure of omasal transport
 - Functional atony
 - Liver abscesses in left lobe of the liver: may place pressure on vagal nerve

Type III: Abomasal Impaction

- Primary abomasal impaction
 - Animals fed dry, coarse roughage
 - Limited access to water
- Secondary abomasal impaction: functional inability to empty contents of abomasum
 - Traumatic reticuloperitonitis adhesions
 - Adhesions of right lateral wall of reticulum
 - Poor motility post abomasal volvulus
 - Foreign bodies may obstruct pylorus: hairballs, placenta
 - Toggle pin fixation for displaced abomasum has been reported to result in pyloric outflow obstruction
 - True pyloric stenosis is rare.

Type IV: Partial Obstruction of Forestomachs; Indigestion of Late Pregnancy

- As fetus develops and enlarges, the abomasum is forced cranially.

- This may interfere with abomasal motility, which may have been previously compromised, leading to impaction.
- These animals may be a combination of type II and type III vagal indigestion.

SYSTEMS AFFECTED

Gastrointestinal

GENETICS

There are no recognized genetic causes or implications for vagal indigestion.

INCIDENCE/PREVALENCE

- There are no reports listing the incidence or prevalence of the disease.
- Vagal indigestion is the most common complication after abomasal volvulus correction.

GEOGRAPHIC DISTRIBUTION

- Type III vagal indigestion may occur more commonly in animals grazed on crop aftermath in dry regions.
- May also occur in the wintertime, when water sources are allowed to freeze

SIGNALMENT

Species

- Reported only in bovines
- Abomasal emptying defect of Suffolk sheep is a similar condition to type III vagal indigestion
 - Lesions in abomasal wall and vagal nerve
 - Genetic syndrome
 - Grave prognosis even with aggressive therapy

Breed Predilections

- Breed predilections in cattle not reported
- Type IV is more common in late pregnant dairy breeds.
- Abomasal emptying defect of sheep occurs in Suffolk.

Mean Age and Range

No reported age ranges, however, lymphoma tends to occur in cattle 4–8 years of age.

Predominant Sex

N/A

SIGNS

GENERAL COMMENTS

- The hallmark signs in patients with vagal indigestion is gradual abdominal enlargement and an L-shaped rumen.
- Vagal indigestion is an unlikely cause of an acutely ill animal and other diagnoses should be considered and ruled out.

HISTORICAL FINDINGS

- Gradual abdominal enlargement
- Intermittent episodes of indigestion and anorexia
- Reduced milk production
- Weight loss
- Decreased fecal output
- May have a history of vomiting or regurgitation
- Animals may be in late pregnancy

PHYSICAL EXAMINATION FINDINGS

- Distended abdomen
 - Rumen full of fluid and/or gas
 - “Papple” shape: large and round dorsally and ventrally on the left, distended ventrally on the right
- Decreased fecal volume
 - Feces may be pasty and have increased fiber length (2–4 cm).
 - Omasum responsible for reducing feed particle size before delivery to abomasum
 - Melena if abomasal ulcer is the cause
- Bradycardia

- Variable
- Has been associated with other conditions, but is an unusual finding in the bovine
- Increased rumen motility
 - May be nearly silent, but is easily felt: motility displaces paralumbar fossa significantly
 - If rumen motility absent, prognosis very poor due to likelihood of significant peritonitis and adhesion formation.
- Abdominal percussion
 - Rumen may ping and be mistaken for a left displaced abomasum.
 - Can be differentiated in size and shape from an LDA
- Abdominal succussion: rumen splashes due to fluid accumulation
- Rectal exam
 - Appreciate L-shaped rumen
 - May be able to palpate a large, distended abomasum, caudally displaced by cranial abdominal pathology
 - May be able to palpate omasum if significant liver pathology, such as abscessation, is involved
- Grunt test and withers pinch for cranial abdominal pain: not sensitive tests

CAUSES

- Abscesses: most common cause of cranial abdominal abscesses in locations that cause vagal indigestion is traumatic reticuloperitonitis (TRP, hardware disease)
- Tumors
- Foreign bodies in the omasal canal or pylorus: sacks, placenta, hairball
- Adhesions
 - May alter normal motility and tension receptor activity
 - TRP or abomasal ulcers
- Vagal nerve injury
 - Rare cause of syndrome
 - Abscesses may lead to neuropraxia.

RISK FACTORS

- Unresolved pneumonia or mediastinal pathology may predispose to type I.
- Exposure to foreign bodies such as wire or twine may predispose to types I–III.
- Large fetal size may be more likely to cause type IV.
- Bovine leukemia virus infection has been associated with development of gastrointestinal tumors in a small number of infected cattle
- Improper placement of a toggle in a left displaced abomasum

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Simple indigestion
- Rumen acidosis
- Traumatic reticuloperitonitis
- Displaced abomasum
- Frothy bloat
- Hydrops
- Ascites
- Diffuse peritonitis: generally not a chronic disease
- Abdominal neoplasia: lymphosarcoma, mesothelioma
- Intestinal obstructions: intussusception, mesenteric volvulus
- Reticulitis—may cause vomiting

- Ingestion of toxic plants or spoiled feed—differential for vomiting: rhododendron and mountain laurel

CBC/BIOCHEMISTRY/URINALYSIS

- CBC: useful to indicate cause of vagal indigestion
 - Leukocytosis: mild to moderate inflammation, relatively early in process
 - Leukopenia: severe inflammation (i.e., diffuse peritonitis)
 - Neutrophil-lymphocyte ratio of 2:1: chronic inflammation
 - Lymphocytosis: suggestive of lymphosarcoma
 - Packed cell volume and total protein
 - May be increased due to dehydration
 - PCV may be low due to anemia of chronic disease.
- Biochemistry
 - Hypochloremia
 - Indicates abomasal reflux into rumen from impaction or forestomach stasis: decreases absorption into blood
 - Type III vagal indigestion results in significant hypochloremia and hypokalemia
 - Severe hypochloremia (<50 mEq/L) is associated with a grave prognosis, but may be corrected with aggressive therapy.
 - Metabolic alkalosis
 - Hypocalcemia- moderate
 - Prerenal azotemia
 - Hypergammaglobulinemia: indicates inflammatory process

OTHER LABORATORY TESTS

- Rumen fluid analysis
 - Elevated rumen chloride (> 30 mEq/L)
 - Indicates abomasal HCl reflux into rumen
 - Occurs with abomasal impaction or any abomasal outflow obstruction
- BLV serology
 - Positive results indicate infection with the virus, however do not indicate the presence of a tumor
 - Very low percentage of cattle with BLV virus will develop a tumor
- Abdominocentesis
 - May be difficult to obtain a diagnosis of peritonitis if it is localized and encapsulated
 - Increased protein and white blood cells indicate peritonitis
 - Lymphocytes in the fluid—supportive of lymphoma
- Fecal occult blood
 - Perform before rectal exam
 - If positive, supports the presence of abomasal ulcers

IMAGING

- Radiography: may visualize cranial abdominal metallic foreign bodies
- Ultrasound examination
 - Perireticular abdomen
 - Assess reticular motility
 - Identify masses or abscesses
 - Abomasum: may appreciate increase in wall thickness if infiltrated with lymphosarcoma

DIAGNOSTIC PROCEDURES

Left-sided exploratory rumenotomy

- Allows investigation of cardia, omasal groove, abomasum, and their surroundings
- Localize masses or abscesses obstructing flow of ingesta
- Allows needle aspiration of masses for cytologic impression: provides a means of diagnosis as well as possible treatment (removal of masses, drainage of abscesses into GI, placing fluid directly into abomasum, and massage for relief of

impaction)

GROSS FINDINGS

Type I

- Foreign body, mass obstructing esophagus
- Chronic thoracic pathology, such as pneumonia or abscesses

Type II

- Intraluminal foreign bodies or masses
- Masses impinging omasal canal
- Localized peritonitis, adhesions, hardware foreign body
- Liver abscesses

Type III

- Dry, impacted abomasum
- Adhesions, hardware
- Pyloric foreign bodies
- Rarely, pyloric stenosis

Type IV

Large fetus cranially displacing abomasum

HISTOPATHOLOGICAL FINDINGS

- In one report, no changes were noted on histopathology of cattle with vagal indigestion secondary to traumatic reticuloperitonitis in the following tissues: vagus nerve, cardia, esophageal groove, reticulo-omasal orifice, omasal canal, and pylorus.
- Histopathology performed on masses will reveal nature of the neoplasia: most commonly lymphosarcoma, papilloma, or squamous cell carcinoma.

TREATMENT

APPROPRIATE HEALTH CARE

Animals with vagal indigestion generally require hospitalization in order to receive treatment for their primary condition and to receive supportive care for associated electrolyte imbalances.

Type I

- Create a rumen fistula
 - Self-retaining trocar
 - Rumenostomy
 1. 2–3 cm in diameter, suturing rumen wall to body wall
 2. Provide a good “seal” to prevent leakage and peritonitis.
 - Will granulate over in a few months, allowing healing of causative lesion
- Most cattle will regain ability to eructate normally over time.

Type II

- Supportive therapy
 - Promote GI motility: ruminatorics and cathartics
 - Fluid therapy
 1. Calcium gluconate
 2. Parenteral or oral polyionic fluids
 3. Transfaunation
 - Systemic antibiotics: in attempt to control local peritonitis
- Surgical therapy
 - Very few animals respond to conservative therapy

- Rumenotomy: palpation of cardia, omasal canal, and reticular wall
- Removal of foreign body or mass
 - Needle biopsy of mass in surgery for definitive diagnosis and prognosis prior to removal
 - Perireticular abscess
 - If firmly adherent to reticular wall, may be incised and drained into reticulum
 - If abscess not firmly adherent, abscess should be drained percutaneously from the right body wall (ultrasound guidance helpful)
- May repeat surgery through paramedian incision to remove the abscess en bloc

Type III

- Carries a poor prognosis
- If secondary to abomasal volvulus, there is no good treatment and a very poor prognosis.
- Fluid therapy
 - Calcium gluconate
 - Intravenous fluids: correct alkalosis and hypokalemia
- Laxatives
 - Magnesium hydroxide/oxide and others
 - 0.5–1.0 kg/day PO
- Surgery
 - May be performed once hydration, electrolyte, and acid/base aberrations addressed
 - Rumenotomy
 - Palpation for presence of masses or abscesses: drain abscess into reticulum or percutaneously as described for type II above
 - May remove abomasal contents through omasal canal without further damaging abomasum
 - Passage of stomach tube into abomasum through omasal canal
 - Infusion of docusate, magnesium sulfate, and fluid into abomasum
 - Massage abomasum through rumen wall.
 - Abomasotomy
 - Last resort
 - Surgery will encourage adhesions and ischemia and inhibit motility.

Type IV

- Rank value of dam vs. calf
 - Consider stage of gestation and potential viability of calf
 - If cow is within 4–6 weeks of full gestation, may be able to support both until fetus can be delivered
 - If there is a considerable amount of time before full gestation, saving both dam and fetus less likely
- Fluid therapy: correct existing hypokalemia, hypocalcemia, alkalosis
- Therapeutic abortion
 - Best option if dam is the priority
 - May induce with corticosteroids with or without prostaglandin
- Surgery: rumenotomy
 - Allows exploration to determine etiology
 - Fine needle aspirate of masses, palpation of the status of stomach compartments allow prognostication

NURSING CARE

Fluid therapy and symptomatic therapies covered for each type above

ACTIVITY

Moderate exercise important to maintain during treatment and recovery to promote motility and general health

DIET

- Supply plenty of fresh water and good-quality, digestible feed.
- Basically, anything the animal will eat, along with good fiber: alfalfa is a good choice.

CLIENT EDUCATION

- Very poor prognosis associated with type III.
- Rumenotomy may alter flavor of milk in cows exposed to rumen gases.
- Recommend good hardware and bovine leukosis prevention strategies.

SURGICAL CONSIDERATIONS

- See above for surgical indications and considerations.
- Rumenotomy, rumenostomy, and percutaneous abscess drainage may be performed in the standing animal with local anesthesia to minimize anesthetic risks: lidocaine paravertebral blocks, inverted L, line blocks.

MEDICATIONS

DRUGS OF CHOICE

- See treatments listed above for each type of vagal indigestion.
- Systemic antibiotics may be indicated after rumenotomy and GI manipulation for 1 to 4 weeks.
- Analgesics—NSAIDs

CONTRAINDICATIONS

- The use of magnesium oxide is contraindicated in the presence of metabolic alkalosis.
- NSAID use contraindicated in the presence of abomasal ulcers, increased creatinine, or uncorrected dehydration
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Observe appropriate withdrawal periods after drug therapy.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

- Patients should be monitored during and after therapy for return of appetite and demeanor.
- Abdominal contour must be monitored once animal is eating well to indicate normal motility.
- Fecal output should be monitored for volume, consistency, and fiber length.

PREVENTION/AVOIDANCE

- Use of magnets in feed mixers and handling equipment to prevent metallic foreign bodies in feed
- Removal of placentas from the environment
- Standard BLV control strategies

POSSIBLE COMPLICATIONS

- Poor motility even after appropriate therapy due to irreversible damage to abomasum
- Abscess or mass recurrence after drainage or removal: liver abscess recurrence rate in one report was two or three of eight cases
- Postoperative peritonitis
- Type IV: Retained fetal membranes and metritis are more common in cattle after artificially induced parturition.

EXPECTED COURSE AND PROGNOSIS

Overall, 33/112 (29.5%) of cases of vagal indigestion of all causes made a full recovery.

Type I

- Good prognosis with rumenostomy, but may not flourish
- If chronic pneumonia was inciting cause, poorer prognosis

Type II

- Fair to good depending on exact etiology
- See below for breakdown by etiology.

Type III

- Poor prognosis
- If secondary to abomasal volvulus, 3 of 26 had a good outcome.

Type IV

- The closer to delivery, the better the prognosis: supporting dam through several weeks of gestation is intensive and usually results in deterioration of the dam.
- Removal of fetus at any stage of gestation likely to improve motility and condition of the cow

Prognosis by Etiology

- Neoplasia
 - Lymphosarcoma, squamous cell carcinoma, etc.—grave prognosis
 - Papilloma—good prognosis with removal
- Abscess
 - Extent of adhesion formation determines prognosis
 - Hardware (TRP) prognosis: good outcomes
 - 7/15 (47%) in cases of uncomplicated TRP
 - 6/17 (35%) TRP with obstruction of digesta passage through reticulo-omasal orifice
 - 1/10 (10%) TRP with obstruction of digesta passage through pylorus
 - Peri-omasal or liver abscess—fair to good: liver abscess retrospective
 - 5/8 cases made a significant improvement
 - 2 or 3 of 8 recurred at 3 months and 1 year postoperatively
 - Perireticular abscesses involving diaphragm and omasum: 74% of 29 cases returned to production for greater than 1 to 4 years postoperatively
- Foreign body: excellent prognosis with removal
- Pregnancy: the closer to parturition, the more favorable the prognosis

MISCELLANEOUS

ASSOCIATED CONDITIONS

Displaced abomasum; abomasal volvulus

AGE-RELATED FACTORS

Older animals affected are more likely to be affected by neoplastic process.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Termination of late-term pregnancy, if dam considered to be much more valuable than fetus, may be useful in most types of vagal indigestion, not only type IV, as fetal removal may promote normal abomasal and omasal location and motility.

RUMINANT SPECIES AFFECTED

- Only reported in bovines
- Abomasal emptying defect of Suffolk sheep: abomasal and vagal nerve abnormalities have been identified.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Animals in dry regions or grazed on crop aftermath should be provided with readily accessible water in order to prevent abomasal impaction.

VAGINITIS

BASICS

OVERVIEW

- Inflammation of vagina
- Infectious causes include bovine herpesvirus 1 (BHV1), *Ureaplasma*, and *Mycoplasma*
- Injuries after dystocia and breeding
- Foreign body

SYSTEMS AFFECTED

Production management and reproductive

GENETICS

N/A

INCIDENCE/PREVALENCE

In one study of genital tracts from nonpregnant cull ewes, 23.2% of the tracts had abnormalities and it was considered that 16.8% had abnormalities likely to interfere with the establishment of pregnancy.

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

Female only

SIGNS

- Affected cows show discomfort—arched back, raised tail, straining, frequent urination, and dysuria.
- Accompanied by vulvar or perivulvar swelling
- Seropurulent or mucopurulent discharge
- Laceration, ulceration, and, in neglected cases, necrosis

Infectious Pustular Vulvovaginitis—Caused by BHV1

Transmission is by venereal or oronasal route. Vaginal examination is characterized by numerous round, white, necrotic lesions on the vulva and vaginal wall, and a copious amount of mucopurulent discharge on the vaginal floor. Intrauterine introduction may cause necrotic endometritis.

Granular Vulvitis—Caused by Ureaplasma Diversum

Chronic persistent infection reduces herd fertility. It is characterized by inflammation, hyperemia of vulvar epithelium with small 1–2 mm raised granules predominant around clitoris, and purulent discharge persists up to 10 days. Vulvar infection is often repeatedly introduced into the vagina and uterus during artificial insemination. It persists for 7 days in the uterus causing an unfavorable environment for the descending embryo.

Mycoplasma—Caused by M. bovis genitalium

The role of *Mycoplasma* as a cause of infertility is questionable, as fertile and infertile cows test positive.

CAUSES AND RISK FACTORS

- Infectious causes include bovine herpesvirus 1 (BHV1), *Ureaplasma*, and *Mycoplasma*.
- Injuries after dystocia and breeding
- Malicious injuries
- Urovagina and pneumovagina
- Application of intravaginal progesterone devices
- Foreign body

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious causes include bovine herpesvirus 1 (BHV1), *Ureaplasma*, and *Mycoplasma*.
- Injuries after dystocia and breeding
- Malicious injuries
- Urovagina and pneumovagina
- Application of intravaginal progesterone devices
- Foreign body

CBC/BIOCHEMISTRY/URINALYSIS

Possible stress leukogram, not generally helpful

OTHER LABORATORY TESTS

- BHV1: round, white, necrotic foci will be noticed. The diagnosis may be confirmed by histologic examination for the presence of intranuclear inclusion bodies and necrotic vaginal epithelium.
- Culture and sensitivity is indicated if an infective agent is suspected.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

- History and clinical signs
- Per-rectal palpation may help to identify the foreign body.
- Vaginoscopic examination may reveal laceration, erosion, necrosis of vaginal mucosa, and accumulation of vaginal discharge. It also helps to locate a foreign body.

PATHOLOGIC FINDINGS

GROSS FINDINGS

- Accompanied by vulvar or perivulvar swelling
- Seropurulent or mucopurulent discharge
- Laceration, ulceration, and, in neglected cases, necrosis
- Infectious pustular vulvovaginitis—vaginal examination is characterized by numerous round, white, necrotic lesions on the vulva and vaginal wall, and a copious amount of mucopurulent discharge on the vaginal floor. Intrauterine introduction may cause necrotic endometritis.
- Granular vulvitis—characterized by inflammation, hyperemia of vulvar epithelium with small 1–2 mm raised granules predominant around clitoris; purulent discharge persists for up to 10 days.

HISTOPATHOLOGICAL FINDINGS

In case of BHV1, round, white, necrotic foci will be noticed. The diagnosis may be confirmed by histologic examination for the presence of intranuclear inclusion bodies and necrotic vaginal epithelium.

TREATMENT

- Should treat the primary condition.

- Local antibiotics to control bacterial infection may be indicated.
- Vaginal douche with saline, 0.1% chlorhexidine might be helpful.
- BHV1: local antibiotics to control secondary bacterial infection. However, in the absence of secondary bacterial infection, BHV1 is self limiting and without complication.
- *Ureaplasma*: the treatment and control procedures should be directed toward minimizing the chance of uterine infection. All AI techniques should employ double-rod technique. Local antibiotics therapy and local douches may control the infection. When herd fertility is extremely poor during acute infection, postbreeding antibiotic infusion might be helpful.
- CIDR application: clean procedure and application of proper disinfectant cream at the time of CIDR insertion may reduce the incidence of vaginitis. Relationship between incidence of vaginitis and reduction in fertility is equivocal. The CIDR device should be removed according to the synchronization protocol.

VESICULAR STOMATITIS

BASICS

DEFINITION

- Vesicular stomatitis is a viral disease that causes blisters, or vesicles, on the coronary bands, interdigital space, mammary glands, and oral cavity of cattle and horses.
- It cannot be clinically differentiated from foot-and-mouth disease, and proper identification is imperative to the economics of the U.S. agriculture industry.
- Sheep and goats are fairly resistant and rarely show clinical signs.

PATHOPHYSIOLOGY

- Vesicular stomatitis virus (VSV) cases tend to occur sporadically during the warmer months in the southwest United States and most often near waterways.
- Introduction into a herd is not always known but could occur through insect vectors, mechanical transmission, and movement of animals.
- Once lesions appear in a herd, direct contact with vesicles and vesicular fluid between animals spreads the virus quite rapidly.
- Vesicles or erosions can be found in the oral cavity, on the feet, and on the mammary gland in cattle.

SYSTEMS AFFECTED

Gastrointestinal, skin, mammary

GENETICS

N/A

INCIDENCE/PREVALENCE

- Incidence varies between geographic locations.
- Morbidity within a herd of naïve animals can reach 90% but mortality is rare.

GEOGRAPHIC DISTRIBUTION

- This disease has been limited to the Americas.
- In the southern United States and Central America, vesicular stomatitis virus has two domestic strains, New Jersey and Indiana-1, which are found in the southern states.
- In addition to the New Jersey and Indiana-1 strains, exotic strains Indiana-2 and Indiana-3 are found in northern South America.

SIGNALMENT

Species

Cattle, occasionally sheep and goats.

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Disease can occur at any time of year but cases tend to cluster during the summer and fall, often during rainier seasons.
- Cases tend to occur sporadically in endemic areas without large outbreaks.

- Cattle may salivate excessively, have a fever, lose milk production, and develop mastitis.
- The disease is usually self-limiting in approximately 2 weeks.

PHYSICALEXAMINATION FINDINGS

Fever, blanched vesicles located in one area of the body, such as the oral cavity and muzzle, the feet, or mammary gland, decreased milk production, inappetence due to oral vesicles, lameness due to vesicles on the coronary band and/or interdigital space, and agitation during milking due to vesicles on the mammary gland.

