The discovery of the NO pathway represented a critical advance in the understanding of cell signaling and subsequently into major new advancements in many clinical areas including, but not limited to, cardiovascular medicine. This seminal finding was viewed as so fundamentally important that the Nobel Prize in Physiology or Medicine was awarded to its discoverers, Drs. Louis J. Ignarro, Robert Furchgott, and Ferid Murad in 1998, a short 11 years after NO was identified. Dr. Valentin Fuster, then president of the American Heart Association, noted in a 1998 interview that "the discovery of NO and its function is one of the most important in the history of cardiovascular medicine." In fact, development of NO-based drugs and therapies is a major priority for big pharmaceutical companies. Drugs like Viagra and Cialis for erectile dysfunction are effective because they affect the NO pathway, which allows for blood vessel relaxation and blood flow into the corpus cavernosum for penile erection. Enhancing this effect through dietary means may provide a safer and more natural alternative.

What is clear is that continuous generation of NO is essential for the integrity of the cardiovascular system, and decreased production and/or bioavailability of NO is central to the development of many disorders. The production of NO from L-arginine is a complex and complicated biochemical process involving a 5-electron oxidation with many cofactors and prosthetic groups carried out by a group of enzymes called nitric oxide synthase (NOS). There are three isoforms of NOS, neuronal NOS (nNOS or NOS 1), inducible NOS (iNOS or NOS 2), and endothelial NOS (eNOS or NOS 3). It is the NO produced by iNOS that is responsible for killing of bacteria. There are many steps or factors that may be altered and may affect ultimate NO production. Once produced, NO can be quickly scavenged before it has a chance to perform its actions. It is, therefore, a war of attrition when it comes to producing bioactive NO, and is a remarkable feat that this short-lived gas is responsible for so many essential cellular activities. Understanding strategies to restore NO homeostasis will represent a major breakthrough in disease management and prevention.

Nitrite and Nitrate in Human Physiology

Although the L-arginine–NO pathway was the first to be discovered, it does not necessarily mean that it is the primary pathway for the endogenous production of NO. In fact, nitrogen cycling in bacteria and production of NO as an intermediate in denitrification may be one of the most primitive pathways known, dating back to the Archean era. The now recognized human nitrate–nitrite–nitric oxide pathway that still relies on bacteria may be a redundant system for overcoming the body's inability to make NO from L-arginine. It appears that we have at least two systems for affecting NO production/homeostasis. The first is through the classical L-arginine–NO pathway. This is a complex and complicated five-electron oxidation of L-arginine and if any of the cofactors become limiting, then NO production from NOS shuts down, and in many cases, NOS then produces superoxide instead. The enzymatic production of NO normally proceeds very efficiently. However, in disease characterized by oxidative stress where essential NOS cofactors become oxidized, NOS uncoupling, or conditions of hypoxia where oxygen is limiting, this process can no longer maintain NO production. Therefore, one can argue saliently that there has to be an alternate route for NO production. It is highly unlikely that nature devised such a sophisticated mechanism of NO production as a sole source of a critical molecule.

This alternate route involves the provision of nitrate and nitrite reductively recycled to NO. Inorganic nitrite and nitrate are still considered at present in the media and public predominantly as undesired residues in the food chain or as inert oxidative end-products of endogenous NO metabolism. However, from research performed over the past decade, it is now apparent that nitrate and nitrite are physiologically recycled in blood and tissues to form NO and other bioactive nitrogen oxides. Nitrite is an oxidative breakdown product of NO that has been shown to serve as an acute marker of NO flux/formation. Nitrite is in steady state equilibrium with S-nitrosothiols and has been shown to activate soluble guanylyl cyclase (sGC) and increase the second messenger cGMP levels in tissues, activities very similar to NO.

Sources and Estimates of Exposure to Nitrite and Nitrate

The health concerns for exposure to nitrite and nitrate have been focused on the levels of nitrite and nitrate in the diet and primarily their content in cured meats. As with any compound, dose dictates poison and at high concentrations, pure nitrite can be toxic. The reported LD50 on a material safety data sheet (MSDS) is 175–180 mg kg^{-1} in rodents. The lowest acute oral lethal dose of nitrite has been reported to vary from 33–250 mg kg^{-1} body weight, which might be applied to children or the elderly. Estimates of the lethal dose of potassium nitrate (KNO_3^-) have ranged from 4 to 30 g. A realistic estimate of a

lethal dose in adults is 20 g nitrate ion or 330 mg nitrate ion per kilogram body weight. The National Academy of Sciences in 1981 concluded that 39%, 34%, and 16% of the dietary intake of nitrite were derived from cured meat, baked goods/cereal, and vegetables, respectively. More recent reports have shown that less than 5% of the total ingested nitrite and nitrate are derived from cured meat sources with the remainder coming from vegetables and saliva. In an assessment of nitrate, nitrite, and *N*-nitroso compounds in the human diet, it was concluded that vegetables contribute more than 85% of the daily dietary intake of nitrate and that endogenous synthesis is an important contributor to humans' overall exposure to nitrate. The National Research Council has estimated, based on food consumption tables, that the average total nitrite and nitrate intake in the USA was 0.77 and 76 mg, respectively. However, more sensitive and accurate analytical methods and changes in agricultural practices over the past few decades may have changed our consumption values. International estimates of nitrate intakes from food are 31–185 mg per day in Europe and in the USA approximately 40–100 mg per day. A healthy 70 kg person produces 1.68 mmol NO per day (based on 1 μmol (kg h)$^{-1}$ NO production). Using the conservative estimates of an average daily intake of 0.77 mg of nitrite would equate to 11.1 μmol per day and 76 mg nitrate would equate to 894 μmol per day or approximately 1 mmol of nitrite and nitrate per day from diet. This almost matches what our body makes from NO if we assume most of the NO goes to stepwise oxidation to nitrite and nitrate. Therefore our steady state levels of NOx, which are routinely used as clinical biomarkers of NO activity come almost 50% from diet. In fact, it has been suggested that people consuming certain diets, such as the dietary approaches to stop hypertension (DASH) diet get more than 1000 mg of nitrate. Nitrate is also used on toothpaste formulations in the form of potassium nitrate, designed for sensitive teeth (approximately 5000 ppm) representing a major source of exposure.

Human Nitrogen Cycle: Reductive Pathways to Produce NO from Nitrite and Nitrate

The bioactivation of nitrate from dietary or endogenous sources requires its initial reduction to nitrite, and because mammals lack specific and effective nitrate reductase enzymes, this conversion is mainly carried out by commensal bacteria in the mouth and gastrointestinal tract and on body surfaces. Nitrate from the diet is rapidly absorbed in the upper gastrointestinal tract. In the blood, it mixes with the nitrate formed from the oxidation of endogenous NO produced from the NOS enzymes. After a meal rich in nitrate, the levels in plasma increase greatly and remain high for a prolonged period of time (plasma half-life of nitrate is 5–6 h). The nitrite levels in plasma also increase after nitrate ingestion. Although much of the nitrate is eventually excreted in the urine, up to 25% is actively taken up by the salivary glands and is concentrated up to 20-fold in saliva. Once in the mouth, commensal facultative anaerobic bacteria reduce nitrate to nitrite during respiration by the action of nitrate reductases. Human nitrate reduction requires the presence of these bacteria – suggesting a functional symbiosis relationship – as mammalian cells cannot effectively metabolize this anion. The salivary nitrate levels can approach 10 mM and nitrite levels 1–2 mM after a dietary nitrate load. When saliva enters the acidic stomach (1–1.5 L per day), much of the nitrite is rapidly protonated to form nitrous acid (HNO_2; pK_a ~3.3), which decomposes further to form NO and other nitrogen oxides. Nitrite excreted in saliva has significant antibacterial properties. Nitrite also contributes to the bactericidal effects of gastric fluids as demonstrated by some studies on the food-borne pathogens like *Escherichia coli*. Nitrite and nitric oxide are also shown to have antibacterial benefits against *Helicobacter pylori*, certain strains of bacteria responsible for dental caries and skin pathogens. This human nitrogen cycle is illustrated in Figure 1.

Once nitrite is absorbed and circulated, it is taken up by peripheral tissues and can be stored in cells. The one-electron nitrite reduction to NO can occur in a much simpler mechanism than the two-electron reduction of nitrate by bacteria. The one-electron reduction of nitrite can occur by ferrous heme proteins (or any redox active metal) through the following reaction:

$$NO_2^- + Fe(II) + H^+ \leftrightarrow NO + Fe(III) + OH^-$$

This is the same biologically active NO as that produced by NOS, with nitrite rather than L-arginine as the precursor, and is a relatively inefficient process. Much of the recent focus on nitrite physiology is due to its ability to be reduced to NO during ischemic or hypoxic events. Nitrite reductase activity in mammalian tissues has been linked to the mitochondrial electron transport system, protonation, deoxyhemoglobin, and xanthine oxidase. Nitrite can also transiently form nitrosothiols (RSNOs) under both normoxic and hypoxic conditions, and a recent research demonstrated that steady state concentrations of tissue nitrite and nitroso are affected by changes in dietary NOx (nitrite and nitrate) intake. Furthermore, enriching dietary intake of nitrite and nitrate translates into significantly less injury from heart attack. Previous studies also demonstrated that nitrite therapy given intravenously before reperfusion (restoration of blood flow) protects against hepatic and myocardial ischemia/reperfusion (I/R) injury. Additionally, experiments in primates revealed a beneficial effect of long-term application of nitrite on cerebral vasospasm. Moreover, inhalation of nitrite selectively dilates the pulmonary circulation under hypoxic conditions *in vivo* in sheep. Topical application of nitrite improves skin infections and ulcerations. Furthermore, in the stomach, nitrite-derived NO seems to play an important role in host defense and in regulation of gastric mucosal integrity. All these studies together along with the observation that nitrite can act as a marker of NOS activity (reflective of total body NO availability) opened a new avenue for the diagnostic and therapeutic application of nitrite, especially in cardiovascular diseases, using nitrite as a marker as well as an active agent.

Oral nitrite has also been shown to reverse NG-nitro-L-arginine methyl ester (L-NAME – a NOS inhibitor) induced hypertension and serve as an alternate source of NO *in vivo*. In fact, a recent research report demonstrated that plasma nitrite levels progressively decrease with increasing cardiovascular risk. Because a substantial portion of steady state nitrite concentrations in blood and tissue are derived from dietary

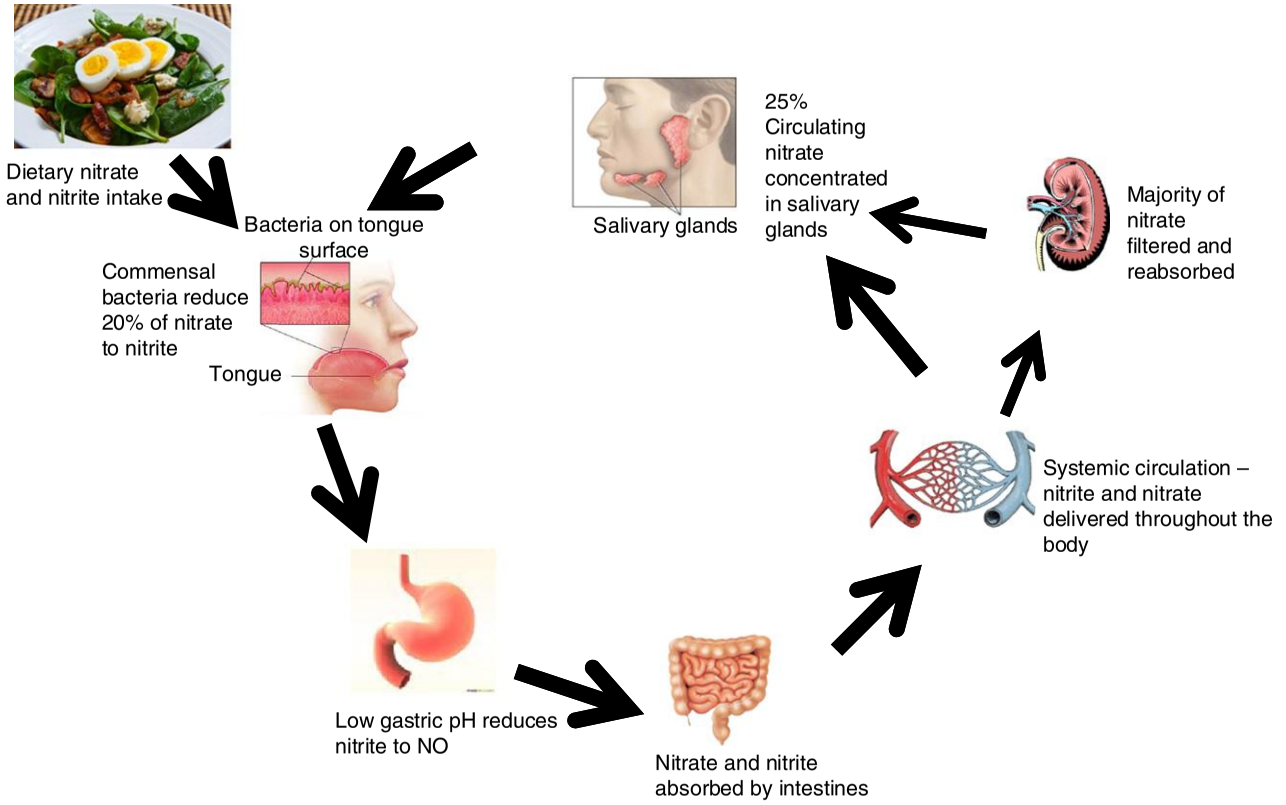

Figure 1 Human nitrogen cycle.

sources, modulation of nitrite and/or nitrate intake may provide a first line of defense for conditions associated with NO insufficiency. In fact it has been reported that dietary nitrate reduces blood pressure in healthy volunteers.

Conclusion

The emerging health benefits of nitrite and nitrate represent a profound change in paradigm from the past 50 years. Until now, scientists have operated under the paradigm of the L-arginine–NO pathway by NOS enzymes as the only pathway to produce NO. As shown in Figure 2, there are a number of recycling pathways to regenerate NO from dietary nitrite and nitrate. The emergence of a redundant pathway for maintenance of NO homeostasis by dietary nitrite and nitrate provides a new mode of intervention and a new paradigm for restoring NO homeostasis. The provision of nitrate and nitrite as sources of NO may then be viewed as a system of redundancy. Therefore, industry efforts to reduce nitrite and nitrate in the curing process may not be meaningful. In fact, nitrite and nitrate therapy or supplementation may restore NO homeostasis from endothelial dysfunction and provide benefit in a number of diseases characterized by NO insufficiency. If so, this will provide the basis for new preventive or therapeutic strategies and new dietary guidelines for optimal health. There are currently a number of clinical trials using sodium nitrite as a therapeutic agent (www.clinicaltrials.gov). From a public health perspective, better recommendations can be made on diet and dramatically affect the incidence and severity of cardiovascular disease and the subsequent clinical events. Replenishing nitrate and nitrite through dietary means may then act as a protective measure to compensate for insufficient NOS activity under conditions of hypoxia or in a number of conditions characterized by NO insufficiency. In fact, use of a rationally designed nitrite- and nitrate-enriched dietary supplement has been shown in a clinical trial to restore NO homeostasis and modify cardiovascular risk factors such as hyperlipidemia.

One cannot help but notice the emerging physiological data on nitrite are strikingly analogous to a vitamin. Vitamine or vital amine was the term coined by Casimir Funk (1884–1967) for the unidentified substances present in food, which could prevent the diseases scurvy, beriberi, and pellagra. A vitamin is by definition any of a group of organic substances essential in small quantities to normal metabolism, found in minute amounts in natural foods or sometimes produced synthetically: deficiencies of vitamins produce specific disorders. We may have identified a new vitamin, perhaps vitamin N. We know that nitrite is produced in relatively small quantities in normal metabolism of L-arginine and reduction of nitrate and is found in minute amounts in natural foods. Many animal studies reveal that nitrite insufficiency exacerbates I/R injury and increases mortality from I/R. There are a host of diseases that are associated with decreased NO availability as measured by nitrite. Becoming more evident is the

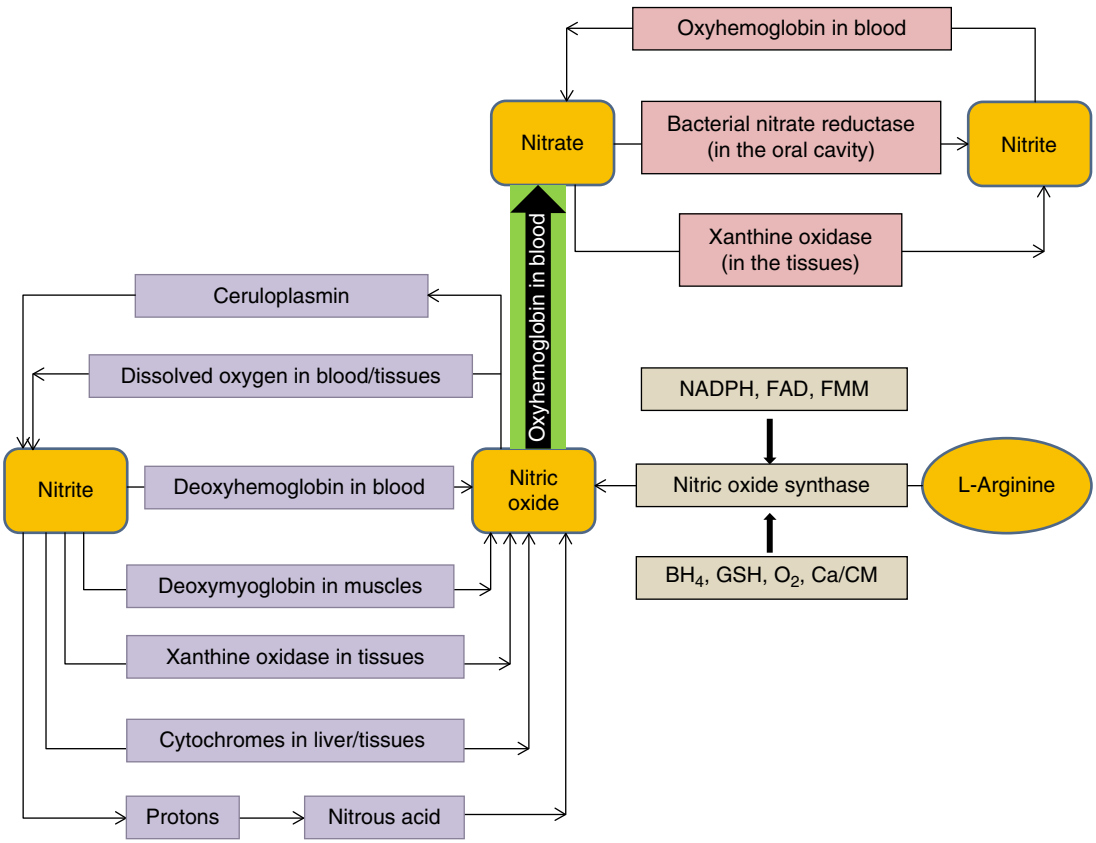

Figure 2 Different pathways of nitrite, nitrate, and NO in human body.

enormous benefit of exogenous dietary nitrite and nitrate in a number of disease models in animals and even in humans. Very little can affect our health more than what we choose to eat and our daily lifestyle habits. The realization of a nitrate–nitrite–nitric oxide pathway suggests that NO can be modulated by the diet independent of its enzymatic synthesis from L-arginine, for example, the consumption of nitrite- and nitrate-rich foods, such as leafy vegetables or meats to which nitrite is added. Diet and nutrition may be the key to NO-related therapies. After all it was Hippocrates who said, "Let food be thy medicine and medicine be thy food." The active agent of some medicinal foods may very well be nitrite.

Glossary

Brine A solution of salt (usually sodium chloride) in water. For meat curing, cure ingredients (sodium nitrite) are added to the salt solution to create a brine to affect a cure in meat.

Corned (beef) Granulated or grain salt was formerly called 'corn,' from old Old Norse, 'korn,' meaning grain.

Cure To preserve meat, as by salting with nitrates and/or nitrites, smoking, or aging.

Dry curing Salt containing nitrates and nitrites are rubbed by hand onto the surface of a meat cut or ham. The pork pieces are packed and left for a few weeks. The product is often overhauled during this period.

***N*-nitrosamines** Potential reaction products generated from nitrites and secondary amines of meat, most of which are carcinogenic. High temperatures, as in the frying of bacon, can enhance the formation of *N*-nitrosamines.

Prague powder 1 (Cure 1) A mixture of 1 oz of sodium nitrite (6.25%) to 1 lb of salt. Both Cure 1 and 2 contain a small amount of FDA-approved red coloring agent, which gives them a slight pink color thus eliminating any possible confusion with common salt; this is why they are sometimes called 'pink' curing salts.

Prague powder 2 (Cure 2) A mixture of 1 oz of sodium nitrite (6.25%) along with 0.64 oz of sodium nitrate (4%) to 1 lb of salt. Both Cure 1 and 2 contain a small amount of FDA-approved red coloring agent, which gives them a slight pink color thus eliminating any possible confusion with common salt; this is why they are sometimes called 'pink' curing salts.

Salometer A specially graduated hydrometer that measures the strength of brines. A 100° salometer reading is equivalent to a 100% saturated salt solution (26.5% salt).

Silent cutter Equipment for mixing and chopping meat and other products through the use of rotating knives.

Wet curing Sometimes called brine (salt and water), sweet pickle (sugar added), or immersion curing, this process has been traditionally used for larger cuts of meat like butts and hams. It is accomplished by placing the meat in a wet curing solution (water, salt, nitrites, and sometimes sugar). Sugar is added only when curing at refrigerator temperatures; otherwise, it may begin fermentation and start to spoil the meat.

Introduction

The origin of salting meats is lost in antiquity, but it is believed that the ancient Sumerian civilization, which flourished in the southern part of Mesopotamia during the fourth and third millenniums BC, was first to practice this process. From a historical perspective, meat curing can be defined as the addition of salt to meats for the sole purpose of preservation, that is, to inhibit or deter microbial spoilage. The preservation of meat resulted from necessity, so that products could be held for extended periods for later consumption. At some point, it was discovered that 'certain' salts (i.e., those containing saltpeter) could impart a unique color and flavor to meats. Granulated or grain salt was formerly called 'corn,' which comes from the Old Norse, 'korn,' meaning grain; thus, when beef was sprinkled with these salts, corned beef was the resultant product.

Scientific principles of meat curing were not applied until the early part of the twentieth century when the growing meat packing industry began to search for ways to improve quality and to extend the shelf life of products. It was discovered that nitrite, not nitrate as originally thought, plays a multifunctional role in the meat matrix: Nitrite is responsible for developing or 'fixing' the characteristic color associated with cured meats; for creating a special flavor so that one can distinguish the flavor of corned beef from that of roast beef; for imparting antioxidant activity to the cooked product, thereby extending its shelf life; and for suppressing the outgrowth and production of toxin from the anaerobic bacterium, *Clostridium botulinum*. Including nitrite at a minimum of 120 ppm also slows the growth of other pathogens such as *Clostridium perfringens* and *Listeria monocytogenes* as well as spoilage bacteria.

Meat color is an essential quality attribute of processed meat products and thus a key factor when consumers make their selections. The pigment responsible for the characteristic color of cooked cured meat products is nitrosyl myochrome/myochromogen (sometimes also referred to in the literature as nitrosyl hemochrome/hemochromogen). It is formed between the reaction of nitrite and the endogenous Fe–protoporphyrin (i.e., heme) meat pigments on thermal processing. In dry-cured ham such as Parma ham, salt is added but not nitrate/nitrite, and there is careful control of temperature and humidity during processing. During the long ripening period, a Zn–protoporphyrin with a stable bright red color is formed; this pigment has been isolated as the main component of red pigments found in these dry-cured hams.

The industry has evolved to the point that quite a diverse list of cured meat products offering great taste, convenience, and versatility is available to the consumer. On account of

 doi:10.1016/B978-0-12-384731-7.00114-8

household refrigeration, the original need to cure meats no longer exists; nevertheless, consumers have become accustomed to certain products in their diet and the increase in variety of products that curing offers. For these reasons, as well as others, the public still demands the availability of cured meat products in the market.

Regulations

Before outlining some curing production procedures, it is important to note that each country has its own set of regulations as to what additives are permitted in a particular meat product, what additives are prohibited, to what maximum level an additive may be used based on the weight of the meat block or the entire formulation, how the finished product must be labeled, etc. It is not within the scope of this article to detail all of the guidelines and exceptions to meat regulations for each country. Therefore, any quantity of an additive specified in this treatise is used solely for the purpose of illustration. For example, sodium nitrite is employed at the level of 156 ppm (0.4 oz 100 lb^{-1} meat) in comminuted products in the US, but this level is based on the weight of the meat block and not that of the finished emulsion or pumped product. In most European countries, ingoing nitrite levels are 100 ppm based on the meat. Canadian regulations, in contrast, permit the use of nitrite in not only the meat but also the complete emulsion or pumped product at the level of 200 ppm. Bacon is an exception to the rule, as ingoing nitrite levels are reduced in most countries: The regulated level in Canada and the US is 120 ppm or 0.012% based on the weight of the pumped product. Knowledge of the regulations is critical for domestic production. For instance, the USDA considers anything with less than 120 ppm uncured and must be labeled as such. Furthermore, processors who want to export their wares to foreign markets must adhere to each country's meat regulations/standards of identity.

Basic Ingredients Needed for Curing

Meat

The meat used in formulations can vary markedly, so careful selection of species and muscle type is required to produce a consistent product. The concentration of myoglobin present in the meats selected will ultimately determine the color characteristics of the cooked cured product. The quantity of meat used in a formulation is called the meat block. Seasonings and other nonmeat ingredients are added based on the weight of the meat block. Typically, a meat processor will calculate the formulation of products based on 100 lb or kilogram batches, but, of course, the actual weight of the batches produced will depend on the equipment available to the processor.

Water or Ice

Water serves as the carrier for curing ingredients in most commercial ham and bacon processing operations. It replaces moisture lost during thermal processing and smoking. In some cases, additional water is pumped into hams, so that the weight of the finished product exceeds its fresh, uncured weight (i.e., the green weight). In the US, labeling of extended products that include added water and other ingredients is based on the minimum meat Protein Fat Free (PFF) percentage. For example, hams with a minimum PPF of 20.5% are labeled as ham. Hams with a minimum PPF of 18.5% are labeled as ham in natural juices. The quality of the water or ice added to meat products directly, or in the form of the brine, can have a profound effect on the product. Low-quality water, as a result of contaminates, pH fluctuations, different sources or seasonal variation, can cause a reduction in the shelf life and create aftertastes and off-colors in products.

Salt

Salt or sodium chloride is the most basic ingredient for curing and is used in every formulation. Although it still affords some preservative effects, salt is primarily added to flavor meat and to solubilize myofibrillar proteins for the product's yield and texture. The amount of salt used in dry cures and brines can vary considerably but to some extent is self-limiting. Too little salt can cause excessive product shrinkage (i.e., not sufficient water-holding capacity), poor binding or emulsion stability (i.e., not sufficient protein extraction), and a reduced shelf life, whereas too much salt can impart an undesirable taste. Only food-grade salt of high purity (i.e., free of nitrite, nitrate, and heavy metal ions) is used in meat processing, as impure salts can impart flavor and color defects to products. One type of salt that has been getting more and more attention is sea salt. Sea salts are as varied as the water from which they are made. This is a favorite additive in natural and organic products. These salts, however, can cause problems because of contaminates including nitrites, nitrates, and heavy metals. The level of salt ranges typically from 1.0% to 2.8% in finished cured meat products.

Cure

After salt, sodium nitrite is the most important ingredient in the cure. It provides the characteristic color and flavor and works with salt to offer bacteriostatic protection against anaerobic bacteria such as *C. botulinum* and *C. perfringens* in processed meat products. It is generally added to pickles or meat formulations in the form of a 'curing salt.' Because it is difficult to accurately weigh out the small quantities of nitrite needed for a formulation, nitrite is preblended with sodium chloride to give a commercial curing salt. Prague powder and Cure 1 are examples of blends for such a curing salt, which is routinely utilized in North America.

Prague powder 1 is a mixture of 1 part sodium nitrite and 15 parts sodium chloride (i.e., 1 oz $NaNO_2$ in 1 lb of salt, or 6.25% $NaNO_2$). The chemicals are combined and crystallized to assure even distribution. An anticaking agent such as glycerin or 1% (w/w) sodium carbonate is commonly incorporated, and in some preparations a red food-grade dye, FD&C Red Dye 3, is added so that one can distinguish this 'curing salt' from regular salt in the processing plant. Depending on the ingredient supplier, the curing salt goes by different names, including sure cure, insta-cure, speed cure, modern cure, and pink curing salt. Prague powder 2 is a mixture of 1 part sodium

nitrite, 0.64 parts sodium nitrate, and 14.36 parts sodium chloride (i.e., 1 oz $NaNO_2$ and 0.64 oz $NaNO_3$ in 1 lb of salt, or 6.25% $NaNO_2$ and 4% $NaNO_3$). It is 'primarily' utilized in dry curing of meat products that do not require cooking, smoking, and refrigeration; however, Prague powder 2 can also be used in slow cured products that are cooked. In Europe, it is often referred to as bacon-curing salt.

When purchasing cure units for specific products (e.g., pepperoni preparation), the curing salt is packaged in a separate bag from all other nonmeat ingredients. This is important because nitrite can react with amines in seasonings, leading to the formation of *N*-nitrosamines. For example, in a 500-lb meat block formulation (i.e., for a US product), 1.25 lb of curing salt at 6.25% nitrite would be placed in a separate bag and put inside or attached to the outside of the main seasoning/binder bag. The operator would only have to add a bag of each product to the formula without additional weighing of the seasonings.

Sweetener

Sweeteners in the form of table sugar (i.e., sucrose), brown sugar, dextrose, corn syrup solids, honey, sorbitol, or lactose are often added to meat products as a flavoring ingredient. Their addition level can vary from 1% to 3% and is product dependent. These sweeteners help to counteract some of the sharpness imparted by salt and have a moderating effect on flavor. Dextrose in particular assists in the formation of the characteristic brown color on the external surface of country hams and bacon during thermal processing via the Maillard reaction and caramelization. The term 'glucose' used by some in the meat industry is a bit of a misnomer; it refers to corn syrup solids or 'glucose solids,' which is a hydrolyzed starch product, and not dextrose itself. Unlike corn syrup, corn syrup solids have a low sweetening power; they have different dextrose equivalents and hence browning potentials. Corn syrup solids are added to meat products for bulk and their ability to hold some water. Lactose also has a weak sweetening capability and may contribute bitterness in certain meat products but is present in sausages when nonfat dried milk is included in the formulation.

Erythorbate

Sodium erythorbate and ascorbate are reducing agents/cure accelerators, which speed up the conversion of nitrite to nitric oxide and thereby shorten the time required to complete the curing process. Residual amounts of erythorbate will also help stabilize the finished product's color. Moreover, erythorbate and ascorbate help to prevent the formation of carcinogenic *N*-nitrosamines that may form from secondary amino residues and residual nitrite in bacon.

Polyphosphates

Phosphates are sometimes added to improve the retention of moisture and to reduce the shrinkage or purge (i.e., cookout) that occurs during the heat processing of hams and bacon. Alkaline phosphates raise the pH of the product, and in doing so, help to solubilize muscle proteins, to improve the bind, and to increase their water-binding capacity and thereby the yield of the finished product. When phosphates are added to brines, it is not uncommon to obtain finished yields for intact hams and shoulders (i.e., picnics) of more than 100%. Polyphosphates have also been reported to retard the development of warmed-over flavor (WOF) and lipid oxidation, supposedly by their action as a metal ion chelator. The maximum regulated level of phosphate in the product formulation in the US is 0.5% with typical usage for hams, bacon, and cured sausages at 0.3–0.5%. Metallic and soapy flavors in meat products have been detected if phosphate levels are greater than 0.45%.

Seasonings and Flavors

Whole or ground spices, spice oleoresins, and seasonings (i.e., compounds containing one or more spices, or spice extractives, which are added to a food during its manufacture or in its preparation before serving) may be used by processors to develop distinctive flavors and to create special cured products. Seasonings should not be overwhelming or diminish the product's natural flavor, but potentiate the product with a blended, well-rounded flavor with no perceptible, undesirable aftertaste. Most flavors are mixed with a carrier such as a sweetener or salt. In recent years, however, flavors have been mixed in or encapsulated by starches, milk ingredients, or soy protein carriers. Today, preformulated cure units with specific flavors are available to processors. For example, California ham spice is a cinnamon and clove flavor mixed into salt or sugar, which is incorporated into ham formulations at levels of $<0.3\%$. Maple seasoning is a flavor that is added to a sweetener to impart a maple flavor in ham and bacon products. However, honey flavor is usually added directly to the meat product from a pure source. When comparing full-fat formulations with reduced-fat formulations, it is important to note that there will be a difference in flavor between the two products even if the same amount of seasoning is added. Low-fat formulations typically use more water to help soften the texture of the finished product, and water will carry the flavor differently. Excess seasoning in low-fat products can at times impart a very unpleasant metallic or astringent taste which lingers on the palate. Thus, the choices and addition levels of seasonings to meat formulations are a bit of an art, as the final balance of flavors will be dictated by the specific product in question. Even if the quality of meat used during formulating is of the highest standard, it becomes of little importance when the product is not properly seasoned.

Many seasoning companies are known by the industry to be predominantly suppliers of meat seasonings. Historically, there are two reasons for this. First, most of the smaller seasoning houses were founded by large meat companies so as to provide seasonings to their processing operations. Second, some seasoning houses marketed meat seasonings because of the technical expertise available from their personnel. Not only did these companies sell seasonings, but they also provided other ingredients like smoke flavors and sausage casings as well as the technical support for the preparation of value-added meat products.

Formulating Meat Products

Formulating any food product is much more than simply recipe development. In fact, some may even call it an art. It involves detailing the required processing steps and in what particular order they must be carried out to produce a high-quality finished product. Decisions when formulating meat products can entail the selection of meats and their levels of addition, choice of nonmeat ingredients such as salt, sweeteners, binders and seasonings, method and length of curing, grind or chop size of meat and fat, oven/smokehouse schedules, type and diameter of casings, as well as type and method of packaging. Formulating meat products also requires preparing a product which meets recognized characteristics set out by the country's standards of identity for that product. For meat companies, innovation is one of the single most important factors in building and maintaining a successful product or brand. A brand can be well recognized, but if over time that brand does not continue to offer value to consumers, it will soon be eclipsed in the market.

When designing meat products, it is practical to formulate by ingredient weight, which is based on the amount of the meat block. When formulating the seasonings, the processor must work in the weight of seasoning per 100 lb or kilogram of meat. Quantities can then be easily converted to percentages and the seasoning formula determined. For meat blocks not in 100 lb or kilogram increments, the percent usage of spice, oleoresin, or seasoning is calculated per pound or kilogram and then multiplied by the weight desired to determine the quantity required. Many processors weigh out the dry ingredients in a controlled-access room where the temperature and humidity are carefully monitored. After weighing, the critical components are often packaged and then assembled for batch production. A checklist must be prepared and verified in order to ensure that all of the materials are accounted for. Meat processors keep very detailed records of all formulas, and most are proprietary. The formulas are designed so that costs can be easily calculated and updated as needed, especially in the case of least cost formulation products. Standard blending or formulation documentation includes a list of ingredients, the weight of the individual ingredients in one seasoning unit, the percent of each ingredient in a batch, as well as the laboratory and plant code numbers.

Brine Preparation

One of the most important steps in ham and bacon production is brine preparation. Brine is a water-soluble solution containing salt, cure (e.g., Prague powder), phosphate, sugar, sodium erythorbate, and seasonings. All of the flavoring materials should be water soluble. There are two schools of thought regarding the temperature of water used for brine preparation. Some processors use warm water to help the dissolution of added solids and then allow the brine to cool to 0–2 °C (32–35.6 °F) before its application to meats. Others have concerns that warm water may cause chemical reactions to occur prematurely (e.g., conversion of nitrite to nitric oxide and then release of nitrogen dioxide gas from the brine) and thereby reduce the brine's efficacy. Such proponents favor the preparation of brines using cold/ice water. Whichever approach is employed, a known weight of water is measured, and all quantities of brine additives are weighed out separately. If using phosphates in the brine preparation, they should be added first and mixed thoroughly with high-speed shearing to ensure their complete dissolution. Other ingredients are added to the brine based on their solubility. Sodium erythorbate and soy isolate or concentrate are both difficult to suspend. Soy, if used, should always be added following the manufacturer's instructions including how much and if shear is necessary to get the plant proteins into suspension. Any product that settles out during brine injection could potentially cause problems in the finished product. Salt is then added and dissolved, followed by the cure and any remaining ingredients such as sugars and water-soluble spice mixtures. Nitrite is almost always added last, or until just before the brine is used, to ensure that less is lost to the environment. Brines are usually covered and held in a cooler – to reach or maintain a temperature of 0–2 °C (32–35.6 °F) – before use. It is important to note that some additives like soy, which are not completely solubilized, require agitation when processing/injecting.

Application of Cures

There are a few means by which meats can be cured. The basic methods include the following:

1. Dry curing – in this technique the curing ingredients, usually salt, sugar, nitrite, and nitrate, are mixed together and rubbed over the surface of the meat cut. The product is then placed in a cool room and the ingredients are allowed to penetrate by diffusion through the muscle tissue. The main disadvantage of this approach is that it is slow and in thicker cuts of meat, spoilage organisms can begin growing before the preservatives reach all parts of the product. More details about dry curing of meats are provided in the preceding article.
2. Brine curing – a brine is prepared by combining the salt, cure, and seasonings in water, which serves as a carrier. The strength of a brine solution or 'pickle' is determined by the amount of salt present. A salometer is a specially graduated hydrometer that measures the strength of brines at a particular temperature (usually 40 °F/4.4 °C) and is calibrated to indicate the degree of salinity (this is essentially a measure of the brine's density). A 100° salometer reading is equivalent to a 100% saturated salt solution, which is typically 26.5% salt (depending on temperature). Larger processors prepare stock solutions of brine at a 100° salometer reading and then formulate working pickles with additional additives at lower strengths. The presence of sweeteners, phosphates, nitrite, and erythorbate in brine will affect salometer readings to an extent. Typical pickles have strengths of 60–70°, with 70° brine being the most common. For brine immersion or cover pickling, the product is simply immersed in the brine for a specified period. For example, hams and shoulders are normally cured for 2–2.5 days per pound in 70° brine. Even though the penetration of ingredients into the muscle tissue may be faster than in dry curing, this technique also suffers from

slowness and is not widely employed by industry. More details about brine curing of meats are provided in another article.

3. Multiple-needle (stitch) pumping – a brine is prepared and then injected mechanically under pressure through needles, which are perforated along the stem near the point, into primal cuts of meat. In this multiple-needle injection technique, a conveyor belt carries meat under a bank of offset needles through which brine is pumped until a desired target weight is achieved. The spacing of the needles, their size, the pumping pressure, spray pattern, and the dwell time between strokes are important variables to ensure good distribution and retention of the pickle. The brine injected into commercial mild-cured products is typically a 70° pickle. The main advantages of multiple-needle pumping include increased product yield, greatly reduced labor costs, and time required for production. After pumping, some products are cooked immediately, whereas others are further processed by immersing them in a brine cure for a period (e.g., Canadian bacon) or subjecting them to a mechanical operation such as tumbling.
4. Tumbling or massaging – although strictly not a basic curing technique, tumbling or massaging of pickle-injected meat cuts is employed to speed up the curing process, to facilitate extraction of salt-soluble proteins, and to improve the texture, bind, water-holding capacity, and yield of the finished product. Tumblers are large stainless steel units that rotate in a circular fashion for a period of time. Nowadays practically all units have vacuum capabilities. Inside, pieces of meat are continuously lifted up by baffles to the upper part of the machine. From here they fall, striking the meat mass below, and produce an intense mechanical action suitable for high-yield products. Muscle fibers are disrupted by this mechanical action, which makes cellular membranes more permeable and facilitates the distribution and absorption of brine. Some degree of massaging also occurs as the chunks slide over each other as the tumbler turns. Tumblers typically provide somewhat more of a destructive effect than massagers on account of the impact force generated from the mechanical action. Thus, not all cured meat products can be tumbled (i.e., bone-in hams). A fitting example for the benefits of tumbling comes from ham production: Hams processed in this fashion are more uniform, as brine uptake is more tightly controlled and pickle pockets are reduced. The tighter control of pickle uptake results from the ability to pump the hams at, or somewhat below, the target pump and then adjusting the product's uptake to the exact percent pump by adding pickle directly to the tumbler. Without the presence of tumblers and massagers in meat processing operations, the higher processing yields and lower production costs associated with a number of value-added meat products could not be achieved.
5. Chopping or blending – dry curing ingredients are distributed directly into ground meat products during the grinding, chopping, and emulsification steps involved in batter preparation. Particle size is important in this process. Larger particles will require more time for cure penetration than very small ones. The particle size can be controlled by the grinder plate size or time in the chopper.

Specific Cured Products

Bacon

In North America, bacon is manufactured from pork bellies. The preparation of the belly is dependent on the desired characteristics of the finished product. Bellies may be cured with or without skin attached. Skinless bellies produce a product that has smoke color and flavor on all sides, whereas skin-on-bellies are usually derinded just before slicing and are identifiable by their distinct white fat. In most preparations, the bellies are first skinned using a skinning machine and then trimmed of ragged edges by knives. Excessive lean at the butt end is trimmed and used for sausage production.

In former times, the bellies were placed in high-salt-containing brines with the lean side down for 4–5 days or were dry cured for 10–14 days. Modern processing operations, however, cannot afford these time or space constraints; green bellies (raw noninjected) are pumped with brine to a specific percentage using a multineedle pickle injector. The injection operation dramatically speeds up the curing processing and also results in weight gain and an even distribution of the cure in the product. In some operations, the bellies are tumbled or massaged after injection for a short period of time (i.e., less than 60 min) with additional brine. Brine pickups of 18–30% can be achieved with a uniform distribution of the cure. However, bacon in the US must return to green weight. The processed bellies are then placed on combs and hung on trees or trucks for thermal processing and smoking. The bacon is partially cooked in an oven/smokehouse according to either a one- or three-step cook schedule until a final internal temperature of ~57 °C (135 °F) is reached; even so, it is still considered as a raw product. Bacon is smoked during all or part of the cooking cycle, depending on the requirements of the desired final product. After processing, the bacon is chilled in a tempering cooler to an internal temperature of −4.4 or −3.3 °C (24–26 °F) before pressing, slicing, and vacuum packaging. Cooling the product allows the bacon to retain its shape during pressing and facilitates slicing. The pressing operation involves placing slabs of processed bacon in a large forming machine where they are compressed to a relatively uniform width and thickness. The pressed bacon is sliced to a set thickness using a high-speed slicer and then graded according to premium slices, secondary slices, and ends or pieces. The shingled bacon is then conveyed to a packaging machine where it is typically vacuum packaged.

Microwaveable bacon is a more recent product in the marketplace. It is bacon that has been thermally processed for a sufficient length to develop the characteristic flavor and texture of fried bacon. This fully cooked product is sliced and then packaged in special packs designed to enhance microwave heating. In this respect, the product can be prepared faster without significant fry out from fat. The convenience and little mess resulting during microwave processing afford an attractive product to food service operators and to the consumer.

Canadian-style bacon, which is sometimes referred to as back bacon, is manufactured using the center portion of boneless pork loins (i.e., longissimus dorsi). Thus, it is a very lean product. Boneless loins are pumped with brine and then held in a cover pickle for 2–5 days. Once removed from the

pickle, the loins are rinsed with cold water, stuffed into casings, and hung in an oven/smokehouse, where they are cooked to an internal temperature of ~70 °C (158 °F). Canadian bacon is sold either sliced or in chunk form.

Wiltshire bacon is made from selected hogs weighing between 68 and 90 kg with special cutting procedures for the carcasses; that being, the shoulder, loin, belly, and ham are left as one piece, whereas the foreleg is removed at the knee and the hind leg at the hock. Additionally, the tenderloin, ribs, neckbone, backbone, aitchbone, skirt, and loose fat are also cut out. The Wiltshire sides are cured by pumping and then placing them in a cover pickle for 7–10 days. After this period, the sides are removed from the pickle and product is held under refrigeration conditions for maturation, which lasts anywhere from 2 to 14 days. The sides are then usually smoked before being shipped to market.

Hams

Hams are very popular cured meat products that are prepared from the hind leg of pork. Meat sizes can vary from whole muscles to relatively small chunks, which are restructured. Some processors are matching muscles to make small 2–3 lb hams as opposed to large whole hams or chunked and formed hams. Various types of hams can be prepared and they include the following: traditional bone-in hams; semiboneless hams; boneless, premium hams; and boneless, sectioned/chopped and formed hams. Most hams are pickle cured with brine consisting of salt, cure, sugar, phosphate, and erythorbate. Once cured, hams can be stuffed into fibrous casings and processed in an oven/smokehouse or, as in the case of some sectioned/chopped and formed hams, be processed using cook-in-a-bag technology to produce a fully cooked ham.

Traditional bone-in and semiboneless hams

Bone-in hams are typically prepared from the whole pork leg with the foot removed. Hams are usually separated from the loin by cutting between the second and third sacral vertebrae parallel to the angle of the hock joint. The resulting whole intact hams contain only three bones – aitch, body (i.e., femur), and shank. When the aitch- and shankbones are removed, the ham is referred to as semiboneless. The aitchbone is sometimes removed alone when preparing spiral-cut country-cured hams. In older times, before processing, hams were trimmed of some collar fat by line workers. At present, processors who do not have abattoirs and bring in raw meat typically purchase Institutional Meat Purchase Specifications (IMPS) 401 or 402 series hams, which already have partially skinned collar fat removed or are fully skinned (402). A prepared brine is injected into the muscle tissue at a certain percentage pump. The product may be immersed in a cover pickle before netting and is then placed on a tree or truck for thermal processing. The ham is thermal processed (with or without smoke), chilled, packaged, and then boxed. Bone-in hams are comprised of the butt, center, and shank. The hams may be sold whole or cut into butt and shank sections.

For bone-in hams, special care is needed when using a multineedle pickle injector to avoid potential damage of the needles should one hit a bone during mechanical treatment. Specially designed bone-in injectors are recommended for use with bone-in hams. Consequently, in many small operations, hams are pumped by hand. Placing the hams in a tumbler or massager for a period to distribute the cure throughout the product aids in creating a uniform cure and prevents against bone souring; however, if tumbled too long, this can also create problems. Hams, and picnics to a lesser extent, may also be cured by artery pumping. This involves pumping brine directly into the tissue's vascular system. A needle is usually inserted in front of the branch in the femoral artery so that the pickle can be distributed throughout the entire ham. Care must be exercised, however, to ensure that blood vessels are not ruptured by excessive pumping pressures. The pumping schedule generally calls for adding 8–10% by weight of the pump pickle. There are some problems, however, with this technique. First, the arterial pathways in the muscle are not uniform, thereby resulting in uneven curing. Second, it is generally recommended to hold the ham under refrigeration conditions after injection to permit not only equilibration of the cure but also the fixation of the cured color. Most important, the success of arterial injection is dependent on attentive work during slaughter and cutting as well as subsequent handling procedures in order to guarantee that the arteries are left intact. Owing to the inherent difficulties with this technique, it is not as often employed as it once was.

Boneless, premium hams

The usual muscle classes for premium hams from the leg area of hogs include semimembranosus–adductor and biceps femoris–semitendinosus. The muscle tissue is generally trimmed, deseamed, and boned. The boneless meat is then pumped via a multineedle injector to a certain pump percentage and then subjected to massaging or tumbling to evenly distribute the cure. In instances where the targeted pumping gain in the hams has not been achieved, brine is added to the tumbler for pickup of the additional amount needed. After tumbling, the muscles are netted together or placed in casings; they are manufactured in either round or flat shapes. In some cases, ham molds are placed on the product before thermal processing to give them the required shape. Round boneless hams are held in cellulose casings, whereas flat hams are prepared by pressing boneless hams together. Before pressing, the hams are stuffed into stockinettes, cellulose, or collagen casings. The pumped meat is then thermal processed and smoked. Afterward, the ham is chilled and finally vacuum packaged. In some instances, the hams are cut in half or to specific pound quantities before packaging.

Boneless, sectioned/chopped and formed hams

These hams are made virtually in the same manner as premium hams except that the biceps femoris–semitendinosus muscles are chopped or sectioned into smaller pieces along with muscles from the shank and the knuckle. The meat from boned hams or ham pieces may be used fresh or after freezing and thawing. All excess surface fat and seam fat should be removed. Brine containing salt, cure, sugar, phosphate, and erythorbate is formulated and pumped into the pieces of ham (typically a 15–30% pump). Tumbling or massaging is used to extract myofibrillar proteins from the muscle tissue to cause the meat pieces to be glued or stuck together. In some cases, shank meat or lean ham trim is finely chopped in a bowl

chopper with added water, salt, phosphate, and cure. Approximately 5–10% of this mixture (based on the pumped weight of hams) is transferred to a massager containing pumped hams. The meats are massaged for 6–8 h and then tightly stuffed into fibrous cellulose or collagen casings of approximately 12.5 cm. The meat chunks should be tightly stuffed to force the pieces together so that they will bind during heating. The product is cooked in an oven/smokehouse. The amount of smoke applied will vary from none to heavy, depending on the desired characteristics for the finished product. During the thermal processing operation, all hams must reach a minimum of 60 °C (140 °F), as this temperature will kill any *Trichinella spiralis*. This nematode parasite is not really a problem anymore; present day microbiological concerns over *Salmonella* spp. and *Escherichia coli* dictate an end-point temperature of 70 °C (158 °F). Because thermal processing is employed to 'set' the premium and section and formed hams by means of heat coagulable proteins, these hams need to reach a temperature of 72 °C (~162 °F). Afterward the hams are cooled to approximately 2 °C (35.6 °F) before packaging. Chilling must be accomplished in a specific time frame to ensure food safety.

A chopped and formed ham is a variation of a sectioned and formed ham. In the former, the meats used are usually smaller pieces. A formulation for a Pullman ham, a typical chopped and formed ham, is given in Table 1.

Table 1 Formulation sheet for a chopped and formed ham[a]

Product: Pullman ham
Yield over green weight: 145%
Batch size: 116 kg

Ingredients	*Concentration in product (%)*	*Level (%)*	*Quantity needed (kg)*
Meat			
Ham meat			68
Shank meat			12
Brine			
Water/ice		77.573	27.30
Salt	2.3	7.411	2.67
Dextrose	1.4	4.511	1.63
Glucose (i.e., corn syrup solids)	1.4	4.511	1.63
Sodium tripolyphosphate	0.50	1.611	0.58
Sodium erythorbate	0.05	0.161	0.060
Prague powder	0.31	1.000	0.36
Flavor	1.0	3.222	1.16

[a]Courtesy of Mr. Daniel J. Prefontaine, President, Saskatchewan Food Industry Development Center, Saskatoon, SK.
Note: Instructions:

- Pass chilled ham meat through a kidney plate.
- Grind chilled shank meat through a 0.12 in. plate.
- Transfer ground shank meat with about half of the phosphate, salt, Prague powder, erythorbate and water/ice to a silent cutter.
- Cut until the product is creamy, then add all remaining dry ingredients and water/ice, followed by blending.
- If all meat in the silent cutter is lean then the temperature is not an issue, but if fats have been added, the temperature must be monitored.
- Once complete, transfer the mixture to a vacuum tumbler and add the coarse-ground ham meat to it.
- Tumble the meats under vacuum for 1 h at high speed.
- Stuff product into water-cook casings.
- Place in 4 × 4 molds.
- Cook product in a water bath/steam kettle to an internal temperature of 72 °C (~162 °F).
- Cool down product by immersing it in cold water.
- Transfer product to a cooler, chill, and when ready slice and vacuum package.

Dry-cured hams

Although dry-cured hams are not as common in North America (the possible exception being the US country-cured hams for southeastern markets in Virginia, West Virginia, Kentucky, Tennessee, North Carolina, South Carolina, and Georgia), they are extremely popular in the Mediterranean region and are revered for their unique flavor as well as other characteristic sensory attributes. In Spain, two important dry-cured products are Iberian and Serrano hams; their production in 1993 was approximately 181 500 ton. During processing there is a loss of water, and diffusion of salt throughout the ham leads to a gradual stabilization of the product, due to a drop in the water activity. Simultaneously, there is a slow degradation of proteins and lipids that results in an accumulation of free amino acids and fatty acids, respectively. Details on the processing of Iberian and Serrano dry-cured hams are described in Table 2, but briefly include the following steps:

1. reception and classification of hams, and then presalting where a mixture of curing ingredients (i.e., salt, nitrate, and/or nitrite) and adjuncts (i.e., ascorbic acid) are rubbed onto the lean muscle surface of the meat;
2. salting, where hams are then placed fat side down, entirely surrounded by salt and arranged in single layers without touching one another. As there is no water added, the curing agents diffuse slowly into the ham and are solubilized by the original moisture present in the muscle tissues. This period usually takes 8–10 days (i.e., 1–1.5 days per kg weight) at temperatures between 2 (35.6) and 4 °C (39°F);
3. during the post salting stage, a complete salt equalization within the hams occurs. The temperature is kept less than 4 °C (39 °F) for a period not less than 20 days but not exceeding 2 months;
4. the last and more complex stage is the ripening/drying stage. Hams are placed in natural or air-conditioned chambers and subjected to different time–temperature/relative humidity (RH) cycles. The temperature is usually maintained between 14 (57) and 20 °C (68 °F) with a RH decreasing from 90 to 70%. Aging of hams takes anywhere from 9 to 24 months. For example, the ripening period for Serrano hams is between 9 and 12 months and for Iberian hams, it can be extended up to 18 or 24 months.

The quality of these two hams depends on the raw materials and the ripening conditions employed. Iberian dry-cured ham is produced from an autochthonous pig that is found in the southwestern region of Spain. These swine feed on pastures or stubble fields during their growing period (until 12/16 months of age, 55/75 kg) and their nutritional requirements are completed with cereals such as corn and

Table 2 Scheme of the approximate conditions for the processing of Serrano and Iberian dry-cured hams[a]

	Serrano ham	*Iberian ham*
Salting	T 0–4 °C RH 75–95% $t > 0.65$ and < 2 days kg^{-1}	
Post salting	T 0–6 °C RH 70–95% $t > 40$ and < 60 days	
Dry curing		
First phase	T 6–16 °C RH 70–95% $t > 45$ days	T 6–16 °C RH 60–80% $t > 90$ days
Second phase	T 16–24 °C RH 70–95% $t > 35$ days	T 16–26 °C RH 55–85% $t > 90$ days
Third phase	T 24–34 °C RH 70–95% $t > 30$ days	T 12–22°C RH 60–90% $t > 115$ days
Fourth phase	T 12–20 °C RH 70–95% $t > 35$ days	
Total Time	$t > 190$ days	$t > 365$ days

barley. During the fattening period, three types of feeding regimes, known as montanera, recebo, and cebo, are possible. For montanera, the basic food is the acorn (*Quercus ilex*, *Quercus rotundifolia*, and *Quercus suber*) and the feeding period lasts from October to December or until a final weight of approximately 160 kg is achieved. For recebo, the acorn is complemented with cereals and mixed feeds. For cebo, only cereals and mixed feeds are used. Meat from acorn-fed pigs commands the highest price and the dry-cured hams so prepared offer a high degree of marbling (resulting from the finishing lipid-rich acorn diet), firm texture, and exquisite characteristic flavor. The Serrano ham is produced from different crossbreeding of white pigs and has lower marbling, firm texture, and a typical flavor. The intensity of the flavor can be controlled by the length of time the ham is allowed to ripen/dry. Complex biochemical reactions, mainly enzymatic, proteolytic, and lipolytic in nature, occur during the dry curing process and contribute to the development of an adequate texture and characteristic flavor.

Corned Beef

Traditionally, corned beef is prepared from the brisket; however, the demand for leaner meat products has some processors preparing it from muscles of the round. The basic corning process used today is multiple-needle injection of pickle into the beef. The pickle used in the preparation of corned beef is similar to that employed in ham and smoked-meat manufacturing. If boneless briskets are used, they tend to be pumped to 120% of green weight, whereas rounds are generally pumped to only 110%. The injected beef is then placed in a cover pickle containing additional spices and herbs, such as bay leaves and allspice, for a few days. Prepackaged corned beef is sold either uncooked or as a ready-to-eat product. In the latter case, the corned beef is cooked in water or steamed to an internal temperature of 67 (~153) to 72 °C (~162 °F).

Table 3 Formulation sheet for bologna

Product: Bologna

Ingredients	*Level (%)*	*Quantity needed (kg)*
Lean pork trim, 80/20	39.24	39.24
Lean beef trim, 85/15	22.00	22.0
Pork trim, 50/50	22.00	22.0
Water (as ice)	10.0	10.0
Salt	1.80	1.80
Sodium tripolyphosphate	0.35	0.35
Garlic powder	0.05	0.05
Paprika	0.25	0.25
Modified food starch	3.5	0.75
White pepper	0.13	0.13
Prague powder	0.30	0.30
Sodium erythorbate	0.05	0.050
Onion powder	0.06	0.060
Nutmeg	0.17	0.17
Ginger	0.10	0.10

Note: Instructions:

- Weigh out all ingredients and keep them separate.
- Grind all chilled meats through a 0.12 in. plate, but keep meats separate from one another.
- Transfer ground lean meats, salt, Prague powder, erythorbate, and half of the ice into the silent cutter.
- Chop to 4 °C (39 °F) and then add ground pork trim (50/50) and the remaining dry ingredients along with the ice.
- Chop on high speed until a temperature of approximately 13 °C (~55 °F) is reached.
- Transfer the batter to a stuffer, and stuff into cellulose casings.
- Heat process and smoke in a smokehouse to 72 °C (~162 °F).
- Cold water shower to reduce internal temperature of product to 32 °C (~90 °F).
- Transfer product to cooler, chill and when ready peel and vacuum package.

Frankfurters, Cured Sausages, and Comminuted Meat Products

Frankfurters, cured sausages, and comminuted meat products such as bologna, salami, and pepperoni are prepared as a meat batter. In its simplest form, a meat batter contains water, protein, fat, and salt. The general steps in preparing sausage products include grinding of meat, chopping of meat, additive addition, stuffing, linking, cooking, peeling, slicing, and packaging. As a general rule of thumb, better meat quality will give a higher quality batter and final product. A typical formulation for bologna is provided in Table 3.

There is a particular order of steps which one must follow when preparing batters. Meats to be used are divided into groups according to how much fat is present. For example, there is the lean or 95/5 (i.e., 95% lean muscle tissue containing 5% intramuscular fat), followed by 80/20 and then the fatter 50/50 trim. In the case of products containing pork, the majority of fat and fatty trims should be hard fats from the

shoulder, ham, back fat, or jowls. Softer fats such as belly trimmings should be limited, as they can cause fat caps and soft texture in the finished product. Each meat type is ground separately to a final grind size, depending on the product of choice. Grinding is a particle size reduction step in which pieces of meat are continuously forced through the holes of a metal plate between the arms of a rotating multibladed knife. The holes bored into the plate have specific diameters (e.g., 3.2, 6.4, 9.5, 12.7 mm; or 0.12, 0.25, 0.38, 0.5 in., respectively). Meats must be comminuted in two or three steps with a sequential reduction in the grind size. It is important to remember, however, that the meats must be kept cold during any grinding operation to prevent smearing/liquidization of the fat.

Ground meats are transferred to a grinder mixer, a bowl chopper, or a silent cutter. Here the mechanical action of the vertically positioned rotating knives in combination with added salt and phosphate will extract myofibrillar proteins from the meat; extracted proteins will help to immobilize fat particles and form a three-dimensional network of filaments that contributes to the overall texture as well as the water- and fat-binding properties of the finished product. The sequence of batter preparation goes as follows: lean meat, phosphate, salt, cure, erythorbate, and half the ice/water are added to the chopper. The chopping process creates sufficient shear to comminute meat and fat into fine particulates as well as to extract protein. Chopping of the raw materials causes a temperature rise of the meat batter; therefore, the use of ice during formulation helps to ensure that the mixture is blended at 0–3 °C (32–37.4 °F). The remaining ice/water is added, followed by fatter meats (e.g., 80/20 or 50/50) and then binders, flours, and seasonings. The rationale for chopping lean meat with salt and water is that maximum solubilization of myofibrillar protein occurs at the higher ionic strength before 'dilution' by fatter meats and binders. This will help to prevent emulsion collapse or 'shorting out' resulting in fat caps, gelatine pockets, and a greasy surface on the cooked product. Reasons for the lack of functionality from the proteins may be due to poor quality meat (e.g., not enough lean meat protein, denatured protein from acidification, and too much collagen), addition of too small amounts of salt and phosphate, overchopping, and incorrect final batter temperatures.

The batter is chopped until a specific end-point temperature is reached, which is dependent on the fat properties of the animal species used. To create a stable emulsion, the added fat must exist as small pieces or droplets so that the protein matrix can coat the surface of fat particles, thereby reducing surface tension; this occurs when the temperature of the batter is raised. Not all products contain meat from only one species; therefore, the end-point temperature of a batter containing a majority of pork should be between 10 (50) and 13 °C (~55 °F); for poultry, 2 (35.6) and 7 °C (~45 °F); and for beef, 13 (~55) and 21 °C (70 °F). Bowl choppers can be used to manufacture both coarse and finely comminuted cured meat products. When a very fine emulsion is desired, some sausage manufacturers pass the chopped meat through a separate emulsifier before stuffing. In such cases, the batter is processed in a silent cutter only to a temperature ranging between 2 (35.6) and 4 °C (39 °F). As it passes through the emulsifier, the temperature goes up, and the emulsification step continues until the final end-point temperature of the product is achieved.

In some emulsion-type products, vacuum chopping will increase the protein extraction and density of the emulsion. Vacuum chopping/stuffing removes most of the air from the emulsion and gives greater product uniformity, reduction in voids, better protein extraction, better color retention, and an increased shelf life. For example, in bologna, which is a large-diameter product, vacuum chopping is desirable to eliminate air bubbles or pockets that could cause color fading and a soft texture to the final product.

Binders or fillers are commonly used in the manufacturing of cured sausages and are normally made up of a combination of soy, cereals, as well as native and modified starches. If a product is high in meat protein and moisture but low in fat, then a high moisture-absorbing binder like starch can be employed. However, in a product with greater fat content, such as a frankfurter, a high protein binder like soy or milk solids might be chosen. Functional protein binders are binders where the protein has not been denatured during their manufacturing and thereby bestow properties to the meat matrix. The benefits of adding functional binders to a formulation include the following: increased protein level, improved texture, reduction in shrinkage, and overall juiciness and cohesiveness to the product.

Once the batter is ready, it needs to be stuffed into a casing. There are special machines designed for this purpose. First, it is important that products be stuffed in casings to their proper diameter so that they resemble the product they are supposed to be. For example, one would not stuff the batter of a pepperoni stick into a salami casing and vice versa. In fact, frankfurters of a relatively large diameter casing, or in natural casings, are often referred to as wieners. Second, the product should not be under or overstuffed in the casing. Understuffing usually results in casings with wrinkles, whereas overstuffing can result in casing breakage during thermal processing. Most casing suppliers provide guidelines of recommended stuffing diameters for products and these take into account shrinkage after cooking. Finally, stuffed products are hung on trucks for thermal processing and smoking in an oven/smokehouse. Some meat plants are so sophisticated that they have continuous processing lines for frankfurter production. After thermal processing, the meat product is chilled, and when ready, it is peeled from its casing, packaged, and shipped to market.

Natural Nitrate- and Nitrite-Free Cured Meats

Owing to the negative perceptions of nitrite-cured meats held by some consumers, there has been an interest of late in the 'so-called' nitrate/nitrite-free natural meat products. Any traditionally cured product produced in the US that does not include addition of a chemically derived form of nitrite is labeled as uncured. As previously discussed, nitrite/nitrate addition to meat products develops a characteristic color and flavor associated with cured meat products to which there is no known substitute. Without its addition, natural processed meat products would appear brown and their flavor would

Table 4 Formulation sheet for a natural hot dog

Product: Natural hot dog		
Ingredients	*Level (%)*	*Quantity needed (kg)*
Lean pork trim, 72/28	52.6	52.6
Beef trim, 50/50	22.7	22.7
Water	20.3	20.3
Sea salt	1.28	1.28
Natural hot dog seasoning	3.10	3.10
Cane sugar, natural flavors, celery powder, onion powder, garlic powder, oleoresin paprika		
Starter culture	0.02	0.02

Note: Instructions:

- Weigh out all ingredients and keep them separate.
- Grind all chilled meats through a 0.19 in. plate, but keep meats separate from one another.
- Mix starter culture with water totaling up to 0.50% of the total batch.
- Mix/chop lean meats, adding in order, salt, half of the water, fatty meats, seasoning, and remaining water.
- Add diluted starter culture.
- Continue mixing/chopping until the meat blend temperature reaches 50–54 °F (10–12 °C).
- Emulsify to 62–64 °F (17–18 °C).
- Stuff and link.
- Place on smokehouse rack and process using the smokehouse schedule: (1) 110 °F (~43 °C), 60 min; (2) 140 °F (60 °C), 20 min; (3) 155 °F (~68 °C), 30 min; (4) 175 °F (~79 °C), 30 min; and (5) 185 °F (85 °C)/30% RH to 165 °F (~74 °C) internal temperature.
- Cold water shower to reduce internal temperature of product.
- Transfer product to cooler, chill and when ready peel and vacuum package.

be appreciably less desirable to the consumer than those of conventionally cured counterparts. The USDA permits the manufacture of uncured versions of typical cured meats according to the Code of Federal Regulations Title 9, CFR 317.17 and 319.2. To circumvent nitrite regulation and labeling issues, natural curing is accomplished by employing sea salt and vegetable juice/concentrate/powder high in naturally occurring nitrates (e.g., celery has nitrate levels typically ranging from 1500 to 2800 ppm, whereas celery juice powder has been reported to contain ~27 500 ppm or 2.75% nitrate) in combination with a nitrate-reducing starter culture (e.g., *Kocuria varians, Staphylococcus xylosus,* and *Staphylococcus carnosus*) to 'indirectly' cure the product. Processors are using both preconverted nitrates (already converted to nitrite) from celery powder and unconverted celery powder with a starter culture that has a nitrate reductase enzyme to convert the nitrates into nitrite. This practice combined with labeling requirements for such products has resulted in a category of processed meats in the US that is confusing and perhaps even misleading to the consumer. Moreover, protection afforded by nitrite addition to meat products against spore germination of *Clostridium botulinum* is potentially compromised in these uncured products, because the conversion of nitrate present in celery into nitrite is not a well-controlled reaction. This raises the specter of the product's microbiological safety in vacuum-packed bags. For this reason, the USDA is also concerned about chilling rates on finished packaged products. If the processor is manufacturing a 'naturally' cured product, the residual nitrite level will more likely not be enough and a more restrictive chilling regime as outlined in Appendix B of the USDA meat regulations would be in order.

For the most part, the processing procedures of natural curing are similar to those operations using sodium nitrite. Nitrate is more stable than nitrite; hence, a sufficient time is required to allow the starter culture to reduce exogenous nitrate to nitrite. The time needed depends on a number of factors including temperature, pH, growth cycle of the starter culture (i.e., number of microorganisms), and level of nitrate in the added celery powder. A good distribution of the ingredients is essential to ensure a uniform cure in such products. If dry, the vegetable powder (i.e., natural nitrate source) is typically blended into the dry seasonings for comminuted products or added directly to curing brines. The starter culture is often first mixed with water before addition to comminuted products and then dispersed via agitation for optimal distribution in the meat product. The USDA allows a maximum 0.5% combined water and starter culture without labeling the added water. The finished product, however, is required to bear a label disclaimer such as 'no nitrates or nitrites added, except for that which occurs naturally in celery juice powder.' A typical natural cooked sausage product formulation and process is given in Table 4.

Glossary

Prerigor boning Process of removing meat from the bones of a meat carcass before the carcass has entered a rigor state.

Refrigeration May be defined as the process of removing heat from any substance to: (1) render colder – reduce temperature, (2) change its state – for example, water to ice, and (3) maintain its state – preserving foods, storing ice.

Introduction

Typically, meat is initially chilled after slaughter in the form of whole eviscerated and dressed carcasses or sides. The majority of carcasses/sides are chilled in conventional air chill rooms, nominally operating at one or sometimes two conditions during the chilling cycle. The rate of heat removal and the resulting rate of temperature reduction at the surface and within the carcass/side have a substantial influence on the weight loss, storage life, and eating quality of the meat produced. European Union regulations require that all red meat temperatures within the carcass/side must be reduced to not more than 7 °C before the meat is further processed, or moved from the chiller, whereas for poultry this temperature is 4 °C. Similar legislation is applied in many other parts of the world. Careful control is required to achieve conditions that will reduce the meat temperature in the designed time cycle. This has to be carried out in the most economic manner taking into account weight loss and energy consumption.

The concept of deboning a 'hot' carcass was first mooted in the early 1970s. Potentially, the hot boning of carcasss has distinct advantages over cold boning. The warm meat is soft and requires less effort to bone, thus occupational overuse injuries are less likely to occur, there is potential for improved yield, and expensive chilling of fat and bones is avoided. There are also benefits in terms of certain processing qualities when hot-boned meat is used to manufacture meat products. However, there are also potential disadvantages of hot boning; for instance, the potential for the meat to be tough, darker in color, and for some primals to be different in shape.

There is no strict definition of the temperature range over which boning can be considered as 'hot.' For example, in Australia, hot boning usually means boning carcasses that have a deep butt temperature of more than 20 °C.

It is useful to consider hot boning in two categories – (1) 'true' hot boning and (2) warm boning. In true hot boning, carcasses or sides are not cooled before they are boned. They are boned within 30–45 min of slaughter. Plants that perform true hot boning often use plate freezers to cool the hot meat. Even with plate freezers, it can be difficult to rapidly reduce the temperature of large beef primal cuts. Bulk-packed product, at average temperatures of 28–30 °C, can normally be cooled in sufficiently rapid time using plate freezers. In warm boning, carcasss or sides are boned after a period of prechilling. Typically, carcasses are prechilled for 30 min to 6 h. Short prechills are used for lamb/sheep and longer periods for beef. Warm boning allows for an increase in throughput on the slaughter floor without having to increase chiller space. After warm boning, primals and manufacturing meat can be cooled quickly enough in air blast or plate freezers to prevent microbial growth.

Microbiology of Hot-Boned Meat

A disadvantage of hot boning is that there is an increased risk that the meat can support the growth of pathogenic bacteria as it cools. In conventional boning, microbial growth on carcasss is controlled by a combination of drying and cooling of the carcass surface. When the meat is hot-boned and packed,

moist meat surfaces may be contaminated and provide an opportunity for microbial growth because they stay moist and warm. The surface temperature of boned meat prepared conventionally in accordance with regulatory requirements is usually less than 4 °C and the core of the meat below 7 °C. At these temperatures, the growth of pathogenic bacteria is stopped or is very slow. In the case of true hot-boned meat, the boneless meat surfaces could be 20–35 °C at the time of packing. At these temperatures, pathogenic bacteria can potentially adapt to their new environment within an hour or two and begin to grow quickly. Therefore, the meat must be cooled quickly to below 7 °C after it is hot boned in order to control the growth of pathogenic bacteria. Both New Zealand and Australia have performance criteria for the cooling of hot boned, boxed beef that are based on the growth of *Escherichia coli* calculated from temperature histories for the centers of boxes.

Quality of Hot Boned Meat

Immediately postmortem, there are two related processes that affect meat-eating quality: (1) a fall in muscle pH and temperature and (2) shortening of the muscle.

The combination of a very rapid fall in pH and slow cooling of the carcass can lead to heat or rigor shortening; whereas a slow fall in pH and rapid cooling can lead to cold shortening. Shortening is undesirable as it can cause moderate to severe toughness. A further important penalty of both cold and heat shortening is a reduction in the ability of the meat to tenderize during aging. Also, both may adversely affect functional properties of manufacturing meat.

Because of the lack of skeletal restraint, these phenomena are more important with true hot boning than with warm or cold boning. Ideally to avoid shortening problems, the aim is to achieve an optimal rate of pH fall during rigor mortis and cooling. However, this is not readily achievable with true hot boning because of the varying cooling rates within a carton of meat.

The application of an electrical current to the carcass on the slaughter floor accelerates pH decline. Electrical currents may be applied via electrical stunning, immobilization, hide-puller probes, or from conventional electrical stimulation (ES). The effects on the rate of pH fall are additive and lead to the early onset of rigor mortis. In some abattoirs where extra low voltage stimulation and downward hide pullers are used, beef sides have attained close to ultimate pH (5.5–6.0) within 60 min of stunning. 'Overstimulation' in this instance is undesirable as it can increase the risk of heat shortening, reduce the aging potential of the product, and in warm (and cold) boning can cause denaturation and paleness of slow cooling internal muscles.

Meat that is taken from a carcass prerigor and promptly subjected to further processing has manufacturing advantages, such as better fat emulsifying and water-holding properties. However, hot-boned meat is usually chilled, or frozen, before it is used for manufacturing. If hot-boned meat cannot be processed immediately after slaughter it is possible to preserve its superior manufacturing properties by very rapid (i.e., cryogenic) freezing. The meat must be frozen while it is still in the prerigor state and held at storage temperatures close to − 18 °C. In fresh beef, or mutton, freezing must be completed within 6 h of slaughter. If the meat is thawed before use, however, biochemical changes take place rapidly, and most of the advantages of prerigor meat are lost.

By adding at least 2% salt (sodium chloride) before freezing, or at the time of thawing (e.g., during chopping), the superior qualities of the prerigor meat can be retained after thawing. When minced thoroughly with the meat, 2% salt has been shown to preserve the water-binding power of fresh (unfrozen) prerigor meat for some days. Comminuted prerigor meat has a water-holding capacity similar to that of similarly treated postrigor meat to which polyphosphates have been added. In some countries, the use of phosphates and other nonmeat additives to improve water-holding capacity and fat emulsifying properties of manufactured meat products is either forbidden, or restricted. The addition of salt to prerigor boned meat before freezing is acceptable, however, as salt is included in the formulation of sausage meats. Therefore, there is an opportunity to better exploit the superiority of hot-boned meat for processed meat products.

Removing muscles from the carcass soon after slaughter changes their normal state. Some muscles are normally stretched on the carcass and become free to shorten when released from their attachments to bones. Others, which usually cool slowly because they are enclosed by other muscles, may be cooled much faster. These differences will affect tenderness development and can cause muscles that are tender when cold boned (e.g., tenderloin) to be toughened when hot boned.

With true hot boning, meat is still in the prerigor state at the time of boning even if electrical stunning, electrical immobilization, or ES has been used. This makes muscles susceptible to adverse temperature/pH combinations. Shortening is particularly likely. To overcome these problems systems such as the Pi-Vac Elasto-Pack system for the prerigor muscles have been developed. These stretch or constrain the muscle during chilling. The Pi-Vac Elasto-Pack system operates by stretching tubes of highly elastic films to the inside walls of a packaging chamber. After inserting the muscle into the chamber, the pressure is released, and the film returns to its original dimensions. The forces from the elastic film stop the diametrical muscle expansion, which would result from the longitudinal contraction of the muscle. It is claimed that it is possible to chill the meat rapidly without detrimental effects on tenderness and produce an attractive shape for cuts. Other systems having similar aims are Tendercut, Tenderstretch and SmartStretch™. Smartstretch™ uses external air pressure to stretch and reform hot-boned primals into a uniform size, using restraining packaging to ensure that the stretch is retained during rigor. The technique has been shown to improve the initial tenderness (0 days aged) of beef striploins from adult cattle, although no effect was found after a 2-week aging period. The treatment increased cooking losses, but had no influence on moisture losses in raw or frozen meat, or on meat color.

With warm boning, many muscles from electrically stimulated carcasses are at least partly in rigor at the time of boning. In this case, muscles are less likely to be affected by adverse postboning temperature/pH combinations. As with

cold boning, skeletal restraint minimizes the risk of the meat being affected by adverse temperature/pH combinations during carcass chilling.

The color and retail display life of hot-boned primal cuts is generally equivalent to that of conventionally boned product. However, in cold boning some of the deeper beef muscles are often paler than the more superficial muscles because of their slower temperature fall and faster pH fall. Hot boning can mean that these cuts are cooled more rapidly leading to less denaturation, leading to darker meat and less two toning than in their cold-boned counterparts. Some studies have also reported a greater color stability in hot-boned steaks. In addition, some staining of the fat of primal cuts with blood from superficial blood vessels has been experienced in hot boning.

Hot and Warm Boning Operations

Hot boning is generally considered to be easier than cold boning, but care needs to be taken when handling the cuts as they may be slippery in comparison. A major health and safety advantage with hot boning is that the problem of hard fat is not encountered. However, difficulty can be encountered in trimming fat from primal cuts. This can result in a fat thickness that is not up to specification and a less attractive cut. However, with the proper training and care, trimming can be done accurately.

In objective studies carried out in the United States, strain gauges were fitted on knife handles to measure the effort required to hot-bone beef. It was claimed that 49% less effort was required to hot-bone beef sides compared with cold boning. In addition, it has been reported that a yield improvement of 1.5–2.0% is achievable with true hot boning compared with conventional boning. This increased yield is a combination of reduced evaporation losses and more efficient removal of meat from the bones. Studies have shown that hot boning reduces the time taken to bone out a beef side from 18 to 14 min. However, it can take some time for boners to become fully competent with hot boning, thus yield advantages may not be immediately obvious.

Beef

The New Zealand meat industry has pioneered the application of hot boning with approximately 20% of beef production processed hot in 2006 with large plants processing up to 80 000 cattle per year. Historically, hot boning plants were used almost exclusively to process manufacturing beef from bulls and cows; however, it is now commonplace to process prime beef animals using hot boning procedures. Regular audits of product quality have demonstrated that eating quality and other quality attributes can match those of meat produced by more conventional cold boning procedures, as long as pH and temperature decline are effectively managed. In contrast it has been reported that Brazil, which is the leading beef export country in the world exporting 1635 million tons in 2011, makes no use of hot boning and only limited use of ES.