CAUSES

- Vesicular stomatitis is an RNA virus in the family Rhabdoviridae.
- There are multiple strains, but those endemic to the United States are New Jersey and Indiana-1.
- Transmission can occur through insect vectors, direct contact with infected animals, and indirect contact with contaminated objects. Black flies (Simuliidae) and phlebotomine sand flies (*Lutzomyia shannoni*) can transmit the virus to animals and transovarially. In the 1982 epizootic of VS in the southwestern United States, the New Jersey serotype was isolated from biting midges (*Culicoides*), mosquitoes (*Aedes*), house flies (*Musca*), and eye gnats (Chloropidae), but their role in transmission is unknown.

RISK FACTORS

- Moving naïve animals to an endemic area, especially during the late rainy season
- Increased population of black flies or sand flies

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Cattle*: Foot-and-mouth disease, infectious bovine rhinotracheitis, bovine viral diarrhea, rinderpest, malignant catarrhal fever, bluetongue, foot rot, chemical or thermal burns
- *Sheep*: Bluetongue, contagious ecthyma, lip/leg ulceration, and foot rot

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

- Due to the seriousness of this disease and the inability to clinically differentiate it from FMD, state and federal authorities should be contacted immediately upon suspicion of cases before sample collection.
- Tissue cultures can be used to isolate the virus; RT-PCR can be used to detect the virus. Viral antibodies (on acute and convalescent sera) and antigen (aseptic vesicular fluid, vesicular epithelium in buffered glycerol or frozen) can be identified using ELISA, CF, and virus neutralization.

PATHOLOGIC FINDINGS

Vesicles in the oral cavity, on the coronary band, or mammary gland will be seen grossly.

TREATMENT

APPROPRIATE HEALTH CARE

NURSING CARE

- Upon confirmatory diagnosis of VSV, animals with lesions should be isolated and given supportive care conducive to the location of the lesions.
- Soft food, or a gruel, and clean water for oral lesions; well bedded, clean stall for lesions of the feet; milked last if there are mammary lesions

ACTIVITY

- Isolated to a pen/stall that has no direct contact with other susceptible animals and no exposure to potential insect vectors
- Calves should be removed from infected dams.

DIET

- Soft forages/gruel for oral lesions, plenty of water
- Do not feed calves milk or colostrum from infected animals.

CLIENT EDUCATION

- Animals with lesions must be isolated to prevent disease spread; no animals can be moved off the property for at least 30 days after the last lesion has healed.
- Equipment and areas of potential exposure at a facility should be cleaned and disinfected before reintroducing any other animals.

SURGICAL CONSIDERATIONS

Local wound debridement may be warranted depending on the extent of the lesion and viable tissue surrounding it allowing it to heal on its own.

**MEDICATIONS****DRUGS OF CHOICE**

N/A

CONTRAINDICATIONS

N/A

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

**FOLLOW-UP****PATIENT MONITORING**

Patients should be monitored for appetite and lesion healing during the course of the disease (approximately 2 weeks).

PREVENTION/AVOIDANCE

- Do not move animals to an endemic area.
- Insect control can help prevent disease spread.
- There is no vaccine available.

POSSIBLE COMPLICATIONS

Secondary bacterial infection of the lesioned area

EXPECTED COURSE AND PROGNOSIS

Most recover without complications in two weeks.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

Fever; blanched vesicles located in one area of the body, such as the oral cavity and muzzle, the feet, or mammary gland; decreased milk production; inappetence due to oral vesicles; lameness due to vesicles on the coronary band and/or interdigital

space; and agitation during milking due to vesicles on the mammary gland

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

- Humans can become infected with VSV New Jersey and Indiana-1 strains and signs include fever, headache, myalgia, and, very rarely, oral vesicles.
- Recovery is usually within 4 to 7 days.

PREGNANCY

There does not seem to be a concern with pregnant animals unless the lesions impede eating or a severe secondary infection develops.

RUMINANT SPECIES AFFECTED

Cattle, occasionally sheep and goats, though rare

BIOSECURITY

- Isolation and quarantine of new stock entering the herd/flock
- Treat and/or cull new animals for disease conditions prior to herd introduction.
- VS is a reportable disease.
- Animals with lesions must be isolated to prevent disease spread; no animals can be moved off the property for at least 30 days after the last lesion has healed.
- Equipment and areas of potential exposure at a facility should be cleaned and disinfected before reintroducing any other animals.

VETERINARY HEALTH CERTIFICATION

BASICS

OVERVIEW

- Health certificates are required to document specific animal health levels and results of diagnostic tests (e.g., tuberculosis and brucellosis) regarding interstate and international trade of animals and animal products. The credibility of such certificates depends on the quality of the data used to establish the status. Veterinarians should regard these certificates not only as legal documents, but also as epidemiologic tools for animal health regulators in the event of a disease outbreak.
- Continued growth in international trade and the developing concepts of zoning and risk assessment demand effective methods of national animal health surveillance and monitoring systems.
- The United States Department of Agriculture (USDA), Animal and Plant Health Inspection Service (APHIS), Veterinary Services (VS) oversees the federal health certification process, but interstate regulations are written and maintained by each state. For clarification on any of the rules and regulations, contact the state veterinarian or the APHIS area veterinarian in charge (AVIC).
- Veterinarians certifying animals or animal products for interstate or international movement must be accredited by the USDA APHIS VS. For further information on accreditation, contact the Veterinary Services office in your state.
- The World Organization for Animal Health (OIE) meets yearly in Paris and its 160+ member countries establish minimal health standards for many diseases of regulatory or public health significance. These standards often impact on import and export requirements for international animal movement.
- International health certificates for the export of animals from the United States are completed by a licensed, accredited veterinarian who certifies herd and animal health status, conducts tests, and records test results for the individual animals being exported.
- Completed and signed international health certificates for the export of animals from the United States must be endorsed by an AVIC in order to be valid.
- The United States has minimal requirements for animals to be exported to other countries. The area veterinarian in charge can assist in finding out the current regulations, tests, and inspections required.
- Each country may have other specific health requirements for entry of animals. The importing country, not the United States, establishes these requirements. Other countries also may have their own certificate format for export. Since export requirements frequently change, obtain the current requirements from the Veterinary Service office in your area before each shipment.
- Export certificates are official documents and they should be typewritten, accurate, and complete.
- In November 2002, USDA APHIS Veterinary Services announced they would work with Communications Resource Inc. (CRI) and GlobalVetLink, LC (GVL) to develop an electronic version of the Interstate Certificate of Veterinary Inspection in designated states for food animals. The electronic health certificate is web-based and incorporates the requirements endorsed by United States Animal Health Association (USAHA).

Reportable Diseases

Veterinarians, veterinary diagnostic laboratories, animals' owners, and agents must immediately report the existence or suspected existence of any reportable disease. Reporting requirements vary by state so consult the office of the state veterinarian for a list of reportable diseases in your state.

Intrastate Sale or Movement

Testing: All dairy breeds of cattle must test negative for brucellosis within 30 days prior to any change of ownership. General exceptions to the testing requirement:

- Calves under 4 months of age
- Cattle sold or consigned to a restricted feedlot
- Cattle sold or consigned to a federally inspected slaughter plant
- Steers and spayed heifers
- Official calfhooch vaccinates under 20 months of age and not parturient or postparturient.

For dairy breeds, an official calfhooch vaccine is an animal vaccinated between 4 and 8 months with Strain 19 vaccine or between 4 and 12 months with RB 51 vaccine. Cattle exempt from testing may be tested if requested by a prospective buyer or to meet import requirements of another state or foreign country.

Identification of Animals

- The National Animal Identification System (NAIS) is in the process of being developed for all species of animals in the United States. Veterinarians should remain informed as this program continues to be developed and implemented. Identification requirements for animals traveling in commerce are likely to change.
- All animals must be individually identified and permanently recorded as to herd of origin prior to being sold or consigned for slaughter. Immediate slaughter means delivery within 7 days to an inspected slaughter plant or restricted feedlot. This identification must be transferred to the blood sample taken for the brucellosis market cattle identification test purposes.
- Exceptions to this identification requirement:
 - Cattle under 24 months of age and not parturient or postparturient
 - Steers and spayed heifers

Scrapie

- The USDA Scrapie Flock Certification Program is designed to monitor flocks and certify scrapie status of animals enrolled in the program.
- The program requires individual animal identification, good record keeping, reporting acquisitions and deaths of animals to USDA and annual inspections by a USDA representative.
- Enrollment in the USDA program fulfills the requirements of the state program. Scrapie Eradication, State-Federal-Industry, Uniform Methods and Rules, September 2003, and Title 9 Code of Federal Regulations, Parts 54 and 79.

Interstate Sale or Movement

- Interstate movement of livestock is regulated at both the state and federal levels.
- Requirements are subject to change, because disease status can change. Prior to shipment, contact the state of destination for current requirements on testing, permits, and health certificates.
- The licensed, accredited veterinarian issuing the health certificate is responsible for ensuring that the shipment meets all requirements of the state of destination.

State Requirements Can be Obtained Through:

- USDA Voice Response Service, 1–800-545–8732, using a touch-tone phone. This service is available 24 hours per day, 7 days a week. Follow the voice prompts and use the individual state codes in parentheses.
- State of destination: <http://www.aphis.usda.gov/vs/sregs>
- When a state of destination requires a certificate of veterinary inspection for large animals, submit white and canary copies of the completed form to the state veterinarian for final review and approval. The blue copy must accompany the shipment of animals. Veterinarians should retain the green copy of the completed form for their records.

International Sale or Movement

- International movement of animals is regulated at the federal level. Consult the local USDA APHIS Veterinary Services Area Office for information.
- Health certificates for export of animals from the United States are completed by the licensed, accredited veterinarian, who certifies health status, conducts appropriate tests, and records test results on the proper health certificate.
- Most completed and signed health certificates must be reviewed, verified, and endorsed by the Veterinary Services Area Office before they are official international health certificates. The area office can work with the licensed, accredited veterinarian to insure that the health certificate meets the requirements of the country of destination.

Forms to Use

- For livestock, horses going to countries other than Canada, and other large animal species, VS Form 17–140, U.S. Origin Health Certificate, unless the country of destination requires a specific certificate.
- VS and APHIS forms may be obtained from the USDA APHIS VS Area Office.
- All diagnostic tests for export certification must be conducted in USDA-approved labs. Retests must be conducted at the same laboratory that conducted the initial test.
- Original test results, not photocopies, must accompany health paperwork when submitted for review and endorsement. There is a fee for services related to the export of animals, including certificate review and endorsement. Contact the area office for exact costs and method of payment.
- Health certificates received at the area office are reviewed, endorsed, and placed in return mail the day received. For return by express service, include a prepaid envelope or billing account number. Appointments can be made for endorsement of certificates in person.
- Veterinary certification: “I certify, as an accredited veterinarian, that the above described animals have been inspected by me and that they are not showing signs of infectious, contagious and/or communicable disease (except where noted). The vaccinations and results of tests are as indicated on the certificate. To the best of my knowledge, the animals listed on this certificate meet the state of destination and federal interstate requirements. No further warranty is made or implied.”
- Owner statement, owner/agent statement (where applicable): “The animals in this shipment are those certified to and listed on this certificate.” (Signature, date, and address required.)

VITAMIN A DEFICIENCY/TOXICOSIS

BASICS

OVERVIEW

- Vitamin A is required by all animals and is produced by the animal through the metabolism of carotene, which is obtained from plants.
- Vitamin A exists as either retinol (also retinoic acid and retinal) or dehydroretinol.
- These are formed from carotene in the liver. Provitamin A and vitamin A precursor represent alternative nomenclatures for carotene. Vitamin A is synthesized from carotene.
- At least 10 forms of plant carotenes can be converted to vitamin A; β -carotene is quantitatively the most important for animal nutrition.
- The conversion of 1 mg of β -carotene to the IU of retinol varies with species: cattle—400 IU; sheep—400–500 IU; pigs—500 IU; horses: growing, 555 IU, and pregnant, 333 IU.
- Peripartum decreases in serum concentrations of vitamins A and E may contribute to impaired immune function in dairy cows.

PATHOPHYSIOLOGY

General Functions

- Maintenance of night vision and the prevention of night blindness
- Xerophthalmia prevention
- Essential for body, bone, and tooth growth
- Required for thyroxin synthesis—prevents goiter
- Protein synthesis
- Conversion of cholesterol to corticosterone
- Glycogen synthesis

Metabolic Function

- Cellular differentiation.
- Immune function—immunoglobulin A and T-helper cell 2 cytokine system.
- Regulates gene expression—crucial in reproduction and embryogenesis
- Hematopoiesis
- Increases bioavailability of inorganic iron

Deficiency

- Vitamin A deficiency would be observed in young animals more often than older animals.
- Liver stores of vitamin A can last for 3 to 6 months.
- Deficiency symptoms include night blindness, xerophthalmia, and xerosis; stunted growth; abnormal bone development and paralysis; unsound teeth; skin abnormalities; ear, mouth, and salivary gland abscesses; diarrhea; kidney and bladder stones; reproductive dysfunction—poor conception, increased fetal mortality.
- Deficiency is alleviated rapidly with vitamin A supplementation (dietary and injectable).

Toxicity

Toxicity symptoms include: appetite loss, hair loss, skin abnormality, swelling in the extremities (especially over the long bones), enlargement of the liver and spleen.

Common Dietary Sources of Carotene

Carrots, yellow corn, alfalfa (legumes), green grass (pasture, hay, or silage)

SYSTEMS AFFECTED

Ophthalmic, immune, musculoskeletal, hemolymphatic, and reproductive

SIGNS

HISTORICAL FINDINGS

- Night blindness, xerophthalmia, and xerosis; stunted growth; abnormal bone development and paralysis
- In one Japanese hypervitaminosis study, Holstein suckling calves expressed severe emaciation, generalized alopecia, domelike cranial deformation, and high mortality. Metaphyseal growth plates of the femur were achondroplastic, segmented, partially resorbed, and replaced with immature bony trabeculae containing degenerated chondrocytes. The metaphyseal growth plates were poorly formed, irregular, partially disappeared centrally, and often sealed with thin bony trabeculae. The cartilage matrix was not homogeneous but was finely fibrous, and chondrocytes were flat and degenerated. The bone lesion was diagnosed as chondrodysplasia due to premature physal closure. These calves had been administered excessive amounts of vitamins A, D₃, and E, and the blood chemistry showed hypervitaminosis A and E.

VITAMIN D TOXICOSIS

BASICS

OVERVIEW

- Vitamin D toxicosis is a condition of oversupplementation of either the enteral or parenteral forms of vitamin D₃ (cholecalciferol, 25-OH-cholecalciferol, 1, 25-OH-cholecalciferol) or from ingestion of plant compounds with vitamin D activity (ergocalciferol or D₂).
- A related condition known as enteque seco or Manchester wasting disease is caused by ingestion of plants like *Cestrum diurnum* (southeastern United States), *Trisetum flavescens* (European Alps), or *Solanum malacoxylon* (South America). These contain a 1, 25-OH-cholecalciferol-glycoside, which effectively induces hypervitaminosis D in grazing animals.

SIGNALMENT

- It was thought that use of active forms of vitamin D₃ would be useful in the prevention of milk fever in periparturient cattle by inducing an elevation in serum calcium. However, this has not had practical use in commercial cattle units, as the response is difficult to titrate.
- A history of parenteral vitamin D injections (usually as a vitamin A, D, and E combination) would suggest hypervitaminosis D, but could be confounded by hypervitaminosis A (although vitamin A has a sparing effect on vitamin D toxicity).
- Replacement of supplemental ergocalciferol with synthetic cholecalciferol has increased the likelihood of toxicity, as there is an increased activity of vitamin D₃ when compared to D₂.
- Ingestion of rodenticides with vitamin D as the active poison can induce toxicosis.
- Grazing pastures growing *Cestrum diurnum*, *Trisetum flavescens*, or *Solanum malacoxylon* can induce a hypervitaminosis D like disease in cattle.

SIGNS

- Initially, cattle become anorexic and depressed. This is followed by weight loss, a reduced milk production (flaccid udder), a pasty discharge around the eyes, muscle stiffness leading to recumbency, polyuria, and respiratory distress (polypnea) that can be accompanied by subcutaneous emphysema and this can progress to death. Just before death a rapid pounding pulse and ketosis has been noted.
- Cardiac arrhythmia has been noted and attributed to elevated serum calcium, as has calcification of the vascular system.
- Mineralization of soft tissue causes the signs associated with hypercalcemia. Tendon and muscle calcification leads to stiffness and recumbency. Renal calcification leads to polyuria, hypercalciuria, and renal failure.
- Withdrawal of the source of vitamin D will stop progression of the disease, but is dependent on how quickly tissue storage depots are depleted and the availability of dietary calcium.

CAUSES AND RISK FACTORS

- Duration and amount of exposure will affect the likelihood of disease. Injected forms of the vitamin are more toxic than the enteral forms because of rumen degradation of Vitamin D.
- While cholecalciferol is more toxic than ergocalciferol in several species, this difference is somewhat less in cattle. High dietary calcium exacerbates the condition, allowing more calcium to be absorbed.
- Low vitamin A status will exacerbate the likelihood of vitamin D toxicity.
- Pregnant cattle are more prone to toxicity than nonpregnant cattle.

DIAGNOSIS

- Dietary vitamin D in excess of normal dietary recommendations of 300 IU vitamin D/kg diet indicates possible exposure

(toxic range: 2,200–25,000 IU vitamin D/kg diet). Doses as low as 2.1 mg 1- α -OH D₃ per dose in 4 doses over 7 days has caused disease, yet single doses of 250 mg of vitamin D₃ (presumably as cholecalciferol) have been reported to have no effect.

- A longer exposure time lowers the threshold for toxicity. This is because of the lipid soluble nature of vitamin D and its storage in fat depots.
- Elevated plasma vitamin D, in excess of 20–50 ng/ml, indicates elevated intake or parenteral exposure.
- Dystrophic calcification of soft tissues compatible with hypercalcemic-induced change from hypervitaminosis D will include nephritic change and renal disease/failure.

DIFFERENTIAL DIAGNOSIS

- Any cause of hypercalcemia: intravenous calcium administration, hyperparathyroidism (parathyroid tumor), lymphosarcoma, gastric squamous cell carcinoma
- In gastric squamous cell carcinoma and lymphosarcoma, parathyroid hormonelike peptides can be produced, inducing hypercalcemia.

CBC/BIOCHEMISTRY/URINALYSIS

- Hypercalcemia is a hallmark sign of vitamin D toxicity but may not be present after withdrawal of the source of vitamin D. However, mineralization of soft tissues will persist and can ossify.
- Hyperphosphatemia, hypercalciuria, isosthenuria, and azotemia will be present depending on the stage and severity of disease.

OTHER LABORATORY TESTS

N/A

IMAGING

Radiographically, all soft tissue can be affected because the fibroelastic tissues around vessels will become calcified.

DIAGNOSTIC PROCEDURES

- Elevated serum calcium and phosphorus and determination of serum vitamin D concentrations greater than 80 ng/ml suggests toxicity.
- Necropsy of animals that died can be pathognomonic.

PATHOLOGIC FINDINGS

Gross Pathology

- Lungs can fail to collapse because of dystrophic calcification.
- Mineralization of the heart, aorta, kidney, stomach, lungs, tendons, and muscles is highly suggestive of hypervitaminosis D.

Histopathologic

- Initially there is a high degree of osteoclastic activity induced by vitamin D. This causes bone resorption of the primary spongiosa and loss of mineralized calcium. This will progress if dietary calcium is low leading to rarefaction of bone.
- Osteosclerosis will occur if dietary calcium is adequate or excessive and osteoblastic activity will result in bone mineralization.
- Osteoblasts will produce a characteristic pattern of abundant basophilic matrix that is virtually pathognomonic for vitamin D toxicity.
- If the exposure to vitamin D is intermittent, then the pattern of osteogenesis and depletion will lead to bands of basophilic matrix. Osteocytic necrosis will occur with high exposure.

TREATMENT

- Removal of the source of vitamin D is critical. Because vitamin D₃ increases intestinal calcium absorption, limiting dietary calcium will reduce tissue calcium deposition.
- Supplementation with vitamin A, estrogen, thyroxin, and glucagon has been suggested to have some sparing effects on progression of disease.
- Supportive care for recumbent animals, treatment of renal disease and/or failure (fluid therapy to maintain electrolyte and

fluid balance), or euthanasia of severely effected animals may be needed.

MEDICATIONS

CONTRAINDICATIONS

- As mentioned, dietary calcium and phosphorus can affect the calcification of soft tissue.
- Reduction in dietary calcium to reduce calcium absorption is required.
- Vitamin A can have some sparing effects on soft tissue mineralization, as can thyroxin, glucagon, and estrogen.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

Severely affected animals should be sold if suitable for human consumption or euthanatized.

PREVENTION/AVOIDANCE

Ensure that the form of vitamin D is known and fed in amounts within expected guidelines for cattle (300 IU/kg diet).

EXPECTED COURSE AND PROGNOSIS

Prognosis and duration of disease is dependent on the dose and duration of exposure.

AGE-RELATED FACTORS

Pregnant cows are reportedly at highest risk.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Pregnant cows may be at highest risk for development of disease.

BIOSECURITY

VITAMIN E/SELENIUM DEFICIENCY

BASICS

DEFINITION

Vitamin E or selenium deficiency occurs when the diet lacks sufficient vitamin E or selenium to maintain normal maintenance, growth, or production.

OVERVIEW

- Deficiency of vitamin E (α -tocopherol) or selenium is common in many regions of the world. Selenium toxicity is reported but can be confounded by toxicity of other trace metals and alkaloids. Vitamin E toxicity has not been reported as a natural condition in ruminants.
- Abortion, infertility, increased incidence of retained placenta, stillborn or weak calves that die soon after birth, and calves that fail to thrive are typical of herds and flocks affected by selenium deficiency.
- Immunosuppression leading to an increase in mastitis and pneumonia can be responsive to selenium and/or vitamin E supplementation. As would be expected, animals with the greatest growth and production demands will manifest selenium deficiency first. Lameness or yearlings with evidence of white muscle disease (WMD) or nutritional myodegeneration (NMD) are commonly observed in problem herds.
- Reduction in the activity of selenium-dependent glutathione peroxidase, with an increase in free-radical-induced cellular damage, is associated with muscle damage in the myocardium and skeletal muscle. A reduction in peroxidation is the rationale for feeding increased vitamin E in finishing rations for cattle; retained red meat color allows for an increased storage life at the market.

PATHOPHYSIOLOGY

- Vitamin E is essential for protecting cell membranes from oxidative damage by allowing for its own oxidation, preventing damage to critical proteins in cell membrane regulation. Selenium-dependent glutathione peroxidase (GPx) was the first protein identified as selenium dependent.
- There have been several different forms of the selenium-dependent GPx identified: the classical cytosolic GPx, gastrointestinal GPx, plasma GPx, phospholipid GPx, and sperm nuclei GPx. These reduce hydrogen peroxide and organic hydroperoxides to stop peroxidation of other cytosolic and membrane constituents.
- Selenium-dependent iodothyronine deiodinase catalyzes the deiodination of T₄ to T₃, reverse T₃ from T₄, and reverse T₃ to T₂. These enzymes can activate or inactivate the thyroid hormone thyroxine. Last, thioredoxin reductases are enzymes with a selenocysteine-active site allowing for the NADPH-dependent reduction of oxidized thioredoxin.
- Reduced thioredoxin is critical for several redox systems, including those for transcription factors and reductases for DNA synthesis. They have been established as critical for regulating cell growth, prevention of apoptosis, and prevention of embryonic mortality.

SYSTEMS AFFECTED

Principally muscle tissues are noted, but thyroid and immune dysfunction affects several organ systems when selenium is deficient. Alterations in muscle and immune function are the systems affected when vitamin E is limiting.

GENETICS

N/A

INCIDENCE/PREVALENCE

Principally young, rapidly growing animals will be affected. Incidence will increase as the severity of deficiency increases. Older animals will not have the severity of muscle damage, as noted in young, rapidly growing animals, but are still susceptible to myodegeneration.

GEOGRAPHIC DISTRIBUTION

Potentially worldwide, depending on species and environment

SIGNALMENT

Species

Potentially all ruminant species are affected.

Breed Predilections

N/A

Mean Age and Range

All animals are susceptible, but younger animals are most commonly affected (including newborns that were affected in utero).

Predominant Sex

Both sexes are susceptible to either vitamin E or selenium deficiency.

SIGNS

HISTORICAL FINDINGS

- As would be expected, animals that are rapidly growing (i.e., nursing calves, lambs, kids) are most frequently affected with the NMD and this can develop either during gestation or after birth.
- Older animals have also been reported to be affected by NMD.
- NMD has been reported in goat kids, and suckling and weanling lambs with adequate selenium status but deficient in vitamin E, possibly suggesting inadequate colostrum intake, low colostrum vitamin E concentrations, or inadequate postnatal vitamin E supplementation.

PHYSICAL EXAMINATION FINDINGS

- Vitamin E and Se deficiency manifest NMD very similarly.
- Generalized leg weakness and stiffness are accompanied by animals crossing their legs while walking and having difficulty rising and standing. Impaired suckling ability due to dystrophic tongue muscles, heart failure, and paralysis have all been noted in NMD.
- Secondary infections such as pneumonia and mastitis are frequently observed. Polypnea may develop in these animals, and this can be accompanied by heart disorders. Myocarditis can induce a pendulum rhythm with reductions in heart sounds.
- A generalized picture of a selenium-deficient herd would include a range of disorders in cows and their calves. Fewer calves born than expected could reflect abortion and subfertility within the herd.
- An increased incidence of retained placenta, stillborn or weak calves that die soon after birth, and calves that fail to thrive are typical of herds affected by selenium deficiency. Calves will often have diarrhea, and mortality can be high. In dairy cows, mastitis has been reported to be responsive to selenium and vitamin E supplementation.
- Selenium-deficient cows will grind their teeth, constantly shift their weight, have difficulty rising, arch their backs, and remain in sternal recumbency (downer cow). As the disease progresses, lassitude, anorexia, increased respiration rate, dyspnea, dark urine, muscle tremors, cardiac conduction disturbances, and death have been noted.
- Reduced sperm production and testicular degeneration have been associated with selenium deficiency. Thioredoxin reductase is a testicular selenoprotein that may underlie the defect in spermatogenesis or maturation associated with testicular atrophy in selenium-deficient bulls. This defect is likely due to disruption of ribonucleotide reductase and alteration in the regulation of transcription factors. This may also explain the lower embryo survival noted in selenium-deficient cows.

CAUSES AND RISK FACTORS

- Currently the National Research Council recommends about 20 IU vitamin E/kg dry matter for stored feeds. Usually supplementation is not needed when cattle are grazed on green pasture; however, ruminants grazed on dry feed should consume approximately 20 IU vitamin E/kg dry matter for optimal production.
- Legume pastures may be an exception as NMD has been noted when cattle are grazed on alfalfa or clover pastures. Serum α -tocopherol concentrations greater than 4.0 $\mu\text{g/ml}$ (0.4 mg/dl) are considered adequate in adult cattle.
- Marginal vitamin E status in adult cattle is associated with plasma α -tocopherol concentrations in the 2.0 to 3.0 $\mu\text{g/ml}$ range. Clinical white muscle disease is common when α -tocopherol levels are below 2 $\mu\text{g/ml}$.
- Selenium requirements are 0.3 mg/kg DM. Diets containing less than 0.1 mg/kg DM may be deficient and would warrant surveillance of animals within the herd for deficiency. Adequate selenium intake is indicated when whole blood selenium is in the range of 0.07 to 0.10 $\mu\text{g/ml}$.

- Cattle are selenium deficient when whole blood selenium falls in the range of 0.01 to 0.04 μ g/ml whole blood and marginal intake is suggested when whole blood selenium is between 0.05 and 0.06 μ g/ml.
- Adequate selenium consumption is indicated when glutathione peroxidase activity is in the range of 25–500 u/mg hemoglobin/minute. When glutathione peroxidase activity is less than 15 u/mg hemoglobin/minute, cattle are considered selenium deficient. Marginal selenium intake is suggested when glutathione peroxidase activity is 15–25 u/mg hemoglobin/minute.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Because the signs and symptoms of either selenium or vitamin E deficiency are fairly nonspecific, a thorough evaluation of the management and feeding practices is needed.
- Neonatal scours can be caused by high exposure to pathogens such as *E. coli* alone, but the immunosuppression associated with selenium or vitamin E deficiency will manifest in higher morbidity and mortality than in sufficient animals.

CBC/BIOCHEMISTRY/URINALYSIS

- Marked elevations (100-fold) in plasma creatine kinase activity have been observed, along with increased plasma aldolase and lactic dehydrogenase activity and decreased alkaline phosphatase activity.
- Lower type 1 deiodinase (5' deiodinase) activity will reduce T4 to T3 conversion lowering circulating T3. Similarly, reduction in the type 3 deiodinase catalyzes the conversion of T4 to reverse T3, and T3 to T2 deactivating the biologically active T3.
- Because of the myodegeneration and myonecrosis, myoglobinuria can be observed in selenium or vitamin E–deficient cattle.

PATHOLOGIC FINDINGS

- Usually, lesions of NMD are localized in those most actively exercised muscles suggesting that free radical production is higher in such muscles.
- Gross examination of animals with selenium or vitamin E deficiency will have skeletal and cardiac muscle streaking (white) with foci of calcification. Severely affected animals can have a chicken flesh appearance of muscle with edema and occasional hemorrhage.
- Nutritional myodegeneration in yearling cattle grazing lush pastures, assumed to be high in polyunsaturated fats, is associated with myonecrosis. Other factors contribute to selenium-deficiency-induced myodegeneration of older calves and exercise has been suggested to be one factor.
- Concurrent pneumonia, diarrhea, mastitis, etc., confound the diagnosis and periodic surveillance of hepatic concentrations of Se and vitamin E is suggested to exclude deficiency as an underlying cause of these complexes of disease.

TREATMENT

- Injection of vitamin E- and Se-containing products can dramatically reduce the severity of disease in deficient herds. Routine supplementation of vitamin E and Se, as salts or meals in pastured animals or in grain mixes of confined animals, will prevent disease.
- Iron Se boluses are efficacious in prevention of Se deficiency for at least a year in many cases. Availability can be restricted by governmental regulation.

CLIENT EDUCATION

Taking the time to help your clients better understand nutritional requirements and their effects on growth, reproduction, and health will greatly help prevent many infectious as well as nutritional diseases in ruminant livestock.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Oversupplementation of selenium is possible. It is important to stay within federal guidelines for supplementation.

POSSIBLE INTERACTIONS

- Maternal dietary status directly affects fetal and neonatal vitamin E and selenium status. Only limited amounts of vitamin E are transported across the placenta, and adequate colostrum intake is critical to supply the neonate adequate vitamin E. Selenium uptake by the fetus is directly proportional to maternal supply. Therefore, adequacy is critical in the last trimester to ensure adequate fetal and neonatal vitamin E and selenium status.
- Arsenic, mercury, cadmium, and copper, molybdenum, and sulfur have been suggested to alter selenium metabolism, but their influence appears to be small.
- Oxalate can decrease selenate transport in sheep and the sulfur amino acids will alter selenium metabolism.
- Dietary protein and sulfur amino acids may limit availability of selenoaminoacid incorporation into proteins.
- Dietary methionine will directly influence the proportion of selenomethionine incorporation into proteins; selenomethionine availability for incorporation into glutathione peroxidase can be reduced when methionine is limiting. Increased dietary methionine allows for increased availability of selenomethionine to selenocysteine conversion for incorporation into selenium-specific proteins.
- Other factors influencing retention of selenium are phosphorus and the selenium content of the diet. Multiple factors affect absorption and retention of selenium, with high dietary protein tending to increase absorption while increasing urinary loss.

FOLLOW-UP

- Monitoring maternal selenium and vitamin E status is prudent in areas with chronic deficiency. Rarely will one nutrient be the only limiting nutritional factor. Combined nutrient deficiency is common and requires surveillance and supplementation to prevent clinical disease.
- Monitoring blood selenium GPx activity is relatively simple, as is quantifying plasma or serum vitamin E concentration.

PATIENT MONITORING

- Ensuring adequate nutritional balance for all nutrients in the recovery phase is important for repair of muscle damage and prevention of additional muscle damage.
- Affected animals should have an improvement of gait and growth within weeks of supplementation.
- Ensuring adequate bedding and access to water and feed is critical for recumbent animals.

PREVENTION/AVOIDANCE

- Dietary supplementation of animals with adequate selenium and vitamin E is needed when feeds contain less than 0.3 mg Se/kg DM and 20 IU vitamin E/kg DM.
- Injection of cattle with vitamin E- and Se-containing products is efficacious in correcting deficiency in the short term, and commercial products are available throughout the world. Oral boluses with sodium selenite are commercially available.
- Daily intake of vitamin E is likely required and oral supplementation is the least costly.

POSSIBLE COMPLICATIONS

- Severely affected recumbent animals will require euthanasia. Animals with intercurrent infectious disease will have a greater likelihood of dying because of their immunosuppression.
- Depending on the severity and duration of deficiency, growing cattle may not be able to gain weight and height compared to peers, even with compensatory growth.

EXPECTED COURSE AND PROGNOSIS

- Rapid improvement of the herd incidence of NMD is expected after supplementation with vitamin E and Se.
- Severely affected animals may not recover sufficiently for production purposes.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Secondary infectious disease is common in affected herds and an increase in pneumonia, diarrhea, and mastitis has been reported.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Selenium- or vitamin E-deficient dams will not provide sufficient selenium or vitamin E to the fetus or from colostrum to allow for adequacy in their offspring. It is important that cattle be fed adequately in the last trimester to allow offspring to be born without causing nutritional insufficiency.

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species are affected.

VOMITOXIN

BASICS

OVERVIEW

- Vomitoxin (trichothecene group B, deoxynivalenol—DON) is produced by a field fungus, *Fusarium roseum*, and is part of the nonmacroyclic group B trichothecenes and includes dioxynivalenol, also known as DON, and its metabolites.
- Trichothecenes are tetracyclic sesquiterpenoids produced by at least six genera of plant fungi including *Fusarium* spp.
- Growth of the fungus requires undulating cool temperatures.
- There are four groups of trichothecene toxins: groups A, B, C, and D.
- DON, or vomitoxin, is the economically most significant due to losses from feed refusal and low growth rates.
- As little as 10 ppm in the field can cause a reduction in feed consumption in cattle.

SIGNALMENT

Ruminants ingesting corn, wheat, and other cereal crops that are moldy.

SIGNS

- Initial signs consist of feed refusal and low rates of gain and production. Often the first sign is feed refusal due to a learned taste aversion to the contaminated feed. There is failure to thrive, possible vomiting, diarrhea, and oral and intestinal necrosis.
- The mechanism of action is via rapid penetration of cell lipid bilayers and access to DNA, RNA, and cellular organelles. There the toxins inhibit protein synthesis by interfering with the initiation phase of ribosomal translation and covalent binding to sulfhydryl groups. They are “radiomimetic,” meaning they mimic the effects of radiation and cause acute necrotizing cytotoxicity of both the epidermis and dermis. This results in stomatitis and hyperkeratosis with ulceration of the gastric mucosa and GI tract.
- There are immunosuppressive effects at the level of T suppressor cells and possibly the helper T cells, B cells, and macrophages. The immunosuppressive effects can result in secondary bacterial, viral, or parasitic infections.
- There can be hemorrhage due to thrombocytopenia or inhibition of platelet function and/or defects in the intrinsic or extrinsic coagulation pathways and depression of clotting factors. This can lead to hypotension, shock, meningeal hemorrhage, and subsequent paresis, seizure, and death.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Castor bean, black locust (lectin) toxicity, or arsenic and other causes of gastroenteritis

CBC/BIOCHEMISTRY/URINALYSIS

Possible mild anemia, leukopenia, thrombocytopenia, and hypoproteinemia. Due to the rapid metabolism of trichothecenes, urinalysis is not diagnostic.

OTHER LABORATORY TESTS

The best diagnostic technique is identification of the trichothecene in the feed by gas chromatography-mass spectrometry.

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Lab analysis of feed samples

PATHOLOGIC FINDINGS

GROSS FINDINGS

Acute exposure to high doses of vomitoxin can result in oral lesions, hemorrhagic enteritis, and ulcerated lymphoid follicles.

HISTOPATHOLOGICAL FINDINGS

Smaller than normal lymphatic organs may be present.

TREATMENT

- Treat symptomatically with steroidal antishock and anti-inflammatory agents that are approved for use in food-producing animals.
- Provide clean feed and water.
- Residues are of minimal concern because of the rapid metabolism of trichothecenes.

MEDICATIONS

N/A

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

FOLLOW-UP

PREVENTION/AVOIDANCE

Inspect feeds for signs of mold and discard.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

With supportive care and clean feed, prognosis is good.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Failure to thrive, possible vomiting, diarrhea, and oral and intestinal necrosis
- Stomatitis and hyperkeratosis with ulceration of the gastric mucosa and GI tract
- Immunosuppressive effects can result in secondary bacterial, viral, or parasitic infections
- There can be hemorrhage due to thrombocytopenia or inhibition of platelet function and/or defects in the intrinsic or extrinsic coagulation pathways and depression of clotting factors. This can lead to hypotension, shock, meningeal hemorrhage, and subsequent paresis, seizure, and death.

VULVITIS

BASICS

OVERVIEW

- Vulvitis (inflammation of the vulva) is relatively common in ruminants where it is often associated with vaginitis (vulvovaginitis).
- Many causes have been associated with this condition. In general, the condition causes few significant problems; however, certain manifestations have been associated with infertility, due to either physical or pathological causes.
- Here, vulvitis will be discussed in terms of its major clinical manifestation.

SIGNS

HISTORICAL FINDINGS

N/A

PHYSICAL EXAMINATION FINDINGS

Catarrhal Vulvitis

Often with a persistent mucopurulent discharge from the vulva; most commonly encountered postpartum where it may be associated with retained placenta, puerperal metritis, or physical injury to the vulva

Granular Venereal Disease

- This is the most common form of vulvitis encountered.
- It is a condition that occurs in most female cattle sooner or later. The condition is seen most commonly in heifers in their first or second natural breeding season.
- GVD appears to be easily and rapidly spread and it varies considerably in severity.
- It is characterized by lymphoid granules or nodules, which can appear acutely with a mucopurulent discharge.
- Mild forms are commonly seen in sheep and goats.
- Possible infectious causes have included *Ureaplasma*, *Mycoplasma*, IBR/IPV virus, *A. pyogenes*, *Streptococcus* spp., *Staphylococcus* spp., *E. coli*, and *H. somnus*.
- In cattle, vulvitis and vaginitis have been associated with *Ureaplasma diversum*. In sheep, *Ureaplasma* has also been

associated with granular vulvitis. In does, a granular vulvovaginitis has been described due to *Mycoplasma agalactiae*.

Necrotic Vulvitis

- May follow severe trauma, ischemia, and infection
- It is not uncommonly encountered following dystocia in heifers, where it may accompany metritis. Here, it is often manifest 1–4 days after parturition, and may last 1–2 weeks.
- Affected animals often show signs of pain, tenesmus, and other systemic signs.
- One form has been described in feedlot heifers where it was associated with *Sphaeophorus necrophorus* infection.
- A necrotic vulvitis may also accompany granulosa cell tumors, which may occur in the vulval region of most ruminants.
- Allergic factors have also been suggested as possible etiological factors.
- An ulcerative vulvitis has been described in ewes, apparently viral in nature.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Transmissible fibropapillomas (cattle)
- Granulosa cell tumors
- Chlorinated naphthalene poisoning
- Contagious ecthyma (sheep and goats)
- Cystic vestibular (Bartholin's) glands

CBC/BIOCHEMISTRY/URINALYSIS

- CBC is generally unrewarding.
- Urinalysis may prove useful in diagnosis.

OTHER LABORATORY TESTS

Culture and sensitivity is indicated if infective agents are suspected.

IMAGING

OTHER DIAGNOSTIC PROCEDURES

Speculum examination/visual observation of vulva is mandatory.

TREATMENT

- Treatment is often unnecessary, especially with milder cases of granular venereal disease.
- Where indicated, local conservative treatment should be considered.

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Usually good
- In sheep, fly strike of vulvitis may lead to complications.
- Occasionally, severe necrotic vulvovaginitis may lead to vaginal stenosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Retained placenta, puerperal metritis, or physical injury to the vulva

AGE-RELATED FACTORS

GVD is seen most commonly in heifers in their first or second natural breeding season.

ZOONOTIC POTENTIAL

Several of these diseases are potentially zoonotic. Care must be taken in the collection of laboratory samples and the diagnosis/treatment of affected animals.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected.

BIOSECURITY

- Isolation and quarantine of new stock entering the herd/flock.
- Treat and or cull new animals for disease conditions prior to herd introduction.
- GVD appears to be easily and rapidly spread, and it varies considerably in severity.

WATER BUFFALO DISEASES

BASICS

OVERVIEW

- When compared to bovine species, water buffalo are much more resistant to disease. This is evident even though most water buffalo are found in hot, humid regions of the world that are conducive to disease transmission.
- Water buffalo are susceptible to most diseases and parasites affecting cattle. Treatment and vaccination protocols are generally similar between the two species.
- Poor ventilation, insufficient sanitation, inappropriate reproductive management, and poor quality nutrition programs all impact production of water buffalo.
- Buffalo calf deaths are a significant problem and impact profitability.
- The wallowing habit of water buffalo also increases the potential of transmission of some waterborne diseases.
- Tail necrosis is a common medical condition in water buffalo.
- Demodectic mange, alopecia, and ulceration are common skin disease conditions.

PATHOPHYSIOLOGY

SYSTEMS AFFECTED

Production management, skin, respiratory, gastrointestinal, immune, reproductive

GENETICS

N/A

INCIDENCE/PREVALENCE

Tapeworms: reported at an incidence of 15% in some tropical environments (*Moniezia* spp.)

GEOGRAPHIC DISTRIBUTION

Asia; potentially worldwide depending on environment

SIGNALMENT

Species

There are two general types of water buffalo: the swamp buffalo (*Bubalus carabanesis*), which are found from the Philippines to as far west as India, and the river buffalo (*Bubalus bubalis*), which are found farther west from India to Egypt and Europe.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Dermatologic

- Edematous skin disease—*Corynebacterium pseudotuberculosis* serotype II is the main cause of ESD. Exotoxin phospholipase D and the lipid contents of the cell wall are the major causes of pathogenesis. The horsefly vector, *Hippobosca equina*, commonly transmits *Corynebacterium pseudotuberculosis* among buffalo.