Immersion chilling has been investigated to improve chilling rates of hot-boned beef cuts. The commercial process that has developed involves vacuum packing hot-boned meat and transferring the packaged cut to a system similar to the auger system used for poultry processing.

ES accelerates the onset of rigor and can be used to minimize if not eliminate cold shortening induced toughness in hot-boned beef. However, studies on beef sides that were hot boned and chilled at -20 or 0 °C showed that the meat from beef chilled at -20 °C was tougher than cold-boned controls after 7 and 14 days of aging. Drip loss from meat chilled at -20 °C was also higher than that hot boned and chilled at 0 °C or cold boned.

Studies have been carried out to determine the effects of hot boning, low voltage ES, and chilling temperature on the tenderness of bovine M. longissimus dorsi (LD) and M. semimembranosus (SM) muscles. Hot-boned muscles, which were not electrically stimulated had higher Warner Bratzler shear force (WBSF) values and shorter sarcomeres than cold-boned muscles. Under fast and slow chilling regimes WBSF values were lower in ES hot-boned LD and SM muscles at days 2, 7, and 14 postmortem than those not electrically stimulated muscles. Hot-boned muscles subjected to slow chilling had longer sarcomeres than those subjected to fast chilling. In hot-boned SM muscles, ES resulted in longer sarcomere lengths. However, ES did not have a significant effect on the sarcomere length of LD muscles. As indicated by WBSF values, all muscles tenderized during aging, including muscles, were 'cold shortened.'

Lamb

As may be expected there appears to have been limited interest or work carried out on the hot boning of lamb. The small size of the lamb carcass makes it amenable to quick chilling and lamb cuts are often sold with the bone in. Few of the advantages of hot boning, therefore, apply to lamb. Nevertheless hot boning of lamb has been proposed as a means to reduce energy costs. Hot boning of lamb has been shown not only to improve flavor and juiciness and decrease cooking loss but it also can reduce tenderness.

In one study on hot boning of lamb after ES, carcasses were placed in a drying room for approximately 35 min with an average temperature of 8 °C to dry the surface of the carcass to limit bacterial growth before hot boning. Within 2 h of slaughter the hot-boned cuts were treated in a SmartStretch™ machine before chilling and aging. The results of the study were that, irrespective of treatments (aging, stretch, or stimulation), 100% of samples would have been acceptable after 0 days on display. However, after 24, 48, and 72 h on retail display, 72%, 86%, and 93% of the samples would be deemed unacceptable to consumers, respectively.

Studies on the eating quality of commercially processed hot-boned sheep meat showed that all samples were tougher than the recommended threshold for table meat. Only 13.5% of the samples met the 'good everyday' requirement following sensory assessment. The authors reported that the application of effective ES is not sufficient to ensure that hot-boned sheep meat will be suitable as a table meat.

Pork

Although cold shortening can produce toughening in pork it is potentially less of a problem than in beef or lamb. Consequently a whole range of rapid chilling and warm/hot boning technologies have been developed for pork. As early as the 1950s, several progressive sausage manufacturers in the United States, who were also engaged in pig slaughtering, deboned hot (less than 1 h postmortem) sow carcasses. The resulting prerigor muscles were treated with salt or sometimes polyphosphates and this procedure improved the water-holding capacity for the production of frankfurters. Today, the majority of sows and some boars, 15% of the total pork production, are hot boned and nearly all the musculature transformed immediately into sausages. This is the most extreme example of accelerated processing currently in commercial operation, from pig to sausage in less than 2 h. The adenosine triphosphate present in prerigor pork acts as a natural glue in the production of restructured products and with the trend toward additive-free food, such processing prerigor bears reexamination.

The rate of diffusion of salt through muscle becomes faster as muscle temperature rises. Also, the still intact arterial system of the pig immediately after slaughter provides a good distribution network for curing brine. Systems have been developed to hot cure bacon by arterially pumping cold brine into the carcass prerigor. This has the added advantage of partially cooling the meat, before immersion chilling in refrigerated brine.

In a hot boning system developed in the late 1980s, loins were removed 30 min postmortem, vacuum packed, held in a water bath at 11 °C for 5 h, and then brine chilled. Drip loss after storage for 21 days at 0 °C was less (0.55%) than the control and other rapidly chilled treatments. Other sensory parameters were similar. In warm processing work, carried out at the same time, loins were removed from carcasses 1, 3, or 5 h poststunning. Three rapid cooling treatments; immersion in brine at −23 °C; CO_2 chilling at −94 °C or packing in CO_2 at −68 °C, were used in the trials. These produced loin temperatures of −2 °C after 1.5–2 h of chilling with no significant difference between treatments. The crust frozen loins were then tempered and mechanically portioned. Pork chilled at 1 h poststunning resulted in high shear force values and short sarcomere length. For a delay time of 3 h or more there were no major differences in muscle color, pH, sarcomere lengths, drip, or taste panel determinations between treatments and a conventionally (0–2 °C chiller) chilled control.

Cold shortening in pork was first confirmed in trials where pork carcasses and sides were chilled immediately after slaughter using air below −30 °C and high air velocities. Further trials showed that ES before rapid chilling alleviated the toughening problems. Other trials have shown that the detrimental effects of accelerated boning on pork tenderness can be overcome with temperature conditioning at 14 °C and aging for 4 days postslaughter. Chilling of muscles at 0 °C following accelerated boning resulted in cold shortening as seen by the reduction in sarcomere length relative to muscles chilled at 14 or 21 °C. Furthermore, the reduced sarcomere length increased drip loss and produced pork of a darker color.

Warm boning as practiced in Denmark is another technology that allows same day processing and distribution. Immediately after dressing, chilling in air at −25 to −30 °C for approximately 80 min is commenced. This brings the surface temperature down to approximately −2 °C. It is therefore necessary to equilibrate the carcass for one or two hours before cutting and boning take place. The total chilling loss is approximately 0.6%. After boning the meat is either vacuum packed for storage and aging; wrapped, boxed and frozen, or cured and tumbled. Not all the heat is extracted during the short initial blast chilling operation and further cooling is required after cutting. Studies showed that there were no differences in the microbial and sensory qualities of the 'warm' processed pork compared with cold-boned controls. Overall yield was 0.8% higher than that from the controls.

It is not uncommon in Spain for pork carcasses to be boned out after a 90 min chilling period. With the exception of the hams the rest of the carcass is immediately butchered into primals, which are further chilled and distributed on the same day as slaughter.

Horse

Although little horse meat is eaten in comparison with other red meats, a considerable amount is produced. There is little data on either conventional or hot processing of horse; however, hot boning is likely to offer similar advantages and disadvantages as for beef. In one published study on the commercial warm boning of horse carcasses the cooling process for warm-boned meat met with standards for hot-boned beef cooling processes based on calculated growth of *E. coli* at box centers. In the plant studied, carcass sides were cooled overnight, or for between only 1 or 2 h. In the latter case, the warm carcasses are divided into quarters and prime cuts of meat removed from the hanging quarters placed directly into bags for vacuum-packaging followed by air blast chilling air at a temperature of −5 °C and a speed of approximately 4 m s^{-1}. For 80% of the temperature histories, the initial temperature was >20 °C and temperatures of 7 and 0 °C were attained within 13 and 26 h, respectively. Numbers of bacteria recovered from cooled carcasses or hot- or cold-boned cuts were generally similar. The microbiological condition of horse carcass quarters delivered to plants in Europe was claimed to be comparable with the microbiological conditions of hanging beef delivered from packing plants to distant customers within North America.

Poultry

Production of deboned poultry meat has rapidly increased since the 1990s. Hot boning of poultry results in similar advantages and disadvantages as for red meat. However, the onset of rigor is far faster in poultry than red meat. As with red meat, ES is often used to speed the onset of rigor, allowing for hot boning without toughening. Electrical stunning at 40 V and high frequency is claimed to significantly improve the texture of chicken and can produce hot-boned breasts with acceptable tenderness. Boning is commonly carried out at

1.5–2 h postmortem. However, breasts are usually boned out after 24 h postmortem.

There have been a number of studies on the eating quality of breast fillets boned at different intervals postmortem. Studies on the eating quality of cooked chicken fillets from either hot boned at 45 min postmortem or cold boned at 2 or 24 h postmortem showed little difference between hot and the 2 h boned fillets. However, the flavor profile of 24 h boned fillets was different from both hot and 2 h boned samples. The 24 h boned were rated less cardboardy and sweeter. In other studies on breasts boned from 0.25 h (hot boned) to 24 h all the meat produced before 6 h postmortem was judged to be tougher than that boned after 6 h or later.

Conclusion

Hot boning of beef, pork, lamb, horse, and poultry carcasses offers a variety of benefits to the processor such as increased boning yield and savings in refrigeration capacity and energy usage compared with conventional cold-boning operations. In addition manufacturers of further-processed products have realized the improved functionality of hot-boned muscles especially in the production of ground beef and pork items.

Common problems with early hot-boned meat systems usually included reduced tenderness, distortion of muscle shape, and darker lean color. However, the use of ES or muscle restraining and aging systems greatly reduces, or eliminates, many of these problems. Prerigor boning and chilling systems are applicable to the meat industry and provide a safe and high-quality product.

Although a number of countries, such as New Zealand and Australia, have embraced the benefits of hot boning, the lack of understanding of, and information about, hot processing, the operational changes required to make hot-boning systems work in current operations, and fear of reduced shelf-life has limited the uptake of hot-boning in other countries, especially in Europe and the Americas.

Glossary

Fabricate (as related to meat cutting) To reduce a carcass into its major and minor components for further use in the retail and foodservice channels.

Primal Large section of carcass usually associated with legs (e.g., round, leg, shoulder, chuck, rib, loin, etc.).

Subprimal Sub-divided portion of primal into smaller pieces more suitable for portioning into steaks, roasts, or chops.

Superior spinous process The most dorsal portion of the vertebrae.

Transverse process The lateral portions of the vertebrae most prominent in the lumbar area of the animal.

Introduction

One of the challenges of communicating cutting and boning information to a worldwide audience is that the nomenclature and terminologies used vary so widely. Many technical references now feature pictorial examples of cuts so that a visual description can then be matched with the word description of it. It is always best to use anatomical descriptions – muscle and bone names – where possible so that the best and most universal description of carcass cutting/boning can be made. One such source is the International Committee on Veterinary Gross Anatomical Nomenclature, which provides detailed muscle and bone names.

The scope of this article will focus on beef, pork, and lamb cutting and boning, but some of the methods and terminologies can be used for other livestock species of importance to some countries around the world. For the most part, prerigor cutting and boning is termed 'hot processing' or 'hot boning,' whereas postrigor cutting and boning usually is referred to as 'cold processing' or 'cold boning.' Because cold cutting/boning is the default method in the developed world, it may just simply be referred to as 'cutting/boning' because it is performed after chilling and limited cold storage. Cutting styles and nomenclature do not differ between hot or cold boning. The debate about the advantages and disadvantages of hot boning are numerous and will be discussed in the article on hot boning.

Early humans probably developed crude cutting/boning procedures as they obtained carcasses from dead animals, through hunting or later through domestication and harvest. People had to find a way to handle the large carcass mass and reduce it into smaller pieces for possible sharing or for consumption over time, especially if performed during the winter months where cold temperatures would have allowed for extended storage for consumption at other times.

Early cutting tools might have been made from stones before the advent of metal where various blade-type devices (e.g., axes and knives) would have been used to cut meat. The development of sawing tools would have assisted the carcass cutting process with band and reciprocating saws used commercially today. In fact, the thin blades of commercial band saws with the small amount of kerf they remove in the sawing process is of great economic importance for large-scale meat processors where even small savings in yields are magnified through the large volume of carcasses processed.

Terminology of Cutting and Boning

Describing the process of converting carcasses into smaller portions is often confusing. For example, in the US, beef carcasses are 'fabricated' into wholesale cuts, using the broad definition of 'fabricate' i.e., 'to make or build something.' This term is usually shortened to state that 'carcasses are being fabbed,' or to describe the room where this process is conducted is simply referred to as the 'fab room' or 'fab area.' These are nonstandard uses of this term, but this simply demonstrates how terminology has evolved to describe various processes in the meat industry in at least one country. For the most part, pork is simply 'cut' so the description of the process and where the location of the process occurs is referred to as 'pork cutting.'

Terms to Describe Wholesale Cuts of Meat

Nomenclature used to describe the wholesale portions from carcasses varies from country to country, and also the nomenclature used to describe the general terms for what these portions are varies widely. The term 'primal' probably has its origin to the fact that a section of the carcass was a 'prime' or 'primary' region and thus this term was developed. Several decades ago, with the advent of widespread vacuum packaged, boxed meat programs, the term 'subprimal' began to be used because it best described smaller portions of primals. For example, the primal loin in beef could be further reduced to the strip loin, tenderloin, top sirloin, and bottom sirloin cuts. The trend today is for even further separation of cuts with some

 doi:10.1016/B978-0-12-384731-7.00147-1

now merchandized as an individual muscle (IM) with the term 'IM' being used in the names to signify such cuts.

Because specific nomenclature and exacting specifications are necessary in buyer–seller relationships, and because the US Federal Government purchases a tremendous volume of meat for various buying programs, the Agricultural Marketing Service of the US Department of Agriculture (USDA) developed the Institutional Meat Purchase Specifications (IMPS) program as a way to have clear descriptions for the ever-evolving number of cuts available in the marketplace. The IMPS system also is used in market-news reporting as a way to note the prices being paid for specific cuts of meat. There are many different IMPS programs, but the ones related to this topic can be obtained from USDA for the categories of beef, pork, and lamb.

In 1961, the National Association of Meat Purveyors (now known as the North American Meat Association) began publishing the *'The Meat Buyer's Guide®'* as a way to provide a pictorial depiction of these cuts. The scope of the guide has grown over the years to include beef, lamb, veal, pork, and poultry, and the guide has been published in a number of different languages to assist buyers and sellers in the world market for meat.

Beef Carcass Cutting

As mentioned earlier, methods of cutting/boning differ among countries and among companies even within a country. Beef carcass cutting is a method of cutting adapted from Savell and Smith, which reflects a US perspective of cutting/boning. Figure 1 depicts beef wholesale cut names used in this article.

Beef sides are separated into forequarters and hindquarters based on historic precedence and whether the ribeye/loin eye is to be evaluated for a grading/classification system. In the US, carcasses are ribbed between the 12th and 13th rib for grading purposes. The exposed ribeye muscle (M. longissimus thoracis) is evaluated for the voluntary USDA quality grade program using human visual or video-image analysis systems.

After grading and sorting by grade, weight, and other factors, sides are separated into forequarters and hindquarters by continuing the original ribbing cut through the plate/flank juncture perpendicular to the outside surface of the carcass. Before making this cut, the inside skirt (M. transverse abdominus) is loosened from its attachment in the flank area and dropped into the forequarter region so that it is not cut when separating the forequarter and hindquarter.

Forequarter Cutting

Here is a brief summary of forequarter cutting/boning that might involve table and on-the-rail methods, depending on facility layout and staffing.

- A knife cut is made between the 5th and 6th ribs through the lean and fat from the vertebrae to the sternum.
- The thoracic vertebra and sternum are sawn through between the 5th and 6th ribs to separate the chuck/brisket/foreshank from the rib/plate section.

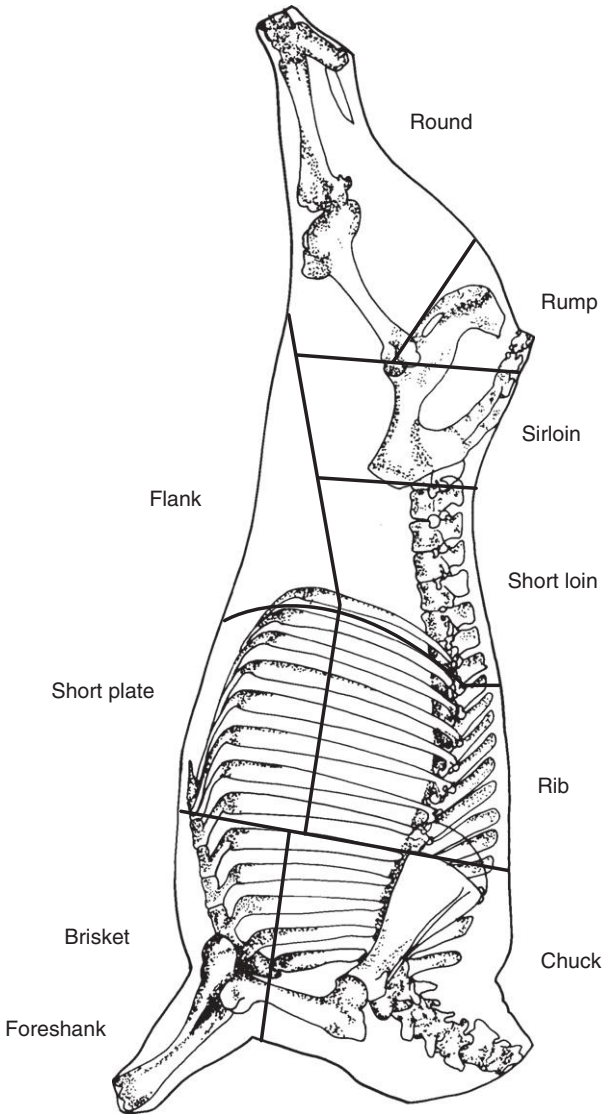

Figure 1 Beef wholesale cuts chart. Courtesy of the American Meat Science Association.

- The rib is separated from the plate by cutting through the ribs at a point measured from the lateral edge of the ribeye muscle (M. longissimus thoracis) on each end of the rib. This distance should be no more than 15 cm from the ribeye muscle on the loin end (posterior) and no more than 25 cm on the chuck end (anterior).
- The foreshank and brisket are removed from the chuck just above the lateral condyle of the humerus by making the cut parallel to the top of the chuck.
- The foreshank and brisket are separated at the natural seam between them.

Forequarter Boning

There are a number of major boneless subprimals that come from the forequarter. Here are a few and how they are prepared.

Beef Rib Ribeye, Lip-On (IMPS 112A)

This is the most common form of boneless ribeye marketed in the United States.

- The wholesale rib that is 15 × 25 cm (length of ribs from the lateral edge of the M. longissimus thoracis) is now cut so that the rib is 7.5 cm (measured from the lateral edge of the M. longissimus thoracis on the loin or posterior end) × 10 cm (measured from the lateral edge of the M. longissimus thoracis on the chuck or anterior end).
- The body of the vertebral column is removed on a band saw exposing a strip of lean between the feather bones (superior spinous processes of the vertebral column) and the rib bones. The feather bones are removed.
- The blade meat (portions of M. subscapularis and M. rhomboideus immediately below, and M. latissimus dorsi, M. infraspinatus, and M. trapezius immediately above the scapula) is removed starting at the ventral end of the rib near the seam in the exterior fat cover and continuing up to the dorsal end of the rib.
- Remove the ligamentum nuchae and the portion of the 'lip' (consists of the M. serratus dorsalis, M. longissimus costarum and associated fat tissues) that exceeds 5 cm from either end of the rib so that the ribeye is 5 cm × 5 cm. This ribeye is now a Beef Rib, Ribeye Roll, Lip-On, Bone In (Export Style), or IMPS 109E.
- Remove the back ribs beginning at the ventral end, being careful to follow the natural curvature of the ribs.

Beef Chuck, Shoulder (Clod) (IMPS 114)

In industrial settings, the shoulder clod (major muscle system that contains the M. triceps brachii, M. infraspinatus, and M. teres major) is removed from the arm chuck, which is a chuck that has the foreshank still attached, but the brisket has been removed.

- The arm chuck is suspended on-the-rail from the foreshank. A cut is made through the M. triceps brachii immediately below the elbow joint to the bone (humerus).
- The seam between the clod and the M. pectoralis profundus is opened.
- The M. triceps brachii is cut along the humerus to the knob portion of the bone (near the juncture of the humerus and scapula). At this point, the seam between the clod and the remaining portion of the chuck should be more evident.
- Continue cutting along the edge of the scapula paying particular attention to the complete removal of the M. infraspinatus from the scapula and the M. teres major from behind the scapula.
- The shoulder clod can be separated into these cuts: Beef Chuck, Shoulder (Clod), Top Blade (IMPS 114D), consisting of the M. infraspinatus; Beef Chuck, Shoulder Tender (IM) (IMPS 114F), consisting of the M. teres major; and Beef Chuck, Shoulder (Clod), Arm Roast (IMPS 114E), consisting primarily of the M. triceps brachii, caput longum (long head) and M. triceps brachii, caput laterale (lateral head).

Beef Chuck, Chuck Roll (IMPS 116A)

The scapula and M. supraspinatus are removed from the remaining portion of the arm chuck. The chuck portion is then separated from the foreshank before further processing.

- Using a band saw, the neck is removed from the chuck by cutting through the 5th-6th cervical vertebrae and parallel to the cut that was made between the 5th and 6th ribs. Make a cut that is immediately ventral to the body of the vertebrae and parallel to the line where the brisket was removed to separate the chuck short ribs and the pectoral muscle (M. pectorales superficiales) from the chuck roll.
- Remove all feather or superior spinous processes, vertebrae, rib bones, and ligamentum nuchae from the chuck roll.
- Remove the M. trapezius and exposed seam fat from the outside surface of the chuck roll along with the prescapular lymph gland.
- The remaining arm portion shall be excluded by a straight cut that is not more than 7.5 cm ventral from the M. longissimus thoracis at the rib end (posterior) and not more than 10 cm from the M. complexus at the neck end (anterior).

Hindquarter Cutting

- Separate the loin/flank and round on a line between the 4th and 5th sacral vertebrae and approximately 2.5 cm anterior to the aitch bone. Cuts through the bone are made with a saw, whereas cuts through the lean are made with a knife.
- Remove the flank from the loin by making a cut no more than 15 cm from the lateral edge of the loin eye muscle (M. longissimus lumborum) at the rib end (anterior) to no more than 2.5 cm from the lateral edge of the M. tensor facia latae in the round end (posterior). There is one saw cut (13th rib) and the remainder is made with a knife.
- Remove the kidney knob and pelvic fat leaving no more than 1.3 cm of fat at any point.
- Separate the short loin from the sirloin by cutting between the last two lumbar vertebrae parallel to the sirloin face (posterior).

Hindquarter Boning

There are a number of major boneless subprimals that come from the hindquarter. Here are a few and how they are prepared.

Beef Round, Sirloin Tip (Knuckle), Peeled (IMPS 167A)

- On the table, remove the caudal vertebrae from the round along with the lean and fat tissue around the top of the aitch bone. Remove the aitch bone paying particular attention to staying very close to the bone. Hang the round from the rail by the hock.
- Begin removing the knuckle by cutting just posterior to the knee cap. Follow the seams between the knuckle and the

M. biceps femoris and M. adductor and along the femur making sure to remove the periosteum as the knuckle is removed.
- Remove the M. tensor fasciae latae, fat, and skin tissue to make this a 'peeled' knuckle.

Beef Round, Top (inside) (IMPS 168)

- Make a knife cut beginning at the posterior section of the top round (M. semimembranosus and M. adductor are the major muscles) on the inside portion of the round.
- Continue removing the top round by following the natural seam and cutting along the femur.
- Finish removing the top round and trim external fat to purchaser's specifications.

Beef Round, Outside Round (Flat) (IMPS 171B) and Beef Round, Eye of Round (IM) (IMPS 171C)

These subprimals may be removed together as the Beef Round, Bottom (Gooseneck) (IMPS 170) before being separated into these two cuts.

- Make a knife cut immediately below the Achilles tendon being careful so that the hock will still be hanging on the hook.
- Continue the cut until the shank muscle seam is found.
- Remove the gooseneck round following the shank muscle seam and down along the femur.
- Remove the heel muscle from the gooseneck round. Separate the eye of round from the bottom round.
- Trim external fat from the eye of round to purchaser's specifications.
- Remove the opaque heavy connective tissue (often referred to as 'silver skin'), seam fat, lymph glands, and cartilage and ligaments. Trim external fat to purchaser's specifications.

Beef Loin, Tenderloin, Full, Side Muscle On, Defatted (IMPS 189A), Beef Loin, Strip Loin, Boneless (IMPS 180), and Beef Loin, Top Sirloin Butt, Boneless (IMPS 184)

These three subprimals are the major cuts obtained from the loin. To remove the full tenderloin, the loin has to remain intact and not separated into the sirloin/short loin sections as previously described.

Beef tenderloin

- From the full loin, remove the kidney and pelvic fat, being careful not to cut into the tenderloin.
- Remove the bottom sirloin flap and flank steak from the flank.
- Begin removing the tenderloin in the tail region by carefully cutting it from its attachment to the lumbar vertebrae.
- Continue cutting the tenderloin away from its attachment to the lumbar vertebrae by following along the body of the chine bones and the finger bones (transverse processes of the lumbar vertebrae).
- When the tenderloin is loosened near the sirloin/short loin juncture, begin removing it from the sirloin face (posterior).
- Carefully roll out the tenderloin by cutting the attachment of the wing (M. iliacus) to the pelvic bone.
- Trim the remaining fat from the tenderloin being careful not to separate the chain (M. psoas minor) from the body of the tenderloin (M. psoas major).

Beef strip loin

- Separate the shell loin from the sirloin by cutting between the last two lumbar vertebrate and parallel to the sirloin face (posterior).
- On the strip loin portion, using a band saw, cut the bodies of the vertebrae away so that there is clear separation between the superior spinous processes and the transverse processes.
- Using a knife, carefully remove the superior spinous processes, transverse processes, and the 13th rib from the strip loin.
- There are several purchaser-specified options that can be used for flank removal: a common one today is 2.5 cm × 0 cm, which refers to making a straight cut at a point 2.5 cm on the rib end (anterior) to a point 0 cm on the sirloin end (posterior) ventral to the loin eye muscle (M. longissimus lumborum).
- Trim the external fat to purchaser's specifications.

Beef top sirloin

- With the full sirloin, separate the bottom sirloin from the top sirloin using a knife and following the seam between the two. The bottom sirloin can be further separated into the Beef Loin, Bottom Sirloin Butt, Ball Tip, Boneless (IMPS 185B) and Beef Loin, Bottom Sirloin Butt, Trip-Tip, Boneless (IM) (IMPS 185C).
- For the top sirloin section, remove the hip bone and sacral vertebrae.
- Trim the external fat to purchaser's specifications.

Pork Carcass Cutting

Here are general procedures for cutting pork carcasses, with Figure 2 depicting wholesale cut name and location. The loin/ham break has some latitude and will vary based on the relative value of each of these cuts. When loin prices are higher than ham prices, the cut will be made closer to the ham; conversely, when ham prices are higher than loin prices, the cut will be made closer to the loin.

General Pork Carcass Cutting

- The leg or fresh ham is separated from the pork side by making a straight cut approximately perpendicular to a line parallel to the shank bones and that passes through a point that is not less than 3.7 cm and not more than 8.8 cm from the anterior edge of the aitch bone. There shall be no more than two sacral vertebrae, but no caudal vertebrae left on the loin.
- The shoulder is separated from the side by a straight cut that is approximately perpendicular to the length of the side. The

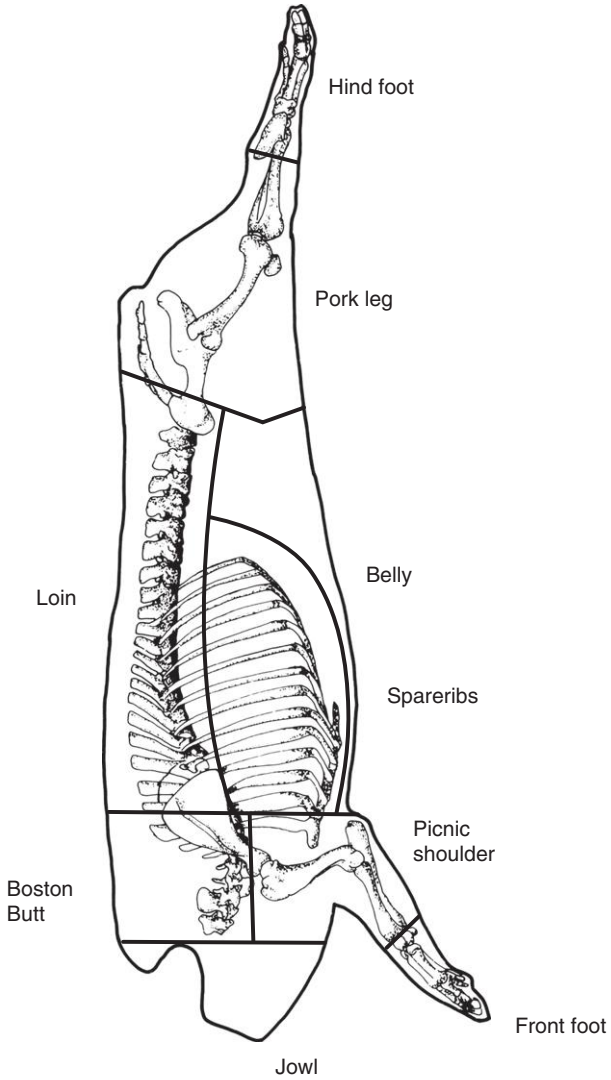

Figure 2 Pork wholesale cuts chart. Courtesy of the American Meat Science Association.

cut is made posterior to, so as not to expose, the elbow, but not more than 2.5 cm from the tip of the elbow. The outer tip of the M. subscapularis shall not extend past the dorsal edge of the base of the medial ridge of the blade bone.

- The belly is removed from the loin making a straight cut (a slight dorsal curvature is acceptable) that extends from a point that is ventral to, but not more than 7.5 cm from the M. longissimus thoracis on the shoulder end, to a point on the leg end ventral to, but not more than 1.3 cm from the tenderloin (M. psoas major).

Pork Shoulder Cutting

- The foot is removed at or slightly above the upper knee joint by making a straight cut approximately perpendicular to the shank bones.
- The jowl is removed by making a straight cut approximately parallel with the loin side that is anterior to, but not more than 2.5 cm from the innermost curvature of the ear dip, then the neck bones, ribs, breast bones, associated cartilage, and breast flap (through the major crease) are removed.
- The skin, dorsal to a straight line parallel to the dorsal side that starts at a point that does not exceed 25% of the distance from the elbow joint to the dorsal side, is removed.
- Fat exposed by the removal of the skin is trimmed to not exceed 1.3 cm or more from the edge of the skin collar, and traces of false lean (M. trapezius) are to be visible.
- The picnic shoulder is separated from the Boston butt by making a straight cut, dorsal to the shoulder point approximately 1.3 cm from the dorsal edge of the blade bone on the loin side, at an approximate right angle with the belly side.

Pork Leg (Fresh Ham) Cutting

- Remove the tail, vertebrae, flank muscle (M. rectus abdominis), M. cutaneous trunci, prefemoral lymph gland, and any other exposed lymph nodes.
- Remove the foot at or slightly above the hock joint.
- The skin and collar fat over the cushion (M. semimembranosus) is removed so that it is smooth and well rounded such that the innermost curvature of the skin is trimmed back at least half the distance from the stifle join to the posterior edge of the aitch bone.
- The skin overlying the medial side (inside) of the M. quadriceps femoris and fat close to the lean overlying the M. quadriceps femoris and pelvic area are removed.

Pork Loin Cutting

- The surface fat of the loin is trimmed to an average of 0.6 cm or less in depth except in the hip bone area (defined as the area contained within two parallel lines, 5 cm on either side of the anterior end of the hip bone and associated cartilage). Fat in the hip bone area is trimmed to the same contour as the rest of the trimmed surface of the loin. Lumbar and pelvic fat are trimmed to 1.3 cm or less in depth.
- At least 5 cm of the false lean (M. trapezius) shall be exposed lengthwise on the blade end of the loin, and the diaphragm and hanging tender are removed.

Lamb Carcass Cutting

Because of their size, lamb carcasses are not split in half during the slaughter-dressing process like beef and pork, so the style of fabrication differs somewhat from these species. Here are some general cutting procedures which Figure 3 depicts lamb wholesale cut name and location.

Carcass Primal Breaking

- The foresaddle is separated from the hindsaddle at the 12th and 13th rib by a cut that follows the natural

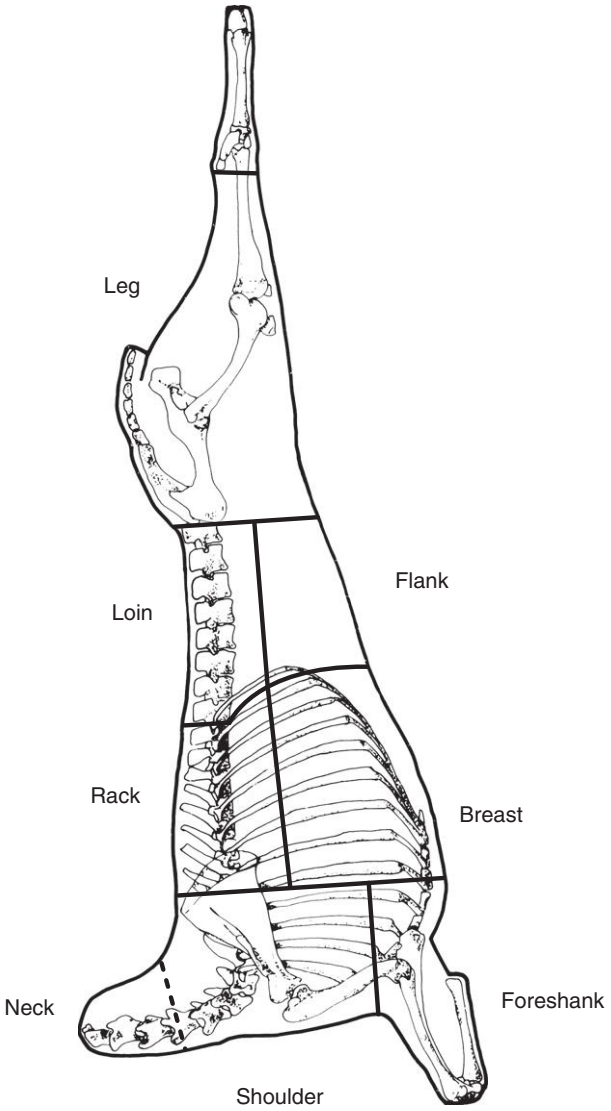

Figure 3 Lamb wholesale cuts chart. Courtesy of the American Meat Science Association.

curvature of the ribs. With this, there are 12 ribs that remain on the foresaddle and 1 rib on the hindsaddle.

- The foresaddle is separated into the shoulder/foreshank/brisket portion of the breast and bracelet (rack and breast) by making a straight cut between the 4th and 5th ribs perpendicular to the back. This leaves four ribs in the shoulder and eight ribs in the rack.
- The hindsaddle is separated into the loin (with the flank attached) and the leg by making a straight cut, approximately perpendicular to the length of the leg, passing anterior to the hip bone and hip bone cartilage.

Lamb Foresaddle Component Cutting

- The shoulder, square-cut is prepared by removing the foreshank and brisket portion of the breast by making a straight cut approximately perpendicular to the rack side (posterior) and through the cartilaginous juncture of the first rib. The neck is removed leaving no more than 2.5 cm of it on the shoulder. The thymus gland and heart fat is removed. If desired, the shoulder can be split into individual shoulders by making a saw cut through the vertebral column.
- The foreshank is separated from the brisket portion of the breast by cutting through the natural seam, which may contain a portion of the web muscle (M. pectoralis superficialis). The trotter or lower foreshank is removed at or above the knee joint.
- The rack is separated from the breast by making a straight cut no more than 10 cm from the lateral edge of the ribeye muscle (M. longissimus thoracis). The diaphragm and fat along the ventral side of the vertebrae of the rack are removed.
- If desired, the rack can be split into half racks by making a saw cut through the middle of the vertebral column.
- The breast can be made into 'Denver Style' ribs by removing the sternum and costal cartilages, fell membrane, M. cutaneous trunci, exterior fat cover, M. latissimus dorsi, and diaphragm.

Lamb Hindsaddle Component Cutting

- The flank is removed from the loin by making a straight cut no more than 10 cm from the lateral edge of the loin eye muscle (M. longissimus lumborum) on both ends of the loin. The diaphragm and hanging tender are removed from the loin.
- If desired, the loin can be made into half loins by making a saw cut through the vertebral column.
- The flank is separated into lean, fat, and bone (13th rib) portions.
- The legs are separated by making a saw cut through the vertebral column and pelvis. A short-cut leg can be made by removing the sirloin by making a straight cut approximately perpendicular to the length of the leg starting at the juncture of the last sacral and first caudal vertebra and passing just anterior to the protuberance of the femur (this exposes the ball of the femur). The short-cut leg can either have the tibia left in (French-style leg) or removed (American-style leg or shank-off leg).

Cutting and Boning Trends for the Future

The widespread adoption of many of the cutting and boning schemes used around the world would not have happened without the development of plastic packaging technologies in the last part of the twentieth century. Vacuum packaging of fresh meats led to extensive and centralized cutting and boning near the point of slaughter, which allowed for innovative styles to be developed. In addition, with the advent of packaging technology, the ability to export meats to great distances and to countries that demanded specific cuts that might have never been used domestically greatly increased the development of new styles of cutting and boning. It is likely that these trends will only increase in the future.

D

DOUBLE-MUSCLED ANIMALS

S De Smet, Ghent University, Melle, Belgium

Glossary

Callipyge A genetic mutation that causes lambs to develop large and muscular rumps, from the Greek for 'beautiful buttocks.'
Double-muscled The exceptional muscular development as a result of a functional mutation in the myostatin gene.
Heterozygous animals Animals having two different alleles of a given gene.
Homozygous animals Animals having the same alleles of a given gene.
Muscular hypertrophy Exceptional muscular development.
Myogenesis The formation of muscle tissue during development of an embryo.
Myostatin A protein that acts as an inhibitor of the growth of muscle tissue.

Introduction

Double-muscled animals are of particular interest to meat producers because they are characterized by an increase in muscle mass and a decrease in fat deposition, resulting in a larger amount of lean meat than in normal animals. The term is mainly restricted to cattle and refers to an inherited condition that has been known for some time but of which the causal mutation in the myostatin gene was recently discovered. The condition is associated with altered physiological and histological characteristics that bring about differences not only in meat quantity but also in animal performance and in meat quality. Therefore, the use of double-muscled cattle in pure breeding or crossbreeding production systems has to be considered carefully, especially because of calving difficulties. Meat quality of double-muscled cattle differs from that of normal cattle in several respects and resembles as well as differs from meat of particular genotypes with enhanced muscularity in other species.

Genetic Background

Double muscling is an inherited condition that occurs in several cattle breeds. However, it is highly prevalent in only two breeds, i.e., the Belgian Blue and the Piedmontese. Different symbols have been used to differentiate between the double-muscled and normal phenotype, of which mh (muscular hypertrophy) and + are the most common. The locus was mapped to the centromeric end of bovine chromosome 2. Identification of double-muscled animals was long based on visual assessment of the degree of muscular hypertrophy, i.e., by looking at protruding muscles and intermuscular grooves under the skin. This is only accurate in classifying normal and homozygous double-muscled animals, but does not allow distinction of heterozygous animals. This has contributed to the controversy in the early studies on the mode of inheritance of the mh allele. Segregation analyses later revealed that the mh allele was partially recessive with the mh/+ animals being distinct but closer to the +/+ than the mh/mh animals. In 1997, several research groups uncovered the genetic cause of double muscling by mutations in the myostatin gene. Myostatin (MSTN, also called growth and differentiation factor 8, GDF8) is a member of the transforming growth factor β superfamily of growth and differentiation factors. First, it was shown that mice in which the myostatin gene had been knocked out had a two to three times increased muscle mass ('Mighty mice'). Because myostatin had been mapped before to the mh region of bovine chromosome 2, it was a very likely candidate gene for the mh locus. Sequencing of myostatin deoxyribonucleic acid from double-muscled Belgian Blue cattle revealed an 11-bp deletion in the third exon causing a frameshift in the active *C*-terminal domain of the gene. Double-muscled Piedmontese cattle have a G to A transition also in the third exon, that changes a cysteine to a tyrosine in the same highly conserved region of the gene.

Later, four additional myostatin loss-of-function mutations were discovered, disproving the initial hypothesis that double muscling would be genetically homogenous and, originating from the Shorthorn breed was then spread from the British Isles to the continent and the rest of the world. Several mutations are shared by more than one breed. Most breeds examined are genetically homogenous, but several show allelic heterogeneity. The molecular dissection of this trait now also allows correct genotyping of animals, and thus a better comparison of the three myostatin genotypes for important traits, a shortcoming that many earlier studies suffered from.

Naturally occurring functional mutations in the myostatin gene have further been described in humans, sheep, dogs, and horses, leading to similar hypermuscularity. In sheep, three different mutations have been reported so far. In the heavily muscled Texel breed, a single-nucleotide polymorphism in the 3′UTR of the gene was found that creates an illegitimate target site for two micro ribonucleic acids (miRNAs) that are highly expressed in skeletal muscle, causing a reduction in messenger RNA concentration and circulating myostatin protein levels, thereby contributing to the muscular hypertrophy. This hypomorphic allele segregates and causes an increase in muscle mass also in several other sheep breeds. No functional mutations in the myostatin gene have been discovered in other domestic farm animal species that have undergone intense selection for muscularity, such as pigs, poultry, and turkey. Only a putative mutation was found in the myostatin gene of Piétrain pigs, a breed that is also known for its heavily muscled phenotype. This fact could be fortuitous, but is likely indicating differences in myostatin physiology in different species.

The finding that an allelic series of myostatin loss-of-function mutations explain most of the cases of double muscling in cattle, demonstrates the important function of myostatin in skeletal muscle. Active myostatin seems to play a key role in regulating myogenesis and acts as an inhibitor of muscle development. The inactivation of the protein causes an increase in the number of late myoblasts because of increased myoblast proliferation or delayed differentiation into primary and secondary myofibres. Myostatin appears to inhibit myoblast proliferation by arresting cell cycle at the G_1-phase, and myoblast differentiation by downregulating the expression of differentiation related genes. Myostatin also maintains satellite cells in a quiescent state. The muscular hypertrophy of double-muscled cattle is mainly the result of muscle cell hyperplasia, i.e., individual muscle fibers are not larger but higher in number, though some muscle fibers are indeed larger. Recently, it was shown that postnatal inactivation of the myostatin gene in skeletal muscle is able to cause a generalized muscular hypertrophy of the same magnitude as that observed for constitutive myostatin knockout mice, demonstrating that myostatin regulates muscle mass not only during early embryogenesis but also throughout development. The growth inhibition of proliferating skeletal muscle myoblasts by myostatin appears to be widely conserved among not only mammalian vertebrates but also avians and fish.

The biological function of myostatin is, however, not restricted to suppressing skeletal muscle growth. Myostatin also appears to play a role in protein metabolism, and more specifically in the regulation of protein synthesis. It has also been shown to regulate glucose metabolism. The effects of myostatin on adipose tissue are less well established, but it is clear that inhibiting its activity results in a large decrease of the fat mass. Myostatin is expressed at low levels in adipose tissue, and increases fat accumulation and adipogenesis. Although this may simply be a consequence of metabolic changes in skeletal muscle, it is likely that myostatin has a direct role in adipose tissue also and in the cross-talk between skeletal muscle and adipose tissue. The bioactivity of myostatin is not solely mediated by increased synthesis or release from skeletal muscle, but requires proteolytic cleavages of the precursor protein. The propeptide, as well as several other ligands, for example, follistatin and GASP-1, prevent receptor binding and activity of myostatin. Follistatin is a potent myostatin antagonist, and transgenic Mighty mice overexpressing follistatin have even greater muscle mass than follistatin transgenics alone. Once activated, myostatin appears to signal by directly binding to its serine/threonine kinase receptor. Downstream intracellular signaling pathways for myostatin are multiple and involve Smad-mediated and non-Smad pathways. As mentioned above, a role for miRNAs in the regulation of myostatin expression has become evident. Conversely, myostatin may regulate the expression of miRNAs.

Evidently, muscle mass is under polygenic influence, and it should be stressed that as a result of ongoing selection, the muscular hypertrophy of the present-day Belgian Blue cattle is much more pronounced than the one of the mh/mh animals three decades ago. Similarly, there are large differences in muscularity between double-muscled animals of identical myostatin genotype from different breeds. However, it is unlikely that there are many other genes with comparable large effects on muscularity as the myostatin gene. The reason why myostatin null alleles, despite intense selection for improved carcass quality, still segregate at low or intermediate frequencies in most breeds tolerating double muscling, is that adverse side effects (see further) do not outweigh the tremendous benefits observed in lean meat yield from cattle possessing this mutation.

Another gene with a major effect on muscularity is the callipyge gene in sheep located on chromosome 18, subject to a special mode of inheritance, i.e., polar overdominance. Similar to double-muscled cattle, callipyge lambs have improved feed efficiency and carcass quality, but because the callipyge condition manifests postnatally, dystocia is not a problem. Unlike double-muscled animals, callipyge sheep show muscle cell hypertrophy, and meat of callipyge lambs consistently has lower tenderness scores, resulting from a reduced degree of calpain-mediated postmortem proteolysis (see Section Carcass and Meat Quality). Pigs having the mutation in the ryanodine receptor gene on pig chromosome 6 leading to the stress susceptibility syndrome as a result of a disturbance in the Ca^{2+} transport of skeletal membranes have also improved carcass quality compared to normal pigs. The biological implications of this mutation are now well established, including large effects on meat quality, but the mechanism for the increased muscle mass, characterized by muscle cell hypertrophy, in stress-susceptible pigs is not elucidated yet.

With the molecular genetics tools now being exploited, other genes affecting muscle development are likely to emerge, for example, the recently described regulatory mutation in the insulin-like growth factor II (IGF-II) locus in pigs with a major

effect on carcass quality and without apparent effects on meat quality. The increased muscularity associated with these genes is associated with differences in animal physiology, in muscle fiber histology and biochemistry and consequently also in meat quality. Similarities but also distinct differences in meat quality compared to the effects of the myostatin gene are thereby observed.

Physiology and Metabolism

Differences in circulating levels of various hormones and several other physiological parameters have been found in double-muscled compared to normal cattle, indicating an altered metabolism in favor of protein synthesis and lipolysis at the expense of lipid synthesis. The production of growth hormone is generally higher, whereas blood concentrations of insulin and IGF-I are normally lower. Concentrations of thyroid hormones are either not different or slightly lower. Small and mostly nonsignificant differences have been found for blood levels of cortisol, testosterone, glucose, α-amino nitrogen, and urea. Blood concentrations of triacylglycerols and nonesterified fatty acids have tendency to be lower and higher respectively. The blood level and urinary excretion of creatinine are clearly higher, in line with the higher muscle mass, whereas the opposite is the case for creatine. Other differences have been found too and it should be mentioned that the evolution of these parameters during development and growth, and the effect of management and nutrition conditions therein (e.g., compensatory growth) may differ at some points for double-muscled compared to normal animals.

Though considerable variation is observed across muscles, double-muscled cattle possess nearly 25% more muscle mass than those cattle lacking the mutation. Conversely, there are sizable reductions (approximately 5–40%) in bone and fat masses as well as significant reductions in the digestive tract size (Table 1). The skin is thinner and external genitalia are less developed. Newborn calves frequently have an enlarged tongue (macroglossia). Normally this disappears at young age, creating only temporary problems when suckling. When persisting, grazing is disturbed in adults. Macroglossia is typical for double-muscled calves. Other congenital and/or inherited disorders are not restricted to double-muscled animals only, but are nevertheless seen more frequently in this kind of animals. Brachygnathia superior and brachygnathia inferior, i.e., an abnormal shortness of the maxilla (upper jaw) and mandible (lower jaw) respectively, and locomotory problems such as extreme flexing as well as extreme stretching of the fore and hind legs, spastic paresis, and other joint problems are common. Some of these disorders apparently do not harm the animal and may even disappear with age. However, locomotory problems may become problematic when gaining weight. Double-muscled animals up to 1 year are more vulnerable to respiratory diseases, increasing calf mortality. The likely reason therefore is the underdevelopment of the cardiorespiratory system. The lower respiratory capacity in combination with the increased muscle mass is also at the origin of the greater susceptibility to exercise fatigue and heat stress. Reduced oxygen transport, aerobic metabolic activity of the muscle, larger heat production, and lower capacity for heat dissipation all contribute to greater stress susceptibility. It has also been suggested that double-muscled animals have a more excitable temperament, but research data to support this are scarce and this statement can be questioned in view of the generally very docile temperament and the lower level of spontaneous activity of these animals experienced in commercial practice.

Table 1 Effects of double muscling (myostatin loss-of-function) in cattle

	Double-muscled phenotype (mh/mh genotype)
Meat production	
Fertility	−
Calving difficulties	+ + +
Birth weight	+ +
Daily weight gain	− 0
Feed intake capacity	−
Feed conversion efficiency	+
Rusticity	− −
Carcass quality	
Dressing proportion	+ +
Organ weights	−
Carcass lean proportion	+ +
Carcass fat proportion	− − −
Carcass bone proportion	−
Cutability	+ + +
Meat quality	
Muscle fiber hyperplasia	+ + +
Muscle fiber hypertrophy	0
Color lightness	+
Myoglobin content, oxidative metabolism	−
Water-holding capacity	− 0
Myofibrillar weakening, proteolysis	−
Connective tissue content	− − −
Tenderness (high connective tissue content muscles)	+ +
Tenderness (low connective tissue content muscles)	0 +
Juiciness and flavor intensity	−
Intramuscular fat content	− − −

Note: The number of '+' or '−' indicates the degree of increase or decrease in double-muscle animals compared to normal animals, and '0' indicates no major effect.

Double-muscled cattle have reduced appetites and feed intakes compared to normal cattle as a result of the reduction of the size of the digestive tract (Table 1). Hence, they require adapted feeding systems for optimal or maximal production. When fed diets that meet their requirements, a more positive nitrogen balance and a reduced feed conversion ratio will be obtained. Urinary nitrogen excretion is significantly reduced, resulting in more efficient nitrogen retention. At the muscle protein level, the fractional rate of net synthesis appears similar, but the fractional rates of degradation and total synthesis are lower compared to normal animals. The rate of protein turnover, defined as the ratio of the fractional rates of net to total synthesis, is thus slower, explaining the higher efficiency of protein retention.

Reproduction, Growth, and Management

In general, fertility is reduced in double-muscled compared to normal cattle (Table 1). Sexual behavior is less distinct, making estrus detection more difficult for artificial insemination. Delays in puberty in heifers and males have been reported, but estrus characteristics and ovarian activity appear similar to normal animals. In males, testicular weight and semen volume and quality are reduced, but this poses little problem for reproduction. Reduced fertility in females is primarily manifested by a somewhat later age at first calving, longer intervals between calving and first estrus and between calving and first service, and a larger number of services per pregnancy. However, gestation length; rate of abortion; and incidence of placental retention, endometritis, and ovarian cysts are apparently not influenced. The most prominent difference with regard to reproduction is, however, the well documented higher frequency of calving difficulties (dystocia) due to a foeto-maternal morphological imbalance at calving. The higher birth weight and width of the calf especially at the trochanters in combination with reduced pelvic dimensions of the dam make delivery more difficult. Assistance on calving and ultimately cesarean section then become necessary in many cases. Part of the reduction in female fertility and rebreeding problems are associated with these calving difficulties. As expected, milk yield is substantially reduced in double-muscled cows.

Birth weight of double-muscled calves is significantly higher compared to normal calves. Postnatal growth rate is not much different or is slightly lower. The combination of comparable average daily weight gain and lower feed intake results in significantly improved feed conversion efficiencies. The improved feed conversion is primarily due to the altered composition of body weight gain toward relatively more protein and less fat deposition, and likely not the result of changes in feed digestibility or maintenance requirements. Feed digestibility is only slightly affected or is decreased on high roughage diets. It is unclear at present if maintenance requirements are really lower in double-muscled animals. Data on total energy requirements during growth and development are also inconclusive, but feed protein requirements are obviously higher in view of the altered composition of weight gain. For finishing, double-muscled animals need high energy (concentrate) diets due to the lower feed intake, and their performance is reduced on high-fiber diets. More generally, they require higher skilled management and are less adapted to harsh environmental conditions.

Animal performances are subject to the influence of many factors including breed, nutrition, and management. Hence, the effects of the double-muscled gene mentioned above may differ according to the breed, the ration, and the management conditions that are considered. However, it is clear that there are distinct differences for many traits that are either beneficial (efficiency of lean growth) or disadvantageous (reduced fertility and dystocia) to the overall production efficiency. The use of pure-breed double-muscled cattle in production systems around the world is limited, mainly because of the calving difficulties, and restricted to Europe where marketing systems favor high carcass yield. However, there is increasing interest for the use of double-muscled crossbreds in many beef producing countries. There is a large variability in the performances of progeny from crossing double-muscled and normal cattle. The likely strategy is to cross double-muscled males with normal females, hereby reducing reproductive problems and maintaining a considerable part of the superior carcass characteristics. Although many of the problems associated with the double-muscling condition are not experienced in crossbreds, these systems still require pure-breed herds to be maintained. The need for routine cesarean sections in pure-breeding systems is, however, sometimes also criticized on animal welfare grounds. More generally, the social acceptance of the use of extremely selected animals is expected to decrease in many societies. Hence, it is unclear at present if or to what extent double-muscled cattle will be utilized in the long term.

Carcass and Meat Quality

The largest merit of double-muscled animals lies in their superior carcass characteristics (Table 1). Because of the slower rate of fat deposition, slaughter maturity is delayed. Inversely, animals of this genotype can be finished to higher slaughter weights. Dressing proportion is significantly increased (approximately 5%) compared to normal animals because of the reduced digestive tract and the lower weight of skin and organs. At similar age or weight, carcasses of double-muscled animals have higher proportions of lean meat and lower proportions of fat and bone. Although prominence is generally given to the muscle hypertrophy in describing the double-muscled condition, the reduced development of the fat tissues is relatively much more distinct. The size but not the number of the fat cells is decreased. The reduction in bone proportion is more moderate. The muscle hypertrophy and the fat and bone hypotrophy are general but not uniform throughout the body. Especially superficial muscles and the hindlimbs compared to the forelimbs are most affected, but differences between studies as to the relative muscle hypertrophy are noticed. Bones of the limbs are shorter and thinner according to the same gradients observed for the muscles. The muscle to bone ratio is maximal at the level of the shoulders and the thigh where the hypertrophy is also most visible. At a comparable level of subcutaneous fat cover, a lower overall carcass fat content is found for double-muscled compared to normal animals. The nonuniform muscle hypertrophy and greater conformation in general results in a different size and shape of most meat cuts and in a higher proportion of more expensive cuts. In commercial practice, this effect of conformation and carcass cutability may add substantially to the difference in carcass value of double-muscled animals, irrespective of the difference in lean meat content. The combination of increases in dressing proportion, carcass lean content, and upgrading of some cuts may yield a difference in the proportion of high value cuts on a live weight basis that amounts to more than a quarter for pure-bred double-muscled compared to normal cattle.

As mentioned above on the genetic determination, the myostatin-deficient condition leads to an increase in muscle fiber number (Table 1). The contractile differentiation during the first two-thirds of gestation and the metabolic differentiation of aerobic oxidative metabolism during the last third of

fetal growth are delayed in double-muscled fetuses. A higher proportion of glycolytic muscle fibers at the expense of oxidative and oxido-glycolytic fibers are thus found at birth and throughout life in double-muscled cattle. Most reports indicate no major changes in the muscle fiber dimensions, and slightly lower as well as higher fiber sizes have been reported. Hence, the relative area of type IIB fibers is increased and the overall muscle metabolism is more glycolytic.

The more glycolytic muscle fiber type results in a faster muscle pH fall postmortem in double-muscled animals, whereas ultimate pH values are generally not different. Concomitantly, the meat is paler, illustrated by higher CIE L* values (Table 1). A lower ratio of CIE a*/b* values corresponds to a less red color tint in line with reduced levels of myoglobin. The higher rate of glycolysis early postmortem, in combination with the increased muscle mass, also leads to slightly higher muscle temperatures postmortem, and consequently an increased degree of protein denaturation. This is expected to affect water-holding capacity unfavorably. However, data on several measures of water-holding capacity have been variable. Slightly higher drip and purge losses are generally found, but lower, unchanged as well as higher cooking losses have been reported. Differences in color and water-holding capacity in comparison with changes in other traits are relatively moderate.

With respect to meat tenderness and palatability in general, literature concerning double-muscled cattle are coherent on most but not all points (Table 1). Meat tenderness and tenderisation are complex phenomena determined by a number of factors. The content and nature of connective tissue content together with the postmortem weakening of the myofibrillar and cytoskeletal network are considered the most important factors, provided that no extreme muscle shortening occurs during rigor development. No difference in sarcomere length in meat of double-muscled animals is observed under normal slaughtering conditions. A large reduction (approximately 25%) in muscle collagen content in double-muscled animals is reported in almost all studies. The perimysial connective tissue network is thinner, but the nature of the perimysial collagen in terms of solubility and crosslink concentrations on a collagen molar basis is not affected. The much lower content of connective tissue explains the upgrading of lower quality cuts to more expensive cuts, allowing for a larger and more homogenous distribution of high quality meat throughout the carcass. In muscles with a low content of connective tissue, like the Longissimus, the positive effect of double muscling on tenderness may be mitigated by reduced myofibrillar and cytoskeletal protein degradation that normally occurs during the tenderisation process. Double-muscled cattle have consistently lower μ-calpain, calpastatin, and cathepsin levels in the Longissimus, associated with changes in protein breakdown and in line with the reduced *in vivo* protein turnover. Total proteolysis and tenderization during full ageing seem to be lower in double-muscled animals. However, observations in the Longissimus indicate that proteolysis occurs at a faster rate early postmortem in double-muscled beef animals, consistent with the more glycolytic muscle fiber type and the earlier rigor development. Data for other muscles on enzyme activities and postmortem proteolysis are very scarce. The overall effect on shear force values is variable, depending on the muscle studied and on the time/temperature treatment of the meat. Across studies and muscles, shear force values of raw meat have always been lower due to the lower collagen content. The literature shows that cooking meat for 1 h at 75 °C, the recommended standard preparation method for shear force determinations, yielded higher values for double-muscled animals, but not in all studies. Because of extensive solubilization of collagen, this procedure of shear force determination can be regarded as a measure of myofibrillar toughness, but is not necessarily a good indication of overall tenderness. The higher myofibrillar toughness of double-muscled animals as a result of reduced proteolysis is apparently only reflected in higher shear force values in heated low-collagen muscles in some studies. Indeed, taste panel tenderness evaluations on cooked meat do always show higher tenderness ratings, although the benefit may be lower for muscles low in connective tissue. Hence, in general meat from double-muscled animals is more tender. Meat of double-muscled animals is particularly suited for raw consumption or after short time heating only, culinary preparation methods prevalent mainly in Western and Southern Europe. Regarding other taste panel parameters, lower juiciness, and beef flavor ratings have been reported, in line with the lower intramuscular fat content.

The meat composition in double-muscled animals is changed according to the altered carcass composition. The meat protein content is higher and, because of the lower collagen content, protein quality in terms of essential amino acids content is improved. The intramuscular fat content is approximately 25% lower when compared to normal counterparts. Differences in fatty acid composition in different fat depots have also been reported. In intramuscular fat, the triacylglycerol content is greatly reduced as a result of the lower fat deposition, whereas the phospholipid content is only slightly lower in line with the lesser amount of cell membranes of the more glycolytic muscles. Accordingly, the contents of saturated and monounsaturated fatty acids are significantly reduced, whereas the contents of polyunsaturated fatty acids are similar or slightly reduced. Consequently, the molar proportions of polyunsaturated fatty acids are significantly higher and those of saturated and especially monounsaturated fatty acids are lower. The ratio of intramuscular polyunsaturated to saturated fatty acids is thus higher in meat from double-muscled animals. Similar but less marked changes are to be expected in other fat depots. There are also indications for alterations in the n-6 and n-3 polyunsaturated fatty acid metabolism, based on differences in the proportions of the long chain fatty acids resulting from elongation and desaturation of linoleic and linolenic acid. The content of conjugated linoleic acids is similar relative to the sum of fatty acids, but is lower on muscle weight basis. Meat oxidative stability of double-muscled and normal animals has not been properly compared at present, but there are no indications for large differences.

Glossary

Effective water diffusion coefficient The amount of water (kg) that passes through a unit area (m^2) in a unit of time (s) under the influence of a concentration gradient of one unit. Diffusion coefficient of water during drying of meat products depends on several factors such as temperature, water, and salt content. The SI unit of diffusion coefficient is $(kg\ (m^{-2}\ s)^{-1})$. The value of this coefficient for diffusion of water in meat typically ranges from 10^{-10} to 10^{-11}.

Heat capacity The amount of heat required to raise the temperature of the material by 1 °C. The SI unit of heat capacity is $J\ kgK^{-1}$. For nonprocessed meat values range approximately from 15 000 to 30 000.

Quick-dry slice process (QDS process®) QDS process is an accelerated drying process for sliced meat products that is applied to the sliced product directly after the fermentation step before the long drying phase. This process results in a dramatically reduced total processing time.

Thermal conductivity A measure of the ability of a substance to transfer heat. The SI unit of thermal conductivity is $(W\ mK^{-1})$. For nonprocessed meat values range from 0.1 for fat to 0.5 for lean.

Vapour pressure of pure water (p_o) The pressure at which distilled water vapour is saturated at a given temperature. The SI unit of p_o is Pa.

Vapour pressure of water in food (p) The pressure exerted by the water vapor in the foodstuff which is in equilibrium with the surrounding air. The SI unit of p is Pa.

Water activity (a_w) Water activity is defined (for practical purposes) as the ratio of the vapor pressure of water in a material (p) to the vapor pressure of pure water (p_o) at the same temperature. When vapor and temperature equilibrium are obtained, the water activity of the sample is equal to the relative humidity of air surrounding the sample in a sealed measurement chamber. Multiplication of water activity by 100 gives the equilibrium relative humidity (ERH) in percent $a_w = p/p_o = \text{ERH}\ (\%)/100$.

Introduction

Drying is a process in which water is removed from a material by evaporation, sublimation, or an osmotic process. Evaporated water is carried away by a stream of air, or it diffuses to an absorber or to a cold surface on which it is deposited as ice (frost) or water drops. Drying with the use of air is called convective drying, whereas diffusion of water molecules predominates in vacuum drying and freeze drying. Evaporation of water from the surface of the material being dried takes place at any temperature when there is a water activity gradient, but the higher the temperature the higher is the rate of drying, especially at the beginning of the process.

The aim of drying is to increase the shelf life of the product and to create new, sometimes unusual, properties in the final product. Dry-cured ham, semidry, and dry sausages are good examples of controlled drying that imparts and develops special texture and flavor in the product. It is worth mentioning that sometimes drying is undesirable because of weight loss and an unpleasant appearance of the dry surface; freezer burn is an example.

Drying is probably one of the oldest methods of food preservation. It takes advantage of the fact that only part of the water in food has the properties of bulk water, i.e., it is a good solvent and an environment in which biological reactions take place. Removing that part of water from food ensures its microbial stability and limits or inhibits chemical and enzymatic reactions.

The state of water in food results from the structure of the water molecule and its interactions with the remaining food constituents. The phenomenon of interaction between water and solute molecules is termed hydration. The nature and extent of hydration shells surrounding the solute molecules depend on the kind of hydrated food constituent. Few water molecules surround ions and small molecules, whereas macromolecules such as proteins or polysaccharides can be hydrated by hundreds of water molecules.

The properties of water in hydration shells differ from those of bulk water. Numerous experiments have shown that

[†]Deceased.

part of water in food is so strongly associated with food constituents that it is not able to form crystals during freezing. The state of water in food is expressed by its activity coefficient, a measure of the thermodynamic chemical potential of water in the system. Under isobaric conditions and at temperatures typical for food processing (−20–120 °C), the properties of water vapor do not differ much from those of an ideal gas. Hence, the activity coefficient can be expressed as the ratio of the vapor pressure of water in food (p) to the vapor pressure of pure water (p_o) at the same temperature and total pressure. The activity coefficient is called the water activity (a_w) and is expressed by the equation:

$$a_w = \left[\frac{p}{p_o}\right]_{P,T}$$

The water activity of pure water is 1 and for absolutely dry material it equals 0. Fresh meat, in the lean portion, has $a_w = 0.98–0.99$. The water activity of meat products is dependent on the additives used and the processing applied. Sausages such as Bologna type, liver sausage, or blood sausage all have water activities in the range 0.93–0.98. Dry-cured ham has a water activity in the range 0.88–0.96, and the value depends strongly on the position within the ham and on the process used. Country-cured hams, ripened or dried for months, have much lower water activities than do raw hams subjected to a short ripening process. Fermented sausages usually have a similar range of water activity but, in some products, can reach a value as low as 0.72. Dried products usually have water activity below 0.7.

Foods that have water activity from 0.60 to 0.90 and moisture between 10 and 40% are called intermediate-moisture foods (IMF). Such meat products as dry-cured ham, semidry and dry sausages, and cabanossi and salami all belong to the IMF classification.

Drying is one method to reduce water activity in food. Evaporation of water removes mostly that portion of the water that has the properties of bulk water, i.e., water activity close to 1. Increasing the proportion of water associated in hydration shells reduces the water activity of the food. The lower the water content, the lower the water activity of the food. However, the water activity and water content are not directly proportional (linear). The actual relationship at a given temperature is called a sorption isotherm (Figure 1). This enables one to predict the water activity of a given food at a prescribed water content. The sorption isotherm is characteristic for a given food, and its shape and course depends on the temperature, chemical composition, and structure of the material.

Most foods have sigmoid isotherms, which means that at the low a_w and high a_w ends of the curve, large changes in water content are needed to change the water activity by a small fraction. In the middle, usually at water activities between 0.2 and 0.6, comparatively small changes in water content cause large changes in water activity. The sigmoid type of isotherm is typical of foods containing proteins and polysaccharides. Foods containing mostly small molecules, for example, sugar or acids, show isotherms that are concave downward.

Drying as a method of reducing water activity in food can be assisted by the addition of substances that lower the water activity of the material. One of the effective depressors of water activity is sodium chloride (common salt, NaCl). At a concentration of 10% w/w, the water activity of the solution at 20 °C is 0.935; at 20% the water activity is 0.839. A saturated NaCl solution has a water activity of 0.755. Hence, by combining salting and drying, products with a sufficiently low water activity can be obtained without excessive dehydration. Good examples of products manufactured this way are charqui, an important meat product in rural Brazil; biltong, produced in South Africa; cecina, characteristic of the province of Leon in Spain; basturma (also known as pastirma), produced in many counties throughout the Caucasus, Balkans, and Middle East; and the traditional Cuban tasajo. All these products belong to the IMF classification.

Drying of Solid Foods

The design and organization of food dehydration depends, in the first place, on the state and kind of material subjected to

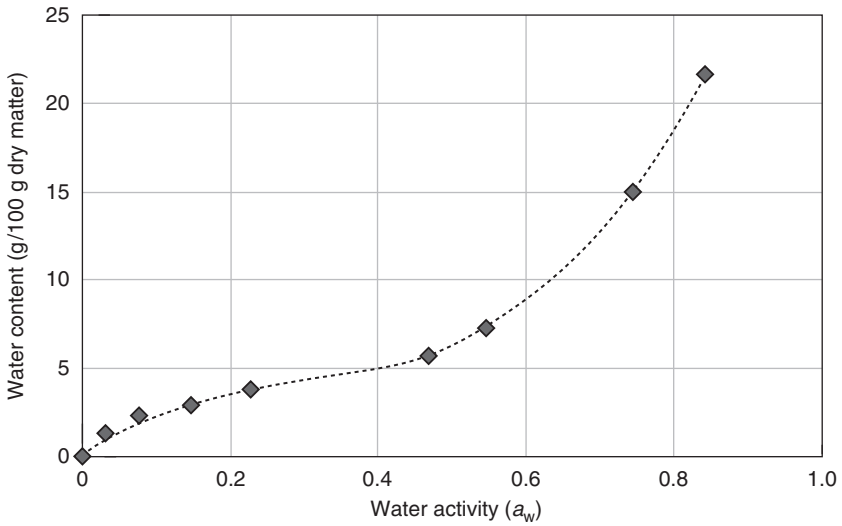

Figure 1 Water sorption isotherm of dried beef.

drying. The state of the food, liquid or solid, determines the equipment, process design, and arrangement.

Drying of solid food is a process in which water present within the microstructure of the solid is evaporated to the surrounding environment. During drying, two processes occur simultaneously:

- Transfer of energy.
- Transfer of water from the interior to the surface of the solid and its subsequent evaporation to the surrounding environment.

Transfer of energy as heat occurs, in most cases, as a result of convection and conduction. In some cases, radiation is also used as a means of energy transfer. Using dielectric, radio-frequency, or microwave energy, heat is generated internally within the solid.

In convective drying of solids, heat is transferred from the hot air to the surface of the solid. This process is dependent on air velocity and its temperature and humidity. The direction of air flow, the size and shape of the solid, and its degree of agitation also affect the rate of heat transfer. Heat transferred from the hot air to the surface of the solid is subsequently conveyed into the interior of the solid. In solid food, conduction is the prevailing mechanism of heat transfer within the solid. It depends on the difference between the temperature of the surface of the solid and the temperature of the coldest point within the solid, on the structure of the solid (its porosity), and on its thermophysical properties (heat capacity and thermal conductivity). In fibrous foods, the direction of heat flow in relation to the orientation of the fibers (parallel or perpendicular) is also important.

Heat transfer in the drying of solids involves two processes: external and internal movement of heat (Figure 2). Hence, two sources of resistances to heat transfer operate: external and internal; these are also referred to as resistance to convective and to conductive heat transfer, respectively. Resistance to conductive heat transfer is usually larger than that for convective heat transfer and is strongly dependent on the water content in the solid. The lower the water content, the larger is the internal resistance to conductive heat movement. As a result, heat transfer within the solid during the final stages of drying is more difficult than at the beginning of the drying process.

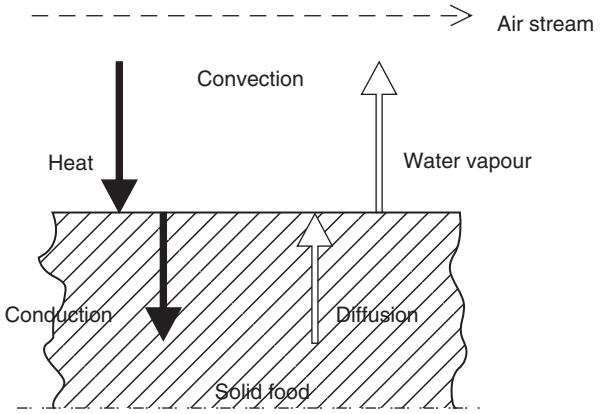

Figure 2 Heat and mass transfer during solid food drying.

The relationship between external and internal heat transfer resistances is important for the quality of the dried product and course of the drying process. A large external heat flux (due to a large difference between the hot air temperature and the temperature of the surface of the solid) sometimes cannot be conveyed within the solid at a sufficiently high rate. In this case, the surface of the solid absorbs most of the energy, water is evaporated rapidly, and a dry layer that is less permeable to water is formed on the surface of the solid. Further evaporation of water is slowed down; drying is reduced and overheating and scorching of the surface can occur.

In some drying methods, heat is supplied to the solid by conduction, which requires very good contact between the surface of the solid and the surface of the heating plate. Hence, this means of heat transfer can be used for drying paste-like materials, which can be spread on to the heating surface, or materials formed (cut) as parallelepipeds. Being in contact with the heating plate, the surface is excluded from the water evaporation process.

Transport of water in the solid being dried proceeds again in two steps (Figure 2). First, water is transported from the interior to the surface of the solid. Different mechanisms for water movement within the solid are applicable, but diffusion and capillary flow prevail in foods; capillary flow occurs only in porous bodies. Second, water is evaporated at the surface of the solid and is transferred as vapor to the surrounding air. This process is a convective mass transfer. Hence, two resistances to transport of water operate during the drying of solids: internal and external mass transfer resistances. The internal mass transfer resistance depends on the effective water diffusion coefficient (which accounts for all possible mechanisms of water transport in the solid) and the temperature of the solid. In moist foods, the effective water diffusion coefficient is weakly dependent on water content and is assumed constant. However, at low water contents (below 20–30% w/w) the dependence of the effective water diffusion coefficient on the water content is very strong. A decrease in water content by a few percentage points can lower the effective diffusion coefficient by two or three orders of magnitude. The external mass transfer resistance depends on the same variables that are responsible for convective heat transfer.

The relationship between external and internal mass transfer resistances affects the course of drying. If the external resistance is larger than or equal to the internal resistance, the flux of water reaching the surface of the solid is constant and drying proceeds at a constant rate. Drying at a constant rate can occur with very moist foods (e.g., some vegetables and fruits) but usually does not occur when the initial water content in a material undergoing drying is below 70–80%. If the internal resistance is larger than the external, less and less water is transported to the surface of the solid. The flux of evaporated water decreases with time and the drying proceeds at a falling rate. The course of drying can be presented as the rate of drying curve (Figure 3), and the transition from the constant to the falling rate of drying occurs at the critical moisture content.

The mechanism of solids drying presented above shows that drying is a simultaneous process of heat and mass transfer in which four resistances occur. In general, internal mass transfer resistance is the most important factor and determines the rate of drying and time the process takes. There are ways to

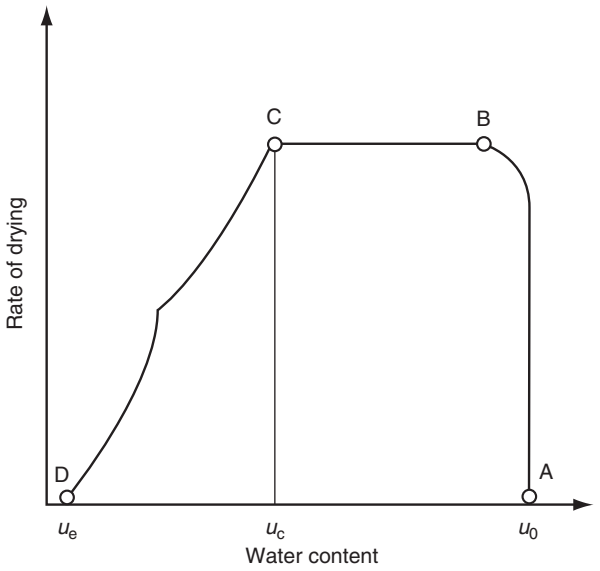

Figure 3 Rate of drying curve for moist food. affect the internal resistance to mass transfer and to take advantage of an increased value in designing the drying process.

The internal resistance to mass transfer can be modified by the predrying treatment of raw material, by its size and shape, and by the variables of the drying process. Predrying treatments include mincing, heating, cooking, freezing, and thawing. Mincing destroys internal microstructure, breaks cell walls and cell membranes, and releases the liquid phase. Minced material forms a capillary porous body in which cavities are filled with liquid, which can easily be transported to the surface for evaporation. Heating and cooking of food causes denaturation of proteins. In effect, cell membranes lose their semipermeable properties, and water movement in the tissue becomes easier. Moreover, denatured proteins are hydrated to a lesser extent than native ones and hence some water is released from the hydration shells. Freezing, especially slow freezing, leads to the formation of large ice crystals, which injure the tissue. Subsequent thawing yields material with destroyed or degraded microstructure, and the drying properties of the material become similar to those of minced material.

The size and shape of the solid are also important. Transport of water from the wet center to the surface is dependent on the concentration gradient (the difference in water concentrations divided by distance). The larger the concentration gradient, the larger is the water flux. Because the concentration gradient is inversely related to the distance over which the water is transported, the water flux or the rate of drying is smaller for larger pieces of food. The shape of the solid also affects the drying rate. For the same distance of water transport, a long cylinder dries twice as fast, and a sphere three times as fast as a plate (slab). The numbers are theoretically derived, but in practice a sphere always dries more rapidly than a cylinder and a cylinder loses water more rapidly than a plate.

Temperature, air velocity, and humidity are important variables of the drying process. Transport of water is faster at higher solid temperatures. Hence, increasing the air temperature causes faster drying. The velocity of the air affects external heat and mass transfer resistances; increased velocity reduces the resistances. However, high air temperature and velocity can lead to rapid evaporation of water from the surface and formation of a crust. The humidity of the air affects the external mass transfer of water; high humidity causes slow drying and prevents crust formation on the surface of the solid. In some processes, the drying air is specially humidified in order to slow down the rate of water evaporation.

Solids can be dried in a variety of types of dryers, but drying of meat and meat products can only be done in certain dehydrators: cabinet dryers, belt dryers, and vacuum tray or rotary dryers.

Cabinet Dryers

A cabinet dryer (Figure 4) is built as an insulated chamber with trays stacked one above another on which material is loaded. The trays may be arranged onto trolleys or may be stacked individually into the slots of the cabinet. Air, forced by a fan, passes through the heater and is then baffled parallel to or across the trays loaded with the product. The flow of air through the layers of the product creates better conditions for

heat and mass transport. Cabinet dryers can be equipped with a recirculation damper, which makes it possible to take part of the exhaust air, mix it with fresh air, and use the mixture as a drying medium. This not only saves energy but also primarily increases the humidity of the air and prevents case hardening and crust formation on the surface of the solid.

Cabinet dryers are batch dryers that are relatively easy to set and control the optimum conditions of the process. They are thus good for drying heat-sensitive materials.

Belt Dryers

A belt dryer is suitable for drying small pieces of cut food. It comprises a long, rectangular drying chamber through which a finely woven wire mesh moves on rollers (Figure 5). Air is supplied from the bottom of the belt and can be recirculated. The speed of the belt is low and can be regulated over a broad range. At a speed of 0.1 m min^{-1} with a drying section 45 m in length, the residence time of the material undergoing drying is 7.5 h. This drying time can be too short for large pieces of food. In this case the belt dryer is used to remove most of the water from the material and final drying is done in another type of dryer, the bin dryer. The bin dryer is a container with a wire mesh bottom in which partly dried material is placed in a thick layer. Air is forced through the layer, and water evaporates until the required moisture content of the material is reached.