- Actinobacillosis
- Yoke gall—chronic injury to the ligamentum nuchae caused by the continuous pressure of a yoke (collar) on the buffalo's neck. This is due to poorly fitted driving equipment and heavily loaded carts driven by buffalo bullocks.
- Cutaneous filariasis (*Parafilaria bovicola*)
- Cutaneous onchocerciasis—cutaneous lesions in the dermis, most apparent in the xiphoid region (*Onchocerca* spp.)
- Mastitis—multiple genera similar to domestic cattle
- Cowpox as well as the buffalo poxvirus
- Mange—three types of mange—psoroptic (*Psoroptes natalensis*), sarcoptic (*Sarcoptes scabiei* var. *bubalus*), and demodectic (*Demodax bovis*)
- Dermatomycosis
- Tail necrosis—several causes have been postulated—*Corynebacterium bovis*, fatty acid deficiency, and microfilaria
- Lumpy skin disease
- Warts
- KCS
- Otitis media
- Caudal tail fold mange

Systemic Disease

- Hemorrhagic septicemia/pasteurellosis
- Anaplasmosis
- BVD/mucosal disease
- Anthrax
- Tuberculosis
- Rabies
- Black leg/quarter
- Foreign body syndrome (similar to TRP)
- Brucellosis
- Foot-and-mouth disease
- Johne's disease
- Rinderpest
- Bovine ephemeral fever
- Malignant catarrhal fever
- Toxoplasmosis
- Nephritis, hydronephrosis, and renal calcification
- Piroplasmiasis
- Pleuropneumonia (mycoplasmal)
- Hypophosphatemia
- Pestes des petits ruminants

Parasitic Diseases

- Ascarid infection—heavy losses of young buffalo calves caused by *Toxocara vitulorum*
- Strongyles—adult buffalo are resistant.
- Echinococcosis/hydatid cyst disease (*Echinococcus granulosum*)
- Coccidiosis (*Eimeria* spp.)
- Filarial nematodiasis
- Trypanosomiasis—buffalo are more susceptible to *Trypanosoma evansi* than cattle.
- Pediculosis—caused by the sucking louse (*Hematopinus tuberculatus*)
- Babesia (*Babesia argentina* and *B. bigemini*)—secondary to infection by ticks *Boophilus microplus* and *Hyalomma anatolicum*
- Lungworm—infestation of the respiratory tract by *Dictyocaulus viviparus*

- Cutaneous filariasis (*Parastrongylus immitis*)
- Cutaneous onchocerciasis—cutaneous lesions in the dermis, most apparent in the xiphoid region (*Onchocerca* spp.)
- Leeches
- Ticks—buffalo are resistant to ticks.
- Tapeworms—reported at an incidence of 15% in some tropical environments (*Moniezia* spp.)
- Ectoparasitism—a primary ectoparasite in Australia and Southeast Asia is the buffalo fly (*Siphona* spp.). Lice and mites may infest buffalo all year, but primarily during the winter season. Mosquitoes and flies affect buffalo during hot/humid weather.
- Mange—three types of mange, psoroptic (*Psoroptes natalensis*), sarcoptic (*Sarcoptes scabiei* var. *bubalus*), and demodectic (*Demodax bovis*)
- Ophthalmic parasites—conjunctivitis caused by *Thelazia* spp. is common.
- Several moth species feed nocturnally on buffalo lacrimal secretions in Asia.
- Synagamus (*Synagamus laryngeus*)
- Hepatic flukes—*Fasciola hepatica* and/or *F. gigantica* are very common worldwide. Snails of *Lymnaea* spp. are common vectors.
- Intestinal flukes—common flukes are *Cotylophoron cotylophorum*, *Calicophoron* spp., *Paramphistomum* spp., *Olveria* spp., and *Ceylonocotyle* spp. Fluke infestations (intestinal and hepatic) are the most common cause of mortality in adult water buffalo maintained in tropical Asian climates.
- Biliary leach—*Gigantocotyle explanatum* causes calf loss.
- Sarcosporidiosis
- Schistosomiasis—can cause enteritis in young buffalo calves less than 2 years of age.
- Theileriosis

Reproductive Disease

- Anestrus—nutritional, anatomical, hereditary, and functional. Anestrus has its highest incidence during the hot season. Small, hard, and inactive ovaries generally are present.
- Subactive/inactive ovaries—secondary to nutritional deficiency
- Excessive follicular atresia with a failure of maturation and ovulation
- Hypojunctional uterus
- Cystic ovaries
- Small, inactive ovaries—often related to a low-phosphorus diet
- Persistent CL
- Encapsulation of ovaries
- Salpingitis
- Cervicitis
- Metritis
- Pyometra
- Endometritis
- Vaginitis
- Iatrogenic reproductive problems commonly occur when artificial insemination programs reflect poor technical abilities and rough handling.
- The incidence of dystocia, abortions, and retained placenta is similar to that in cattle.

Management-Related Issues

- Respiratory infections—primarily due to poor management
- Diarrhea—found mainly in calves
- Decreased milk production
- Lameness
- Iatrogenic infertility
- Bloat/tympany
- Mastitis

MEDICATIONS

DRUGS OF CHOICE

Similar to those used in domestic bovine

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- When compared to bovine species, water buffalo are much more resistant to disease. This is evident even though most water buffalo are found in hot, humid regions of the world that are conducive to disease transmission.
- Tail necrosis is a common medical condition in water buffalo.
- Demodectic mange, alopecia, and ulceration are common skin disease conditions.

AGE-RELATED FACTORS

- Buffalo calf deaths are a significant problem and impact profitability.
- Diarrhea—found mainly in calves
- Adult buffalo are resistant to strongyles.
- Schistosomiasis—can cause enteritis in young buffalo calves less than 2 years of age.

ZOONOTIC POTENTIAL

Several of these diseases are zoonotic. Care must be taken in the collection of laboratory samples and the diagnosis/treatment of affected animals.

PREGNANCY

Several of these diseases cause abortion in water buffalo.

RUMINANT SPECIES AFFECTED

- Swamp buffalo (*Bubalus carabanesis*) and the River buffalo (*Bubalus bubalis*)
- The incidence of dystocia, abortion, and retained placenta is similar to that in cattle.

BIOSECURITY

- Isolation and quarantine of new stock entering the herd/flock
- Treat and or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT

Water buffalo are susceptible to most diseases and parasites affecting cattle. Poor ventilation, insufficient sanitation, inappropriate reproductive management, and poor-quality nutrition programs all impact production of water buffalo.

WATER BUFFALO MANAGEMENT

BASICS

OVERVIEW

- Water buffalo belong to the family Bovidae, subfamily Bovinae, and the genus *Bubalus*.
- There are about 151.5 million water buffalo in the world, 96.6% of which are found in Asia.
- The world's major concentration of buffalo is in India with 56% or 94 million animals followed by China and Pakistan.
- Water buffalo are restricted to environments where there is a hot, humid climate with plenty of water in which to cool.
- Water buffalo were introduced to Europe by crusaders returning in the Middle Ages, and outstanding herds still exist in Italy and Bulgaria.
- They have been introduced to South and Central America recently and are performing well.
- In May 1975, water buffalo were imported to Gainesville, Florida, to investigate the potential of water buffalo for aquatic weed biocontrol. They are also found in Hawaii and the southern region of the United States.
- In the United States, Brazil, Venezuela, and Australia, water buffalo are managed on rangelands.

GENETICS

- There is only one breed of swamp buffalo, but certain subgroups have specific inherited characteristics.
- There are 18 river buffalo breeds, which are classified into five major groups designated as the Murrah, Gujarat, Uttar Pradesh, Central Indian, and South Indian breeds.
- Among the river buffalo breeds, the best-known are Murrah, Jafarabadi, Surti, Nili/Ravi, Mehsana, Kundi, and Nagpuri, which are mainly concentrated in India and Pakistan.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

- Potentially worldwide, depending on environment
- There are two general types of water buffalo: the swamp buffalo (*Bubalus carabanesis*), which are found from the Philippines to as far west as India, and the river buffalo (*Bubalus bubalis*), which are found farther west from India to Egypt and Europe.

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNALMENT

Species

- Swamp buffalo (*Bubalus carabanesis*) and river buffalo (*Bubalus bubalis*)
- The river buffalo constitutes about 65% of the total world buffalo population of 168 million head, and accounts for 92% of buffalo milk produced worldwide.
- Swamp buffalo are generally slate grey in color with a droopy neck, and appear oxlike with massive sweptback horns. They wallow in any water and prefer muddy conditions, which makes them excellent animals for work in rice cultivation on paddy fields.
- River buffalo are generally black or dark grey in color with tightly curled or drooping straight horns. They prefer to wallow in clear, running water, and they are often used in milk production.
- There is only one breed of swamp buffalo, but certain subgroups have specific inherited characteristics. The buffalo of Thailand are large in size and weigh up to 1000 kg. In China they are small, weighing up to 300 kg. In Indonesia they have

coat characteristics of black and white spots.

- There are 18 river buffalo breeds, which are classified into five major groups designated as the Murrah, Gujarat, Uttar Pradesh, Central Indian, and South Indian breeds.
- Among the river buffalo breeds, the best-known are Murrah, Jafarabadi, Surti, Nili/Ravi, Mehsana, Kundi, and Nagpuri, which are mainly concentrated in India and Pakistan.
- The majority of water buffalo are nondescript due to centuries of indiscriminate breeding without specified selection criteria.
- The river type has 50 chromosomes and the swamp type has 48 chromosomes.

Breed Predilections

- Buffalo come in many different sizes from small animals of 250 kg to heavy breeds up to 1000 kg.
- The largest breeds stand 5–6 ft (1.5–1.8 m) high, are up to 9 ft (2.8 m) long, and may weigh over 2000 lb (900 kg).
- The dull black or dark gray body has little hair; it absorbs heat easily and has few sweat glands. To some degree, the animal may substitute a fur coat with a thick, subcutaneous fat layer.
- The horns spread outward and upward, measuring up to 7 ft (2 m) across.
- The water buffalo is known as a sluggish breeder. First calves are usually produced at about 24 to 36 months of age, but recent studies show that with adequate nutrition and good management, buffalo can reach puberty at about the same age as cattle (18 months).
- They generally produce two calves every 3 years.
- The gestation period for buffalo is about the same as cattle, 287 days.
- Peak calving season is January and February.
- Buffalo calves generally weigh 45–55 pounds at birth.

Management

- They have immense strength but are very docile with people they are accustomed to.
- The classic buffalo in Asia belongs to a small farm, and millions of water buffalo are managed in intensive “backyard” systems. Herds of 2–50 animals owned by small or marginal farmers; around urban centers herds of 20–50 are common.
- Buffalo have important qualities as feedlot animals. They can be herded and handled with relative ease because of their placid nature.
- In the United States, Brazil, Venezuela, and Australia, water buffalo are managed on rangelands.
- They require more drinking water and more standing space than cows.
- Because of their poorly developed thermoregulatory mechanisms, buffalo need to wallow or need sprinklers during hot weather in order to keep their bodies cool.
- Their housing generally requires higher roofing to improve ventilation.
- Buffalo need stronger barriers than those used for cattle, and the wires should be closer together and lower to the ground to avoid having them lift the fences up with their horns.
- They must be handled quietly and calmly because of their timid nature.

TREATMENT

DIET

- Buffalo are more efficient in converting highly fibrous low-grade foods than domestic cattle. Paddy straw and crop residues are common feed sources.
- Buffalo are remarkable for their feed conversion ability.
- Buffalo have a larger gut with a slower passage of digesta and a higher rate of crude fiber digestion.
- They are better converters of nonprotein nitrogenous (NPN) compounds into protein than domestic cattle. This gives an opportunity to improve poor-quality roughage with various NPN compounds.

MISCELLANEOUS

Economic Considerations

- For thousands of years, this animal species has provided draft power, milk, meat, and hide to millions of people, mainly small-scale farmers.
- Buffalo are used for a variety of agricultural operations such as plowing paddy fields, lifting water from wells, and transporting farm produce to nearby markets.
- More than 5% of world milk comes from buffalo and 95% of it comes from Asia.
- India is the world's largest buffalo milk producer with about 35% of milk animals producing almost 70% of the total Indian milk.
- Buffalo feeding and management is cheaper than cattle feeding and management, and buffalo farmers also get a 50% higher price for their milk.
- Buffalo milk contains more total solids (16%) compared with the solids (12%–14%) found in cow's milk. Buffalo milk butterfat content is usually 6%–8% compared with domestic dairy cow butterfat levels of 3%–5%.
- Buffalo farming is one of the substantial secondary income sources for small farmers in Asia. Usually women take care of buffalo feeding, milking, and selling of milk.
- Water buffalo offer a major source of meat in Asia. The buffalo meat industry is expanding.
- Asia produces 91%–92% of the world's total buffalo meat, with India being the world's largest buffalo meat producer followed by Pakistan, China, Nepal, and Thailand.
- Carcass characteristics of buffalo are similar to domestic cattle with the average dressing percentage of 53%.
- Water buffalo also provide a major work force in Asia, and it is probably the most adaptable and versatile of all work animals.

WATER QUALITY ISSUES

BASICS

OVERVIEW

- The quality and quantity of water is important for health and productivity of ruminants. Some of the risks implicit in inadequate water quality include: decreased weight gains, poor feed conversion rates, and adverse effects on animals' health.
- Poor quality water and barriers to adequate quantity of water adversely affect growth, reproduction, and productivity resulting in loss of profitability.
- Physical, chemical, and microbial constituents determine water quality. The physical components can range from gross contamination of water by fecal, organic materials and biofilms to depth and condition of containers used to hold drinking water.
- Some chemical attributes of water can be detrimental to animal health at abnormal levels. These include pH, total dissolved solids (TDS), soluble salts, salinity, hardness, sulfates, nitrates, and nitrites.
- Ruminants are unique in that they are more sensitive to excess amounts of both nitrates and sulfates. This is due to ruminal conversion/reduction to toxic forms of nitrites and sulfides. This sensitivity is not seen in monogastric species.
- The microbiological quality of water is also important. Standing and running water may contain *Escherichia coli*, *Salmonella* spp., *Leptospira* spp., fusobacterium, and cyanobacteria (blue-green algae).
- Water supplies containing excessive levels of nitrate, TDS, sulfate, and other constituents can affect growth and production of all classes of animals.
- Drinking-water quality and availability should be evaluated in a practitioner's differential diagnosis for poor performance or nonspecific disease conditions in livestock.
- Evaluating water quality includes obtaining a thorough history, evaluating chemical and physical components of samples, and asking questions relevant to water safety. A thorough laboratory examination of animal specimens and water samples should be evaluated.
- The USDA's National Animal Health Monitoring System evaluated beef feedlot water sources for nitrate, nitrite, sulfate, and total dissolved solids in 1999. It tested 263 feedlots from 10 states. The results showed no water sample exceeded the recommended limits for nitrates, almost all samples had nitrite and total dissolved solids within normal limits, and approximately three-quarters of the water samples had sulfate levels considered safe.

All ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

Depending on water quality:

- Moderate rumen nitrites: decreased animal weight gains and poorer feed conversion rates
- Excess rumen nitrites: neurological signs of nitrite toxicity
- Excess rumen sulfides: neurological signs of polioencephalomalacia (PEM)
- Excessive alkalinity: physiologic and digestive upsets in livestock
- *Salmonella* spp.: diarrhea, fever, loss of production, abortions
- *E. coli*: gastrointestinal signs, coliform mastitis, septic meningitis/arthritis in younger animals
- *Leptospira* spp.: infertility, low or diminished milk production, widespread late-term abortion
- *Fusobacterium*: chronic lameness, possible sepsis
- Cyanobacteria (blue-green algae): muscle tremors, liver damage; can lead to death

CAUSES AND RISK FACTORS

- Breach in sound biosecurity protocols for management of drinking water
- Damaged casings in old wells
- Shallow wells are more easily contaminated with nitrogenous compounds than deep wells

DIAGNOSIS

- The U.S. Environmental Protection Agency (EPA) has recommended limits of certain pollutants and other substances found in water.
- [Table 1](#) compiles water quality recommendations in the United States.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Basic laboratory evaluation of water quality for livestock should include measurement of TDS, sulfate, nitrate-nitrite, and coliform bacteria. Supplementary water tests may include pH, sodium, iron, magnesium, chloride, calcium, potassium, manganese, and farm specific contaminants.

TREATMENT

Adequate water container hygiene for animals. Hygiene procedures include frequent cleaning and emptying of containers, proper maintenance of old wells, and applying appropriate disinfectant (e.g., chlorine < 4 ppm).

MEDICATIONS

N/A

CONTRAINDICATIONS

N/A

FOLLOW-UP

- Annual water tests are recommended for private wells, especially shallow wells. The water sample should be sent to a certified testing laboratory for analysis.
- The water analyses will typically include the following tests: total coliform bacteria, pH (acid or alkaline level), total dissolved solids, total soluble salt, salinity, hardness, nitrates, sulfate and other factors depending on location of the farm.

WATTLE CYSTS

BASICS

OVERVIEW

- Wattles are small pencil-like appendages of skin and cartilage located most commonly on the ventral neck and occasionally on the ears or face of goats.
- Wattle cysts are unilateral or bilateral fluid-filled swellings at the base of the wattles or at the site of previous wattle amputation.
- Wattle cysts may enlarge over time or decrease in size if the contents leak through the skin surface.
- Wattle cysts are thought to be a developmental malformation of the second branchial cleft.

SIGNALMENT

- Wattle cysts occur in goats of several breeds; there is no sex predilection.
- Wattle cysts are present at birth but may go unnoticed until the animal grows and the cysts enlarge.
- Cysts may range in size from 1 to 5 cm and are filled with a clear fluid of varying consistency from thin to thick.
- Wattle cysts are reportedly heritable by an undefined route.

SIGNS

- Wattle cysts present as soft tissue swellings located subcutaneously at the base of the wattles or site of wattle amputation.
- Cysts are variable in size, shape, and fluid consistency but their location is diagnostic.

CAUSES AND RISK FACTORS

Wattle cysts are a heritable fault and may be considered a defect in show goats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Corynebacterium pseudotuberculosis* abscess
- Hematoma or seroma resulting from trauma

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Fluid aspiration using aseptic technique reveals clear, acellular fluid. Anatomic site is pathognomonic for the condition.

PATHOLOGIC FINDINGS

Histopathology reveals walls of stratified squamous epithelium with hair follicles and occasionally cartilage.

TREATMENT

Surgical removal of the superficial subcutaneous intact cyst utilizing local anesthesia may be considered for show goats. Goats have very thin musculature near the wattles and particular care should be made to avoid underlying structures such as the jugular vein and carotid artery.

MEDICATIONS

WEIGHT LOSS: BOVINE

BASICS

DEFINITION

Weight loss is defined as a decrease in body weight. The loss may be acute, chronic, physiological, or pathological. Although it is not considered a weight loss, decrease in daily weight gain is an abnormal physiological condition as well.

PATHOPHYSIOLOGY

- Weight loss may occur as a result of anorexia, increment of nutritional requirements, unbalanced diets, or a combination of these factors.
- Anorexia may be pathological or physiological. Pathological anorexia occurs secondary to any systemic disease or local condition affecting the digestive system or oral cavity.
- Physiological decrease in feed intake may occur during the last month of gestation and the first weeks of lactation. This depression is markedly evident at calving and during the peripartum period. Heat stress is another physiological condition noticeably affecting dry matter intake.
- Increment of nutritional requirements occurs under normal and pathological conditions.
- Fever or any inflammatory process including tissue damage increases nutritional requirements, mostly protein. Parasitism is a representative case of pathological weight loss.
- Examples of physiological increase in nutritional requirements include lactation, last trimester of gestation, and animal growth. Unbalanced diets, especially diets deficient in microminerals and vitamins, and diets reduced in energy and protein may promote poor growth rates or weight losses.
- Weight loss may be acute or chronic.
- Acute weight losses are typical under pathological conditions that markedly affect dry matter intake such as lameness, rumen acidosis, and displaced abomasum or physiological conditions such as early lactation.
- Chronic losses are typical in pathological conditions such as parasitism, chronic diarrhea (e.g., Johne's disease), or physiological conditions such as aged animals.

SYSTEMS AFFECTED

- Dependent on gender and age of the animal
- Mature animals decrease body weight primarily through the breakdown of fat reserves. Peripheral fat is initially utilized, followed by abdominal and perirenal fat. After fat utilization, animals catabolize muscle proteins.
- Musculoskeletal

GENETICS

Several genetic or congenital conditions might affect growing and performance. Examples include dwarfism, cleft lip/palate (palatoschisis), and ventricular septal defect.

INCIDENCE/PREVALENCE

Incidence of weight loss will depend directly or indirectly on the incidence of disease related to a decrease in feed intake or the increase of nutrient requirements. All lactating animals, especially during the first trimester of lactation, mobilize body reserves potentially losing weight and body condition.

GEOGRAPHIC DISTRIBUTION

Worldwide, a location where drought is common or the feed supply is compromised

SIGNALMENT

SIGNS

Anatomically depressed left paralumbar fossa, decrease in body condition score, and manifestation of skeleton prominences and emaciation

CAUSES

Any factor that depresses the animal's appetite, increases nutritional requirements, or inconsistent feed management (e.g., unbalanced diets, poor feed quality, macro/micro-nutrient deficiency, etc.)

RISK FACTORS

Diseased animals, environmental management (e.g., heat stress, mud, insect control, etc.), feed management, nutritional quality, drought, age, gender, physiological stage, season, location

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Weight loss may be difficult to diagnose.
- Might be secondary to other pathological conditions (see [Table 1](#)).

CBC/BIOCHEMISTRY/URINALYSIS

Anemia, altered white cell profile, altered albumin to globulin ratio, elevated nonesterified fatty acids, increased creatinine and blood urea nitrogen, increase of specific enzymes related to tissue damage (AST, alkaline phosphatase, GGT, creatine kinase), elevated ketone bodies, low micromineral levels

OTHER LABORATORY TESTS

Dependent upon specific disease condition(s) and differential diagnosis

IMAGING

May be helpful to rule out foreign body in individual animal

DIAGNOSTIC PROCEDURES

- Visual observation, body condition scoring, weight of animals, record analysis
- Assessment of management
- Complete dietary/nutritional analysis may be indicated.

PATHOLOGIC FINDINGS

Emaciation, decrease or absence of adipose tissue, especially in abdominal organs and decreased or stunted growth. Evaluate body condition scores.

TREATMENT

APPROPRIATE HEALTH CARE

Dependent upon whether the weight loss is secondary to a pathological or physiological condition.

NURSING CARE

Feed management

ACTIVITY

N/A

DIET

- Important in unbalanced diets or increased nutrient requirements
- Animals losing weight secondary to diseases may need special diets.
- Complete dietary and nutritional evaluation may be necessary.

CLIENT EDUCATION

Understanding weight loss that may be secondary to other conditions

SURGICAL CONSIDERATIONS

N/A

MEDICATIONS

DRUGS OF CHOICE

- Vitamins (A, D, E, B complex) and minerals (mostly microminerals), feed additives (monensin, probios, propionate, propylene glycol), growth stimulants may be indicated dependent upon weight loss.
- Treatment should be predicated upon disease condition.
- If lameness is evident, hoof care should be established.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

FOLLOW-UP

PATIENT MONITORING

Body condition scoring, feed evaluation, weight and behavior evaluation

PREVENTION/AVOIDANCE

Based on the primary cause of weight loss

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

Dependent upon the primary cause of weight loss

MISCELLANEOUS

ASSOCIATED CONDITIONS

Decrease in productivity

AGE-RELATED FACTORS

Older animals are more likely to lose weight inherent to aging; young stock are susceptible to diarrhea diseases.

ZOONOTIC POTENTIAL

Some infectious conditions (e.g., salmonella, leptospirosis, Johne's) should be considered as potential zoonosis diseases.

PREGNANCY

Can negatively affect growth and weight gain

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species

BIOSECURITY

Considered in the case of infectious disease associated with weight loss (Johne's disease, salmonellosis, etc.).

PRODUCTION MANAGEMENT

Adequate feed intake and environmental management

WEIGHT LOSS: GOATS

BASICS

OVERVIEW

- Chronic persistent weight loss
- In most cases, establishing a definitive diagnosis will allow the practitioner to institute appropriate therapeutic measures, correct deficient management procedures, or institute suitable prevention and control programs to reduce ongoing or future losses to the client.
- Through the use of careful clinical examination and knowledge of the likely causes of progressive weight loss, a definitive diagnosis can often be made, although this is not always possible, even with rigorous investigation.
- There are a number of reasons that goats may become thin: some are management related and some are related to disease agents that have a long-term negative effect on the animal.

SYSTEMS AFFECTED

Musculoskeletal; potentially all, depending on condition

GENETICS

SIGNALMENT

Species

Caprine

Breed Predispositions

- Dairy breeds include the Alpine, La Mancha, Nubian, Saanen, and Toggenburg breeds.
- Cashmere and Angora goats are common fiber breeds and the Boer, Kambling, Ma Tou, and Pygmy are meat breeds.

Mean Age and Range

N/A

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- History should include age and number of animals affected. Particular attention should be paid to composition of the diet or pasture, stage of the production cycle, deworming practices, pasture rotation strategies, and herd status regarding *Mycobacterium paratuberculosis* spp. avium, CLA, and CAE.
- Owner reports regarding appetite are important because Johne's disease is relatively unique in that severely affected animals often have good appetites.

PHYSICAL EXAMINATION FINDINGS

- A complete physical examination should be performed on any goat presenting chronic weight loss.
- Particular attention should be paid to pallor of mucous membranes and the presence of submandibular edema because these findings support the diagnosis of helminthiasis.
- Oral examination will reveal the presence of advanced age, oral erosions, and poor dentition.
- Physical examination will often reveal evidence of chronic infections such as pneumonia or external abscesses supporting

a diagnosis of CLA.

CAUSES AND RISK FACTORS

Common Causes

- Helminths
 - Gastrointestinal nematodes
 - Tapeworms
 - Flukes
 - Lungworms
- External parasites
 - Coccidiosis
 - *Mycobacterium avium* spp. paratuberculosis
 - Diet
 - Dentition
 - Internal abscesses due to caseous lymphadenitis (CLA)
 - Chronic infections including pneumonia and mastitis
 - Chronic organ dysfunction including kidney and liver disease
 - Caprine arthritis-encephalitis (CAE)
 - *Mycoplasma mycoides* arthritis
 - Foot rot: *Bacteroides nodosus* (*Dichelobacter nodosus*), *Fusobacterium necrophorum*
- Rare or exotic diseases
 - Scrapie
 - Tuberculosis
 - Meliodosis
 - Viral pulmonary adenomatosis (jaagsiekte)
 - Rinderpest
 - Peste des petits ruminants
- All listed causes are addressed in detail in separate chapters. The reader using this chapter to guide the diagnosis of a goat with chronic weight loss is encouraged to review all these chapters.
- Specific history and physical examination results unique to the above differential diagnoses will likely greatly increase or decrease their likelihood, focusing ancillary diagnostic testing if the diagnosis is not obvious following the initial examination and database.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Wasting Diseases

Amyloid
Bacterial infection
Behavioral—inadequate feed space
Blindness
Caprine arthritis-encephalitis (CAE)-interstitial pneumonia
Caseous lymphadenitis (CLA)
Cobalt deficiency
Cestodes
Chronic mastitis
Coccidia
Enterotoxemia

External parasites
Foreign bodies
Infection
Johne's disease
Locomotor problems—foot rot, foot scald, foot abscess, polyarthritis, fracture, nerve damage, rickets
Lungworms
Malnutrition
Nematodes
Neoplasia
Nutritional problems—copper, cobalt, protein, vitamin A deficiency; carbohydrate deficiency
Oral problems—tooth loss, disease
Orf
Pasteurella infection
Peritonitis-rumenitis, liver flukes, internal abscesses, intraperitoneal drugs
Plant toxins
Pulmonary adenomatosis
Rinderpest
Salmonella
Scrapie
Trematodes
Tuberculosis
Viral infections

Wasting/Inappetence

- Amyloidosis
- Bacterial infection
- Caprine arthritis-encephalitis (CAE)
- Chronic gastrointestinal parasitism
- Cobalt deficiency
- Johne's disease
- Ketosis
- Malnutrition
- Milk fever
- Neoplasm
- Salmonella
- Teeth/mechanical
- Viral infection

CBC/BIOCHEMISTRY/URINALYSIS

Dictated by the specific differential diagnosis being pursued

OTHER LABORATORY TESTS

- The initial database should include a routine fecal examination for helminth and coccidia oocysts, hematocrit and serum protein concentration.
- These tests will usually be sufficient to confirm the diagnosis of gastrointestinal parasitism, the most common cause of chronic weight loss in goats. The practitioner is cautioned that many goats with unrelated disease processes will have positive fecal examinations.
- A positive fecal is suggestive but not pathognomonic for gastrointestinal parasitism.

IMAGING

Dictated by the specific differential diagnosis being pursued

OTHER DIAGNOSTIC PROCEDURES

Dictated by the specific differential diagnosis being pursued

TREATMENT

Varies with cause

MEDICATIONS

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

- If a diagnosis of gastrointestinal parasitism has been made, a follow-up fecal examination should be scheduled 10 days after appropriate deworming to document the efficacy of deworming.
- Anthelmintic resistance has become widespread and common. Likewise, dramatic reductions in fecal egg counts unaccompanied by improvement in clinical signs is suggestive that a different or additional differential diagnosis is responsible for the chronic weight loss in the affected goat.

MISCELLANEOUS

ASSOCIATED CONDITIONS

See specific diseases.

AGE-RELATED FACTORS

Age hierarchies exist in feeding behavior.

ZOONOTIC POTENTIAL

Certain specific zoonotic diseases (e.g., orf, salmonellosis, tuberculosis) can cause weight loss. Care should be taken in the collection of diagnostic samples.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Caprine

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Management factors associated with weight loss:

- Low-quality diets or low-quantity diets
 - Goats should have a diet that consists of 8%–13.5% CP depending on the stage of their production.
 - Energy requirements will vary and are the highest during lactation. The best means to evaluate the ration is to have forage analysis performed.
- Inadequate feeder space
 - For multiple goats, ideally more than one feeder should be used.
 - 1.4 to 2 linear feet per head is required per goat.
 - Keyhole feeders work well.

- Inadequate space
 - With dry lot confinement, there should be 35–100 sq ft per animal.
 - Less individual animal space increases fighting and aggression.
- Breed-specific aggression
 - French Alpine and Toggenburg breeds tend to be more aggressive.
 - Nubians tend to be shy and submissive.
- Age hierarchy is also an important consideration.

Author: Jeff W. Tyler

WESSELSBRON DISEASE

BASICS

OVERVIEW

- Acute arthropod-borne infection of sheep, cattle, and goats
- The causative agent is a hemagglutinating flavivirus.

SYSTEMS AFFECTED

Liver, reproductive (occasional abortion), CNS in newborn animals, abomasitis

PATHOPHYSIOLOGY

- Adult infection usually subclinical
- Newborn animals with a high mortality.
- Virus infection occurs year round with little seasonal distribution.
- Abortive disease with congenital malformation of the fetus. Primarily malformation of the CNS with arthrogryposis in cattle and sheep.
- *Hydrops amnii* in ewes
- Associated with *Aedes* spp. mosquito infestation; warmth and increased ambient moisture content may play a part in viral maintenance. It can occur in conjunction with Rift Valley fever during heavy rainfall periods.

GENETICS

None

INCIDENCE/PREVALENCE

Varies with geographic location

GEOGRAPHIC DISTRIBUTION

Africa including Madagascar

SIGNALMENT

- Cattle, goats, and sheep; usually newborn; isolated from vertebrates and arthropod vectors
- The virus has been reported in horses, pigs, ostriches, a gerbil, a dog, a camel; serologic evidence exists in other wild ruminants.

PATHOLOGIC FINDINGS

- Lesions in adult animals are usually mild.
- Hepatomegaly and concomitant icterus are seen in young animals and feti.
- Abomasum mucosal petechiation and diffuse ecchymoses. Chocolate brown contents are usually evident secondary to the disease.
- Liver is generally yellowish, orange or brown.
- Mild, moderate to marked necrosis of liver parenchyma
- Individual or associated groupings of necrotic hepatocytes, which may contain eosinophilic inclusion bodies, are diffusely scattered throughout liver lobules. Kupffer cell proliferation is evident.
- Enlarged lymph nodes
- Gastrointestinal hemorrhage

SIGNS

- Abortive disease with congenital malformation of the fetus; primarily malformation of the CNS with arthrogryposis in cattle and sheep
- Anorexia, weakness, tachypnea, fever, listlessness

CAUSES AND RISK FACTORS

- Virus infection occurs year round with little seasonal distribution.
- Associated with *Aedes* spp. mosquito infestation; warmth and increased ambient moisture content may play a part in viral maintenance. It can occur in conjunction with Rift Valley fever during heavy rainfall periods.
- High mortality rate in lambs

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rift Valley fever, abortive diseases, toxic plant ingestion
- Wesselsbron disease is a milder infection than Rift Valley fever with lower morbidity and mortality, less liver destruction, and lower abortion rates.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

- Serodiagnosis is based on complement fixation, virus neutralization, and hemagglutination inhibition.
- Hemagglutination inhibition tests tend to cross-react.
- Intracerebral inoculation of newborn mice is used for virus isolation.
- Virus neutralization is utilized to confirm virus identity.
- Intraperitoneal injection into weaned mice is used to differentiate Wesselsbron disease from Rift Valley fever.

TREATMENT

No treatment is currently available. Prevention should be based on a sound vaccination program.

MEDICATIONS

N/A

Control

- Stable valuable animals.
- Avoid wet areas where possible.
- Immunization with an attenuated vaccine. Vaccinate 3–6 weeks prior to breeding. Vaccination of pregnant females may lead to abortions and congenital defects.
- Postvaccination immunity is lifelong.
- Mosquito control, though helpful, is difficult.

CONTRAINDICATIONS/POSSIBLE INTERACTIONS

N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Primarily malformation of the CNS with arthrogryposis in cattle and sheep.
- *Hydrops amnii* in ewes

AGE-RELATED FACTORS

Newborn animals with a high mortality

ZOONOTIC POTENTIAL

- In humans it can cause a generally nonfatal influenza, with occasional CNS involvement.
- Precautions should be taken to prevent human infection while performing necropsies of animals suspected of having Wesselsbron disease.

PREGNANCY

Abortive disease with congenital malformation of the fetus; primarily malformation of the CNS with arthrogryposis in cattle and sheep.

RUMINANT SPECIES AFFECTED

Sheep, cattle, and goats; potentially all ruminant species are affected.

BIOSECURITY

Virus infection occurs year round with little seasonal distribution.

PRODUCTION MANAGEMENT

Immunization with an attenuated vaccine. Vaccinate 3–6 weeks prior to breeding. Vaccination of pregnant females may lead to abortions and congenital defects.

SYNONYMS

N/A

WILD RUMINANT POPULATION HEALTH MANAGEMENT

BASICS

OVERVIEW

- As a result of ever-increasing public interest and awareness of wildlife-related issues, veterinarians are frequently asked to comment on, or become involved with, free-ranging wild ruminants.
- Direct involvement with an injured or sick wild ruminant may be relatively infrequent, whereas questions regarding specific wild ruminant diseases or more generalized health and management concerns may be encountered more frequently.
- In North America, tens of millions of wild ruminants occupy wide-ranging and varied habitats. They include: white-tailed, mule, and black-tailed deer; indigenous wild sheep; elk; moose; caribou; mountain goat; pronghorn antelope; bison; and a variety of nonnative exotics.
- Challenges regarding health management issues of wild ruminants cut across continents, from Africa and Asia to Europe and other regions of the world.

MISCELLANEOUS

Current Issues

- Many practitioners have not had the opportunity to develop extensive background and experience regarding wild ruminants and understandably are often not in a position to address issues with the same level of expertise as specialty trained wildlife veterinarians, biologists, or management experts.
- From a private practitioner's perspective, knowing one's limitations and where to go for assistance may be of greatest value.
- In North America, increasingly visible and controversial urban deer problems; issues relating to tuberculosis and brucellosis among deer, elk, and bison; periodic wild ruminant die-offs due to bluetongue (BT) or epizootic hemorrhagic

disease (EHD); and concerns regarding the spread of prion-induced chronic wasting disease (CWD) are representative of the scope of wild ruminant controversies upon which veterinarians are increasingly being asked to comment.

- Interventions directed toward maintaining and improving the “health” of wild populations are often far different than those undertaken on behalf of individual animals.
- The domestic/wild ruminant interface will continue to have importance for the veterinary clinician.
- The interrelationships of domestic and wild ruminant disease entities are numerous. For example, it is well recognized that North American bighorn sheep (BHS), *Ovis canadensis*, are negatively impacted by, and highly susceptible to, *Pasteurella* spp.-induced pneumonia, and that domestic sheep have played an integral role in the epidemiology of that disease complex.
- Management strategies designed to separate domestic and wild sheep populations have been useful in reducing outbreaks among wild sheep and enhancing their populations.
- Wild ruminant population reduction has been broadly implemented in outbreaks of tuberculosis and chronic wasting disease (CWD) among white-tailed deer (*Odocoileus virginianus*) in Michigan and Wisconsin, respectively.
- The basic epidemiologic principle of reducing population levels (coupled with limiting movement of live animals and carcasses) to lessen the opportunities for disease transmission can be, and have been, effective in advancing the long-term health prospects of wild ruminant populations.
- Intervention strategies impacting on wild ruminant health, in addition to local or regional population reductions may include the use of immunizations.
- In the United States, ongoing research efforts are focused on developing effective immunizations for elk (*Cervus elaphus*) and bison (*Bison bison*) as part of brucellosis control efforts in the Greater Yellowstone Ecosystem (GYE).
- Subsequent to the historic pandemics of rinderpest among domestic cattle and wildlife (to include numerous ruminant species) in Africa, the Middle East, Asia, and other regions, vaccination has emerged as the cornerstone of efforts undertaken by the Global Rinderpest Eradication Program.

Practitioner Roles

- The practicing livestock veterinarian is uniquely positioned to observe disease entities that may directly impact on wild ruminants as well as the domestic animal patient.
- Observing clinical disease in ruminant livestock may be the first indication of possible wild ruminant involvement.
- The international veterinary communities, along with national, state, and local practitioners and administrators, have a responsibility to conscientiously communicate in all areas of domestic and wild ruminant health and management in order to maintain the stability of food supplies, the environment, and the economies upon which the world is dependant.
- By undertaking some preliminary groundwork, one can ease the task of dealing with wild ruminant issues and assist in successfully responding to whatever questions/challenges may occur.

Useful Preparations

- Generate a list of important contacts
 - Federal/state/university diagnostic laboratories
 - Local/state wildlife/management specialists
 - State agriculture/domestic ruminant specialists
 - State and local public health departments
 - Wildlife disease focused organizations/associations
 - International contacts are generally accessible via federal and university-based contacts.
- Gain familiarity with federal/state/local regulations
 - Wildlife possession and treatment statutes
 - Reportable diseases
- Gain familiarity with important regional wild ruminant diseases
 - Diseases having domestic and/or human health implications (i.e., brucellosis, anthrax)
 - High visibility, ruminant/species-specific diseases (i.e., CWD)
 - Periodically occurring epizootic diseases (i.e., EHD/BT)
- Refer “management” issues to management professionals
 - Social and politically charged management issues belong with the responsible federal, state, or local agencies having scientific and legal oversight responsibility.

- When in doubt, obtain professional wildlife disease/management expertise!

Summary

- Successful efforts to effect useful management strategies impacting on the health of wild populations of ruminants must, by necessity, be a collaborative effort.
- The nature of the core professional training of veterinarians (domestic animal medicine and surgery) inevitably results in less rigorous attention being paid to training in wildlife diseases.
- Expanded training in this specialty results from post–veterinary school graduate education.
- Management issues involving free-ranging wild ruminants are primarily associated with the training of professional wildlife biologists, and not addressed in traditional veterinary education.
- Clearly, the relationship of domestic and wild ruminant foreign animal diseases (FADs), and the associated implications for bioterrorism, brings the importance of wild ruminant population health clearly into perspective.
- Vigilance in pursuing unusual wild animal mortality events is a critical element of the nation's focus on disease surveillance.
- It is essential, therefore, to combine the expertise of all animal/human health and natural resource professionals when considering the health of wild animal populations, be they ruminant or otherwise.

WINTER DYSENTERY

BASICS

OVERVIEW

- Acute, contagious diarrheal disease of cattle with worldwide distribution, occurring in closely confined cattle during winter months
- Usually recognized as dark, bloody, liquid diarrhea with concurrent drop in milk production, anorexia, and depression
- Clinical signs commonly observed either prior to or during diarrheal phase include nasolacrimal discharge and cough.
- Milk production decreases dramatically and clinical disease may persist for several weeks. Pregnant cows and recently fresh or lactating cows are most commonly affected. Calves may also demonstrate similar clinical signs and attack rates.
- Mortality is low, but morbidity is high in larger herds. Herds with prior history of winter dysentery are at greater risk of developing clinical disease.
- Winter dysentery has been reported in cattle worldwide.

PATHOPHYSIOLOGY

- To date, the exact cause is unknown. However, increasing evidence suggests that bovine coronavirus may be casual when appropriate animal and environmental conditions are present. Viral particles invade the colonic mucosa resulting in death and necrosis of the colonic epithelial cells.
- The loss of epithelial barrier function results in transudation of proteinaceous fluid and blood. The increased volume of fluid presumably results in loose, dark, and sometimes bloody stool.

SYSTEMS AFFECTED

Primarily gastrointestinal tract; careful evaluation of herd records may demonstrate mild respiratory signs and diarrhea in cows and calves on some dairies.

GENETICS

No breed predilection; more common in dairy animals

INCIDENCE/PREVALENCE

- Acute, contagious diarrhea in cattle that occurs sporadically in epizootic form during the colder months of the year
- Disease occurs more commonly in northern states (USA) and Canada, but also has been documented to occur in Australia, the United Kingdom, Europe, Israel, and Japan.
- Morbidity is generally high, with low mortality.

GEOGRAPHIC DISTRIBUTION

- Potentially worldwide, depending on time of year
- Disease occurs more commonly in northern states (USA) and Canada, but also has been documented to occur in Australia, the United Kingdom, Europe, Israel and Japan.

SIGNALMENT

- Primarily adult dairy cows, either soon after calving or within the first 100 days in milk
- Pregnant cows appear to be at reduced risk.
- Some outbreaks have been reported in beef cattle and feedlot calves.

Species

Dairy and beef cattle

Breed Predilections

N/A

Mean Age and Range

Calves may demonstrate similar clinical signs and attack rates as adult cattle.

Predominant Sex

Pregnant cows and recently fresh or lactating cows are most commonly affected. Calves may also demonstrate similar clinical signs and attack rates.

SIGNS

HISTORICAL FINDINGS

- Acute onset of voluminous, dark, and bloody diarrhea occurring in anorexic, depressed cows that have reduced milk production
- Reduced rumen fill and dehydration result in weight loss. Blood in feces may be mixed evenly in feces or may be present in clots. The feces generally have a fetid odor.
- Affected animals may develop diarrhea and respiratory signs (dyspnea, coughing, nasal and lacrimal discharge).
- Usually epizootic in nature with 10–100% morbidity. Most commonly in adult dairy cattle with dramatic reductions in milk production in the fall and winter. Winter dysentery has also been documented in adult beef cattle and feedlot calves.

PHYSICAL EXAMINATION FINDINGS CAUSES AND RISK FACTORS

- Cattle in herds with recent exposure and immunologic response to BVDV or BCV (> 4-fold increase in serum titer), cattle housed in tie stalls or stanchion barns, and facilities using the same equipment to manage manure as well as feed are at increased risk for development of winter dysentery.
- Cows with high fecal BCV ELISA antigen and high acute serum BCV IgG antibody titers that seroconvert (> 4-fold increase) are at greater risk for development of WD.
- Pregnant cows are at decreased risk for WD.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Diarrheic diseases caused by BVD virus, Coccidia, gastrointestinal parasites, *Salmonella* spp., *Campylobacter* spp., *Mycobacterium avium* subspecies *paratuberculosis* (Johne's disease), heavy metal intoxications (As, Cd), organophosphate toxicity, dietary induced gut disturbances
- *Mycobacterium avium* subspecies *paratuberculosis* is not often a problem in outbreak form.
- *Campylobacter* spp. has not been isolated from cattle with WD.
- Coccidiosis is not generally a problem in adult cattle, fecal evaluation may rule out coccidia and gastrointestinal nematodiasis.
- Heavy metal intoxication is often accompanied by high mortality in groups of cattle.
- Organophosphate intoxication includes acute death, neurologic animals, salivation, lacrimation, urination, and defecation.
- Diet-induced diarrhea is often accompanied by lameness, reduced milk fat, or protein/fat inversion.
- Bloody stool or diarrheic feces with blood clots may indicate clostridial enteritis (jejunal hemorrhage syndrome).

CBC/BIOCHEMISTRY/URINALYSIS

- Not generally helpful in diagnostics; if persistent, dysentery may result in anemia.
- Monitor PCV, hydration, and acid/base balance in chronic cases.

OTHER LABORATORY TESTS

Diagnostic testing including fecal culture for bacterial causes (*Salmonella* spp., *Campylobacter*, *Mycobacterium avium* subspecies *paratuberculosis*, serology for BVDV, BCV, IBR, Johne's, rotavirus, campylobacter, cryptosporidium, BRSV, BAV3, and BLV; fecal evaluation for viral particles (electron microscopy).

IMAGING

WOOL ROT

BASICS

OVERVIEW

- Fleece rot is a skin disease caused by prolonged and excessive wetting of the skin resulting in exudation and discoloration of the wool.
- It is characterized by superficial inflammation, seropurulent exudation, and putrefaction that attracts blowflies (*Lucilia cuprina*) to oviposition.
- Fleece rot causes severe financial loss through downgrading of wool and cutaneous myosis by blowflies.