Belt dryers have large yields and can be used in large-scale production. Some products can stick to the belt and can be difficult to remove at the discharge end of the dryer. A long drying section can be divided into sections in which the temperature of the air can be adjusted according to the heat sensitivity of the material being dried.

Vacuum Dryers

Rapid drying under atmospheric pressure requires temperatures as high as 70 °C and large volumes of air in contact with the product. This affects quality disadvantageously. To lower the drying temperature and eliminate contact with the air, drying under vacuum can be applied. In vacuum dryers, heat is supplied by conduction and external mass transfer resistance is much larger than that in convection dryers. Hence, drying is a long process, but the quality of the final product is superior to that obtained in convection dryers.

Vacuum cabinet dryers are designed as hermetically insulated chambers in which solid trays are heated by circulating a suitable heating medium. Contact between the food and tray surface is very important as well as the amount of food loaded on the tray. Product sticking to the tray surface can create a problem with emptying and cleaning the dryer.

The vacuum rotary dryer is a stationary, jacketed, cylindrical shell, mounted horizontally with a revolving center tube on which a set of paddle arms with blades is mounted (Figure 6). The heating medium is delivered to the jacket, hollow center tube, and paddle arms. Solid pieces of food are loaded into the cylinder, the vacuum is pulled down, and stirring or agitation is initiated by rotating the center tube. Mixing the material prevents sticking to the heating surface, exposes the material's surface to evaporation, and facilitates heat transfer by conduction. Vacuum rotary dryers are batch dryers; they provide good control of the process parameters and the rate of drying is faster than that in vacuum cabinet dryers.

Freeze Dryers

Freeze drying is another method of drying under vacuum. However, in this case the food is frozen before drying and drying parameters are below the triple point of water (Figure 7). Pure water can exist in all three phases – as gas (vapor), liquid, and solid (ice). The triple point is that combination of pressure and temperature at which all three phases are in equilibrium and can coexist. When the parameters are above the triple point, the change from solid to vapor must go through the liquid phase: hence the melting of solid occurs. When temperature and pressure are kept below the triple point values, sublimation occurs and a direct change of ice to vapor

takes place. Because the water vapor pressure over food is lower than over ice, the pressure in a freeze dryer must be kept well below 610 Pa; it is usually 200 Pa or below. The temperature of the material is also kept well below the freezing point of the food; usually it is below −10 °C.

Before the freeze drying process, the food is frozen in auxiliary equipment and then loaded to the freeze dryer. Freezing is a very important process and strongly affects both the sublimation process and the quality of the freeze-dried product. The larger the ice crystals and, in consequence, the more injured the tissue, the easier will be the transport of water vapor through the dry porous tissue, leading to a relatively short freeze drying period. However, the adverse influences of slow freezing on food quality are well known and, in designing the freeze drying process, a compromise must be made between process time and the quality of the product.

A freeze dryer (Figure 8) is usually built as a cabinet dryer equipped with shelves heated electrically (for small-scale production) or with circulating hot mineral oil. Frozen product is loaded onto shelves, vacuum is pulled down to the required value, and controlled heating is started. The heating is controlled in such a way that the product never reaches a temperature at which melting would occur. Water vapor sublimed from the product is resublimed (i.e., it forms ice) on the condenser, whose temperature is well below the sublimation temperature (−40 to −50 °C).

Heat and mass transfers in freeze drying are hampered by large internal and external resistances. Heat is conducted through the frozen layer to the zone of ice sublimation, whereas water vapor must pass the already dry layer and reach the condenser by diffusion. Large resistances are responsible for long freeze drying times, which are several hours and may exceed 24 h.

Freeze-dried products are superior in quality to those dried under atmospheric pressure. However, freeze drying is the most expensive method of drying because of very low pressure, the freezing of the food, and long process time.

Figure 9 Drying room for fermented sausages.

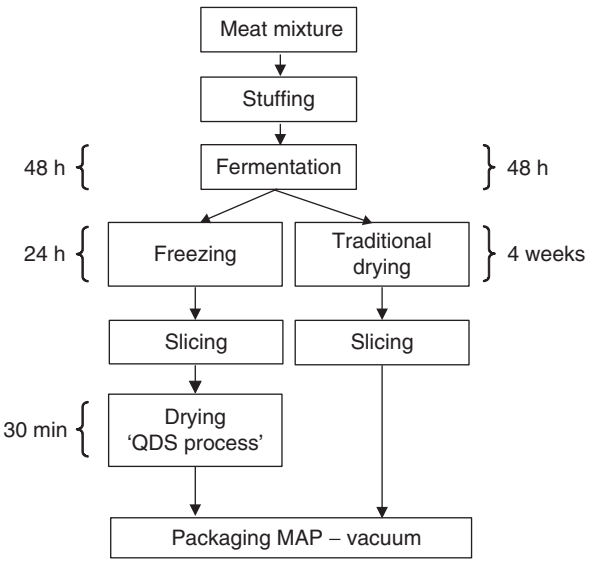

Figure 10 Comparison between traditional and Quick-dry slice process for sliced fermented sausages.

Traditional Meat-Drying Facilities

Some traditional meat products such as dry-cured ham, semidry, and dry sausages are obtained by removing a certain amount of water from the material by evaporation. This is a drying process, but it is done under specific conditions in drying rooms (Figure 9).

The design of a drying room makes it possible to control temperature, humidity, and air flow. Usually the air circulates in the room, and this can be achieved by natural or forced convection. Drying of dry-cured ham is done at increasing

Figure 11 Quick-dry slice process facility for sliced fermented sausages.

temperatures ranging from 3 °C to room temperature. During that time 30–40% of initial weight is lost and the water activity of the product (especially on the surface) decreases sufficiently to prevent microbial spoilage. Circulating air is changed 15–50 times per hour.

Drying of sausages depends on their variety and the diameter of the product. Stuffed sausages are first fermented by lactic acid bacteria and then hung in a drying room with air relative humidity of approximately 80%. The sausage loses some water but case hardening is avoided. In some cases, the air temperature is lowered to approximately 10 °C and the relative humidity to 70%. The air is circulated by a fan dimensioned to move from 15 to 75 times the chamber volume per hour. The process continues for 15–60 days, and the sausages lose 25–50% of their original weight. The growth of inoculated molds on the surface of sausages can be promoted by controlling the air's humidity and temperature to produce special types of sausages. Addition of glucono-δ-lactone to the batter of raw fermented sausage (salami type) strongly accelerates the acidification of sausage chubs and thereby substantially shortens the period of ripening.

Recently, a new drying-maturing process, quick-dry slice (QDS), has been proposed for sliced products (Figures 10 and 11). Sausages are fermented to the desired pH and are then frozen, sliced, and dried in a continuous system that combines

both convective and vacuum drying. With the QDS system, the traditional drying process could be reduced to 30 min, without any negative effect on safety. The QDS process reduces the acid taste and increases the color intensity of fermented sausages. Moreover, some sensitive colorants (e.g., Ponceau 4R) do not fade during the process.

Drying of Solutions and Suspensions

The most versatile method of drying liquids is spray drying. A solution or suspension with appropriate viscosity or consistency is sprayed into a cylindrical chamber in which it comes into contact with hot air. Spray drying consists of three steps: atomization of the fluid, the drying of droplets, and the separation of dry powder from the air stream (Figure 12).

Atomization is achieved using a rotating wheel or a nozzle. This is the most important operation in the spray drying process. The method of fluid atomization and its variables determine the size and the size distribution of the drops, and their trajectory and speed in the drying chamber. The size of the drop determines the heat and mass transfer surface and influences heat and mass transfer resistances. Generally, the smaller the droplet diameter, the faster is the drying. Another important variable characterizing the spray is the size distribution. Because the rate of drying is inversely proportional to the droplet diameter, it is evident that the variability of the drying time will increase with the variability of the drop size. However, the stream of hot air conveys the drops, and their residence time in the drying chamber is not very dependent on their size. In consequence, small particles leave the drying chamber with a low water content and can be overdried, whereas large particles can be moist and underdried. The difference in moisture contents of small and large particles can be detrimental to the quality of the product during storage.

Drops formed by a rotating wheel atomizer are 20–250 μm in diameter. The area for evaporation is large and drying takes a few seconds. Rapid evaporation maintains a low droplet temperature. Hence, high drying air temperatures can be applied, in the range of 150–200 °C. Particles leaving the drying chamber have temperatures between 70 and 90 °C.

The drying chamber is a cylinder with a conical bottom in which the spray makes contact with the hot air. The most common design is a concurrent system in which the droplets fall down the chamber with the air flowing in the same direction. Circulation of air in the drying chamber and trajectories of the particles undergoing drying should prevent the deposition of wet particles on the chamber wall.

The dry powder is collected at the bottom of the drying chamber. It can be removed together with the exhaust air and product in the powder/air separation system. Commonly, the exhaust air is removed at some height above the bottom of the drying chamber. The product then accumulates at the bottom of the chamber and is discharged by means of a valve. Exhaust air carries only the fine particles, which are separated from the gas stream in the separation system.

Separation systems consist of cyclones though, in some cases, bag filters are used. In cyclones, particles with a diameter larger than 15 μm are removed with high efficiency. Bag filters remove particles with diameter larger than 2 μm.

Because of low product temperature and short drying time, spray drying is suitable for the drying of heat-sensitive products. However, economic spray drying can be done only with large-scale production. Meat extracts and purées can be dried by a spray drying technique.

One product commonly manufactured by spray drying is dried blood plasma. This is concentrated by evaporation and is then fed to a spray dryer. The inlet temperature of the hot air is between 120 and 190 °C, but the outlet temperature should not exceed 70 °C. The drying time is very short and ranges from 2 to 4 s. The moisture content of dried blood plasma is between 5 and 8%.

Quality of Dried Products

Drying causes numerous physical and chemical changes in food. Some of these changes can be used to enhance the quality and nutritional value of the food or to create new properties that are appreciated by consumers.

Physical changes caused by drying include shrinkage, shape alteration, surface modification, and modification of mechanical properties. Most of these texture modifications are due to moisture and temperature gradients occurring in the solid being dried. The larger the gradients, the larger are the stresses developed in the material. Under the stress, the material shrinks, its shape is deformed, and the surface develops wrinkles and creases. Shrinkage, shape distortion, and surface modification depend on the method of drying and the extent of dehydration. Convective drying at a low drying rate creates small moisture gradients. Hence, the stresses developed in the material are small; the body shrinks uniformly; there is no shape change; and the surface, owing to the material's elasticity, evenly follows the change of size of the solid body. Under these conditions, shrinkage is equal to the volume of the evaporated water. The traditional method of dry-cured ham production is a good example of such a process.

Convective drying done at high drying rates can produce large shrinkage stresses. The dry surface loses elasticity and cannot follow the change of volume. Consequently, the surface wrinkles and creases. If the drying is too fast, internal cracks and fissures are formed. These are the typical events occurring during spray drying, though they cannot be seen by the naked eye. Meat dried by convection or under vacuum is also exposed to these physical changes, some of which take place during production of semidry and dry sausages.

In freeze drying there is no liquid phase, hence these are no moisture concentration gradients. Temperature gradients are too small to create large stresses and freeze-dried material retains the shape and size of the frozen material. Freezing is the step in the freeze drying process that causes injury to the internal structure of the material.

Evaporation of water and increased concentration of solids change the mechanical properties of the solid. Resistance to deformation, chewiness, juiciness, ease of biting, cutting, slicing, etc., are altered and the extent of the change depends on the kind of dried material, the degree of dehydration, drying mode, and predrying treatment applied.

Chemical changes caused by drying are mainly due to elevated temperature and increased concentration of solubles. In some cases, contact with air can have deleterious effects on the quality of the final product. Increased concentration of solubles can affect the quality of the product at water contents at which water can act as a solvent. Hence, changes of the degree of ionization, redox potential, solubility, and the catalytic activity of food constituents can be expected in material undergoing drying at high and moderate water contents. Proteins can be denatured or their spatial conformation can be changed, and high concentrations of reactants can promote chemical reactions. Nonenzymatic browning reactions can occur, and precursors can be formed that facilitate color changes during storage of dried product. Contact with oxygen causes oxidation of lipids and oxidation of pigments that occur naturally in food.

Physical and chemical changes caused by drying usually affect the quality of the product unfavorably. However, with an appropriate choice of drying variables and mode of drying, suitable equipment, and predrying treatment, physical and chemical changes can be controlled and high-quality or novel sensory attributes can be obtained. Near infra-red equipment has been proposed as an on-line system to measure the water content and water activity at the product surface. This information can be used to set up the drying conditions in the drier (relative humidity, temperature, and air flow) as a function of the product characteristics.

Glossary

Antibiotics These are the drugs utilized to treat and/or prevent various bacterial infections.
Concentrated Animal Feeding Operation (CAFO) It is defined by the US Environmental Protection Agency describing animal production units that potentially fit specific pollution and/or waste profiles.
Mandatory country-of-origin labeling (COOL) This is the US law dictating country of origin for various meat products.
North American Free Trade Agreement (NAFTA) It is the agreement between the US, Canada, and Mexico detailing trilateral trade law among the three countries.
Rights These are the moral and/or legal rights of animals recognized by society.
Traceability It details various production and/or attributes maintained throughout the supply chain.
Welfare It is the general sense of animal well-being.
World Trade Organization (WTO) It deals with legal rules of trade among nations ensuring that trade flows smoothly and freely.

Background

The past half century ushered in a period of sustained economic growth across the globe. Flourishing economies generally establish a higher standard of living that includes greater consumer demand for conveniences and measures of health and safety. More specific to the meat industry, economic growth also leads to changes in tastes and preferences and commonly includes pursuit of improving one's eating standards often characterized by a desire to include more animal protein within the diet. The expansionary period that began in the 1960s occurred largely within the developing regions (vs. developed countries) and strongly underpinned new opportunities for consumer spending on meat and meat products within those countries.

Convergence of shifting consumer preferences coupled with an ever-expanding population strongly boosted meat demand. This subsequently led to the need for increased meat production throughout the world. Global meat production (beef, veal, pork, broiler, and turkey combined) grew more than 500% between 1960 and 2010 (45.447 vs. 243.396 mmtons, respectively).

Despite steady growth and new market opportunities across the globe, the meat production business has proven especially challenging in recent years. Gains in overall production equate to a larger, more defined, and more easily targeted industry. That reality, along with advancements in technology and communication, has culminated to bring about increased attention and scrutiny for all participants associated with animal agriculture and meat production.

Stakeholders at all levels are dealing with new and developing concerns surrounding the business. Aside from normal, routine consumer market issues, a number of nonroutine developments have arisen. Primarily, there is increasing desire for public involvement in various issues associated with meat production. Moreover, transition of economic growth away from developed countries to developing regions highlights the meat industry's connectedness to a variety of interacting forces throughout the world.

As noted above, increasing economic prosperity often leads to increased meat consumption. In most businesses, that would typically prove favorable. However, for meat production, that reality also serves to be a double-edged sword. Once economic prosperity becomes sufficiently high, consumer

 doi:10.1016/B978-0-12-384731-7.00208-7

priorities tend to shift across a variety of attributes. For example, attributes associated with the production process (such as animal welfare) become more heavily weighted in purchasing decisions. In other words, fundamental attributes such as food safety, nutrition, taste, convenience, etc. become relatively less important items (albeit still essential), whereas other attributes become relatively more important. Therein enters many of the intricacies of decision making and policy navigation for the meat industry going forward.

Many policy issues and challenges are relatively uncharted and potentially redefine how the industry carries out business from a strategic perspective. Key areas of policy arise in several key categories oriented around: (1) meat products; (2) production processes and the supply chain, and (3) overarching legal and trade issues. Several key issues are highlighted below. The list is neither comprehensive nor clear cut, given the variety of issues and potential for crossover among the categories. However, such imprecision further underscores the increasing complexity surrounding meat production.

Product-oriented Policy Issues	Production-oriented Policy Issues
Food safety (pathogen-induced and residue derived)	Animal welfare and well-being
Health and wellness attributes	Environmental stewardship and regulation
	Animal health/Antibiotics
Trade/Legal Issues	Industry Business regulation (including biofuels)
Labor/immigration regulation	Source verification and traceability
International trade regulations	Biotechnology
	Interaction with the biofuel industry

Animal Welfare

Consumers generally expect respective food purchases to be nutritious, flavorful, and safe. However, rising affluence also leads to alternative attributes being increasingly important across the food system. Increasing interest and awareness among consumers of farm-to-fork connectedness have especially driven production-oriented issues to the forefront in recent years. The outcome being that all participants in the supply chain are investing more time and resources to dealing with such issues. Foremost among those issues includes animal welfare.

The industry has traditionally countered broad concerns about animal welfare by demonstrating that animals grown in mainstream production systems are increasingly well cared for. In fact, overall management knowledge has never been more advanced. The upshot of those developments leads to better care and subsequent animal comfort. That reality is ultimately reflected by enhanced productivity across all of animal agriculture. There exists any number of favorable trends when considering items such as improved animal health, increased growth rates, and advances in reproductive efficiency.

However, from a policy perspective, for many individuals, improved animal health, increased growth rates, and advances in reproductive efficiency are inadequate measures of animal care and/or welfare. Such opponents of the meat industry contend that well-being of an animal also include more intangible factors such as freedom from fear and/or freedom of social interaction. In particular, policy discussions often revolve around animal housing for animals involved in production – especially those housed in confinement operations. The issue typically includes topics such as gestation crates for sows, battery cages for laying hens, veal crates, and feedlot pens. Opponents of such housing argue that animals should be allowed opportunities for social interaction while also providing opportunity to turn around, lie down, stand up, and/or fully extend their limbs at all times. There have been a number of efforts, especially notable in the US, to pass state regulations to limit confinement-type operations to provide such attributes.

Meanwhile, animal activists are also increasingly calling other management practices into question including concerns around beak trimming, castration, dehorning, clipping needle teeth, tail docking, etc. The primary argument is that meat production during the past few decades has dramatically changed. Activists advocate that modern meat production has increasingly moved to 'industrial' facilities emphasizing a concern only for productivity and completely disregards humane treatment of animals.

Meanwhile, a recent rise of undercover investigations appearing on the internet from groups such as Humane Society of US, People for Ethical Treatment of Animals, and Mercy for Animals have provided ammunition for those calling for sweeping changes within animal agriculture, including potential elimination of raising livestock for consumption purposes. Such movements have led to laws in several states in the U.S. banning specific production practices (e.g., sow gestation crates, veal crates, and battery cages). The threat of ongoing lawsuits and/or ballot initiatives has led to several states (e.g., Ohio and Kentucky) to be proactive in developing animal care oversight boards. Simultaneously, throughout the European Union many such initiatives are underway.

Public and social media outlets have also led to increasing awareness among consumers about animal welfare/animal care issues. Many large companies are responding accordingly. For example, McDonald's recently announced (February 2012) that it would work with suppliers to implement the phasing out of gestation crates associated with normal production practices. Similarly, the Humane Society of the US and the United Egg Producers announced a cooperative agreement to replace conventional battery cages with new housing systems providing hens more room and to prohibit sale of eggs and egg products that do not fall within the newly established guidelines (July 2011). Finally, the Compass Group – the largest global food and support service company – has also announced similar requirements for its pork and egg supply chain (March 2012).

It should be noted that animal welfare is a very different concern from animal rights. Animal rights groups typically promote vegetarianism and believe that animals should not be utilized for any purpose, that is, some groups advocate a liberation agenda contending that animals have rights (similar to humans) and hence should not be utilized for any purpose (food, recreation, or research).

Environmental Stewardship and Regulation

Concerns around animal welfare and well-being often intersect with environmental stewardship and regulation. Growing adoption of production models emphasizing economies of scale draw the attention of those concerned about environmental degradation and subsequent societal costs. The forefront of environmental policy issues typically surrounds several key topics: waste or nutrient management, water quality and utilization, and air pollution or odor.

Waste management becomes an especially important issue to manage when considering public perception and management of concentrated animal feeding operations (CAFOs), that is, such production units typically house larger numbers of animals in greater density (compared with more traditional production methods) and thereby larger amounts of waste are collected and/or stored in relatively small areas (e.g., manure lagoons). Regulation surrounding CAFOs has become increasingly stringent and rigorous over the years – all CAFO operators must maintain updated operating permits and undergo constant monitoring by regulatory agencies.

However, opponents argue that if/when such resources are mismanaged and/or neglected, these units can potentially produce environmental problems – either acute or chronic in nature. Concerns about waste management inherently also involve policy discussions revolving around water quality: The concern being that CAFOs may represent increased potential for water contamination, be it point source (directly identifiable) or nonpoint source (diffuse) pollution. Therefore, animal agriculture finds itself dealing with regulatory pressures revolving around specific nutrients within various watersheds. And finally, increased regulatory pressure also comes on the air pollution/odor front, especially in areas where the urban/rural interface is mounting.

From a more overarching, international perspective, the most notable environmental policy concern revolves around the very existence of meat animal production itself. Much of that attention in recent years result from the release of the United Nation's Foreign Agriculture Organization's publication entitled Livestock's Long Shadow (2006). The report asserting, "…climate change is the most serious challenge facing the human race. The report states that the livestock sector is a major player, responsible for 18 percent of greenhouse gas emissions measured in CO_2 equivalent. This is a higher share than transportation." The report has since been demonstrated to include several major miscalculations but nonetheless served to provide significant traction toward policy discussion and development.

Meanwhile, environmental policy pressure also arises relative to land and/or resource utilization coupled with the integration of ecological and social equity. Those broader concerns invoke the concept of 'sustainability' and will more likely be an important driver of policy evolution within meat production systems in future years. A recent paper by Pretty *et al*. (see further reading) summarizes, "Vital work needs to be done to establish more precisely what 'sustainable food' represents, and to identify best practice standards across a wide range of activities throughout the [food supply chain]."

Nonetheless, the concept has led to several key companies, along with external partners, to proactively address the issue. For example, 2012 marked a new venture entitled the Global Roundtable for Sustainable Beef – a coalition of stakeholder companies and organizations. The founding members include: AllFlex, Allianca de Terra, Cargill, Elanco, Grupo de Trabalho da Pecuaria Sustentavel, JBS, McDonald's, Merck Animal Health, National Wildlife Federation, Rainforest Alliance, Roundtable for Sustainable Beef Australia, Solidaridad, The Nature Conservancy, Walmart, and World Wildlife Fund. The endeavor's mission is to assess and promote more efficient, environmentally sustainable beef production practices.

Antibiotics

There generally exists a large degree of confusion and ambiguity about antibiotic use in livestock production. That is largely because such usage is a relatively nuanced issue often being commingled with the broader connotations surrounding consolidation and/or industrialization of animal agriculture. Therefore, there is a high degree of potential for misleading claims. Regardless, the use of antibiotics in food animal production derives broader concerns about antimicrobial resistance in humans (AMR).

A variety of public interest groups are highly interested in the subject of AMR. Such concern is especially amplified when considering nontherapeutic use within livestock production. Opponents often claim that general and rampant overuse of antibiotics in animal agriculture leads to drug-resistant bacteria, an increasing threat to human beings.

Such arguments are predicated on the following logic: Antibiotics fed to livestock at subtherapeutic levels facilitate establishment of resistant strains of bacteria and absolute containment at the local farm environment proves elusive. That scenario inevitably put citizens at risk because such strains prove unresponsive to treatment if they are able to cause illness. Therefore, the argument is that such use must be curtailed and future approval of new antibiotics in livestock should be preempted (new development should be saved for human usage).

AMR concern often gets leveraged to advance ideologies and/or policy proposals to limit antibiotic use in farm animals. The most commonly cited example supporting an antibiotic ban comes from Denmark, where nontherapeutic antibiotic use has been banned in animal agriculture. However, since the ban, therapeutic use in animal production has increased. Moreover, no scientific documentation exists that reflect antibiotic resistance in the human population has declined since the ban.

Policy implementation suggesting simple fixes or solutions leads to false sense of security. That is because numerous complexities surround development of antibiotic resistance. Several other risk factors also contribute to development of AMR, including large hospitals, socialized care of elderly persons, and increased social interaction via international travel. Therefore, policy must key on proper assessment and subsequent management of risk – comprehensive, science-based strategies in both livestock production and human health. Moreover, AMR results from intricate interactions among (1) specific antibiotic class, (2) specific pathogen, and (3) host population. Therefore, predicting and/or preventing

broad or wide-scale resistance, based on simple policy solutions, is highly challenging because of the large number of specific antibiotic/pathogen/host combinations. As a result, there is no scientifically documented link establishing antibiotic use in livestock and increased resistance in humans. In fact, quantified research assessment of potential farm-to-patient resistance represents a 'very low risk of human treatment failure'.

Finally, policy pressure revolving around antibiotic resistance often invokes the previous two issues discussed: animal welfare and environmental regulation. That is because antibiotic usage in animal production commonly gets tied to the overall 'factory' or 'industrial' farming model – the argument being that antibiotic utilization would be unnecessary if animals were not housed in confinement. Therefore, the three issues often become inherently linked with policy discussion.

Dietary Guidelines

Obesity progressively receives attention as a global epidemic as obesity rates continue to climb. For example, the Center for Disease Control estimates that two-thirds of the US population is now overweight; more than half of that segment, or fully one-third of the total population, falls into the obese categorization. To that extent, human weight management is not simply an individual matter; rather, it is now a collective, public health concern stemming from lost productivity and rising health care costs associated with obesity. Rising prevalence of obesity and subsequent health problems (claims revolving around type-2 diabetes, heart disease, various cancer types, etc.) have served as a platform to advance a vegan and/or vegetarian agenda. From a public health point of view, many argue that the parallels among increased meat consumption and obesity rates represent a meaningful relationship. Therefore, reduced meat consumption is often promoted as conducive with healthier lifestyles and hence should be eliminated from the diet. These opposition groups often utilize rhetoric revolving around a general theme of meat being unnecessary in the diet and detrimental to individual health. The dietary issue has been especially leveraged of late around other matters within animal agriculture, that is, food choice and/or availability converges with other matters of policy (such as environmental degradation, resource exploitation, animal welfare, etc.). Stated another way, policy discussions addressing healthcare costs (due to heart disease, obesity, type-2 diabetes, and the like) are sometimes aimed directly at animal agriculture, citing meat production and increasing corporate pressures as contributing to broader health concerns.

International Trade

Structural shifts in developing countries have moved economic activity to new areas of the world. Meanwhile, technology gains in transportation and communication have driven international trade of all types of material goods as costs of logistics and supply chain coordination have declined. However, as global interconnectedness increases, managing global governance and trade policy becomes both increasingly difficult and important. That reality is evidenced by several key, long-standing trade embargoes around meat and/or meat products. When such embargoes are principally unfounded, it often escalates to retaliatory trade measures that include other products including grain and/or other manufactured material goods.

Animal health is an especially important consideration with regard to meat production and international trade policy. Therefore, moving animals and/or meat products across international borders requires more stringent sanitary and phytosanitary policies. International trade requirements increasingly mandate some form of identity preservation and source verification. For such verification to be meaningful, traceability must exist throughout the entire supply chain. Therefore, many countries now require individual animal identification and meat traceability as precursors for import status.

Traceability is often a mandate to ensure that animal disease requirements dictated by the World Organization for Animal Health (OIE) are strictly followed. The OIE promotes international cooperation to control the spread of transboundary animal diseases while also providing expertise to establish public health standards and improve legal framework for trade. Countries with such systems generally possess increased competitive advantage when negotiating market access with those not possessing such systems. However, implementation of such systems can prove cumbersome, complicated, and often controversial. That has been especially evident in the US as the country progresses through various attempts at mandatory animal identification. The attempts are made to ensure rapid tracking capabilities in the event of serious animal disease events and/or outbreaks (e.g., bovine spongiform encephalopathy or foot and mouth disease, respectively).

Animal disease traceability is very different from market-driven traceability – the latter more focused on value-added credence attributes such as age verification, natural programs, animal welfare, etc. A secondary level of such discussion revolves around country-of-origin labeling (COOL). Implementation of a mandatory system within the US (effective 2008) has played an especially important role within the North American Free Trade Agreement (NAFTA) framework. Legality of the labeling law is now in question due to a 2011 World Trade Organization (WTO) ruling: COOL is not WTO compliant, as per NAFTA requirements, and effectively represents a nontariff trade barrier. Regardless of the dispute's outcome, the law will more likely lead to important ramifications around a whole host of products in future trade negotiations.

Finally, many countries often must manage trade policy from a more internal approach. Those discussions can be especially contentious with food and/or food production. Many antitrade proponents, regardless of the country in question, promote a sense of national security – food production should not be included in discussions and/or negotiations revolving around trade. That perspective argues food should remain immune from the broader forces of global economic change. That influence makes trade development policy especially difficult because consumers in all countries desire goods that come from free trade – which is often in the form of meat or

meat products. That ultimately creates an inconsistency between protectionism on one side and free market capitalism on the other.

Interaction with the Biofuel Industry

Introduction of biofuels policy in the US initiated some important influences on the meat production business. It represents a whole new dimension for agriculture that has arisen during the past five years or so. The dynamics have dramatically shifted the business environment for all of agriculture (not to mention its indirect influence on consumers across a number of venues). From a policy perspective, it has initiated a more wide-reaching debate about food versus fuel.

More directly, the influence of ethanol policy on the meat production business has been derived primarily in the form of higher feed and other input costs. However, it has also created an inexorable linkage among commodities of all types. That connectedness among markets along with increasing speed of commerce and globalized trade ultimately means that biofuel policy in any country has ramifications to the meat industry throughout the world. Specifically, it has given rise in recent years to renewed concerns about food costs and the role of speculators on all commodity prices across the globe – speculators often being accused of unduly profiting from their respective positions while the rest of the world (especially the impoverished) are unduly punished by rising costs.

Internal Business Regulation

Much of the discussion above focuses primarily on public–industry interaction. However, the meat industry also wrestles with several ongoing and contentious internal policy struggles because many of the traditional trade and production strategies have blurred over time. Most notably, there is divided ideology about adaptation strategies and future competitiveness – much of it centered around production sector competitiveness issues. Consolidation remains a very important and controversial issue within agriculture with distinct and well-entrenched opinions about its long-term impact on the industry.

To date, much of agriculture's transition stems from consolidation in the food processing, manufacturing, wholesaling, retailing, and service sectors. The industry has evolved to become more efficient to meet rising consumer demand across the globe. Coordination of the supply chain facilitates improved cost controls, more efficient scheduling of inputs, and processing assets. The meat industry has transitioned accordingly – from relatively uncoordinated commodity-sorting systems to growing adoption of more specialized production. Restaurant and retail companies desire to offer high quality, competitive products while also facilitating consistent and predictable inventory turnover; in turn, processors seek development of specified capabilities from producers to deliver those attributes.

These endeavors increasingly enhance the bottom line for companies, especially in the face of rising costs; information-based supply chain coordination efforts improve efficiency while emphasis on differentiated, value-enhanced production boosts revenue. That has not occurred at the exclusion of the production sector (albeit comparatively more pronounced in the pork and poultry sectors compared with the beef complex). The trend to larger operations has occurred to leverage some economies of scale and management, but it is done not only to implement cost efficiencies but also to facilitate better input quality control and to ensure that specifications are met at all levels of production.

However, the meat business, at least at the production level, remains relatively large, diverse, and fragmented. Consequently, there exists wide opinion about how business should be conducted: The struggle often vacillates between pressures to evolve to ever-increasingly synchronized systems approach versus maintaining a more traditional independent, segmented structure (adhering to other more important values surrounding production systems). Those arguing for the latter have seemingly been bolstered with renewed consumer interest in the food system – that is reflected by success of several popular books during the past decade along with various documentaries. Such coverage tries to engage the audience in seeing the connections between retail and restaurant food business and ensuing production of the products which they merchandise.

Conclusions

Meat production and animal agriculture are increasingly an important, dynamic, and demanding business from a number of perspectives. Animal agriculture must continue to pursue increased output and efficiencies in order to satisfy consumer demand and meet the needs of a growing global population. Simultaneously, those same consumers increasingly view themselves as stakeholders in the production and marketing system. Food activism has steadily increased with each passing decade since the 1970s, gaining significant traction in recent years. Regulatory reform must consider both cost competitiveness and social implications.

Glossary

Aging The process of meat tenderization that is an enzymatic process occurring over time.
Calpains Components of the enzyme system acting on cytoskeletal proteins during meat tenderization.
Current Electrical term defining flow of electric charge.
Cytoskeletal proteins A set of structural proteins (includes titin, nebulin, and desmin) that are denatured by calpains.
dpH/d*t* The rate of fall in pH that takes place following the electrical stimulation.
Drip or purge Water that increases over time arising from the protein denaturation as meat tenderises – it is additional to that from prerigor myosin denaturation that can also occur.
Electrical stimulation (ES) The application of an electric current through a carcass postmortem that accelerates the rigor process.
Hot boning A process when the meat is removed from the carcasses before rigor mortis in contrast to cold boning when meat is removed after rigor mortis.
Myofibrillar proteins The muscle contractile proteins, actin and myosin.
ΔpH The actual fall in pH that occurs immediately after electrical stimulation.
Postmortem The period after harvest when the pH falls until rigor mortis and subsequent aging.
Preslaughter The period before slaughter where factors such as stress can affect meat quality.
Protein denaturation A process whereby proteins lose their tertiary and secondary structure such as by application of acids or heat – water that is part of the tertiary structure can be released.
Pulse waveforms Characteristics of specific electrical stimulation parameters.
Rigor A term for individual muscle fibers that have been depleted of adenosine triphosphate, whereas rigor mortis is a term where muscles stiffen after all muscle fibers enter rigor.
Shear force The force (N) applied to a standardized piece of meat to shear it.
Shortening A process that occurs when prerigor muscle is cooled below 10 °C – additionally it also occurs as muscles enter rigor (rigor shortening).
Ultimate pH The pH that is reached when muscles reach rigor mortis.
Voltage Electrical term defining the electrical potential difference.

Introduction

'Electrical stimulation' (ES) or 'stimulation' are general terms used for describing a passage of any electrical current through a muscle or carcass and the abbreviation ES is used in this article generally to apply to the process in which an electric current is passed through carcasses with the aim of ensuring that the meat is tender. Tenderness is a major consumer requirement (toughness is its inverse) and it is quantified using either consumer panels, trained sensory panels, or objective measurements such as shear force (force required to shear through a cooked piece of meat). ES has been used to improve the tenderness of meat from deer, goats, sheep, cattle, and various poultry species, and in certain circumstances for pigs, and is perhaps one of the recent most significant factors in improving meat quality. In some situations its application has introduced small problems of its own such as human safety considerations, but overall the improvement in tenderness far outweighs these minor problems. Although it is not possible to increase meat tenderness beyond that limited by connective tissue, it is possible to ensure the meat routinely reaches the highest degree of tenderness it is capable of achieving.

ES of muscle from harvested animals hastens the process of rigor mortis (defined when adenosine triphosphate (ATP) production ceases). It does this by causing muscles to undergo work via anaerobic glycolysis, resulting in an initial pH fall (ΔpH) followed by a change in the rate of pH fall (dpH/d*t*). The combined effect is that the muscles enter rigor mortis before the muscle temperature falls to values producing cold shortening and toughening.

Early post slaughter, stimulation can be applied using relatively low voltages that effectively operate via the nervous system. With increasing delays before stimulation, higher voltages are then required to directly stimulate the muscles.

 doi:10.1016/B978-0-12-384731-7.00149-5

The electrical parameters generally used must consider the appropriate waveform and pulse frequency, duration, prestimulation delay, chilling rate, and type of species involved.

Although ES ensures that cold shortening is avoided, aging also starts at a higher temperature and is consequently more rapid. However, evidence suggests that there are other mechanisms involved in tenderization (defined as the reduction in toughness postrigor), such as modification of the enzyme systems and possibly fiber disruption and protection of the enzymes responsible for tenderization.

ES must be considered as part of a total process from slaughter through chilling to final sale, and has particular advantages for hot boning, where the shortening and toughening conditions that would occur for nonstimulated muscles during chilling are avoided. With appropriate ES and chilling rates, hot-boned meat is as tender as normal cold-boned meat, especially if a wrapping procedure is also used to avoid shortening.

History

The association between muscle/meat and electricity started with Galvani, although the earliest reported use for meat improvement was by Benjamin Franklin, in 1749, who electrocuted turkeys, with the result that they were 'uncommonly tender.' During the 1950 s it was shown that ES could improve meat tenderness of beef, but no commercial application of the process occurred. Stimulation of horse muscle was used experimentally to examine the microbiology of pre and postrigor meat from the same animal at the same temperature.

The incorporation of a practical system into the slaughtering process was first used in New Zealand and then Australia to avoid toughness resulting from cold shortening. It is now widely used in many other countries with a variety of parameters (Box 1). In New Zealand, ES was originally used to accelerate rigor mortis before sheep meat and beef was frozen. For cattle, shortening is less of an issue as temperatures fall more slowly than sheep, but ES in many circumstances enhances tenderization with a general improvement in quality and reduction in the differences among cattle breeds.

In initial commercial operations, loins and legs from nonstimulated lamb carcasses put into a blast freezer (−5 °C within 2 h of slaughter) and later cooked from the frozen state were exceedingly tough, with only approximately 1% of the loins assessed as acceptable on the basis of shear force. In contrast, nonaged loins from similarly processed, but high voltage-stimulated lamb carcasses gave approximately 75% of shear force values in the acceptable range. For small, easy-to-chill lambs, the improvement is therefore dramatic, ensuring that the majority of rapidly frozen meat is acceptable. For cattle, shortening is less of an issue, but ES still enhances the rate of tenderization. The combination of ES and a specified further aging period to achieve a desired tenderness level underpins the accelerated conditioning and aging (AC&A) standard that currently applies in New Zealand abattoirs for sheep and lambs.

Description

Events During Electrical Stimulation

ES involves passing an electric current through the bodies or carcasses of freshly harvested animals. This electric current causes the muscles to contract, increasing the rate of glycolysis and results in an immediate reduction in muscle pH (ΔpH) that ranges from 0.6 pH units at 35 °C to 0.018 units at 15 °C, suggesting that ES of warm carcasses should take place soon after slaughter to maximize efficacy. Following the pH fall, there is a temperature-dependent acceleration of the rate of glycolysis (dpH/dt) and subsequent early rigor mortis development (Figure 1).

The increased rate of pH fall after ES seems to occur with a wide range of electrical parameters and even occurs as a consequence of high frequency electrical stunning and kicking movements post slaughter. Although the ΔpH is generally lower with low-voltage ES, the same rate of poststimulation pH fall is achieved as with high-voltage systems.

The rapid development of rigor mortis ensures that postmortem aging starts earlier, improving meat color, and provides increased muscle stiffness that facilitates early boning.

Electrical Stimulation Systems

There are numerous physical methods by which ES can be applied and many different possible electrical specifications (see Box 1 for representative electrical parameters). A new generation of systems developed in Australia for both sheep/lambs and beef were designed to impart the response observed with high-voltage ES, but without the danger associated with such systems. The pulse width is reduced and the peak voltage

Box 1 Typical ES parameters in common commercial use. It should be noted that these are representative and many variations are used

- 200 V, 60 Hz applied in bursts of 1 s on, 1 s off for 60 s duration for beef in the US
- 1130 V peak, 14.3 alternating pulses per s applied for 90 s within 30 min of slaughter for sheep are lambs in New Zealand
- 80 V peak, 15 unipolar pulses per s, square or half sine wave, applied for 15–30 s within 5 min of slaughter for beef in New Zealand
- 800 V rms bidirectional half-sinusoidal, 14.3 pulses per s applied within 40 min postslaughter for beef and lamb
- 80 V peak, 15 unipolar pulses per s applied for 30 s within 20 min of slaughter for beef in Sweden
- 40 V peak, 15 unipolar pulses per s applied using an anal probe with durations for 40–50 s within 5 min of slaughter for beef in Australia
- Voltage controlled to deliver up to 2 A peak for 30 s at 15 pulses per s up to 2.5 ms duration applied within 30–40 min for sheep and lambs in Australia. A variation to this includes modulated frequency, for example, for a 6 electrode system 10, 15, 25, 10, 15, and 25 Hz
- 400 V peak 2 ms pulses at 15 pulses per s in Australia for beef

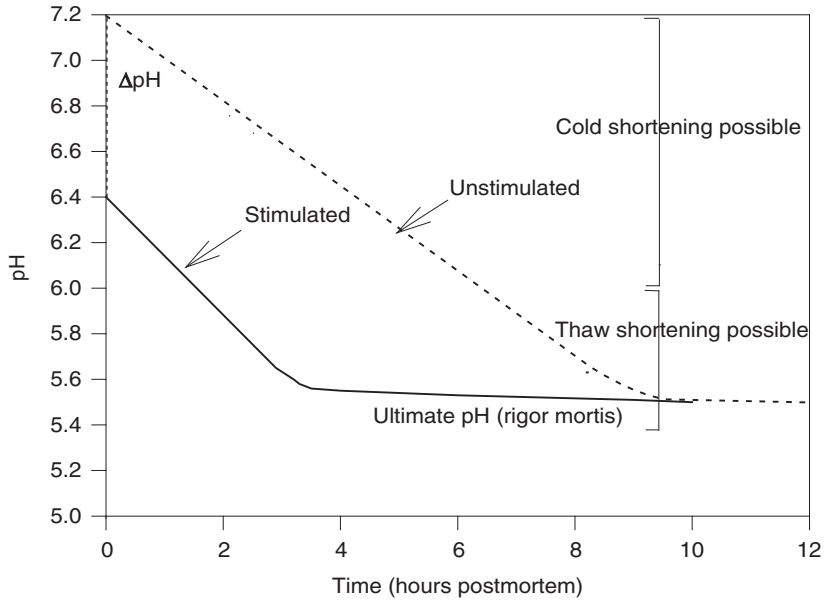

Figure 1 Postmortem pH fall in muscles after ES and held at a constant 35 °C. During stimulation, the muscle pH falls (ΔpH). Nonstimulated beef muscle has a rate of pH fall (dpH/d*t*) of 0.18 pH units per hour. After stimulation, the dpH/d*t* is increased to 0.3 pH units per hour. The time that muscle is at cold shortening temperatures is clearly reduced.

is decreased compared with high voltage ES, but the lower rms voltage developed (rms is the 'average' voltage and is explained later) ensures that the systems are much safer for workers (see Box 1). Regardless of species, ES can be applied immediately after slaughter or at any point in time thereafter until the muscles become unresponsive. The time until muscles fail to respond is related to the natural rate and extent of glycolysis and the voltage and or current being applied, the duration of ES, and the type of response expected. Procedures range from stimulating stunned but not bled animals, to whole bodies, skinned bodies, carcasses, or sides or even primal cuts.

Most commercial ES systems employ the carcass rail as ground and a live electrode contacts some other point of the body, carcass, or side as shown in Figures 2, 3a,b, and 4. In the most basic systems, the live electrode contact is a clip manually applied to the head or neck of the body (such a clip would replace the lower rubbing bar in Figure 2) as it is suspended by one or both hind legs, resulting in a current flow to the grounded rail support or top electrode. A range of other systems have also been developed for beef ES, covering both batch and continuous operations. The batch systems might involve manually inserted electrodes or electrode bars that move out to make contact with the body or carcass. In these systems, the carcass or carcasses are enclosed within a shielded cabinet during ES. Continuous systems consist of stationary rubbing electrodes (Figures 2 and 3) or, where the ES is applied to carcasses before inspection, the electrode system consists of a moving series of electrodes. For poultry, heads can be placed in a trough filled with water with the rail being the other electrode.

In New Zealand, electrical stunning of cattle is widely used; and the stunning current is applied to a restrained head in a stunning box and followed by application of additional currents to cause cardiac arrest (if nonhalal) with reduced poststun carcass movements. Following stunning, current is often immediately applied to the body for ES before the animals are ejected from the stunning box in some New Zealand plants. Some carcass electrical immobilization may cause a pH fall (although some recent immobilization parameters do not cause a pH fall and are exempt) as will the application of electrodes to the back muscles to stiffen them during downward hide pulling. New immobilization systems have been developed in Australia for sheep/lambs and beef.

Figure 2 Low-voltage ES of cattle in a meat processing plant. The current (120–400 mA, 15 pulses per s) passes between the top rubbing bar electrode and a lower rubbing bar electrode (often earthed). An alternative arrangement can use a clip attached to the nose. The duration of ES ranges from 30 to 60 s. Bleeding out rate is generally increased. The application of ES is from the electrode at top rail to the hind leg with only one carcass on any electrode at any one time. Photograph courtesy New South Wales Primary Industries, Australia.

Figure 4 A typical high-throughput system using a high voltage ES facility for sheep postdressing, in which the current passes through the carcass between two rubbing bars. Photograph courtesy New South Wales Primary Industries, Australia.

More sophistication and protection for humans is required as voltages increase, such as in high-voltage systems for sheep and lambs (Figure 4). However, safety is enhanced with the development of systems with shorter pulse widths and increased voltages utilizing reduced rms voltages. In one New Zealand abattoir, an effective single in-line high-voltage ES system coped with a peak kill of 20 000 carcasses per day. Typically, for high voltage situations, the ES is applied less than 30 min after slaughter where dressed carcasses are suspended by metal or plastic skids and gambrels from a grounded rail and moved through a stimulation tunnel to make contact, at shoulder level, with an electrode supplied with high voltage pulses (see Figure 4).

Electrical Stimulation Parameters

Any electric current above a certain threshold will stimulate muscles, and for this reason stunning or immobilization currents can have a beneficial effect on tenderness by also accelerating glycolysis. The current flow is dictated by the applied voltage and carcass characteristics such as pelt cover, animal size (determining resistance) and fatness (potential insulation), and contact area (in particular reduced contact with shin). However, in commercial situations where high voltage ES is used, large peak current flows occur (e.g., in excess of 2 A peak per carcass). In situations where many carcasses are stimulated simultaneously on the same electrode system, very sophisticated power supplies, delivering up to 60 A total, are needed for the pulsed currents and currents are not necessarily shared equally between carcasses. Development of new systems for sheep/lambs and beef in Australia using short pulse widths and moderate voltages use segmented electrodes to ensure that each electrode only contacts one carcass at a time. This allows computer-controlled electronics to give a precise, but adjustable current to each carcass to match the requirements of a particular carcass type (Figures 2 and 3a,b). The current pulses in these systems use very rapid rise times that appear to provide a greater stimulation effect with lower peak current to give very effective results (Box 2).

Voltages used vary from 32 to 3600 V (historically). The value specified might be that of the peak or the rms (root mean square) voltage, or in some cases the average over the total time. The rms voltage is the effective value or heating

Box 2 Meat characteristics following ES. Color (redness (a^*), color stability at 630/580 nm, shear force (*M*), pH, predicted temperature at pH 6.0 (°C), for the m. longissimus of electrically stimulated (800 mA, pulse width 0.5 ms, peak voltage of 300 V, 15 Hz, for 60 s) and nonstimulated lamb carcasses (40 per treatment). Chilled at 4.2 °C. All values are predicted means (s.e.d.)

Trait	*Stimulated*[a]	*Nonstimulated*	*s.e.d.*
Initial loin pH	6.34a	6.79b	0.04
Predicted temperature at pH 6.0	24.8b	13.9a	1.50
Shear force (*M*) at 1-day aging	36.0a	44.0b	2.40
Redness (a^*)	7.70a	7.00a	0.32
Color stability (630/580 nm)	3.20a	3.00a	0.14

[a]Stimulation treatment was at a current of 800 mA with a pulse width of 0.5 ms for duration required. Means followed by the same letter in a row are not significantly different ($P = .05$).

capacity of a waveform. For a sine wave, the rms value is the peak voltage divided by $\sqrt{2}$. For 1130 V peak, 50 Hz, the rms voltage is 800 V. However, for many derived (nonsinusoidal) waveforms the rms may be quite different and ineffective. For one version, termed the Meat Industry Research Institute of New Zealand (MIRINZ) waveform, every seventh half-sine wave of a 50 Hz sine wave is used and the rms voltage is the peak voltage divided by $\sqrt{14}$. Figure 5 illustrates the meaning of the different terms used to describe voltages and waveforms. Defining a waveform with a frequency (expressed in Hz) is likely to lead to confusion unless the waveform is also defined in terms of shape, duration, and pulse spacing. Square waves also can be used and may be unipolar or bipolar and applied as discrete pulses or even as pulse trains.

Extensive research in Australia particularly in sheep and lambs has demonstrated that ES systems must be validated and optimized to ensure effective operation – in other words mere application of electricity does not guarantee a satisfactory result. In instances where this does not happen or system monitoring is not employed ES can be relatively ineffective. In some situations with multielectrode systems, lights are used to indicate when each electrode is operating, to limit ineffective ES. Although any stimulation increases dpH/d*t*, it is only optimum parameters (duration, peak voltage, and pulse characteristics) that increase the fall ΔpH significantly. It is likely where ES is not regarded as effective or useful the resultant ΔpH has not been sufficient.

Safety

Occupational safety has been of utmost importance during experimentation and implementation of ES, especially when peak voltages as high as 1130 V are used. In some instances, safety concerns have effectively prevented commercial adoption of the process but, as indicated, modifications to pulse width resulting in much lower rms voltages have meant that the safety concerns are negligible. When required, isolating switches, warning lights, and proximity switches are used. For frequencies of 50 or 60 Hz, cardiac arrest is highly likely with any form of contact by personnel, but cardiac arrest is less likely with the pulsed waveforms now used. Systems have been developed for ES of beef carcasses ranging from continuous operations to manual insertion of electrodes. In past systems, the carcasses were enclosed within a shielded cabinet during ES. The new narrow-pulse systems have eliminated the need for this shielding. There are also food safety issues to consider. For example, where the stimulation is applied to carcasses before inspection, but after the hide is removed, the electrode system needs to be sterilized between carcasses.

Until recently, plants have applied ES to beef carcasses with an electrode on the nose or stick wound and grounding via the rail from which the carcass is suspended. Under these conditions the resistance of the narrow portion of the hind leg with high bone and tendon but low muscle content can be very high. The relatively high resistance encountered is due not to the bone component per se but to the narrow points of contact at the rigid interface, thus reducing contact area and severely limiting current flow. An anal electrode has been used in Australia for beef to provide good contact in the hindquarter, and using this system effective low-voltage ES has been achieved. The new narrow-pulse systems allow automatic application (Figures 2 and 3a,b) using rub bars as higher peak voltages can be used safely to overcome the increased electrical resistance of the bars.

Other Meat Quality Responses to Stimulation

In most instances ES is applied with the aim of ultimately improving tenderness, but there have been reported some minor adverse effects such as ES-mediated meat color changes. In most cases the stimulation has been suboptimal/ineffective and the chilling conditions inappropriate. It seems unlikely that electricity on its own affects meat color. The potential interaction of low pH and high temperature on prerigor meat are only present for a short time due to early rigor mortis (see below). Because of early rigor following ES, color changes are not identical at 24 h (typical results in Box 2). This is expected as electrically stimulated meat is in fact biochemically further along the postmortem pathway, including being more tender – this makes a slight difference at 24 h but not is not significant for aged meat.

Similarly, glycolysis is rapid following ES so the consequent early rigor mortis, even with a slow temperature decline of very large/fat beef carcasses, is so brief and does not produce significant myosin denaturation (it does not therefore mimic pale, soft, exudative (PSE) pork). Any drip that does occur following ES is expected as a consequence of early rapid tenderization, but the extent is similar to that without ES for the same tenderness (see below).

Denaturation of muscle protein (myosin) during the prerigor period, can occur to a small extent even for nonstimulated carcasses if the chilling rate is slow and even occurs to some degree under normal chilling conditions for all species – it is a characteristic of prerigor muscle, so it is not a direct stimulation effect. The temperature and pH conditions that

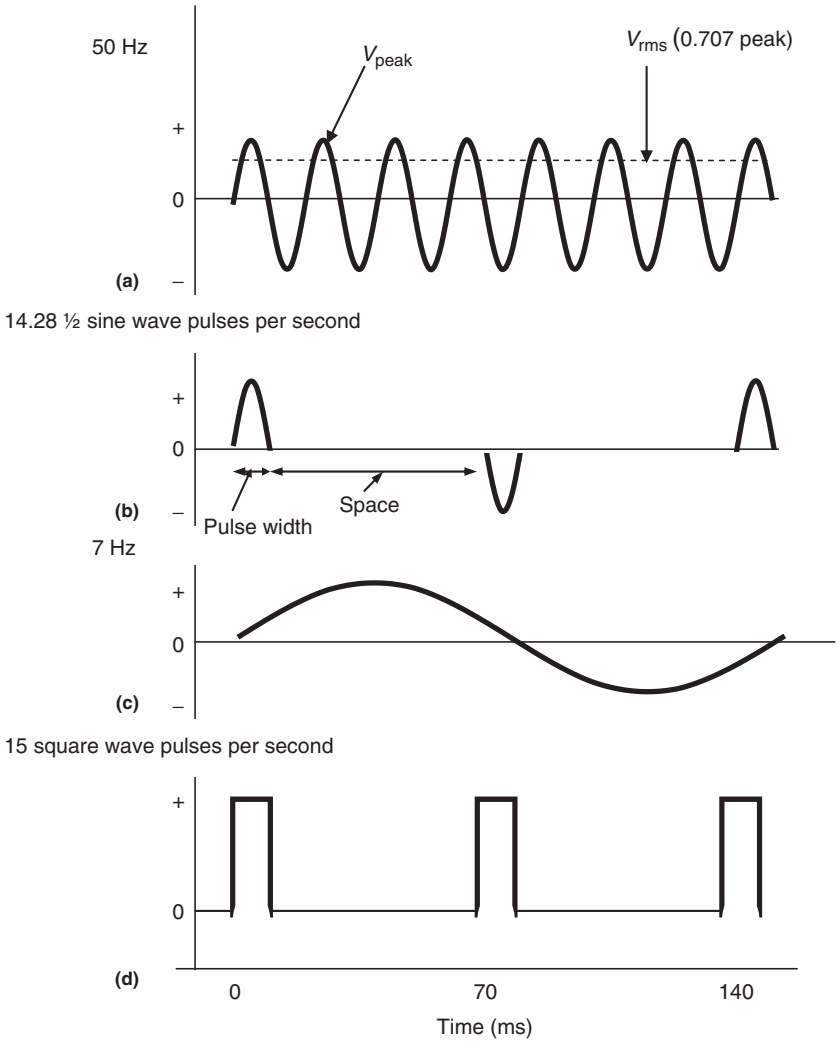

Figure 5 Terms used to describe pulses and waveforms illustrated by sinusoidal (a and c), half sinusoidal (b) and square wave pulses (d). In (a) there are 50 sinusoidal cycles per second (100 half sine wave pulses); peak and rms voltages are indicated. The pulses in (b) are obtained by cutting out half-sinusoidal pulses, which in this case gives 10 ms duration pulses, 14.28 pulses per second, with the same peak voltage. The pulse width (mark) and space between pulses give the mark-to-space ratio used to specify a single repetitive cycle, with the polarity of pulses and the number of cycles per second required to complete the description. The waveforms (b) and (c) both have the same period (inverse of frequency) and peak amplitude, but have different shape characteristics. Square wave pulses (d) can have variable widths depending on the characteristics desirable, and only a particular stimulation waveform is shown here.

result in myosin denaturation and drip have been modeled by Gerald Offer for pork and beef during glycolysis and cooling and he showed that once rigor occurs there is no further myosin denaturation. In particular, Offer stated, "If the rate of glycolysis is very high, although the muscle experiences particularly severe denaturing conditions so that the rate constant of denaturation reaches high levels, these are experienced for a sufficiently short time that the total amount of myosin denatured is lower rather than higher." This means that the brief prerigor exposure to elevated temperatures, following ES, reduces myosin related drip compared with longer prerigor exposure without ES at lower temperatures. In fact increasing stimulation effectiveness increases ΔpH and this in turn reduces the time to rigor and thus exposure to denaturation conditions.

Without ES, muscle held at constant elevated prerigor temperatures appears to have a reduced tenderization by inhibiting calpain activity. In contrast, with ES not only the prerigor exposure duration is reduced but also some fibers enter rigor almost immediately and the rest of the muscle fibers rapidly follow – the degree depending on initial prerigor glycogen – so full tenderization can then take place.

Postrigor cytoskeletal denaturation and tenderization is associated with production of free water. This means that the early appearance of drip as muscles tenderize rapidly at high temperatures, is a consequence of rapid and extensive tenderization, but there is no more drip for equivalent tenderization. The appearance of drip is unfortunate, but its appearance means meat has tenderized. Conditions that reduce drip generally also reduce tenderization.

Factors That Influence Effectiveness of Stimulation

Fall in pH upon Stimulation

The magnitude of ΔpH is governed by muscle fiber type, initial glycogen stores within the muscle, the electrical characteristics (current, frequency, pulse shape, and stimulation duration), temperature of muscle, and the time after death at which ES is applied. Postmortem delay, through a combination of lower muscle temperature and lower initial pH reduces ΔpH, but not the extent of pH reached – ES effectiveness and tenderness is not reduced.

Effects of Muscle Type on Stimulation Response

There is a difference in response to stimulation between various muscles that depends on muscle fiber type and the ratio of fiber types. Fast-twitch beef m. cutaneous trunci, largely composed of white muscle fibers, gives higher values for ΔpH (and dpH/d*t*), whereas in the slow-twitch m. masseter, composed of red fibers, there is neither a distinct ΔpH nor an acceleration of dpH/d*t*, which is naturally rapid (0.4 pH units per h).

Frequency, Voltage/Current, Pulse Shape, and Polarity Effects

Most beef and sheep muscles have a greater physical response, prolonged contraction, and a concomitantly greater ΔpH in the range from 9 to 16 pulses per second than at any other frequency, and most ES systems encompass these frequencies (Figure 6). In general, the higher the current (at a constant resistance, current increases with increased voltage) the greater will be the effect. This response will be asymptotic to some maximal value, however, so continually increasing the current will not lead to a continuing increase in effect once the ES parameters are supramaximal. The advantage of pulsed currents is that the energy of the electrical input is lower, with a smaller chance of melting structures in the current pathway such as the Achilles tendon.

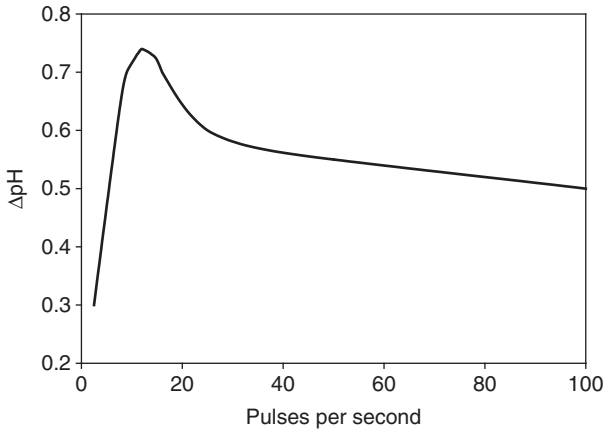

Figure 6 The effect of pulse frequency on the ΔpH value. The greatest effect lies between 7 and 15 pulses per second and these frequencies are chosen in most ES systems, although the effect is significant at all frequencies. With pulsed waveforms, the electrical input to the carcass is low and this is a major advantage, with lower heating.

There is recent evidence that the pulse shape (at a constant peak voltage/current) has an influence on the ES effect. Rapid-rise time rectangular pulses appear to have a greater stimulation effect compared with sinusoidal pulses of the same peak voltage/current. The width of the pulses also influences the stimulation effect.

Recent studies in Australia have explored this in some detail and have found that as the pulse width is reduced the effectiveness of ES diminishes slightly, but this reduction can be more than compensated for by an increase in the current. The consequence is that the rms voltage (a function of pulse width, frequency, and peak voltage) increases only slightly, but the effective ES effect is dramatically increased. With low-voltage ES, the greatest ΔpH values were obtained when the positive electrode was attached to the cranial end of the animal.

Changes in the Rate of pH Fall (dpH/d*t*) upon Stimulation

Almost any stimulation can affect dpH/d*t*, including unexpected stimulation arising from electrical stunning, immobilization of carcasses, electronic bleeding and even effects from current application during downward hide pulling. Rates of pH fall are slowest in nonstimulated muscles from curarized animals and there are even increases in dpH/d*t* with any vigorous muscle movement during slaughter. There can be a twofold increase of dpH/d*t* with stimulation bursts as short as 5 s. Unfortunately, coupled with the other adverse situations in susceptible species such as pork (e.g., stress and nondesirable genetics), a poor outcomes results. Some studies have shown when stimulation is sufficient (in other words a high ΔpH) this does not occur, but this has not been explored fully.

These increases in glycolytic rate can be explained by stimulation causing a reduction in the energy of activation (the amount of energy needed to start the reaction in excess of that already possessed by the molecules). If the activation energy is high, the rate is low and vice versa. The energy of activation (E_a) for the rate of pH fall of nonstimulated muscle has been calculated in a range of situations, with values from 40 to 110 kJ mol^{-1}. In one study for stimulated muscle, the E_a was 70 kJ mol^{-1} and for nonstimulated muscle from the same animal the E_a was 50 kJ mol^{-1} suggesting that fundamental changes, perhaps in enzyme activity, are induced by ES. In addition, dpH/d*t* is strongly affected by temperature, being faster at higher temperatures, so that an increase in temperature (increase in the kinetic energy of the molecules and hence in the rate) has a greater effect on dpH/d*t* of stimulated muscle than that of nonstimulated muscle. These changes are possibly a consequence of irreversible changes to ATPase activity that dictate the rate of ATP hydrolysis and therefore pH decline. For example, Ca^{2+}-activated actomyosin ATPase activity increases following ES, possibly owing to increased Ca^{2+} sensitivity, which in turn could account for the lower E_a.

Electrical Stimulation and Hot Boning

Hot boning (i.e., the process of boning the carcasses before attainment of rigor mortis in most muscles) has many

economic advantages (savings in energy, space, labor, and time). The major constraints to the use of hot boning have been the slippage of one muscle relative to another within a primal cut, which is considered visually less appealing, and the extra shortening of excised muscles subjected to rapid chilling. Aging is effective when muscle shortens by less than 20% (but reduces if shortening is greater), so hot boning and aging is feasible if temperatures are controlled.

The role of ES in hot-boning applications is clearly to hasten the onset of rigor mortis, so that cold shortening and rigor shortening are minimized. Rapid cooling subsequent to rigor mortis, with its greater control of microbial proliferation, especially in vacuum packaging, can then be used without irrevocably toughening the product. More effective ES is required when very rapid chilling systems are employed. ES by itself cannot prevent cold shortening encountered within rapidly chilled hot-boned meat.

In general, hot boning without ES (and also without any prevention of shortening) has resulted in a disproportionately greater increase in the toughness of beef muscles compared to those that are normally stretched when carcasses are supported by the Achilles tendon (e.g., beef m. psoas major). The sarcomere length of cold-boned psoas has been recorded at 3.3 μm (stretched), whereas when hot-boned product it has been fallen to 1.95 μm – close to that of the rest length of most muscles in the body, but further shortening occurs in other muscles. The observation that rigor at approximately 15 °C produces the most tender meat, whether hot-boned or restrained, suggests that further temperature control will result in significant tenderness improvements, but ES still significantly further improves tenderness.

Scientific Basis for Tenderization Involving Electrical Stimulation

Rigor Mortis, Cold Shortening, Rigor Contracture Calcium Levels, and Optimum Tenderization

If there is sufficient ATP in some fibers, cold shortening can still occur when muscle temperatures fall below 8 °C. A rule of thumb, for the prevention of cold shortening is to maintain temperature above 10 °C until muscle pH falls below 6.0.

Start of Tenderization

Proteolysis arising from the action of calpains takes place takes place to a minor extent prerigor, but significant tenderization through cytoskeletal proteolysis commences at rigor mortis, and can continue even in shortened muscle (without the meat becoming tender). If the longissimus muscle has been stretched (e.g., 'Tenderstretch' or SmartStretch™), then the beneficial changes due to tenderization occur earlier, but not necessarily to a greater extent. Under the same chilling regimen, stimulated muscles enter rigor mortis and commence to age at a higher temperature than nonstimulated muscles and hence initially experience faster tenderization. Early tenderness measurements will be substantially different for stimulated muscles compared with nonstimulated muscles.

Structural Effects

Histological images of stimulated muscle have shown on occasion the appearance of contractile bands containing predominantly stretched, ill-defined, and disrupted sarcomeres. The linkage between improved meat tenderness and physical disruption is plausible, as ES treatment has improved tenderness under circumstances where no cold shortening was evident. However, it is unclear whether it is the physical disruption per se that has caused the effect or whether the physical disruption facilitates aging in other ways, such as enhancing proteolysis. Contracture bands are not a direct consequence of electric current passing through the muscle, but are rather due to the supercontracture caused through localized excessive release of calcium ions from the sarcoplasmic reticulum (and also failure by the sarcoplasmic reticulum to pump calcium out). It could be this extra calcium that assists tenderization, since the key proteases are calcium dependent.

It is possible that physical stretching/tearing leads to an acceleration of proteolysis as a result of greater exposure of proteolytic substrates within muscle fibers, in addition to the direct effect of physical tearing. Stretched longissimus muscle (Tenderstretch) is initially more tender and the proteolysis starts from this greater tenderness, but the final tenderness is likely to be similar, being limited by connective tissue cross-linking with the final tenderness therefore not being affected. It has been shown that red muscles such as the masseter do not exhibit an increase in rate of pH fall upon ES, but do show evidence of supercontracture. However, white muscles such as the cutaneous are not so susceptible to cold shortening and show almost no supercontracture, yet the rate of pH fall is increased by ES. This raises the question whether structural alteration itself significantly affects meat tenderness of stimulated muscles, whereas there is no direct solid evidence available at the present time to discount the importance of physical alteration.

Impact of Physical Disruption on Ions

If the physical disruption is great enough to cause early release of calcium ions from the sarcoplasmic reticulum and mitochondria into the sarcoplasm, this will have a direct effect on activation of the calpain enzyme system and muscle shortening. It has been estimated that free calcium concentration could be raised to more than 100 μmol l^{-1} by an influx of extracellular calcium ions into the myofibrillar space. However, the evidence indicates that low-voltage ES per se does not lead to an increased release of 'free' calcium ions into the sarcoplasm. Calcium concentration in the intracellular space increases during ES, but the released calcium ions are taken back to the resting state into the sarcoplasmic reticulum if energy reserves are not completely depleted during ES treatment. This suggests that at the same temperature, stimulated muscle will be momentarily exposed to higher levels of 'free Ca^{2+}' and thus increased proteolysis. Under normal circumstances this extra Ca^{2+} is sequestered back into the sarcoplasmic reticulum. However, this reuptake process may be retarded if the sarcoplasmic reticulum pumps are affected. In addition, the stimulation accelerates pH decline, which is mirrored by an increase in 'free' Ca^{2+} and consequently an early activation of the tenderization process. Recent studies

have suggested that stimulation irreversibly damages the calcium pump so that it is less efficient at sequestering Ca^{2+} from the cytosol. This could also give rise to increased proteolysis via calpain system.

Effect of Stimulation on Calpain Enzyme Activity

There are several possible explanations why ES might increase the activity of specific enzymes such as the calpains (in addition to being fully available after rigor mortis). It may be due to some intrinsic effect associated with the rapid pH decline, with a low pH at elevated temperatures, that affects the processes governing the activation and inactivation of the calcium dependent proteases, or it could be due to a flow-on effect associated with a significant increase in 'free' calcium, which leads to activation of the calpains, particularly μ-calpain.

Because ES alters the postmortem pH–temperature relationship, it is reasonable to expect some effect on endogenous proteolytic enzyme systems (especially the calpain system) and the rate and extent of postmortem proteolysis. *In vitro* estimations show that the endogenous calpains within skeletal muscle can degrade the myofibril component within an hour, suggesting that ES might confer an advantage to the enzymes responsible for aging at a higher rate of proteolysis in those

Box 3 Clarification of issues relating to ES with questions and answers that explain positive unexpected outcomes from early rigor and early tenderization

Issues raised	*Answers*
Are there any disadvantages of stimulation?	No, other than safety requirements that have to be met. No clear evidence that there are adverse effects in heavy fat carcases
Can there be too much stimulation?	No, provided the correct pulse frequencies are used, otherwise there could be resistive heating. Stimulation produces its effect through the muscles doing work and this ceases when the pH falls sufficiently. Thus over stimulation is not possible – it is self-limiting
What are the optimum stimulation parameters?	There are a range of frequencies around 12–20 pulses per second. The pulse width can range from 2–10 ms and the stimulation duration must be sufficient to result in a significant pH fall (40+s). The required duration therefore depends on the applied voltages from 80 to 1100 and the time of application after slaughter. See **Box 1** for examples
How important is contact?	Good contact is important for the maximum current to flow. It is this current rather than applied voltage that needs to be standardized and some units are current controlled to ensure reproducible results. More reproducible results ensure if the pelt is removed before stimulation, as contact is better
What is the effect of stimulation on drip?	As meat tenderises drip is produced. Drip appears early following stimulation but there is the same drip for the same tenderization
Can stimulation produce a PSE-like condition?	No, PSE in pork arises from severe myosin denaturation prerigor and in worst cases a lot of drip is produced because myosin is a major muscle protein. Tenderization occurs via cytoskeletal denaturation postrigor mortis of smaller amounts ($<10\%$) cytoskeletal proteins so no extremes of drip thus not PSE
Following stimulation the temperatures are high and pH low and myosin denaturation could occur	Partially true but not significant. Myosin denaturation will occur to some extent even at low temperatures even without stimulation. Following stimulation rigor occurs rapidly for most muscle fibers and when these are in rigor they are protected from serious adverse effects. The remaining fibers are minimally affected by a brief exposure
What is the difference between high- and low-voltage stimulation?	High-voltage stimulation stimulates the muscle directly. Low-voltage stimulation acts via the nervous system. There are a wide range of useful parameters. Thus the pH falls are not identical. As the voltage rises the duration of stimulation needed to produce optimum effects decreases
Does stimulation work mainly through reducing cold shortening?	Only to a small extent. Cold shortening is an issue in small carcasses like sheep when rapidly chilled, but even when cold shortening does not occur meat is still more tender
What is the main advantage of stimulation?	Meat tenderises faster and to a greater extent and therefore customer-ready earlier. The reduction of refrigerated storage capacity required for long aging should lower costs
Are there disadvantages with long storage following stimulation?	No, stimulation ensures meat is ready for the customer earlier, but this takes the order of days. Chilled storage in transit takes weeks and a day or two earlier does not matter. However, meat tenderises fully following stimulation
Are there texture differences through stimulation?	Has been raised as a theoretical issue, but has not been discernable commercially (other than being more tender)
Can a heat ring occur?	Yes, this may occur with slow cooling but then disappears early during aging
Can stimulation upgrade cuts?	No, but it can ensure a given cut reaches its potential tenderness and it might appear to be upgraded compared with unsatisfactory processing
Does stimulation affect some breeds more than others?	Without stimulation there can be significant tenderness differences between breeds, but with stimulation this difference largely disappears and both are more tender than without stimulation

muscles. ES however, does not appear to have a role in activation of lysosomal enzymes under normal chilling conditions.

Unclear Interpretations of Stimulation Effects

ES is often regarded as a variation to normal meat processing – merely enhancing entry into rigor mortis and avoiding cold shortening, but this is only partially true. Without ES, problems with prolonged high rigor temperature cause both myosin protein denaturation and reduced aging – this does not appear to occur to the same extent with electrically stimulated muscles where similar exposure to high rigor temperatures are brief. Extrapolations from unstimulated to stimulated systems are therefore problematic as the two situations are not comparable as mentioned above. Even so, in some experimental studies without chilling it appears that even with ES, prolonged prerigor temperatures above 38 °C may inhibit tenderization to a minor extent.

Adverse effects of ES appear to be rare and many controversial issues arise possibly arising from ineffective ES with poor chilling (hence the emphasis on optimum ES parameters and optimum chilling above) or not measuring comparable indices at equivalent times. The implication that ES increases total drip appears misplaced, for example, and experimental evidence is either unclear, minor, or is not supported. The pre- and postrigor sources of drip therefore need to be explored in more detail to characterize this situation fully.

As overall muscle responsiveness ceases when the pH falls to approximately 6.3 during ES, it is physiologically not possible to over stimulate as muscles cannot respond. Although ES is necessary where cold shortening is an issue, several studies show that ES also ensures the greatest possible tenderness.

Elevated rigor temperatures in the absence of ES inhibit tenderization at the end of aging. Although early tenderness levels may be superior, final tenderness may not reach the levels for meat entering rigor at lower temperatures – thus without ES it is necessary to cool carcasses to temperatures where maximum tenderization occurs. The Meat Standards Australia (MSA) temperature window for optimum chilling was designed with this in mind. For other classes of carcasses (lambs/sheep and lighter beef) ES is needed to achieve the relevant MSA temperature/pH windows.

Is ES effective for pork? With optimum ES the answer is sometimes unexpectedly yes for some breeds. Other very stress-susceptible breeds such as Pietrain do not give good results. Surprisingly when successful, problems of excess drip do not appear to arise (other than as the expected consequence of tenderization). Insufficient ES, however, appears to set in place conditions that result in PSE as mentioned above.

In the case of unstimulated poultry, fast rigor entry and subsequent aging is normally rapid. An even faster rigor entry after ES allows wing removal, breast to be trimmed and portioning early without rigor toughening (adverse rigor effects seem to be more severe in poultry than other meats) in approximately 1 h without quality deterioration.

Conclusion

It is clear that ES improves meat quality and there are no clear disadvantages with proper chilling (**Box 3**), and optimization of parameters produces significantly better results. This improvement is maximized when meat is rapidly chilled to reach temperatures close to 15 °C and some advantages are summarized in **Box 2**, for tenderness, color and color stability. However, ES does not significantly improve inherently tender meat beyond baseline tenderness and cannot improve on the toughness associated with intemediate pH meat (i.e., ultimate pH 5.8–6.2) or improve upon the tenderness achieved from procedures such as Tenderstretch. Drip that appears is a consequence of degradation of cytoskeletal proteins during aging appears earlier for the same level of tenderization with or without ES.

Although ES of carcasses hastens the onset of rigor mortis and reduces cold-induced shortening and toughness, there can be other effects such as early activation of the calpain system, possibly involving elevation of calcium at critical times, which can hasten cytoskeletal protein degradation and generally positively contribute to tenderness, with concomitant fiber disruption potentially contributing. Because ES alters the postmortem pH–temperature relationship it is reasonable to expect some effect on endogenous proteolytic enzyme systems (primarily the calpain system) and subsequently the rate and extent of postmortem proteolysis and enhancement of the activity of the enzymes responsible for aging by the elevated temperatures that exist at that time.

ENVIRONMENTAL CONTAMINANTS

M Rose, The Food and Environment Research Agency, Sand Hutton, York, UK

Introduction

Environmental contaminants arise in meat as a result of chemicals present in the areas where the food is produced and from the use of contaminated animal feeds in the production process. Most organic contaminants arise initially as a result of industrial processes combined with the properties of the compounds themselves in that they persist in the environment as a result of their chemical stability and other physicochemical properties. These compounds are termed persistent organic pollutants (POPs). Elements and some radionuclides may also be present as a result of the geology and geography of the regions where the animals, birds, or fish are farmed or produced, combined with the location of production and type of feed ingredients used. Stable environmental contaminants may also be resistant to metabolism in plants or animals, and this can lead to bioaccumulation as higher trophic levels of the food web are reached. Because fish are at or close to the top of the aquatic food chain, and farm animals are similarly placed in the terrestrial food chain, levels of these persistent ubiquitous contaminants can accumulate in the tissues of fish and meat-producing animals. Where meat and fish by-products are used for animal feed, there is further scope for the elevation in levels of these compounds, unless they can be removed during processing.

Pesticides

Residues of pesticides are more commonly associated with foods of plant origin than with meat and other food products of animal origin. Nevertheless, there is the potential of residues arising, for example, from the use on animals of insecticides, such as organophosphates, pyrethroids, and carbamates; however, these are rapidly metabolized and therefore unlikely to be found in high concentrations or long after application. Some pesticides are classed as POPs and hence residues of them can be found in the environment and can also be present in animal feed ingredients, for example, cocoa bean husks. The occurrence of organochlorine residues in cows' milk produced in countries where the organochlorine pesticides have not been used for some years may be attributed to the use of contaminated animal feed or animal feed ingredients imported mainly from less developed countries where the pesticides are still in current use. Such pesticides include dichlorodiphenyltrichloroethane (DDT), lindane (hexachlorocyclohexane, γ-HCH) and other HCHs, hexachlorobenzene (HCB), aldrin and dieldrin, chlordane, etc. together with their degradation products and metabolites. In more developed countries, the application and use of pesticides is legally controlled in such a way that residue levels occurring in food are minimized. Where they are used according to good agricultural practice, residues of these pesticides should not exceed maximum residue levels (MRLs), which are set on the basis of what is achievable by best practice, i.e., correct application rates and minimum harvest intervals.

Most of the more developed countries have in place monitoring programs to examine both home-produced and imported food; although the emphasis of these programs is directed toward foods of plant origin, there is a significant level of monitoring of animal and fish products. The number of MRL exceedences in fruits and vegetables is typically a few per cent (usually between 3% and 5%), whereas the number of violations for meat and animal products is generally well below 1%.

Persistent pesticides may also be found in aquatic systems. They may arise from direct use in wetlands where they may be used to control vector insects (e.g., DDT has been used to control the spread of malaria by mosquitoes) and may also be used in fish farming (e.g., some organophosphates are used to control sea lice infections of farmed salmon). Pesticides, especially herbicides, can also enter river systems as a result of rainwater and irrigation wash-off from agricultural land into rivers. The potential for these compounds to biomagnify and to accumulate in fish and other aquatic fauna is strong. The residues will reenter the land-based food chain if fish are eaten by wildlife or are caught for human consumption.

The organochlorine pesticides are highly lipophilic and can quickly accumulate in oily fish. There have been particular problems with eels caught in river estuaries, partly because of their oily nature and longevity and also because of the environments they inhabit.

Toxaphene

Toxaphene, or camphechlor, is a complex mixture of polychlorated bornanes (CHBs) and other camphenes. It was one of the most heavily used chlorinated pesticides in the world, with the total quantities used estimated in megatonnes, which is comparable to the usage of polychlorinated biphenyls (PCBs) (see Section Dioxins and Polychlorinated Biphenyls). Toxaphene has been shown to undergo long-range transport and is recognized as a ubiquitous environmental contaminant. Like other organochlorine pesticides, it has also been shown to bioaccumulate in aquatic organisms. Human exposure comes largely from human milk – for breast-fed infants (especially if the mother has been eating a diet rich in oily fish) – fish, and

seafood. Although toxicological data are scant, toxaphene is a probable carcinogen and is a known endocrine disruptor. Owing to weathering and biotransformation, the residue composition in food of marine or animal origins will not necessarily reflect the original pesticide mixtures used.

Dioxins and Polychlorinated Biphenyls

Polychlorinated dibenzo-*p*-dioxins (PCDDs) and dibenzofurans (PCDFs) (collectively referred to as 'dioxins') arise as a result of combustion processes, as by-products in the manufacture of organochlorine compounds, or as a result of activity of the chlorine industry. They are chemically stable and are ubiquitously present in human tissues, even when there is no history of occupational or accidental exposure. Although exposure could occur through inhalation of air, dermal absorption, consumption of drinking water, and consumption of food, the last is the predominant route for the general population and accounts for more than 90% of human exposure.

Although there are a total of 210 dioxins, only the 17 laterally substituted congeners, i.e., those that contain chlorine at the 2, 3, 7, and 8 positions persist and accumulate in animal tissues. These congeners form only a small proportion of the total output from many sources and environmental pollution. These 2-, 3-, 7-, and 8-substituted congeners are regarded as significantly toxic and have thus been the main focus of most exposure studies. They are highly lipophilic and are thus found primarily in fatty tissues, such as human and animal fats and fish oils.

PCBs are a group of compounds that were manufactured until the 1980s for use in various ways, including electrical products (e.g., as a dielectric in transformer oil). They are ubiquitous environmental pollutants, and it has become widely accepted that some PCBs elicit dioxin-like biochemical and toxic responses. These are the coplanar PCBs, i.e., those with no or only one *ortho* substituent. Assessment of the health risks of exposure to dioxin-like chemicals must, therefore, consider these PCBs in addition to the dioxins. The amount of information pertaining to dioxin-like PCBs in foods is somewhat less than for PCDDs/PCDFs themselves but is growing rapidly. However, PCBs have a variety of other biological effects, and although consideration of 'dioxins' is incomplete without the inclusion of dioxin-like PCBs, the different types of toxic effects of these and other PCBs should be taken into account.

Because of their toxicity, both dioxins and dioxin-like PCBs need to be measured at extremely low concentrations in food, and the sum of dioxins and dioxin-like PCBs present is usually expressed in picograms ($1\ \text{pg} = 10^{-12}\ \text{g}$) of dioxins (as toxic equivalents to the most toxic 2,3,7,8-tetrachloro dibenzo-*p*-dioxin (TCDD)) per gram of food. Analysis at these concentrations is technically extremely challenging and expensive and is probably the most complex chemical analysis that is carried out as part of regular monitoring programs. The majority of PCB analyses are carried out by gas chromatography using more routine methods, but these often do not measure the dioxin-like PCBs, which are present at much lower concentrations in the environment than other congeners.

In addition to the general environmental contamination from dioxins and PCBs, there have been specific isolated events that have resulted in the release of these compounds into the environment and hence to their incorporation into food within a localized area. Such incidents have included the accident in Seveso in 1976, when a manufacturing plant producing a chlorinated herbicide exploded, scattering several kilograms of 2,3,7,8-TCDD (the most toxic of the dioxins) around the immediate locality of the factory; the spraying of contaminated 'Agent Orange' herbicide (2,4,5-trichlorophenoxyacetic acid) in Vietnam in the 1960s conflict in order to defoliate the jungle; the Yusho- and Yu-cheng-contaminated rice oil incidents in Japan and Taiwan, respectively; and the contamination of animal feed with transformer oil containing PCBs and (to a lesser extent) dioxins in Belgium in 1999. In 2008, animal feed derived from waste food contaminated by dioxins in heating oil used to dry the feed was supplied to 7 pork producers and 38 cattle farms in Ireland, resulting in a recall of all Irish domestic pork and pork products that had been exported to 23 countries.

Tolerable Intake

In 1990, the WHO established a tolerable daily intake (TDI) of 10 pg per kg body weight (bw) for 2,3,7,8-TCDD, but in 1998, an expert consultation concluded that the TDI should include other dioxins and PCBs that exhibit a similar toxic effect. The concentrations of the toxic congeners were weighted according to their toxicity using Toxic Equivalency Factors (TEFs) to give units expressed as toxicity equivalents (WHO-TEQs) and were established as a range of 1–4 pg WHO-TEQ per kg bw per day. The concept of TEFs was developed to facilitate risk assessment. These TEFs have been established to express concentrations of mixtures of 2,3,7,8-substituted PCDDs and PCDFs and some nonortho and monoortho chlorine-substituted PCBs that possess dioxin-like activity in toxic equivalents (TEQs) of 2,3,7,8-TCDD. Concentrations of the individual substances in a given sample are multiplied by their respective TEF and subsequently summed to give the total concentration of dioxin-like compounds expressed as a TEQ.

$$\text{TEQ} = \sum[\text{PCDD}_i \times \text{TEF}_i] + \sum[\text{PCDF}_i \times \text{TEF}_i] + \sum[\text{PCB}_i \times \text{TEF}_i]$$

More recently, at the end of May 2001, the Scientific Committee on Food (SCF), an expert committee that advises the European Commission, decided that the tolerable intake should be expressed on a weekly rather than a daily basis and set a tolerable weekly intake (TWI) of 14 pg WHO-TEQ per kg bw per week. The WHO/FAO Joint Expert Committee on Food Additives (JECFA) established, in June 2001, a provisional tolerable monthly intake (PTMI) of 70 pg WHO-TEQ per kg bw per month. Current estimates of consumer exposure show that intake of dioxins and dioxin-like PCBs is between 1.2 and 3 pg WHO-TEQ per kg bw per day, which is a range that overlaps with the range of the recommended limits. It is, therefore, important that steps are taken to reduce the amount of these substances found in food by the implementation and enforcement of pollution control measures.

Legislation

Although regulatory limits for dioxins in food have been set on an ad hoc basis by various authorities in the past, the European Union (EU) became the first body to set extensive and comprehensive limits for these compounds. These EU regulations came into force in July 2002, and include limits for PCDDs/PCDFs in food and animal feed. There was a stated intention to revise these limits with a view to making them stricter before the end of 2004. In 2005, the WHO reevaluated the weightings given to individual dioxin and PCB congeners and produced a revised set of toxic equivalence factors (TEFs) to use when calculating the TEQ. New EU limits were eventually proposed in 2011 and came into force on 1 January 2012. They use the new TEF scheme and have been lowered for some food types. An additional set of limits for the nondioxin like PCBs was also introduced, based on the sum of six marker PCB congeners. Mandatory targeted testing for animal feed has been proposed.

Concentrations in Meat and Fish

Because PCDDs/PCDFs and PCBs are lipid soluble, for most food types containing more than approximately 2% fat, the concentrations found are reported on a fat-weight basis rather than on a whole-product basis. This gives more consistency for comparisons of samples containing variable concentrations of fat, such as dairy products, which show more variability with respect to dioxins on a whole-weight basis than on a lipid basis. For some samples, however, reporting on a fat-weight basis may lead to confusion. Fish can show large seasonal variations in fat content, which can result in an illusion of variation, even if the body burden with respect to dioxins remains constant.

As pollution control measures are introduced and come into effect, levels of dioxins and PCBs in meat have started to show a downward trend. The same is true, but to a lesser extent, for fish.

Most available data suggest that mean dioxin levels on a fat basis in pork in most cases are lower than for beef, poultry, or mutton; concentrations on a fat basis in animal livers are higher than in other tissues for the same species.

There is a widespread data reported for fish, probably because of the large number of species, and also the geographical differences in the levels of contamination in the various fishing grounds from which the fish originate. Typically, many species of white fish contain lower levels than oily fish species and some shellfish species. This is especially true when sourced from a relatively highly polluted area. Certain fish species originating from the Baltic region are recognized as containing high concentrations of PCDDs/PCDFs and PCBs. A significant proportion of fatty fish from this region, such as Baltic herring and Baltic salmon, are unlikely to comply with the EU limit for dioxins, and these fish would, therefore, be excluded from the Swedish and Finnish diets. There are indications that such an exclusion would have a negative health impact in Sweden and Finland due to the nutritional importance of omega-3 fatty acids, vitamin D, and other ingredients in the fish, some of which are especially beneficial in low-light countries. Consequently, there is a local exemption to compliance with this legislation. Sweden and Finland have in place a system that informs consumers of the dietary recommendations about the consumption of fish from the Baltic region, in order to avoid possible health risks.

Another source of dioxins in meat can be from pentachlorophenol (PCP)-treated wood (for preservative purposes) used to house farm animals and poultry. PCP can contain traces of dioxins in a characteristic congener profile, and there have been incidents when this was thought to account for the elevated contaminant levels found in meat.

How do these become residues in meat? It says above that: "They are POPs and behave in the environment in a similar way to the dioxins and PCBs."

Trace Elements

The main sources of metals and other elements in food come from the environment. Some of these, such as arsenic, can be endogenous in some circumstances (e.g., in Bangladesh, where there is groundwater contamination), whereas others, such as lead, normally arise as a result of pollution from industry and other human activities. Elements can also arise in food as a result of certain agricultural practices; for example, cadmium from impure or contaminated phosphate fertilizers can pollute farm land. Manufacturing processes are also potential sources of contamination; for example, tin can be introduced to the food supply from the canning process. It is also possible to introduce trace metals during food preparation when metals, glazed ceramics, or enameled utensils are used.

Trace elements are of interest because of their possible health effects. Unlike the other categories in this section, some of the elements such as iron and calcium have health benefits. Others have no known beneficial biological functions and long-term high-level exposures may be harmful to health. Elements in this class include mercury in organic mercury compounds, which are known neurotoxins; lead, which can impair neuropsychological development; inorganic arsenic, which is an acute poison and a human carcinogen; and cadmium, which can cause kidney failure. High levels of tin can cause acute abdominal problems. Many metals such as copper, chromium, selenium, and zinc are essential to health at appropriate levels but become toxic at higher levels of exposure.

Toxicity and bioavailability of trace elements can depend on the form in which they are present in food. For example, organic forms of mercury, such as methyl mercury, are much more toxic than inorganic elemental mercury. In contrast, it is the inorganic form of arsenic that is more toxic than the organic compound forms, such as arsenobetaine.

Trace elements are assessed for safety by comparing dietary intake estimates with recommended safe levels. The figures usually used are the provisional tolerable weekly intake (PTWI) values and provisional maximum tolerable daily intake (PMTDI) values as recommended by the FAO/WHO Joint Expert Committee on Food Additives. These are estimates of the amount of a substance that can be ingested on a weekly or daily basis over a lifetime without any known risk to health.

Some of the routes of the largest exposure to toxic trace elements, especially mercury and arsenic, are from fish and

shellfish that can bioaccumulate these contaminants from polluted waters.

Fish can take up mercury from marine sediments, and fish and farm animals can be exposed as a result of pollution from industrial emissions. The high exposure of human populations that consume large quantities of fish to mercury has led to interest in the neurological development of children from such areas, for example, Faeroe Isles and Republic of Seychelles.

Similarly, arsenic and aluminum may be found at elevated concentrations in fish. Other elements, such as copper, lead, and cadmium, may be found at higher levels in offal, although this is generally eaten in relatively small amounts and exposure to toxic elements from this source is, therefore, still small for most segments of the population. Concentrations of lead in meat and other foods are following downward trends because of measures to reduce lead in the environment in recent years following the introduction of a number of important pollution control measures, such as the move to unleaded fuel for motor vehicles and unleaded paints.

Radionuclides

Natural and artificial radioactive elements can be found in food. Both types normally enter the food chain as a result of general environmental contamination. Like their nonradioactive counterparts, deposition from the atmosphere or from contaminated water results in direct exposure for farm animals or can result in uptake from contaminated soil or surface deposition onto plants that are, in turn, consumed by farm animals and result in contamination of meat.

Natural Radioisotopes

Three different types of natural radioactive elements can occur in food. The first are those that have always been in the lithosphere and have half-lives measured in millions of years, such as uranium 238, thorium 232, and potassium 40. The second group is composed of daughter elements resulting from the disintegration of the longer life parent elements. Radium 226, produced from uranium 238, is an example of this type. Radium, in turn, can decompose to produce radon, which is also unstable and can generate lead 210 and polonium 210. The third group consists of isotopes formed by the action of cosmic rays in the atmosphere. An important product generated in this way is carbon 14, made by the transmutation of nitrogen.

Natural radioisotopes account for approximately a quarter of the total background dose of radiation to which one is exposed.

Artificial Radioisotopes

Artificial radioisotopes that can be found in food increased greatly following the explosion of the Hiroshima bomb in 1946. Increases were also particularly rapid during the 1960s, when the nuclear powers carried out many atmospheric tests. In addition, smaller amounts of artificial radioactivity are released into the environment by nuclear power stations and their associated plants that process the waste materials. A still smaller contribution arises from medical and research uses.

When an atomic bomb explodes or a nuclear reactor operates, a mixture of radioactive elements is produced from heavy isotopes such as uranium 235 and plutonium 239. Lighter radioactive isotopes may be produced as a result of fission, such as strontium 90 (half-life 28 years), cobalt 60 (half-life 5.3 years), ruthenium 106 (half-life 1 year), cesium 137 (half-life 30 years), and iodine 131 (half-life 8 days). There are also various activation products, including zinc 65 (half-life 245 days) and carbon 14 (half-life 5760 days). Activation products are not produced directly by the fission process but are produced alongside as a result of the action of atomic radiation, especially neutrons, on elements naturally present where the reaction occurs. Elements used in medicine, industry, and research can also be produced by a process of neutron bombardment of selected target atoms in specially designed reactors.

In addition to environmental levels, the relative uptake of radioactive isotopes is an important consideration when considering food and meat contamination. Plutonium can be extremely hazardous when directly ingested, but plants take up plutonium compounds only with difficulty. Its salts are less soluble than those of cesium or strontium, so it is unlikely to enter the food chain in significant quantities by this route. Surface contamination of plants and direct ingestion are of greater concern for this type of element.

Nuclear reactors can result in the contamination of seas and rivers by the discharge of low-level waste or by accidental release into either the atmosphere or the aquatic ecosystem. Some forms of marine life can concentrate cesium 137 and other radioactive isotopes in their tissues, as they do with some nonradioactive isotopes. Flatfish concentrate this isotope by a factor of 20 compared with surrounding seawater concentrations. Zinc 65 has been found to bioaccumulate in the flesh of oysters near the discharge pipes of nuclear power stations. Monitoring programmes for radioactivity in food place a large emphasis on fish and marine products because of this possibility, although so far no serious concern to health with regard to biomagnification of these isotopes has been identified.

Incidents Resulting in the Contamination of Food with Radionuclides

Chernobyl

The world's worst nuclear power accident occurred at Chernobyl in the former USSR (now Ukraine) in April 1986. A reactor at the Chernobyl nuclear power plant, located 80 miles north of Kiev, went out of control, creating a chain reaction that resulted in explosions and a fireball that blew off the reactor's heavy steel and concrete lid, releasing a large radioactive cloud into the atmosphere.

The Chernobyl accident killed more than 30 people immediately, and as a result of the high radiation levels in the surrounding 20-mile radius, 135 000 people had to be evacuated.

Levels of radioactivity resulting from the explosion are still unexpectedly high and are expected to remain so for another 50 years. Levels of radioactivity found in fish caught from lakes

in the UK and Norway, and in lambs grazing on upland hills, were found to be unexpectedly high after the incident owing to contamination, particularly with cesium 137. During the first 5 years following the accident, concentrations of this radioactive element in most foodstuffs and water decreased by a factor of 10, but since then, the rate of decrease appears to have slowed down. At the end of 2011, the UK Government proposed to remove all remaining controls on the movement of sheep from the restricted areas, based on the assessment that the risk to consumers from radioactivity in sheep meat resulting from the Chernobyl nuclear accident is now very low. Berries, mushrooms, and fish from some areas of the former Soviet Union are more likely to continue to be restricted from sale for some years, and fish from some lakes, such as Lake Kozhanovskoe, are thought to remain under restriction for approximately another 50 years.

Fukushima

On 11 March 2011, an earthquake of magnitude 9.0 hit off the northeast coast of Japan. The subsequent tsunami struck the Fukushima nuclear power plants and radionuclides were released into the environment. As part of the risk management process, provisional regulation measures for radionuclides in foodstuffs were taken. For radiocesium, uranium, plutonium, and transuranic α emitters, these limits were set to keep the committed effective dose (an estimate of the radiation dose to a person resulting from inhalation or ingestion of a given amount of radioactive substance) less than 5 mSv year^{-1}. For radioiodines, they were set to keep the committed equivalent dose to the thyroid less than 50 mSv year^{-1}. Tap water, raw milk, and some vegetables were the first foodstuffs found to be contaminated, but fish with radionuclides above levels of concern were detected soon afterward.

Meats, including beef, did not generally exceed the provisional regulation value for radiocesium, but measures were taken to insure that farm animals did not graze in the affected area and were not given contaminated feed.

As a result of the incident, it was possible to detect low levels of radionuclides in foods produced around the globe, but the major impact was on food produced around the plant. Many countries placed restrictions on the import of food from Japan. A massive program of monitoring was brought into effect by the Japanese authorities and, at the time of writing, restrictions are still in place.

Note

Environmental contaminants might be associated with specific incidents but many classes are ubiquitous within the environment and are present in all of the food we eat. The concentrations of many of these contaminants in food are very low, and we should be reminded of the work of Paracelcus who lived from 1493 to 1541 and taught us that 'the dose makes the poison.' Having said that, although the concentrations of these contaminants might be very small (e.g., a few parts per trillion or even quadrillion for dioxins and similar organic contaminants), these concentrations in foods give rise to exposure close to the levels shown to give rise to adverse health effects in experimental animals. But any risk assessment should form part of a risk-benefit analysis and many of the foods that contribute significantly to the source of these contaminants, such as oily fish, also have many health benefits associated with their consumption. Pollution control measures together with efforts to regulate food contaminants in some parts of the world have resulted in a reduction in the amounts of some of these contaminants in food over recent years.

N_2O Nitrous oxide.
N Nitrogen.
P Phosphorus
ppb Part per billion.

Introduction

In 2007, global meat production was close to 280 million ton (Mton), corresponding to approximately 40 kg meat per person as a global average, of which pork dominated with approximately 40% of total supply followed by poultry representing approximately 30% (Figure 1). For the past 20 years, production from mono-gastric animals has expanded much faster than from ruminants, and also milk production has had a smaller growth rate than pig and poultry. According to reports from the Food and Agriculture Organization (FAO), the demand for animal products is predicted to double by 2050 relative to a year 2000 baseline. The FAO report 'Livestock's Long Shadow' highlighted the environmental impacts of the fast-growing global livestock sector and this issue has gained a lot of attention in society over the past years. Recently, also dietary shifts, reducing overall intake of animal products in high-income countries, are increasingly discussed as a necessary mitigation option.

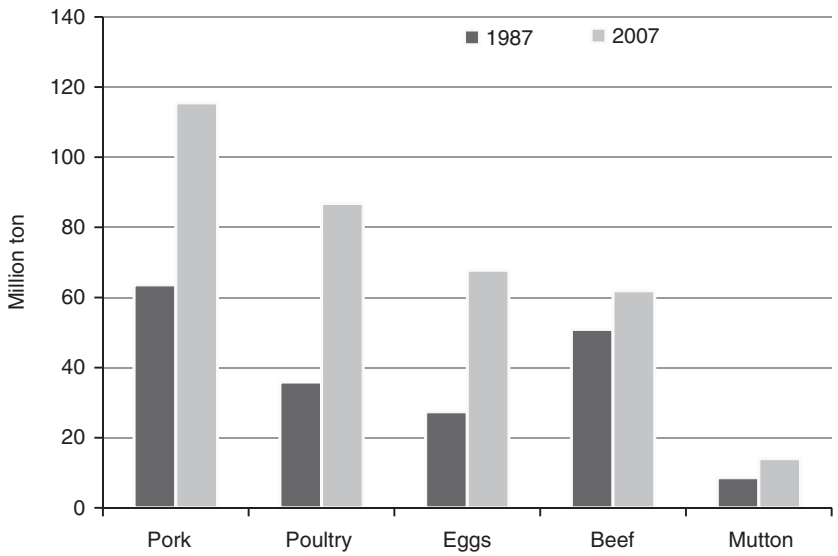

Figure 1 Global production of meat and eggs, 1987 and 2007. Reproduced from FAO, 2009. The state of food and agriculture – Livestock in the balance. Available at: www.fao.org/docrep/012/i0680e/i0680e.pdf (accessed 20.01.14).

 doi:10.1016/B978-0-12-384731-7.00170-7

This article gives a short overview of the most important environmental aspects of livestock production: effects of land occupation and land conversion, interference in nitrogen and phosphorus cycle, emissions of greenhouse gases, and use of chemicals, and it is suggested that solutions must be found in both production and consumption phase of animal products.

Impacts Related to Land Use

The livestock sector today occupies approximately 30% of the global land surface and is thus the largest anthropogenical use of land. Approximately one-third of total arable land is dedicated for feed crop cultivation and in all, livestock production accounts for 70% of all agricultural land on the planet according to 'Livestock's Long Shadow.' The expansion of agriculture over the past 200 years has been dramatic, in 1750, total agricultural land was less than one billion hectare and this has increased almost fivefold in only 200 years. Agricultural expansion has had an enormous impact on habitats, biodiversity, carbon storage, and soil conditions such as erosion and organic matter. Globally agriculture has already converted 70% of grasslands, 50% of savanna, 45% of temperate deciduous forests, and 27% of tropical forests. Expansion of livestock production is a key factor in deforestation, especially in South America where approximately 70% of deforested land is occupied by pastures and feed crops (mainly soybeans) cover a large part of the remainder.

Biodiversity

One of the most direct drivers of biodiversity loss is land use change. Examples of this is conversion of temperate grasslands into arable land, or tropical forests into pastureland resulting in local extinction of most plant species and the associated animals whose habitat is largely determined by the composition of plant species. According to the Millennium Assessment, over the past few hundred years, humans have increased species extinction rates by as much as 1000 times over background rates that was typical in Earth's history. Because future scenarios predict that further 10–20% of grasslands and forestlands are projected to be converted mainly into agriculture by 2050, the impact of livestock's land requirement for feed and fodder production on biodiversity losses must be better understood and dealt with.

Rapidly growing demand for meat is the most important driving force for expansion of soybeans in South America. In Brazil, much of the soybean expansion has taken place in the cerrado biome where more than half of approximately 200 million hectare has been transformed into pasture with monoculture grass species and cropland in the past 35 years. The cerrado biome has the richest flora among the world's savannas and high levels of endemism (species not found elsewhere in the world). Deforestation rates have been higher in the cerrado than in the Amazon rainforest, and conservation efforts have been modest: only 2.2% of its area is under legal protection. Numerous animal and plant species are threatened with extinction.

Effects of livestock on biodiversity in Europe are described in a report from the Joint Research Centre of the EU Commission, investigating greenhouse gas (GHG) emissions and other impacts from European animal agriculture. Agricultural intensification has resulted in homogenization of large areas of European rural landscape. Of special importance to livestock production is farming system specialization (livestock vs. arable) with the loss of mixed farming system, larger farming units leading to removal of noncropped areas and field boundaries. But there are also positive impacts of cattle, the biodiversity in European seminatural grassland is very high and their management is dependent on grazing livestock. Very large proportions of Europe's most threatened bird species, vascular plants, and insects live in these grasslands and other 'high nature value farmland.'

Impacts Related to Nutrient Use

Mismanagement of nutrients in primary livestock production is the major reason for the large negative human interference with the global nitrogen (N) and phosphorus (P) cycles and this is informatively described in research papers of Erisman *et al.* (2008) and Cordell *et al.* (2009). In 2005, more than 100 Mton synthetic fertilizer-N and N in leguminous plants were an input in global agriculture whereas only 17 Mton N was consumed by humans in food. And as for P, it is estimated that less than 20% of the mined phosphate rock aimed for fertilizers ends up as P in humans' food. Important for the low overall use of nutrients in world agriculture is the fact that so much of the biomass produced is used for feeding the livestock. Utilization of N in an animal's feed is normally in the range of 10–35% (with cattle in the lower and poultry in the higher range) meaning that the majority of feed N ends up in manure. This is also the case for P, with utilization rates between 15% and 40%, varying for livestock categories and feeding systems.

Nitrogen

The yearly anthropogenical nitrogen input in the biosphere is estimated at approximately 140 Mton N of which ~85 Mton is industrial fertilizer production, ~33 Mton biologically fixed in leguminous crops, and ~21 Mton produced in combustion processes and emitted as nitrogen oxides. This nitrogen input is in the form of reactive N as opposed to the major constituent of the atmosphere, inert N_2. Consequently, each year, approximately 120 Mton reactive N enters agricultural production. The recently published book 'The European Nitrogen Assessment' provides the most comprehensive analysis of the nitrogen problem in agriculture and society.

Ammonia (NH_3) from livestock manure is a major pathway of losses of reactive N from agriculture. Globally, total nitrogen excreted in manure is estimated at approximately 112 Mton N (range 93–132 Mton) per year, thus amounting to the same magnitude as the input of new reactive N in agriculture. Ammonia losses provide approximately 20% of excreta-N in average, and there are great potentials for better use of manure in global agriculture, thus reducing emissions

and lowering input of synthetic N-fertilizer, which are based on fossil fuels in production.

Yearly losses of N in leaching and erosion from agricultural land are estimated at approximately 40 Mton N globally. The indicator 'Nitrogen loading indicator' is used for assessing watershed nutrient loads and shows that in Europe, water pollution from nitrogen is mainly the result of livestock production and fertilizer use. In India and southern parts of South America, livestock production is the dominant contributor whereas in North America and China, synthetic fertilizers dominate the total N load. However, when applying a life cycle-perspective on these findings, a considerable share of N-fertilizers is used in the cultivation of feed crops (e.g., 60% of European grains are used for feed) and leaching from the fertilizer use in these crops production is a result of demands in the livestock sector.

Emissions of the GHG nitrous oxide (N_2O) also represent a loss of reactive N from agriculture, but in absolute numbers, this is much lower than those of ammonia and nitrate. This is further discussed under in Section GHG Emissions and Global Warming.

Phosphorus

Mined phosphate deposits are mainly used in food production; as fertilizers (80%) and mineral feed (5%), whereas the remainder goes to industrial uses, mostly detergents. With current use it is estimated that today's economically exploitable resource will be depleted within 125 years and total reserves (the 'reserve base') within 340 years.

In the early 2000, global fertilizer use was roughly 15 Mton P per year in agriculture and approximately the same amount is produced in livestock manure annually of which approximately half is returned to agriculture and the rest is lost via land-fills, nonarable soils, and waters according to Cordell *et al.* (2009). Phosphorus in human excreta makes up approximately 3 Mton P per year and of this, only approximately 10% is returned to agriculture. It is obvious that livestock manure and human excreta must be better recycled to be used in agriculture to reduce the continuously growing use of fertilizer phosphorus.

When cereals are used as feed, there are large P flows from the fertilized croplands to animal manure at livestock production units. Besides this P-flow, there are also substantial P fluxes in byproducts from cereals and pulses used in concentrates, via food and feed industry and finally ending up in manure. For example, after milling wheat, the majority of P in the grain ends up in the byproduct wheat bran whereas the flour for human consumption has a low P content. After extraction of soybeans and rapeseed, most of the crops' uptake of P is destined for the feed coproduct meal/cake and the vegetable oil produced only holds a small amount of P. Production of especially pork and poultry animals leads to large P flows from mined fertilizer phosphates to crop production (grain and soybeans), via feed and food industry to feed concentrates.

Eutrophication and Acidification

Aquatic eutrophication means nutrient enrichment mainly from N and P of the aquatic environment. Excess input of nutrients increases the primary production of fast-growing algae and plants adapted to low-nutrient conditions decreases. Also in the fish community there are shifts due to changes in the habitats. Under severe conditions, nutrient enrichment of coastal stratified waters (having sharp temperature gradients preventing mixing surface and bottom waters) can cause anaerobic or nonoxygen conditions and result in significant bottom fauna mortality and fish mortality.

Terrestrial eutrophication is mostly an effect of excess input of N, as vegetation in natural ecosystems is mainly controlled by the limited availability of this nutrient. Atmospheric N deposition from human activities (most important NH_3 from manure and NO_x from traffic) leads to increased loads of N and, from this, follows changes in structures and functions in N-limited ecosystems. As explained earlier in the Section Nitrogen, NH_3 volatilization from manure represents a significant N loss from agriculture and of total N excreted by the livestock, as much as 20–40% can be lost as NH_3, depending on farming system, feeding routines, application methods, etc. Ammonia can also be an acidifying pollutant because it has a strong acidifying effect as a result of soil nitrification involving the conversion of ammonium into nitrate by microorganisms. Depending on the state of the ecosystem where the ammonia is deposited, the acidifying impact varies. Up to a certain level, a natural ecosystem can absorb deposited N, but above that level, excess nitrogen is leached and thus, the soil is 'N-saturated.' In forests saturated with N, nitrification and leaching of base cations and nitrate are usually the most important mechanisms behind soil acidification. There is a close interaction between terrestrial eutrophication and acidification.

GHG Emissions and Global Warming

Unlike industrial and transport systems, carbon dioxide (CO_2) from fossil fuel use is the least important GHG emitted from the animal sector. Instead, it is emissions of methane (CH_4) and nitrous oxide (N_2O) that contribute mostly to livestock products' GHG emissions. Also CO_2 emissions due to land use and land use change (LULUC), most important from deforestation, are important sources of greenhouse gases, see Figure 2. The global warming potential (GWP) for different greenhouse gases is normally calculated for a 100-year time horizon in kilogram carbon dioxide equivalents (kg CO_2e): CO_2 1, CH_4 25, and N_2O 298. FAO has estimated that global livestock production make up approximately 15% of total GHG emissions when land use-related CO_2 emissions also are included.

Methane

As seen in Figure 2, enteric fermentation is the most important source of CH_4 emissions from livestock production. CH_4 is also emitted from slurry storages and in a warm climate, this source can be substantial. Methane is approximately 25 times more effective in trapping heat in the Earth's atmosphere than CO_2 and its atmospheric concentration has increased from approximately 715 ppb preindustrial to 1774 ppb in 2005, i.e., by close to 150%. According to 'Livestock's Long Shadow,'

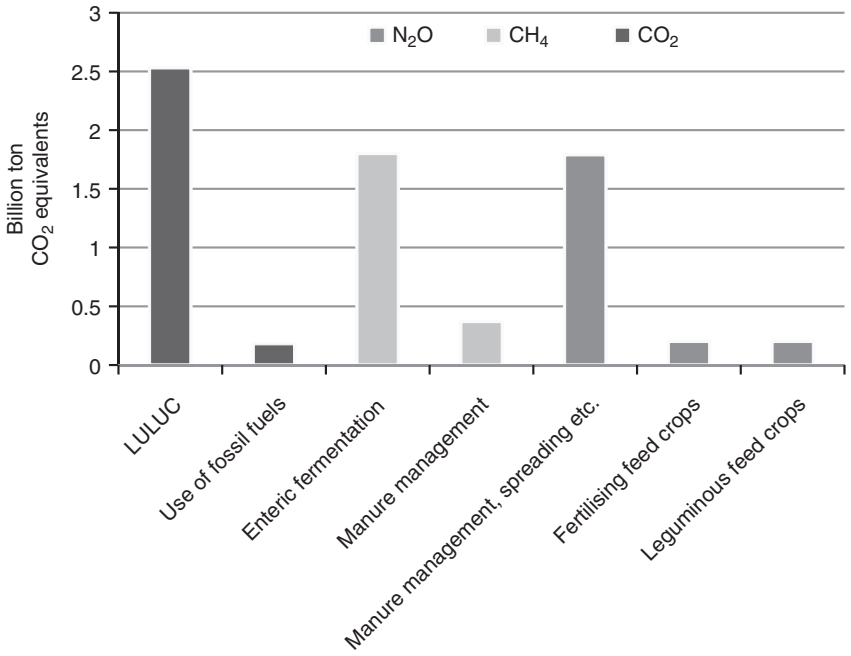

Figure 2 Emissions of greenhouse gases (CO_2, CH_4, and N_2O) from the global livestock sector. Reproduced from FAO, 2006a. Livestock's long shadow – Environmental issues and options. Available at: www.fao.org/docrep/010/a0701e/a0701e00.HTM (accessed 20.01.14).

global emissions from enteric fermentation and manure management in 2004 were 85.63 and 17.52 Mton CH_4, respectively. This corresponds to approximately 2.58 billion ton CO_2 representing approximately 5.3% of total global GHG emissions in 2004.

Nitrous Oxide

Emissions of the GHG nitrous oxide (N_2O) also represent a loss of reactive N in agriculture, but in absolute numbers, much lower than the losses of reactive N as ammonia and nitrate. Globally, it is estimated that approximately 2.8 Mton N yr^{-1} (1.7–4.8) is lost as N_2O–N from agriculture, mainly due to denitrification and nitrification processes in the soil and also nitrogen transformations in manure.

Manure storage, manure spreading in fields, and ammonia emissions from manure give rise to substantial N_2O emissions from the global livestock sector (Figure 2). Nitrous oxide is a strong GHG that is present in very low concentrations in the atmosphere. It is approximately 300 times more effective than CO_2 in trapping heat and has a very long atmospheric life-time (>100 years). Preindustrial concentration was approximately 270 ppb N_2O, which has grown to 319 ppb in 2005, i.e., an 18% increase. N_2O emissions have become more important in the second half of the twentieth century as a result of the strong increase in synthetic N fertilizer use in agriculture.

Carbon Dioxide

As seen in Figure 2, emission of fossil CO_2 is of minor importance for the global livestock sector's GHG emissions. But this is not the case for a highly industrialized region, such as the EU27, where the Joint Research Center of the EU Commission estimates that approximately 20% of the European livestock sector's GHG emissions come from the use of fossil fuels in animal production.

CO_2 emissions from land-use change processes are closely connected to expanding agricultural production and land clearance. Carbon emissions from forest clearing constituted approximately one-third of total anthropogenical CO_2 emissions in the period 1850–2005. In the past 50 years, there has been a stabilizing (or even decrease in agricultural land) in many regions but in the tropics, deforestation is still occurring rapidly. During the 1990s, it is estimated that tropical deforestation gave rise to CO_2 emissions in the order of 3.7–8 Gton CO_2 per year, comprising 14–25% of total anthropogenical emissions. Today, land use change, mostly deforestation, accounts for approximately 10% of global CO_2 emissions, and the emission trend has been falling over the past 10 years compared to levels during the 1990s. There are large uncertainties in estimates of GHG emissions from deforestation.

Indicators of a Changing Climate

The Intergovernmental Panel on Climate Change (IPCC) reports about a changing climate: The average global temperature has increased by 0.74 °C during the past 100 years (1906–2005) and during that period, average Arctic temperature has increased almost twice the global average. This global warming has led to a number of observed changes, for example, mountain glaciers and snow cover have declined on average in both hemispheres, global average sea level has risen at an average rate of 1.8 mm per year from 1961 to 2003, long-term trends from 1900 to 2005 have been observed in precipitation amount over many large regions, more intense and

longer droughts have been observed over wider areas since the 1970s, particularly in the tropics and subtropics, and widespread changes in extreme temperatures have been observed over the past 50 years. Cold days, cold nights, and frost have become less frequent, whereas hot days, hot nights, and heat waves have become more frequent.

Chemicals

Pesticides are chemical substances used to kill or control any pests, mainly weeds, insects, and fungus-attacking crops. There are large economic incentives to use pesticides to reduce the occurrence of pests and hence increase the quality and quantity of crop yield. In addition, use of pesticides is less labor-intense than traditional agricultural management practices. The disadvantages are pesticides potentially have toxic effects on humans and ecosystems and there are increasing risks of resistant pests. The impact of pesticides on different organisms varies greatly depending on their toxicity (direct and indirect), persistence, and fate. The use of pesticides and associated changes in management practices may also lead to biodiversity decline.

Extensive use of and reliance on one or only a few pesticides may also result in increased resistance to the pesticide(s) due to natural selection in the targeted weed-, fungi-, insect populations. An immediate example that is related to livestock production is a growing number of weed species that have evolved resistance to the important herbicide glyphosate, mainly occurring in areas where farmers grow feed crops (most importantly soybeans, but also maize) that have been genetically engineered to tolerate glyphosate. Owing to adaptation and natural selection in weed populations, the increased and often exclusive reliance on glyphosate to manage weeds in genetically engineered crop systems have led to that resistance to glyphosate having evolved in some weed species.

Veterinary medicines are another important chemical group used in livestock production and antibiotics are, by far, the most commonly used veterinary medicines and of great significance to modern livestock production, not only to treat diseases but also to promote growth and improve feed efficiency. Not all antibiotics are absorbed by the animal; sometimes 30–90% are excreted in manure. After excretion, the metabolites may still be bioactive and transformed back to the parent substance. The effect of pharmaceuticals on the environment has emerged as a scientific field over the past years.

Also for medicines, resistance is a growing problem. The main concern regarding the widespread use of antibiotics in veterinary medicine is the development of resistant bacterial strains, a health risk to both humans and livestock animals. Of special concern is antibiotic therapy in food-producing animals. Direct contact with animals, and thereby the risk of bacteria spreading via the food chain, enables the selection of bacterial strains resistant to antibiotics used in human therapy.

Conclusion

Livestock production is a key driver of environmental change. Already at present, the global livestock sector is one of the top two or three most significant contributors to some of the most important environmental problems, at every level, from local to global. The FAO prognosis of doubling global animal production to 2050 means the task of cutting the environmental impact per unit of livestock production by 50% to maintain the level of damage at the present level. This presents an enormous challenge to stakeholders in the livestock sector to reduce the sector's environmental impact. It involves improving efficiency in crop and animal production, reducing enteric CH_4 emission, improving manure management and handling, solutions discussed by de Boer *et al.* (2011). In recent years, there have been increasing discussions about the total intake of animal products in high-income countries and the possible need in future for reducing intake of animal products so that food-related emissions will meet future climate targets, this issue is further discussed in papers by Wirsenius *et al.* (2011), Garnett (2011), and Cederberg *et al.* (2012).

EQUIPMENT CLEANING

KJ Allen and S Wang, University of British Columbia, Vancouver, BC, Canada

Glossary

Chemical energy Energy derived from cleaning agents used to disrupt the chemical interactions in a soil–surface interface.
Cleaning agent A chemical used to disrupt and solubilize soils.
Contact time Time allotted for cleaning agent to interact with a soil.
Food contact surface Equipment surface that physically contacts food during production.
Mechanical energy Physical (i.e., kinetic) methods (e.g., scrubbing, pressure sprays, turbulent flow) used to create energy for the disruption of soil–surface interactions.
Planktonic cells Bacterial cells that are suspended in a medium (i.e., not attached to a surface).
Sanitizer Chemical agent used to inactivate microorganisms.
Soil Any substance present in a food production environment that should not be present.
Surface energy The energy associated with a soil–surface interaction that must be overcome for effective soil removal.
Thermal energy Heat energy used to facilitate disruption of soil–surface interactions.

Introduction

The maintenance of a hygienic plant environment is a fundamental requirement for the consistent production of food that is safe, wholesome, and stable during the specified shelf-life. An inability to reliably and effectively clean and subsequently sanitize food production equipment may lead to increased risks of product spoilage and/or contamination by allergens and/or pathogenic microorganisms. Accordingly, appropriate efforts should be made to minimize the presence of soils before, during, and after production of food.

Soil removal is essential before the application of sanitizing chemicals. It is well established that cleaning and sanitizing contribute equally to reductions in numbers of microorganisms on equipment surfaces. For this reason, appropriate cleaning agents and strategies can be selected only with knowledge of the types of soil expected from individual raw materials and from processed food products. Inadequate cleaning may lead to soil accumulation. Biofilms may then form on equipment surfaces, and cause corrosion, reductions in processing efficiency, and problems with finished product quality. When deciding on procedures for control of soils, the benefits from cleaning and sanitation must be weighed against the related costs. Although increases in the number or duration of breaks in production for cleaning and sanitation will enhance soil control (Figure 1), they also result in higher costs for cleaning/sanitation chemicals, water, sewage, energy, and labor (Table 1). Accordingly, to balance cleaning-related costs against production efficiency and control of microbiological contamination, environmental trend analysis of microbiological data may be used to fine-tune production–sanitation cycles.

Soils, Surfaces, and Cleaning

The original definition of a soil was any material or substance that is, but should not be, present on a solid substrate (i.e., surface) of interest. Although this definition recognizes that a soil may be any sort of material (e.g., dirt, dust, grease, food derivatives, etc.), it does not take account of the complex natures of many soils. Subsequent definitions categorize soils on the basis of their solubility in acid, alkali, or water. These definitions are highly relevant to the selection of cleaners that will appropriately interact with and thus solubilize a soil. More recent classifications of soils recognize their essential chemical properties. Thus, soils are characterized as mineral (lime, milk stone, etc.), organic, or microbiological, or composite when a soil is composed of two or more of the simpler soils; but not all soils conform to this classification. Nonconforming soils include dust and debris. Organic soils are further categorized as carbohydrate (CHO), lipid, or protein based, and these subcategories may be further characterized. For example, CHOs may be identified as being water soluble or producing Maillard reaction products following heating. Such information is important as water-insoluble soils and Maillard reaction products are more difficult to remove than water-soluble CHOs. For proteins, it is essential to know the denaturation temperature and the appropriate pH to use for cleaning. Processing or cleaning waters at temperatures above the denaturation temperature or cleaning solutions of inappropriate pH may cause partial or total denaturation of soluble proteins, which consequently become insoluble and difficult to remove from surfaces. In addition, the fluidity and solubility of soil lipids should be considered, that is, whether the lipids are water soluble or insoluble, and whether they are liquid or solid at room temperature. Knowledge of these matters allows realistic considerations of the complex nature of soils, and facilitates appropriate cleaner selection.

Another key factor that affects soil deposition on equipment surfaces is the nature of the surface. It is well established that surfaces that are corroded, have obvious defects, or are porous are more difficult to clean than smooth surfaces, and may have microbial harborage sites in which biofilms can develop. The difficulty with removing soils from such surfaces is a result of the much greater area available for contact with soils than is available on smooth surfaces. Further, while suspension of a soil in water requires the input of energy, soil adherence to surfaces is an energetically favorable process. The more interaction there is between a soil and a surface, the more energy is required to disrupt the interactive forces in order to displace and remove the soil. Cracking and pitting of smooth, impermeable surfaces increases areas for adherence of soil, and therefore equipment with such defects should be avoided.

Interactions between soil and surface are determined by the chemical composition of the surface as well as its roughness. Thus, to maximize cleanability, all surfaces in food production environments should be smooth and made of hygienically acceptable materials (Table 2). Therefore, equipment should be constructed from hygienic grade plastics, rubbers, stainless steel, etc., whereas porous materials, such as wood, should be strictly avoided. The chemical reactivity of the surface has a critical effect on the deposition of soils on both food contact surfaces (FCS) and nonfood contact surfaces (nFCS). Various grades of stainless steel are available in which the contents of chromium, nickel, and other metals alloyed with iron are adjusted to improve corrosion resistance under different conditions of use. These formulations balance cleanability, durability, and resilience to oxidizing compounds routinely used in sanitation programs. Importantly, sanitation crews should report any corrosion, pitting, or damage to equipment to allow the matter to be corrected before product safety or quality is compromised.

Surface Energy

To effectively remove a soil, the surface energy (SE), i.e., the interaction between the soil and the surface, must be overcome. Energy used to overcome the SE may be chemical,

Table 2 Characteristics of hygienically acceptable and unacceptable surfaces observed in food production environments and equipment

Material	*Characteristics*	*Precautions/suggestions*
Wood	Draws moisture and lipids into porous structure; alkalis degrade it	Its use should be avoided due to hygienic and structural concerns
Black metals	Acids and chlorinated compounds will corrode them	Tinning or galvanizing minimizes corrosion. Neutral detergents should be used for cleaning
Tin	May be corroded by strong acid or alkali cleaners	Tin surfaces should be used only for surfaces that do not contact food
Concrete	Etched by acidic foods and cleaning compounds	Acid-resistant, dense concrete should be used in production environments; alternative, use acid brick
Glass	Should be smooth and impervious, but may be etched by strong alkaline cleaners	Mild cleaners should be used for cleaning
Paint	May be etched by strong alkaline cleaners	Nontoxic paints may be used in production environments if issues with peeling are unavoidable
Rubber	Firm, nonporous rubber should be used. Organic solvents and strong acids may degrade it, though it is resistant to alkaline detergents	Rubber cutting boards warp and dull knives
Stainless steel	Smooth, impervious, resistant to corrosion, may oxidize at elevated temperature, nonmagnetic, easy to clean	Expensive. Halogen compounds may corrode stainless steel

mechanical (i.e., kinetic), or thermal, or a combination of these. Cleaning chemicals provide chemical energy to break apart and disperse soils, and keep removed soils suspended in solution so that rinsing is effective for carrying away the dislodged soil. Mechanical energy may be generated by scrubbing, pressure sprays, or turbulent flow in pipes, vessels, etc. that are cleaned using a clean-in-place (CIP) system. One of the most effective yet commonly overlooked means of overcoming SE is scrubbing. Thermal energy enhances most chemical and physical methods of reducing soil–surface interactions. For example, heated cleaning water increases the efficacy of chemical cleaners approximately twofold for every increase of 10 °C. This is particularly useful for lipid-based meat soils, as application of heated cleaning solutions that exceed the melting temperature of the fat greatly enhances its removal. However, if soils include proteinacious components, care must be taken not to exceed 55 °C because above this temperature protein denaturation may occur with the formation of insoluble residues that are difficult to remove. Moreover, at temperatures >50 °C, sublimation of iodine-based sanitizers may occur, reducing the antimicrobial activity of the sanitizer.

In addition, time is a key factor for the effectiveness of a cleaning program. In general, the longer cleaning-related chemicals remain in contact with soils, the more successful the soil removal process will be. Conversely, if the contact time between soil and cleaning compounds is not sufficient, stubborn soils may persist on equipment surfaces. Costs linked to chemical, mechanical, and thermal energy inputs may be reduced by prolonging the contact time between cleaning agent and the soiled surface; and combining chemical, mechanical, and/or thermal energy inputs in a cleaning regime will reduce the respective energy input required from each energy source. That is, less detergent will be required if the cleaning water is heated and the surface is scrubbed. However, if cleaning efficacy is enhanced by increased scrubbing or the use of higher concentrations of detergent, the cost of labor, or cleaning agent will increase. Suggested combinations of energy input are detailed in Figure 2. Overall, smaller items such as utensils, pails, and molds require a high input of mechanical energy, with soil removal being improved with soaking in a solution of chemical cleaner before scrubbing. Disassembled equipment that can be transported to soaking tanks should be treated in a similar manner. In contrast, for larger equipment, manual and thermal energy inputs are often necessarily limited, resulting in increased reliance on chemical and thermal energy. However, reduced concentrations of chemical cleaners and lower water temperature may then have to be used to minimize risks to workers engaged in cleaning. In such circumstances, increased cleaning agent contact time may be used to aid in soil removal.

The quality of water used for cleaning is also important. Hard water with high concentrations of calcium and magnesium salts, sulfates, and bicarbonates reduces the activities of some cleaning and sanitizing agents. Therefore, it is advisable to soften cleaning water with chelating agents or sequesterants. In addition, softening of cleaning water will minimize the deposition of stubborn mineral deposits on equipment surfaces. Obviously, potable water must be used for cleaning all food production equipment and facilities.

Composition of Soils

The composition of soils deposited during the production of food will reflect the raw materials used, the end product, and the processing technology or technologies employed. In addition, microorganisms present in or on raw materials or in the production environment may contaminate surfaces of equipment and, ultimately, the food being produced. In the production of raw and processed meat products, predominant soils consist of lipid and proteinacious components. These soils often accumulate to high levels during long production runs, thereby limiting the effectiveness of CIP cleaning and

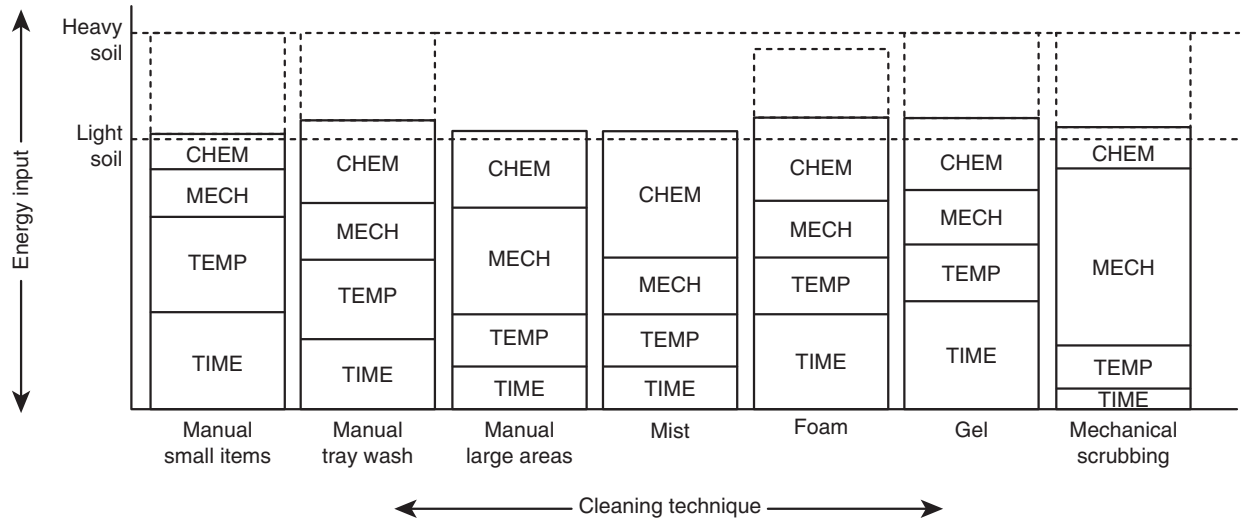

Figure 2 Suggested combinations of energy input for the removal of light and heavy soils. Adapted with permission from Holah, J.T., 2003. Cleaning and disinfection. Table 3 Soil solubility characteristics and suggested cleaning agent properties

Nature of soil	*Solubility characteristics*	*Recommend cleaning agent*
Carbohydrates, organic acids, salts	Water soluble	Mild alkaline detergent
Proteinacious (e.g., fish, meat, poultry)	Alkali soluble, slightly acid soluble, water soluble	Chlorinated alkaline detergent
Starch-rich (e.g., fruits, tomatoes)	Alkali soluble, partially water soluble	Mild alkaline detergent
Lipid-rich (e.g., adipose, butter, oils, etc.)	Alkali soluble, water insoluble	Mild-to-strongly alkaline detergents
Inorganic soils (e.g., hard water deposits, milk stone)	Acid soluble, alkaline insoluble, water insoluble	Acid cleaners

sanitation strategies. Solubility characteristics of soils and the type of cleaning agents recommended for use with each type of soil are shown in Table 3.

Soil Removal

Strategies for effective cleaning are specific to each food production facility. However, a general step-wise strategy for effective soil removal in most production and processing facilities is as follows: (1) gross soil should be physically removed before moving any equipment, and then utensils and movable equipment should be disassembled and moved to a location suitable for cleaning activities; (2) gross soils along the production line and throughout the production environment should be removed, with larger soils being picked up to prevent the unnecessary spreading of soils; (3) because lipid- and protein-rich soils can be expected in meat production facilities, equipment should be subjected to an initial rinsing with hot water at temperatures $<55\,^{\circ}C$; (4) remaining soil should be disrupted using chemical, mechanical, and thermal energy, while adhering to the concentrations and contact times recommended for each cleaning agent; and (5) equipment should be rinsed with preferably pressurized hot water at $<55\,^{\circ}C$ to facilitate dispersion of soils from equipment surfaces being cleaned.

Following soil removal and sanitation, potable water should be used to remove cleaning and sanitizing agent residues from equipment surfaces. Although levels of microorganisms should be greatly reduced by cleaning, microorganisms may still be present on surfaces and/or in hard-to-clean areas. As such, after rinsing it is important to remove excess water from FCS and nFCS throughout the production environment. Moisture facilitates the survival and proliferation of microorganisms. Therefore, after cleaning, equipment and the processing facility should be dried as much as is practicable.

It should be noted that the cleaning process itself may serve to disperse soils in undesirable ways. If cleaning agents are not effective in keeping soils suspended, re-deposition of soils on equipment may occur, at their original sites or elsewhere. In addition, the use of pressure sprayers to remove large accumulations of soil will lead to increased soil deposition throughout the production environment. Both high-pressure/low-volume and low-pressure/high-volume sprayers generate aerosols, which have been shown to redistribute bacteria and soils within a production area. Accordingly, it may be necessary to limit the use of pressure sprayers in areas where risks of microbiological contamination of product are high.

Hygienic Design of Equipment and Facility

The persistence of bacterial pathogens in food processing environments poses major risks of processing and/or post-processing contamination of product. Equipment that is not hygienically designed or is improperly installed or maintained will compromise the efficacy of a cleaning and sanitation program by introducing harborage sites in which pathogens will be protected from sanitizing treatments. For example, if meat slicers are not designed to permit easy and quick disassembly, routine cleaning may not be carried out effectively. Accordingly, slicers have been identified as the sources of product contamination in several listeriosis outbreaks linked to ready-to-eat meats. Similarly, equipment used in facilities for breaking beef carcasses have been shown to present major sanitation challenges. Therefore, hygienic design of the food processing equipment and premises is a critical prerequisite for effective cleaning and sanitation.

Standards for sanitary fabrication, construction, and design of food processing equipment have been developed by a variety of standards organizations, such as 3-A Sanitary Standards, Inc., the National Sanitation Foundation, and the European Hygienic Energy & Design Group. Although there are some differences among these standards, the objective of all is the application of sound sanitary principles in the design and manufacture of food processing equipment. The general requirements for hygienic meat processing equipment are:

1. Equipment should be made of compatible materials. Materials used for construction of food processing equipment shall be completely compatible with the product, the processing environment, and cleaning and sanitizing procedures. To ensure durability, materials should be corrosion and abrasion resistant and, where applicable, capable of being shaped.
2. Self-draining. All pipelines and equipment should be self-draining. Residual liquids in or on equipment harbor and promote microbial growth or, in the case of cleaning fluids, result in chemical contamination of product or corrosion of equipment surfaces (Figure 3).
3. No dead spaces and niches. Hollow areas should be hermetically sealed and introduction of dead spaces during installation should be avoided. Equipment parts should be free of pits, cracks, corrosion, and other visible defects (Figure 4).
4. Accessible for inspection, maintenance, cleaning, and sanitation. Equipment should be designed so that all product contact surfaces can attain the required sanitized or sterilized condition. Equipment with obvious defects should be replaced.

5. No microbial ingress. Where appropriate (e.g., aseptic processes), equipment should be designed to prevent microorganisms migrating from the external environment onto product contact surfaces, either directly or via soils.
6. Hygienic design of maintenance enclosures. Maintenance enclosures and human–machine interfaces, such as push buttons, valve handles, and panels, should be designed so that they prevent the entry and/or accumulation of soils. Enclosure surfaces should be sloped to an outside edge to avoid them being used for storage (Figure 5).
7. Validated cleaning and sanitizing protocols. Procedures for cleaning and sanitation should be clearly described and proven effective. Care should be taken to ensure that chemicals recommended for cleaning and sanitation are compatible with the equipment and manufacturing environment.

In general, if care is not taken to ensure the hygienic design of the processing facility and equipment, effective cleaning will be severely compromised because of microbial harborage sites and biofilm development.

Cleaning Compounds

The primary function required of a cleaning compound is to disrupt soil–surface physicochemical interaction. Major considerations in cleaning compound selection are: (1) the physicochemical characteristics of the soil to be cleaned; (2) the chemical characteristics of the cleaning agent(s); (3) the application method; and (4) the surface area and

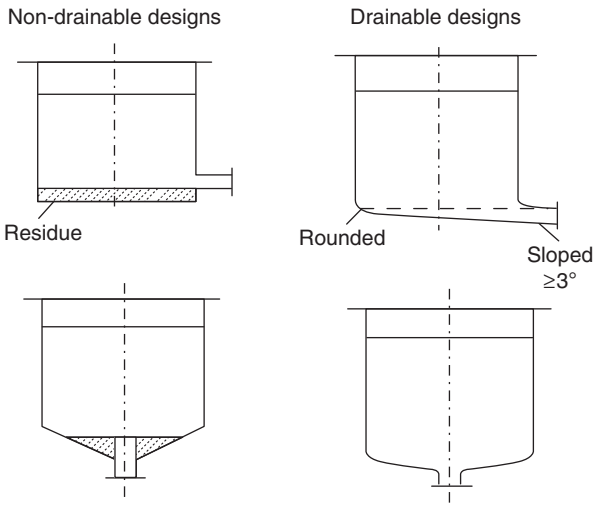

Figure 3 Examples of acceptable vs. unacceptable self-drainage design for tanks and vessels. Adapted from EHEDG, 1995. Hygienic design of equipment for open processing. Trends in Food Science and Technology 6 (9), 305–310.

design of the equipment to be cleaned. Generally, meat soils comprise lipids and proteins. To effectively remove these, alkaline cleaners with a pH of 11 or higher are commonly used. Specific types of cleaning compounds used for meat soil removal are:

1. Strong alkaline cleaners. These are used to saponify fats and remove heavy meat soils on metal surfaces, such as those found in smokehouses, boiling tanks, soak tanks, rail trolleys, and hooks. These agents pose serious risks of chemical injury to workers and may corrode surfaces and darken aluminum equipment. Components of strong alkaline cleaners include caustic soda and silicates having high N_2O:SiO_2 ratios. The addition of silicates to caustic soda, however, reduces corrosiveness and improves soil penetration and rinsing properties.
2. Heavy-duty alkaline cleaners. The active ingredients of these cleaners may be sodium metasilicate, sodium hexametaphosphate, sodium pyrophosphate, or trisodium phosphate. Although these generally do not corrode aluminum, the addition of sulfites may be necessary to reduce corrosion of tin alloys. These agents are frequently used for CIP, and for cleaning high-pressure rinsing equipment and mechanized equipment found in meat and poultry plants. They can, however, corrode metal parts and may cause eye damage and irritation of the skin and respiratory tract.
3. Mild alkaline cleaners. Mild alkaline cleaners commonly contain sodium bicarbonate. Liquid mild cleaners are frequently used for hand cleaning lightly soiled areas in meat processing plants, and are compatible with most surfaces. In the meat industry, they are used as general-purpose cleaners for hide washing equipment, floors, walls, and equipments made of rubber or plastic.

Although increased chemical energy may be applied by increasing cleaning agent concentrations, concentrations exceeding manufacturer recommendations may result in denaturation of proteins, thereby reducing cleaning effectiveness.

Biofilms

Biofilms form on surfaces. They are complex communities of microorganisms that are embedded in a matrix of polysaccharide materials secreted by the microbes themselves. Biofilms can form on any surface that is exposed to nonsterile water or other liquids, including but not limited to walls, floors, drains, process lines, pipes, and surfaces on/in refrigeration and air handling units. When bacteria colonize a surface, the cells secrete extracellular polysaccharide, proliferate, and eventually form a mature biofilm. Biofilms may not be effectively removed by cleaning agents because the bacteria within them are more resistant to heat and sanitizers than their planktonic forms. Biofilms may also enhance the corrosion of stainless steel, and bacteria from biofilms are continuously sloughed off into the foods and/or food processing environment. Biofilm formation is of particular concern with equipment that is difficult to clean, such as slicers and equipment requiring disassembly for cleaning. With such equipment, cleaning agents may not be effectively delivered to all parts of the equipment, leading to ineffective soil removal. Persistent soils will provide substrates for microbial growth and biofilm development, potentially leading to quality and/or safety issues. For example, two US listeriosis outbreaks 12 years apart were linked to a single turkey meat producer. The causative strains in both outbreaks were shown to be identical by molecular typing, and had been recovered from the food production facility in between the outbreaks. Biofilm formation throughout a food production facility should be closely controlled by preventing the establishment of harborage sites.

Biofilms may also impact operating efficiency. Accumulation of biofilms on processing equipment may reduce processing-related heat transfer, promote corrosion, or foul filters.

At this time, there are no specific procedures for the removal and disinfection of biofilms from equipment surfaces. As bacteria within biofilms may be up to 1000 times more resistant to biocides than planktonic organisms, biofilm removal cannot be achieved by increasing sanitizer concentration alone. Rather, combinations of chemical and mechanical energy must be used to improve the delivery and efficacy of cleaning and sanitizing agents. The use of cleaners and sanitizers in combination may enhance removal of biofilms. A suitable combination of cleaner and sanitizer can dissolve the biofilm and the organic material to which it adheres, allowing the sanitizer to inactivate the released cells. Current information also suggests that the application of heat with chemical sanitizers can be more effective against biofilms than chemical sanitizers alone. However, the application of heat may lengthen sanitation time, incur higher energy costs, negatively impact parts of equipment such as seals and gaskets, and increase risks to workers.

Difficulties associated with biofilms may be increased by the increasing duration of production runs. To optimize production efficiency, production runs in the food industry generally are becoming longer, with minimal down-time for sanitation. Although the use of hygienic equipment, inspection/maintenance, and the appropriate use of cleaning and sanitation chemicals may efficiently control microbiological contamination when run times are not extended, longer production runs inevitably lead to increased soil deposition and longer periods before any biofilms are disturbed. This may contribute to increased opportunity for biofilm formation and issues with maintenance of a hygienic production environment. Novel measures for control of biofilms are being sought. These include the use of enzyme-based detergents that may degrade biofilms, bacteriophages that can infect biofilm cells, and bacterial metabolites that affect the activities of cells in biofilms. These methods would be highly specific, nontoxic, and usable in-process, and thus could be feasible approaches for controlling microorganisms commonly found in food plant biofilms. However, they have as yet not been successfully applied in the food industry.

Assessing the Effectiveness of a Cleaning Program

Evaluation of the efficacy of cleaning should be carried out before sanitation. The methods available for rapid assessment of cleaning efficacy include: visual inspection of the equipment and environment; adenosine triphosphate (ATP) bioluminescence monitoring to detect the presence of ATP from

eukaryotic (i.e., meat tissues) and prokaryotic cells; and protein indicator strips to detect protein-based soils remaining on equipment. Failure to meet the standard specified for a test of cleaning should result in repetition of the equipment cleaning protocol.

Summary

Effective cleaning of equipment used in the processing and production of meat and meat-based products is an ongoing challenge. Raw materials and processed meat products contaminate equipment surfaces with soils rich in fats and proteins, which are difficult to remove. A thorough understanding of expected soil chemical properties is required to select appropriate cleaning agents, most of which are alkaline based. Combinations of chemical, thermal, and mechanical energy inputs should be used to maximize the removal of stubborn soils while minimizing costs of energy, labor, and cleaning agents. If food production equipment is not hygienically designed and properly maintained, or is made of inappropriate materials, the cleanability of equipment surfaces is diminished. Under such circumstances, microbial harborage sites develop in which organic substrate and resident microorganisms accumulate, resulting in biofilm development. The goal of a cleaning program should be to minimize opportunities for biofilms to form. If equipment cleaning is effectively executed, issues with premature spoilage, allergens, and/or pathogens in end products will be minimized.

Biltong: A Major South African Ethnic Meat Product

PE Strydom and B Zondagh, Animal Production Institute, Irene, South Africa

Glossary

Enterotoxin (not to be confused with endotoxin) A protein toxin released by a microorganism that targets the intestines.

Gamma radiation It is also known as gamma rays, denoted by the Greek letter γ that refers to electromagnetic radiation of high frequency and therefore high energy per photon.

Humectant A substance that absorbs or helps another substance to retain the moisture.

Osmophiles Microorganisms adapted to environments with high osmotic pressures, such as high sugar concentrations.

Water activity It is a measure of the availability of free water, and its value is governed by the degree to which ionic or other more weakly charged substances bind water.

Introduction

Biltong is a traditional South African meat snack consisting of strips of salted, flavored, and dried lean meat. The word 'biltong' is derived from the Dutch words 'bil', which means round or buttock, and 'tong' (or tongue), which describes the long strips of meat. For centuries, mankind has endeavored to preserve meat. Salting and drying of raw meat was a practice born of necessity by many of the forbearers who did not have any other facilities or methods with which to preserve meat. Through innovative upmarketing and subjection to modern processing and packaging technology, biltong has evolved from a food security type of commodity food to a market-driven premium snack.

The Traditional Method of Making Biltong

Biltong has probably been made since the 1650s when Jan van Riebeeck hosted a halfway house at the southern point of Africa. Later, biltong became a staple protein source of the pioneers on their expeditions into Southern Africa (1700–1800). During the Second Anglo-Boer War (1899–1903), Boer soldiers relied on biltong as a protein source when fresh meat from game and cattle became scarce. In earlier days, the whole carcass was used to cut biltong, but in modern times mostly muscles low in connective tissue from the round (buttock) and sometimes from the loin and tenderloin are used. In the mother tongue, biltong cut from the eye of the round (m. semitendinosus) is called 'predikantsbiltong' (Dutch for church minister's biltong), that from the fillet (m. psoas), 'ouma se biltong' (Dutch for grandma's biltong), and any cuts with high levels of connective tissue, are called 'vrinnebiltong' (Dutch for friend's biltong).

Meat from relatively young and lean carcasses is preferred for making biltong, as fat does not preserve well and becomes rancid, whereas meat from old animals will produce tough, sinewy biltong. The meat is processed by first removing all excessive connective tissue and trimming excessive fat if necessary. Depending on the muscle type and drying conditions,

the meat is usually processed into long strips varying between 25 and 100 mm in width. Coarse salt, in the proportion of 2–3%, is added by sprinkling the thin pieces and hand rubbing the thicker ones. Other spices, such as pepper and freshly roasted ground coriander, and ingredients such as brown sugar are often included as part of the traditional recipe. Sugar added at low levels prevents the hardening effect of salt without sweetening the final product (humectant function). Vinegar is sometimes sprinkled over the meat strips before they are packed in a container and left to pickle for 12–24 h. Brown or balsamic vinegar or wine or apple cider vinegar may be used. Excess salt is then removed by washing the pickled meat strips with a weak solution of warm vinegar water. This also helps to preserve the meat during the initial drying by delaying microbial growth. The salted meat strips are hung on small wire hooks on a piece of wire or a rod in the shade in a cool draughty place away from flies and dust. In humid environments, thinner strips are cut to prevent mold formation and spoilage. In addition, bicarbonate of soda is sometimes used to prevent spoilage, whereas saltpeter (a nitrate) is often added to bring out a red color in the final product through curing.

Biltong can be consumed after it has lost 50% of its weight, but in the absence of chilling or freezing facilities, further drying is advised for prolonged preservation. At 50% weight loss, beef biltong is at its best with a dry brown layer on the outside and soft, moist red tissue underneath. Meat from different game species is also very popular for making biltong, but owing to its peculiar taste, it is preferred when thoroughly dried ($>60\%$ weight loss).

Preservation, Storage, and Shelf Life of Biltong as an Intermediate Moisture Food

According to definition, biltong can be described as an intermediate moisture food (IMF). An IMF is characterized by a moisture content of approximately 15–50% and a water activity (a_w) between 0.6 and 0.85, which is less than what is normally present in natural fruits, vegetables, or meats but more than what is left in conventionally dehydrated products. In addition, IMF contains sufficient dissolved solutes to decrease water activity below that required to support microbial growth. As a consequence, IMF does not require refrigeration to prevent microbial deterioration.

There are two factors of major importance to produce microbiologically stable and safe biltong, namely, the salt and moisture contents. These factors can actually be related to one another through the concept of water activity, or a_w. The a_w of microbiologically stable biltong should be less than 0.70, with pH 5.5. However, a wide variation in a_w is encountered, because specific standards for processing of biltong do not exist. The a_w of commercial biltong varies from 0.30 to 0.92 (average 0.74). Bacterial growth usually ceases at an a_w of <0.75, where some yeasts and fungi continue to grow at levels as low as 0.62. A survey of the mycoflora of biltong indicated that moulds of the *Aspergillus glaucus* group were most frequently implicated in biltong spoilage. Although these osmophiles, which are capable of growth at low water activities, are not noted mycotoxin producers, their growth on biltong is nevertheless undesirable and results in economic losses. Studies indicated that yeasts are the predominant component of the mycoflora of biltong. In addition, the risk of pathogenic contamination, *Staphylococcus aureus* and *Listeria monocytogenes* in particular, is also high because many consumers prefer biltong with moisture content higher than 40% ($a_w > 0.85$). These conditions could favor the growth of these pathogens and the production of enterotoxins because both are tolerant of salt and reduced a_w. Reasons for contamination are (1) Raw meat from abattoirs that may be significantly contaminated, (2) lack of proper hygiene practices by manufacturers, and (3) the frequent selling of an unpacked product together with raw meat in butcheries. In commercial biltong production, proper hygiene practices are, therefore, essential. Proper drying of products, if accepted by the consumer, will decrease initially high counts of microorganisms to levels acceptable for most food safety regulations. Alternative interventions include the use of gamma irradiation, and low levels of irradiation (≤ 4 kGy) even showed improved flavor development of moist biltong, which could normally have a bland taste.

Commercialization of Biltong

Over time, biltong developed from a basic, staple, preserved food of pioneers and provisions of soldiers to a traditional food kept by farmers slaughtering their own cattle in the time before urbanization increased. Even during the earlier days of urbanization, biltong was a commodity mostly preserved by the local butcher, but today, it is increasingly becoming a branded delicacy that is grabbing more space on snack shelves. Biltong is still produced on the small scale for commercial purposes as well as for private use because of the fairly low entry costs in terms of facilities. However, it is believed that large-scale operations are more likely to survive price fluctuations of the required raw material (fresh, high-quality meat). More importantly, consumers are becoming ever more concerned about the quality and consistency of what is now becoming a luxury snack. Small-scale operations cannot offer the required quality standards or the required marketing and distribution backup. Furthermore, export opportunities are growing but are impossible to exploit without an EU and hazard analysis and critical control points (HACCP) certified factory.

Although small-scale and domestic operators are using more modern procedures such as artificial drying methods in cabinets and tunnels, larger operations operate in factories with wet and dry restricted areas (adoption of HACCP and ISO 9001), sophisticated portioning and cutting machinery, drying rooms (four day turnover), and packaging and labeling machines. Today, interesting variations on the basic product offer the consumer a range of choices from the traditional biltong to spicy 'snapstix' (very dry and thin meat strips) to paper-thin tearing biltong ('wafers' or 'leaves'). In addition, the basic flavor ingredients are complemented by hints of cloves, ginger, mace, garlic, chili powder, allspice, aniseed, and/or herbs such as thyme. Pineapple juice could be included in the manufacturing process to improve tenderness. Modern packaging methods, such as nitrogen flushing or vacuum packaging, ensure an extended shelf life, and the snack image is further promoted by offering different pack sizes from as small as

50 g. Long, thin perforated plastic packets allow moisture to evaporate before and after it is sold, but molds can still develop on the surface if the biltong is too moist.

Apart from product development strategies, innovative marketing by larger producers also adds to biltong's commercial success. One such strategy has been to use television to capitalize on biltong's strong links with sport, especially rugby, in South Africa. Brand names such as 'Halftime' are used in this regard.

From a traditional meat product born out of the need for food preservation, biltong has progressed through a production-driven commodity food to a market-driven and branded premium snack.

Glossary

Dried meat A method of meat preservation which can be achieved through dehydration of fresh meat. It is one of the most ancient methods of extension of shelf life used in meat. The process can be carried out with a very low level of investment (using only solar energy), or may be performed in a more mechanised environment, with various processing steps during the manufacturing process.

Lamini group A group of mammals, which include the four species (alpaca, vicuña, guanaco, and llama) of South American camelids.

Salting A preservation process that considers the use of salt, followed by a long period of drying.

Sausage Product usually made from minced and/or ground meat from different food producing animals. In the traditional sausage production system, after processing, meat is stuffed in tripe, hence the typical cylindrical form of sausages. However, nowadays sausage casing can be done in natural or synthetic products (edible or not). Sausages may be preserved, amongst other methods by curing, drying, smoking, etc.; but they can also be fresh, hence needing cooking before consumption.

Water activity (a_w) Availability of water, defined as the ratio of the equilibrium of vapor pressure of water over the system and the vapor pressure of pure water at the same temperature.

Introduction

Though the South American countries have many cultural similarities, they also have many differences between them. These differences are reflected in the variability of their meat products.

Before the arrival of the Spanish, in 1492, the population in the Americas relied on their autochthonous fauna as a meat source, among these the most relevant were alpaca (*Lama pacos*), capybara (*Hydrochoerus hydrochaeris*), guanaco (*Lama guanicoe*), llama (*Lama glama*), nutria (*Myocastor coypus*), collared peccary (*Tayassu tajacu*), greater rhea (*Rhea americana*), lesser rhea (*Rhea pennata*), yacare (*Caiman crocodilus yacare*), tegu lizard (*Tupinambis merianae*), and green iguana (*Iguana iguana*).

After the arrival of the conquistador European, domestic livestock were gradually introduced, these breeds are the ones that currently dominate the local market, and make South America the largest meat producer in the world.

As well as the introduction of new domestic animals for human consumption, several meat products were brought from Spain, Italy, and Portugal. The production of these meat products, in some cases, was modified from the European original version to adapt the product to the local taste, climate, and availability of raw ingredients.

Regional Products

Dried Meats

There has long been a requirement to preserve meat products in a way that allows their consumption at a later time. The most common, and oldest methods, to extend the shelf life of meat products are salting and drying, which by reducing the water activity (a_w) of the product can help to extend shelf life and control the development of pathogenic microorganisms.

To obtain a more homogenous effect, the treated meat is normally cut into small pieces. Though traditionally the meat used in this process has been sun-dried in the open, nowadays meat dryers are widely used, allowing a faster, hygienic, and more controlled process.

In South America, as well as all around the word, dried meat products are still used in traditional cooking. Among these products the authors highlight *carne de sol*, *cecina*, and *charqui*.

Carne de Sol

This is a dried meat product consumed in Brazil. It is produced from beef and sometimes from goat meat.

The meat used to produce carne de sol is cut in thin strips, which are salted and then dried by exposing the meat to air-drying in a covered place from 2 to 4 days. Though the direct translation of its name means 'sun meat,' during its processing the meat is never exposed directly to sunlight. Instead, the meat is dried for a short time resulting not only in a hard and salty surface, which works as a protection barrier against microorganisms, but also keeping a juicy and tender inside.

After this process the product can be stored without the need of refrigeration for a long period of time.

Cecina

This product is originally from Spain and it has become popular in Paraguay, Peru, and few other South American countries. It appears that the name is derived from the latin word 'siccus,' which means dry.

It can be produced from beef and also from horse meat. As with other dry meats included in this section, traditionally cecina is salted and dried under the sun. However, this product is not necessarily dried in thin strips as entire meat cuts are used for the process.

 doi:10.1016/B978-0-12-384731-7.00223-3

It is a ready-to-eat food product that does not need further processing.

Charqui

The name of this product comes from the quechua 'ch'arki.' It has been produced in South America from before the arrival of the conquistador and can still be found in all South American countries. Originally, it was elaborated with meat from the native species of the Lamini group (llamas, alpacas, and guanacos) but nowadays, due to the introduction of new species during the colonization period, this product is produced mostly from beef and horse meat (Figure 1).

The meat used for charqui is normally lean and is cut into thin pieces, followed by salting and drying under the sun. It can be consumed directly or as an ingredient in Latin American cuisine, mainly in dishes like soups and stews.

Sausages

Most of the most popular sausages in South America have European roots, not only Spanish and Portuguese but also with a large Italian and German influence. Chorizo, mortadela, salchichón, and salame are only few examples of how European immigrants influenced the development of the charcuterie in South America.

Like many other sausages, the most popular products in South America, linguiça and longaniza, are generally served as part of a heavy meal, typically accompanied by rice, beans or potatoes. Feijoada, for example, is a traditional dish, very common in Brazil, which incorporates linguiça with beans and other foods.

There are many types of meat products in South America with a wide variety of colors, flavors, and textures. These products constitute an important part of the local economy and tradition. Indeed, owing to the economic growth the elaboration has become more mechanized, but the processing is still based on the traditional manufacturing processes.

This section will highlight four food products that stand out for either their penetration in the region and/or for the modifications that have experimented to adapt to local ingredients and taste.

Butifarra

Butifarra is a traditional Spanish product that has become highly popular in the northern part of South America, especially in Colombia.

This cooked fresh sausage is elaborated using beef, but butifarras made of chicken or pork can also be found. In some areas a mix of these three kinds of meats are used in its production.

Lean meat, fat, and spices are mixed and then cased in edible tripe. Whereas the Spanish version of this product has a cylindrical shape, the Colombian one is more spherical. After casing, the butifarras are cooked in boiling water and can be consumed immediately because they do not require a ripening period.

Linguiça

Linguiça is a sausage that has its origin in Portugal and is very popular in Brazilian cuisine.

There are many varieties of this product, so it can be produced from pork or from more than one kind of meat, can be smoked or not, can be cured or not, can be added with fat or produced more lean, and it can be cased in natural or artificial edible casing (Figures 2–4).

Most commonly it is prepared with pork and up to 20% of beef plus the added seasoning.

Linguiças must be stored for a period of time to develop the desired organoleptic characteristic of the product. In case the product is intended to be smoked, the storage time can be in the smoking chamber. After the ripening period, the product must be stored under refrigeration until commercialization.

Longaniza

This meat product is originally from Spain; however, it is highly popular not only in South America, but also in Mexico, the Caribbean, and the southern regions of the USA.

Figure 1 Beef charqui.

Figure 2 Brazilian sausage Linguiça Calabresa. Courtesy of Eduardo A. Norkus (DVM).