PATHOPHYSIOLOGY

- The inciting factor is prolonged wetting of the skin and matting of the wool, for example from rain or dipping.
- Continued wetting of the skin for at least 8 days or 100 mm of rain will reproduce the disease.
- Temperature is not a factor in disease development.
- The primary factor for susceptibility is the sensitivity of the skin to prolonged wetting.
- Chronic wetting of the skin results in acanthosis, hyperkeratosis, and edema of the lower layers of the epidermis and subsequent infiltration of the area by neutrophils and other polymorphonuclear leukocytes (PMNs).
- Microabscesses form and exudate is discharged into the lower layers of the epidermis.
- Prolonged wetting of the skin, high humidity in fleece environment, and the availability of nutrients from serous exudates allow for indigenous skin flora, opportunistic flora, and bacteria such as *Pseudomonas aeruginosa* to proliferate.
- Chromogenic bacteria (*Pseudomonas* spp.) cause discoloration of the fleece. *P. indigofera* produces a blue color and *P. aeruginosa* produces a green color. Other bacteria may produce yellow, brown, greenish-brown, or red discoloration.

SYSTEMS AFFECTED

Skin and hair (wool)

GENETICS

- There is a genetic predisposition to fleece rot with some sheep breeds being more susceptible than others.
- There are differences among breeds and between individuals within a breed.
- Breeds with lower wax content, irregular fiber size, and thicker wool fibers are more susceptible.

INCIDENCE/PREVALENCE

- Common problem in sheep
- Incidence varies from 15 to 90%.

GEOGRAPHIC DISTRIBUTION

- Worldwide but most common in Australia and New Zealand during wet season
- Also of concern in South Africa and United Kingdom

SIGNALMENT

- Can occur in any age, sex, or breed of sheep
- Most common in younger sheep after succession of wet days from either rain or dippings

SIGNS

- Except for the fleece, sheep are otherwise normal.
- Some sheep may show evidence of pain, rubbing, and/or biting at affected skin sites.
- Lesions are most common on the dorsum with the skin becoming red-purple in the early stages followed by exudation and matting of the wool.
- Affected areas are wet and the wool easily epilates.
- Parting of wool in affected areas reveals exudation and commonly diffuse discoloration or bands of discoloration.

- Fleece rot is characterized by a greenish discoloration of the wool fibers with a seropurulent crust. Most common discoloration is greenish but it may be yellow, yellow-brown, or red-brown.
- Affected areas emanate a putrid odor and attract blowflies.
- General health is unaffected, but in cases with severe ulceration, death can occur due to sepsis.
- A chronic ulcerative necrotic dermatitis on the tail, udder, and legs associated with a greenish discoloration of fleece following excessive rain in the Mediterranean has been seen.

CAUSES AND RISK FACTORS

- Major cause is prolonged wetting coupled by a “less water proof” fleece.
- Fleece staple is a major factor in the cause of wool rot. A long fleece reduces skin wetability but, once wet, the skin and fleece dry out more slowly. Short staple fleece is rapidly penetrated by water but dries out more quickly.
- Compact fleeces with high wax contents are most resistant.
- Breeds with open fleece and poor staple structure are more prone.
- Susceptible sheep have smaller follicle groups and higher densities of follicle populations with more primary follicles; sheep with more secondary to primary hair follicle ratios are more resistant.
- Susceptible sheep have thicker wool fibers growing from primary follicles.
- Susceptible sheep have irregular wool fibers that retain water in the fleece longer making the fleece more susceptible to rot than resistant sheep.
- Resistant sheep have better fleece closure and higher wax content allowing water to run off the wool; sheep that are more “waterproof” are more resistant.
- Yellowish fleece color (high suint content) is found in more susceptible sheep.

DIAGNOSIS

- Clinical diagnosis based upon finding compatible historical (i.e., prolonged wetting) and clinical signs
- Characteristics of lesions
- If needed, bacterial isolation of causative agent
- Impression smears of exudate reveal gram-negative rods.

DIFFERENTIAL DIAGNOSIS

- Major differential diagnosis is dermatophilosis.
- Scab formation and skin ulceration are absent in fleece rot, but present in dermatophilosis.

CBC/BIOCHEMISTRY/URINALYSIS

Affected sheep may have leukocytosis and neutrophilia.

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Skin biopsy

PATHOLOGICAL FINDINGS

Skin biopsy shows suppurative intraepidermal pustular dermatitis and superficial folliculitis.

TREATMENT

- Affected sheep are not treated and it is usually of no benefit.
- Chemical drying of fleece may decrease wetness and incidence of fleece rot.
- A mixture of zinc and aluminum oxides with sterols and fatty acids applied as a mist may be protective.

- Chemical drying agents should be compatible with other dipping chemicals (i.e., insecticides).
- Prevention through selection of sheep with fleece resistant to wool rot is the most practical approach.

MEDICATIONS

N/A

PREVENTION

- Shearing sheep before wet season may minimize wool rot along with selection of breeds that are resistant to fleece rot.
- Some degree of control may be affected by selection of fleece rot-resistant sheep.
- Heritability of resistance is estimated to be between 0.35 and 0.4 and selective breeding programs are recommended for high-risk areas.
- A killed *P. aeruginosa* vaccine has been found to be protective against severe exudation and may be a viable option in the future.

POSSIBLE COMPLICATIONS

- Affected animals are susceptible to blowfly strike.
- Affected sheep may develop secondary *P. aeruginosa* infections of the skin characterized by granulomatous scabs on wool-free areas of legs and scrotum.

EXPECTED COURSE AND PROGNOSIS

N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Affected sheep are at risk for blowfly strike.
- Prolonged wetting of the skin may predispose sheep to “pink rot,” which is caused by a bacterial infection of the skin with *Bacillus* spp. Affected fibers are found at shearing and appear as a mat of wool in creamy pink exudate.

AGE-RELATED FACTORS

Wool rot is more common in young sheep.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Sheep

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

- Fleece rot is of major economic concern.
- Fleece wetability can be determined by taking a sample of staple and placing it in a wet plastic cylinder with one end in water. The mass of water taken up in a given time is measured. Results are consistent and capable of distinguishing

resistant sheep from susceptible sheep.

WOUND MANAGEMENT

BASICS

DEFINITION

- A wound is defined as a break in the epithelial integrity of the skin that could extend deeper into the dermis, subcutaneous fat, fascia, muscle, or bone.
- The healing process can be aided by providing the proper environment for living tissue to repair itself, but the best mechanism is the natural process.

SYSTEM AFFECTED

Musculoskeletal

SIGNALMENT

Any age, sex, species, or breed of ruminant

SIGNS

May vary depending on the severity and location of the wound

CAUSES

- *Penetrating or puncture wounds*: these are deceptive in nature and may appear minor, but should always be considered serious. Bacteria, dirt, and other foreign material are often carried into the deep tissue by the penetrating object such as a nail or piece of wood.
- *Incised wound*: injury made by a sharp object such as a knife, glass, or a thin metal object that leaves the wound edges cut rather clean.
- *Lacerated wounds*: unlike incised wounds, these have rough and irregular edges and are more prone to infection.
- *Abrasion*: a scrape, friction burn, or excessive rubbing are common in abrasions. They are a minor problem compared to the others and involve only the top layer of the skin.

DIAGNOSIS

- The decision to close a wound to achieve primary intention or to let it heal by secondary intention is often based on experience. This can be based, as guidance, on the “golden period,” which is the number of hours that a wound can heal with first intention. The length of time of the golden period varies with the blood supply to the region, the extent of injury, the degree of contamination, and the injury’s anatomic location.
- Any wound that shows signs of infection should not be closed. This is diagnosed by the presence of heat, pain, and swelling of the area. It should be cleaned and left open to heal by secondary or tertiary intention.

DIFFERENTIAL DIAGNOSIS

N/A

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

- *Ultrasonography*: Investigates the severity of soft-tissue injury, joint abnormality, periosteal lesions, and wounds
- *Radiography*: Necessary in puncture wounds and fractures to evaluate the severity of the wound and presence and location of a foreign body, and to establish a better treatment and management of the wound.

DIAGNOSTIC PROCEDURES

- Restrain the patient, chemically or physically, as necessary.
- Control bleeding. If the blood flow is profuse and pulsating, an artery may be severed and a tourniquet must be applied. Wounds that do not bleed in a pulsating manner may be controlled by a clean compress bandage directly over the wound.
- After bleeding is under control, examine the wound to evaluate the extent of injury and tissue damage.

TREATMENT

- Initial assessment of the injured animal should include vital signs, history, and location of the wound.
- Most wounds in ruminants can be managed with the aid of chemical restraint (tranquilization) and local and regional anesthesia. General anesthesia is indicated if the injury is extensive and during cast application.
- In the preparation of the wound, the edges should be clipped and scrubbed gently with an isotonic solution and germicidal agent. Excise and debride wound of dead tissue and foreign bodies.
- Most traumatic wounds are sutured but without undue tension. It is preferable to leave some wound edges apart, rather than apply sutures under pressure, because they will produce ischemia of the wound edges and a larger defect may result.
- Drains are indicated in the presence of unobliterated dead space or if there is likelihood of fluid accumulation.
- Penetrating or puncture wounds are usually not sutured but are allowed to drain. Subsequent irrigation may be necessary to flush out debris.
- Incised and some lacerated wounds are usually repaired by suturing, depending upon the degree of contamination.
- Abrasions that are cleaned respond well to many of the commercial products available for wound treatments.
- Systemic antibiotics are always recommended for the treatment of traumatic wounds, especially if heavily contaminated. To be effective, antibiotic administration needs to be initiated as soon as possible and adequate dosage levels need to be maintained.
- The use of local antibiotics or antibacterial agents is controversial. Exudate on the wound often prevents effective contact of the agent with the microorganisms and many local medications retard wound healing. But when *Pseudomonas* species are involved, betadine ointment is appropriate.
- Protecting a wound by bandaging may protect the area against further contamination, and also aids in the immobilization of the wound's edges, accelerating the healing process.

MEDICATIONS

- The vast selection of topical applications that are available makes choosing the proper medication difficult. Several of these compounds have questionable value, others may be harmful, and many will, in fact, retard the natural healing of the wound.
- It's always recommended to treat wounds with systemic antibiotics that are approved for use in food-producing animals.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Steroids should not be used in pregnant animals.
- Steroid use may undermine the healing process.

FOLLOW-UP

PATIENT MONITORING

- Check the evolution of the wound and its healing process, and supervise for any possible extended infection.
- Inappetence can be a sign of septicemia, so monitor the patient throughout the healing process.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Tissue necrosis, sepsis, and loss of function are all associated conditions.

ZOONOTIC POTENTIAL

Several secondary wound diseases are zoonotic. Care must be taken in the collection of laboratory samples and the diagnosis/treatment of affected animals.

PREGNANCY

N/A

RUMINANT SPECIES AFFECTED

Potentially, all ruminant species can be affected.

BIOSECURITY

Treat and or cull new animals for disease conditions prior to herd introduction.

YAK MANAGEMENT AND DISEASE

BASICS

OVERVIEW

- Yak (*Poephagus grunniens* or *Bos grunniens*) thrive in conditions of extreme harshness throughout Asia.
- Yaks are found predominantly in the Qinghai-Tibetan Plateau. The plateau extends over 2.5 million sq km (about 1 million sq mi) of Asia.
- Approximately 1.3 million yak are marketed in China annually. It has been estimated that the annual Chinese yak production is 226,000 tonnes of meat, 13,000 tonnes of fiber, and 170,000 hides. Chinese milk production was 1.4 million tonnes for 1989 and 715,000 tonnes for 1997. These estimates may be far below actual production levels.
- Yaks are mated for the first time when they are 3–4 years of age and generally calve every 2 years or twice in 3 years, producing 4–5 calves in a lifetime. Hybrids can calve annually.
- The average length of the estrous cycle is approximately 20 days (range 18–22 days) with the duration of estrus less than 24 hours. Estrus can be difficult to detect.
- Gestation length is around 258 days.

SYSTEMS AFFECTED

Production management, nutritional

GENETICS

- Hybridization of yak with cattle has been utilized to increase meat and milk production. The hybrids are usually found at lower altitudes and in less harsh environmental conditions than the typical yak environment.
- Hybridization commonly employs yak females mated to bulls of local cattle breeds and artificially with imported dairy breeds. Hybrids are mated back (back-crossed) to either yak or cattle bulls. F1 males are sterile.
- F1 yak hybrids adapt well to the local environment; backcross hybrids to cattle are less well adapted to the environment and a loss of heterosis generally occurs.

Yak Hybrid

- Hybridizing yak with *Bos taurus* or *Bos indicus* cattle: Holstein-Friesian and Simmental cattle are commonly utilized to increase milk production in yaks.
- Hybrids are less well adapted to harsh conditions and high altitudes and are generally managed at intermediate elevations and require improved husbandry practices.
- The first hybrid (F1) females reach sexual maturity earlier and are bred a year earlier than the average yak.
- F1 males are sterile.
- F1 hybrids generally grow faster and become larger than straight-bred yak.
- Backcrosses to yak (or to breeds of cattle) are smaller than the F1. Milk yield is higher in hybrids than in the straight-bred yak. Backcrosses give less milk than the F1. The fat percentage of the milk of hybrids is usually lower than that of yak.
- Reduced productivity, relative to the F1, makes backcross generations undesirable.

Nutrition

- Feed intake: yak consume less feed than cattle due in part to their smaller rumen capacity.
- Dry matter intake (DMI in kg per day) of the growing yak can be estimated as $DMI = 0.0165 W + 0.0486$ (W is body weight in kilograms), and that of the lactating yak as $DMI = 0.008W^{0.52} + 1.369Y(W^{0.52})$ (W is metabolic body weight, Y is milk yield, kg per day).
- Voluntary intake (VI) of the yak varies with the season and grazed plant heights. VI ranges from 18 to 25 kg of fresh forage in summer to 6 to 8 kg per day of poor-quality grass under colder grazing conditions.
- Other factors affecting feed intake levels include feed type, feeding conditions, environmental climate, age, animal size,

and sex.

- Rumen volume ranges from 32.3 to 66.8 liters in the mature yak.

Energy Nutrition

- The thermoneutral zone for the growing yak is estimated as 8°C–14°C.
- The fasting heat production (FHP) of the growing yak can be estimated as $FHP = 916 \text{ kJ per kg } W^{0.52} \text{ per day}$.
- The metabolizable energy requirement for maintenance (ME_m) in growing yak is around $460 \text{ kJ per kg } W^{0.75} \text{ per day}$.
- Metabolizable energy requirement in the growing yak can be estimated as $ME \text{ (MJ per day)} = 0.45W^{0.75} + (8.73 + 0.091 W) DG$ (DG in kg per day), where W is weight in kg and DG is daily gain (in kg).
- Researchers observed that lactating yak have better utilization of dietary energy than dry yak cows. Another study with lactating yak indicated that yak cows have a lower efficiency of metabolizable-energy utilization for milk production (averaging 0.46) than dairy cattle (*Bos taurus*).
- The daily metabolizable energy requirement of growing yak has been estimated as $ME \text{ (MJ/d)} = 0.45W^{0.75} + (8.73 + 0.091 W) DG$, where W is the body weight and DG is daily gain (kg), and the efficiency of utilization of metabolizable energy for growth (k_g) in yak is 0.49.

Protein Nutrition

- There is no difference in the digestibility of dietary nitrogen between lactating and dry yak cows.
- Yak can use nonprotein nitrogen as efficiently as domestic cattle.
- Rumen degradable crude protein requirements for maintenance ($RDCP_m$, g per day) in the growing yak are around $6.09W^{0.52} \text{ g per day}$.
- Crude protein requirements for daily gain ($DG \text{ } RDCP_g$, g per day) in growing yak can be estimated as $RDCP_g = (1.16/DG + 0.05/W^{0.52})^{-1}$.
- Total crude protein requirements for growing yak can be calculated as $RDCP \text{ (g per day)} = 6.09W^{0.52} + (1.16/DG + 0.05/W^{0.52})^{-1}$.
- Utilization efficiency of dietary protein in the yak differs with diet composition and feeding level, age, sex, body condition score, and animal production level (e.g., growth, lactation).
- Researchers reported no difference between lactating and dry cows in crude protein digestibility, although lactating yak tend to consume more feed than dry yak.
- Yak may have evolved a mechanism to recycle more nitrogen to the rumen than cattle.

Mineral Nutrition

- Mineral nutrition is poorly understood in the yak.
- Researchers have found that inorganic phosphate (P) is sufficient for various categories of yak (calves, heifers, dry cows, and lactating cows) during the warm season when grazing was on alpine meadows with good-quality pasture. But in the spring and early summer, dietary phosphate failed to meet yak requirements.
- Chinese researchers suggest that yak living in the Qinghai Lake area are suffering sodium (Na) and copper (Cu) deficiency and there may be a shortage of molybdenum on Tianzhu alpine rangelands.

Diseases Affecting the Yak

Bacterial Diseases

- Anthrax—common in many regions of Asia.
- Botulism—*Clostridium botulinum* (type C has been identified in Tibet).
- Brucellosis—common among yak throughout Asia. In Sichuan, Qinghai, and Tibet, sample groups of yak were tested over the period 1952–1981, and an average of 17.4% (1.8%–56.3%) tested positive. Researchers reported that between 13% and 17% of yak in various groups on Haiyan pastures in Qinghai province were positive. Both *B. melitensis* and *B. abortus* have been identified as infective agents. *B. melitensis* is more prevalent in China and *B. abortus* is more commonly isolated in the former USSR. *B. melitensis* strain Biovar 3 is found most commonly.
- Calf scours—in some herds, 30%–40% of calves develop diarrhea. This appears most common in spring-born calves; however, scours in young calves have been reported as a major cause of death in two studies with yak. Both studies isolated *E. coli*. Researchers reported a scour incidence of almost 80% within the first month of life. In another study, a mortality rate due to *E. coli* infection in yak calves was 20%–30%.

- Caseous lymphadenitis—tends to be herd specific
- *Chlamydia* spp.—*Chlamydia* spp. appear commonly in some yak herds. Researchers examined yak herds and found the incidence to be 10.8%. In another study, an incidence of 42.7% among 553 yak was found. Another study reported yak abortion outbreaks in Qinghai province caused by *Chlamydia psittaci* infection. Tests on serum samples collected from yak that had aborted showed positive tests in 45 of 155 samples.
- Contagious bovine pleuropneumonia—caused by *Mycoplasma mycoides* occurs in yak between 2 and 10 years of age. It is generally reported during the winter and spring months. Researchers reported a high incidence of 54% in Ganzi County of the Sichuan province. Other researchers reported an incidence of 1.9% for herds in Tibet with pleuropneumonia and a mortality of 17% among those affected.
- Leptospirosis—commonly reported as causing abortion in herds
- Mastitis—the incidence appears less than in domestic dairy cattle. Relatively low milk yield and the common practice of calf suckling may help decrease the incidence of mastitis. One outbreak in Hongyuan County in Sichuan was due to a streptococcal infection. Another study reported common bacterial isolates in yak herds in Nepal. Bacteria isolated from the milk samples were *Staphylococcus aureus*, *Streptococcus agalactiae*, other *Streptococcus* spp., and *Coliform* spp.
- Pasteurellosis—reported to occur every year as hemorrhagic septicemia. Researchers in Tibet (over the period 1976–1979) noted a 0.34% incidence of hemorrhagic septicemia among yak, with a mortality rate among affected animals of nearly 36%.
- Salmonellosis—common among yak in China. Generally reported in calves between 15 and 60 days of age. Isolates included *S. typhimurium*, *S. dublin*, and *S. newport*. Researchers found in five counties of Gansu province (1950–1980) a *Salmonella* spp. incidence rate of 40%, with a mortality of 35%. Studies from 25 counties in Tibet (over the period 1976–1979) recorded a 10.5% incidence rate with 56% mortality in Qinghai.
- Tetanus—common with punctures and shearing wounds
- Tuberculosis—susceptible to the bovine strain of *Mycobacterium tuberculosis*. Researchers tested 1749 yak in Tibet and found that 12.7% of animals reacted positively.
- Other bacterial diseases—include *Coxiella burnetii* infection, keratoconjunctivitis, and campylobacteriosis

Viral Diseases

- Bovine viral diarrhea/mucosal disease (BVD/MD)—researchers collected serum samples from yak herds in the northwestern and southwestern provinces of Shaanxi, Gansu, Ningxia, Qinghai, and Sichuan to determine antibody levels for BVD/MD. Detectable antibody levels in yak herds reached 30.08%, with the levels in Sichuan herds being the highest (38.46%), followed by Gansu (29.41%) and Qinghai (28%).
- Foot-and-mouth disease—commonly found in many yak producing regions of Asia
- Infectious bovine rhinotracheitis—Chinese researchers tested yak serum samples finding 45 samples positive to ELISA and 44 positive to serum neutralization test for infectious bovine rhinotracheitis.
- Rinderpest—yak are highly susceptible to rinderpest with reported outbreak mortality rates of 90%–100%.
- Other—rabies, vesicular stomatitis, calf diphtheria, and parainfluenza 3

Parasitic Diseases

Ectoparasitism

- Babesiosis—caused by *Babesia Bigemina*
- Hypodermiasis—hypodermiasis is a significant problem in yak. Researchers reported that out of 1149 yak examined in Sichuan province, hypoderma larvae were found in 84.2%. Young yak between 1 and 3 years of age were reported to be the most susceptible. Three varieties of *Hypoderma* spp. (*H. bovis*, *H. lineatum*, and *H. sine*) have been identified. *H. lineatum* is the most prevalent, accounting for 70%–80% of all cases.
- Ticks, fleas, lice, and mites—families of mites found on yaks include Psoroptidae and Sarcoptidae.

Endoparasitism

- Gid (coenurosis)—coenurosis is of economic importance in Bhutan. Animal mortality is caused by the intermediate stage of *Coenurus cerebralis*. About 70% of the gid cases were reported in young animals (1–2 years of age). Researchers reported the presence of hydatid cysts among 50 yak in Sikkim. Eighty percent were found to be positive for the gid. In China, the incidence of hydatid cysts in 535 Gannan yak examined was reported to be 41.8%.
- Liver fluke—common in China and caused by *Fasciola hepatica*. Economically, fascioliasis is one of the most important diseases in yak. Infestation rates of 20%–50% are not uncommon. Researchers in Nepal noted a 58% infestation rate in fecal samples evaluated for liver fluke eggs.