Figure 3 Brazilian sausage Linguiça carne frango (with chicken meat). Courtesy of Eduardo A. Norkus (DVM).

Figure 4 Brazilian sausage Linguiça carne mista (pork and beef). Courtesy of Eduardo A. Norkus (DVM).

Longaniza (Figure 5) is a sausage filled with minced pork mixed with fat (usually belly pork) and spices. Normally natural intestine (from pig) is used for casing, but also synthetic collagen is used at times. Synthetic collagen casing is preferred in large companies, because it helps to standardize the product and reduces the risk of biological contamination in the food product.

This sausage is normally long and relatively thin in size. It can be consumed raw if the longaniza has been cured and dried (a process that takes several months), but most commonly this sausage is commercialized as a fresh sausage, hence must be consumed cooked (traditionally fried or in barbecues).

Salchicha de Huacho

This product, also known as salchicha huachana, is typical from Peru. Its elaboration is similar as in longaniza; hence, pork, pork belly, and spices are normally used in the elaboration of this product. After mixing the ingredients, either natural or synthetic edible collagen can be used for casing.

Figure 5 Chillán's longaniza, the most famous Chilean sausage.

Figure 6 Prieta or morcilla, sausage made from pork blood.

A peculiar characteristic of this sausage is its bright yellow color due to the use of annatto in its production. Annatto is a natural colorant used in food production, which is extracted from the South American plant *Bixa orellana*.

Salchicha de Huacho is a fresh sausage and it must be cooked (usually fried) before consumption.

Miscellaneous

Chunchul

Chunchul is not technically a meat product, it is instead elaborated from the small intestine of cattle and its name and variations (Argentina, chunchuli; Chile, chunchules; Colombia, chunchurria; Peru, chinchulin) came from the quechua ch' unchul (intestine). This product varies in its name and preparation across South America, but basically the small intestine of cattle is emptied and washed. The product can be presented as twisted and braided intestines, or similarly as a sausage. It must be cooked before consumption and it is very popular in barbecues.

Prieta or Morcilla

Prieta (Chile) (Figure 6) also known as morcilla (Argentina, Peru) or rellena (Colombia) is a sausage made mostly of the blood from pigs. In some countries blood from cattle and/or goat is also used. It is a food product that was introduced to the region by Spanish settlers.

In addition to the basic ingredient (blood) it can also contain fat, rice, nuts, and spices. The ingredients used will vary according to the country. Once the mix is ready, an edible casing (natural or synthetic) can be used.

It can be consumed hot immediately after cooking, or cold; though the latest is normally blood sausages that have been dried and ripened before consumption.

Glossary

Angkak Red fermented rice powder.
Soy sauce A condiment made from a fermented paste of boiled soybeans, roasted grain, brine, and *Aspergillus oryzae* or *Aspergillus sojae* molds. It originated in China in the second century BCE and spread throughout Asia and today is also used in Western cuisine and prepared foods.

Introduction

Chinese cuisine has become ubiquitous in most countries of the world. This article does not directly cover the various cuisines originating from China or nearby Southeast Asian countries as these are extensive and are more appropriately covered by the websites. Through trade many of the Asian cuisines, such as Indonesian, Malaysian, and Thai, have blended. This article covers the way various meat products are made and used.

There are more than 100 different types of traditional Chinese meat products (TCMPs) in mainland China. Many of these products can also be found in Southeast Asian countries and in metropolitan cities where there is a sizeable ethnic Chinese population. These products can readily be produced in home kitchens as well as in restaurant kitchens. A few of the TCMPs are now manufactured in meat processing plants using the latest meat processing technology and machinery, while maintaining the characteristics of Chinese dietary customs and product formulations; examples include Chinese-style pork sausages (Figures 1 and 2) and Jinhua ham. Many TCMPs are named after cities or geographical regions. For example, Jinhua is a city in Zhejiang province, which is in southeastern China and situated south of the Yangtze River Delta.

As a result of the relatively low water activity (a_w) of these meat products (e.g., the a_w of the different grades of Chinese-style pork sausages ranges from 0.59 to 0.71), a high degree of dehydration (e.g., Jinhua ham has a moisture content of 52% at 40 days postproduction, and 34% when 1-year-old) (Figure 3) and high cooking temperature, TCMPs are generally marketed unrefrigerated. A majority of Chinese dried meat products are in fact intermediate-moisture foods that are stable at ambient temperatures and can be consumed directly from the package.

Product Characteristics

The bulk of TCMPs are made from pork, the most common meat of choice for the majority of the Chinese people. There

Figure 1 Unpackaged Chinese sausage.

 doi:10.1016/B978-0-12-384731-7.00194-X

are also a few TCMPs that are made from beef, mutton, chicken, duck, rabbit, and game meat.

The basic product formulation is a combination of different amounts of salt, sugar (cane sugar and malt sugar are commonly used), soy sauce (either light or dark), Chinese wine (e.g., rice wine and the rose wine *Mei Kuei Lu Chiew*), vinegar, and monosodium glutamate. Also included in the formulation is a variety of spices and seasonings including star anise, cinnamon, clove, fennel, nutmeg, ginger, orange peel, garlic, and green onion (scallions).

A natural food coloring that is used in some TCMPs is red fermented rice powder (*angkak*). This is a product of rice fermented with the fungus *Monascus purpureus*. The addition of a small quantity of this powder, approximately 1.5–3 g per kilogram of sausage meat, results in maximum red color, which is stable and retains the color in the final product. It is an excellent natural substitute for nitrite in meat curing solutions.

Many of the dried or semidried TCMPs have a relatively high salt content of more than 4%. In the case of cured meat, for example, the Nan An pressed-cured ducks (*Ban Ya*), the salt content is as high as 9–10%.

Another characteristic of Chinese dried meat is the sweet taste. For example, dried beef has a sugar content of 15%, and the sugar content of the different grades of Chinese-style pork sausages ranges from 10% to 25%.

Figure 2 Short Cantonese dried sausages.

Figure 4 Siu mei platter including roast pork (bottom), roast goose (top), smoked ham (left), and unroasted white cut chicken and jellyfish (center).

Figure 3 Jinhua ham.

To a very large extent, TCMPs are characterized by regional flavors:

- The northern (Beijing-style) flavor has a long history from the Ming dynasty (AD 1368–1644). The products are characterized by a strong flavor and liberal use of many types of spices. Representative products are roasted mutton, and cooked and seasoned beef and pork.
- The southern (Suzhou-style) flavor is characterized by a rich and heavy flavor tinged with sweetness from a liberal use of wine and sugar. Representative products are roasted meats and dried meats.
- The Cantonese flavor is characterized by a sweet pleasant taste from the liberal use of sugar (Figure 4). The main processing method is drying by hot air or smoke generated from burning charcoal made of special fragrant wood. The products are brightly red colored. The best-known products are roasted suckling pigs and Cantonese-style Chinese sausages (*lap cheong*).
- Sichuan flavor (also Szechuan) cuisine is characterized by spiciness, the result of liberal use of hot chilli, black pepper, sesame oil, ginger, and *huajiao* (also known as Sichuan pepper, *Pericarpium zanthoxyli*).

Table 1

Class	*Subclass*	*Some notable representative products*
Cured products	Salted products[a]	Salted pork legs
		Nanjing salted ducks
	Cured products	*La Rou*[b]
		Sichuan cured rabbit (*Cha Si Tu*)[c]
Braised and seasoned products	*Jiang Rou*[d]	Beijing *Ching Jiang Rou* (beef/pork)
		Wuxi[e] pork ribs braised in soy sauce
		Hangzhou[f] *Jiang Ya* (whole duck)
		Shanghai five-spice pork
Smoked and roasted products	Smoked products	Chinese bacon
		Smoked pig tongue
		Smoked chicken
	Roasted products	Peking ducks
		Cantonese *Cha Shao*[g] (pork)
Dried products	Wind-dried products	Yunnan[h] *Fung Ji* (wind-dried chicken)
	Meat floss[i] (shredded meat)	Taichang shredded pork/beef
	Barbecued meat slices[j]	
Sausages	Chinese-style sausages[k]	Guangdong-type
		Wuhan-type
		Harbin-type
Hams	Raw hams (*Huo Tui)*	Jinhua hams[l]
		Southern hams
		Northern hams
		Yun hams

[a]Salted products are raw products.

[b]*La Rou* are cured meat (pork, also beef and lamb) products produced in the last month of the Chinese lunar calendar. Guangdong, Sichuan, and Hunan *La Rou* are some of the better-known products. They are normally boneless products; some of the Hunan *La Rou* are bone-in. They are subjected to lengthy natural ageing and dehydration processes in the cold winter months. *La Rou* appears oily and shining on the surface; the fat is golden yellow and translucent, and the meat pinkish-red. Guangdong *Guan Dao Rou* is meat from the pig's hind quarter carved into the shape of a saber, 20 cm long and 1.5 cm thick (imagine the fat as the curved blade and the meat at the back of a saber).

[c]Sichuan province in southwest China is renowned for its cured rabbits. The presentation of the product is unique, in the shape of a silkworm cocoon; thus the Chinese descriptive term *Cha Si*.

[d]*Jiang Rou* are meats marinated in soy sauce. They have a strong soy sauce flavor. In addition to soy sauce, fermented black bean is also used in some products.

[e]Wuxi is a city in eastern China, in Jiangsu province, and is near to Shanghai. The product is known for its salty-sweet taste and delicate aroma.

[f]Hangzhou is the capital city of Jiangsu province in eastern China.

[g]*Cha Shao* literally means 'cooked in forks,' so called because the pork strips are held in fork-like sticks and cooked in flames.

[h]Yunnan province is the most southwest region of China, sharing borders with Myanmar, Laos, and Vietnam.

[i]Meat floss (*Rou Song*), also known as shredded meat, is usually made from pork, beef, or chicken meat. The shredded dried meat is golden in color and has a distinctive flavor and sweet taste. *Rou Song* that come in pork and beef flavors tastes a little like beef jerky. The meat undergoes a process that includes chopping, steaming, frying, and shredding by hand. Soy sauce, sugar, fennel, ginger, and wine are used as seasonings.

[j]Made of either pork or beef. Pork slices are the most popular. Also known as *Rou Gan* in China, and *Bak Kua* in Singapore and Malaysia.

[k]There are more than 30 varieties of traditional Chinese sausages. They are raw, nonfermented products with an a_w in the intermediate-moisture range ($\sim$0.75). According to the degree of sweetness, i.e., the amount of sugar added in the sausage formulation, traditional Chinese-style sausages can be divided geographically into three groups: (1) Harbin-type sausages from northern China province of Heilongjiang, which are characterized by a low sugar content of $\sim$1.4%; (2) Wuhan-type sausages from the central China province of Hubei, which have a moderate sugar level of $\sim$4%; and (3) Guangdong-type sausages from the southern Chinese province of Guangdong, which contain at least 6% sugar, often much more. The Chinese-style pork sausages typically contain large pieces of meat and diced fat ranging from 0.5 to 1 cm in size.

[l]Jinhua ham is a premium meat product that has the excellent quality attributes of Kentucky country ham and Blue Ribbon Virginia ham in the United States. The hams are dry-cured in the winter season. After about 9 months, the hams are carefully shaped to ensure that the leg is straight and the hoof is sickle-shaped. They are then graded according to their appearance and saltiness. The four acclaimed unique properties of Jinhua ham refer to its color, aroma, taste and appearance, and thin skin and fine bones.

Classification of Traditional Chinese Meat Products

TCMPs can be classified according to the animal species, product formulation, processing methods, or product characteristics. Table 1 gives a classification of TCMPs based on the combined criteria of processing methods and product characteristics.

Curing of meat is done by dry rubbing or soaking, or a combination of both. Soaking is a common practice for small cuts where the meat is submerged in brine. A typical brine is composed of crude salt and some flavoring ingredients. As crude salt is normally contaminated with nitrate, no additional nitrate or nitrite is required to initiate the curing reaction.

Braised and seasoned meats are cooked in marinades with soy sauce as the basic ingredient. Cooking is done first on high heat. The heat is then gradually reduced to medium or low. These products have a 'melt-in-the-mouth' characteristic. The different product formulations typically incorporate five different spices, each having a distinctive flavor: star anise, cinnamon, clove, prickly ash, and fennel seeds.

Processing of hams traditionally involves slow fermentation (2–3 months) and long ageing (3–4 months). The total processing time can be up to 9 months. Finished products have a 55–60% yield.

Chinese and Related Cuisines

The Eight Culinary Traditions of China are Anhui, Cantonese, Fujian, Hunan, Jiangsu, Shandong, Szechuan, and Zhejiang cuisines. However, there are also many styles of Chinese cuisine outside China that include Vietnamese, Singaporean, Malaysian, Indonesian, Indian, and American. There are a number of websites that cover these styles. In other words, Chinese cuisine is popular around the world wherever there is ethnic Chinese population. The use of meats such as pork, beef, and chicken were relatively limited in the past and in places like Vietnam and Cambodia, fish is the main protein. American Chinese food typically treats vegetables as a side dish or garnish, whereas traditional cuisines of China emphasizes the use of vegetables. The use of carrots and tomatoes (from the New World) is a latest addition. Native Chinese cuisine makes frequent use of Asian leaf vegetables like *bok choy* and *kai-lan* and puts a greater emphasis on fresh meat and seafood. Stir frying, pan frying, and deep frying tend to be the most common Chinese cooking techniques used in American Chinese cuisine (Figure 5), which are all easily done using a wok. The symptoms of a so-called Chinese restaurant syndrome or 'Chinese food syndrome' have been attributed to a glutamate sensitivity, but carefully controlled scientific studies have not demonstrated such negative effects of glutamate.

Conclusion

TCMPs are representative of the Chinese people's rich cultural and culinary heritage and diversity.

Much before scientific technology was applied in meat processing, the Chinese people had, through intelligent and creative manipulation of product formulations in step with the winter season's favorable weather conditions, produced many of the well-known products such as Jinhua hams and Chinese-style sausages. Hurdle technology in meat processing, elucidated by Leistner in 1985 is an important scientific development in improving the microbiological stability of traditional meat products. It has explained the scientific background for some of the traditional methods used in

Figure 5 A Chinese buffet restaurant in the United States.

China, and Leistner has visited China and further improved the safety of some of the Chinese processing methods.

Further improvement in the quality attributes of TCMPs by application of modern meat science and technology such as the hurdle technology in the industrial scale production will thus benefit the trade in these products globally.

Glossary

Appertization It is a thermal processing procedure which sterilizes perishables by heat (110–130 °C).
Back pudding Sausage made with blood.
Charcuterie Etymologically the term refers to 'chairs cuites' (cooked flesh). In its present meaning it represents products from meat processing.
Collagen It is the fibrous protein constituent of bone, cartilage, tendon, and other connective tissue. It is converted into gelatin by boiling.
Dry curing The process involving the use of cure (potassium nitrate or sodium nitrite) mixed with salt followed by a long drying.

Introduction

Many of the meat products have been produced in France for centuries. These products and recipes constitute an important culinary heritage, part of the French gastronomy, and also a significant part of French local and national economy. Meat is a major component of French consumption.

Traditionally, the two most common and popular ways to use meat are stews (e.g., braised meat dishes like beef bourguignon or veal blanquette) and 'charcuteries' (mostly prepared in a delicatessen with pork meat like salami, sausages, cooked ham, dry-cured ham, paté, rillettes, and black pudding). Typical French products and dishes with their characteristics and French names are described in this article.

Braised Meat Courses

In France, before the era of modern breeds and agricultural specialization, the farmers were mostly looking for versatility in the livestock selection. Animals were taking part in field work, giving enough milk fat to make cheese, but were also meat providers at the end of their life. At that time, meat was generally pretty tough and was usually cooked slowly for a few hours and mixed with vegetables. In France, the meat was not roasted until the end of the nineteenth century and not grilled before 1945.

This slow cooking by boiling allows the muscle collagen to turn into gelatin. Gelatin modifies the textural properties of the dish and mainly behaves as a thickener for dishes in a sauce. In fact, in France, any good stew should combine not only bones, fat, and meat but also a good supply of collagen through bone addition.

The source of gelatin is mainly sourced from beef tail, foot, marrow bones, and back ribs.

- Bones: they give taste to the dish and texture to the sauce.
- Fat muscles: they give the taste. Flanken-style ribs (cut of meat taken from the short ribs of beef) as well as the trapezius muscle are often used.
- Lean muscles: give chewing and volume to the dish, but they taste very neutral. Several cuts are used, such as beef chuck, aglet baroness, eye of round steak, and bottom round roast.
- Stringy and sinewy meat pieces: these are gelatinous pieces. They give the moisture and the texture to the sauce. It takes approximately 5 h of cooking for these meat cuts to gelify their collagen and become softer. Several cuts are used, such as beef cheek, shank, and corned beef briskets. These three kinds of pieces in equal proportions will give a balanced and tasteful braised meat dish.

France has accumulated lots of braised meat's recipes with wide varieties of regional expressions.

With Beef/Bull

- Bœuf mironton (mironton of beef): cooked in beef stock and braised in tomato sauce with pickles.
- Bœuf bourguignon: like its name suggests it comes from Burgundy and is slowly cooked in red wine.
- Beef carbonnade: it comes from the north of France and it is braised in dark beer.
- Gardianne de taureau (traditional bull herd leader): from Camargue in the south of France: bull marinated in red wine with onions, bacon, and orange peel and then braised.
- Pot-au-feu (boiled beef): cooked in water with onions, carrots, leeks, and potatoes.
- Bœuf à la ficelle (beef with the string): fillet of beef hung with a string attached to a wooden spoon placed across the pan and cooked in water with turnips, carrots, and leeks.

With Veal

- Blanquette de veau (veal blanquette) (Figure 1): this recipe is the favorite French meal in France; it consists in a veal stew with white sauce. Veal meat used for blanquette is a little expensive and has enough fat in parts (parties), so that the meat does not dry out during the cooking; cuts include height of rib, back of the knee or, breast of veal support, i.e., tendron (middle-cut breast of veal). Veal meats are cooked in a broth made of water, onions, carrots, leeks, garlic, and white wine. Then a sauce is made with a 'roux'

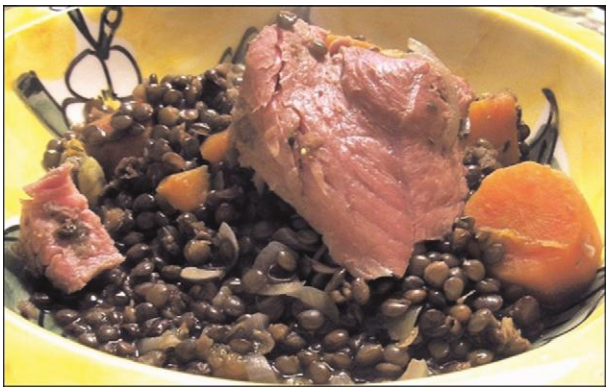

Figure 1 Streaky bacon with lentils.

Figure 2 Veal blanquette.

and in the cooking broth, mushrooms as well as lemon juice are added. The veal is served in the sauce.

- Veal Marengo: diced veal stew with tomatoes, carrots, onions, mushrooms, veal broth, and white wine.

With Pork

- kig ha farz breton: from Brittany, in the west of France: smoked pork breast and foreleg cooked with vegetables in water with a buckwheat flour dough cooked in a canvas bag in the meat broth.
- La potée auvergnate (hotpot): from Auvergne in the center of France: pork breast and foreleg ham cooked for 2 h in water with cabbage, carrots, celery, leeks, onions, and potatoes.
- Petit salé aux lentilles (streaky bacon with lentils) (Figure 2): From Auvergne: pickled pork slowly cooked with lentils in water.

With Other Meat

- Rabbit: civet de lapin aux pruneaux (rabbit stew with prunes): it is slowly cooked with red wine.
- Games: civet de lièvre (hare stew), civet de sanglier (wild boar stew): marinated in red wine (and cognac sometimes) with onions and carrots, then braised slowly in the wine of the marinade.
- Innards: tripes à la mode de Caen (braised tripe Caen's style): braised with carrots in white wine and tripes à la lyonnaise braised with onions in a tomato sauce.

Charcuterie (Delicatessen)

Etymologically, the term refers to 'chairs cuites' (cooked flesh). In its present meaning, it represents products from meat processing. Meat preservation, based initially on salting and smoking, has been deeply connected with the development of 'appertization' combined with cold chain and packaging techniques.

Dry Sausages/Saucisson et Saucisse Sèche

There are 'saucisson' recipes dating back to the Roman Empire. In France, the first appearance of the word 'saucisson' (a word of Italian origin) dates from 1546 in a book by Rabelais and shows how the transalpine cuisine had already penetrated in France.

It is made of animal's gut stuffed with minced meat. The lining is generally composed of two-third of meat and one-third of fat added with salt, sugar, curing agents, and spices. The mix is stuffed into a casing for a mild ripening and drying of 3 months. The basic processing is still the same but mostly mechanized (to respond to mass consumption). During curing, the dry sausage acquires organoleptic qualities due to the physicochemical transformations of myoglobin, carbohydrates, fats, and proteins of the filling.

The most commonly used meat is pork, but there are also 'saucissons' made from bull (e.g., in Camargue in the south of France) or wild boar, poultry, donkey, and pork liver ('figateli' sausage in Corsica).

Being easy to preserve, the dry sausage is a very popular dish in France; it is consumed in all occasions and is served with drinks or for picnics.

Cooked Ham/Jambon de Paris and Dry-Cured Ham/Jambon Sec

These products were invented by the Gauls. Although it was the product of early smoking and salting preservation specialists, the ham recipe was quickly taken over and adapted by other people. The ham is represented in some frescoes and stained glass windows of the Cathedral Notre Dame de Paris. It became the 'star food' of the Middle Ages and the basis of the rural nourishment because it could be preserved easily. Nowadays, in France, two kinds of ham are produced:

- Cooked ham or jambon de Paris (Figure 3): this is the most popular delicatessen type food eaten in France. It represents almost 70% of the processed pork. Basically, it is a pork leg that has been deboned and reshaped, injected with brine, and then cooked in a flavored broth. It is sometimes

Figure 3 Jambon de Paris.

cooked in a cloth sewn around the ham (jambon au torchon). It is commercialized with or without rind.

- Dry-cured ham or jambon sec: many regions of France have their own ways of preparing such a ham. All these regions share a special climate: close to mountain with a draining wind. The quantities of salt and the time of curing vary according to the traditions. The drying adds the final touch and gives the characteristics and quality of cured ham. The ham's weight ranges from 5/6 kg to 9 kg depending on the region. In France, the most renowned hams are Jambon de Bayonne, Jambon d'Auvergne, and Jambon de Savoie. Bayonne ham enjoys EU Protected Geographical Indication (PGI) status. This certification requires professional processors to comply with specifications that provide the consumer with a finished product of optimal quality. Proteolysis in dry-cured ham occurs throughout processing but at different rates and to varying extents depending on salt penetration and water migration. The processing of Bayonne hams, which lasts 9 months, follows the sequence: salting, settling, oven drying, air drying, fat covering, and ripening.

Pâtés/terrines/Rillettes

In the Middle Ages, terrines and pâtés were distinguished by their mode of cooking: terrines were cooked in clay (terre) containers, which explain their name. Pâtés (pies) were baked in dough not necessarily edible at that time. This crust was very thick to protect the stuffing during cooking and transport. Over the years, each province has developed its 'pâté' recipe typical of its land:

- pâté Rennais (de Rennes in the west of France) is traditionally made with pork meat and cooked in the oven.
- In the seventeenth century, the Picardie region was deemed to be well stocked with game. This region is one of the richest regions in France in pâtés and terrines' recipes: Duck pâté d'Amiens, partridge pâté de Montdidier, and also hare and woodcock pâtés.

Nowadays, 'pâtés' are mostly made from pork meat, liver, fat, and lean pieces for the moisture and texture.

Blood Sausage or Black Pudding/White Boudin (Boudin Noir/Boudin Blanc)

Black pudding, of red-brown hue, gets its color from blood from which it is made. The ingredients are put into gut/intestines and cooked. There are as many recipes as regions of France. Pork butchers use more or less spices and add them depending on the region, for example, bread crumbs, Swiss chards, spinach, fresh herbs, flour, eggs, cream, and pig's rind or foot.

Black pudding is one the oldest known deli foods. It was invented in the antiquity by a Greek cook named Aphtonite.

'Boudin' blanc, for its part, is made from white meat (poultry, veal, pork, and pork fat). 'Boudin' (black or white) is still much being appreciated by French people. In 2002, as much as 14 730 tons of black pudding and 6962 tons of white pudding were produced.

Conclusion

The French cuisine offers a huge variety in the names of dishes and in the way they are prepared and these traditions are part of the culinary traditions of French people. The cuisine also is underpinned by the way the meat is produced on the land, especially for each particular agriculture region, the stories surrounding the way the dishes first were created, the traditions accompanying the dish's development, and how the cuisine was modified in the past to take account of seasonality. The two main traditional ways to use the meat in France are meat dishes braised in sauce/stock and 'charcuteries' (delicatessen). The variety of names and variability across the country associated with these aspects of the French meat cuisine are difficult to cover fully. This article provides an overview of the most famous ones.

Glossary

Ammerländer Schinken/Knochenschinken/Dielenrauchschinken/Katenschinken Dry-cured ham from the northwestern region of Lower Saxony in Germany.
Badisches Schäufele Cooked, cured, and smoked pork shoulder produced typically in Baden (Germany).
Bayerischer Leberkäse Coarsely or finely chopped emulsion-type meat loaf produced by roasting (Germany).
Braunschweiger Mettwurst Sliceable fermented sausages from a region around the town Braunschweig (Germany).
Eichsfelder Feldgieker Fermented dry-cured and sliceable sausage produced by air drying from a region of Central Germany; veal bladders are used as casings.
Frankfurter Würstchen Cured emulsion-type sausages with sheep casings and a typical smoky flavor and color from Frankfurt am Main (Germany).
Göttinger Feldkieker Fermented dry-cured and sliceable sausage produced by air drying from an area around the town Göttingen (Germany) and using a bladder as casing.
Göttinger Stracke Fermented dry-cured and sliceable sausage produced by air drying from an area around the town Göttingen (Germany).
Greußener Salami Long-term fermented sausages produced in Thuringia (Germany).
Halberstädter Würstchen Cured and intensively smoked emulsion-type sausages with sheep casings from Halberstadt (Germany) mainly sold as conserved products.
Hofer Rindfleischwurst Spreadable fermented and smoked sausages containing beef and backfat from a region near the Bavarian town Hof.
Holsteiner Katenschinken/Katenrauchschinken Dry-cured and cold smoked ham from the federal state of Schleswig-Holstein (Germany).
Kassler Cooked, cured, and smoked pork loin or neck.
Knacker Emulsion-type sausage (Knockwurst) with a typical smoking flavor and color.
Leitsätze für Fleisch und Fleischerzeugnisse des deutschen Lebensmittelbuches Part of the German Food Codex containing guidelines for German meat and meat products.
Münchner Weißwurst Noncured emulsion-type sausages with hog rounds as casings from Munich (Germany).
Nürnberger Rostbratwurst/Nürnberger Bratwürste Noncured emulsion-type sausages in sheep casings (length 7–8 cm) for frying from the area around Nuremberg (Germany).
Pfälzer Leberwurst Spreadable and noncured liver sausages with a typical spicy flavor of marjoram from Rhineland-Palatinate (Germany).
Pfälzer Saumagen Coarse emulsion-type sausage filled in hog stomach from Rhineland-Palatinate (Germany) containing pieces of blanched potatoes and pork, and bacon.
Regensburger Coarsely or finely chopped emulsion-type sausage from the region around the town Regensburg (Germany).
Roter Schwartenmagen Blood sausage with pieces of head pork.
Rügenwalder Teewurst Spreadable fermented sausages containing honey or glucose syrup.
Schwarzwälder Schinken Dry-cured ham with an intensive cold smoking flavor and dark color from the region of Black Forest (Schwarzwald, Germany).
Schwarzwurst Blood sausage.
Stuttgarter Schinkenwurst Coarse emulsion-type sausage.
Teewurst Spreadable fermented sausage produced by a finely or coarsely chopped batter.
Thüringer Leberwurst Spreadable and cured liver sausage with a typical flavor of marjoram from Thuringia (Germany).
Thüringer Rostbratwurst Medium finely comminuted sausage for frying and grilling without nitrite curing salt as well as with an intense marjoram flavor from Thuringia (Germany).
Thüringer Rotwurst Blood sausage with a spicy clove and marjoram flavor from Thuringia (Germany) containing precooked cured cubes of lean meat, heart, or tongue.
Weißer Schwartenmagen Cooked sausages produced by head pork, jowl, and jellied brawn.
Westfälischer Knochenschinken Dry-cured ham produced by a long-term ripening with bone-in and with a mildly smoky and spicy flavor from Westphalia (Germany).
Wiener Cured emulsion-type sausages in sheep casings with a typical smoky flavor and color from Frankfurt am Main (Germany).
Ansbacher Preßsack Cooked sausages produced by cured head meat, jowl, and jellied brawn from the region near the Bavarian town Ansbach (Germany).

Introduction

More than 1500 different kinds of meat products and sausages are produced in Germany. The different types of meat products are defined by the raw materials used, their special quality attributes as well as by the key analytical values. A complete list of products and their specifications can be found in the 'Leitsätze für Fleisch und Fleischerzeugnisse des deutschen Lebensmittelbuches', a section of the German Food Codex containing guidelines for German meat and meat products.

 doi:10.1016/B978-0-12-384731-7.00196-3

Some German meat products are traditional ethnic products that are typical of a specific region (Figure 1). An overview of the principal classification of German meat products, together with examples, is provided in Table 1.

When a product acquires a reputation that extends beyond the national borders of the region or country of its origin, it may find itself in competition with similarly named but counterfeit products that pretend to be genuine German sausages. In 1992, the European Union, therefore, established authentication systems such as the 'Protected Designation of Origin,' 'Protected Geographical Indication' (PGI), and 'Traditional Speciality Guaranteed' labels to promote and protect the authenticity of ethnic food products. As an example, ethnic meat products that have been granted PGI protection, or have PGI protection applications pending, are shown in Table 2. These ethnic meat products may also simultaneously be registered as trademarks at the German Patent and Trade Mark Office, with trademarks being linked to the geographical origin of products. However, most of the ethnic meat products in Germany are not protected by such authentication systems. Below, select traditional ethnic products that are of particular popularity in Germany are presented in more detail.

Figure 1 Some typical German meat products: (clockwise from top left) Schwarzwälder Schinken, Pfälzer Leberwurst, Thüringer Rotwurst, Stuttgarter Schinkenwurst, Rügenwalder Teewurst, Nürnberger Rostbratwürste, (down left to right) Münchner Weißwurst, Nürnberger Rostbratwurst, Rügenwalder Teewurst.

Dry-Cured Ham

Schwarzwälder Schinken (Black forest ham)

The process used to produce 'Schwarzwälder Schinken' is shown in Figure 2. The raw material consists of deboned rear pork shanks without or with topside. It is obtained from pigs raised on farms located in the black forest region of Germany dedicated to the production of raw material for 'Schwarzwälder Schinken'. The farms are regulated with respect to feed type, raising conditions, and pig species to ensure a top quality of the raw material. After slaughtering, the raw material is subjected to a quality analysis before use. Parameters that are controlled include pH (<6 to ensure absence of dark, firm and dry – DFD meat), core raw material temperatures of below 4 °C, quality of the cuts as the removal of excess backfat, their weight, and an appropriate ratio of lean meat to set backfat (approximately 20% of lean meat). The pH value in particular is a decisive factor for determining whether the raw material is

Table 1 An overview of the classification of ethnic German meat products

Meat products	*Description*	*Examples*
Dry-cured ham	Salted and cured ham (smoked or air dried)	Schwarzwälder Schinken (Black forest ham), Ammerländer Schinken, Holsteiner Katenschinken, Westfälischer Knochenschinken
Cooked cured meat products	Different cuts (ham, loin or shoulder) of pork, beef, or veal	Kassler (cured and smoked pork loin), Badisches Schäufele (cured and smoked pork shoulder)
Fermented sausages (raw sausages)	Dry cured sausages (sliceable)	Greußener Salami, Göttinger Stracke, Göttinger Feldkieker
	Finely or coarsely minced and cured sausages (spreadable)	Rügenwalder Teewurst, Braunschweiger Mettwurst, Hofer Rindfleischwurst
Cooked sausages (emulsion-type sausages)	Finely chopped (usually heated for consumption)	Frankfurter (frankfurters), Wiener, Knacker (knockwurst), Bayerischer Leberkäse (meat loaf), Halberstädter Würstchen, Münchner Weißwurst
	Coarsely chopped	Regernsburger, Bayerischer Leberkäse (meat loaf), Stuttgarter Schinkenwurst
	Addition of pieces of meat	Pfälzer Saumagen (added with pieces of pork and potatoes)
Cooked sausages	Liver sausages (spreadable)	Thüringer Leberwurst, Pfälzer Leberwurst
	Blood sausages	Thüringer Rotwurst, Pfälzer Blutwurst, Roter Schwartenmagen, Schwarzwurst
	Head meat, jowl (jellied brawn)	Ansbacher Presssack, Weißer Schwartenmagen, Weißer Presssack
Sausages for frying	Fried, broiled, or grilled sausages	Nürnberger Rostbratwurst, Thüringer Bratwurst/Thüringer Rostbratwurst

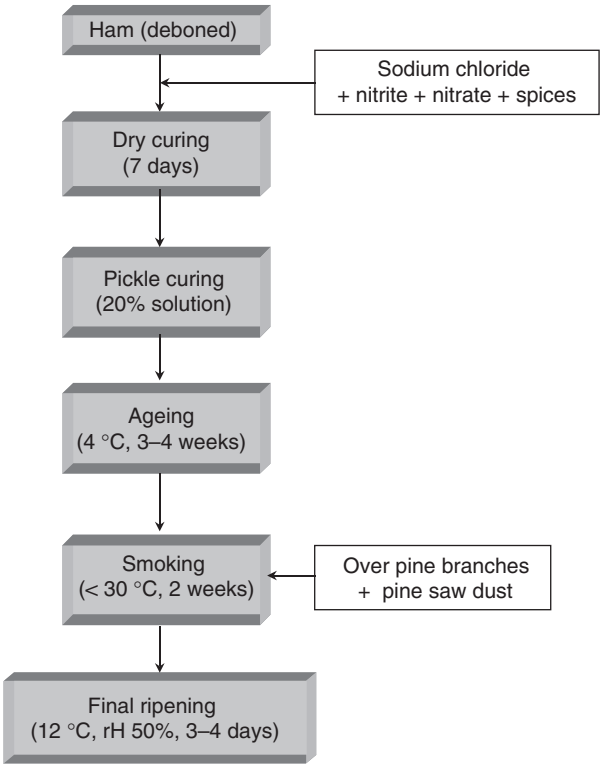

Figure 2 Production process of Schwarzwälder Schinken.

suitable for use in the production of 'Schwarzwälder Schinken' as the surface of hams may become slimy and gooey after drying and the consistency gummy if the pH value of the raw material exceeds 6.0. Another very important factor is to correctly trim the raw material, which in turn determines the ratio between fat and lean meat. The salt and spice mixture used contains nitrite curing salt and/or nitrate and a characteristic spice blend composed of, for example, juniper, whole pepper, garlic, and coriander. Each ham is dry-rubbed with the spice and salt blend, and multiple hams are then stored together in a sealed container. During storage, salt gradually diffuses into the meat. Every second day, hams are turned. Within 3–4 days, a natural brine begins to form and accumulate in the container. As soon as a natural brine has formed, additional brine is added to completely cover hams. The process of brining is completed within 2 weeks. The hams are then removed from the container, washed, and dried. The hams are then laid on a metal grid or hung and allowed to age in a controlled environmental chamber at a temperature of <5 °C and a relative humidity of 60–80% for 2 weeks. During the aging step, moisture is lost, and salt concentration profiles are equilibrated throughout the ham, both key steps to ensure the microbiological safety of hams. After aging, the hams are finally cold smoked for 2–3 weeks at 20–25 °C using pine wood that is the hallmark of the black forest region. The hams are then again aged at a relative humidity of ~50% at 15 °C. After completion of the aging process, hams have lost ~25% of their initial weight. The salt content of the final product must not exceed 15% on a dry matter basis and the ratio between fat and lean meat must not exceed 25% with a water-to-protein ratio of 2.2:1. The final product is characterized by a smoke-covered black surface, a dark-red interior color, a tender texture and an intense smoky and aromatic but not overall salty flavor. In former times, the production of 'Schwarzwälder Schinken' was only possible in the black forest, a forest-dense region in the southwestern part of Germany with general altitudes of approximately 800 m above sea level as the climatic conditions there required for the production of hams were similar to those described above.

Ammerländer Knochenschinken

This special dry-cured ham originated in or near Oldenburg, a town in the northwestern region of Lower Saxony. The raw material from a special variety in this region consists of rear pork shank with topside containing no bone and should weigh ~12 kg. Initially, the raw material is dry cured with nitrite curing salt, sea salt, brown sugar, pepper, juniper, and pimento for a minimum of 10 weeks by manually dry-rubbing the salt and spice mix into the meat once a day. After curing,

the product is hung for approximately 2 weeks for aging. Temperature and humidity conditions during curing and aging should follow standard protocols for ham processing. The hams are then weakly and preferably cold smoked with beech shavings at a high relative humidity for ~10 weeks. A further aging step follows under the above conditions for ~6 weeks. Taken together, the process takes 9 months. The ham has a final water-to-protein ratio of 2.5:1. Owing to the use of beech wood, the surface of products attains a slightly golden color whereas the interior is intensely red; has a very tender texture; and a very lightly smoky and mildly salty flavor.

Westfälischer Knochenschinken

'Westfälischer Knochenschinken' is a highly traditional product that traces its roots back to the twelfth century. In those early times, the production could only be carried out during the cold and moist winter months. The raw material again consists of a whole, bone-in pork hindquarter. In former times, the pigs were fed a special accord diet that was said to yield especially tender and dark red colored pork. The ham is dry-rubbed with a mixture of nitrite curing salt, potassium nitrate and sugar and stored in a closed container with a total curing time of 3–6 weeks to allow for the development of a natural brine. Unlike the production of 'Schwarzwälder Schinken', no additional brine must be added. Once a week during the curing, the hams are turned and resalted with the curing mixture. After 3 weeks, the brine is removed and the hams again left to cure for a period of 3 weeks. Afterwards, they are washed, dried and scrubbed and hung in chambers to allow surface moisture to evaporate and are subsequently smoked. Smoking involves either a long-term cold smoke process with beech wood or an alternating aging process in the open air that is interrupted by the above-mentioned cold smoke process for a total of 5 months. The entire production takes between 6 and 18 months, depending on the sensory quality of the product such as tenderness. The product is sold with the bone being removed. 'Westfälischer Knochenschinken' has a characteristic intensely golden surface and a dark red interior. Its flavor may be described as being mildly smoky and spicy. The texture is very tender.

Fermented Sausages

Greußener salami

This salami is produced in Thuringia, a state on the southeast of Germany, which was subjected to the rule of France in 1897. In contrast to the conventional rapid production of salami (Figure 3), in which starter cultures or glucono-δ-lactone are used to quickly lower the pH value, allowing for a short fermentation time of less than 4 weeks. The manufacturing of the 'Greußener' salami involves a long-term fermentation process that requires a minimum of 5–6 weeks. The raw material for this salami consists of high-quality beef void of sinews and free of fat, and roughly trimmed pork and backfat. The spices used include pepper, garlic and a variety of other spices such as nutmeg. The meat is coarsely ground using a meat grinder and further processed on a bowl chopper. To obtain a well-defined fat distribution in meat without causing the fat to be emulsified, the material should be partially frozen before chopping. After processing on the bowl chopper, the meat batter is filled into cellulose casings at a temperature of −2 °C to −4 °C, hung in a smoking chamber and cold smoked at intervals using beech wood for 4–5 days. Temperature is controlled and the pH is monitored during the smoking

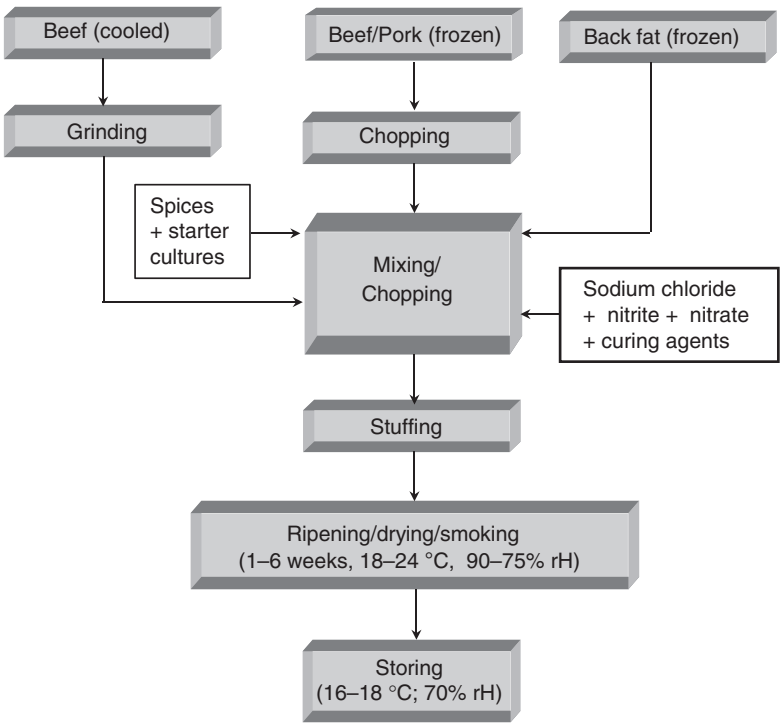

Figure 3 Production process of sliceable fermented sausages (Salami).

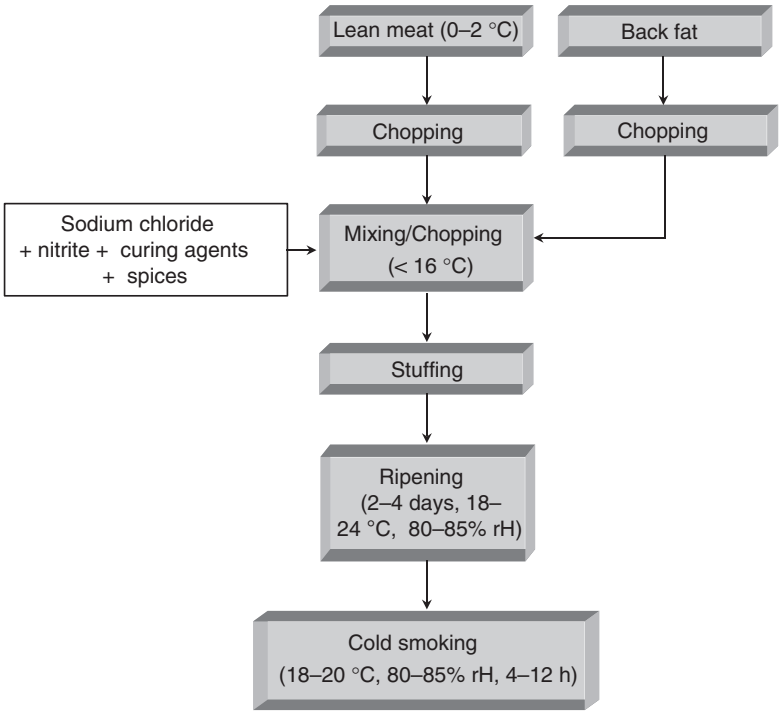

Figure 4 Production process of spreadable fermented sausages (Teewurst).

process. After smoking, the salami is ripened for 4–5 weeks to a final weight of 65–70% of its original weight. This salami has a mild pepper aroma, a stable dark red color and a very firm texture, which allows for the sausage to be easily and thinly sliced.

Rügenwalder Teewurst

In contrast to the production of other spreadable fermented sausages (Figure 4) that belong to the general class of 'Teewürste', the 'Rügenwalder Teewurst' contains honey or glucose syrup. The Rügenwalder Teewurst is made from beef and/or pork with a low content of connective tissue and a fat content of below 45%. Before processing, the raw material is chilled to −1 °C to +2 °C. After mincing and chopping of the lean meat, fat is added. The mixture is then processed on the bowl chopper to attain a finely dispersed (creamy) batter. The batter is filled into a cellulose casing and fermented for approximately 24–48 h at 16–24 °C at a relative humidity of 80–90%. Sausages are then cold smoked at 18 °C, until the products attain an intensely smoked and spicy flavor and a deep red color.

Cooked Sausages

Emulsion-type sausages

Germany is known for its wide variety of sausages but particularly for those that belong to the category of emulsified sausages. Some emulsified sausages are only salted with sodium chloride, such as the 'Gelbwurst', or the 'Münchner Weißwurst', but most sausages such as the 'Lyoner', the 'Halberstädter Würstchen', or the 'Frankfurter' contain nitrite curing salt.

Halberstädter Würstchen

Halberstadt is a town in the central region of Germany and the traditional manufacture process of the 'Halberstädter Würstchen' dates back to more than 100 years. This sausage is a cured emulsion-type-sausage made from finely chopped pork (~45%), beef (~15%), backfat (~15%), and ice (~25%). The batters are filled in thin, tender natural sheep casings (rounds) and are hot smoked for 40–50 min at an average smoking temperature of 60–75 °C. Direct firing with an underfloor furnace fed with beech wood causes the temperature in the smoking chamber in intervals to briefly reach temperatures above 110 °C. This also causes a continual reduction in relative humidity (<25%) to take place. Characteristic features of these sausages are their brown color and an unmistakable, intense smoky flavor. The sausages are mainly sold as a conserved product, for example, in a glass or metal jar.

Frankfurter Würstchen

In Germany, 'Frankfurters' have been known since the thirteenth century and have been protected under the name 'Frankfurter Würstchen' since 1860. The name has been exclusively used for such sausages since 1929. A butcher from Frankfurt, Johann Lahner first manufactured these sausages in Wien and, because of this, they are also known as Wiener or Wiener Würstchen in Germany. Today and, in contrast to the original 'Frankfurters', Wieners are manufactured from pork and beef whereas Frankfurters are made with pork only. They are cured emulsion-type-sausages with a finely chopped batter consisting of ~45% lean and desinewed pork, 25% fat and 30% ice filled in sheep casings (rounds). The sausages have a mildly spicy and smoky flavor and a golden-brown color, a fact that is based on the addition of white pepper and nutmeg

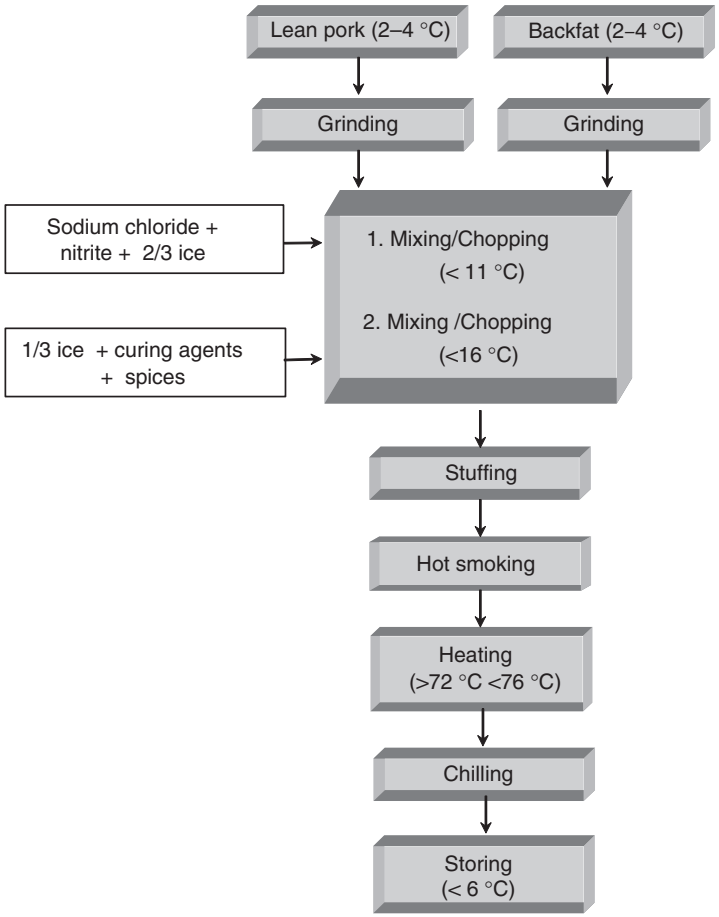

Figure 5 Manufacturing process of Frankfurter Würstchen.

or due to the hot smoking process. After filling, the sausages are first dried at 50 °C and then smoked at 50–60 °C for 45–50 min. In Figure 5, the manufacturing process of Frankfurters is shown.

Münchner Weißwurst

The birth of the 'Münchner Weißwurst' occurred on 22 February 1857, in an inn at the center of Munich, and was the result of an accident. The butcher was planning to prepare an emulsion for an uncured Bratwurst requiring the use of small sheep intestines. However, as sheep casings were not available, he used hog rounds instead. Moreover, for fear of sausages bursting, he cooked the sausage instead of frying them. Original Münchner Weißwurst contained veal, fat, water, and cooked rind from calves head or other connective tissue from calves. Today, this sausage may be made from both veal, beef from heifers, and/or pork and pork jowls. Veal and/or pork, precooked rinds and pork jowls, and fat are ground separately using a 3 mm plate. The chilled lean meat is only coarsely chopped with sodium chloride and additives such as citrates or phosphates. Then, two-thirds of the total amount of ice and the fat are added and chopped to a temperature of ~7 °C. The remaining one-third of ice and a spice blend consisting of onion, pepper, and lemon powder is added, and the mix further chopped to a temperature of 10 °C. The precooked and minced rinds and fresh parsley are added to the emulsion at the very end of the chopping process. The emulsion is then filled into hog rounds, and the sausages are then heated in hot water until they reach a core temperature of 70 °C. They are then chilled in cold water. Overall, the sausage must contain no more than 30% fat and 25% external water. For consumption, the Münchner Weißwurst is best served warm and should be eaten without its casing and additionally with sweet coarsely ground mustard.

Pfälzer Saumagen

'Pfälzer Saumagen' is the hallmark meat products of Rhineland-Palatinate, a state in the Midwest of Germany. The peculiarity of this coarse emulsion-type sausage is the use of a rather high amount (up to 33%) of blanched and cubed potatoes and/or carrots. Defatted pork is coarsely minced. A portion is set aside to be later added to the emulsion. The other portion is emulsified with backfat and ice and typical spices such as marjoram, pepper, nutmeg, and onions are added. A characteristic feature of 'Pfälzer Saumagen' is that the batter is filled into a hog stomach (after having it combined with the above mentioned coarsely minced pork portion) and is then heated. For consumption, Pfälzer Saumagen is best pan-fried and served with Sauerkraut.

Liver Sausages

These spreadable sausages must contain at least 10% liver to be classified as liver sausages. High-quality liver sausages contain at or above 25% pork liver. At contents of 20% liver, no additional emulsifiers are needed because the liver is able to fully stabilize the emulsion. As a first step in the manufacturing of liver sausages, blood vessels and larger bile ducts that may cause a bitter taste are removed from the liver. After rinsing, the liver is finely chopped until it begins to foam. Precooked lean pork belly and fatty pork cuts of the belly or backfat are chopped and then cooled to a temperature of 58 °C, at which time the liver may be added and the batter is further chopped. Temperature before filling of the paste-like mass in casing should not be lower than 40 °C; otherwise solidification may occur making filling impossible and the mechanical strain results in a partial separation of fat and gel.

Thüringer Leberwurst

Thüringer Leberwurst is a liver sausage with a smoky and spicy taste and contains braised onions, pepper, and marjoram from Thuringia. The sausage is normally filled into natural casings or sold in glass jars. The method of production is schematically shown in Figure 6. The principal ingredients are fatty pork cuts, lean pork, and fresh liver. Lean and fatty pork are precooked in hot water, allowed to cool (< 58 °C), and then minced with fresh liver and braised onions using a 3 mm plate. The spices and the nitrite curing salt are then mixed into the mince. Once a homogenous mixture is obtained, the minced mixture is immediately filled into either natural casings, such as hog chitterlings, beef and hog middles, or artificial casings. The sausages are then heated to a core temperature of 75 °C. This temperature is required to inactivate, for example, lactic acid bacteria. Then the sausages are cooled and smoked using beech wood until they assume a characteristic yellow color.

Pfälzer Leberwurst

The manufacturing of this liver sausage is similar to that of Thüringer Leberwurst with the exception of not being cured. The product is more of a home-style sausage often produced during home slaughtering. It consists of a coarsely comminuted liver sausage in the absence of curing salt. It has an intense taste of marjoram. After heating of the pork and fatty pork tissue, broth may be added to the mixture to compensate for cooking losses.

Blood Sausages

High-quality blood sausages such as Thüringer Rotwurst are made from a raw blood and rind containing batter with cube-shaped pieces of precooked lean meat, liver, heart or tongue, and small amounts of backfat. This mixture was heated to 80 °C. Products of lower quality contain fatty pork, for example, pork belly, jowls, and/or backfat.

Thüringer Rotwurst

This sausage is a blood sausage of higher quality because it is made from select raw materials including 55% precooked lean pork with a maximum of 5% visible fat, 25% precooked jowl without rind, 5% pork liver, 7.5% cooked rind, and 7.5% pig blood. Nitrite curing salt and spices such as black pepper, onions, thyme, clove, and marjoram are added. A particular feature of this sausage is that cubes of lean meat must be

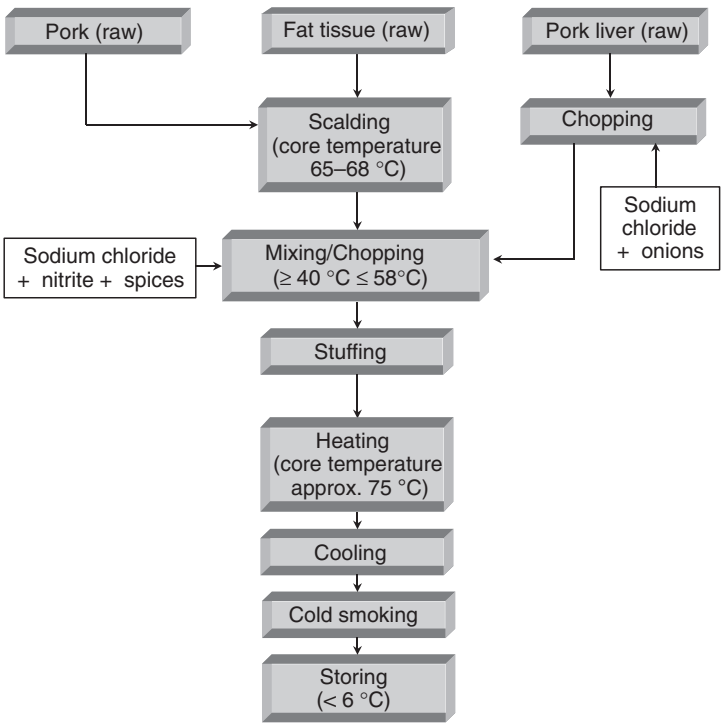

Figure 6 Manufacturing process of Thüringer Leberwurst.

inserted, for example, at least 35%, some of which may be replaced by liver, heart, or tongue. The lean pork and jowl are injected with a cold brine solution, pickled in brine for 12 h, and heated to 80 °C. Cooked rind, onions, and liver are added and minced through a 3 mm plate. Lean meat is scalded. The salt and spices are added and blended into the mixture and blood is finally added. The mixture is filled into hog or beef bungs, caps, stomach, and pig fat ends, and cooked in a water bath for 80 min at 85 °C or filled into glass jars or metal cans.

Special Sausages for Frying

Nürnberger Bratwurst and Nürnberger Rostbratwurst

These small sausages are excellent for frying or grilling. They stem from the area around Nuremberg, a city in Bavaria (the southernmost state of Germany). They were first mentioned in 1462. They do not contain nitrite and are 7–9 cm long with a weight of 20–25 g before heating. The roughly defatted pork is chopped and mixed with salt and spices such as pepper, caraway seed, nutmeg, and marjoram to form a cohesive medium minced batter, which is then filled into small sheep casings. The product is ideally sold raw to be directly grilled or fried. For convenience, they are often sold preheated. A typical method for the consumption of Nürnbergers, particularly in some parts of Franconia, is to heat the sausages in a stock of vinegar, onion, bay leaf, juniper, cloves, and a small amount of salt. In this case, the final products are known as 'Saure Zipfel.'

Thüringer Rostbratwurst

This medium finely comminuted sausage without nitrite curing salt and with a spicy taste is a product that has a centuries-old tradition in Thuringia. The first documented reference is dated back to 1404. The sausage is made from coarsely trimmed pork, pork jowls without rind, and sometimes also trimmed veal or beef. Spices such as pepper, caraway, marjoram, and garlic as well as salt are added to the meat and the mixture is homogenized to a batter that can be filled into a natural small diameter sheep or pig casing. The sausages are linked at approximately 20 cm intervals and cooked at 75 °C for 1 min per millimeter diameter. They are highly aromatic sausages with an intense marjoram flavor and are ideal for grilling.

Glossary

Biryani Indian meat dish made with rice and highly flavored with fried condiments and seasonings.
Dry salted meats The meat is cut into long strips up to 0.5–1 in. in breadth or into small chunks. Cuts are sun dried after adding salt and turmeric powder, which gives a long shelf life, and they are rehydrated before cooking.
Goan Vindaloo Meat preparation from Indian state of Goa using pork, wine, and garlic.
Haleem Type of meat porridge prepared from meat, whole wheat, and lentils along with spices and condiments, which are constantly stirred to make a thick semisolid mass.
Kabab Comminuted meat product made out of minced meat or small-to-large cuts of meat, which is charbroiled to a give smoky flavor.
Kargyong An ethnic sausage-like product from the Himalayan region prepared from yak meat or beef or pork and called yak or lang or faak kargyong, respectively.
Kashmiri wazwan meats Traditional meats from Kashmir including rogan josh, nate-yakhni, tabak manss, aab gosht, rista, and goshtaba prepared by experienced chefs called wazas.
Keema A comminuted meat product traditionally prepared from the low-grade and less expensive cuts of meat, especially of goat or lamb meat.
Kolhapuri mutton Prepared from carefully selected goat or lamb meat, with preferred meat cuts comprising three components: tambada rassa, i.e., red curry, phandhara rassa, i.e., white curry, and mutton sukka, i.e., roasted mutton.
Meat pickle Intermediate-moisture meat product prepared for preserving meat for a long time and making it ready to eat and convenient.
Momo/dumpling Meat fillings of minced pork or any other meat are stuffed in flattened dough made of maida (wheat flour) along with finely chopped onions, ginger, garlic, coriander, and vegetables.
Pish pash/khicheri Meat products made from meat and rice (1:1 ratio for pish pash and 1:2 ratio for khicheri) cooked together along with onions and spices.
Rapka Meat is dried over a traditional home kitchen flame for several weeks by hanging it on a rapka, which is made of bamboo.
Tandoori After marinating the meat product is cooked at high temperature within a tandoor (earthen oven) by way of smoking, grilling, and baking, thereby giving tandoori flavor.
Tikka Boneless meat is cut into small pieces and baked like tandoori in a tandoor following marination in spices and yoghurt.

Introduction

There are several traditional meat products and recipes in the Indian subcontinent, viz. India, Pakistan, Bangladesh, Nepal, Sri Lanka, and other neighboring countries in the region, owing to their similar cultures and the availability of spices. These meat products have percolated down through history and have metamorphosed into spicy ethnic Indian meats. The history of the Indian subcontinent depicts various culinary practices amalgamated into Indian cuisine embodying the cultures of the different settlers. The blend of various aromatic spices with meat and meat products is the basis for ethnic/traditional Indian meats. The diversity of the region has had an impact on the type of meat products available in different parts of the Indian subcontinent and further afield. The meats common to the region are kabab, tikka, biryani, curry, meat pickle, and dry salted meat, among others. The north has tandoori, Kashmiri wazwan meats comprising meats such as rogan josh, nate-yakhni, tabak manss, aab gosht, rista, goshtaba, and shaljam gosht; the south has Hyderabad haleem, Chettinad dishes of Tamil Nadu, and Kerala lamb stew; the west has Kolhapuri mutton and Goan vindaloo; and the east has momo/dumpling, rapka, pish pash, khicheri, kargyong, korma, dopiyaza, etc.

The increasing per capita income in the Indian subcontinent has increased the demand for meat and the traditional/heritage meat products cater to this requirement. The small quantity of the meat produced in the region is processed further into value added and ready-to-eat products as compared to the Western world. Thus, researchers are focusing on standardization of the product profiles and mechanization of ethnic meat product processing. The local knowledge base and information pertaining to the ingredients, local taste preferences, and the history of product formulations passed down through the generations help in the overall improvement of the products. Along with researchers and academicians, the meat industry is also trying to develop these ethnic products for domestic as well as international markets. Undoubtedly, ethnic Indian meat products are quite popular in the western world, especially in the UK and USA. The Indian government is trying to protect these indigenous meat products through the Geographical Indication of Goods (Registration and Protection) Act, 1999, which came into force in September 2003. The quality and distinctiveness of the meat products belonging to particular regions of the country are classified in the fourth schedule of this act under class 29.

The prominent meat products originating from India, Pakistan, and neighboring countries are discussed in this article.

Tandoori

The tandoor is an earthen oven and tandoori is the meat product cooked in the tandoor. The origin of the tandoor is in

 doi:10.1016/B978-0-12-384731-7.00220-8

the Thar desert of northwestern India and eastern Pakistan where it is primarily used by the Bhatti tribe. Thus, in India another name for tandoor is Bhatti. Tandoori meats are made out of marinated tender flesh that is deskinned and defatted before being cooked in a special cylindrical clay oven. This oven is used for high-temperature cooking at 450 °C with the help of fired charcoals or wood. This kind of cooking is a combination of smoking, grilling, and baking, giving the meat product a unique tandoori flavor as well as the color, texture, and taste. The most common meat used in tandoori is tender broiler chicken meat with superficial incisions on the body of the cuts or whole chicken. Marination is done for at least 2 h in the blend of spices with ginger-garlic paste and yoghurt and then the meat is smeared with salt and lemon juice for at least 15 min. Tandoori chicken products can have a shelf life of 8 h at 30 °C, 24 h at 3 °C, and 15 days at −15 °C. The antibacterial properties of the spice mix as well as the high temperature in the tandoor help to improve the shelf life of tandoori products.

Tikka

The meaning of tikka is 'bits and pieces' and thus it refers to the meat, mostly boneless chicken, that is cut into small pieces and baked like tandoori in a tandoor following marination in spices and yoghurt. While cooking, butter or oil is frequently brushed over the chicken to ensure that it remains tender and moist and is not overcooked. Tikka can be served as chicken tikka sizzler wherein it is served on a red hot plate along with onions. Tikka sizzlers are also eaten in Afghanistan along with India and Pakistan. Tikka can also be used as an ingredient for preparation of chicken tikka masala. Tikka masala is a gravy dish containing tikka chunks, cream, a blend of Indian spices, and gravy containing sauce and tomatoes. Other than chicken meat, tikka is prepared out of mutton, i.e., lamb meat pieces.

Wazwan Meats

The specialty meat products of the Kashmir Valley are wazwan meats. These are the several kinds of meat products traditionally prepared by experienced chefs called wazas. Rogan josh, nate-yakhni, tabak manss, aab gosht, rista, and goshtaba, among others, are the important products prepared from prerigor hot-boned tender lamb meat. In the series of the meats served in wazwan, the goshtaba is the last one to be served.

Rogan Josh

The name of this red hot lamb meat product is a combination of the words rogan, which means color, i.e., red color, and josh, which means either passion or heat. The mild Kashmiri chilies impart the red color and make it mildly hot, but the real color of the dish is credited to the extract from dried flowers, locally called Marwal. The lamb meat is marinated for 2 h and along with the marinade it is added to the spice mix in oil and cooked over mild heat until it is browned. Then it is stirred while scraping at the bottom of the cooking vessel to develop the characteristic flavor.

Nate-yakhni

In this product the nate, i.e., meat chunks of approximately 5–6 cm in size, are precooked in boiling water for 20 min and then curd, salt, spices, condiments, and ghee are added and boiling is continued for 20 more minutes to obtain the desired consistency called yakhini. This is a popular meat preparation owing to the blend of curd with meat flavor.

Tabak Manss

The rib portion of lamb meat is utilized for this product preparation after chopping it into small pieces and then steam cooking after application of salt and turmeric. The rib bones are then removed and only the finger meat is shallow fried in ghee over mild heat for a long time. The product is very much enjoyed due to its semidry and crispy nature.

Aab Gosht

Aab gosht is a lamb curry cooked in milk. Lamb is boiled in water with salt, ginger-garlic paste, and aniseed powder to make a stock. The milk is then boiled with green cardamom, onions, pepper, and ghee, to which the lamb stock is added. The mixture is then stirred thoroughly until it boils well.

Rista and Goshtaba

Rista and goshtaba are prepared from minced lamb meat that is manually pounded along with fat using a specially designed wooden hammer over a wooden or stone platform. While pounding the meat, salt and ground cardamom are added. Ice cubes are also added so that the meat does not heat while being minced. The meatballs or koftas are prepared manually with the palm of the hand from meat batter and are cooked in the mutton stock gravy. A separate yoghurt sauce is prepared from strained yoghurt, which is cooked by adding water, spices, condiments, salt, and ghee. The koftas are drained out from the stock gravy, added to the yoghurt sauce, and then simmered for a while before the product is ready to serve hot. They mainly differ in their flavors owing to the different formulations used for preparation of the yoghurt sauce. The natural taste, texture, and flavor of these traditional meatballs in yoghurt sauce provide them with an advantage over mechanized minced meat products. Thus, their market potential can be exploited by small-scale industries by packaging them in low-density polyethylene pouches for increased shelf life up to 7 days in refrigerated storage.

Kabab

The invention of kabab is credited to medieval soldiers who used to grill meat on their swords in fires in the open field. The Indian royal houses during the period of the Delhi Sultanate (AD 1206–1526) relished kababs and thereafter it became the most savored meat product in the region. There are many varieties of kabab, which are commonly prepared in India as well as Pakistan. Kababs are comminuted meat products made out of minced meat or small-to-large cuts of meat.

Traditionally, the meat used for kabab is lamb but over the years different types of meats have been used as per local and regional taste. Usually, kababs are charbroiled but nowadays they are also prepared by grilling, roasting, and stewing with the help of modern cooking equipment. Irrespective of the method used for cooking the internal temperature should be 75±2 °C, which can be achieved by charbroiling at 230±2 °C for 3 min or oven roasting at 180±2 °C for 12 min. The higher temperature of charbroiling also helps to lower the cooking loss and thus charbroiled kababs become juicier than oven cooked kababs. Charbroiled kababs have a typical smoky flavor owing to the contact of the charcoal with the meat; they also have a brown appearance, have more yield, and are juicier as compared to oven cooked kababs.

With increasing preference for chicken meat in the region chicken kababs are becoming more popular. Emulsion technology is being harnessed to utilize the spent hen chicken and by-products along with binders such as polyphosphate, maida (wheat four), potato, and soy in combination with mutton for higher yield. A refrigerated shelf life of up to 10 days makes the product a better choice over regular meat. Some researchers have developed a dehydrated chicken kabab mix packed in metalized polyester pouches that has a shelf life of up to 6 months at ambient temperature (27±2 °C); instant kababs can be made from this mix.

There are several variants of kababs found in and around India as well as Pakistan. The kakori and galouti kababs of Uttar Pradesh in India are usually made from goat meat. The kalmi kabab prepared from chicken meat is quite famous in Delhi, but there are several other varieties such as boty, lasoni, reshmi, tikka, tangdi, and bihari that are popular in India. Pakistan has its own varieties of kababs such as seekh, shami, chapli, ban, sajji, etc., that are relished by the local populace.

Biryani

This is a traditional meat product with lamb meat or chicken and rice (usually basmati) as the main ingredients along with fried condiments and seasonings. The rice is partially cooked with bay leaves, green cardamom, black pepper, and cinnamon sticks. The meat blended with partially fried condiments and seasonings is first marinated for two hours and then cooked separately. The meat and rice are then layered on each other and steamed on slow heat, which renders the contrasting flavors of both rice and meat in the resultant dish. The shelf life of biryani is limited but the meat industry is improvising to create ready-to-eat biryani, especially chicken biryani. There are many varieties of biryani found in the Indian subcontinent with slight differences in recipes. They are named locally, for example, Hyderabadi dum biryani, Lucknowi (Awadhi) biryani, Bhatkali, Kacchi, Moradabadi, Calcutta, Kozhikode, Dindigul, Sindhi, Memoni, and Tahari, with slight variations in their ingredients and preparation.

Haleem

Haleem is a type of meat porridge prepared from chicken, goat, or buffalo meat, traditional to India and Pakistan. Hyderabad in south India is especially known for haleem. The meat is boiled with water, whole wheat, and lentils (soaked overnight) along with spices and condiments until it develops a semisolid consistency. The preparation is stirred and the bottom of the pan is 'scrubbed' continuously. The tenderized meat is mashed well and heated slowly over a low flame for a long time to make it semisolid. Once it is ready, crushed fried onions and butter oil are added and it is served with lemons and mint leaves. A meat to wheat ratio of 3:1 is optimum and the product can also be frozen (−18±1 °C) to obtain a shelf life of up to 30 days.

Kolhapuri Mutton

Kolhapur is at the heart of Maharastrian nonvegetarian cuisine culture. The delicious and spicy Kolhapuri mutton is prepared from the carefully selected goat or lamb meat with preferred meat cuts. The Kolhapuri mutton recipe comprises three components: tambada rassa, i.e., red curry; phandhara rassa, i.e., white curry; and mutton sukka, i.e., roasted mutton. The key element in making these three recipes is preparation of the mutton stock.

For mutton stock preparation the meat is cut into medium-size pieces and marinated with salt, turmeric powder, ginger, and garlic paste for 1 h. After marination the meat is cooked in a pressure cooker with sufficient water and kept aside as a stock.

Tambada rassa is a mutton curry, generally spicy, which is prepared by using a special homemade red chili powder that contains ground onions, garlic, and other spices. At the start, a spice mix of cumin seeds, sesame seeds, bay leaves, cinnamon sticks, pepper, cloves, dry red or green chilies, and poppy seeds are sautéd in two spoonfuls of oil. Dry grated coconut and sliced onions are dry roasted until they turn brown. The roasted coconut, onions, and the spice mix are ground in a grinder along with the coriander leaves and some water to make a paste. For preparation of the curry, oil is heated in a vessel and the sliced onions, special homemade chili powder, turmeric powder, grated coconut, and grinded paste along with the water are added. This is boiled and then the mutton stock with a few meat pieces is added for further steaming until the oil is separated. This gives a nice red hot mutton curry to which some lime juice is added for a special taste.

Pandhara rassa preparation requires the same mutton stock. To start, chopped onions, dry grated coconut, sesame seeds, and poppy seeds are ground in a grinder to make a paste. Next the cloves, cinnamon, and black pepper are roasted in pure ghee, to which the ground paste is added along with salt and the mutton stock with a few meat pieces. This is boiled and white coconut milk is added for the typical taste.

Mutton sukka is prepared from all the cooked meat pieces that are left in the mutton stock after preparation of the tambada and phandhara rassa. Initially, chopped onions are roasted in oil until they turn brown, and then salt and the paste of spice mix prepared for tambada rassa are added. Next, all the meat pieces from the stock are added along with the special handmade chili powder and coriander leaves. This mix is stirred for some time and is ready to serve. Though this meat preparation is popular worldwide, it is misinterpreted in many places through the addition of extra quantities of chilies without the special homemade Kolhapuri chili powder.

Goan Vindaloo

Goa was a Portuguese colony and has been influenced by Portuguese culinary practices. Goan vindaloo is an Anglo-Indian meat dish known for its tangy taste and has evolved into a fusion of a Portuguese meat dish and the traditional spices of western India. The name vindaloo is derived from the Portuguese name 'Carne de Vinha d' Alhos' and the speciality of this meat preparation is the usage of wine and garlic. Pork is the meat usually used for vindaloo but other meats such as lamb, chicken, and beef can also be used. In some parts of India potatoes are also added to the meat owing to the misconception that 'aloo' in vindaloo signifies the addition of aloo (i.e., potato in Hindi).

The vindaloo spice mix is prepared by soaking Kashmiri red chilies (which give more of a color than pungency), cloves, cinnamon, cardamom, cumin seeds, mustard seeds, pepper, garlic, ginger and sugar in wine (particularly pheni wine which is made out of cashew fruits), vinegar, and coconut milk for half an hour. After soaking the spice mix is grinded to make a paste. Next, the meat is marinated with salt and vindaloo spice mix for up to four hours. If needed, a meat tenderizer such as papaya paste can be added to the marinade. Onions are fried in oil until they turn brown and the marinated meat is added for cooking. It is cooked over a medium flame until the meat is fully cooked.

Meat Pickles

Meat pickles are the easiest way of preserving meats for long periods of time and making the meats ready-to-eat and convenient. These intermediate-moisture food products made out of different meats are preserved at ambient temperature due to reduced water activity, low pH, and undissociated molecules of added organic acids. Meat pickles are popular in northern and north-eastern India. The meats commonly used for pickling are chevon, pork, chicken, and carabeef, i.e., buffalo meat. Pickle made from chicken gizzard is also eaten indigenously. At ambient temperature the shelf life of the meat pickle can be up to 60 days, but if antioxidants such as butylated hydroxyanisole, butylated hydroxytoluene, and sodium ascorbate are added and packed in Polyethylene terephthalate bottles it can be several months. The meat is cut into uniform chunks of 2.5–5 cm (1–2 in.) and pressure cooked with salt in a pressure cooker. After cooking the meat chunks are acidified with 2.5% acetic acid (v/v)/vinegar and then deep-fat fried until they turn brown. A smooth fine paste of spice mix with red chilies, tomatoes, onions, coriander, ginger, garlic, cumin, turmeric, lime juice, and yoghurt is heated in oil. The meat chunks are added to the spice mix and blended by gentle cooking on slow heat. They should be heated until the oil is fully released as this oil only gives a preservative effect. Addition of antioxidant to the pickle helps to maintain the flavor and overall acceptability of the product during storage.

Momo/Dumpling

Momo is a traditional meat based delicacy in the north-eastern hill regions of India, especially Sikkim, Assam, Meghalaya, Manipur, Mizoram, Nagaland, Ladakh, and Himachal Pradesh. Momo is said to be a Tibetan origin word and the product is popular in Tibet, Nepal, Bhutan, and China. Meat fillings of minced pork or chicken or goat/lamb, buffalo, or yak meat are stuffed into flattened dough made of maida along with finely chopped onions, ginger, garlic, coriander, and some vegetables. This is shaped into a round pocket or crescent and then steamed for 15–20 min. They may be pan or deep fried after steaming and are generally served with sauce or pickle.

Rapka

Rapka is a type of semidry meat product produced from the meat of mithun and yak. It is popular in the north-eastern hill regions of India for its smoky flavor. The meat is dried over a traditional home kitchen flame for several weeks by hanging it on a rapka, which is made of bamboo. Over the period the meat is semidried by the flames and this imparts a distinct smoky flavor.

Pish Pash and Khicheri

Pish pash and khicheri are traditional and regularly eaten meat dishes of north-eastern India. These two products are made from meat and rice (1:1 ratio for pish pash and 1:2 ratio for khicheri) cooked together along with onions and spices. Vegetables such as cauliflower, beet root, peas, and carrots are also added. They are cooked on a low flame until they become soft and semisolid in consistency. Chicken is the most common meat used but they can be prepared from other meats as well.

Keema

Keema is a comminuted meat product usually prepared from low-grade and less expensive cuts of meat (goat or lamb or any other meat). It is a highly perishable product owing to its comminuted nature, i.e., due to breakdown of the muscle structure and exposure to oxygen. It can be stored for up to 2 days at ambient temperature, but better packaging and/or refrigerated storage along with the usage of hurdle technology helps to extend its shelf life. Hurdle technology for pressure cooked chevon keema by application of humectants such as sugar, isolated soy protein, skimmed milk powder, and sodium chloride; acidulants such as lactic acid; preservatives such as spices, sodium nitrite, and sodium ascorbate; and vacuum packaging increase its refrigerated shelf life by up to 18 days.

Keema can be used for the preparation of curry, kofta (meatballs), and enrobed meat product samosa. Samosa is a traditional Indian fried product for which different vegetarian stuffings are used, but recently minced chicken meat stuffing has been introduced along with other vegetarian stuffs/spices and it is highly preferred in the market.

Dry salted Meat

Dry salted meat can be prepared from both small and large ruminant meats. The meat is cut into long strips up to

12.5–2.5 mm (0.5–1 in.) in breadth or into small chunks. They are sun dried after adding salt and turmeric powder. This gives a long shelf life to these products and they are rehydrated before cooking. In western Maharashtra, particularly in adjoining areas of Kolhapur, the dry salted meat is called 'Chunchunya,' which is oil fried before eating. In Pakistan there is a dried lamb meat called 'Landhi,' which originated in Balochistan province. Sheep are specially fattened for landhi meat, which is eaten during the winter season. In the north-eastern region these dried meats are called Satchu or Suka ko masu or Chartayshya.

Kargyong

Kargyong is an ethnic sausage-like product from the Himalayan region prepared from yak meat or beef or pork and called yak or lang or faak kargyong, respectively. The finely chopped meat and its fat is mixed with salt, garlic, and water; this mixture is stuffed into a natural casing (intestines) called gyuma. After sealing the casing is boiled for 20–30 min and air dried/smoked on bamboo over a kitchen oven for 10–15 days. Similar products called Kheuri (sheep stomach is used as casing) and Chilu (fat is stuffed instead of meat) are prepared in Sikkim. In the Kumaon region there are variants called Geema and Arjia.

There are several other meat products that are prepared with slight variations from the traditional meat preparations already in vogue, e.g., shaljam (meat cooked with turnip) and variants of meat curry similar to Kolhapuri red curry such as korma, chettinad, keralite stew, and dopiyaza. There are many cookbooks that include recently improvised dishes that are mainly based on the original ethnic meat products, and these can be even further modified to meet individual preferences.

Conclusions

Traditional meat products are part of the identity of a local culture and have unique sensory attributes to satisfy the gastronomic desires of the vast majority of a local populace. They have immense potential to generate income and employment for the local people by organized production of these products. At present there are many products that are not scientifically standardized and for which there is no comprehensive information available for their commercial production. The present preparation in batches is time consuming and there is limited shelf life. Thorough knowledge of their formulations, process optimization, commercial production, advanced packaging, and cold chain for distribution could definitely put many potential traditional meats on the world map. Retort pouch processing can be applied to some of the ethnic meat products from the Indian subcontinent such as curries, pickles, biryanis, keema, goshtaba, and haleem to exploit their market potential. Certain products, such as tandoori, owing to their protein-rich and low-fat nature can be marketed as healthy foods. With better know-how and technology, the ethnic/traditional meat products from the Indian subcontinent could become more popular and more widely available worldwide.

Japan and Korea

YH Brad Kim, Purdue University, West Lafayette, IN, USA
A Jang, Kangwon National University, Chuncheon, Republic of Korea

Introduction

Japan and Korea share many similarities in environments and cultures in general, which is very understandable when considering the geographical and historical close relationships between these two countries. In terms of eating culture, for example, consumption of three meals a day (mostly including steamed rice, soup, and/or vegetables) using chopsticks and spoons (rather than knife and fork) is typical in both countries. The limited amount of arable land, due to the large areas of mountainous terrain and four distinct weather seasons of both Japan (multi-island) and Korea (peninsula), has contributed to diets based on the consumption of grains and vegetables (and/or seafood) rather than large quantities of meat and/or processed meat products. However, meat consumption in Japan and Korea has been gradually increasing and thus various and unique meat-based diets have developed. The influence of religion on East-Asian cultures (namely, Confucianism and Buddhism) has resulted in a greater emphasis on food preparation and presentation (visual appearance) based on philosophies of harmony within the body and a close commune with nature. Particularly, the historical application of 'yin and yang' in both health and diet has been extended to Korean cuisine. Although there are many similarities in lifestyle between the two countries, each country also has its own distinctive meat-based cuisine.

Japanese Meat-Based Cuisine in General

Japanese cuisine has historically been influenced by both China and Korea. However, such influences have mingled with unique Japanese natural resources and culture contributing to a well-established Japanese cuisine. Japan has a relatively short history of developing meat-based foods in its tradition, compared to other neighboring Asian countries. This is likely due to both the historical influence (as Buddhism prohibited the consumption of meat and fish) and the natural/geographical restriction (with the mountainous terrain limiting large open areas of arable land) in Japan. Thus, the Japanese have developed more of a seafood-based cuisine rather than one based on meat products such as beef, pork, and chicken. One of the most popular Japanese specialties is sushi (fish and rice mixed with rice vinegar called su; Figure 1). Sushi is formed with fish (or other seafood) and rice to make decorative, finger-food sized mounds served with pink, pickled ginger and soy sauce with wasabi (green horseradish-like condiment) for dipping. Various types of sushi have been developed such as Nigirisushi (rice topped with sliced raw fish called sashimi), squid, cooked octopus, crab, shrimp, omelet strips, salmon, sea urchin (uni), or flying fish (tobikko) and makisushi (wrapped in a strip of seaweed; often a roll of sushi rice with cucumber, tuna, mushrooms, or other fillings wrapped in a sheet of seaweed and sliced into individual pieces). The increasing popularity of sushi has 'migrated' into the Westernized style sushi (e.g., California roll) to suit the Western palate, which often includes beef or chicken teriyaki as well.

The Japanese meat-based foods were substantially revised and then were popularized for general consumers after the Meiji restoration in 1867. One particular delicacy is Kobe beef, which refers to beef from the Tajima strain of Wagyu cattle (Japanese black Angus breed) raised in Japan, which is well-recognized for its flavor, tenderness, and juiciness due to high-marbled fat composition within meat (Figure 2). Although Kobe is the main cattle strain known world-wide, there is also Yonezawa (also named Omi) and Matsusaka named after the areas in which they were raised and are equally respected in Japan. The Kobe (or other breeds) beef is often prepared as grilled-steak, steamed in a boiled pot as shabu-shabu or sukiyaki, or even thinly sliced fresh raw as sashimi. Pork is often prepared as the agemono-style dish of deep-fried breaded pork cutlets (called tonkatsu; Figure 3). Chicken is a

Figure 6 Yakitori (http://en.wikipedia.org/wiki/File:Cooking_yakitori.jpg).

favorite as grilled/marinated skewers called yakitori (teriyaki sauce-glazed skewers), and may also be served as sashimi.

Deep-Fried Japanese Meat-Based Dishes

'Karaage' is a deep-fried (agemono) bite-sized meat nugget coated with a mixture of egg, seasoned wheat flour or potato starch, and water before deep frying in a light vegetable oil (Figure 4).

'Tempura' is a very similar dish to Karaage but the ingredients used are mostly seafoods, such as prawns, fish, and/or vegetables.

'Korokke' is a breaded and deep-fried flat patty containing minced meat, seafood, or vegetables with mashed potato or white sauce rolled in wheat flour, eggs, and breadcrumbs (Figure 5). Korokke is originally related to a Portuguese dish, the croquette, which was introduced in the early 1900s.

'Katsu' is another agemono dish of deep-fried breaded chicken cutlets or pork cutlets (tonkatsu; Figure 3). The meat (pork fillet, pork loin, chicken, or fish fillet) for katsu is usually seasoned with salt and pepper, coated lightly in flour, eggs, and bread crumbs before being deep-fried. It is normally served with steamed-rice, miso soup, shredded cabbage, and katsu sauce.

Grilled/Pan-Fried Japanese Meat-Based Dishes

'Yakitori' is grilled/marinated chicken usually cooked on charcoals or gas/electric grill as yakiniku style (Japanese barbecue). The several bite-sized chicken pieces are skewered on a bamboo skewer and often lightly glazed with teriyaki sauce made with mirin (Japanese popular condiment; a kind of rice wine), sake, soy sauce, and sugar (Figure 6).

'Teriyaki' is one type of grilled yakimono dish: a broiled, grilled, or pan-fried meat, fish, or chicken marinated with teriyaki sauce. The meat is dipped in or brushed with the teriyaki sauce several times during cooking. The sauce is made with mirin (Japanese popular condiment; a kind of rice wine), sake, soy sauce, and sugar or honey (and sometimes with ginger, sesame, or garlic) by boiling (reducing) to reach the desired thickness.

Steamed Japanese Meat-Based Dishes

'Shabu-shabu' is a type of nabemono (Japanese hot pot) dish (food that is slowly simmered at the table and one-pot dish; Figure 7) similar to a Mongolian hot pot. 'Sukiyaki' is also very similar in style in that both consist of thinly sliced small pieces of beef and vegetables and served with sukiyaki sauce made from coconut, fermented tofu, tahini, peanut butter, sugar, garlic, lime, and spices. However, shabu-shabu is generally considered to be more savory and less sweet than sukiyaki. A more expensive beef slice cut, such as Kobe beef rib eye, may also be used, but often pork, crab, chicken, duck, or lobster is used. The dish is prepared by simmering a thin slice of meat and pieces of various vegetables in boiling broth in the pot. After the meat is cooked, vegetables are then cooked in the broth and eaten with sauce – noodles, also often cooked in the pot and consumed with the broth at the end.

Korean Meat-Based Cuisine in General

Korea has natural historical associations with both China and Japan, as geographically Korea is located between both countries. Yet, in spite of this, Korea has maintained and developed a distinctive culture (including a special cuisine style) independent of both these countries. One of the most unique characteristics of Korean cuisine is the highly seasoned meal preparation and colorful presentation of dishes. In particular, the mixture and balance of the five tastes (sweet, sour, bitter, hot, and salty) and five colors (white, red, black, green, and yellow) in foods based on the application of 'yin and yang' in both health and diet context, are considered important for serving dishes. Korea is not geographically suitable for raising livestock on an extensive scale (although a significant number of cows, horses, pigs, and chickens are raised) as the mountainous peninsula mostly forms the country's backbone, but hunting and fishing are quite common. Populations once hunted game meat such as deer, wild boar, and pheasants. Some ancient Korean cultures (especially the Goryo dynasty) refrained from the slaughter of cattle and eating meat because of the influence of Buddhism. However, various unique meat-based dishes have been developed since the thirteenth century. Traditional Korean meat-based cuisines can be classified according to the animal species, cooking, or processing methods. However, meats are usually dried as jerky, roasted (gui) on a charcoal grill (bulgogi), steamed (jjim) or boiled for soup (tang), and casseroled (jeongol or sinsullo). For roasting meats, charcoal and gas or electric grills are now used. The use of charcoal is the most traditional cooking method and Koreans especially prefer lump charcoal to the more common pillow-shaped briquettes and hexagonal sawdust briquettes elsewhere. Bulgogi is one of best known Korean barbeque dishes that is marinated with bulgogi sauce including soy sauce, garlic, onions, and sesame oil.

Korean meat products are usually consumed as banchan (side dishes) of the meal and in particular anju (a side dish consumed with alcohol). Among the various Korean meat cuisines, beef and beef variety cuts are especially popular. Cubes, thin slices, or small ribs of marinated beef from Hanwoo (Korean native cattle) and other various cuts are grilled at the table over a small charcoal brazier or gas grill and are one of the most characteristic Korean meat-based dishes (Figure 8). Also, many cuts/portions of pork and chicken are

Figure 7 Shabu shabu (http://en.wikipedia.org/wiki/File:Shabushabu.jpg).

Figure 8 Korean barbeque of Hanwoo beef on charcoal grill and Hanwoo galbigui on gas grill.

used in Korean cuisine in variety of cooking methods such as steaming, stewing, boiling, and smoking.

Grilled/Pan-Fried Korean Meat-Based Dishes

'Gogigui' is a particular method of grilling beef, pork, chicken, or other kinds of meat and by-products. The small size (thin) meat cuts are grilled at the diner's table on a gas or charcoal brazier, which is often built into the table as well (Figure 8) and consumed with dipping either in sesame oil sauce mixed with salt and pepper or with doenjang, a flavorful fermented soybean paste. Along with meat, sliced onions and garlic, mushrooms or pepper are grilled and consumed with lettuce (and other leafy vegetables) by wrapping together all these cooked vegetables, meat, and sauce (called ssam). Steamed rice and doenjang soup (similar to miso soup in Japan) are often served together.

'Bulgogi' (or Neobiani) is one of the most well-known Korean specialties along with kimchi, a spicy fermented cabbage dish heavily seasoned with garlic, onions, and chilli peppers (Figure 9). Bulgogi is usually made from thin slices of loins (or other prime beef cuts) marinated with a mixture of soy sauce, sesame oil, garlic, and pepper to enhance flavor and tenderness. Pork, chicken, and duck meat can also be used for bulgogi marination. Grilling techniques using grid irons or perforated dome griddles that sit on braziers are often used for cooking. Pan-cooking is also common and it produces a delicious and very flavorful broth.

'Samgyepsal gui' consists of thick, fatty slices of pork belly meat (uncured portion used to make bacon). It is grilled on charcoal or pan-plate and Koreans eat it directly from a grill as ssam with side dishes such as various vegetables (lettuce,

Figure 9 Bulgogi served with various banchan (side dishes), leafy vegetables, and sauce (http://en.wikipedia.org/wiki/File:Korean.food-Bulgogi-02.jpg).

Figure 10 Samgyepsal gui (pork belly) and kimchi on charcoal grill.

Figure 12 Dak galbi (marinated diced chicken cuts in a chilli pepper paste) on a hot plate.

Figure 11 Galbi (marinated beef short ribs with a Korean soy sauce) (http://en.wikipedia.org/wiki/File:Korean.food-Galbi-03.jpg).

Figure 13 Raw and barbequed makchang (pork/beef intestine) on charcoal grill.

Figure 14 Jokbal (pig's feet) with fermented shrimp sauce and various vegetables.

Figure 16 Sundae (Korean-style blood sausage) (http://en.wikipedia.org/wiki/File:Korean.food-Sundae-01.jpg).

Figure 15 Bossam (http://en.wikipedia.org/wiki/File:Korean_cuisine-Bossam-01.jpg).

perillar leaves, sliced green chilli peppers, raw garlic, onions, and fermented kimchi). Kimchi is an almost universal accompaniment to Korean dishes. Most Koreans prefer samgyepsal gui to other meats and this makes it a much more expensive cut compared to most other parts of pork meat (Figure 10).

'Galbi' is another famous Korean style barbeque along with bulgogi. Galbi literally means 'rib,' so when it comes to galbi-gui, it indicates cooked ribs, although it is often used without the suffix 'gui' for the marinated-grilled beef (or pork) short ribs (Figure 11). Galbi is normally made with beef ribs (called so galbi; 'so' means beef) marinated in a Korean soy sauce including soy sauce, sesame oil, rice wine, garlic, and pepper. The meat attached to a short rib is uniformly filleted in flat layers and is marinated in the sauce for a period of time. Pork ribs or chicken cuts can be used for galbi as dwaeji galbi ('dwaeji' means pork) or dak galbi ('dak' means chicken), respectively. Just like other gogigui dishes, grilled (or pan-fried) galbi is served with various vegetables (often cooked on the grill together), steamed rice, banchan (side dishes), and doenjang soup. Galbi can also be cooked as galbi-jjim (braised in a sweet soy sauce) or galbi-tang (soup containing pieces of galbi) as galbi-applied dishes. LA galbi is another popular modernized galbi dish and as the name suggests, it originates from the Korean immigrant community in Los Angeles, CA, USA. Basically, it is marinated in a similar way to normal galbi, but the rib is thinly cut across the bone (thus thickness of meat/rib is approximately 0.5 cm).

'Dak galbi' is a popular Korean chicken dish made from marinated diced chicken cuts in a chilli pepper paste (gochujang) with sliced cabbage and sweet potato cooked together on a hot plate. Literally, dak galbi means chicken ribs, but it uses most cuts of the chicken (Figure 12).

'Makchang and gopchang gui' is pork or beef large intestines grilled over charcoals or frying pan. Careful preparation needs to be done to remove unfavorable odors and excessive fat. It is served with dipping sauce made from a mixture of doenjang (Korean fermented bean paste), ground garlic, and chopped scallions (Figure 13).

Figure 17 Korean traditional samgyetang (ginseng chicken soup) served with kimchi.

Figure 18 Seollongtang with steamed rice and kimchi.

Steamed/Soup Type Korean Meat-Based Dishes

'Jokbal' is pig's feet steam-cooked with soy sauce and spices such as ginger, garlic, sugar, and rice wine. Once it is completely cooked, bones are either removed or left attached, and the meat is cut into slices and served cold often accompanied with fermented shrimp sauce (called saeujeot) for dipping or ssamjang (mixed paste condiments with doenjang and gochujang). Jokbal is rich in gelatins and thus gives unique greasiness and flavor. It is often eaten as ssam by wrapping in lettuce with other vegetables by hand (Figure 14).

'Bossam' is a type of typical Korean ssam dish that uses steamed pork (usually shoulder or belly portion cooked in a similar way to jokbal) wrapped in lettuce topped with various leafy vegetables, garlic, onions, and freshly made kimchi often accompanied with ssamjang (Figure 15).

'Sundae' is a type of blood sausage, steamed pig (or cow) intestines stuffed with various contents such as cellophane noodles (called dangmyeon), barley, and pork blood. However, as variations, different kinds of sundae fillings can be stuffed such as rice, kimchi, soybean sprouts, and scallions (Figure 16).

'Samgyetang' is representative of summer cuisine in Korea and also known as ginseng chicken soup. Traditionally, it is made from whole chicken (especially 35-days old chicken), Korean ginseng, dried jujube, whole garlic, and ginger. Owing to the highly nutritious compounds in the chicken soup, Korean people believe it helps to recover the exhausted body in the hot summer (Figure 17).

'Seollongtang' is a beef bone stock; beef leg bones (sometimes ox tail) are boiled/simmered for from several hours to an entire day to extract a nutritious broth containing collagen and minerals. Spring onions, pieces of steamed sliced beef cuts, and noodles are often added in seollongtang to bring more flavor and good taste. Additional seasoning including salt, ground black pepper, red pepper, minced garlic, and chopped spring onions can be added to seollongtang based on personal taste. Kimchi and steamed rice are also served alongside (Figure 18).

Raw Korean Meat-Based Dish

'Yukhoe' is made from raw chopped/ground beef seasoned with various sauces, spices, and other ingredients such as soy

Figure 19 Hanwoo beef yukhoe (marinated raw beef dice) and sashimi.

sauce, sugar, salt, sesame oil, onions, garlic, sesame seeds, black pepper, Korean pear, and a raw egg yolk. Sashimi is served with very fresh raw meat sliced into thin pieces. Owing to safety, only fresh meat can be used and served with sesame oil and salts (**Figure 19**).

Glossary

Dry curing The typical process involving the use of cure (potassium nitrate or sodium nitrite mixed with salt) followed by long drying.

Drying Products are slowly dehydrated thorough progressive reduction in relative humidity, reaching relevant losses in weight due to water evaporation.

Lipolysis The enzymatic breakdown of lipids with the formation of free fatty acids.

Proteolysis The enzymatic breakdown of proteins with the formation of peptides and free amino acids.

Water activity (a_w) It indicates the availability of water in a food and is defined as the ratio of the equilibrium water vapor pressure over the system and the vapor pressure of pure water at the same temperature.

Introduction

There are many types of meat products in the Mediterranean area that have been produced for centuries. These products exhibit a wide variety of flavors and textures. Today, these products still constitute an important part of the local economy, culture, gastronomic heritage, and tradition. Even though the technology has evolved and become mechanized, the basic processing still relies on traditional manufacturing processes, mostly based on salting and ripening. The products develop intense and characteristic texture and flavor, especially during ripening and drying, where enzymes and microorganisms play an important role. The drying of these products is a common practice due to the privileged Mediterranean climatic conditions. Main types of products and their specific characteristics are described in this article.

Mediterranean Meat Products

Dry-cured ham constitutes one of the main and representative products in Mediterranean countries. Some of the most well known of them are Spanish jamón Ibérico and jamón Serrano, French jambon de Bayonne, Italian prosciutto di Parma and prosciutto San Daniele, Portuguese presunto, and Croatian Istrian dry-cured ham. The production of these hams is based on a careful selection of the raw materials (back legs from specific pig crossbreeds), control of time and processing conditions at key stages like salting (for the penetration of salt and other curing agents), postsalting (to allow salt and curing agents to diffuse through the entire piece), and ripening/drying (for water loss and flavor development). The weight loss may reach 35%. Hams are rigorously controlled at the end of the process for the quality of color, texture, and flavor. Minimum processing time is usually more than 9 months, but for the highest quality such as Iberian hams, the processing time may last up to 24–30 months. The result is a ham with extremely rich flavors that are generated through enzymatic reactions. An Iberian dry-cured ham is shown in Figure 1. These hams are usually consumed raw, cut into thin slices (Figure 2), without further smoking or cooking.

Lacón is a dry-cured product similar to dry-cured ham but produced using the foreleg. It is also salted and dried but the processing time is shorter, usually approximately 4–5 months and is mainly produced in Spain.

Dry-cured loin is an entire piece produced from pork loin. It is cased and rubbed out with salt and spices and dried for 1–2 months until reaching a water content of approximately 50%. Its name is lomo curado in Spain. Another similar product produced from beef in Greece is pastirma.

Culatello is produced in Italy from the large part of the ham near the bottom. It is packaged with the pig's bladder and tied using slip knots in order to keep its nice round shape. Then, culatello is salted and dried like the hams. The

Figure 1 Iberian dry-cured ham (Jamón Ibérico).

 doi:10.1016/B978-0-12-384731-7.00192-6

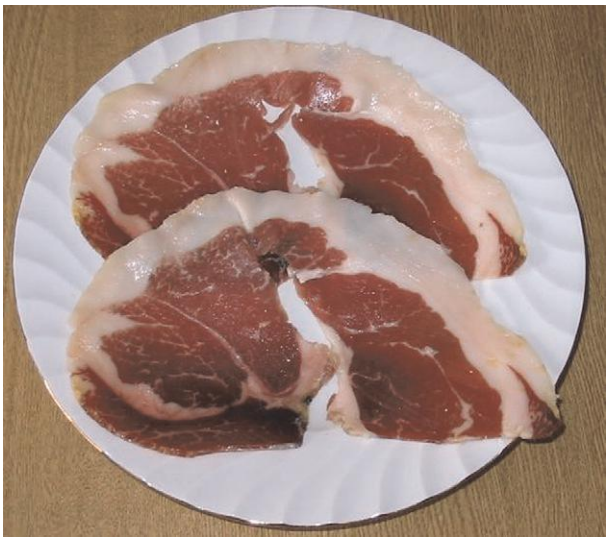

Figure 2 Cross section of Iberian dry-cured ham showing typical marbling.

Figure 3 Typical presentation of sliced chorizo as served in restaurants.

processing is usually between 10 and 14 months. Culatello di Zibello is produced in Parma (Italy).

Coppa is a type of Italian salami made from pork shoulder butt which is salted for 7–10 days and dried for 2–4 weeks. The shape is cylindrical and drying depends on the natural climate conditions in the valley of origin.

Bresaola della Valtellina is a well-known meat product produced in an Italian Alpine valley. Bresaola is made from selected beef cuts from the leg, trimmed of fat, salted, and optionally marinated with additional wine, sugar, and some spices for 7–10 days, stuffed in natural or artificial casings, and dried for more than 4 weeks. The final product has a bright red color and is eaten raw as very thin slices. A similar product, known as cecina, is produced in Spain.

Mortadella Bologna was originated in the sixteenth century in the outskirts of Bologna, where meat was ground in a mortar. Mortadella is produced from pork meat and fat, finely ground and minced, stuffed in natural or artificial casings, and thermally treated to an internal temperature of 68 °C. The final product has a uniform pink color, and white fat spots are evenly distributed through the meat mixture.

Italian salami, like Milano salami, is produced from finely ground pork meat and fat, mixed with salt, sugar, curing agents, and spices, and stuffed into a casing for slow and mild ripening and drying that may take as long as 3–6 months, sometimes even longer. The cross-section is red, with well-defined fat particles having the size of a rice grain. Other products include Hungarian salami, Greek Lefkada salami, and Spanish salami.

French saucisson is produced from coarse ground pork meat and fat, mixed with salt, sugar, curing agents, and spices, and stuffed into casing for a slow and mild ripening and drying. Fermentation occurs at low temperatures, usually <20 °C with slow acid generation and does not fall below pH 5.0. Smoke is not generally applied except for typical sausages in Hungary. The total processing may take up to 6 months, sometimes even longer. The cross-section is dark red, with well-defined large fat particles. Well-known dry fermented sausages include Spanish salchichón and French saucisson d'Alsace.

Spanish chorizo is based on pork and beef with added pork fat, salt, sugar, curing agents, and spices like red pepper, paprika, garlic, and oregano and stuffed in either natural or artificial casings. It is fermented for 1–2 days and ripened and dried for 1–3 months. There are many types of chorizo depending on the diameter, shape, size, sensory characteristics, and geographic origin. In general, it is characterized by a cross-section with an intense red color and uneven distribution of fat (Figure 3).

Most of these Mediterranean typical products have been protected with European Union certifications like the Denomination of Protected Origin (DPO), the Protected Geographical Indication (PGI), or Traditional Speciality Guaranteed (TSG). There are many DPOs in the Mediterranean area. In case of Spain, there are three for Iberian hams: Guijuelo, Dehesa de Extremadura, and Huelva and one for non-Iberian hams, which is denominated Teruel. However, jamón Serrano is Traditional Speciality Guaranteed. Raw materials, processing conditions, and quality of the finished products are rigorously controlled by respective Consortiums or Local Entities who are responsible for achieving the established requirements. For instance, the Serrano Foundation controls all hams produced in Spain which are stamped as Serrano. In a similar way, the Parma consortium controls the hams produced in Parma and stamped as prosciutto di Parma.

Glossary

Dawood Basha Minced meat with rice.
Hawawshy bread Minced meat and wheat dough.
Kebabs Grilled, roasted, and stewed dishes of large or small cuts of meat or even ground meat; it may be served on plates.
Masmat A dish containing head meat, stomach, eyes, and tail.
Membar A dish containing the lungs, spleen, large intestine, esophagus, and rice.
Nakanek A seasoned traditional sausage from uncured beef trimmings.
Pastrami A seasoned, dry-cured longissimus.

Introduction

Meat products made from different ingredients are produced to meet consumer demands. In the Middle East, local foods are available in a huge variety derived from culture. Religion also influences the variety and unique flavor differences found in the Middle Eastern foods. Muslims, Christians, Jews, and Arabs have specific preferences for and prohibitions against certain ingredients, such as lamb, fish, beef, or pork. Particular ingredients and preparation techniques are specific to specific religious groups.

The Middle Eastern Meat Products

Owing to religious considerations, the bulk of meat products consumed in the Islamic Middle Eastern area are prepared from cattle (beef and buffalo), mutton, lamb, goat, camel, and sometimes poultry. Because of local habits, horse meat is also used in countries in northwest Africa, such as Tunisia, Algeria, and Morocco.

Lamb and mutton are particularly favored in the Islamic region, where pork consumption is forbidden. These types of meat are seasoned and grilled as kebabs, a popular food in the Arab world. Chicken is a popular everyday food, but quail, pigeon, goose, and duck are also commonly eaten. Christian communities in the Middle East consume a lot of traditional pork products, such as ham, frankfurters, and mortadella.

Sausages

The word sausage is derived from the Latin *salsus*, meaning salted or preserved. Salami is mentioned frequently in the pre-Christian period and may be associated with the Greek city of Salamis in Cyprus. Sausages may be defined as foods prepared from chopped and seasoned meat formed into a symmetrical shape. The origin of sausages dates back to ancient history, because they were mentioned as early as AD 228 by Athenaeus in the *Deipnosophists*, the oldest known cookbook.

Sausage types in the Middle East are grouped according to processing methods. The following groups can be considered to be ethnic products.

- Fresh sausages with the traditional name 'nakanek' are made from uncured beef trimmings. They are delicately seasoned and are very popular. They require refrigerated handling and cooking before consumption.
- Uncooked smoked sausages are usually cured and smoked but not cooked. They require refrigerated handling.
- Fermented and heavily smoked all-beef sausages were originally produced in Lebanon. The fermentation was originally caused by a natural microflora but is now a result of using starter cultures.

The individual sausage varieties in the Middle Eastern countries are distinctive, not only due to the uniqueness of the seasoning but also due to the type and coarseness of mincing the meat constituents as well as the manner in which the sausages are stuffed and processed. In addition to animal tissue, they contain flavors derived from olive oil, garlic, rosemary, black pepper, cardamom seeds, cinnamon, coriander, onion, paprika, nutmeg, ginger, cloves, and a variety of fillers and binders including maize, wheat, oat, and rice flour, which are specific to the Middle East.

Pastrami

Pastrami is popular in the Middle East and is made from the complete muscular longissimus dorsi, which is dry-cured, aged for 7 days in curing tanks, and then air-dried for another 4 days before it is coated with a paste composed of finely powdered Greek paprika and salt. The pastrami is then hung for at least 15 days for completion of the curing before it is sliced just before consumption. The color is dark red.

†Deceased.

Other Meat Products

Other meat products consumed in the Middle East include those made with minced meat and corned beef.

Minced meat with rice (Koftet ros) is usually known as Dawood Basha. It is also mixed with burgol and kobaba. Corned beef is made from beef (approximately 80%), fat (maximum 15%), salt (maximum 3%), and sodium nitrite (maximum 0.005%).

Traditional Meat Dishes

A number of traditional meat dishes are consumed in the Middle Eastern countries. These are described briefly below.

- A sweet dish is made from the lungs, spleen, large intestine, esophagus, and rice (Membar). These products are usually cut and fried in oil. Such meat dishes are popular and traditional in Egypt but are sometimes also eaten in Syria and Turkey.
- Masmat is a dish including the lower part of legs (known as Kawareh), head meat, stomach, eyes (known as Gawaher), and tail (known as Akkawi).
- Blanched feet of buffalo or cattle are traditionally used in Egypt and Syria. The soup created in the process is very nourishing.
- Kobeba is a traditional dish in Lebanon and Syria. It is prepared by mixing beef with an equal amount of broken wheat. It is cooked with tomato and 'kesk' (an Egyptian speciality based on milk and flour).
- Hawawshy bread is a special dish originating from Egypt and is made by mixing minced meat with wheat dough in the shape of bread and baking it in an oven.

Glossary

Barbecue A method of cooking over low heat for long periods of time that involves the application of wood smoke. This is most often done in an oven that uses wood as the primary source of heat. It is to be differentiated from the term 'barbecue' as a synonym for outdoor cookery on a grill.
Bologna A medium to large diameter cooked sausage that is normally used as a sliced luncheon meat.
Jerky A term applied to a thin dried meat that is shelf-stable and ready-to-eat.
Shelf-Stable Meat products that require no refrigeration.
US Department of Agriculture Food Safety and Inspection Service (USDA-FSIS) The regulatory agency of the US government responsible for meat and poultry.

Introduction

The statement that 'necessity is the mother of invention' was never more true than in the development of various ethnic meat products. Local conditions of climate and availability of ingredients plus the need to preserve food for long periods without refrigeration led to the development of meat products that have now become part of our culture. For example, jerky is no longer an item of necessity but has evolved into a popular snack item in the US.

Pemmican

The origin of pemmican is usually attributed to the North American native people. Pemmican is a mixture of dried meats and dried berries or fruits which, by tradition, were pounded together and mixed with melted or partially melted animal fat. It can be compared to modern-day 'energy bars' and served the same purpose, that is a high-energy compact ration that is shelf-stable. Very little, if any, pemmican is produced commercially. There are, however, some commercial derivations of pemmican that have been used in the past as military or camping rations. One of the chief problems in the stability of pemmican and similar products is the high fat content and the tendency to develop oxidative rancidity.

Whole-Muscle Jerky

Whole-muscle jerky can be made from a variety of lean meat, poultry, game and fish sources. It consists of thin strips of lean muscle tissue, usually cut parallel to the muscle fibers. The meat is cured and generally smoked. In the US, jerky is required to reach a moisture:protein ratio (MPR) of 0.75:1 to be labeled as 'jerky'. To be considered shelf-stable (not requiring refrigeration) jerky should be dried to a water activity (A_w) of at least A_w 0.85 and preferably lower.

The meat that is selected for use in jerky is usually less than 10% fat and should be as free from visible connective tissue as possible. It is sliced approximately 5 mm thick parallel to the muscle fibers. The length and width of the strips may vary. To aid in obtaining uniform slices, the meat may be sliced in a partially frozen state. It is cured by applying a dry mixture of curing ingredients and spices. Predominant spices and flavorings include ground black pepper, ground allspice, and garlic powder. Salt content is usually in the range of 3% of the meat weight. A variety of other spices and flavorings can be added depending on consumer preferences. Cayenne pepper is often added to give a spicy flavor. Application of the dry spices and flavorings, curing ingredients, and salt can be achieved effectively by using a tumbler.

Following the application of the salt, cure, and flavoring ingredients, the meat mixture is then held for 24 h at 4 °C to allow the curing ingredients to penetrate the thin strips of meat prior to the drying and smoking process. Following curing, the strips are either hung on combs or laid on racks. Smoke can be applied in a traditional manner or by drenching or atomizing liquid smoke. A variety of wood sources can be used such as fruitwood, mesquite (a very resinous wood that produces a pungent flavor), alder, or any of the traditional hardwoods. This smoking and drying is usually done at a temperature of 60 °C. Care must be taken to prevent 'case hardening', which will ultimately interfere with the correct drying process.

Once the appropriate degree of dryness is reached, the product is ready for packaging and shipment. Jerky may be vacuum-packaged or packaged in a high-oxygen and moisture-transmitting package. Any type of package or container that allows for a high-humidity atmosphere should be avoided, because this will encourage mold growth.

Restructured Jerky

Jerky can be made as a restructured as well as a whole-muscle product. The same lean raw material is first minced through a coarse plate (13 mm) and then mixed with the spices and flavorings, salt, and curing ingredients. It is then reminced through a 3 mm plate. The mixture is extruded in strips approximately 5–9 mm thick and 20 mm wide. The length can be variable, depending on consumer preferences. After extrusion, the strips are laid on perforated metal or plastic screens

for immediate drying and smoking. Drying and smoking procedures are the same as for the whole-muscle product. Packaging procedures are also the same. Restructured jerky lends itself to a continuous processing system.

Another process for forming restructured jerky is to form the meat mixture into a loaf with the desired dimensions of length and width. The loaf is then frozen and subsequently tempered to a convenient slicing temperature. It is then sliced into strips of appropriate thickness. This procedure is less efficient than the preceding one and is only used where small quantities are produced.

Summer Sausage

The term 'summer sausage' is applied to a variety of US semidry sausages similar to the European cervelat sausages. These sausages enjoy their greatest popularity in the midwestern US. The name originated from how this product was first made. Farmers would make sausage in the fall and winter months, and this sausage would be hung in the smokehouse or similar location, and because of fermentation of sugars that were added to the product, the sausage would be safe for consumption during summer months, without refrigeration. This product generally will have a rather low pH, sometimes as low as 4.6. Summer sausage is usually a mixture of beef and pork, although sausages made of beef alone are common. These sausages may be fermented or acidified using various acidulants such as encapsulated acid or glucono-δ-lactone. The US Department of Agriculture Food Safety and Inspection Service requires that summer sausage have an MPR of 3.1:1 or less, a pH of 5.0 or less, as well as fully cooked and smoked to be considered as shelf-stable. For consumer protection, those summer sausages that do not meet shelf-stable requirements should be labeled 'Keep Refrigerated'.

The final mincing size for this product ranges from 3 to 5 mm and the predominant spice used is black pepper along with coriander and mustard. Sometimes whole peppercorns and whole mustard seeds are added and the product may contain garlic. It is smoked or natural smoke flavoring is added.

Fibrous, collagen, natural or laminated casings are used; casing size ranges from 40 to 120 mm. Some of these sausages may be stuffed in a variety of novelty casings ranging from those shaped like American footballs to beer bottles. Summer sausage is often a component of food gift boxes in the US because of its shelf-stability.

Lebanon Bologna

This sausage is unique to the area around the town of Lebanon, PA, USA. It probably has its origin in the European cervelats. It is an all-beef product with a final mincing size of 2–5 mm. Casings are the same as those used for summer sausage. It is fermented to a very low pH (approximately 4.5). The predominant spice used is black pepper. The product is very heavily smoked and has a distinctly 'tangy' and smoky flavor.

Scrapple

Scrapple is a product that originated in eastern Pennsylvania. It consists of a corn (maize) meal that is cooked to a thick gruel or mush to which is added cooked meat and meat by-products. The mixture is then chilled in loaf molds. The chilled loaf is sliced by the consumer and fried. It is usually served as a breakfast item. It should contain 40% meat and meat by-products. Cooked pork head meat is the typical meat source. Characteristic spice flavorings are pepper and sage.

Hamburger or Ground Beef Patties

The ubiquitous hamburger has become a staple of the US fast food industry and a symbol of US culture worldwide. The origins of the 'hamburger' (a ground beef patty) are clouded in conflicting legend. Suffice it to say that the popularity of this fast food staple mushroomed after World War II with McDonalds given the credit for leading the charge.

Depending on regulatory labeling requirements, the patty is made from beef skeletal muscle with restrictions placed on the addition of nonmeat fillers, extenders, or texture modifiers. Final grind size of the meat is usually 3 mm. Conventional wisdom places the fat content at 20%, plus or minus 2% for optimum palatability. There have been attempts to market lower fat versions of the hamburger but these have not attained any great consumer acceptance. Patties may either be marketed as fresh (nonfrozen) or frozen. Patty forming is accomplished using a variety of high speed forming machines. Rapid freezing is mandatory to maximize palatability. Particular attention needs to be paid to microbiological safety with special emphasis on *coliforms*, particularly Shiga Toxin producing *Escherichia coli*'s such as *E. coli 0157:H7*.

Barbecue

This is another particular US phenomenon. Within the US there are wide regional differences in what is considered barbecue. Common to all of the regions is the use of less tender cuts of meat that have been slow cooked at low temperatures over a wood fire or in a wood fired oven or with some other application of smoke. Usually a mixture of spices is applied to the surface of the primal cut and a sauce 'mopped' on the surface during cooking or applied to the finished product after cooking. Characteristic of all true barbecue is the 'smoke ring', a red color that develops in the first few millimeters of the surface as a result of exposure to oxides of nitrogen from the combustion gases of wood. Some of the regional variations of barbecue are: In Kansas City, MO, USA barbecue means pork spare ribs or back ribs served with a thick, sweet, tomato and molasses-based sauce. In Memphis, TN, USA it would be any cut of pork, including ribs that uses a sweeter, tomato-based sauce. As you move south and east it is pork with thinner sauce that is vinegar-based, often with red pepper flakes. A unique version characteristic of Columbia, SC, USA is pork with sweet, vinegar and mustard-based sauce. In Texas, barbecue usually means beef brisket with a spicier sauce similar to the Kansas City version. In addition to pork shoulder cuts, ribs, and beef brisket you may find whole hog, beef ribs, lamb, goat, and poultry.

A variation of barbecue is 'pulled pork' where pork shoulders cuts are cooked at low temperatures until the meat shreds easily. This cooked pork is marketed as a heat-and-eat product covered in an appropriate regional barbecue sauce. There are beef and poultry versions of this product.

Buffalo or Hot Wings

This terminology has nothing to do with the species, water buffalo or the American bison. It is a finger food that originated in the 1960s. According to legend it can be traced to the Anchor Bar in Buffalo, NY, USA (hence the name, Buffalo) and consists of the meatier joints of the chicken wing. The joint proximal to the body, called the 'drumette', is the meatiest and the preferred raw material. The next joint, called the 'flat' is sometimes used. The wing joints are fried and then tossed with a cayenne pepper sauce that usually contains butter and hint of garlic. The wings may be smoked and precooked prior to frying. Boneless versions of the bone-in wings are growing in popularity. Variations of this flavoring are applied to other cuts of meat and poultry. This product has become closely identified with sporting events in the USA. The National Chicken Council estimates that 1.25 billion wings were consumed on Super Bowl XLVI Sunday alone. Recently, an entire food industry has grown up around the Buffalo flavoring and wings have become one of the more valuable parts of the chicken.

Chili Con Carne

Chili con carne (usually referred to simply as chili) consists of coarse ground (6 mm) or diced meat slow cooked with a sauce containing chili peppers and usually tomatoes. The meat is normally beef although pork, lamb, and goat could also be used. Other flavorings such as cumin, onion, garlic, oregano, and even unsweetened chocolate may be added. Beans (navy, pinto, kidney, or black) are often added. The mixture is often sterile canned. Chili con carne is typical of the Southwestern USA and Mexico.

Glossary

Coarse ground Trimmings with the diameter 5–20 mm.
Curing Preserving, usually restricted to preserving with salt, nitrates and/or nitrites and other condiments, using dry or wet (brine) methods.
Meat specialties A wide variety of products that have in common only the fact they are chopped or comminuted meats and edible offals, seasoned, and usually cooked or baked rather than smoked.
Sausages Made from uncured or cured meats, ground, seasoned, stuffed into casings, smoked or un smoked, heated or dried under controlled time–temperature–humidity conditions.
Smoking Applying smoke on meats for color, flavor, and preservation.
Trimmings Pieces removed or cut in the process of trimming, usually the edible lean portions, use for sausages.

Introduction

The oldest written information about processed meat comes from ancient Greece and the Roman Empire, but at present, Central Europe is probably the number one region in the world with respect to consumption and variety of processed meat products. Varied climatic conditions required many methods of meat preservation (salting, curing, marinating, smoking, cooking, and drying) used in different combination with specific types of meat (pork, beef, game, mutton, horse, and poultry), resulting in many different kinds of final products. Every day in the Czech Republic, Germany, and Poland hundreds of different processed meat products are manufactured and their consumption (40–50%) is the highest of the total meat consumption in the world.

Polish Meat Products

In Poland, most of the processed meat products with a very specific taste and aroma that can be considered ethnic are prepared from pork (sometimes with a small addition of other types of meat, i.e., beef, poultry, game, etc.). The pork is obtained from local pig breeds raised under extensive conditions. The meat of such animals has a rather high content of intramuscular fat (marbling).

Polish processed meat can be divided into four groups: smoked meats, sausages, meat specialties, and canned meat. Smoked meats are produced from whole primary cuts of pork. Typical Polish products of this group include Polish smoked ham and Baleron. Sausages are products made from pork trimmings (sometimes with addition of beef, game, or poultry). Krakowska, Kabanosy, Mysliwska, Lisiecka, and Jałowcowa are specific Polish sausages. Meat specialties are products prepared from meat trimmings and offal, with additional cereals (barley grits and/or buckwheat), blood, and seasonings. Native to Poland in this category is Krupnioki. Intensive development of technology and techniques has resulted in similar methods used for meat canning around the world. One of the best-known Polish products in this group, Polish canned ham sold under Krakus brand name, should be specifically mentioned.

Polish smoked ham is produced out of whole pork hind legs (bone-in or bone-out), dry-cured for 20–30 days or by wet method for 10–14 days, smoked in warm smoke, cooked, and smoked again for specific color and taste development.

Polish baleron is produced from pork neck, dry-cured for 24 h, and then immersed in curing brine for another 8–10 days. It is then allowed to drain for 24 h, is stuffed in natural or collagen casings, smoked in warm smoke, cooked, and cooled. The cross section of the final product shows a very dark meat color with marbling. This produces a very specific flavor and juiciness.

Krakowska sucha/krakowska dry/ is produced from pork trimmings (85%), hard pork fat (usually back fat – 10%), and beef trimmings (5%) with the addition of spices (black pepper, nutmeg, and garlic). The meat is dry-cured for 3–5 days, coarse ground and mixed, stuffed into natural or collagen casings of 60 mm diameter, smoked in warm smoke, cooked, and dried for 10–23 days. The final product with its very characteristic flavor has an exceptionally dark color of coarse ground lean and designed meat with small particles of fat evenly distributed over the surface of the cross section.

Polish kabanos is produced from lean and regular pork trimmings (50/50%) coarse ground (no smaller than 8 mm of diameter) and dry-cured for 1 day. Spices are added (black pepper, nutmeg, and caraway) and the mixture is stuffed into natural (sheep) or collagen casings with a diameter no bigger than 22 mm, smoked in warm smoke, baked, and dried for 3–5 days. The final product has very specific texture and flavor.

Mysliwska (Hunter) sausage is produced from cured (dry curing for 2 days) pork trimmings of different content of fat and connective tissue and degree of grinding (class 1 – lean meat trimmings through a 20 mm plate), meat trimmings (class 2 with fat content of approximately 20%) through a 8 mm plate, meat trimmings (class 3 – with some connective tissue) through a 3 mm plate, and then chopped in a cutter with addition of 5% of ice and spices (black pepper, juniper,

 doi:10.1016/B978-0-12-384731-7.00193-8

Figure 1 Jalowcowa.

Figure 2 Kabanosy.

Figure 3 Krakowska sucha.

garlic, and sugar). To trimmings class 1 and 2, a marinating solution is added (water, acetic acid, and rapeseed or sunflower oil in ratio of 1:1:1) and mixed with chopped meat of class 3 and stuffed into natural pork casings of diameter no bigger than 22 mm, smoked in warm smoke, baked, and dried for 5–7 days up to 70% of the final yield. The final product has very specific texture and flavor.

Figure 4 Mysliwska.

Lisiecka sausage is produced from cured (dry curing for 2–4 days) pieces of selected ham muscles (excluding semitendinosus and quadriceps femoris) and 15% of 'regular' pork trimmings (50:50 of lean and fat). Meat trimmings are ground with spices (white pepper and garlic) and mixed with pieces of ham muscles and 5% of iced water, then stuffed into natural casing and formed into rounds with diameter of 35–40 cm. Smoking is done in traditional smokehouse using wood of deciduous or fruit trees for 4–5 h. The final product has very specific texture and flavor.

Jałowcowa (Juniper) sausage is produced from pork trimmings and hard pork fat (usually back fat), sometimes with addition of small amount (5%) of beef trimmings, dry-cured, mixed with spices (pepper and juniper), coarse ground, stuffed into natural or collagen casing, smoked in warm smoke, cooked, smoked again in cold smoke, and dried for 3–5 days. The final product also has a very specific flavor, which results from the spices, the types of meat used, and the technological procedure.

Krupnioki is produced from pork dry-cured head meat trimmings, liver, jowls, cereal (i.e., barley grits and/or buckwheat), blood, and spices. The meat trimmings and jowls must be precooked in water and the cereal grits should be precooked in broth (from previous cooking). Then, all the ingredients are coarse ground and mixed with spices (salt, black pepper, marjoram, allspice, and onion), stuffed into natural or collagen casings, smoked in warm smoke, cooked, and cooled.

Kabanosy, Myśliwska, Jałowcowa, and Lisiecka sausages obtained a European Union Certificate of Traditional Speciality Guaranteed Products (Figures 1–4).

The production of these sausages in Poland amounts to approximately 100 000 tons annually. Approximately 40% of these products are being sold to other countries, mainly the UK and US.

None of these products are similar to Polish sausages produced in the US. The closest is Lisiecka but produced using ham muscles.

EXSANGUINATION

MH Anil, Cardiff University, Cardiff, UK
K von Holleben, BSI Schwarzenbek, Schwarzenbek, Germany

Glossary

Bleeding/exsanguinations A procedure where the blood vessels in the neck or chest are severed.
Cardiac arrest Stopping heart beat.
Halal slaughter A slaughter procedure that adheres to Islamic teachings where the animal is dispatched by severing the blood vessels of the neck following a prayer.
Kosher The meat produced following Shechita.
Shechita The Jewish method of slaughter carried out by a trained Jewish slaughterman, shochet.
Slaughter The process of exsanguination that ensures the animal cannot recover sensibility.
Sticking Cutting the blood vessels for bleeding.
Stunning The procedure where an animal is rendered unconscious before exsanguination.

Introduction

Exsanguination is the process of severing major blood vessels in order to let sufficient blood out to kill an animal and/or complete the slaughter process. Blood is also let out of the carcass to maintain meat quality and food safety. In cases where head-only preslaughter stunning is used to render an animal reversibly unconscious or religious slaughter without stunning are employed, exsanguination is aimed at killing animals. In this situation, the cause of death would be the loss of blood, insufficient blood supply to the brain resulting in cerebral ischemia and loss of brain function, cardiac shock, and cessation of heart beat (cardiac arrest). However, if a nonreversible stunning method, such as cardiac arrest by an electric current (head and chest application) is used, this could be regarded as a killing method because most of animals would not regain consciousness even if exsanguination was not performed. Nevertheless, cause of death in these animals will often be exsanguination not by the stunning method itself, because blood loss from sticking has a more rapid effect on the brain. Effects of slaughter methods on exsanguination have been reviewed extensively (Figure 1).

Figure 1 Shechita slaughter knife.

Exsanguination Techniques

During slaughter, severance of tissues and blood vessels is carried out using knives of different types with varying thicknesses and lengths. Although ordinary slaughter knives can be used for Halal slaughter (Muslim method), length can vary from 10 to 30 cm, even longer for Shechita (Jewish method) which is applied without stunning (more than 35 cm for cattle). Shapes can also be straight and curved. Jewish slaughtermen use specialized knives called chalaf. Much attention is paid to maintaining these knives whose sharp edges must not have any indentations. Cutting action can be a transverse cut, or partly stabbing and retrograde type.

Two exsanguination methods are commonly used in slaughterhouses. The first method is commonly known as neck cutting and it involves severing two carotid arteries and two jugular veins in the upper neck, often behind the mandibles (jaw bones), and is used to slaughter sheep, rabbits, and poultry. The second method is known as chest sticking and it involves severing brachiocephalic trunk by inserting a knife through the thoracic inlet anterior to the sternum and is used to slaughter cattle and pigs. Chest sticking, also known as thoracic sticking, is carried out on the unconscious animals presented for exsanguinations in a recumbent position on a cradle or conveyor or hoisted on to a overhead rail. As mentioned previously, chest sticking involves severance of the brachiocephalic trunk, a single large vessel emerging from the aorta and leading to common carotid arteries to supply the head with oxygenated blood to the brain and has been shown to be very effective in that brain function is lost rapidly

in comparison with neck cutting due to profuse bleeding. However, during slaughter without stunning, chest sticking is not applied as it is not considered to be practical and is probably against religious rules and tradition. Time to loss of blood and consciousness following slaughter without stunning can vary and depend on species, techniques, number of vessels cut, and physical restrictions on the rate of bleeding.

Pain During Exsanguination

The issue of whether the neck cut is painful has received much controversy and discussion.

There are two different views about the pain during the cut. Those who favor slaughter without stunning on religious grounds think the cut is quick and painless and others argue that varying degrees of severe pain is inevitable. It is claimed that Shechita works as a stunning method and death occurs immediately due to rapid loss of blood. It has been reported that there is no visible reaction from the body and legs of restrained cattle to the neck cut. It is also claimed that neck cutting without stunning with a very sharp knife maintains animal welfare and creates a situation where no pain is felt by the animal due to rapid physiological changes. Similar claims are also made for halal slaughter.

In contrast, other scientists claim that there will be substantial pain involved due to extensive tissue damage. The pain that might be perceived by the animal during the cut and afterwards depends on a number of factors. Under the most successful slaughter conditions, if the incision is performed by a highly skilled slaughterman using a sharp knife, the level of pain inflicted will be the lowest though not totally eliminated. Deviation from this scenario will probably worsen the severity of pain in an exponential manner.

After recent methodological developments related to quantitative analysis of the electroencephalogram (EEG), the experience of pain can now be assessed more precisely. This methodology has been applied during neck cutting in calves and provided evidence for the first time that the act of slaughter is associated with noxious stimulation that would be expected to be perceived as painful.

Exsanguination, Blood Pressure, Cerebral Perfusion, and Loss of Consciousness

Total blood volume is equivalent to 8% of body weight and 18% of cardiac output perfuse the brain. Following effective stunning and slaughter by neck cutting, 40–60% of total blood volume is lost until carcass dressing. Exsanguination results in a dramatic drop in blood pressure leading to a state of shock, and it is also claimed that loss of consciousness occurs rapidly following slaughter without stunning.

In cattle, the time to reach critical levels of blood loss following exsanguination by neck cutting is highly variable and this period can be affected by a number of factors. In addition to ineffective severance of blood vessels, anatomical differences and occlusions of the cut arteries in cattle can lead to recovery episodes in blood pressure. In sheep, however, the rate of loss is much quicker after neck cutting.

The brain of ruminants is perfused with blood from 'rete mirabile,' a vascular network connected to the carotid and vertebral arteries. In cattle, there are extra anastomosis and blood supply to rete mirabile and brain sometimes even after exsanguination, whereas in sheep and goats this is not the case.

Although perfusion is possible, some people claim that the cerebral blood flow after a neck cut would not be sufficient to supply the brain. However, it has also been found that when carotid arteries are cut, the cut end of the arteries sometimes develop aneurysms leading to significant occlusion that impede bleeding efficiency and, as a consequence, prolong the time to onset of isoelectric electrocorticogram (ECoG) in calves. In the same study, it was also found that when carotid artery occlusion occurred, vertebral artery blood flow was maintained, which is the main reason for the delayed onset of unconsciousness in calves slaughtered without stunning.

Sharpness of the knife and performing a complete uninterrupted cut could influence the occurrence of vasoconstriction, clotting, and ballooning also known as carotid occlusion, or aneurysms.

Following slaughter without stunning, it is imperative that consciousness will be lost; however, the time to onset of unconsciousness depends on a number of factors such as the method of restraint, quality of the cut as well as species differences. Time to loss of brain function in cattle has been studied by various researchers who examined electrical activity of the brain using EEG or ECoG, evoked responses as well as animal reactions and reflexes, and found variations. Review of results showed using time to loss of spontaneous brain activity as indicated by an isoelectric or flat EEG/ECoG varied from 10 s to more than a minute; loss of evoked responses from 10 s to 2 min. In regard to sheep, however, similar studies obtained much shorter durations between 2 s and 43 s.

The implications of the above findings are that, following neck cutting, delays in time to loss of consciousness would be serious welfare problems. Certainly any impediment and slowing of blood flow after a cut could raise animal welfare concerns due to delayed loss of consciousness and other poor welfare states originating from the inhalation of blood into trachea.

Blood Loss and Retention

It is of importance to remove as much blood from the carcass as possible during slaughter with or without stunning. It is often claimed that stunning would adversely affect the rate of bleed out and total loss. However, some researchers examined exsanguination and compared stunning and slaughter versus slaughter with no stunning in sheep and cattle. They found no differences in both bleed-out rates and total blood loss at the end of bleed-out time.

Earlier reported studies measured blood hemoglobin content in different muscles as an indicator of bleed out quality. It was found that hemoglobin did not differ in muscles of sheep and calves that were subjected to captive bolt stunning or Shechita. It is claimed that Shechita bleeding and blood loss could still be better after Shechita because of the very sharp knife used and efficacy of cut. Based on existing studies and

available results, it is reasonable to suggest that regardless of whether preslaughter stunning is used or not, blood loss is unlikely to be different.

Carcass and Meat Quality

Stunning and slaughter can have certain effects on carcass and meat quality. These are carcass defects such as hemorrhages, bruising, and broken bones. Blood splash (petechial hemorrhages) in the muscles of sheep can occur due to inappropriate (rough) preslaughter handling, electrical stunning using high voltages, and sometimes due to possible nutritional or unknown factors. These defects and resultant downgrading can occur during slaughter with and without stunning. Prompt and efficient neck cutting following head-only electrical stunning of sheep and lamb minimizes or eliminates any detrimental effect of rising blood pressure on carcass and meat quality, including hemorrhaging or blood splash. Neck cutting in sheep and lambs while the heart is still pumping should result in 75–85% of total possible blood being lost in the first 60 s. As a consequence of prompt exsanguinations following head-only stunning, the carcass would have lost half the circulating blood volume that could be drained from the carcass prior to the onset of clonic convulsive phase. Therefore, blood pressure, under normal circumstances, should not be responsible for hemorrhages.

EXTRUSION TECHNOLOGY

PP Lewicki[†]

This article is a revision of the previous edition article by PP Lewicki, pp 460–465, © 2004, Elsevier Ltd.

Glossary

Coextrusion The extrusion of multiple layers of material simultaneously. It utilizes two or more extruders to melt and deliver a steady volumetric throughput of different viscous plastics to a single extrusion head (die) which will extrude the materials in the desired form.

Cold extrusion The extrusion used mainly to produce food without distortion of its constituents and also to mix, knead, and mold a product in one process.

Die A material-shaping device.

Extruder screw Ingredients that are uniformly pretreated are fed to the extruder screw. Single screw can have different designs; the most popular are as follows: (1) The diameter of the root of the screw increases and the screw pitch decreases along the barrel; the barrel diameter is constant; (2) The diameter of the root of the screw is constant and the screw pitch is either constant or decreases along the barrel; the barrel is tapered. In the twin-screw extruder, the bore of the barrels is shaped as two parallel overlapping cylinders. Two screws rotate in these cylinders and their arrangement can vary depending on the intended product quality. Possible arrangements include counter-rotation and corotation and the engagement of the screws can be full, partial, or none.

Extrusion cooking A method used to texturize starch-based and protein-based materials. Texturization is achieved by damaging the tertiary and quaternary structure of biopolymers, by rearrangement of polymer chains, and by formation of spatial structures that impart particular texture to the final product.

Pressure flow A backward flow, which causes distortion of the helical movement of the mass, which results in an intensive kneading of the dough.

Introduction

The process of extrusion combines several unit operations. Regardless of the purpose of extrusion, mixing, kneading, shaping, and forming are always taking place in the process. Such extrusion is termed cold extrusion. When the process is done at high temperature and high shearing forces, it is called hot extrusion or extrusion cooking.

The design of extruders depends on the mode of operation (cold extruders or extruder-cookers). In general, the extruder consists of a barrel(s) with a screw(s) that conveys the material toward the interchangeable die. Single-screw and twin-screw extruders are manufactured. The barrel(s) is jacketed and, in some designs, the screw can be heated or cooled.

Cold extrusion is used mainly to produce food without distortion of its constituents. It is used to mix, knead, and mold a product in one process. Extrusion cooking is used to create new food properties, especially a specific texture due to porosity, fibrosity, rearrangement of molecular conformation, and structural organization of biopolymers. The creation of new texture by extrusion cooking is the main objective of the process.

[†]Deceased.

Cold Extrusion

Cold extrusion is used to produce pasta, hot dogs, pastry dough, and some confectionery products such as chewing gum and liquorice. The extruder has a deep-flighted screw with a constant pitch and depth that operates at low speed in a smooth barrel. In processing pasta, the screw is divided into two sections or two screws are used one after the other (Figure 1). The feed section has a larger pitch than that in the kneading section. In the feed section, food components are mixed into a homogenous mass and its water content is adjusted to the desired value; in pasta processing, the feed moisture content is 22%. The homogenous mass is then conveyed to the kneading section. The mass follows a helical path down the screw channel. Its velocity varies from lowest at the root of the screw to the highest at the top of the channel. A die restricts mass flow and pressure builds up in the barrel. The pressure difference causes pressure flow in the space between the flights of the screw and the barrel wall. The pressure flow is a backward flow, which causes distortion of the helical movement of the mass (Figure 2), which results in an intensive kneading of the dough. Stretching, mixing, and pressing of the dough generates heat and the temperature of the mass can increase by 15–20 °C. Because each product should be extruded at its optimal temperature, the barrel is cooled with

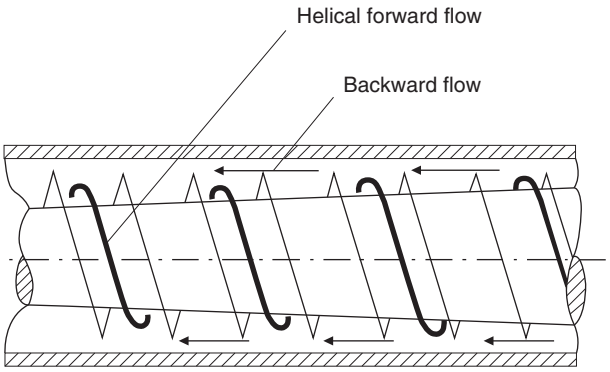

Figure 2 Flow of mass in the extruder barrel.

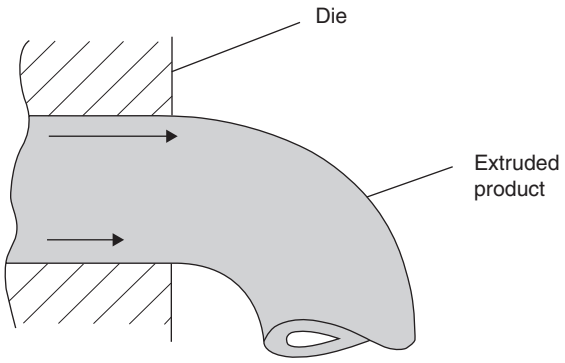

Figure 3 Effect of flow in the die on the shape of the extruded product.

water. The extrusion temperature for pasta should be below 55 °C. Temperatures exceeding the optimal value cause an increase of the pressure in the barrel and results in undesirable changes in food constituents. High pressure at the die increases energy consumption and affects the shape and surface quality of the extruded product.

The mixed and kneaded mass is pressed through the die. The flow through the die must be a plug flow, and shearing forces should be as small as possible. The extruded material should not expand and should keep the shape acquired in the die. Teflon coating of the die inserts gives low friction, so that the extrusion is done with low energy consumption and the surface of the extruded mass is smooth. The shape of the extruded material is determined by die inserts that produce velocity differences in the flowing mass. For example, if one part of the mass flows faster in the die than on other part, the extrudate bends and forms elbow (Figure 3).

Pasta extruders work at pressures of 6–8 MPa with screw speed of 30–40 rev min^{-1} and velocities in the die with Teflon inserts of 65–80 mm s^{-1}. Product moisture content is equal to that of the feed mixture. For efficient operation, the screw must be full of material, so the feed rate is an important variable in cold extrusion.

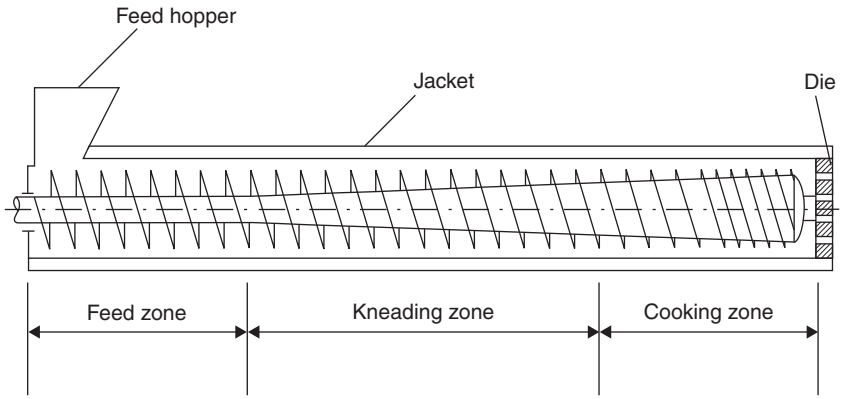

Figure 4 Extruder-cooker.

Extrusion Cooking

Extrusion cooking is widely used to texturize starch-based and protein-based materials. Texturization is achieved by damaging the tertiary and quaternary structure of biopolymers, by rearrangement of polymer chains, and by formation of spatial structures that impart particular texture to the final product.

Single-Screw Extruders

A cooking extruder can be divided into three parts: feeding, kneading, and cooking zones (Figure 4). The feeding zone is a chamber in which granular materials are moistened and heated. It has one or two mixing/conveying screws with large pitch. In the feeding section, materials are mixed, moistened, and heated in order to obtain a somewhat compressed, uniform mass. Shearing is low and the structure of biopolymers is not injured in this section of the extruder.

The uniformly pretreated ingredients are fed to the extrusion screw. This screw can have different designs; the most popular are as follows:

- The diameter of the root of the screw increases and the screw pitch decreases along the barrel; the barrel diameter is constant.
- The diameter of the root of the screw is constant and the screw pitch is either constant or decreases along the barrel; the barrel is tapered.

Both designs make it possible to compress the mass while it is conveyed from the feed zone to the die. To increase friction, the internal wall of the barrel is ribbed or corrugated.

In the kneading zone (the initial part of the extruder screw), the material is compressed, with some shearing, and heated. The heat is generated as a result of viscous dissipation, and further heat can be added through the barrel jackets. The temperature of the kneaded mass at the end of this zone is close to or exceeds 100 °C. The hot, melted, and worked-out mass forms a viscous, plasticized material.

The kneaded mass is further compressed, sheared, and heated in the cooking zone. In this zone, the pressure flow (due to pressure differences in the barrel) is significant and the mass is highly sheared. Heat is generated by dissipation of mechanical energy and the temperature of the mass increases rapidly. Very high shearing forces cause mechanical damage to polymer molecules. The temperature of the mass in the cooking zone, depending on the product, reaches 150–200 °C. The residence time in this zone is less than 5 s. Hot, melted material is discharged through the die. Discharge pressure depends on the product and can be as high as 70 MPa.

Water in the mass has the same temperature as the material, and at the moment of discharge it is superheated with respect to the ambient conditions. To restore equilibrium, water evaporates instantly and provides the most of the force that causes expansion of the product. A porous structure with low density is formed. Most of the water evaporates to the surrounding atmosphere and the water content of the product is much lower than that of the feed. Typical feed moisture is between 11% and 28%, whereas the product moisture content is below 5%.

The design of the die strongly influences the quality of the product. The shape of the die and the extent of expansion determine the shape of the product. The shape of the die also influences the shear rate and strain and, consequently, influences the texture of the finished product. A tapered die opening reduces shearing of the flowing mass and causes damage to macromolecules. It requires a relatively low backpressure. The product is less expanded and has a smooth surface that is more resistant to mechanical stress than the interior. An abrupt change in cross-section of the die opening causes extensive damage to food components and generates a large expansion. A fine porosity and a soft, pithy texture are created. Forcing the mass through the orifice causes storage of viscoelastic energy in the material, which attains rounded shape on relaxation. The surface of the product is irregular and corrugated. Cooling of the die can reduce expansion of the product on discharge.

In general, the conditions of flow of the mass in the die significantly influence the texture of the finished product. The more the mass is sheared in the die, the finer texture is formed, and the product is softer, more porous, and crumbly.

Temperature, shear rate, and strain are the processing parameters that affect the quality of the product in the single-screw extruder. The main variable that affects processing parameters is the moisture content of the feed materials. The moisture content is responsible for the flowability of the mass

and the energy requirement for extrusion. The lower the water content, the greater the energy required to cause the flow. As a result, the mass is strongly sheared, and the dissipation of viscous energy as heat increases the temperature of the dough. More damage is done to macromolecules than at higher moisture contents. Barrels with sectioned jackets make it possible to vary the temperature and control the slip at the barrel wall. At low wall temperatures, the slip is small and the shearing rate increases. The design features also influence the shear rate in the extruder; the design and speed of the screw, and the internal wall pattern of the barrel are the most important considerations.

The main drawback of single-screw extruders is their sensitivity to feed rate, and a complete filling of the screw must be ensured. With partial filling, control of extrusion parameters is not good, and the quality of the product becomes variable.

Twin-Screw Extruders

Twin-screw extruders are widely used in food processing. The bore of the barrels is shaped as two parallel overlapping cylinders. Two screws rotate in these cylinders and their arrangement can vary depending on the intended product quality. Possible arrangements include counter-rotation and corotation and the engagement of the screws can be full, partial, or none. The twin-screw extruder with corotating fully intermeshing screws (Figure 5) is one example of extruder classifications.

An extruder with two nonintermeshing screws works as a single-screw extruder but has a higher output. Mixing, kneading, cooking, and conveying in the intermeshing screws are accompanied by self-cleaning of the screws' surfaces. Corotating screws ensure good mixing and shearing in the whole mass of the product. The mass is not compressed between the screws and the extruder can work at high speeds. Counter-rotating screws are used with materials of low viscosity or materials that slip in single-screw extruders. Hence, oily, sticky, or very wet materials are handled in twin-screw machines. The conveyed material is compressed between the screws and the screws thus work at low speeds.

Corotating, fully intermeshing twin-screw extruders are the most common type in the food industry. The feeding zone is only partly filled with raw material, because twin-screw extruders have a greater ability to convey material down the screw's length. This increased conveyance builds up the pressure at the die and back-flow of the product ensures good filling of the screws. Strong shearing and mixing within the volume of a twin-screw extruder leads to homogeneity of the structure and texture of the product. Kneaded and cooked product leaves the screws and forms a single stream before entering the holes of the die for extrusion.

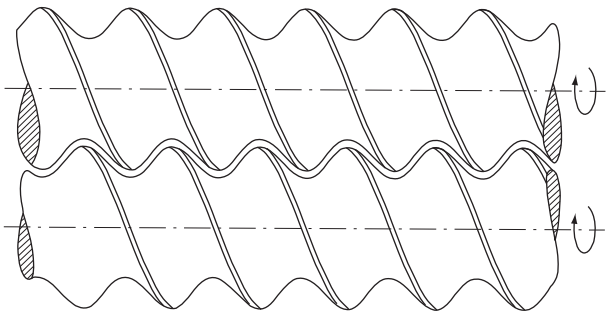

Figure 5 Intermeshing corotating screws.

Coextrusion

Products of composite texture or with filling can be produced by coextrusion. For composite products, two extruders are used or an extruder and a pump may be used. A special die makes it possible to combine two components or to add filling to an outer shell (Figure 6). A pump or extruder continuously feeds material into the extruded outer shell product; the combination is achieved in the die. The water activity should be similar in the extruded outer mass and the filling; otherwise water transfer can occur, and the quality of the product will change during storage.

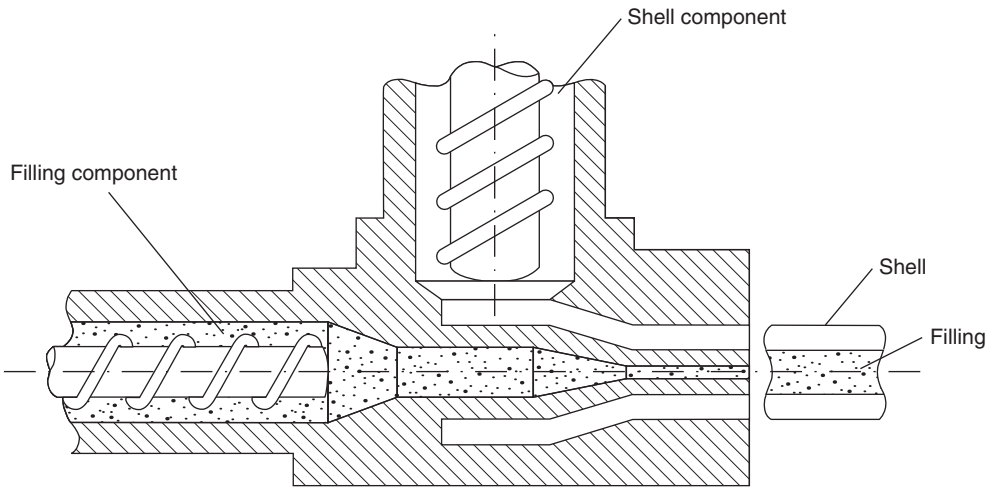

Figure 6 Principle of coextrusion.

Coextrusion is widely used in food production. It is used to produce filled confectionery, filled breakfast cereals, filled snack foods, etc. In meat processing, the process is used in two ways, either to produce filled products or to form an outer skin of collagen dough on sausage products. In some designs, a filled product can be covered with an outer skin in two steps.

Meat products produced by coextrusion include sausages with a central filling (e.g., sausage filled with cheese or apple sauce), bread rolls filled with sausage, filled meat croquettes, filled meat balls, etc. Coextrusion is used to coat a base material with an outer skin. Meat batter is coated with collagen casing, or other hydrocolloids can be used that form a gelled skin. The skin can contain spices or flavors, so coextrusion can become a technique for producing specialty multicomponent foods.

Meat Analogs

High temperatures, large shearing forces and laminar flow in the extruder cause changes in the tertiary and quaternary structure of proteins, align the chains along the streamlines of flow, induce cross-linking and form a layered meat-like structure. Defatted soy flour, concentrate, or isolate is used as raw material. Soy protein, mostly in the native state and with a nitrogen solubility index of 50–70, is the preferred ingredient.

The soy protein is fed into the preconditioner, moistened to 33–45% water on a dry weight basis; the pH is adjusted to the required value and preheated to 80–90 °C. At lower pH values (5.5), the product is chewy, whereas at a higher pH value (8.5), textured protein is tender and rapidly absorbs water. Preconditioned material is fed into the extruder and reaches a temperature of 140–160 °C. Chemical cross-linking occurs, and a layered structure is formed. The more the material is compressed in the extruder and the higher the screw speed, the greater is the degree of cross-linking that occurs, and the more meat-like is the structure. To produce a highly layered structure, side-discharge dies are used for textured vegetable protein. Cooling the mass at the die yields denser, meat-like structures that need longer hydration times. Textured soy protein produced by extrusion cooking forms layered products that absorb approximately three times their weight of water and simulate meat structure.

Textured proteins can be produced at capacities reaching 3 t h^{-1}.

Thermoplastic Starch

Starch mixed with water and some other plasticizers such as glycerin, glucose, or sorbitol and extruded at high temperature forms foil, which application is foreseen as biodegraded packaging material. To increase its mechanical strength, some cellulose fibers, from flax or hemp are added. Addition of some fats increases elasticity of the foil.

The extruded foil is amorphous but during storage acquires some crystallinity. The amount of crystals and the type of crystal structure depends on the processing parameters. The crystallites are formed by amylose helices and their amount increases with increasing humidity of the surrounding air.

The main problem that has been investigated recently, is the instability of properties of the foil under the environmental conditions.

Quality of Extruded Food

Extrusion causes physical and chemical changes in the material undergoing processing. The most pronounced physical change is development of porosity, which at low water contents creates crispness, crunchiness, and a texture typical of extruded products. The cell structure in a porous material is also responsible for its mechanical strength and solubility and ease of biting or breaking. Sounds generated during biting or breaking are depending on the cell structure, the water content, and the ability of the extruded product to absorb water during eating. All the variables responsible for the texture of an extruded product can be manipulated during processing, which means that the quality of the product can be adjusted to the needs and expectations of consumers.

Extrusion can be treated as a high-temperature, short-time process. The chemical changes, therefore, are typical of those resulting from that process. High temperature and increased pressure cause changes in the tertiary and quaternary structure of proteins. Laminar flow and large shearing forces align polymer molecules along the streamlines and form layered structures. Cross-linking by sulfur bridges occurs and the new structure is stabilized by newly formed hydrogen bonds. In general, extrusion does not alter protein digestibility, but at very high temperatures oxidation and destruction of sulfur-containing amino acids can take place. In the presence of sugars, the availability of lysine is decreased in extruded products.

Starch undergoes gelation during extrusion. At high temperatures and in the wet material, some hydrolysis can take place. Moreover, large shearing forces can cause fragmentation of polymer chains and, in consequence, maltose and oligosaccharides are present in extruded products. Gelled starch and the presence of low-molecular-weight carbohydrates make the extruded products easily digested.

Extrusion of materials containing fats and oils forms complexes of those constituents with starch and protein. These complexes are more resistant to oxidation than free fatty acids, and the extruded products are more stable during storage. However, complexes of fats with starch are more resistant to amylolytic enzymes and the content of dietary fiber in extruded product increases.

Vitamins are generally stable under extrusion conditions. Vitamins of the B group decrease by 25%, but retention of thiamin, riboflavin, pyridoxine, niacin, and folic acid in cereals can be as high as 95%. Losses of ascorbic acid and vitamin A can be up to 50%. Vitamin E and β-carotene contents decrease little during extrusion.

Some antinutritional agents occurring in certain raw materials, for example, trypsin inhibitor can be destroyed during extrusion. Consequently, the nutritional value of the product can be improved by extrusion.

During extrusion cooking, a toxic compound – acrylamide is formed. The reagents are asparagine coming from proteins and reducing sugars. The optimum temperature for acrylamide formation is 140–180 °C. The toxicity and cancerogenity of acrylamide was proved in experiments on rats, but doses were very

high in comparison with contents of that compound in foods. In French fries, content of acrylamide is approximately 700 μg kg^{-1}; in potato chips, 550 μg kg^{-1}; in corn flakes, 330 μg kg^{-1}; and in breakfast cereals, 130 μg kg^{-1}. There is no limit set for the content of acrylamide allowable in foods. World Health Organization states that there is no reliably identified threshold for the risk of acrylamide concentration. However, it is recommended to change processing parameters and lower acrylamide contents as much as possible. In 2010, The European Chemical Agency added acrylamide to the list of substances of very high concern.

Economics of Extrusion

Extrusion is a versatile process in which, by changing minor ingredients and the operating conditions, new products with special properties can be produced. Other methods or technologies cannot create the same properties as those of extruded foods. Comparison of traditional methods of breakfast cereal production with production by extrusion shows substantial savings in raw materials, energy, labor, and capital investment. Production of flat bread by extrusion requires an energy input around 0.1 kWh kg^{-1}, whereas traditional technology consumes 10 times more energy. When the extruder is used as a forming machine (in pasta or sausage production), the energy consumption is approximately one-fifth of that in extrusion cooking and is in the range 0.02–0.03 kWh kg^{-1}.

Extrusion is a high-production process that is quite amenable to automation. Low-density cereals can be produced at rates higher than 1 t h^{-1} and expanded pet foods are produced at rates as high as 25 t h^{-1}.

A very important feature of the extrusion technology is the negligible production of waste and effluent. Moreover, waste products of meat processing combined with starch or cellulose by-products can be extruded and produce valuable components of feeding stuffs.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 97 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise.

There are four features that help you find the topic in which you are interested:

1. The contents list.
2. Cross-references to other relevant articles within each article.
3. A full subject index.
4. Contributors list.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Meat, Animal, Poultry and Fish Production and Management: Antibiotic Growth Promotants.

> *See also*: Chemical Analysis: Sampling and Statistical Requirements; Standard Methods. Foodborne Zoonoses. Growth of Meat Animals: Metabolic Modifiers. Microorganisms and Resistance to Antibiotics, the Ubiquity of: Antibiotic Resistance by Microorganisms. Residues in Meat and Meat Products: Feed and Drug Residues; Residues Associated with Meat Production

3 Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

PREFACE

The Encyclopedia of Meat Sciences, second edition, an extensive revision of the first edition published in 2004, covers all the essential meat topics, ranging from animal production, processing, analytical procedures, and food safety, to final consumption including health issues and nutritional aspects. There are more than 230 articles and these provide a greater breadth of coverage than any existing work on meat science. In addition to publication in print, the Encyclopedia is also available for licensing online that can allow regular updating. The articles are designed to bring a nonexpert up to a level of understanding the interactions among the various disciplines covered in the articles. Most articles are 3000–4000 words long and include a list of Further reading and Websites to expand the content beyond the immediate scope of this work. The Encyclopedia is, therefore, a valuable resource for several levels of education and experience.

The Editors gratefully acknowledge the contributions of the authors of the articles and the Editorial Advisory Board. The board not only proposed subjects to be covered, but also found contributors and then reviewed the articles. The work involved in an Encyclopedia such as this requires an extensive interactive cooperation among the Editors, the Editorial Advisory Board, the contributors, and the publishers, particularly the staff of the Major Reference Works division of Elsevier. The staff included Nancy Maragioglio, Donna de Weerd-Wilson, Anna Gebicka, Cari Owen, Will Bowden-Green, Sam Mahfoudh, Zoey Ayres, and Marise Willis.

The Editors are particularly grateful to Cari, Will, and Sam, who worked very closely with us and who diligently pursued all avenues to obtain contacts with contributors, maneuvered around obstacles, facilitated the day-to-day management, and linked everyone together to meet the deadlines.