- Endoparasitism—in one study, researchers examined fecal samples collected at random from adult yak and yak calves from western Bhutan. Results showed that in adult yak, 19% were positive for *Strongylus* spp., while among the calves 37% were positive for *Strongylus* spp., 2% for *Coccidia* spp., and also 2% for *Trichuris* spp. Another study of yak in Sikkim showed a 62% helminth infection rate. Indian researchers reported that of yak fecal samples, over 50% were positive for various helminth eggs (i.e., *Trichuris*, *Strongylus*, *Dicrocoelium*, and *Ascaris*).

Miscellaneous Conditions

- Blue-green algae—a common condition in Bhutan secondary to seasonal algal blooms.
- Pyrrolizidine alkaloid poisoning—deaths among yak in Bhutan were found to be due to pyrrolizidine alkaloid poisoning. *Senecio* spp. predominated.
- Micronutrient deficiency—yak may have an inadequate copper uptake due to an inherently low capacity to absorb dietary copper.

INCIDENCE/PREVALENCE

Abortion and other causes of premature termination of pregnancy in yaks are between 5% and 10%; however, the percentage rises with interspecies hybridization.

GEOGRAPHIC DISTRIBUTION

- Yaks are found extensively on the plateau of western China and Tibet at altitudes from 2000 to 5000 meters.
- Chinese yak numbers are estimated to exceed 13 million, of which 15% are hybrids.
- Other areas with yak populations include Mongolia in the Hangay and Hovsgol mountains, Pamir in the west to Lake Baikal in the east, alpine areas of the northern Caucasus, the Yakutsk valley of Siberia (Yakutia), Nepal and Bhutan, Indian northern provinces and in the territory of Sikkim, in the alpine areas of Afghanistan and Pakistan, adjacent to the Qinghai-Tibetan Plateau; parts of Europe (including Switzerland and Austria), Canada, and Alaska.
- In addition, there are yak in zoological parks in Europe, North America, and Australia.

SIGNALMENT

Species

Yak (*Bos grunniens* or *Poephagus grunniens*)

Breed Predilections

Twelve yak breeds are officially recognized: Jiulong yak and Maiwa yak in Sichuan; Tianzhu white yak and Gannan yak in Gansu; Pali yak, Jiali (alpine) yak, and Sibu yak in Tibet; Huanhu yak, plateau yak, and the “long-hair-forehead” yak in Qinghai; Bazhou yak in Xinjiang and Zhongdian yak in Yunnan.

Mean Age and Range

- The Jiulong breed grows more rapidly than those of the plateau type.
- By 3 to 3 1/2 years of age, Jiulong males reach approximately 58% of their 6- to 6 1/2-year-old (mature) weight.
- Females at 1 year of age reach 5%–10% more of their mature size than males.

Predominant Sex

N/A

SIGNS

HISTORICAL FINDINGS

- Growth and development of the yak are highly influenced by environmental factors.
- Birth weight is low, ranging from 10 kg to 16 kg, and represents about 3%–7% of adult weight.
- Most calves are born from April to July, with May being the peak month for delivery. Birth weight can vary with month of calving.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Reproductive difficulties and abortion are not uncommon in yak.

AGE-RELATED FACTORS

- By 3 to 3 1/2 years of age, Jiulong males reach nearly 58% of their 6- to 6 1/2-year-old (mature) weight.

- Females at 1 year of age reach 5%–10% more of their mature size than males.

ZOONOTIC POTENTIAL

Anthrax, brucellosis, *Chlamydia* spp., *S. typhimurium*, *S. dublin*, *S. newport*, and tuberculosis are all zoonotic diseases. Care should be emphasized in the collection of laboratory samples.

PREGNANCY

Most calves are born from April to July, with May being the peak month. Birth weight varies to some extent with month of calving.

YEW TOXICITY

BASICS

OVERVIEW

- Yew, an ornamental shrub or tree, is one of the most toxic and relatively common causes of poisonous plant death in livestock.
- Three common varieties are kept as ornamentals: English yew (*Taxus baccata*), Japanese yew (*Taxus cuspidata*), and common yew (*Taxus accata*). They are woody perennial plants with flat evergreen leaves.
- The leaves are light green on their underside and are similar to pine needles but are broader in needle width. Animals are poisoned when yew plant trimmings are thrown into the pasture or if yew is planted within browsing reach. The yew berry is bright red in color and grape sized.

PATHOPHYSIOLOGY

- The toxic compound is taxine, which is a cardiotoxic alkaloid. It is rapidly absorbed from the gastrointestinal tract and interferes with cardiac function by inhibiting sodium and possibly calcium channels.
- The various cardiac effects include bradycardia, ventricular dysrhythmias, cardiac arrhythmias, third degree heart block, ventricular tachycardia, ventricular fibrillation, and cardiac arrest.

SYSTEMS AFFECTED

Cardiac and nervous systems

GENETICS

N/A

INCIDENCE/PREVALENCE

Sporadic; Iowa State University diagnostic laboratory reported 10 to 12 cases per year.

GEOGRAPHIC DISTRIBUTION

Found throughout the United States, Australia, and Japan. However, it is found in many parts of the world.

SIGNALMENT

Animals consuming yew are usually found to have died suddenly. Livestock may die within 15 minutes of consuming the plant.

SIGNS

- A truly sudden death in animals that were otherwise healthy. If affected animals are seen prior to death, some show no obvious clinical signs whereas others may suddenly collapse or become downers for a short time prior to death.
- Cardiac auscultation should reveal dysrhythmias and bradycardia depending on the amount of yew consumed.
- Other signs such as depression, trembling, gastroenteritis, dyspnea, and convulsions have also been reported. Animals are commonly found dead.

CAUSES

Many cases result from a well-meaning neighbor or owner that feeds the evergreen trimmings or whole plants to livestock. Some cases may occur due to livestock getting into or being allowed access to the plant in nonpastured areas such as yards or parks.

RISK FACTORS

- Animals on marginal diets may be most apt to consume larger quantities of the plant. However, the plant is extremely toxic and quantities as small as 0.5% body weight can result in death in ruminants.
- Dried/wilted plants are equally toxic. One bite of the plant will kill an ewe or cow within 5 minutes. The plant is apparently very palatable to livestock.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Anything that will cause sudden death such as arsenic, lead, organophosphates, nitrates, cyanide, anthrax, clostridial myositis, electrocution, or lightning should be considered as differentials.

CBC/BIOCHEMISTRY/URINALYSIS

Due to rapid onset of symptoms, of questionable diagnostic value

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

DIAGNOSTIC PROCEDURES

Because death is so rapid postconsumption, evidence of the plant will be present within the animal's environment and upon necropsy will be found within the rumen.

PATHOLOGIC FINDINGS

Very little gross or microscopic evidence can be found, but the parts of the plant can be removed from within the rumen or stomach. In cases that survive 2–3 days prior to death, reddening/irritation of the gastrointestinal mucosa may be evident.

TREATMENT

APPROPRIATE HEALTH CARE

- Activated charcoal at an oral dose of 1–2 lb (2.2–4.4 kg) for an adult cow (one-half this dose for a mature ewe/doe) appears to be an appropriate alternative when rumen emptying/gastrotomy cannot be performed.
- All exposed livestock should be treated, as it is sometimes impossible to determine animals that have not consumed the plant. In one outbreak, complete cessation of death occurred postatropine and activated charcoal treatment.
- Cathartics may also be administered.

ACTIVITY

Affected stock should be handled with care so as to reduce excitement and exercise. Activity can induce additional cardiac dysfunction, which could lead to death.

DIET

N/A

CLIENT EDUCATION

- This is an educational experience within itself but the toxic and lethal effects of this plant should be emphasized.
- Cleanup of the source should be total and complete because all parts (except the flesh of the berry) are toxic even when dry or wilted. Alternatively, the contaminated area should be fenced off until complete cleanup can be conducted.
- Because of the potentially devastating effect on the owner that fed the plants to the livestock, grief counselors should be considered/consulted.

SURGICAL CONSIDERATIONS

- Surgery (rumenotomy) to empty the rumen of the toxic plants should be considered in valuable livestock and livestock with sentimental value.
- Taxine will continue to be absorbed as long as yew is in the gastrointestinal tract. Most outbreaks involve multiple livestock, making rumen emptying less practical.

MEDICATIONS

DRUGS OF CHOICE

Atropine is the drug of choice to help control bradycardia and cardiac arrhythmias. The recommended dose is 0.5 mg/kg with a quarter of this given IV and the rest administered IM or SQ. This dose can be repeated every 3–12 hours for 1 to 2 days, however rumen motility and subsequent appetite may be decreased.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Exercise and excitement may result in sudden death. Atropine can produce cessation of rumen motility.

POSSIBLE INTERACTIONS

N/A

ALTERNATIVE DRUGS

N/A

**FOLLOW-UP****PATIENT MONITORING**

Ruminants treated with rumen emptying should have rumen transfaunation performed at the time of surgery.

PREVENTION/AVOIDANCE

Don't feed yew and don't allow livestock access to areas that contain the plant (lawns around the home or buildings). Never allow yew plants or trimmings near cattle, sheep, goats, or any other animal that may consume the plant. The red yew berry is not considered toxic, but consumption is discouraged.

POSSIBLE COMPLICATIONS

N/A

EXPECTED COURSE AND PROGNOSIS

- Livestock that have been treated can be expected to survive, however relapses and possibly death may occur due to absorbed toxin when rumen emptying is not performed.
- Subsequent deaths did not occur in one herd in which atropine and activated charcoal were the only treatments.

**MISCELLANEOUS****ASSOCIATED CONDITIONS**

None

AGE-RELATED FACTORS

Neonates may be less likely to consume toxic quantities.

ZINC DEFICIENCY/TOXICITY

BASICS

DEFINITION

- Zinc is an essential trace element that is responsible for numerous critical cellular and molecular functions.
- Zinc deficiency has been shown to affect metabolism, growth, reproduction, immunity, endocrine functions, and cellular physiology at the molecular level.
- Zinc is primarily absorbed in the small intestine by either active or passive transport. Low concentrations of zinc in the intestinal lumen are largely absorbed by active transport, while high luminal concentrations can be passively absorbed.
- Zinc toxicity is rare, first because absorption of zinc from the intestine is reduced by the presence of large luminal concentrations. Second, as intracellular concentrations of zinc increase, production of the zinc-binding protein metallothionein (MT) is induced. Both of these mechanisms help to prevent toxic levels of zinc in the circulation.
- Peruminant animals are more susceptible to zinc toxicity than adults.

PATHOPHYSIOLOGY

- Zinc deficiency can cause a number of clinical signs and physiologic abnormalities. The diverse influence of zinc on physiologic functions of the body occurs because it allows DNA and RNA to fold into a functional conformation. Thus, cellular production of proteins, cell division, and cell growth are reliant on zinc.
- Zinc is also essential for action of a number of cellular signal transductions including calmodulin, protein kinase C, inositol phosphate formation, Na-K ATPase activity, protein phosphatase activity, thyroid hormone binding, and estradiol receptor binding.
- In a zinc-deficient state, any systems that have a high metabolic rate of cellular turnover will be adversely affected.
- Zinc deficiency is associated with the following alterations in systems throughout the body.
 - An alteration in prostaglandin metabolism occurs in zinc deficiency, which affects the arachidonic acid cascade, luteal function, and myometrial contractions.
 - Epithelial cells throughout the body have a high cellular turnover rate; therefore, any system that has epithelial cells is adversely affected. The gastrointestinal system will have a decrease in microvillus length that can lead to a maldigestive, malabsorptive diarrhea. The dermis has lesions consistent with parakeratosis. There is thymic hypoplasia and marked lymphoid depletion, resulting in immunosuppression.
 - Zinc deficiency has severe effects on the reproductive system in both male and female animals. Reproduction dysfunction in males includes degeneration of the seminiferous tubules and abnormal Leydig cell numbers and morphology, which are associated with reduced circulating testosterone and abnormal sperm development. Pregnant females will abort, have fetal mummification, lower birth weights, teratogenic defects, altered myometrial contractility, increased risk of hemorrhage postpartum, and reduced viability of offspring, depending on when the zinc deficiency occurs during gestation.
 - Alterations in immune function have also been reported in zinc-deficient ruminants; these include a decreased response to hypersensitivity, decreased CD4 positive T lymphocytes and B lymphocytes, and lymphopenia. Cellular immunity is affected by a decreased number of circulating neutrophils and macrophages.
 - Zinc deficiency causes an alteration in the ability of the liver to mobilize vitamin A. This can result in night blindness. It is believed that pathology of the blindness results from alterations in the metabolism hepatic retinal binding protein.
 - Alterations in the musculoskeletal system result in weak, listless animals that appear reluctant to move. Calves have a poor suckle reflex and reduced weight gain. It is believed that there is an alteration in the transport of ions across cell membranes that affects contractility of skeletal muscle. Overall bone density and size is also decreased in animals deprived of adequate zinc levels during growth.
 - Zinc deficiency affects appetite in two ways: (1) by limiting the production of neurotransmitters in the brain responsible for appetite stimulation, and (2) by reducing insulin's influence on carbohydrate metabolism.

- The pathophysiology behind zinc toxicosis has not been adequately defined. In general, toxic levels of zinc decrease feed intake and weight gain. High levels of zinc in the rumen alter microflora function, which results in a decrease in VFA production. The primary impact of excess zinc in the diet is in relation to its effects on hepatic copper storage and calcium absorption by the intestine.

SYSTEMS AFFECTED

- Dermis
- Gastrointestinal
- Endocrine system, specifically thyroid hormone, growth hormone, insulin metabolism, and testosterone production
- Reproduction
- Hepatobiliary function, in relation to vitamin A mobilization
- Immune system, primarily cellular immunity, but can affect humoral
- Musculoskeletal

GENETICS

- Bovine hereditary zinc deficiency is an autosomal recessive disorder that results in inadequate amounts of zinc being absorbed from the gastrointestinal tract. It is a hereditary disease that affects Friesian cattle.
- Inherited epidermal dysplasia is a lethal, single, autosomal recessive trait that affects Holstein-Friesian cattle in Canada. Death results from a failure to metabolize zinc.
- Inherited parakeratosis in shorthorn beef cattle is believed to be an associated zinc metabolic disease process. The mode of inheritance is a single autosomal recessive trait.

INCIDENCE/PREVALENCE

- The incidence and prevalence of zinc deficiency is dependent on whether the animals are being fed zinc-deficient forages. Areas that have low levels of zinc in their soil rarely report widespread zinc deficiency in ruminant populations.
- Zinc availability in feeds tends to be higher in legumes than in cereal grains. The exception to this occurs in some legumes with large numbers of zinc chelators that decrease the bioavailability of zinc ingested.

GEOGRAPHIC DISTRIBUTION

States/provinces in the western United States and Canada tend to have forages with low concentrations of zinc. This does not coincide with widespread clinical zinc deficiency, however.

SIGNALMENT

Species

Zinc deficiency can occur in all ruminants.

Breed Predilections

There is no breed predilection unless it is a hereditary disorder in zinc absorption or metabolism. In that case, Friesian cattle, Holstein-Friesian crosses, and shorthorn beef cattle are more susceptible.

Mean Age and Range

Young preruminant animals are more susceptible to development of clinical signs.

Predominant Sex

Male goats appear more susceptible to decreased zinc intake.

SIGNS

PHYSICAL EXAMINATION FINDINGS

Zinc Deficiency

- Diarrhea
- Excessive lacrimation
- Nasal discharge
- Excessive salivation
- Oral ulcers
- Hypopigmentation and poliosis
- Poor suckle reflex in calves
- Anorexia
- Skin lesions that consist of deep fissures that accumulate serum and crusting. The distribution of the lesions is the lateral

commissures of the oral cavity, behind the pinna, flank, external nares, perianal region, and the fetlocks.

- Stiff gait
- Poor weight gain
- Reduced milk production
- Reduced testicular development
- Night blindness
- Posthitis and vulvitis in lambs, due to enlargement of the sebaceous glands.

Zinc Toxicity

- Diarrhea
- Anorexia
- Decrease in weight gain
- Pica
- Polyuria
- Polydipsia
- Pneumonia
- Cardiac arrhythmia
- Seizures
- Decrease in milk production
- Submandibular edema
- Ulcers in the oral cavity and esophagus
- Gastritis

CAUSES

- Consuming a zinc-deficient diet
- Failure to absorb zinc from the gastrointestinal tract
- Failure to metabolize zinc once it is absorbed
- Excess copper in the diet can induce a zinc deficiency due to preferential binding by metallothionein
- Ruminants rarely succumb to zinc toxicity. Its primary cause is oversupplementation or ingestion of zinc-containing metallic objects.

RISK FACTORS

- Animals with high dietary levels of copper and iron are predisposed to zinc deficiency.
- Cattle that have a hereditary predisposition to zinc deficiency
- Ruminants that would have access to galvanized material or old car batteries could ingest a toxic level of zinc.
- Oversupplementation of trace minerals in feed can cause zinc toxicity.

DIAGNOSIS

- A chemistry profile can be run to evaluate alkaline phosphatase levels. The levels decrease concurrently with zinc plasma levels. Alkaline phosphatase declines about 10 days after the decline in plasma zinc.
- Plasma or serum zinc levels can be measured. Care needs to be taken to insure that blood is collected in royal blue top tubes that do not have zinc in the stopper. Normal values can range between 0.8 and 1.2 mg. Zinc supplementation should begin if plasma levels are below 0.5 ppm.
- Declines in zinc and in alkaline phosphatase precede the presentation of clinical signs.
- Zinc toxicity, serum bilirubin, and alkaline phosphatase levels are elevated.
- Zinc levels can be assessed from the liver, kidney, and urine. Liver levels are variable and not specific.
- A feed analysis can also be done to assess trace mineral levels in feed.

DIFFERENTIAL DIAGNOSIS

- Vesicular diseases

- Systemic infections
- Ectoparasites
- Conditions causing gastritis and/or diarrhea
- Conditions causing infertility
- Conditions causing respiratory diseases
- Conditions causing congenital malformations of the fetus
- Ketosis
- Copper deficiency
- Vitamin D deficiency or calcium, phosphorus imbalance
- Vitamin A deficiency
- Laminitis
- Lyme disease
- Diabetes mellitus

CBC/BIOCHEMISTRY/URINALYSIS

Zinc Deficiency

- Lymphopenia
- Decreased alkaline phosphatase
- Decrease in carbonic anhydrase
- Decrease in liver alcohol dehydrogenase
- Decrease in free T4

Zinc Toxicity

- Hemolytic anemia with a regenerative response
- Increase in bilirubin
- Increase in alkaline phosphatase
- May see an increase in BUN
- May see an increase in creatinine
- Hematuria
- Proteinuria
- Urinary casts

OTHER LABORATORY TESTS

- Erythrocyte metallothionein concentrations can be measured using enzyme-linked immunosorbent assay. The metallothionein concentrations decrease in zinc deficiency and the levels are unaffected by transient plasma zinc concentrations, but are affected by other metallo-ions.
- Zinc salivary concentrations can be measured too, but are not specific.
- Hair and fleece zinc concentrations can be measured, but there is a lot of variability in the concentrations so it is not very specific.

IMAGING

None

DIAGNOSTIC PROCEDURES

A liver biopsy can be performed to assess zinc concentrations.

PATHOLOGIC FINDINGS

Zinc Deficiency

- Parakeratosis is a classic finding in zinc deficiency. The distribution of lesions is the mucocutaneous junctions, the inguinal area, below the fetlocks, around the pole and the stifles.
- Poliosis (lightening of the hair around the orbits)
- Loss of crimping in wool
- Deformed hooves
- Oral and esophageal ulcers

- Thymic atrophy in young animals
- Decreased long bone length in growing animals
- Inflamed gastrointestinal mucosa
- Decreased accessory sex gland size
- Abnormal morphology of sperm
- Histopathological examination of the male reproductive tract will reveal a decrease in Leydig cell numbers and degeneration of the seminiferous tubules.
- Histopathological examination of the immune system will reveal a depletion of lymphoid tissue in the spleen, lymph nodes, and Peyer's patches.
- Histopathology examination of the dermis may reveal irregular epidermal hyperplasia, marked neutrophilic exocytosis, and extensive confluent parakeratosis.

Zinc Toxicity

- Pulmonary emphysema
- Pale myocardium
- Hemorrhage in the cortex and medulla of the kidney
- Degenerative changes in the liver

TREATMENT

Zinc Deficiency

- Several forms of oral zinc supplementation can be used to correct zinc deficiency. The most common forms used are zinc oxide and sulfate.
- Antibiotics may also be administered prophylactically to prevent secondary opportunistic infections.

Zinc Toxicity

Removal of the source of the zinc is the first step. For ruminants, that may mean doing a rumenotomy and removing a zinc-containing object from the rumen.

APPROPRIATE HEALTH CARE

- Supportive fluid therapy may be warranted, if diarrhea could result in dehydration.
- May need to supply nutritional support in the form of total parenteral nutrition if a malabsorptive, maldigestive diarrhea persists.
- Clean, dry environment to prevent infection of cutaneous lesions

NURSING CARE

Supportive therapy and ancillary treatments should be given to address any presenting clinical signs.

ACTIVITY

Animals will usually self-limit activity.

DIET

- Make sure that the animals are consuming balanced rations with all essential minerals and nutrients.
- In zinc-deficient areas, producers can treat soil and forages with zinc-rich fertilizers.
- Salt licks containing 1%–2% zinc can be provided as a supplemental mineral source.
- Lactating and pregnant animals have increased zinc requirements, but most feed sources accommodate the increased need.
- In general, dietary zinc requirements will vary according to production status.
- Most ruminants require between 20 and 40 mg of zinc per kilogram of body weight daily.

CLIENT EDUCATION

- Zinc deficiency is not a significant problem even in deficient-soil areas. Be sure clients understand the importance of trace mineral supplementation.
- It is important for clients know what environmental hazards may be present on their farms that can lead to zinc toxicity. Usually, this is not a problem unless the pasture contains a lot of mechanical debris that ruminants may chew on. Areas that are enclosed with galvanized fencing could have shards of material that ruminants could ingest. The galvanized metal

will dissolve in the reticulum or rumen and release zinc slowly.

SURGICAL CONSIDERATIONS

- If zinc deficiency is diagnosed, correct the deficiency prior to performing any elective surgeries to avoid delayed wound healing.
- Remove metal objects containing zinc by rumenotomy if necessary.