Michael Dikeman and Carrick Devine
Editors, August 2014

INTRODUCTION

Meat consumption by hunter–gatherers predated the agricultural revolution. Consumption of meat and fish runs in parallel with human development that is still in process. Humans and animals have now coexisted for thousands of years for their mutual benefit, even though their relationship is changing. Meat does not come from a single, or even a few, animal species, but is derived from a wide variety of species ranging from poultry to pigs, cattle, sheep, goats, and wild game to thousands of species of fish. While many of these species are now intensively farmed, some still coexist with nomadic tribes, whereas, others are raised by families in small village communities, or are even hunted by remnants of hunter–gatherer communities. The second edition of the Encyclopedia of Meat Sciences discusses how the domesticated species evolved; the wide range of harvesting methods for animals, poultry and fish; the historical changes in production, processing and nutritional value, including the beneficial effects of optimum amounts of meat in a diet.

The meat industry is based on obtaining animals, poultry, and fish from pastures, feedlots and specialized intensive production systems, and from extractive industries such as fishing. It is understandable, therefore, that the genetics and management of animals and production systems are prominent in the Encyclopedia. However, the broad field of meat science is much more than harvesting animals and processing meat from them. It includes issues such as preslaughter stress and its effects on meat quality; religious issues; animal welfare; and humane slaughter techniques, all of which are extremely important to ensure that meat quality, cultural issues, and market requirements are harmonized.

Processing methods for the various species are different, but they have all historically developed to ensure, either by conscious design or by experience, that the underlying principles of physiology and biochemistry in the conversion of muscle to meat are optimized. Biochemistry and physiology are extremely important and fundamental disciplines, because they explain how unfortunate, undesirable processing defects such as PSE or cold shortening and toughening can occur and can be avoided. Progress in this area has also enabled significant changes in production and subsequent quality since the first edition of the Encyclopedia of Meat Sciences in 2004.

Understanding these changes requires an appreciation of the structure of carcass tissues, from gross carcass attributes to consideration and understanding of changes at the ultrastructural level. The form and function of muscle tissues, how they change through growth, how they impinge on meat quality, and the way that connective tissue and fat can be major contributors to the final product quality are all covered in these pages. Topics such as cold shortening that can cause meat toughening or inhibition of tenderisation are explained, as well as how procedures such as electrical stimulation evolved to prevent these problems. Assessment of meat quality from measurements such as muscle pH, tenderness prediction through spectral measurements on uncooked meat, color changes on display and storage, and reduction of microbial contamination are critical for many aspects of the meat industry and are also discussed.

There have been many and significant advances in meat animal production based on genetic, nutrition, growth biology, and metabolic modifier research. In regard to meat processing, advances in refrigeration and freezing technology, which is the foundation of perhaps the most important changes ever encountered for food is discussed. Even so, such advances also depend on the way in which microbiology and packaging are integrated to ensure wholesome products with a long shelf life, minimal spoilage, and desirable sensory attributes. However, there are many other ways to preserve food that are also important. Of ever-increasing importance is the topic of food safety, which must receive extensive attention because meat is a perishable product and is critical for a high quality of living and even for human survival. Meat marketing and pricing in all its forms, from wet markets to hotel, restaurant and institutional trade, and transportation are also important. Whole-tissue meat is usually cooked, so, many of the desirable attributes such as flavor development relate to the temperature interactions with various proteins and sugars during cooking. Other cuts are processed in various ways, from smoking to mincing to sausages and the technologies involved are covered.

Not all muscles or cuts of meat are suitable for the same cooking and preparation methods. Therefore, out of necessity, a vast range of highly desirable products has evolved with variations from one ethnic background to another. Other products are merchandized through fast-food restaurants. One can now consume a hamburger in China that is almost identical to that in Chile or in the United States owing to a consistency of product specifications that has become universal. Meat is not only a major source of quality protein and some vitamins and minerals; it often forms the central part of a meal, and is desirable to have the appropriate flavors, aromas, and appearance to conform to the expectations and the way meat is used in various cultures.

This second edition of the Encyclopedia of Meat Sciences also covers controversial health-related aspects of meat consumption and this aspect needs considerably more research. In recent years, the ready availability of meat and other foods has given rise to some health concerns. However, the issues are not always what they seem. The positive and potential negative health-related aspects of meat eating are addressed by experts in dietary and health aspects of meat consumption, but the effect of a single food item should not be considered in isolation.

The wide coverage of topics will ensure that this second edition of the Encyclopedia of Meat Sciences will be an important resource for students or professionals with an interest in meat science or those engaged in the livestock and meat industries. Most of the articles in the second edition are not only a revision of those in first edition but there are additional areas covered. The relatively short nature of the articles makes the Encyclopedia easy and interesting to read.

Glossary

Maillard reaction (French pronunciation: [majaʁ], mah-yar) A form of nonenzymatic browning similar to caramelization. It results from a chemical reaction between an amino acid and a reducing sugar, usually requiring heat.

Matrix-assisted laser desorption/ionization (MALDI) A soft ionization technique used in mass spectrometry, allowing the analysis of biomolecules (biopolymers such as DNA, proteins, peptides, and sugars) and large organic molecules (such as polymers, dendrimers, and other macromolecules), which tend to be fragile and fragment when ionized by more conventional ionization methods. The type of mass spectrometer most widely used with MALDI is the TOF (time-of-flight) mass spectrometer, mainly due to its large mass range.

Metametabolomics Metabolomics represents the systematic study of the metabolome, i.e., the collection of all metabolites in a biological cell, tissue, organ, or organism, which are the end products of cellular processes. The combined analysis of metabolomes of different members of an ecological system is referred to as metametabolomics.

Principal component analysis (PCA) A mathematical procedure that uses an orthogonal transformation to convert a set of observations of possibly correlated variables into a set of values of uncorrelated variables called principal components. The number of principal components is less than or equal to the number of original variables.

Strecker degradation A chemical reaction that converts an α-amino acid into an aldehyde by an imine intermediate. It is named after Adolph Strecker, a German chemist.

Introduction

The chopping or mincing of meat and fat with curing salt and/or sugar together with spices, herbs, and other plant material, followed by the stuffing of such mixture in casings to form a 'sausage' that is left to ferment and dry, is a practice dating back to centuries before the Common Era. Since these early beginnings, variations in 'meat' species, in nature of ingredients and additives used, and in processing technology have yielded a tremendous variety of 'fermented meat products', almost all differing with site of production. Their shelf life and safety, as well as the specific flavor, texture, and color, are determined by combinations, varying in relative importance, of acidulation brought about by lactic acid production and by the lowering of water activity (a_w) via salt addition (curing) and drying. These effects also trigger enzymatic reactions, by both meat and microbial enzymes, which lead to complex flavor development.

The presence of curing salt and the limited availability of oxygen select for a specific microbiota, consisting mostly of lactic acid bacteria (LAB) and catalase-positive cocci (mainly coagulase-negative staphylococci; CNS), which are adapted to the meat substrate and withstand low water activities and anaerobic conditions. Nowadays, these microorganisms are usually added as starter cultures to standardize the production process. The LAB initiate fermentation that lowers the pH to final values between 4.5 and 5.5, inducing the denaturation of salt-solubilized protein to a gel that can be sliced. An adequate (rapid) reduction of pH, the use of curing salt, and a lowered a_w are the major factors determining both shelf life and safety.

Considerable recent research efforts have generated more detailed knowledge of the interrelated microbiological,

biochemical, chemical, and physical changes taking place during 'meat fermentation', emphasizing two major developments:

- Detailed identification of the diversity within the microbial species involved using methods of molecular genetics, as well as their metabolic features affecting product quality and safety.
- Although industrial and commercial interests favor the development of starter cultures, the importance and variability of enzymes, present in the meat and/or fat raw materials, is now fully recognized.

The many intricate interactions between microorganisms, meat and fat enzymes, and processing conditions determining sausage quality encompass more than the concept of fermentation and are therefore better referred to as 'metabolism.'

The Processing of Fermented Sausages

The industrial production, mainly in continental Europe, from where the technology was transferred to the United States and Australia, referred to as 'ripening,' is separated into two consecutive periods: fermentation followed by drying/maturation. Technologies differ mainly in the length of the total ripening period in relation to that of the fermentation period. High initial rates of lactic acid production resulting from the use of starter cultures that lead to pronounced lactic acid generation and/or high temperatures during fermentation are usually associated with rather short drying periods. The drying period may even be omitted, as in 'summer sausage,' prevalent in parts of the United States and fermented at 38 °C. In Europe, a major distinction can be made between the so-called Northern-type and Mediterranean-type sausages. Northern-type sausages usually contain both beef and pork as raw meats, are ripened for short periods (up to three weeks), and are usually subjected to smoking. Shelf life and safety are mainly due to the fast drop to acid pH (<5.0 after three days), usually at temperatures >24 °C, and to smoking rather than to drying. Mediterranean sausages mostly use only pork and are heavily seasoned, ripened for longer periods (several weeks or even months), mold-ripened, and seldom smoked. Acidulation is slower, usually takes place at lower temperatures (<24 °C), and ends at higher pH values (above pH 5 after three days or more). To compensate for negative effects on shelf life, extensive drying is applied, reducing water activity.

Raw Materials and Additives

Chilled meats (frozen meat tempered to approximately −4 °C) and frozen (<-18 °C) porcine fats after removal of rind (e.g., lard) are most often mixed in a ratio of 2:1. Lard and sausage meat (ham trimmings, jowls, and throats as well as shoulders and bellies) make up 10% and 20%, respectively, of the pork carcass. They are selected mainly on the basis of bacteriological quality, visual fat content, pH (<5.8), and unsaturation ($<12\%$ polyunsaturated fatty acids in fat), as well as oxidation status (minimal peroxide value) of the fat. Widely used ingredients and additives are salt (2–4%) containing sodium nitrite ($NaNO_2$) (added as curing salt containing 0.4–0.6% $NaNO_2$), glucose (0.5–1%), sodium ascorbate or ascorbic acid (0.5–1%), and spices. Nitrite is used because of its antibacterial, color-forming, antioxidant, and flavoring properties. Although the technological and microbiological justification is discussed, part or all of the nitrite is substituted for by potassium nitrate (KNO_3) in Mediterranean-type sausage. Nitrate is then converted into nitrite due to bacterial nitrate reductase activity, present in meat-associated catalase-positive cocci, mostly CNS. Both ascorbate and ascorbic acid are used to improve the stability of the red nitrosylated pigment, an effect closely associated with the prevention of lipid oxidation. Ground pepper (0.2–0.3%) is usually present in all types of sausages. Mediterranean types in particular may contain higher levels (1–3%) of other spices such as paprika and garlic that have been shown to be effective antioxidants, comparable to ascorbate. Additional additives sometimes used for Northern-type sausages are phosphates to improve stability against oxidation and to steer water content; glucono-δ-lactone (GdL, 0.5%) to ascertain fast chemical acidulation with negative effects on flavor development; manganese sulfate (~50 ppm) as cofactor for LAB to stimulate acidification; vegetable proteins (mainly soy isolate), which may also accelerate fermentation; and milk powder or lactose as bulking agent.

Comminution or Chopping

Raw materials and additives, including bacteria (and sometimes yeasts) as starters, are added for mixing and chopping, often under vacuum, in a mincer or cutter. The cutter consists of a set of knives that rotate rapidly ($1–3\times10^3$ rpm), producing a batter in a bowl that rotates slowly (10–20 rpm). The relative speeds of the knives and bowl and the sequence of addition of raw materials and additives determine the fat particle size and are optimized to produce a batter within less than 5 min at temperatures below 2 °C, ensuring minimal damage to the fat tissue.

Stuffing

In most industrial processes, the batter is immediately stuffed under vacuum into natural, semisynthetic (collagen), or synthetic casings that are permeable to water and air, and both ends are clipped. The sausage diameter (e.g., 2–15 cm) is related positively to the relative importance of fermentation (pH) versus drying (a_w) for stability.

Ripening

The sausages, hung in racks, are most often placed in air-conditioned fermentation chambers at high relative humidity (RH) and usually left for ripening in two consecutive stages: fermentation driven by bacterial growth and, mostly after transfer to another chamber, drying for increased stability and development of additional sensory characteristics. Temperature–RH–time combinations during fermentation differ between Northern (20–28 °C/60–90%/62 h) and Mediterranean (5–24 °C/60–90%/100 h) types, whereas drying is carried out under similar conditions (14 °C/78%) for anywhere between 2 weeks (Northern) and several months

(Mediterranean). In the USA, 'summer sausage' production is based on fermentation temperatures exceeding 30 °C with little drying. It has been recommended to have air RH values not more than 5–10% lower than the water activity value of the sausage (expressed as a %) to prevent case hardening, and recommended air speeds are approximately 0.1 m s^{-1}. Controlled fermentation and ripening in air-conditioned surroundings consume considerable amounts of energy, and alternative methods, involving the use of fresh air, have been proposed, inspired by the traditional methods for Mediterranean-type sausages and adapted to local climatic conditions.

Smoking

During the fermentation period, as soon as the red surface color has developed, Northern-type sausages are usually subjected to smoke, generated by controlled combustion of (oak) wood (300–600 °C) to minimize the production of polycyclic hydrocarbons. Smoke contributes to antimicrobial and antioxidant effects, in addition to generating specific flavor and color components, and may be substituted by the use of liquid smoke flavorings. Smoking is hardly used in the production of Mediterranean-type sausages, but is used in Hungarian and Rumanian products, where a light smoking period precedes fermentation.

Microorganisms Involved and the Use of Starter Cultures

In meat fermentation, two main groups of bacteria are considered important: the LAB and CNS. The usually low initial population of LAB in the raw material (3–4 log CFU g^{-1}) becomes dominant during the fermentation step (8–9 log CFU g^{-1}) and is mainly responsible for the safety as well as the flavor and texture of the product through lactic acid production. Some LAB also produce bacteriocins that may contribute to microbial safety, in particular toward *Listeria monocytogenes*. *Lactobacillus sakei*, and to a lesser extent *Lactobacillus curvatus* and/or *Lactobacillus plantarum*, generally constitute the main LAB species. *Staphylococcus carnosus* and *Staphylococcus xylosus* are the main CNS species mainly held responsible for color stabilization, decomposition of peroxides, and contribution to flavor through metabolism of end products of proteolysis and lipolysis. The latter two species are mostly encountered because they are typically applied in starter cultures. Nevertheless, during spontaneous fermentation processes, other species such as *Staphylococcus equorum* and *Staphylococcus saprophyticus* may be just as important. There seems to be considerable variability within CNS with respect to pH sensitivity, overall competitiveness, and flavor generation. Although fermentation may rely on the 'house microbiota' for traditional products, 'starter cultures' have been used since the middle of the twentieth century and are added as frozen or lyophilized cultures ($1–5\times10^{6}$ g^{-1}) for industrial sausages, but also increasingly so for artisan products. Selection of such starters requires knowledge of their potential to outgrow indigenous bacteria in the sausage environment. More importantly, selected strains should not lead to sensory defects or adversary health effects (e.g., biogenic amines), and yield, if possible, additional advantages such as the generation of specific antimicrobial components (e.g., bacteriocins), nutritional properties (e.g., probiotic strains), or exceptional flavor characteristics. This is a difficult but challenging task, considering the large microbial diversity demonstrated in similar types of meat products, also on intraspecies level. Studying the DNA of the sausage microbial ecosystem allows definition of microbial ecology and diversity, whereas RNA analysis and (meta) metabolomics will highlight the microbial populations that are metabolically active, thereby contributing to the fermentation process. The very large numbers of LAB and CNS strains in the bacterial communities developing during sausage fermentation reflect genes determining resilience to the environmental changes within the sausage mixture, involving, for instance, water activity, redox, pH, and oxygen levels, as well as the potential for biofilm formation and cell aggregation. Nevertheless, initial microbial diversity narrows down during the production process, in particular for the LAB where *Lactobacillus sakei* is by far the most competitive species. The specialized 'metabolic repertoire' required has been highlighted within the complete genome sequence of *Lactobacillus sakei* 23 K. This specialized adaptation by *Lactobacillus sakei* has been demonstrated via genome analysis, metabolite kinetics, modeling, and gene expression studies, with respect to its ability to metabolize alternative energy sources such as arginine and nucleosides. Such genome analysis may further allow for new biotechnological approaches to meat fermentation, involving fundamental aspects of the diversity of bacteria adapted to this specific environment, as well as their use as starter cultures involving defined functional properties and absence of potential hazards. Indeed, several commercially available starters have a long history of apparent safe use in industrial meat applications, but recent evidence has stressed that their potential production of toxins and biogenic amines is of major concern. The other and major important criterion in the evaluation of starter strain safety is the presence of transmissible antibiotic resistance markers. The presence of intrinsic resistance and resistance due to mutation of chromosomal genes presents low risk of horizontal dissemination and such strains should be acceptable for consumption. Safety assessment of starter strains should therefore focus on antibiotic profiles and transferable genetic determinants, as acquired resistance by mobile elements may present a risk for public health. In addition, molds (usually *Penicillium* spp.) that may occur on the external surface of Mediterranean sausages may produce mycotoxins. Growth of undesirable molds on the sausage exterior is prevented by pretreatment of the casing with potassium sorbate or pimaricine solutions. Additionally, nonpathogenic molds may be applied as starter cultures to outcompete the potentially hazardous background microbiota.

Sausage Metabolism and pH

During ripening, sausages represent a dynamic matrix, which is affected by actions from both endogenous and microbial enzymes. The most obvious aspect consists of lactic acid production by LAB, mostly originating from the conversion of

endogenous and/or added carbohydrates. LAB produce important amounts of both D(−) and L(+) lactic acid isomers. The resulting pH decrease is counterbalanced by the salt-solubilized and partly hydrolyzed muscle proteins and by ammonia production. In addition, fungal growth may lead to lactic acid consumption and result in pH increase.

Carbohydrates are the main substrate for fermentation but, varying with sausage diameter, respiration also occurs as indicated by oxygen consumption. Moreover, the joint action of bacterial and meat enzymes on sausage protein and lipid fractions represents another important transformation. Paucibacterial meat incubations have demonstrated the importance of acid-activated muscle and fat endogenous proteases and lipases. Myosin and actin are mainly hydrolyzed by the muscle proteinase cathepsin D, activated at acid pH, and producing polypeptides that are further hydrolyzed to small peptides (1–10 kDa) and amino acids by endogenous and microbial peptidylpeptidases and aminopeptidases, respectively. Further deamination and decarboxylation yield small amounts of ammonia and amines, respectively. Provided starter microorganisms do not produce amines, amine production mainly reflects initial bacterial contamination of the raw materials used. Further insight into the proteolytic action of endogenous proteases and the limited contribution of microbial enzymes has recently been provided by proteomic investigations involving identification by Matrix-Assisted Laser Desorption/Ionization-Time-of-Flight (MALDI-TOF) mass spectrometry of peptides separated by two-dimensional (2D) electrophoretic analysis. Likewise, it has been demonstrated that endogenous lipases are almost exclusively responsible for the liberation of free fatty acids during ripening. This lipolysis involves preferential release of polyunsaturated fatty acids, because of the more important phospholipase activity on muscle membrane phospholipids and the specificity of fat cell lipases. It is clear that both free amino acids and free (unsaturated) fatty acids are major precursors for the production of flavor volatiles. This involves bacterial metabolism of, for example, branched chain amino acids, particularly leucine, as well as chemical changes leading to fatty acid oxidation end products and possibly Strecker degradation of amino acids.

Development of Sensory Quality

During the combined, consecutive, and interactive changes that take place during fermentation and drying, the specific color, texture, and flavor characteristics of the different sausage types are developed.

Color

The reddish cured meat color is due to the formation of nitrosylmyoglobin in a complex set of reactions involving the formation of nitrogen oxide (NO) and its subsequent reaction with myoglobin and metmyoglobin, producing red and grayish colors, respectively. The subsequent acid-induced denaturation of the globin moiety ensures the stable red color. Nitrite initially acts as a potent oxidant, producing nitrosylated metmyoglobin on mixing, which has subsequently to be reduced during drying. With nitrate, formation of the nitrosylating NO requires the reduction of added nitrate by catalase-positive cocci (mostly CNS). The latter bacteria are, however, pH-sensitive, which hampers their activity in later periods of Northern-type sausage processing.

Texture and Mouth-Feel

The sausage texture is due to the coagulation of the salt-soluble muscle proteins (mainly myosin) solubilized by chopping. The coagulated gel surrounds fat and meat particles and is stabilized during drying. Unbalanced acidulation induces myosin coagulation and proteolysis hampers texture development, as is the case in attempts to shorten ripening time by the use of freeze-dried meat, encapsulated lactic acid, and glucono-delta-lactone.

Flavor

Flavor, i.e., the combination of taste and aroma, and texture are perhaps the most important sensory characteristic of fermented sausages, as they convince the consumer to repeatedly buy the product.

Volatile compounds that determine aroma (smell or odor) are often considered separately from the nonvolatiles determining taste through receptors on the tongue. Nevertheless, it should be realized that taste and aroma are sensed in an integrated manner. In addition to saltiness, a sour or acid perception is the most relevant taste, in particular in Northern-type sausages. Its intensity is correlated with the presence of D-lactate and acetate. ATP (adenosine triphosphate) metabolites, such as inosine monophosphate (IMP) and hypoxanthine, small peptides (1–10 kDa), and free amino acids contribute to taste as well, mostly of the umami type. Free higher fatty acids are considered to be of less importance.

More than 200 volatile compounds originating from fermented sausages have been identified by gas chromatography and mass spectrometry in the sausage 'head space' and their pattern has been used for product differentiation. The majority are derived from spices and smoking in Mediterranean and Northern-type sausages, respectively. However, only a limited proportion is of sensory relevance for the typical 'fermented sausage' flavor. Some compounds represented by acetic acid, acetaldehyde, diacetyl, and acetoin are derived from carbohydrate metabolism. The main aroma-determining compounds, with the highest odor activity values, are, however, derived from protein metabolism, such as 3-methyl butanal, 3-methyl butanol, and 2-methyl butanal, and are important from the beginning of ripening. Apart from microbial amino acid metabolism, these compounds are also products of the Strecker degradation of amino acids. It has therefore been suggested that Maillard reactions, although normally requiring high temperatures and low water activities, may be of some importance in sausage fermentation. Hexanal, heptanal, and 1-octen-3-ol have also been identified as probable main contributors to the fermented sausage aroma. Lipid-derived compounds are generated mainly at the end of the process by both physicochemical and microbial changes and also include propanal, pentanal, ethyl 3-methyl

butanoate, 3-methyl butanoic acid, 2-methyl propanoic acid, ethyl hexanoate, and nonanal.

Effect of Processing

It has been demonstrated that interrelated processing variables such as the type of starter, vacuum stuffing, temperature, a_w, RH, sausage diameter, and rate of drying affect the relative importance of the metabolic changes described above and thus the final sensory quality of the product. For instance, a rapid drop in pH stimulates the activity of muscle cathepsin D and lysosomal acid lipase, active at acid pH, but inhibits bacterial amino acid metabolism. Reducing the diameter of the sausage and/or increasing the rate of drying may reduce (endo)-proteolytic activity but increases the relative importance of acetate production and respiration of substrates involving oxygen consumption. As a consequence of a more pronounced denaturation, pig muscle proteolytic and lipolytic enzyme activities were shown to be lowered by breed-related higher rates of postmortem muscle pH decline. Effects of animal genetics and production systems on flavor volatiles in cured meat products have been demonstrated as well, as interactions occur between animal species and starter used, affecting quality in salami production. Such findings may, for instance, be related to the existence of porcine gene polymorphisms of cathepsin D. Processing conditions and metabolic changes not only affect the nature of volatiles formed but also conditions determining their liberation during chewing. These include sausage pH, salting-out effects of additives, and the binding of flavor-determining volatiles by sarcoplasmic and other proteins. These findings imply that partial NaCl substitution in meat products by other salts should be considered not only for their salting-out effect but also for their effect on protein-binding ability.

Microbial Stability and Safety

The microbial stability and safety of the sausage is obtained by the introduction of successive 'hurdles' for undesirable microorganisms. The lowering of the redox potential, due to the omission of oxygen by chopping under vacuum, is

enhanced by addition of ascorbic acid or ascorbate. This inhibits aerobic bacteria and improves the bactericidal effectiveness of nitrite, an important hurdle. During fermentation, LAB inhibit undesirable bacteria mainly through the production of lactic acid and the associated pH drop but also by production of compounds such as acetic acid, hydrogen peroxide, and, in some cases, bacteriocins. The subsequent drying of the sausage continues the reduction in the water activity, due to addition of salt, to values that prevent growth of spoilage and/or harmful microorganisms (e.g., $a_w < 0.92$ or < 0.94 at pH < 5.0). Correct interaction of all 'hurdles', including the application of smoke in Northern-type production, usually ensures stability and safety. Nevertheless, incidence of pathogens has occasionally been reported, as well as food scares related to fermented sausage consumption.

Modeling the Nature and Dynamics of Ripening

It has been confirmed repeatedly that the safety, shelf life, and sensory quality of fermented sausages are the result of an extremely complex set of interacting microbiological, physical, and (bio)chemical changes during ripening. Some of the complexity of the physical and (bio)chemical characteristics of Northern and Mediterranean types of sausage, as well as their variability and differences, is illustrated in Table 1.

The technological control, evaluation, and standardization of such a complex system of characteristics and changes (involving, for example, the use of nonmeat proteins, spices, altered temperature/RH combinations, sausage diameter and type of casing, and type of starter and carbohydrate) requires comprehensive knowledge of the many interactions involved. Failure to accept this may lead to the loss of traditional flavor of Mediterranean-type sausages, for example, when highly acidifying starter LAB and high amounts of nitrite are used. It is becoming clear that the flavor of Mediterranean-type sausages is associated with a specific pattern of proteolysis, characterized by a lower peptide/free amino acid ratio as well as higher ammonia concentrations (Table 1). This pattern is related to changes in pH, dry matter (DM), and a_w interacting with the type of fermentation as determined by fermentation temperature, length of ripening, starter culture, type of meat used, and sausage diameter. Comprehension of these relations and their use for predictive purposes can be facilitated by the use of simple models. Such models may be analytical or mechanistic:

- Analytical models describe linear or exponential kinetics of time-related changes in sausage metabolite concentrations, microbial characteristics, or sensory quality characteristics.
- Mechanistic models relate weight losses to changes in DM content, in pH, in a_w, and in texture; the kinetics of pH change to lactic acid and ammonia production; and the amounts of end products (lactic acid, acetic acid, ammonia, aroma compounds, etc.) produced and substrate (carbohydrates, oxygen, etc.) metabolized within the framework of biochemical and microbial stoichiometry (Figure 1).

Although such models are over-simplified, they have been supported by experimental data within experimental error and have been used to evaluate the effects of starter culture, sausage diameter, and chopping intensity on the relative importance of

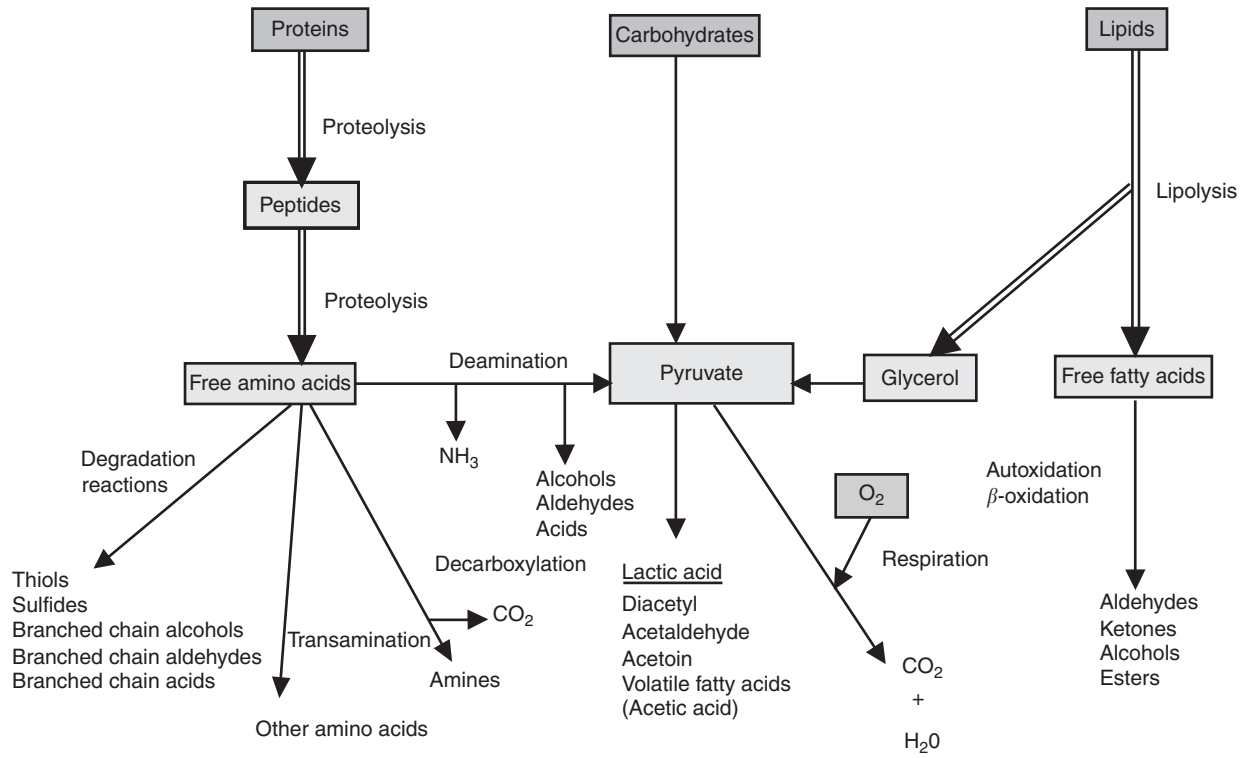

Figure 1 Simplified overview of sausage metabolism. Double lines indicate pathways with a major contribution of muscle and adipose tissue enzymes.

respiration versus carbohydrate and protein fermentation. Evaluation of the effects of technological changes on sensory characteristics and aroma analyses involves more intricate multivariate statistical models such as principal component analysis (PCA). Although there is still a long way to go before control of flavor formation by the use of CNS starters, for example, is adequate, these tools for data analysis have shown the importance of starter species in accelerating flavor formation.

Fermented Sausages as 'Functional Meat Products'

Processed meats have been subject to increasing health concerns from both the consumer and science community. Improving the 'health value' of fermented sausages is a continuing challenge for production technologists. Fermented sausages have, for instance, been reduced in fat content and successfully enriched with orange fiber, short-chain fructo-oligosaccharides, and long-chain *n*-3 polyunsaturated fatty acids. Enrichment in calcium used amounts allowing these sensorial adequate sausages to be considered a 'source of calcium.' The addition of probiotic lactobacilli is actively investigated, including, for example, conjugated linoleic acid-producing strains, but work should include investigation of their survival rate and persistence in the human intestinal tract, as well as their antibiotic resistance. A larger bottleneck is the demonstration of true probiotic effects in humans via dedicated studies. The now widely recognized association of processed (i.e., cured) meat intake with the incidence of colo-rectal cancer should also motivate fermented sausage processing technologists to try and alleviate this problem. In this respect, the use of nitrite may be reconsidered as acceptable no-nitrate/nitrite-added commercial hams, bacons, and frankfurters have been produced. In fact, not only may there exist a causal relationship between colo-rectal cancer incidence and the presence of nitrite and/or the formation of nitrosyl-haem, but nitrite was also shown to prevent the formation of the red pigment Zn-protoporphyrin. This compound has been reported to inhibit hemin-induced DNA damage and colonic cell hyper proliferation, is a major chromophore in dry-cured Iberian ham and in Parma ham cured without nitrite, and may be produced by enzyme treatment to de- or transmetallize metalloporphyrins. It should also be realized that the nature of the fermentation/ripening period of dry-cured meat products may contribute to sausage 'functionality,' as it has been suggested that oligopeptides hydrolyzed by muscle dipeptidyl peptidases can generate angiotensin-I-converting enzyme inhibitory dipeptides (e.g., antihypertensive peptides).

Glossary

Ciguatera toxin A toxin that causes food poisoning when it becomes concentrated in the flesh of tropical and subtropical predatory fish. The toxin is produced by blooms of dinoflagellates (phytoplankton microorganisms).

Pauly reagent 4-Sulfobenzenediazonium (CAS no. 4332-41-6), a substance forming an intensely colored (therefore, easy to detect) product when attached to amines.

Puffer fish toxin Tetrodotoxin, a powerful (and often fatal) blocker of nerve transmission produced by symbiotic bacteria for use against predatory organisms by the puffer fish (and other members of the Order Tetraodontiformes) and blue-ringed octopuses of the tropical and subtropical genus *Hapalochlaena*.

Rheometer (from Greek, *rhein*, flow) An instrument used to measure the resistance of flesh to physical pressure, which is proportional to freshness.

Scombroid poisoning Illness, including urticaria, caused by the presence of large amounts of histamine in stale (or insufficiently refrigerated) fish. This histamine is produced in large amounts by bacterial action. Symptoms (such as urticaria) resemble an allergy, mimicking the body's natural release of histamine in response to an allergen.

Shellfish toxin A group of toxins found in various kinds of shellfish following contamination from toxin-producing dinoflagellates (cf. Ciguatera toxin).

Torry meter An instrument that measures the dielectrical properties of fish as an objective assessment of freshness (Torry is the name of the research station in Scotland where it was originally developed).

Zero-order kinetics A direct linear relationship where the independent variable has no power function (i.e., x to the power 1; log $1=0$, hence a zero-order logarithmic relationship).

Introduction

Fish not only is a high-protein food but also provides many other essential food elements in a diet. However, the whole process of fish collection, preservation, and storage is fundamentally different than the standard farming practices for terrestrial meat animals, because of the way degradation occurs. This article covers factors affecting fish quality, its measurement, and the inspection process.

The quality of food can be estimated in two ways: food safety and functional quality (Table 1). Safety is judged by whether or not food contains toxic substances, which can be detected by chemical or biological assessment. Functional quality considers food for its commercial value, nutritive value, and good flavor. These can be estimated either by sensory assessment or by instrumental analysis.

Sea foods on the one hand are well known to contain various beneficial components for human health, such as n-3 polyunsaturated fatty acids (e.g., eicosapentaenoic acid and docosahexaenoic acid), taurine, and vitamin D. On the other hand, sea foods often include certain hazardous components from the sea or produced after landing (Table 2). Hazardous components are classified into various types (Table 3). Toxic substances from the sea can be detected only by chemical and biological analysis, although humans can usually avoid them by experience. Hazardous components produced after landing are related to deterioration (freshness loss) of sea food, especially fish. It is, therefore, important to determine the degree of freshness to prevent harm to the consumer.

Table 2 Factors compromising the functionality and safety of food

Functionality-undermining factors – Possibly judged by five senses	
Color	
Odor	
Alien substance	Originated in habitat
	Parasitic worms, other organisms, garbage, etc.
	Originated from land
	Insects, garbage, hair, yarn, or glass
	Metal, plastic, etc.
Microorganisms – Fungi and bacteria	
Change in form	
Change in physical properties	
Safety-related factors – Cannot be judged by five senses	
Originally involved in aquatic organisms – Natural toxins	
Originated from biological concentration	
Heavy metals, radioactive elements, and environmental pollutants	
Mixed during processing	
Microorganisms (bacteria and fungi)	
Heavy metals	
Toxins – Histamine	
Lipid peroxides	
Food additives	

Table 3 Hazard factors found in seafood

Biological hazards	Pathogenic bacteria	*Vibrio*, *Escherichia coli*, etc.
	Food-spoiling bacteria	Bacteria that spoil food by producing toxic substances (amines) and unpleasant odors
	Viruses	Norovirus and hepatitis A virus, etc.
	Parasites	*Anisakis*, *Cryptosporidium*, etc.
Chemical hazards	Biological	Shellfish toxin, puffer toxin, ciguatera toxin, mycotoxins, histamine, and heavy metals
	Human origin	Food additives, antibiotics, pesticides, fungicides, and heavy metals Detergents and environmental hormones
Physical hazards		Glass shards, metal, wood, yarn, etc.

Freshness Assessment and its Evaluation

Freshness is assessed by a variety of methods, including sensory, chemical, and physical methods, each with its own merits and demerits (Table 4).

Sensory Method

Subjective assessment of the sensory quality of fish is quick and instrument free and can be used in every situation, but because it is subjective, the results vary according to the assessor. Unfortunately, this method cannot be used for frozen fish. It is possible to standardize sensory assessment data to achieve objectivity and accuracy by training assessors to examine fish. Personal bias is further reduced by using a panel of experts to examine fish and averaging the independent assessments statistically. Such sensory panels can be expensive to set up and run, and their use is justified in only a few instances.

Chemical Method

The chemical method is based on measurement of substances in fish that change after death. There are three main groups of chemicals used for this purpose: adenosine-5′-triphosphate (ATP)-related compounds, nonvolatile biogenic amines (products of decarboxylases), and volatile compounds (products of reduction processes).

Overview of adenosine-5′-triphosphate-related compounds of fish postrigor

Soon after death or cessation of circulation, natural enzymes present in the tissues begin to break down ATP in the muscle to form adenosine-5′-diphosphate (ADP), adenosine-5′-monophosphate (AMP), inosine-5′-monophosphate (IMP), inosine (HxR), and finally hypoxanthine (Hx) (Figure 1). Among the enzymes present is 5′-nucleotidase (5′-Ntase), which catalyses the dephosphorylation of IMP to HxR and is unique due to its lower activity than other enzymes in fish and shellfish muscle in the range −5 to +20 °C and its zero-order kinetic property. This means that IMP will accumulate in early postmortem fish muscle and decrease both linearly and independently of time during storage, at least during the initial stages of spoilage. The monitoring of the decrease of IMP and other nucleotides and the increase of HxR and Hx has thus been used widely for evaluation of fish freshness. The production of HxR and Hx has also been attributed to bacterial enzymes after a long storage period.

Table 4 Methods for fish freshness assessment and its evaluation

Classification	*Concrete assessment method*	*Evaluation*	
		Merit	*Demerit*
Sensory	Outward appearance (color, clearness of the eyeballs, and presence of scratches), hardness (rigor mortis), smell, body shape, and touch	Quick and simple assessment No need for equipment	Subjective analysis Uncertainty Variation among panelists
Chemical	Nucleic acid-related compounds (*K* value), histamine levels, ammonia, and trimethylamine (TMA)	Objective and exact assessment Theoretical data	Relatively time consuming Instruments indispensable
Physical	Hardness (rigor index; RI), texture (rheometer), Torry meter, and impedance	Nondestructive measurement Quick assessment	Need confirmation by chemical analysis Variation with species and body parts
Microbiological	Total count, spoilage bacteria, and pathogenic bacteria	Disease prevention effect	Time consuming No criteria regarding number of bacteria

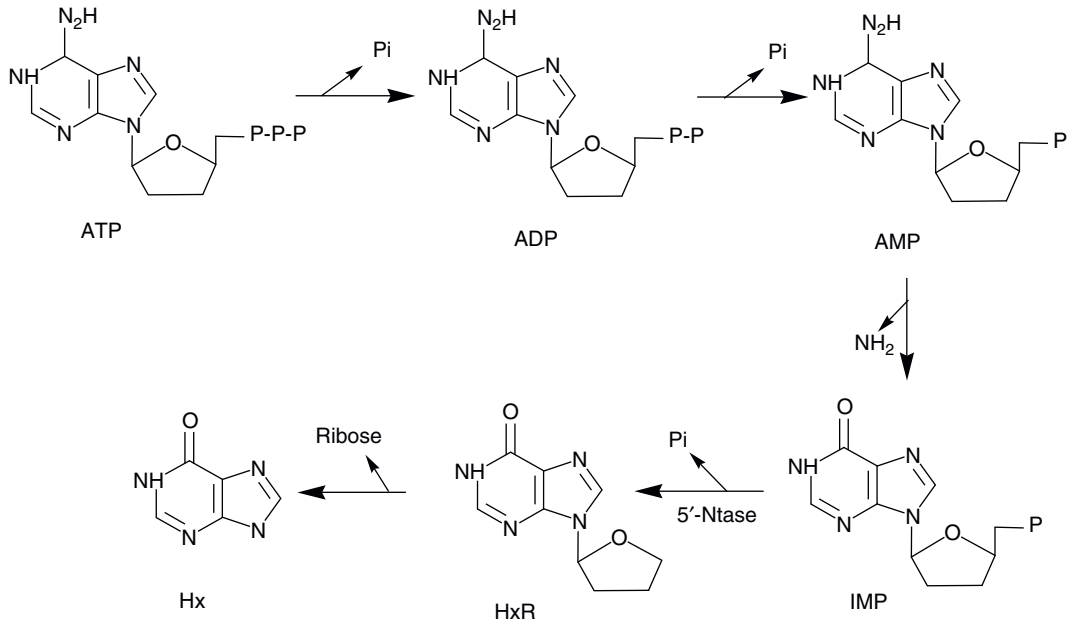

Figure 1 ATP degradation steps in fish flesh.

Measurement of adenosine-5′-triphosphate-related compounds and use for freshness assessment

Various methods for the analysis of ATP-related compounds have been proposed, including ion exchange chromatography, high-performance liquid chromatography (HPLC), enzymatic methods, enzyme colorimetric methods, enzyme-sensor methods, and near-infrared spectroscopy. Among these methods, complete analysis of nucleotide catabolites is possible only by ion exchange chromatography and HPLC. Other methods measure only one or two specific compounds, such as IMP, HxR, or Hx.

Saito *et al.* proposed the *K* value as an index of freshness or spoilage in fish. It is calculated from the values of HxR, Hx, and total nucleotide levels in fish at the time of measurement and is defined according to eqn [1]:

$$K\% = \frac{[\mathrm{HxR} + \mathrm{Hx}] \times 100}{[\mathrm{ATP} + \mathrm{ADP} + \mathrm{AMP} + \mathrm{IMP} + \mathrm{HxR} + \mathrm{Hx}]} \quad [1]$$

It was observed that in freshly caught fish, the *K* value could be as low as zero, for moderate-quality fish 10–20, values of more than 50 are reached after 10 days of storage on ice, and the highest values, up to 90, were observed in spoiled fish. The *K* value showed excellent agreement with sensory assessment when measured for a number of different species of fish. However, marine mollusks and crustaceans degrade ATP in a different way than that by finned fish, mostly via the adenosine pathway. In spite of this, the *K* value can still be used generally

for freshness assessment, and it is presently considered to be one of the most appropriate indicators of fish freshness. The main drawback of the method is that it requires expensive instrumentation, such as HPLC, and a relatively long analysis time per sample, so the *K* value method has been used mainly in the laboratory and is not used widely on-site in fisheries. Recently, a simpler rapid method for *K* value analysis has been developed on the basis of paper electrophoretic separation and ultraviolet (UV) irradiation.

Measurement of K value by paper electrophoresis: The 'freshness checker'

Sato developed a fast and simple *K* value-measuring instrument named the Freshness Checker (available from QS-Solution). It is based on four steps: preparation of an extract from small pieces of fish (approximately 250 mg) with 600 µl perchloric acid; application of 3 µl extracts onto electrophoresis paper and separation of nucleotides and nucleosides+bases by electrophoresis at 800 V for 5 min; detection of results by UV irradiation and digital imaging of two spots (spot A in the anodal position and spot B in the original position of sample loading; Figure 2); and calculation of *K* value using a computer program (Figure 3). Spot A includes nucleotides, such as ATP, ADP, AMP, and IMP, and spot B includes nucleosides +bases, such as HxR and Hx. The computer program Spot Analyzer calculates the integration ratio of the two spots (spot size and density), according to eqn [2]. In this way, *K* value can be calculated in less than 10 min.

$$K\% = \frac{[\text{Integration value of spot B}] \times 100}{[\text{Integration value of spot A}] + [\text{Integration value of spot B}]} \quad [2]$$

Nondestructive assessment of fish freshness by near-infrared and phosphorus-31 nuclear magnetic resonance

Near-infrared (NIR) spectroscopy is used widely in the agricultural and food processing industries for measuring fat, protein, and moisture in fish, meat, and crops. It is a rapid, sensitive, and nondestructive method for analysis of organic materials with little or no sample preparation. An NIR spectroscopic method has been applied for estimation of Hx and of the *K* value for tuna, mackerel, cod, and salmon. It is noteworthy that NIR spectroscopy gives a prediction correlation of 0.98 with an error of 1.04 days and has proven useful for evaluating fish freshness. The use of partial least squares regression for calibration provides a higher correlation coefficient of prediction for inspection of fish freshness.

Nondestructive phosphorus-31 nuclear magnetic resonance (^{31}P-NMR) is used to evaluate the degree of fish freshness by measuring levels of creatine phosphate (PCr), ATP, and inorganic phosphate (P_i). The ratios of [PCr]/P_i and [ATP]/P_i decrease rapidly and continuously during acceptable stages of deterioration and have been demonstrated as potential indices to estimate fish freshness. The biggest drawback to these methods is the very high expense of the instruments.

Physical Methods

Rigor index

The most dramatic exterior change after death is the development of rigor mortis. This is similar to that in other red meat species but with a different time course, and it is easier to measure because of the way the muscles are arranged. Shortly after death, the muscle is totally relaxed and this limp elastic state continues for some hours; thereafter the muscles become

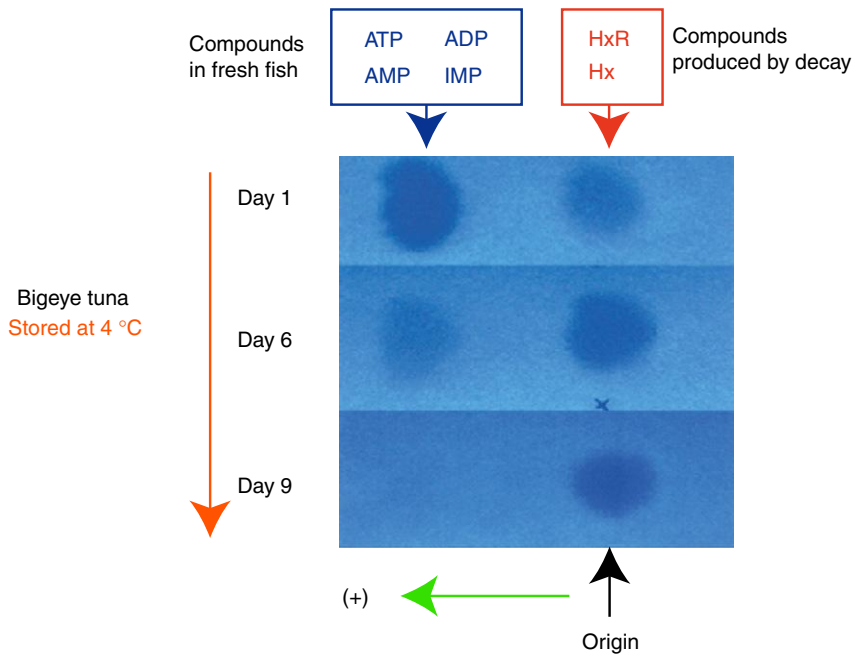

Figure 2 Electrophoretic separation of freshness-related compounds.

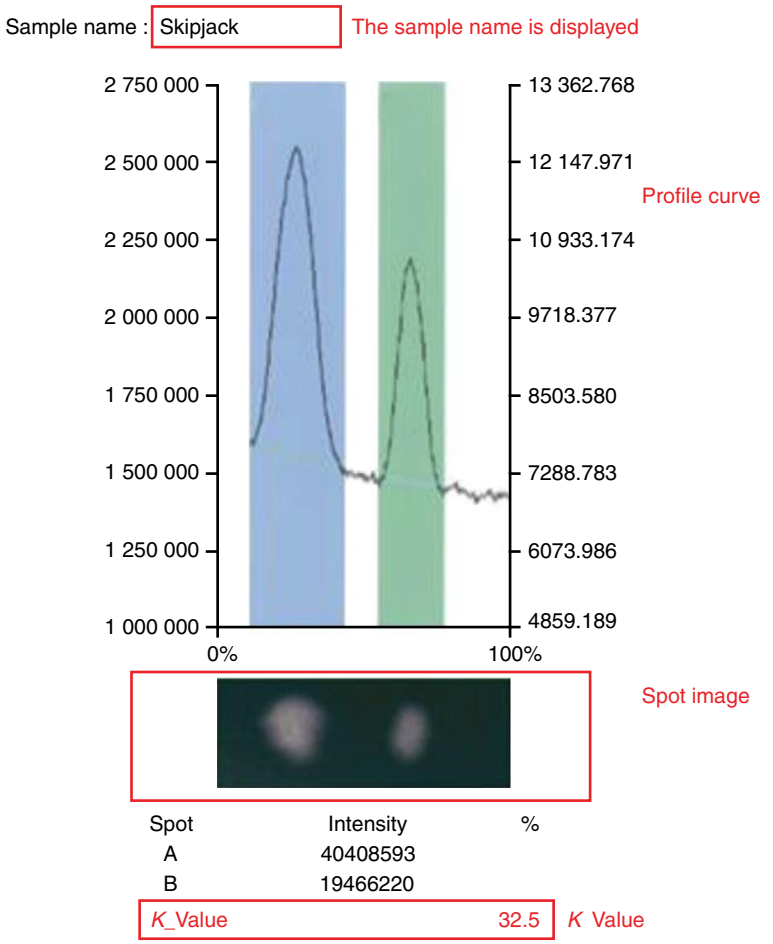

Figure 3 *K* value estimation by Spot Analyzer.

rigid. When fish are hard and stiff, the whole body becomes inflexible and the fish is in a state of rigor mortis. This condition usually lasts for several hours or a few days, and thereafter the rigor resolves. The resolution of rigor mortis, which is mainly due to autolysis, relaxes the muscles again, and they become flaccid but are no longer as elastic as before the onset of rigor. The state of fish body hardness and stiffness is expressed by the rigor index, as shown in Figure 4, and is calculated according to eqn [3].

$$\text{Rigor index} = \frac{L_0 - L}{L_0} \times 100 \qquad [3]$$

The onset, duration, and tension of rigor are influenced by preslaughter stress and physical activity, storage temperature, and the differences between premortem temperature and postmortem storage temperature. Fish use by Japanese consumers can be generally summarized as follows in relation to the state of rigor mortis:

- *Phase 1:* From the moment of slaughter to the end of rigor mortis resolution. The flesh is very fresh and has a good and delicate flavor, with a fresh neutral smell and no fishy odor. Consumers can eat the fish raw as 'sashimi' or 'sushi' and can sometimes enjoy raw fish just after slaughter ('ikizukuri,' live fish cooking). While very fresh, the flesh does not have much 'umami' or very strong taste. Consumers enjoy mainly the texture of the flesh and the delicate specific taste.
- *Phase 2:* After rigor mortis resolution. The fish is still fresh but is eaten after being cooked as a grilled or boiled fish. The flesh has no off-flavors but sometimes a slight fishy smell. The texture is still pleasant.

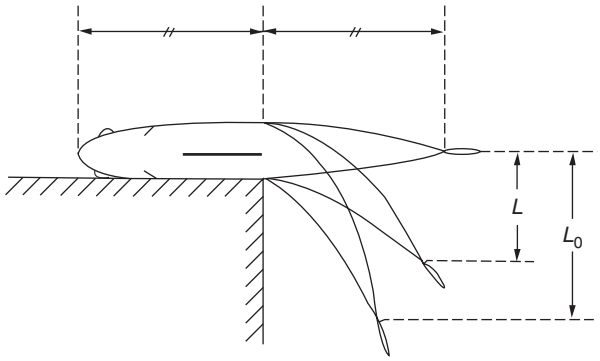

Figure 4 Expression of rigor index. L_0, status just after slaughter; L, status at rigor.

- *Phase 3:* There is sign of spoilage and a range of volatile, unpleasant smelling substances are produced, depending on the fish species. The volatile compounds may be trimethylamine (TMA) or ammonia. TMA has a very characteristic 'fishy' smell. At later stages, unpleasant odors of ammonia, sulfur, and rancidity develop. The texture becomes either soft and watery or tough and dry. This phase is relatively short.
- *Phase 4:* The fish can be characterized as spoiled and putrid.

Texture

It is well known that the hardness of fish flesh decreases gradually after death. This phenomenon is an autolytic change induced by protease activity. There have been attempts to use the textural property for assessment of freshness. Textural properties of fillets from several fresh fish have been measured by a rheometer (Yamaden model 3305, Tokyo) using a flat-ended cylinder at selected time intervals after death. Fish slices (10 mm thick) were measured at right angles to the orientation of the muscle fibers. Regardless of whether rigor had been reached or not, the hardness (breaking strength) of all the tested fish, except for tiger puffer, decreased sharply within 24 h after death and then decreased more gradually, although the values varied markedly between species. These findings suggest that tenderization of fish muscle starts shortly after death, independent of rigor development and regardless of fish species.

The main problems with these methods are sample preparation, the nonuniform structure of fish flesh, and the different orientation of structural elements within the flesh. For example, hardness and shear force values of raw Atlantic salmon (*Salmo salar*) fillets differ along their length: harder toward the posterior.

Electrical sensors

After death, the cellular and microsomal membranes of fish flesh are denatured and damaged. As a result, the ionic strength and electrical properties of the cells and tissues alter. Conductivity changes have been expected to provide a method for measuring postmortem changes or the degree of spoilage, so instruments have been developed to measure electrical conductivity and impedance. Such an instrument is the Torry meter. The data obtained by the Torry meter show good correlation with time after death, independent of the fish species. Electrochemical impedance spectroscopy in the frequency range of 0.1 Hz–100 kHz has been used to measure carp, herring, and sea bass during storage after death at 4, 15, and 25 °C. It is worth noting that this method offers a simple and rapid *in situ* measurement of the onset of spoilage. The phase angle and admittance changes are the best freshness indicators from which the four categories of freshness may be defined for all the species of fish tested.

Safety Assessment

The main hazardous factors related to human life or health found in fish and other sea food are puffer fish toxin, ciguatera toxin, shellfish toxin, histamine, *Vibrio*, and other pathogenic bacteria. The toxins can be detected by routine biological or chemical methods. This article will deal only with histamine analysis and histamine-forming bacteria.

Histamine

Histamine is well known as the substance causing allergy-like food poisoning after ingestion of scombroid fish that are not chilled adequately between harvest and consumption. Histamine intoxication is, therefore, often called scombroid poisoning and is derived from free histidine in fish muscle released by histidine decarboxylase originating from histamine-forming bacteria. The main symptom of food poisoning due to histamine is an itchy rash called urticaria. The worldwide network for harvesting, processing, and distribution of fish and fish products has made scombroid poisoning a global problem. In fact, scombroid poisoning is now the most common form of seafood-borne disease in the US. Mackerel, bonito, and tuna contain high levels of histidine and consequently are susceptible to the accumulation of histamine with subsequent histamine poisoning. The problem with histamine in seafood is quite serious even today, but the details of the production and diffusion of histamine in scombroid fish are well known from the research of Tao *et al*.

As histamine is rather easy to detect and estimate, the histamine content is specified in standard regulations and is used as an index for freshness, quality, and danger of scombroid poisoning. The United States Food and Drug Administration's (FDA's) 'Fish and Fishery Products Hazards and Controls Guide' states that histamine is generally not uniformly distributed in a decomposed fish. If 50 ppm is found in one section, it is possible that other sections may exceed 500 ppm. The FDA has, therefore, specified a safe maximum limit of 50 ppm. The biggest problem is the methodology for histamine determination. When determining histamine in fish, it is very important to separate the histamine completely from the very large amounts of interfering compounds, such as free histidine and carnosine. Therefore, careful and tedious pretreatment is required to avoid contamination with interfering compounds.

Recently, two rapid methods based on an enzyme oxygen sensor assay and enzyme-linked immunosorbent assay have been devised. The first-mentioned method measures the decrease in oxygen concentration in the reaction mixture and uses an antigen–antibody reaction. Both methods can obtain results within 30 min and determine whether a sample contains more or less than 50 ppm histamine, which is the current FDA action level. These tests have several advantages over existing test protocols as they can be evaluated visually. They are also insensitive to salt content, which is a problem with other tests. The drawbacks of these methods include the expensive instruments and high operating costs due to the use of enzyme kits.

A simpler method has been developed on the basis of a one-step derivation of histamine by Pauly reagent and HPLC separation. However, this method requires an expensive instrument and a skilled operator. Recently, an even simpler rapid method has been developed for histamine analysis

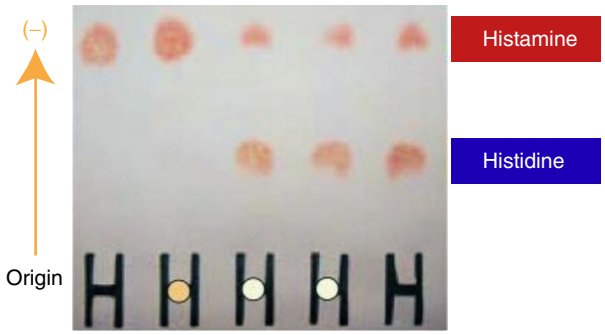

Figure 5 Electrophoretic separation of histamine and histidine.

based on paper electrophoretic separation and Pauly reagent development.

Determination of histamine by paper electrophoresis: The 'Histamine checker'

Sato *et al.* developed a new quick and simple analytical method for histamine determination in fish and other seafood. It consists of sample extraction, adsorption on a paper disc, application of the paper disc on electrophoresis paper, electrophoresis for only 5 min, drying, and color developing by Pauly reagent. Histamine can be satisfactorily detected and completely separated from histidine, carnosine, and other Pauly reagent-positive compounds (Figure 5). This method does not need expensive instrumentation or any tedious pretreatment to eliminate potential interference from other imidazole compounds, such as histidine or carnosine. It can be used to detect histamine in multiple fish and seafood samples simultaneously, detecting as little as 15 ppm histamine, with an absolute minimum detection limit of approximately 10 ng histamine on one spot. The merits of the method are that it is rapid, simple, and can determine several samples simultaneously. It is sold as the Histamine Checker from QS-Solution.

Microbiological Methods

Microbiological methods assess freshness and hygienic quality by measuring the total count of bacteria or sometimes the number of spoilage bacteria or pathogenic bacteria. Total counts vary according to the incubation conditions. The nutrient medium for seawater bacteria requires addition of 2.5% sodium chloride compared with the medium for freshwater bacteria. It is proposed that a tentative total bacterial number for acceptance should be 10 million organisms per gram. However, it should also be noted that there is no correlation between the total count and the presence of bacteria of public health significance. There are many problems related to traditional microbiological examination, such as tedious pretreatment, requirement for skill in execution and interpretation of the results, time-consuming incubation, and so on. To resolve these problems, several new methods have been developed.

Direct count by phase contrast microscopy or fluorescence microscopy is very rapid. The staining of cells with acridine orange and detection by fluorescence microscopy have earned widespread acceptance as the direct epifluorescence filter technique. The main disadvantages with direct counting are sensitivity and inaccuracy, which result from the inclusion of both live and dead bacteria.

Indirect estimation of microorganisms has been proposed, such as measurement of bacterial ATP, deoxyribonucleic acid, carbon dioxide released by bacteria, heat generated by bacteria, conductance, capacitance, and impedance. These methods can provide rapid results, but the main disadvantage is a requirement for efficient separation of bacteria from the fish flesh being tested.

Quick detection and counting of histamine-forming bacteria

Histamine-forming bacteria (HFB) can be detected simply and rapidly by filtration with two-layer membranes and membrane incubation, followed by microscopic observation. Liquid samples, including seawater and seafood, can be assayed on-site using this method. Liquid samples are filtered through a two-layer filtration system, using a pair of circular (25 mm diameter) membrane filters (upper 10 μm mesh, lower 0.2 μm). For seafood samples, the flesh is minced with nine volumes (v/w) of sterilized saline solution under aseptic conditions, kneaded inside a plastic sachet, and then the soluble fraction is filtered by the above method. The membrane filter set is then rinsed with 10 ml sterilized saline solution.

The lower 0.2 μm membrane filter is placed on artificial seawater agar medium (pH 5.8) containing histidine (0.5%), with bromothymol blue (0.04%) as a pH indicator, and incubated at 35 °C (Figure 6). HFB are detected as colonies surrounded by a blue halo on the 0.2 μm membrane filter after 5 h of incubation (Figure 7). The color change in the agar medium can be attributed to an alkaline shift after histamine formation by HFB. Histamine production ability by colonies with a blue halo is confirmed by prolonged incubation in histidine broth medium at 35 °C for 24 h. This is a fairly rapid and simple method for detecting HFB and can be applied to food hygiene systems, such as hazard analysis and critical control point in seafood processing lines.

The colony number can be calculated as follows. With an optical microscope using an 18 mm eyepiece lens and a 10× objective lens, the area of optical view is 2.543 mm^2 (of course, this must be calculated for the particular microscope and lens combination being used). The valid filtration area is 210 mm^2. The average number of colonies (originally single organisms from the food being tested) can be calculated by summing the counts in several fields, and the mean number of colonies per gram of sample can be calculated as in the following eqn [4]:

$$\text{Colonies per g of sample} = \frac{\text{Mean number of colonies} \times 210 \times \text{dilution ratio} \times \text{dilution volume (10 ml)}}{2.543 \times \text{Sample weight (g)} \times \text{filtered volume (1 ml)}} \quad [4]$$

FOODBORNE ZOONOSES

MT Destro and VB Ribeiro, University of São Paulo, São Paulo, SP, Brazil

Glossary

Foodborne Disease Sickness that is carried or contracted by eating food or water.

Gastroenteritis Inflammation of the lining membrane of the stomach and the intestines characterized especially by nausea, vomiting, diarrhea, and cramps.

Hemolytic uremic syndrome (HUS) A disorder that usually occurs when an infection in the digestive system produces toxic substances that destroy red blood cells causing kidney injury.

Ready-to-eat Food products that are prepared in advance and can be eaten as sold.

Zoonoses Diseases and infections that are naturally transmitted between vertebrate animals and humans.

Introduction

Diseases caused by foodborne agents constitute a worldwide public health concern due to the huge volume of food being produced and consumed throughout the world on a daily basis. In industrialized countries, up to 10% of the human population may annually suffer from foodborne zoonoses, but the real incidence is likely to be much higher. This scenario is probably worse in developing countries. The Centers for Diseases Control and Prevention (CDC-USA) estimates that each year, 1 in 6 Americans (or 48 million people) fall ill, 128 000 are hospitalized, and 3000 die of foodborne diseases. According to data from countries of the European Union, more than 320 000 human cases are confirmed each year of foodborne zoonoses.

Definition

Zoonoses are infections and diseases that are naturally transmissible directly or indirectly, for example via contaminated foodstuffs or from animals to humans. Nevertheless, foodborne zoonotic diseases are caused by consuming food or drinking water contaminated not only by pathogenic (disease-causing) microorganisms such as bacteria and their toxins, viruses, and parasites, but also by prions. The severity of these diseases in humans varies from mild symptoms to life-threatening conditions.

Infective Pathways

There are different transmission routes by which zoonotic agents can be introduced into a food supply chain, especially with regard to the meat processing. The main route is established when an animal becomes contaminated with a pathogen, which may or may not produce clinical signs of disease, and is processed with the food, for example, raw meat cuts. The pathogen is transferred to the product, and if it is consumed without adequate handling or cooking, disease might occur.

Zoonotic Agents Associated with Meat

Meat can be derived from a variety of birds, reptiles, and mammals, especially cattle, swine, sheep, goats, and poultry (chicken, duck, and turkey). Meat animal carcasses and meat cuts can be easily contaminated during processing and, if not properly handled, processed, and properly preserved, they can support the growth of and serve as sources of different spoilage and pathogenic microorganisms.

A variety of sources can contribute to microbial contamination during harvesting, chilling, and cutting processes, when the muscles and viscera of animals are exposed to the environment. Contamination sources include air, water, soil, feces, feed, intestines, processing equipment, utensils, and humans.

Activities involved in the process of animal slaughtering and carcass dressing can result in contamination of the exposed cut surfaces of muscle tissue by both Gram-negative and Gram-positive bacteria, as well as yeasts, molds, and viruses. The most important microorganisms associated with meat are listed in Table 1 and the following sections describe some of the most frequent zoonoses according to European Food Safety Authority (EFSA) and CDC (USA).

Campylobacter

Campylobacter species are pathogens associated with human gastroenteritis in both developed and developing countries. Campylobacteriosis in humans is caused by thermotolerant *Campylobacter* spp. and the infective dose of these bacteria is generally quite low (less than 100 viable organisms). The species most commonly associated with human infection is *Campylobacter jejuni*, followed by *Campylobacter coli* and *Campylobacter lari*, but other *Campylobacter* species are also known to cause human infection.

The most common disease associated with *C. jejuni* and *C. coli* in humans is an acute inflammatory enteritis following an incubation period of approximately 3 days (ranging from 18 h to 8 days). The disease results in cramping and profuse

Table 1 Zoonotic agents associated with meat contamination and possible occurrence of foodborne zoonoses

Bacteria	*Yeast*	*Molds*[b]	*Virus*	*Other*
Campylobacter	*Candida*	*Aspergillus*	Norovirus	Prions[c]
Salmonella spp.	*Saccharomyces*	*Penicillium*	Hepatitis	
Clostridium perfringens	*Cryptococcus*	*Fusarium*		
Verotoxin-producing *Escherichia coli* (VTEC)	*Pichia*			
Listeria monocytogenes	*Rhodotorula*			
Yersinia enterocolitica	*Trichosporon*			
Clostridium botulinum	*Debaryomyces*			
Bacillus cereus[a]				
Staphylococcus aureus[a]				
Clostridium difficile				
Enterococcus sp.				

[a]Pathogens that produce toxins responsible to cause disease.

[b]Mycotoxin-producing agents responsible to cause foodborne zoonoses.

[c]Infectious protein particles similar to a virus, but lacking nucleic acid that is considered to be the agent responsible for scrapie and other degenerative diseases of the nervous system.

diarrhea accompanied by fever, headache, dizziness, or myalgia. In rare cases, after an infection caused by *Campylobacter* spp., some serious diseases have been reported, for example, Guillain–Barré syndrome (the most common paralytic disease in the USA) and Miller-Fisher syndrome.

This pathogen is widespread, and present in many farm animals; poultry is very susceptible to colonization with high numbers of *Campylobacter*. The average incidences of *Campylobacter* spp. in animals and foods, according to different studies, were approximately 33% for live chickens; 53% for chicken meat; 56% for turkey meat; 32% for geese, ducks and other fowl; 45% for cattle; 6% for beef cuts; and 27% for pork and pork meat.

According to EFSA, campylobacteriosis has remained the most frequently reported zoonotic disease in humans in the European Union (EU) since 2005. Overall, 212 064 confirmed cases of this disease were reported in 2010, which represents an increase of 6.7% compared to 2009. The overall notification rate of human campylobacteriosis was 48.6 per 100 000 population. As in previous years, children under the age of 5 had the highest notification rate (126.8 per 100 000 population). However, the case–fatality rate for human campylobacteriosis was low (0.22%).

According to the last report of the CDC (USA), the estimate was that 6365 cases of acute gastroenteritis due to campylobacteriosis infection occurred in 2010. The overall notification rate of human campylobacteriosis in 2010 was 13.6 per 100 000 population.

Salmonella *spp.*

Salmonella is one the most important species of the Enterobacteriaceae family and this genus is divided into two different species: *Salmonella enterica* and *Salmonella bongori*. *Salmonella enterica* is subdivided into the subspecies *enterica*, *salamae*, *arizonae*, *diarizonae*, *houtenae*, and *indica*. Additionally, *Salmonella* is further divided into serotypes using the serotyping scheme developed by Kaufmann and White, for example, *S. enterica* subsp. *enterica* serovar Derby (or *Salmonella* Derby). There are more than 2600 serovars of zoonotic *Salmonella* and the prevalence of the different serovars changes over time.

Salmonella has long been recognized as an important zoonotic pathogen of economic significance in animals and humans. Salmonellosis is usually characterized by the acute onset of fever, abdominal pain, nausea, diarrhea, and sometimes vomiting, after an incubation period of 12–36 h. Symptoms are often mild and most infections are self-limiting, lasting for a few days. However, in some patients, the infection can be more serious and the associated dehydration can be life threatening. When *Salmonella* causes systemic infections, such as septicemia, effective antimicrobials are essential for treatment. Mortality is usually low, and less than 1% of reported *Salmonella* cases have been fatal.

According to EFSA, in 2010, a total of 99 020 confirmed cases of human salmonellosis were reported in the EU. This represents a decrease of 8.8% over the previous year. The EU notification rate for confirmed cases was 21.5 cases per 100 000 population. The case–fatality rate of human salmonellosis in that year was 0.13%. Detection of *Salmonella* was reported from a wide range of foodstuffs, but the majority of data were from various types of meat and meat products. The highest proportions of *Salmonella*-positive units were reported for fresh broiler meat and fresh turkey meat, at average levels of 4.8% and 9.0%, respectively. In fresh pig meat, 0.9% of tested samples were found positive for *Salmonella* and, in the case of fresh bovine meat, 0.2% of sampling units were positive.

The CDC (USA) has estimated that 8256 cases of salmonellosis occurred in 2010. The overall notification rate of human infection due to *Salmonella* in 2010 was 17.6 per 100 000 population with a case–fatality ratio of 0.4%.

Clostridium perfringens

Clostridium perfringens is an important pathogen of human gastrointestinal (GI) tract and can cause food poisoning, antibiotic-associated diarrhea, and sporadic diarrhea. The most important toxin made by this bacterium when in the human GI tract is *Clostridium perfringens* enterotoxin (CPE).

Although ubiquitous in the environment, only a small subpopulation of *C. perfringens* (usually less than 5%) harbors the CPE gene (*cpe*). The number of *C. perfringens* cells

(*cpe*-positive and *cpe*-negative strains) present in most nonoutbreak food samples is generally lower than 10 cfu.

Clostridium perfringens foodborne disease is third in incidence among foodborne illnesses in the United States, causing about 965 958 cases annually. Beef, poultry, gravies, and dried or precooked foods are common sources of *C. perfringens* infections. Deaths are uncommon, but might occur in the elderly, debilitated, or people otherwise predisposed to disease.

The key event for disease is the mishandling of foods from preparation to consumption, observed especially for poultry and beef. Failure to refrigerate after cooking can provide an opportunity for germination of spores and multiplication of vegetative cells. When this food is consumed, vegetative cells sporulate in the gut producing and releasing CPE in the process. The resulting diarrhea and cramping are solely due to the effect of CPE; illness is typically brief and self-limiting with symptoms typically resolved within 24 h.

Escherichia coli

Among the different groups of *Escherichia coli* present in animals and foods, the most important as a zoonosis is the shiga toxin/verotoxin-producing *Escherichia coli* (STEC/VTEC), a group characterized by the production of a shiga-like toxin. Many serogroups of *E. coli* have the potential to cause STEC/VTEC-associated illness, but the predominant serogroups in clinical cases are O45, O26, O91, O103, O111, O121, O145, and O157. STEC/VTEC infection is one of the most important forms of foodborne illness as it can lead to serious and sometimes fatal complications. Acute symptoms are generally self-limiting and include abdominal pain, watery diarrhea, which may become bloody, and sometimes vomiting. Fever is either mild or absent. Additional complications can occur, including hemolytic uremic syndrome (HUS, mainly in children) and thrombocytopenic purpura (mainly in adults). Approximately 5% of STEC/VTEC infections result in HUS, and mortality from HUS is around 10%. Human infection can be acquired through the consumption of contaminated food or water, or by direct transmission from person to person, or from infected animals to humans.

Bovine meat is considered a major source of foodborne STEC/VTEC infections for humans, although other forms of transmission have been identified. In 2010, 8566 bovine meat units were tested in Europe and 0.5% was found to be STEC/VTEC-positive and 0.1% STEC/VTEC O157-positive. The EU disease notification rate in that year was 0.83 per 100 000 population, a slightly higher rate than in 2009 (0.75 per 100 000 population).

Escherichia coli O157:H7 has been studied more than any other serotypes of STEC/VTEC as it was the first recognized causative agent involved in foodborne outbreaks resulting in severe cases of disease and some deaths in children. It appears that STEC/VTEC serogroups other than O157:H7 might be responsible for up to 50% of VTEC illness in both Canada and the United States. The uncertainty about the real incidence of non-O157 STEC/VTEC in foods is due to a lack of routine testing for these organisms, as well as difficulties in finding good markers to identify and distinguish them. *Escherichia coli* O157:H7, however, presents two unique physiological characteristics (non-sorbitol fermenting and β-D-glucuronidase negative) not shared by other STEC/VTEC and this can facilitate its identification.

Listeria monocytogenes

The bacterial genus *Listeria* currently comprises eight species, but human cases of listeriosis are almost exclusively caused by the species *Listeria monocytogenes*. The risk of contracting listeriosis is high for immunocompromised persons, the elderly, pregnant women, and neonates. Thirteen serotypes of *L. monocytogenes* have been identified, but only three serotypes (1/2a, 1/2b, and 4b) are associated with the majority of outbreak or sporadic cases of listeriosis.

Listeria species are organisms that are widely distributed in the environment, especially in plant matter and soil. The principal reservoirs of *Listeria* are soil, forage, and water; other reservoirs include infected domestic and wild animals. The main route of transmission to both humans and animals is believed to be through consumption of contaminated food or feed. Cooking at temperatures higher than 65 °C destroys *Listeria*, but the bacteria are known to survive under adverse conditions, forming biofilms and multiplying at temperatures as low as 4 °C. Cross-contamination of the product can occur after the killing steps, and *L. monocytogenes* occurrence in ready-to-eat (RTE) foods with a relatively long shelf life is of particular concern.

Listeria monocytogenes infection might result in a wide range of clinical symptoms. Infection can be noninvasive (gastroenteritis, fever) or invasive. The latter can lead to influenza-like symptoms, meningitis, central nervous system damage, and, in pregnant women, fetal infection and/or abortion. Incubation times for invasive infection can be up to 90 days, increasing the difficulty of attributing a particular food vehicle to cases.

Listeria monocytogenes has been recovered from many different foods, and conversely, a variety of different food items such as raw and processed meats, soft cheese, raw milk, hot dogs, seafood, and fresh vegetables and fruits have been linked to both sporadic cases and outbreaks of listeriosis. Pork meat and processed pork products, such as deli meats, have been implicated in *Listeria* outbreaks in European countries during the past decade. *Listeria monocytogenes* is of particular concern in raw, undercooked, or RTE foodstuffs.

Listeriosis cases have been reported mainly in the Northern hemisphere, with very few reports in the Southern hemisphere. A total of 1601 confirmed cases of listeriosis were reported in 2010 by the European Union. As in previous years, elderly persons were especially affected by the disease, with 60.2% of cases occurring in individuals over the age of 65. Overall, a high case–fatality rate of 17.0% was recorded among those cases for which information was available (2009: 16.6%). The EU notification rate was 0.35 per 100 000 population in 2010, which was slightly lower than in 2009 (0.4 per 100 000 population).

The CDC (USA) estimated that 125 cases of listerioses occurred in 2010. The overall notification rate of human listeriosis in 2010 was 0.3 per 100 000 population. However, the case–fatality ratio was approximately 12.8%, the highest among all foodborne zoonoses.

Yersinia enterocolitica

Yersinia enterocolitica is an important foodborne enteropathogen known for causing the disease termed yersiniosis. Clinical manifestations of yersiniosis ranges from mild gastroenteritis to invasive syndromes like terminal ileitis and mesenteric lymphadenitis.

Yersiniosis occurs mostly in young children with symptoms of mild gastroenteritis. However, in elderly persons and in patients with underlying conditions (iron overload, cirrhosis, diabetes, cancer, etc.) systemic forms of the disease are often observed. Symptoms typically develop 4–7 days after exposure and last an average of 1–3 weeks. In older children and adults, right-sided abdominal pain and fever might be the predominant symptoms and can often be confused with appendicitis. Other symptoms such as rash, joint pain, and/or bacteraemia can occur. Infection is most often acquired by eating contaminated food, particularly raw or undercooked pork meat. The bacterium is able to grow below 4 °C making contaminated refrigerated food a probable source of infection.

Even though this species comprises 6 biotypes and nearly 50 serotypes, the most frequently implicated serotype in human disease worldwide is O:3 with almost all strains belonging to biotype 4. Swine are the main reservoir of pathogenic *Y. enterocolitica* strains, harboring them in tonsils and in the oral cavity. The most common route of transmission of yersiniosis is through contaminated water and foods. Data concerning the incidence of *Y. enterocolitica*, and related species in foods, are well documented in many countries throughout the world. In Europe in 2010, 4.2% and 4.1% of pork meat and derived products samples tested positive for *Yersinia* spp. and *Y. enterocolitica*, respectively. Besides that, 6776 confirmed human yersiniosis cases were reported in that region indicating a slight decrease (10%) compared to 2009 ($N=7533$). *Yersinia enterocolitica* was the most common species reported in human cases and was isolated from 91.0% of all confirmed cases.

The CDC (USA) estimated that 159 cases of yersiniosis occurred in 2010. The overall notification rate of human infection due to *Yersinia enterocolitica* in 2010 was 0.3 per 100 000 population.

Norovirus

Viruses are the smallest of all self-replicating organisms, and consist solely of a small segment of nucleic acid encased in a simple protein shell. This definition covers the norovirus and is a good starting point for consideration of viruses of importance for food safety. The family Caliciviridae belongs to the Picornavirus-like superfamily – small, RNA viruses without an envelope. The calicivirus particles measure between 27 and 38 nm and consist of a spherical protein shell and genome of a single strand of approximately 7.6 Kb RNA. The caliciviruses known to infect humans belong to two genera: the genus Norovirus (NoV) and Sapovirus (SaV). The genus NoV is further subdivided into an increasing number of genogroups.

As small and simple organisms, with a small genome, viruses rely to a great extent on the enzymes of the host cell they invade to undergo their replicative cycle. Unlike bacteria, viruses are obligate intracellular species and show tissue tropism, i.e., efficient replication of the human NoVs occurs only in the gastrointestinal tract of humans; replication in other human tissues has not been detected. Although NoV genotypes have been found in beef cattle and swine, none of these animal genotypes have ever been detected in human patients.

Several studies have identified NoV in samples of bovine and swine, demonstrating that NoV strains can be present in livestock. In addition, NoV has also been isolated from retail meat samples, highlighting a possible route for indirect zoonotic transmission of NoVs through the food chain.