MEDICATIONS

Zinc Deficiency

- An oral drench or bolus of zinc sulfate, oxide, or acetate can be used on animals diagnosed with zinc deficiency. In preruminants, 1 gram of elemental zinc can be mixed into milk replacer or given by oral bolus in a gel cap. In adult cows, up to 14 grams of elemental zinc can be given every other day until clinical signs of zinc deficiency resolve or plasma zinc levels return to normal.
- An injectable suspension of 600 mg of zinc powder in 0.5 ml of oil can be prepared and injected intramuscularly in the neck.
- Antibiotics are warranted to prevent secondary bacterial infections.

Zinc Toxicity

Calcium disodium (EDTA) can be used to chelate zinc and prevent further absorption. It can also chelate other essential divalent cations such as copper, magnesium, and calcium.

DRUGS OF CHOICE

Zinc oxide, sulfate, and acetate; drug withdrawal periods for meat and milk must be monitored.

CONTRAINDICATIONS

Zinc is a metallo-ion that competes with copper, cadmium, and manganese for binding site on metallothionein. If excess zinc is administered, it can result in deficiency of these metallo-ions and vice versa.

PRECAUTIONS

See Contraindications above.

POSSIBLE INTERACTIONS

Phytates in the rumen can bind zinc and prevent proper absorption.

ALTERNATIVE DRUGS

None

FOLLOW-UP

- It is sometimes difficult to diagnose zinc deficiency; therefore, response to therapy should be monitored for definitive diagnosis.
- Alkaline phosphatase levels can be monitored in both zinc deficiency and toxicity, since they tend to stabilize prior to resolution of clinical signs.

PATIENT MONITORING

- The first clinical signs to resolve in adult ruminants are excessive salivation and diarrhea.
- As zinc deficiency is corrected in young calves, they will show improvement in their suckle reflex resulting in increased weight gain.

PREVENTION/AVOIDANCE

- Be aware if you are in a geologically zinc deficient area, and recommend supplementation to your clients.
- Be sure there are no stray sources of zinc in pastures that ruminants can ingest.

POSSIBLE COMPLICATIONS

None

EXPECTED COURSE AND PROGNOSIS

- Once diagnosed and treated, zinc deficiency will resolve quickly with few long-term effects. Young animals that have had zinc deficiency during periods of long bone growth may be stunted indefinitely. Male ruminants with decreased reproductive development will resume and continue development once supplemented without long-term effects on sexual productivity.
- Depending on the dose and persistence of exposure, zinc toxicity may have long-term effects on the animal's health and productivity.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Pneumonia
- Delayed wound healing
- Poor hair growth
- Poor reproductive performance

AGE-RELATED FACTORS

Young growing animals are more sensitive to zinc deficiency.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Zinc deficiency can cause congenital defects in the fetus of a dam affected during gestation.

RUMINANT SPECIES AFFECTED

All ruminant species can be affected with zinc deficiency and zinc toxicity.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

Feed a balanced ration with mineral supplementation.

APPENDIX 1

CLEANING AND DISINFECTION

BASICS

OVERVIEW

- Two important components of ruminant practice and effective biosecurity programs are cleaning and disinfection.
- This chapter will focus on the effectiveness of different products for specific disease agents, factors that may reduce their effectiveness, and important disinfection concepts for veterinarians to impart to their livestock-owning clients.

SYSTEMS AFFECTED

Production management

GENETICS

N/A

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on species and environment

SIGNALMENT

Species

Potentially all ruminant species

Breed Predilections

N/A

Mean Age and Range

N/A

MISCELLANEOUS

Diseases and Agents of Disease

- Viruses (enveloped and nonenveloped)
 - Enveloped viruses: BLV, BRSV, BVD, corona virus, cow pox (vaccinia), herpes mamillitis, IBR, MCF, papular stomatitis virus, PI3, rabies, vesicular stomatitis virus
 - Nonenveloped viruses: bluetongue, foot-and-mouth disease, papillomatosis, papillomavirus, rotavirus
- Bacteria (e.g., *Salmonella* spp., *E. coli*, *Mycoplasma* spp., *Staphylococcus* spp., *Streptococcus* spp., foot wart spirochetes)
- Protozoa (e.g., *Cryptosporidium parvum*)
- Fungi (e.g., ringworm)

Transmission

- Many of these disease agents can be carried on and transmitted by fomites.
- Possible fomites include: hands, needles, multidose syringes, ear taggers, tattooers, boots, coveralls, nose-tongs, halters, sleeves, feed buckets, and feed-hauling equipment.
- To reduce the possibility of disease transmission:
 - Clean and disinfect equipment between cows and between farms.
 - Clean table/truck/tires between farms.
 - Clean boots/coveralls between farms.

Use of Disinfectants

- Use the right product concentration for the right contact time.
- Most products are inactivated with too much manure or blood.
- The solutions may need rejuvenation to be effective.
- Clean the surfaces before disinfection.
- Disinfectants vary in their ability to kill different kinds of disease agents.
- They need to be stored properly.
- Read the *label*!

Types of Disinfectants

- Acids/alkalines
- Ammonia
- Alcohols
- Aldehydes
- Chlorhexidine (an antiseptic)
- Halogens: iodine/chlorine
- Peroxides
- Phenolics
- Quaternary ammonium

Acids and Alkalines

- Alters the pH and enzyme activities of microbes.
- Can be very caustic
- Examples include muriatic acid, acetic acid, and sodium hydroxide (NaOH).
- Acetic acid at 4%–5% (vinegar is 4%) can be effective against FMD virus.
- Sodium hydroxide (lye) at 2% can be effective against FMD virus. Add 2.7 oz lye to 1 gallon water.

Ammonia

- A single ammonium compound
- A 5% solution has some activity against *Cryptosporidium parvum*.

Alcohols

- Kill bacteria and enveloped viruses at many different concentrations
- No action against spores or nonenveloped viruses
- Require time to work
- Limited activity in presence of organic matter
- Damage to rubber and plastics, rapid evaporation and are flammable
- Irritation to skin with prolonged contact

Aldehydes

- Wide germicidal spectrum
- Slight to moderate residual activity
- Effective in presence of organic matter
- Irritating formaldehyde fumes, must be mixed properly, possible carcinogen
- Examples: formaldehyde, glutaraldehyde.

Chlorhexidine

- Bactericidal, virucidal, fungicidal, not effective against spore-forming bacteria
- Ineffective against some important species
- Maintains effectiveness in presence of organic material
- Inactivated by hard or alkaline water
- Some residual activity but must remain in contact for 5 min
- Some examples: Nolvasan, Chlorhex, Chlorasan solution

Halogens

Iodine and Iodophors

- Iodophors are combinations of elemental iodine and a substance that makes the iodine soluble in water.
- Iodophors are effective against bacteria, fungi, and many viruses.
- Not very sporicidal
- Act to denature proteins
- Least toxic
- Inactivated in presence of organic material; must have color to be potentially active
- Requires prolonged contact; poor residual activity; can stain clothing and porous surfaces. Examples include Betadine, Povidone, Weladol, One Step

Chlorines (e.g., chlorine bleach)

- Can eliminate both enveloped and nonenveloped viruses, fungi, and bacteria; not effective against spores
- Good, fast-acting disinfectants on clean surfaces, but quickly inactivated by dirt and manure
- Inexpensive
- More active in warm water than in cold water
- Available chlorine is taken up by organic material; therefore, often valuable to disinfect at least twice with this compound; no residual activity.
- Irritating to skin and corrosive to metal. Fumes are irritating.
- Examples: Clorox, Chloramine-T, and Halazone
- Sodium hypochlorite (NaOCL) or household bleach (stock concentration 5.25% available chlorine) is effective against most viruses at a concentration of 0.1%. Add 30 cc (ml) (or about 1/8–1/2 cup) of household bleach into a gallon of water or 1 gallon of bleach plus 50 gallons of water. A 3% solution is recommended for FMD virus (2 gallons of chlorine bleach to 3 gallons water).

Oxidizing Agents

- Hydrogen peroxide and other oxidizing agents like peracetic acid and propionic acids or acid peroxygen systems.
- Active against bacteria, bacterial spores, viruses, and fungi at quite low concentrations.
- These agents work better at higher temperatures.
- Retain more activity in the presence of organic material than iodine or chlorine-containing disinfectants.
- Good activity against anaerobes; not effective against spores
- Ineffective in presence of organic matter
- Examples include hydrogen peroxide; Virkon S is a combination of peroxides and an organic acid with a pH 2.6.
- Virkon S at 1% is labeled as being effective against FMD virus and is effective against *Mycobacterium avium paratuberculosis*–Johne's disease. Solution is stable for about 7 days.

Phenolics

- Phenols are coal-tar derivatives and turn milky in water. Phenols are effective antibacterial agents and effective against enveloped viruses.
- Work better at higher temperatures
- Retain more activity in the presence of organic material than iodine or chlorine-containing disinfectants
- Not effective against enveloped viruses and spores
- Not compatible with detergents, limited residual activity, and can cause tissue irritation
- Examples include Environ, One-Stroke, Lysol, Pine-Sol, Cresi-400, Discan, and Tek-Trol

Quaternary Ammonium Compounds

- These agents are bactericidal, virucidal (enveloped viruses) not sporicidal, limited fungicidal.
- Generally odorless, colorless, nonirritating, and deodorizing
- Have some detergent action and are good disinfectants
- Some inactivated in the presence of some soaps or soap residues, hard water salts
- Antibacterial activity reduced in presence of organic material
- Has some residual activity; noncorrosive
- Examples include Roccal, Germex, Zephiran.

Natural Disinfecting Agents

Natural forces that reduce pathogen loads in the environment include sunlight, heat, cold, drying (desiccation), and agitation.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

ASSOCIATED CONDITIONS

N/A

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

Many of the agents listed are zoonotic. Care must be taken in the diagnosis, cleaning, and disposal of potential infected materials.

PREGNANCY

APPENDIX 2

CLIENT COMMUNICATION

BASICS

OVERVIEW

- Good communication is the foundation of a good veterinarian-client relationship. It is among the most important factors determining the volume of future caseload from your clients.
- Client communication can be the most difficult yet the most important skill we must master to be successful. Many veterinarians have changed careers because of their frustrations in dealing with clients and coworkers. With so much riding on the quality of your communication, you should be compelled to be the best communicator possible. This requires that you take 100% responsibility for all communication in which you are involved. That means having good command of both ends of the communication process.
- Most financially successful veterinarians are not only skilled in a specialized area, but are very good at client communication.
- Clients frustrated by automatic bank tellers, electronic supermarket checkout stations, and similar depersonalizing machines will place ever-increasing value on their scarcer human contacts.
- Seek first to understand, and then be understood, be empathetic. Ask questions and let the client talk. If we start by finding out what clients think is urgent and important, they are more likely to be receptive to what we think they need to improve or manage better.

MISCELLANEOUS

Effective Listening Skills

The most significant of all client-veterinary rapport builders is good listening skills. It is extremely important to become a good listener. It will benefit your practice in the following ways:

- Accurate history—good listening skills allow for an accurate exchange of information, which is critical for serving the client and patient properly.
- Reduced misunderstandings—good listening skills help eliminate misunderstandings, thereby increasing client satisfaction with your services and enhancing their perception of your professional competence.
- Increased client rapport—when clients feel you understand them and have listened effectively, it creates greater client trust. Good listening improves trust and maximizes the probability of maintaining a professional relationship in the future.
- Differentiation—since most people are poor listeners, good listening skills will improve your practice competence.
- The initial interview—(1) shapes client perception of the veterinarian and staff; (2) defines the service to be provided in terms of both problem and goal, and (3) is an important opportunity for client education (e.g., production management, herd health improvements, possible increased client/producer profits). In many cases, the initial interview may in fact be the most significant communication before outcome determinative events.

Self-Evaluation Skills

- How good are you at communicating with your clients? Let us examine ourselves. Self-critical thinking involves our ability to evaluate objectively one's own thought processes and beliefs, with reflective skepticism.
- Francis Bacon stated, "Man prefers to believe what he prefers to be true." This is reinforced by a survey of one million high school seniors (Gilovich, 1991). Seventy percent thought they were above average in leadership ability, and only 2% thought they were below average. *All* students thought they were above average in ability to get along with others, 60% thought they were in the top 10%, and 25% thought they were in the top 1%. A survey of college professors showed that 94% thought they were better at their jobs than their colleagues (ibid).
- Self-critiquing with a positive attitude builds confidence. It's all about self-talk, what are we telling ourselves. We can control our subconscious.

Effective Communication with Your Clients

- Valuing client feedback
- Seven canons of client communications (adapted from Collins 2004, *Effective Communication with your Clients*).
 - Ignorance is folly.
 - Speed of reply to messages
 - Awareness of feedback
 - Treat all clients with courtesy.
 - Respect your client's confidentiality.
 - Correlating information between you and your clients
 - Securing client information

Being an Effective Listener

- There are two tests of effective listening:
 - Is the information being received and understood by the listener?
 - Does the speaker perceive that he/she is being understood?
- By necessity, most veterinarians are reasonably proficient as listeners. Since they rely heavily on information the client provides, they listen carefully to get the facts straight.
- However, many veterinarians are not as good at creating the perception that they are receiving the information.

Obstacles to Good Communication

- Most people are not very good listeners. It is estimated that only about 60% of spoken information is accurately received.
- There are several reasons the information doesn't get through (adapted from J.A. Kline, *Listening Effectively*):
 - The veterinarian/speaker is unclear or not specific enough causing the listener to make assumptions.
 - The listener is not paying attention due to lack of interest in the subject matter.
 - The listener is preoccupied with other matters.
 - The veterinarian/speaker is not saying what the listener wants to hear.

- The listener is busy formulating a rebuttal to something the speaker said previously.
- Most miscommunications are the result of poor listening, not poor articulation. Most people are passive listeners. Even when information is received and understood, the listener fails to acknowledge it.
- Passive listening also allows misunderstandings to go undetected.

Active Listening Skills

- The communication process consists of speaking and listening.
- Passive listeners take an active role in communication only when it is their turn to speak, leaving the process beyond their control at least half the time. Taking 100% responsibility for communication requires you to be specific and articulate in your own speech, and to actively facilitate the quality of the other party's communication when you are listening.

The Power of Questions

- Used properly, questions can give you great power in facilitating excellent communication with your clients as well as everyone else.
- Questions are the key to taking control of a conversation. The person asking the question is in control.
- Ineffective communicators don't ask enough questions. They tend to make statements and then stop, allowing the other person to make a statement. When you do that you relinquish control to the other party.
- The purpose of communication is the effective exchange of information.

Asking Relevant Questions (adapted from Italo, 1996)

The first rule of good communication is to ask frequent relevant questions. This is a very simple process where you listen carefully to the content and then ask questions that seek clarification, verification, motivation, or specificity.

- Clarification—Clarifying questions are those you ask when there seem to be inconsistencies or when you are not sure you understand what the person is trying to say. These questions are very important in avoiding misunderstandings.
- Verification—Verifying questions are questions you ask to verify that the information has been correctly received. It is particularly important to ask verifying questions when you have drawn a conclusion based on what has been said.
- Motivation—Motivational questions help you understand the reasons why people act and they give you insight into how they are likely to behave in the future.
- Specificity—People tend to speak in generalities. It is particularly important to ask specifying questions if the speaker is in an emotionally charged state. The more emotional we are, the more we tend to generalize. This is because our thought patterns become much more reactive and less analytical when we are upset.
- Relevant questions—Show interest in what the speaker is saying. When the speaker perceives you are interested, it creates a feeling of mutual respect.
- Acknowledging the speaker—There is little that is more frustrating than the feeling that someone you are talking to isn't listening. Speakers look for certain cues that acknowledge the message is being received. When speakers don't notice the cues they are looking for, they get the impression you aren't listening.
- Auditory and visual cues—When the speaker is speaking you should give both auditory and visual signs that you are listening.
- Listening check—This is a powerful tool that is extremely effective in creating rapport and improving the quality of your communication. A listening check is a statement that summarizes your understanding of what was just said. For instance: "So, what I hear you saying is that your sister is being unfair to you." There are two types of listening checks: listening checks for content and listening checks for feelings. Use listening checks frequently with your clients. It will improve your professional relationships.
- Don't get defensive—Defensiveness in communication only causes each party to become more entrenched in their position.
- Don't make the client wrong—No one likes to be wrong. If you make your clients feel wrong, it will surely embarrass them.
- Don't use absolutes—There are very few absolutes in life. Phrases using always, never, impossible, every, none, are seldom true and only serve to supercharge and polarize the conversation.
- Encourage interruptions—Interruptions are vital to good communication. They allow immediate feedback and prevent frustration and preoccupation. Encourage interruptions. You should also interrupt when appropriate. An appropriate interruption should be immediate making a comment or asking a question that is directly relevant to the speaker's latest idea.

- Use an open body language—Your body language communicates how you are feeling. You should be very aware of maintaining a friendly and open body language with clients. Lean forward and listen with interest. Don't cross your arms or legs. This makes you look uneasy and defensive.

Client-Veterinarian Communications

- Help staff members streamline, personalize, and customize their communications to individual clients.
- Help associates and staff effectively manage their services to their existing client base. Effective communications helps:
 - Deliver more revenue, a higher degree of client satisfaction, and higher client retention
 - Reduce the frequency and length of calls to the veterinarian
 - Eliminate misunderstandings and poor communications
 - Increase professional integrity
 - Allow staff and associates to track the results of the management implementation
- Empower client communications through:
 - A consultative approach to develop an effective solution to clients' agriculture- and management-based problems
 - A full array of integrated services that would enable clients to use one veterinary provider
 - Superior customer service, utilizing new technologies, while ensuring confidentiality and integrity

Client's Expectations, Objectives, and Options

With effective communication, veterinarians should discuss the following with their clients.

Client Objectives and Expectations

- Specific veterinary services the client will receive from the veterinarian
- Specific results the veterinarian is likely to achieve for the client
- Costs associated with achieving those objectives
- Time required to complete the veterinary services and achieve the results

Client's Instructions

- Choice of options or strategies the client instructs the veterinarian to pursue
- Impact of choosing particular options or strategies
- Estimated fees and disbursements relative to those instructions

Advice Given to the Client

- Options of treatments and procedures recommended by the veterinarian
- Explanation of the drug withdrawal times and the importance of a valid veterinarian

Client-Patient-Relationship (VCPR)

Referral to other veterinary, animal science, university or consulting professionals

Course of Action

- Strategy to be undertaken by the veterinarian
- Estimated length of time required to complete the plan of action

Risk Analyses

- The client's potential liability
- The veterinarians potential liability
- Risks or benefits associated with the services
- Veterinarian's and, if different from the veterinarian, the client's assessment of whether or not the likely outcome is justified by the expense or risk involved

Fees and Disbursement Communications

The veterinarian should provide the client with a timely estimate of the fees or disbursements involved so that the client is able to make an informed decision. The estimate should reasonably include the following.

Basis for Charging Professional Fees

- Hourly rate
- Flat fee
- Other method of charging

Amount and Payment Date of Any

- Initial monetary retainer
- Ongoing monetary retainers
- Accounts

Billing Frequency

- Facts or circumstances that form the basis of the cost estimate
- Possible facts or circumstances that may result in an increase or decrease in the estimate

Summary

- In your clinic, client communication starts with the receptionist who answers the phone. Is he or she warm, friendly, and helpful? If not, the clients will already be insistent and defensive when you talk to them.
- The words “no” or “we can’t” have harsh implications. You can always find a way around using it by saying “we’ll try, but” After all, we are always trying.
- If we recognize and have the desire to improve our communication skills, we need to take a critical look at our approach and how the client reacts to our suggestions.
- If your attitude is positive, there is always a better or improved way to deal with people.
- Communication is a life-long learning experience.

Tripelennamine hydrochloride, for allergic rhinitis

Tristeza. *See* Babesiosis

Triticum

Tritrichomonas foetus

Trypanosomiasis

TSE. *See* Transmissible spongiform encephalopathy

Tsetse disease. *See* Trypanosomiasis

TSH (thyroid stimulating hormone)

Tuberculosis

bovine

small ruminant

Tule elk, Johne's disease in

Tylosin

for acidosis

for bovine respiratory disease complex (BRD)

for *Chlamydia*

for chlamydiosis

for contagious bovine pleuropneumonia

for contagious caprine pleuropneumonia

drug interactions

for keratoconjunctivitis/conjunctivitis

for liver abscesses

for mastitis

for mycoplasmal infections

for necrotic stomatitis

Type I hypersensitivity. *See* Anaphylaxis

U

Udder. *See also* Mammary gland

cleft dermatitis

differential diagnosis of skin diseases of

edema

mastectomy

precocious

teat amputation

teat burns

teat lacerations

teat lesions

Udder intertrigo

Ulcerative posthitis

Ulcers

abomasal

corneal

sole

third compartment in South American camelids

ulcerative posthitis

Ultrasound

mammary gland

pregnancy diagnosis

umbilical hernia

Umbilical hernia

Urachus, patent

Urea nitrogen, analytical testing of

Urea toxicity***Ureaplasma***

Urethra, ruptured

Urethral catheterization

Urethral process amputation

Urinary PDG (pregnanediol-3 α -glucuronide)

Urinary system

acute renal failure

amyloidosis

leptospirosis

obstructive urolithiasis

pyelonephritis

urolithiasis in small ruminants

Urolithiasis

obstructive

in small ruminants

Urticaria

Uterine anomalies

Uterine neoplasia

Uterine prolapse**Uterine torsion**

Uterus didelphys

V

Vaccination. *See also* specific diseases and agents

beef cattle

cervidae

dairy cattle

sheep

Vagal indigestion

Vaginal/vulvar neoplasia

Vaginitis

Valgus deformity

Valve disorders. *See* Bacterial endocarditis

Variocoele

Varus deformity

Vasodilators, for congestive heart failure

Vasogenic shock

Vena cava thrombosis syndrome, posterior

Venereal disease

Campylobacter

granular venereal disease

trichomoniasis (trichomonosis)

Venooclusive disease. *See* Pyrrolizidine alkaloids

Verminous bronchitis/pneumonia. *See* Parasitic pneumonia

Vertebral body fractures

- Vertebral spondylosis
- Vertical hoof cracks
- Vertigo. *See* Coenurosis
- Vesicular exanthema
- Vesicular glands
 - examination of
 - seminal vesiculitis
- Vesicular stomatitis**
- Vestibular lesions, symptoms of
- Veterinary health certification**