NoVs are the major causative agents of classical viral gastroenteritis in all age groups. After a short incubation period of 12–48 h, the disease is characterized by an acute onset of symptoms such as nonbloody diarrhea, vomiting, fever, nausea, weakness, myalgia, headache, and abdominal pain. Hence, the illness is referred to as 'gastric or stomach flu.' A typical NoV infection is self-limiting and treatment focuses on supportive care, prevention, and treatment of dehydration.

A NoV infection often originates from the ingestion of contaminated food or water, or from person-to-person contact. Contamination with small numbers of Nov particles can be enough to cause disease, with as low as 100 particles needed. Infected individuals shed the viruses in stool as well as orally. Aerosolized vomit droplets have also been implicated as a mode of transmission. NoVs (like all viruses) require a living host in order to replicate and are, therefore, incapable of multiplying in food, unlike bacterial pathogens. The CDC (USA) estimated that 23 million cases of acute gastroenteritis due to NoV infection occur every year, which is nearly 60% of all reported foodborne illnesses. Preventing contamination by proper food handling, sanitation, and hygiene is very important in the control of foodborne NoV illness.

Emerging Foodborne Pathogens

Some foodborne diseases are well recognized but considered emerging because they have recently either received more exposure in the news or increased in prevalence. For example, bovine spongiform encephalopathy (BSE), a fatal, transmissible, neurodegenerative disease of cattle, was first discovered in the United Kingdom in 1985. The cause of the disease was traced to an agent related to scrapie in sheep, which contaminated recycled bovine carcasses used to make meat and bone meal additives for cattle feed. In human populations, exposure to the BSE agent (probably via contaminated bovine-based food products) has been strongly linked to the appearance of a new transmissible spongiform encephalopathy of humans called new variant Creutzfeldt–Jakob disease.

Other foodborne pathogens are considered emerging because they are new microorganisms or because the role of food in their transmission has been recognized only recently. Since the description of the genus *Enterococcus* in the 1980s, many taxonomic investigations have resulted in assignment of about 30 species and the two most prominent representatives are *Enterococcus faecium* and *Enterococcus faecalis*. Several species of enterococci can be easily distinguished from other cocci by the ability to grow at 10 and 45 °C, in 6.5% NaCl, in the presence of 40% bile, and at pH 9.6. The enterococci are important in environmental, food, and clinical microbiology because they can be found in the intestines of food animals and can contaminate the meat while slaughtering. In raw meat products (beef and pork cuts), *E. faecalis* and *E. faecium* are the most

predominant species isolated, with mean counts ranging from 10^4 to 10^8 CFU per 100 cm^2.

Enterococcus can not only contaminate raw meats, but they can also be associated with processed meats. Cooking of processed meats might confer a selective advantage on enterococci as these bacteria are known to be among the most thermotolerant of the nonsporulating bacteria. *Enterococcus* are typical opportunistic pathogens and can cause infection in patients that have severe underlying disease or that are immunocompromised. They can cause bacteremia, endocarditis, urinary tract, and other infections. The question whether food strains possess an intrinsic lower pathogenic potential than clinical isolates has still not been fully answered and additional data are needed.

Another emerging foodborne pathogen is the species *Clostridium difficile*, an anaerobic, spore-forming bacterium that can produce toxin A or B on colonization of the gut. Patients at risk for *Clostridium difficile* infection (CDI) subsequently develop diarrhea or, in severe cases, pseudomembranous colitis. Traditionally, elderly and hospitalized patients who had been under antibiotic therapy were considered to be the most vulnerable to CDI. Because food animals can be colonized by *C. difficile*, and the bacteria has been isolated from retail meats, some researchers speculate that *C. difficile* is a food-associated organism and consumption of contaminated meat could be responsible for increased community-associated CDI.

Although the issue of zoonotic transmission of *C. difficile* was raised more than 20 years ago, and the finding of overlapping PCR ribotypes in animals and humans, *C. difficile* isolates have stimulated research in this field and the question of whether zoonotic transmission occurs has not been answered. Circumstantial evidence that *C. difficile* strains from animals were infecting humans (or vice versa) has been reported several times in recent years. Some studies conducted in Europe have persistently reported low prevalence rates, for example in up to 3% of meat samples, in contrast to the United States and Canada, where *C. difficile* is generally reported at much higher rates, for example in up to 42% of meat samples. Further studies are required to provide relevant data on the sources, transmission routes, growth, and survival of *C. difficile* in foods.

There is a question that one must take into account when thinking about foodborne zoonoses: 'Why do foodborne diseases emerge?' New foodborne disease threats occur for a number of reasons including: (1) globalization of the food supply, (2) the inadvertent introduction of pathogens into new geographic areas, (3) travelers, refugees, and immigrants exposed to unfamiliar foodborne hazards while abroad, (4) changes in microorganisms (development of new virulent strains in old pathogens, development of antibiotic resistance or through changes in the ability to survive in adverse environmental conditions), (5) demographic changes in the human population – the population of highly susceptible persons is expanding worldwide because of aging, malnutrition, HIV infections, and other underlying medical conditions, and (6) changes in lifestyle with higher numbers of people eating out (restaurants, canteens, fast food outlets, and street food vendors) or buying preprepared meals.

FOREIGN BODIES

LB Christensen and HD Larsen, DMRI/Danish Technological Institute, Roskilde, Denmark

Glossary

Dark field radiology An emerging technology taking advantage of diffraction of X-rays in fibrous matter.
Detectability The size of the smallest foreign body of a given material that is detectable in a specific product with a true probability error of 1%.
Detection limit A true error probability of 1%, which is calculated with a 95% confidence.
Hyperspectral vision A vision-based technology using many narrow spectral bands.
Phase contrast An emerging technology taking advantage of the refraction of X-rays in (soft) matter.

Definition and Implications of Foreign Bodies in Meat – Intrinsic Foreign Bodies

An intrinsic foreign body (FB) originates from the same animal species as the contaminated product does but, by definition, constitutes matter that does not belong in the actual product. Examples of intrinsic FBs (Table 1) could be hair, skin, bone fragments, blood vessels, teeth, or cartilage. Some of these materials could be natural parts of some products but unwanted and subject to complaints in other products. Depending on the definition and quality requirements for a given product, different definitions exist as to which intrinsic materials should be considered FBs.

Contamination with visible amounts of feces, oil, or bile is highly unacceptable to all consumers. Fecal contamination implicates a potential health risk to the consumer and there is zero tolerance to the occurrence of such contamination. Some beef abattoirs detect fecal contamination by fluorescence in UV light from the chlorophyll content of feces. However, the fluorescence method is very costly to establish and effective only when a considerable amount of the feed for slaughtered animals contains substantial amounts of chlorophyll. The method of choice is, therefore, often visual inspection. At high slaughter line speed, visual inspection is problematic. Steam vacuuming of high-risk areas is recommended.

Skin and hair is not acceptable to the consumers. The impact on food safety is generally low, but contamination of cattle carcasses with hair is often followed by dried soil and/or feces, and therefore the zero tolerance principle also includes skin/hair at beef abattoirs. Visual inspection at high slaughter line speed is problematic and, again, steam vacuuming of high-risk areas is recommended.

Teeth, fragments of teeth, and bone fragments can be small and sharp. They can cause harm and unpleasant experiences for the consumer. In high-risk products, detection with X-ray is necessary in order to detect small bone fragments effectively.

The acceptance of cartilage varies and whether or not it is considered critical depends largely on the country or region in which the given product is sold, because food safety is not affected by the occurrence of cartilage. The method of detection is visual inspection.

Blood clots and tissue with visual bruises are generally not considered of importance to the food safety, but several small or one large (more than 15 cm wide) hemorrhage is considered a major quality defect. The method of detection is visual inspection.

Pathological lesions, such as encapsulated abscesses and scar tissue from earlier disease, are generally of relatively low or no importance to food safety. However, they are highly unacceptable to the consumer. Furthermore, some pathological lesions constitute a threat to consumer health. Therefore, the effective detection of pathological lesions is critical. The method is visual inspection.

Table 1 Examples of intrinsic foreign bodies, their general impact on food safety, and the typical method of detection at the production line

Type	*Impact and food safety*	*Detection method*
Feces and bile	High/zero tolerance	Visual inspection
Skin, hair, etc.	High/zero tolerance	Visual inspection
Teeth and bone fragments	High	X-ray
Cartilage	Low	Visual inspection
Blood clots/lesions	Low	Visual inspection
Pathological lesions	High	Visual inspection

Definition and Implications of Foreign Bodies in Meat – Extrinsic Foreign Bodies

An extrinsic FB originates from the environment in which the animal lived, was slaughtered, or from the production line where the meat has been processed and packed.

Examples of extrinsic FBs (Table 2) could be needle parts (due to injections during upbringing), insects, wood, metal, plastic, glass, knives, gloves, and other equipment. The most frequent extrinsic FBs found in meat are forgotten personal equipment or parts of broken machinery, knives, tools,

 doi:10.1016/B978-0-12-384731-7.00222-1

Table 2 Examples of extrinsic foreign bodies, their general impact on food safety, and the typical method of detection at the production line

Type	*Impact and food safety*	*Detection method*
Metal/needle parts	High	X-ray/metal detector
Glass	High	X-ray
Concrete/ceramics	High	X-ray
Plastic	Moderate/high	X-ray or inspection
Rubber	Moderate	X-ray
Wood	Moderate/high	Inspection
Soil	Moderate/high	Inspection
Paper	Low	Inspection
Oil from conveyor	Low	Inspection

containers, and other materials in the immediate vicinity of production.

Extrinsic FBs are, in general, highly unacceptable to consumers and often constitute a high risk to consumer health and loss of confidence to the product and manufacturer.

Metal, such as needle parts from syringes, knives, parts of broken knives, or other metal, is highly unacceptable for the consumer and poses a serious risk for injuries. Application of detectable needles with a high content of magnetic alloys is recommended. Metal detectors or X-ray facilities should be used to detect metal parts in meat and meat products.

Presence of glass is critical to consumer health and is very difficult to detect visually when mixed into a product. Therefore, glass should never be present in production and packing facilities. Lamp glass and neon tubes should be repaired outside production hours and all broken glass be collected and secured effectively if accidents happen. Glass can be detected by X-ray.

Concrete and ceramic contamination typically arises from pieces of wall, ceiling, or floor that fall undetected into a product as a result of some kind of accident during production. Concrete and ceramics are unacceptable, pose risks to consumer health, and can be detected by X-ray. However, concrete or ceramics that are broken down to gravel particles may not be detected by X-ray.

Plastic and rubber are used for personal equipment, such as gloves or aprons, containers, tools, conveyor belts, and machine parts during production of meat and meat products. Some types of hard plastic can produce sharp fragments that constitute a risk to consumer health. Transparent types of plastic may even not be visible in the products. Soft plastic or rubber are generally of low or no importance to food safety but are unacceptable to the consumer. Rubber and some types of plastic can be detected by X-ray. However, plastic types that cannot be detected by X-ray are widespread, including polyethylene (PE) aprons that have the comparable X-ray absorption to fat.

Wood is generally only allowed in production facilities where all products are packaged. Wooden fragments are generally of moderate importance to food safety but are unacceptable to the consumer. Wood can be detected only by visual inspection.

Soil is generally of moderate importance to food safety, but soil contains massive amounts of diverse environmental bacterial flora. Further, soil occurring in the vicinity of animals raised for meat is often mixed with fecal matter and should be treated as such. Visual inspection is the only detection method for small soil particles. However, larger lumps of dirt may be detected by X-ray.

Clean paper is of low importance to the food safety but unacceptable to the consumer. Paper in production facilities should be avoided. Paper can be detected by visual inspection.

Oil from the conveyor is a frequent contamination risk. Only oil that is safe to consume should be used. Oil contamination is detected by visual inspection.

How to Assess the Risk of Foreign Bodies in a Production

In general, whether an FB constitutes a food safety risk or just an impairment of quality, the problem should be handled under a processing plant's Hazard Analysis and Critical Control Point (HACCP) or Quality Analysis of Critical Control Points plans, respectively.

Legislation and Customer Demands

In general, legislation states that physical hazards are not allowed to constitute any risk to consumer health. Good manufacturing practice must be observed. Potential risks must be assessed. Where relevant, the risk must be a critical control point. Apart from these general guidelines, the legislation on FBs is quite sparse. However, major retail chains and other major customers often set much more specific requirements including choice of detection technology, occurrence frequency of certain acceptable foreign materials (mainly intrinsic in origin), control/calibration of the required technical solutions, and handling of any contaminated product.

The International Food Standards (IFS Version 6, Jan 2012) include FB management as one of ten Knock Out requirements and correspondingly the British Retail Consortium (BRC Version 6, Jan 2012) includes details on management and handling of (mainly extrinsic) foreign material.

Technologies for Detection of Foreign Bodies in Meat

X-Ray Scanning and Metal Detection

When preventative measures fail, a technical screening system may be appropriate. Many commercial suppliers of screening systems are available. The two main techniques for screening systems are shown in Figure 1.

The metal detectors show good sensitivity to ferromagnetic types of FB and, to some extent, to some other metals like stainless steel and aluminum. X-ray systems are more costly than metal detectors (by approximately 5–10 times) but provide very sensitive screening to a broader range of FB materials like glass, metals, bones, polyvinyl chloride, and stones. Detailed technical descriptions may be found in manufacturers' literature. In this context, focus will be on some general aspects relevant to technical screening systems.

It is important to realize that no single technical solution is applicable for all types of foreign objects. As part of the

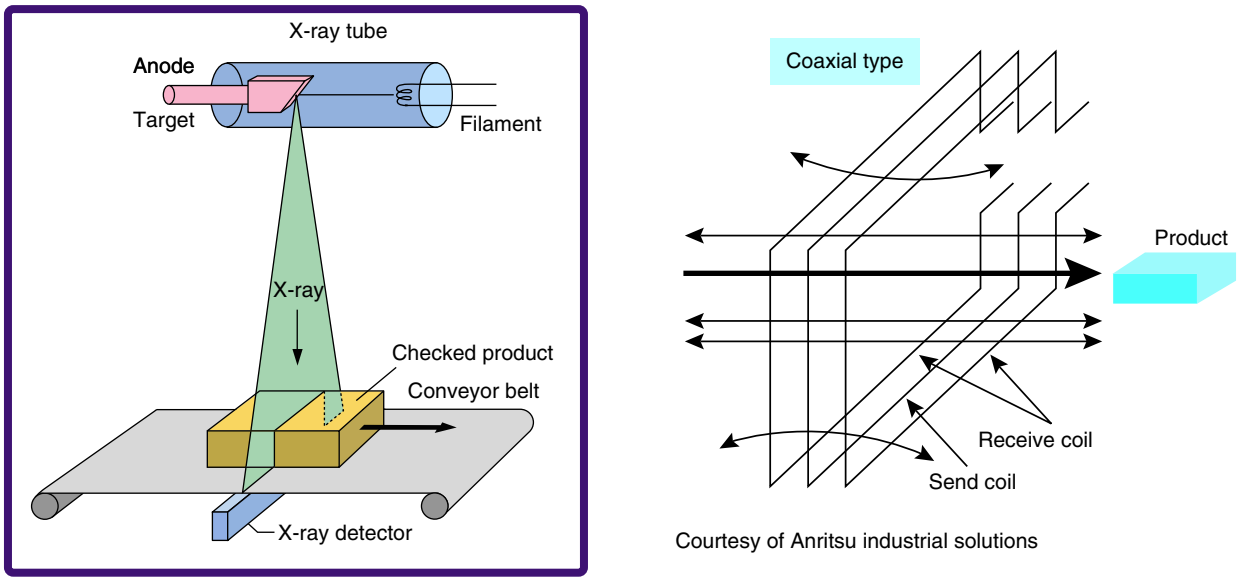

Figure 1 Techniques for screening meat and meat products for foreign objects. To the left, an X-ray system and to the right, the general principles of metal detection, provided with balanced receiver coils.

HACCP analysis, one important task is to identify the hazard level for the relevant types of FB for a specific product. The result of this determination will reveal the primary types of FB. Another important issue is that the customer should agree on the result of the analysis and the agreement should include a level of test for FBs in the product to be delivered. The agreement should include determination of the largest acceptable size of all relevant FBs and how these determinations are made and documented.

A detector signal difference between a 'clean' and a contaminated product is defined as the contrast. All detection technologies rely on a contrast between the meat product and the primary foreign objects in order to identify those objects. Thus, the challenge for the producer is to establish the best contrast situation by proper choice of technology and setup for the primary types of FB.

X-Ray Contrast

The contrast in X-ray systems originates from the difference in absorption of the X-rays by the pure meat product and the FB. As the absorption is depending on sample thickness and tissue composition, the contrast of a given FB varies with each meat product. Thus, it is not possible in general to 'extrapolate' the detection performance from product to product.

The absorption of X-ray energy is proportional to the atomic number and the density of the material. Values for a selection of materials are given in Table 3.

The contrast may be expressed on a scale normally applied in the medical field of computerized tomography (CT) scanning, the Hounsfield scale. This scale is based on the linear attenuation coefficient of X-rays in water. Water is defined to assume a reading of zero Hounsfield units (HU), see below. Another reference point is air, which is defined as a −1000 HU reading. All types of biological tissue and pure elements may then be expressed on the scale (in HU) through the linear attenuation coefficient.

Table 3 Linear attenuation coefficient and Hounsfield value for some materials relevant to meat production. The difference in Hounsfield units (here calculated at 50 keV) reveals the potential contrast of Foreign bodies materials to meat and fat tissue

Material	*HU range*	μ_m *(50 keV)* cm^{-1}
Fat	−180 to −20	0.198
Muscle	20 to 180	0.238
Bone	600 to >2000	0.38
Iron	>60 000	15.417
Acrylic	88	0.247
Polyvinyl chloride	1825	0.641
Teflon	1114	0.480
Polyethylene	−146	0.194
Polystyrene	−72	0.211
Blood	64	0.241
Glass	1970	0.674
Aluminum	3379	0.994
Concrete	2459	0.785
Calcium[a]	5961	1.579
Water	0	0.227

[a]Can exist only as part of various compounds (CaOH, hydroxyapatite, etc.).

The data calculated at 50 keV, shown in Table 3, express the theoretical potential detection of different contaminants when compared with meat and fat attenuation, either expressed in HU or as a linear attenuation coefficient. It may be deduced that poly(methyl methacrylate) PE, and polystyrene (PS) should be avoided in a meat-producing facility, because these polymers have a very subtle contrast to fat and meat tissue, compared with teflon, which is much more detectable.

To estimate the contrast to a small FB, the total attenuation of the radiated beam has to be integrated along the path length

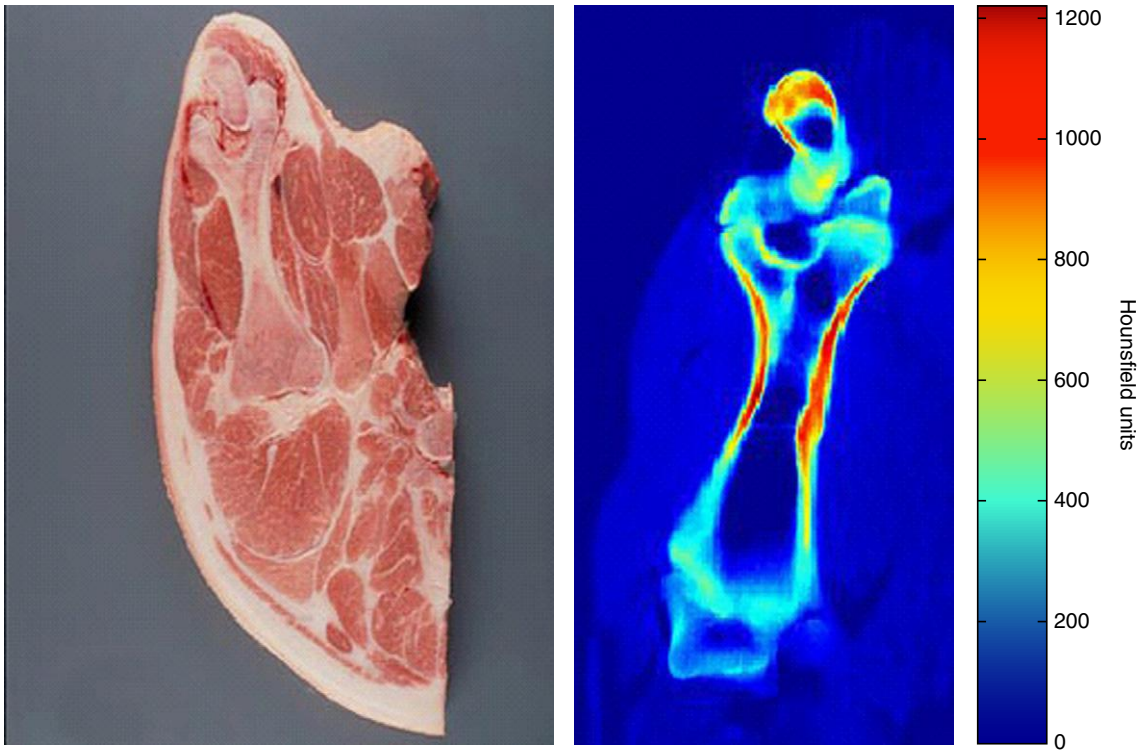

Figure 2 CT scan of porcine bone (humerus) at 120 keV. It is clearly seen that the density expressed in HU varies within the bone, from less than 200 to more than 1000 HU. Please note that negative HU readings are set to zero for reasons of clarity.

through the product using the following formula:

$$\frac{I}{I_0} \cong \exp(-(\mu_m x_m + \mu_{FO} x_{FO}))$$

The emitted intensity I_0 is attenuated to a level I during transition through a thickness x_m (cm) of material with a linear attenuation coefficient of μ_m (exp is the exponential function). For example, 15 cm of pure muscle and a 2-mm thick piece of iron FB in a 50 keV screening system. The meat will reduce the intensity to 2.8% of the emitted radiation. Inclusion of the iron object reduces the intensity further to 0.13% or a contrast ratio of approximately 6.7 dB. This ratio is sufficient for an automatic algorithm to detect in an online system.

Now change the iron object to a piece of glass of the same dimension. The 15 cm of meat leads to the same 2.8% attenuation as previously and the glass reduces the intensity further to 2.45%, leading to a contrast of a little more than 0.5 dB. A contrast of this level is somewhat more challenging to detect using automatic means. If the meat is now substituted by adipose tissue, the two contrast ratios can be recalculated to be 13 and 0.7 dB for iron and glass, respectively. Thus, the contrast between both types of FB and the background material increases when the background material changes from a high attenuating type of tissue, such as meat, to a low attenuating type, such as adipose tissue or fat. When the product thickness decreases, the contrast improves further.

One other important type of FB in meat is bone. Human bone has a reading on the Hounsfield scale in the range 600–1000 HU. This range indicates that bone material is not a fixed material with respect to X-ray attenuation and this principle can be extended to animal bones, even though they are not directly comparable to human. Furthermore, the trabecular part of bone forms a continuous range of density (mineral content and porosity) in the transition between dense cortical bone material and pure cartilage, with HU readings from 600 to 180 (Figures 2 and 3).

Owing to the cutting processes, the trabecular part is a very important FB as the end parts of bones are most frequently present in the raw material of many meat products. This fact presents a severe challenge to conventional X-ray systems. Recently, however, dedicated low-energy X-ray systems, working at 15–25 kV, have demonstrated encouraging results on cartilage detection; an example is shown in Figure 4.

The cost of increased contrast in lower energy ranges is an increase in the total absorption in the meat product, thus low-energy scanning systems are required to have more penetrating X-ray power.

Electromagnetic Contrast

Although it is not as obvious as for X-rays, the concept of contrast in the electromagnetic screening systems is still the difference in detection signal between a pure (clean) product and the signal when placing a FB of a given size into the product.

Metal detectors may assume many preferred embodiments, but all exploit the electric and magnetic properties of FB material.

The general principles are discussed according to the illustration shown in Figure 5.

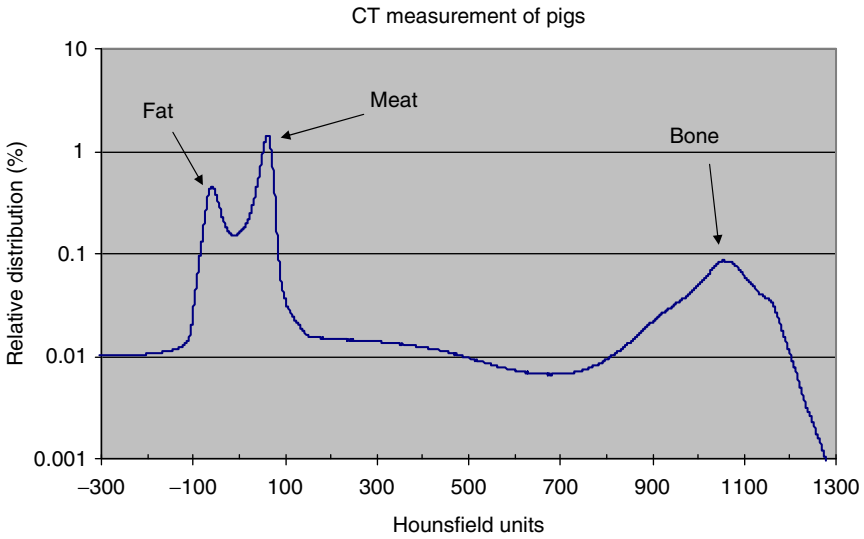

Figure 3 CT measurements of pig carcasses illustrate very clearly the continuous range of HU values between 'bone' and meat tissues. The relative number of voxels (volume-pixels) of each HU value is averaged for more than 100 pigs. The peaks originating from fat, meat, and bone tissue are clearly seen. Please note the log scale of the vertical axis.

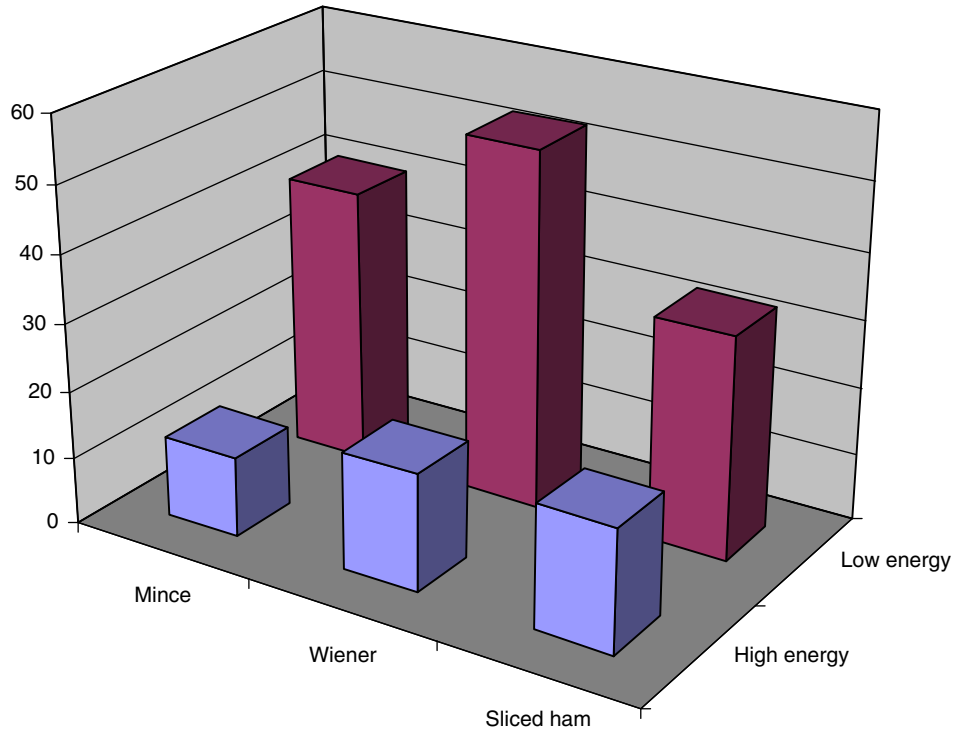

Figure 4 Measuring the contrast between cartilage and three different products (minced beef, Wiener sausages, and sliced ham) shows a considerable increase in contrast when reducing the X-ray energy from high (approximately 45 keV) to low (approximately 25 keV).

An electric coil generates a magnetic field in the aperture of the metal detector. The alternating field is detected by one or more receiver coils that are sensitive to disturbances of the field pattern within the detector aperture. The frequency of the field may assume values from less than 100 kHz to more than 1 MHz.

Most systems are based on a balanced phase-sensitive receiver where the passage of a metallic type of FB will disturb the phase balance between the receiver coils either by magnetic deflection (iron or nickel), which is the dominant effect at low frequencies, or by current absorption (stainless steel or aluminum), which is the dominant effect at frequencies more than 1 MHz.

As the sensitivity of metal detectors relies on generation of a magnetic field within an electric coil, the sensitivity

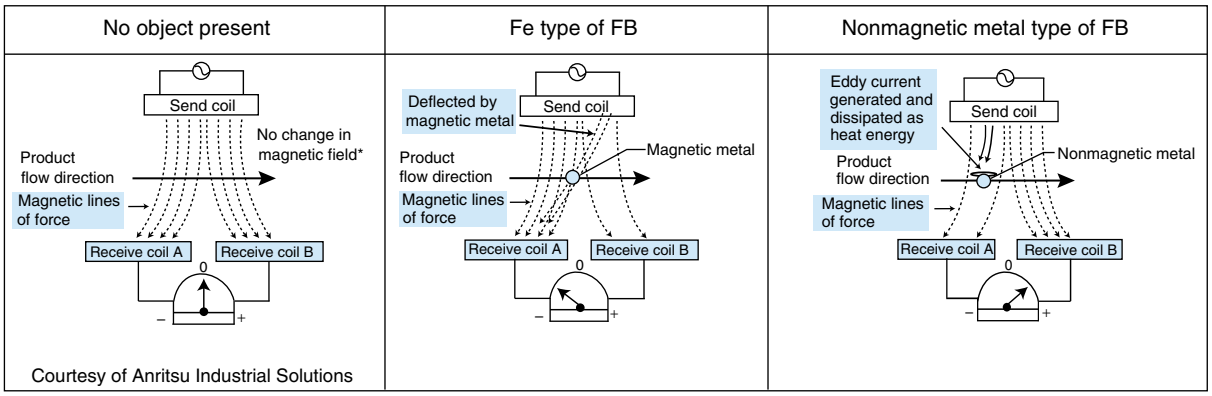

Figure 5 Field deflection in a metal detector, magnetic deflection of Fe types of FB, and current deflection of nonmagnetic types of FB.

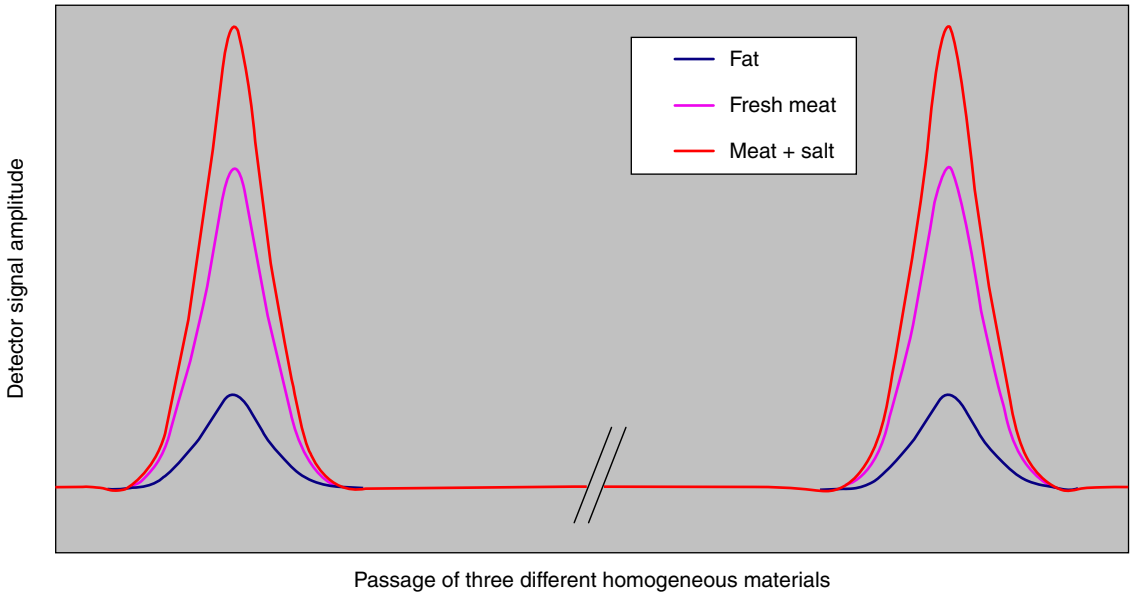

Figure 6 The detector signal amplitude is proportional to the squared receiver signal. All three (long) objects assume the same physical size.

inevitably becomes a function of distance from the FB to the coil. The smaller the distance, the more sensitive the device; in other words, for a specific meat product always choose a metal detector with the smallest aperture (coil) possible. When testing the metal detector, always place the test piece in the center of the opening, where the field is weakest and the sensitivity is at a minimum.

The passage of an ideal homogeneous product through a balanced coil system affects the detector as a function of the material and of its position in the detector aperture. When the product enters the first detector coil, the balance is disturbed. This is also the case when the product leaves the second detector coil. The disturbance generates the output signal of the detector. When the homogeneous product is symmetrically placed in a balanced coil system, the impact is balanced out (Figure 6).

Introducing a metal FB in a specific product changes the detector signal even further. In Figure 7, an idealized situation is shown, with a small spherical piece of iron in the middle of two different long products.

The effect of the FB is the same in both cases, but the product effect is higher for meat than for fat, thus leading to a high contrast in fatty products compared with pure meat products, due to the considerable difference in conductivity. Furthermore, a decrease in temperature to below the freezing point reduces ion mobility, thus leading to a better contrast in metal detectors.

However, the inclusion of salt in the recipe for a meat product increases the conductivity (due to a higher ion concentration) and thus reduces the contrast between the meat and metal FBs. This is an important feature for electromagnetic coil detectors: the contrast is recipe dependant. Fatty products, however, possess a lower conductivity than meat, thus promising an even better contrast to conductive metals.

A heterogeneous product does not produce the idealized output signals shown in Figure 7. A product consisting of a meat and fat mixture generates a weighted average signal between the two constituents, so variation in the meat/fat ratio leads to a different signal in the metal detector. This introduces a risk of rejecting even clean products. Owing to the effect of

the shape of the FB, manufacturers recommend metal spheres as test FBs. But, for real applications with randomly shaped FBs, test experiments should be designed using FBs that the instrument will be required to detect in practice.

Determination of the Specific Detection Limit

Every measurement is subject to a certain small contribution of randomness, also called noise. This is valid for all kinds of measurements, including measurements of X-ray radiation in a FB detector.

The positive or negative random noise contribution will be added to the signal from the FB itself. The noise contribution can, therefore, increase or decrease the signal from the FB according to the sign of the contribution.

When measuring by X-ray radiation, the true value of the measurement can be estimated by repeating the measurement several times under identical measurement conditions. The same method should be used when determining the true value of the detection limit for a given setting of the threshold value in the FB detector. To determine the true value accurately (corresponding to 100% confidence), the measurement must be repeated infinitely many times. Fewer measurements will do, however, if the true value is to be determined with, for example, 95% or 99% confidence.

In principle, the task of determining the true value of the detection limit is impossible, but, in practice, a test can be

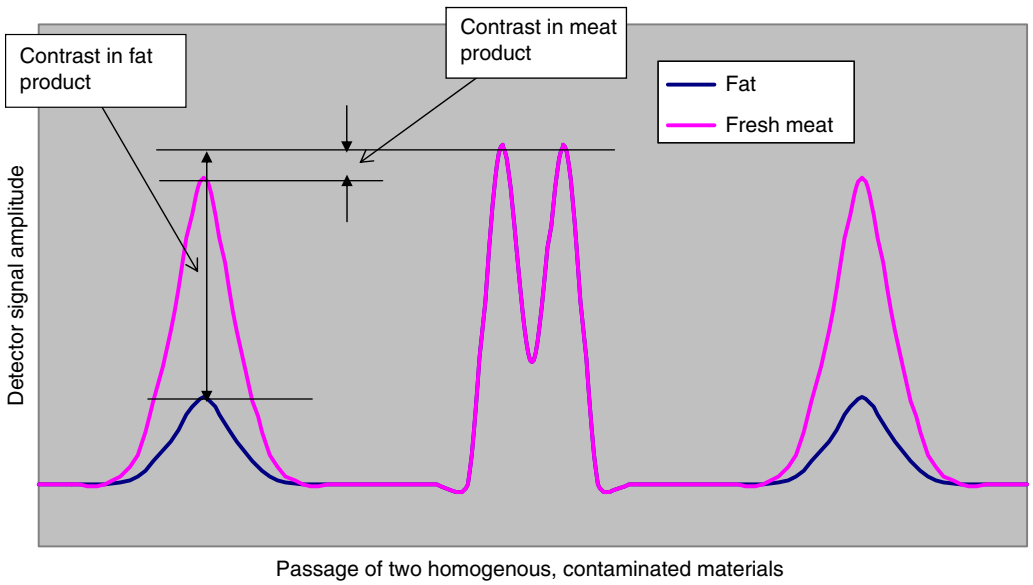

Figure 7 Illustration of the detector signal in the case of a centrally placed contaminant product. When the contaminant is symmetrically placed in the detector aperture, the signal from the two coils is in perfect balance, thus the detector output is reduced.

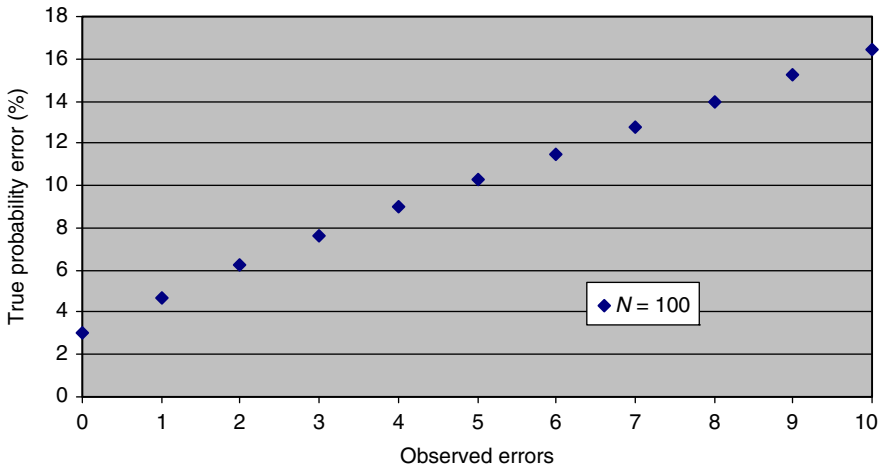

Figure 8 TEP calculated from a test with 100 repetitions. The different number of errors observed are shown on the x-axis and the corresponding TEP. The TEP is calculated with 95% confidence.

made to estimate the true value with good confidence. After setting up the detector, it is the true value that the producer will experience as the production runs through the detector.

As an example of determining the detection limit of an instrument, a metal sphere of Ø 0.5 mm might be placed in a sausage package. With a constant setting of the X-ray equipment, the same packing and metal sphere would be sent through the detector 100 times. The metal sphere will be detected every time, which means that there are no errors. For that reason, it might appear reasonable to assume that the detection limit is less than Ø 0.5 mm, with 100% confidence, and this setting will always detect metal spheres of Ø 0.5 mm and more, during production of this product. However, this is not necessarily true. It is quite possible for the instrument to have a chance of detecting the object that is less than 100% and still detect the object 100 times out of 100 attempts during a test, just as it is possible to toss a coin three times and have it show 'heads' each time – something that one would expect to occur once out of every eight times one made such a trial.

Number of repetitions: $N = 500$

Size (mm)	Number of errors	True error probability
0.2	10	0.034
0.3	3	0.016
0.6	0	0.006
1.0	0	0.006

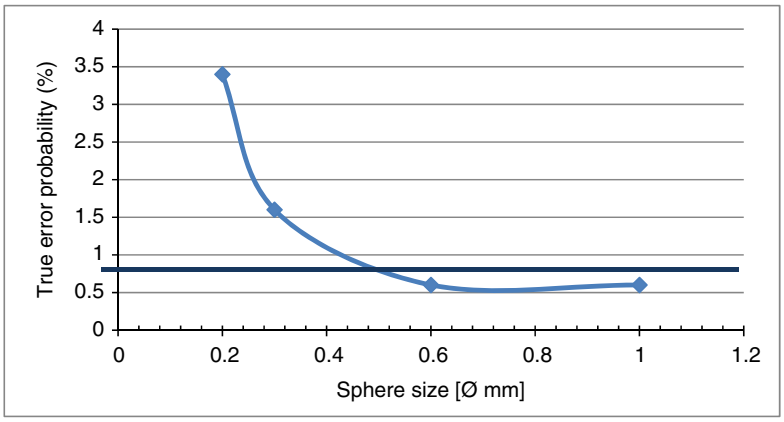

Figure 9 The result from an experiment with four different metal spheres is seen in the table. The experiment is repeated 500 times and the number of missed detections is calculated for each sphere. These numbers result in the TEP seen in the table. Making the diagram of the results leads to an estimate of the detectability of 0.44 mm (sphere) from the intersection of the TEP curve with the 1% line.

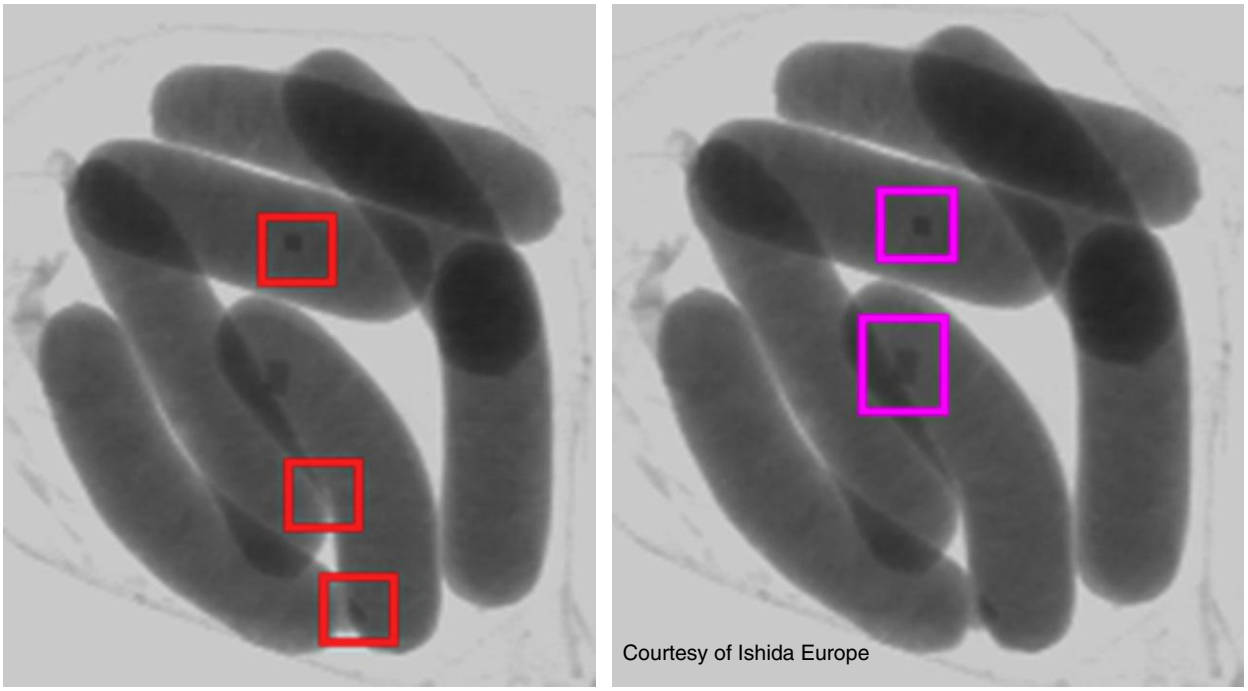

(a) (b)

Figure 10 Shown above is an example of the benefit of using dual-energy detection of FBs in randomly oriented sausages. The conventional single energy (a) includes two false positives and a moderate detection performance compared with the dual-energy example (b), reducing the risk of false positives and improving the detection performance at the same time.

In fact, a so-called strength consideration of the 100 repetitions tells that the probability of errors, i.e., the system fails to detect a metal sphere of the size mentioned, is no more than 3%, with 95% confidence. If the measurement can be repeated 200 times without errors, which means that the sphere is found in all 200 cases, it can be said – with the same confidence – that the true error probability (TEP) can be reduced to 1.5%. If the measurement can be repeated 500 or 1000 times – still without errors, and the sphere is detected every time – the TEP must be 0.6% or 0.3%, respectively. However, if the sphere had been missed in some of the tests, then the TEP would be higher than stated above. Figure 8 shows an example of how the true probability for errors is increased with the number of errors observed in a test ($N=100$).

The authors recommend defining the detection limit as the TEP of 1%, stated with a specific confidence of 95%.

According to Figure 7, it can be concluded that 100 repetitions are not enough if the authors wish to express their opinion of the TEP of 1% with 95% confidence, even if no errors are observed. The number necessary can be determined to $N=300$. If this number of repetitions cannot be implemented, the authors can only express their opinion with less confidence.

If there is a wish to determine the detectability (i.e., the size of the smallest sphere detectable with 1% TEP) of a scanning system in greater detail, a test with a range of small spheres must be made. The smallest sphere must be so tiny that it will not be detected in some of the repetitions. An example of such an experiment using 500 repetitions is

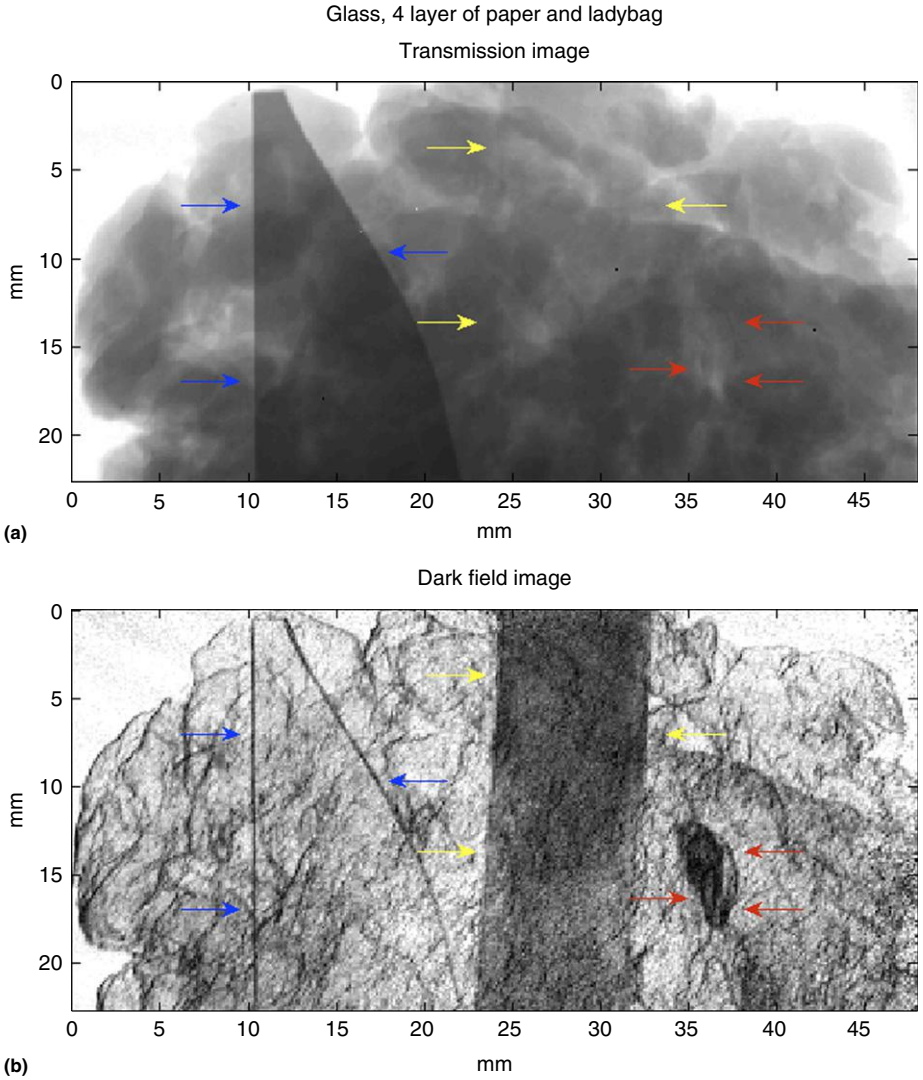

Figure 11 In the figure, the difference between conventional absorption (transmission) and dark field radiology is very obvious. The performance is illustrated using a piece of glass (blue arrows), four sheets of paper (yellow arrows), and an insect (ladybug, *Harmonia axyridis*; red arrows). The fibrous structure of paper and ladybug generates a high contrast dark field radiogram (bottom) compared with the conventional absorption measurement. On the contrary, the glass material has no diffracting inner structure but a considerable attenuation giving high absorption contrast.

shown in Figure 9 below. The table (shown left in Figure 9) shows the observed number of missed test pieces and the corresponding TEP. From the graph, it is deduced that the detectability is 0.44 mm for the setting and product used in the trial.

The same statistical argument as described above is used if tests are to be made to specify the number of false positive FB detections in pure products.

If no false positives are found in 300 representative (pure) products, it can be – with 95% confidence – said that the production of the specific product will experience less than a 1% rate of false positives with the given setting of the X-ray detector.

Finally, the producer must assess the (small) probability that metal FBs will be present in the product. The producer can then use the test results to quantify the reduction in occurrence that could be achieved by using the detecting system.

Emerging Technologies

Hyperspectral vision is also known as multispectral vision and may be considered as a development of conventional color vision based on RGB (red, green, and blue) detection. The new technology provides sensing of the surface reflection of the food product at distinct wavelengths. A few vendors offer hyperspectral vision and more are expected to follow. One of the benefits of this technique, compared with narrow wavelength sensing, is a high sensitivity to foreign materials such as cartilage, fat, and sinews, but detection of thin sheets of plastic like PS and PE is also provided with the new technology. However, one drawback carried over from color vision is that it is restricted to monitoring the surface only.

Dual-energy X-ray is adapted from the medical field of bone density measurements and has been used for some years for fat content determination. This modality is, however, also beneficial for FB detection because it copes with the challenge of product thickness variability. In Figure 11, both thickness and linear attenuation contribute to the total absorption, so by introducing a second measuring energy, two equations for the absorption in the same product are obtained. The two equations may be solved mathematically to give both thickness and average linear density, thus improving the specificity of the detection algorithm. An example is shown in Figure 10, where sausages in random orientation are measured with one energy and with dual energies, respectively. The improvement is noticeable; both a reduction of false positives and better detection contribute to a more versatile and reliable system.

Emerging medical X-ray modalities have recently entered the food scanning industry, providing screening potential with a very high sensitivity to soft and to fibrous materials. This technology explores the full refractive index and not only the absorption difference between materials, so the much more delicate phase term and scattering microstructure contribute to the detection as well as absorption. By using a conventional X-ray source in a grating-based interferometer setup, the X-ray is converted into a spatially coherent instrument able to detect the absorption difference, phase delay, and scattering impact from fibrous structures like insects, wood, and paper. An example comparing the contrast performance of transmission (absorption) with dark field scanning of a minced meat product is given in Figure 11. The improved contrast of fibrous foreign material is clearly seen.

FUNCTIONAL FOODS

K Arihara, Kitasato University, Towada-shi, Japan

This article is a revision of the previous edition article by K Arihara, volume 1, pp 492–499, © 2004, Elsevier Ltd.

Glossary

Angiotensin I-converting enzyme (ACE) inhibitory peptides The peptides having antihypertensive effects and are utilized for functional foods. Such peptides are found in hydrolyzates of many food proteins.

Food protein-derived bioactive peptide Various bioactive peptides have been found from enzymatic hydrolyzates of food proteins (e.g., meat proteins). As representative bioactivities, ACE inhibitory and antioxidative properties have been studied.

FOSHU Foods for specified health use. Foods based on the knowledge concerning the relationship between foods or food components and health that are expected to have certain health benefits and have been licensed to bear labeling claiming that a person using them may expect to obtain that health use through the consumption of these foods.

Functional food Processed foods having disease-preventing and/or health-promoting benefits in addition to their nutritive value.

Functional meat product Meat products with additional physiologically functional properties. Utilization of functional ingredients (e.g., vegetable proteins, fibers, and probiotics) is one approach to develop this kind of products.

Nutraceutical compound Chemicals found as natural components of foods or other ingestible forms that have been determined to be beneficial to the human body.

Prebiotics Nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon and thus improve the health of the host.

Probiotics Viable microbial food supplement that beneficially influences the health of the host.

Introduction

Foods are basically evaluated by their nutritional value. In other words, the most important factor for evaluation of foods is the 'primary' function of foods, i.e., the role of standard nutrient components. This primary function is particularly important for people who are suffering from a shortage of food. The 'secondary' function of foods, which is defined as sensory properties such as taste, flavor, appearance, and texture, is also critical for the food industry in many countries.

In addition to these functions, during the past few decades, much attention has been paid to 'tertiary' function of foods. Tertiary function is the role of food components that are expected to prevent diseases by modulating physiological systems (e.g., immune, endocrine, nervous, circulatory, and digestive systems). As examples of tertiary functional properties of foods, anticarcinogenicity, antimutagenecity, antioxidative activity, and antiaging activity have been studied. Owing to increasing concerns about health by consumers, efforts have been made in food industries in many countries to develop new foods with tertiary functions. Such foods having tertiary functions are regarded as 'functional foods.'

Numerous food components showing tertiary functions have been isolated and characterized. For example, many vegetables have been shown to contain a variety of biologically active phytochemicals. There has been an accumulation of scientific findings in recent years regarding the roles of such components in the prevention of diseases. Rapid progress has been made in the development of functional foods based on the results of studies on food components providing positive health benefits other than normal nutritional benefits. There has been extensive research and development in the field of functional foods in the dairy industry. Also, many traditional fermented dairy products have been rediscovered as foods with physiological functionality.

However, studies of tertiary functions of meat and functional meat products have been limited until recently. By increasing or introducing bioactive properties, it should be possible to develop new meat products with potential health benefits. Such meat products would open up a new market in the meat industry. In this article, an overview of functional foods is given and then examples of meat-based functional products are described. The potential benefits of meat components on human health and the development of novel functional products are also discussed.

Overview of Functional Foods

The term 'functional food' was coined in Japan in the early 1980s. Although there is no universal definition of functional food, a typical and simple definition is "processed foods

 doi:10.1016/B978-0-12-384731-7.00172-0

Table 1 Representative functional ingredients used for FOSHU products

Ingredients	*Targets*

Glycocides	Blood pressure level
Sterol esters	Cholesterol level
4-Aminobutanoic acid	Blood pressure level

having disease-preventing and/or health-promoting benefits in addition to their nutritive value." Functional foods overlap with nutraceuticals, medical foods, probiotics, designer foods, pharmafoods, and vitafoods.

Japan is also the first country to have formulated a specific regulatory approval process for functional foods. In 1991, the concept of foods for specified health use (FOSHU) was established. According to the Japanese government, FOSHU are foods based on the knowledge concerning the relationship between foods or food components and health that are expected to have certain health benefits and have been licensed to bear label claims that a person using them may expect to obtain in improved health through the consumption of these foods. Most FOSHU products utilize functional ingredients to help in the maintenance of a healthy human body. Such food ingredients are listed in Table 1. As of March 2012, 990 FOSHU products in 13 categories have been approved in Japan. As a representative example of approved FOSHU products, Ameal-S is a sour milk product containing milk protein-derived antihypertensive peptides (Val Pro-Pro and Ile-Pro-Pro). Daily ingestion of this product is expected to reduce the risk of hypertension. Another example of popular FOSHU products is a yogurt fermented with *Lactobacillus rhamnosus* strain GG. Strain GG, a representative strain of probiotic lactic acid bacteria, has been shown to be effective for intestinal disorders. Products containing the GG strain have been marketed in more than 20 countries under license from a Finnish company.

Regulations for functional foods have not yet been well established in most countries. Also, there are distinct differences in the approach to functional foods between legislators in Japan, the USA, and Europe. For example, in the USA, functional foods are regulated under the same regulatory framework as are conventional foods and dietary supplements. FDA's regulatory scheme does not recognize functional food to be a distinct regulatory category. However, the complexities of developing a functional food to be in compliance with EU food legislation are more considerable.

Functional Meat Products

Meats are rich in essential nutrients, such as proteins, vitamins, and minerals, and also contain other compounds thought to be physiologically functional. Meat could therefore be considered as functional food without any additional processing. Numerous low-fat or fat-free meat products have been developed in many countries, with the USA at the head of the list. Low-salt and sugar-free meat products (e.g., roast ham and sausages) have been developed in Japan. In addition to these 'free' and 'low' type of products, meat products with additional physiologically functional properties have been introduced in some countries. Utilization of functional ingredients is one approach to develop the functional meat products. Such ingredients include vegetable proteins, fibers (e.g., oats, sugar beet, soy beans, and peas), antioxidants, probiotics, and prebiotics (intestinal *Lactobacillus* and *Bifidobacterium*).

Dietary fibers or soy proteins have been used as functional ingredients in FOSHU products in Japan. A pork Vienna-type sausage product that contains indigestible dextrin, a water-soluble dietary fiber made from potato starch, is claimed to have beneficial effects on intestinal disorders. Another example is a pork frankfurter that is a low-fat sausage product containing soy proteins. It is claimed that an acceptable blood cholesterol level can be maintained by consumption of this product. Other than the approved FOSHU products, meat products with additional fibers, proteins, and minerals (e.g., calcium) have also been marketed. Vegetable proteins have been used in meat products for their nutritional and functional value. Soy proteins are typical proteins with health-enhancing activity. They are thought to be effective for preventing cardiovascular diseases, cancer, and osteoporosis. Soy-based ingredients also contain another group of bioactive components, isoflavones. A sausage formulated with a modified potato starch was marketed in the USA. Such dietary fibers contribute to the improvement of intestinal microflora and the reduction of fat intake. Healthier lipid formulation is also a remarkable approach for developing functional meat products.

A group of meat products named Apilight (e.g., pork sausages, hamburger steak, and meat-balls) is unique and profitable for consumers. These are products made from a formulation that excludes ingredients causing allergy symptoms. Although meat is less allergenic than common allergy-induced foods, such as milk, eggs, and soy, meat products (e.g., sausages) often contain vegetable, egg, and/or milk proteins. People with allergies are often affected by allergens in such ingredients. These products have been approved as allergen-free products by the Japanese government. Also, gluten-free and/or lactose-free meat products have been produced in some countries. Possible approaches for functional modification in meat products are summarized in Table 2.

Meat-Based Bioactive Compounds

Nutraceuticals are defined as "chemicals found as natural components of foods or other ingestible forms that have been determined to be beneficial to the human body in preventing or treating one or more diseases or improving physiological performance." Although most nutraceutical compounds have been

found in plants, several attractive meat-based bioactive substances have been studied (e.g., carnosine, anserine, L-carnitine, conjugated linoleic acid (CLA), glutathione, taurine, creatine, coenzyme Q10, choline, balenine, creatinine, lipoic acid, putrescine, spermidine, and spermine). Representative meat-based bioactive substances (Figure 1) are described here. Emphasizing physiological activities originating from meat is one spontaneous approach for developing functional meat products.

Histidyl Dipeptides

Through diet, especially fruits and vegetables, interdiction and neutralization of free radicals have been shown to occur. This beneficial action of food is attributed to the antioxidant potency of various compounds, including ascorbic acid, vitamin E, beta-carotene, and polyphenolic compounds. Antioxidants in fruits and vegetables may decrease the risk of cancer.

Several endogenous antioxidants have been found in skeletal muscle (e.g., tocopherols, ubiquinone, carotenoids, ascorbic acid, glutathione, lipoic acid, uric acid, spermine, carnosine, and anserine). Both carnosine (beta-alanyl-L-histidine; Figure 1(a)) and anserine (N-beta-alanyl-1-methyl-L-histidine; Figure 1(b)) are antioxidative peptides containing histidine. They are the most abundant antioxidatives in meats. The concentrations of carnosine in meat range from 500 mg kg^{-1} in chicken thigh to 2700 mg kg^{-1} in pork shoulder. Anserine is especially abundant in chicken muscle (e.g., 980 mg kg^{-1} in skeletal muscle). Most meat extract products contain carnosine and anserine. These peptides have been reported to play roles in wound healing, recovery from fatigue, and prevention of diseases related to stress. Because anserine is more digestion-resistant than is carnosine, the physiological function of anserine would be more effective than that of carnosine in the human body. For this reason, functional food ingredients with high concentrations of anserine (ca. 98%) purified from fish extracts have been developed.

L-Carnitine

L-Carnitine (beta-hydroxy-gamma-trimethyl amino butyric acid; Figure 1(c)) assists the human body in producing energy and in lowering levels of cholesterol, calcium to improve skeletal strength, and chromium picolinate to help build lean muscle mass. L-Carnitine is abundant in skeletal muscle, especially in beef (e.g., 1300 mg kg^{-1} in the thigh). A fruit juice product containing L-carnitine that is marketed in the USA is advertised as having several beneficial effects, such as maintenance of stamina and fast recovery from fatigue. Also, a product containing much L-carnitine and carnosine, which is used as a functional food ingredient has been marketed in Japan. This product is made from a by-product of corned beef.

Conjugated Linoleic Acid

CLA, which was initially found in cooked beef, is composed of a group of positional and geometrical isomers of octadecadienoic acid (18:2). CLA is most abundant in fat of ruminant animals, because it is converted from linoleic acid by rumen bacteria. After its absorption in ruminant animals, CLA is transported to mammary tissue and muscle. Beef fat contains 3–8 mg CLA g^{-1} fat. The most common CLA isomer found in beef is octadeca-*c*9, *t*11-dienoic acid (Figure 1(d)). Because this fatty acid has anticarcinogenic activity, much interest has been shown in this compound. Commercially available CLA supplements utilized for many studies are usually the mixture of several CLA isomers (e.g., *c*9, *t*11, 41%; *t*10, *c*12, 44%; and *t*9, *t*11/*t*10, *t*12, 7%). Some recent studies claim that *t*10, *c*12-isomer (Figure 1(e)) exhibits stronger physiological activities than *c*9, *t*11-isomer. However, most animal products (e.g., beef and cow's milk) contain only a trace amount of *t*10, *c*12 CLA isomer. The CLA content of foods is increased by heating (cooking and processing). Besides its anticarcinogenic

property, CLA also has antiatherosclerotic, antioxidative, and immunomodulative properties. CLA may also play roles in control of obesity, reduction of the risk of diabetes, and modulation of bone metabolism.

Development of Novel Functional Meat Products

Functional meat products have been developed to some extent. Also, several promising bioactive compounds have been found in meat. Two possible directions of development of novel functional meat products are described here.

Meat Protein-Derived Bioactive Peptides

Many bioactive peptides are generated from food proteins (e.g., milk proteins). As such peptides, antihypertensive, opioid, immunostimulating, antimicrobial, antithrombotic, hypocholesterolemic, antioxidative, and prebiotic activities have been studied. Some of these bioactive peptides are found in hydrolysates of muscle proteins. Angiotensin I-converting enzyme (ACE) plays an important physiological role in the regulation of blood pressure. Several inhibitors of ACE have been found to be effective as antihypertensive pharmaceuticals. Antihypertensive peptides derived from various food proteins have been discovered. Enzymatic hydrolysates of meat proteins have been found to exhibit potent ACE-inhibitory activity and antihypertensive activity in spontaneously hypertensive rats. Peptides, named myopentapeptides A (Met-Asn-Pro-Pro-Lys) and B (Ile-Thr-Thr-Asn-Pro), were identified in the enzymatic hydrolyzate of porcine myosin. Because several food products, such as sour milk and soup products, containing antihypertensive peptides have been marketed for hypertensives, the hydrolysates of meat protein and their corresponding bioactive peptides might be utilized for functional foods.

Even in antihypertensive peptides, it has been found that antioxidative and prebiotic peptides are generated from meat proteins by enzymatic digestion (Table 3). These bioactive peptides might exist in fermented meat products, because meat proteins are hydrolyzed by muscle and bacterial enzymes during fermentation and storage. Fermented meat products, as well as fermented dairy products, might be rediscovered as functional foods. It is also possible that ingestion of meat proteins will contribute to the maintenance of human health, because digestive enzymes such as pepsin could generate bioactive peptides from meat proteins.

[a]The one-letter amino acid codes were used.

Probiotics, Prebiotics, and Synbiotics

Although starter lactic acid bacteria are widely used for producing fermented meat products, unlike in dairy products, little attention has been given to therapeutic activities of these bacteria in meat products. The main approach for improving the beneficial physiological properties of dairy products has been the development of 'probiotic lines' of traditional fermented products. Thus, it seems possible to develop meat products that are beneficial for health by using probiotic bacteria. Probiotic foods have been defined as "viable microbial food supplement that beneficially influences the health of the host." Also, probiotic foods are regarded to be functional if they have been satisfactorily demonstrated to beneficially affect one or more target functions in the body beyond adequate nutritional effects in a way that is relevant to either an improved state of health and well-being or reduction of risk of disease.

In 1998, a German producer launched a salami product containing three intestinal strains (*Lactobacillus acidophilus*, *Lactobacillus casei*, and *Bifidobacterium* sp.). This product is claimed to have health benefits and is thought to be the first probiotic-like salami product to be marketed. Shortly after, a Japanese producer began to market a new meat-spread product fermented with probiotic bacteria (*Lactobacillus rhamnosus* FERM P-15120). *L. rhamnosus* FERM P-15120 has been screened from the collection of human intestinal lactobacilli for meat fermentation. However, further scientific studies on the relationship between ingestion of such products and human health are needed.

In the food industry, much interest has also been shown in the utilization of prebiotics, which are defined as "nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon and thus improve the health of the host." Oligosaccharides and dietary fibers are representative prebiotic substances used for processed foods. Such prebiotics have been utilized for several meat products. A mixture of probiotics and prebiotics, which is called synbiotics, is utilized for many foods, such as fermented dairy products. Because meat products with probiotics, prebiotics, and synbiotics have a great future potential, it is expected that increasing interest will be shown in basic research and potential applications for developing new functional meat products.

Conclusions and Future Prospects

Possible strategies for developing healthier meat and meat products, including functional foods, are listed in Table 4.

Table 4 Strategies for developing healthier meat and meat products

Modification of carcass composition
Manupilation of meat raw materials
Reformulation of meat products
Reduction of fat content
Modification of the fatty acid profile
Reduction of cholesterol
Reduction of calories
Reduction of sodium content
Reduction of nitrites
Incorporation of functional ingredients

Although functional meat products were described mainly from the viewpoint of food processing in this article, all aspects of animal production and product processing should be considered for developing healthier products. Through manipulation of animal feed, the composition of animal products can be improved. The effects of feed supplements, such as vitamin E, on meat properties (e.g., color, lipid stability, and sensory quality) have been characterized extensively. However, there has not been sufficient study on their effects on health benefits of fresh meat for humans. Several studies have shown that feeding conditions of animals affect the contents of bioactive components, such as L-carnitine and CLA, in animal products. Further such efforts are expected for creating differentiated meat and meat products with potential human health benefits. However, there are still some difficulties in marketing functional meat products: functional meat products are unconventional, and consumers in many countries do not recognize meat and meat products as healthy foods, unlike milk and dairy products. Thus, further studies are needed to demonstrate the benefits of meat and meat components for human health. Along with accumulation of scientific data, there is an urgent need to inform consumers of the exact functional value of meats.

GENOME PROJECTS

Modern Genetics and Genomic Technologies and Their Application in the Meat Industry – Red Meat Animals, Poultry

G Plastow and H Bruce, University of Alberta, Edmonton, AB, Canada

This article is a revision of the previous edition article by C Bendixen, volume 2, pp 501–505, © 2004, Elsevier Ltd.

Glossary

a* value Color axis from the Commission Internationale de L'eclairage color space describing redness (+ a*) and green (− a*).

Cooking loss Proportional change in weight of meat after cooking.

Marbling Colloquial term applied to intramuscular fat due to it resembling the flecks of white in marble.

Pearson correlation (r) Coefficient indicating linearity of relationship between two parameters.

Warner–Bratzler shear force The force required to cut cooked meat perpendicular to the muscle fiber direction.

Introduction

Genomics holds great promise for application in the meat industry in terms of managing eating quality. Since the late 1960s, genetics, and specifically crossbreeding, have been used to increase animal growth rate, carcass size, and carcass leanness; however, genomics now offers promise of selection of genotype within the genetic line. Most genetic improvement within the meat animal species has focused on increasing growth rate and feed efficiency, which produced an increase in the proportion of glycolytic muscle fibers in skeletal muscles. The increase in this muscle fiber type was associated with increased cooked meat toughness ('decreased cooked meat tenderness' would be preferred) as well as decreased fatness and this selection practice reduced consumer acceptability of meats. Recent genetic selection has looked at selecting for tenderness and marbling in an effort to increase the eating quality of meat from chickens, and cattle and pigs in particular.

Meat Tenderness

Meat tenderness is the most important factor affecting consumer satisfaction and, despite the factors affecting it being well understood, meat tenderness is difficult to predict or control at processing. Chilling rate within coolers can vary dramatically with location within the chiller and the response to electrical stimulation in beef processing can vary with carcass size and fatness and electrical stimulation parameters. Selection of meat animals for tenderness might reduce the effect of the postmortem environment and can potentially distribute an economic advantage to producers who select livestock for the trait.

Beef

Initial investigations focused on the activity of the proteolytic enzymes of the calpain (CAPN) family and their inhibitor calpastatin (CAST) in the muscles of Brahman cattle (*Bos indicus* spp.) because beef from the Brahman cattle is much tougher than that of cattle *Bos taurus* spp. CAPN and CAST were targeted for study because they retain the proteolytic and the inhibitory activity, respectively, in the skeletal muscle postmortem; and increased CAPN and decreased CAST activities were associated with increased cooked beef tenderness. The genetic study of CAST activity has indicated that it is heritable, with the greatest heritability observed in *B. indicus* cattle ($h^2 = 0.45 + 0.17$), and genotypic correlations between it

and cooked meat tenderness as measured by Warner–Bratzler shear force are approximately $r=0.70$ in Brahman cattle. Phenotypic correlations between CAST and Warner–Bratzler shear force have been lower than the genotypic correlations, however, indicating that the 'environmental' factors such as those affecting the carcass early postmortem are still significant in determining cooked meat toughness. These environmental influences on shear force decrease the heritability of shear force ($h^2=0.29$, 7 days postmortem, Brahman cattle), making it difficult to use as a selection criterion itself (Dikeman*et al.*, 2005 reported h^2 of 0.40 at 14 days).

Bovine meat quality marker panels are commercially available and include single-nucleotide polymorphisms (SNPs) for both CAPN and CAST. The GeneSTAR® marker panel available from Pfizer Animal Health™ includes SNPs in three genes: two SNPs in CAPN1, one in CAST, and one in thyroglobulin (TG5), an anonymous quality gene. The SNPs are identified as CAPN1 (316-T2) for CAPN1 (4751-T3). A second company, Igenity®, also markets a tenderness marker panel TenderGENE® that contains the same SNPs for CAPN1 316-T2 and 4751-T3 as well as a second polymorphism in CAST described by University of Guelph researchers (UoG-CAST). The preferred homozygous genotype for UoG-CAST was associated with a 35% decrease in the proportion of tough beef steaks at 7 days postmortem and was associated with carcasses that had an increased fat yield ($1.44+0.56\%$) and a decreased bone yield. Sires have been identified that have genotypes for tender beef as well as decreased back fat thickness; therefore, sufficient genetic variation exists to potentially select for cattle that produce tender beef without a reduction in carcass lean yield.

Commercially available bovine marker panels contain multiple SNPs for CAPN and CAST because the effects of their haplotypes are additive. If animals have favorable mutations in all of the SNPs in CAPN and CAST, there is a potential for a decrease in cooked beef toughness of up to 1 kg of Warner–Bratzler shear force, a difference that would be detected by most consumers. The applicability of these marker panels varies with subspecies, with the μ-CAPN 316-T2 and CAST markers best suited to selection for tenderness in purebred and crossbred *B. taurus* populations, whereas the other μ-CAPN SNP is applicable to both *B. taurus* and *B. indicus* cattle.

There might be significant commercial advantage in using such a panel for marker-assisted selection for meat quality because the frequency of the preferred alleles might be relatively low. For example, in one population studied, approximately 64% of 550 heads were not homozygous for the favorable alleles for CAPN and only 32% had one of the favorable alleles for this polymorphism. This polymorphism is also associated with the greatest reduction in shear force; however, as noted above, combining the three markers can yield the greatest improvement. Hence, there is a lot of improvement possible from increasing the frequency of the 'tender' alleles (depending on the starting frequencies).

Although these markers have been commercialized and are being used for marker-assisted selection of breeding stock, CAST and CAPN markers explain at most 25% of beef tenderness variation. This means there is potential to identify additional markers and to increase the value of such approaches. One interesting gene is DNAJA1, which was identified by functional genomic studies. Initial results suggest that reduced expression of DNAJA1, whose product is involved in apoptosis, accounts for 63% of beef tenderness (although this is likely to be an overestimate as is usually the case for small research studies). The mechanism by which DNAJA1 downregulation would improve meat tenderness is unclear. One possibility is that its downregulation in the muscles of cattle that produce tender beef might lead to muscle cells in the live animal being prone to apoptosis and thus there might be a requisite increase in proteolytic activity related to cell turnover. It might also lead to muscle cells entering apoptosis and necrosis earlier postmortem than cattle without this allele of DNAJA1, which would initiate proteolysis of sarcomeric muscle proteins while the carcass is warm, thus enhancing proteolytic enzyme activity and potentially meat tenderness. The implications for other traits need to be explored. For example, such an effect might impact the health of these animals or their feed efficiency, given the possibility of increased cell turnover, which might increase the basal metabolic requirements and the residual feed intake.

Changes in toughness have also been observed with the bovine F94L variant mutation for myostatin, the muscle regulatory factor controlling muscle fiber proliferation during embryo myogenesis, which produces increased loin muscle area in affected cattle (myostatin mutations are the basis for 'double muscling' in some breeds such as the Belgian Blue (BB)). Homozygous cattle for this gene variant appear to have increased cooked meat tenderness as indicated by a lower peak shear force of approximately 15% at 1 day postmortem and of 12% at 26 days postmortem compared to heterozygous cattle. However, heterozygous cattle exhibit little advantage over nonvariant cattle, with reduction in peak shear force values of only 4% and 2% at 1 and 26 days postmortem, respectively. (The extensive Germplasm Evaluation Project at the US Meat Animal Research Center, does not support the BB heterozygotes being slightly more tender; 5.91 kg for BB vs. 5.07 kg for Angus at 7 days, and 4.89 kg for BB vs. 4.08 kg for Angus at 14 days postmortem when compared at a constant age. The differences were greater at constant marbling and constant fat thickness). Further research is warranted on this variant so that its impact on production performance and meat quality can be used to advantage in the cattle industry.

Pork

Testing for well-known mutations such as the ryanodine receptor 1 mutation (RYR1) is usually conducted so that pigs with this mutation are not included in research or breeding populations because this mutation has a dominating effect on reducing muscle pH, increasing muscle deposition, and lowering meat quality. Even so, the effect on meat quality is essentially recessive, with pork from heterozygote animals being close to normal pork. The PKRAG3 gene mutation is approached similarly, as it causes comparable reductions in pork eating quality by rendering adenosine monophosphate-activated protein kinase (AMPK) insensitive to intracellular AMP levels causing abnormally high sequestration of glycogen

in the muscle. PKRAG3 mutations that negatively affect pork eating quality are numerous, however, with multiple missense substitutions described for this gene. The largest effect is a dominant mutation (RN) associated with the Hampshire breed, although this allele has been found in other breeds. The mutation was originally identified because of its large impact on the yield of processed ham using a particular method from the French 'Rendement Napole.' Interestingly, the effect is countered by the presence of processing aids such as polyphosphates, so that this can be thought of as a genotype x treatment effect. It also explains why the impact was more important in Europe where there was a trend away from using additives in food production. However, it illustrates how these types of effects (e.g., chilling regimen, carcass stimulation, etc.) need to be taken into account when studying the genomics of meat quality.

Porcine markers for melanocortin 4 receptor (MC4R, Sus scrofa chromosome 1 (SSC1)), leptin receptor (LEPR, SSC6), cathepsin Z (CTSZ, SSC17), CAST (SSC2), tissue necrosis factor (TNF, SSC7), heat shock protein 70.2 (HSP70.2, SSC), myostatin (MSTN), and adenosine monophosphate deaminase 1 (AMPD1, SSC4) have been found that are associated with pork meat quality. Many of the markers are associated with more than one meat quality characteristic or measurement, with differences in additive and dominance effects among the traits. For example, CAST has been associated with Warner–Bratzler shear force, cooking loss, and sensory juiciness, chewiness, and firmness. All of these effects need to be taken into account when considering the value of the markers (see Section Genome-Wide Association Studies). Transcriptome analysis correlating ribonucleic acid (RNA) concentration for different genes to pork quality traits has shown that cooked loin shear force was related to the activation of complement proteins usually promoted by ischemia. This result suggests that preapoptotic homeostatic mechanisms of the muscle cell might encourage sarcomere protein proteolysis either directly or indirectly and concur with observations made in bovine muscle that increased beef tenderness is related to the rapid onset of apoptosis/necrosis.

At the time of writing this, there is no marker panel commercially available to assist with carcass and meat quality trait selection for pigs. The PorcineSNP60 BeadChip is available for genotyping pigs from populations where meat quality is known and it contains approximately 60 000 SNPs, but its cost is prohibitive for use in general herd selection. The BeadChip presently is useful as a research tool, and research using it is now beginning to identify SNPs associated with various aspects of meat and carcass quality. Despite no commercial marker panel existing for the selection of meat quality in pigs, reports have been published showing the use of sets of markers to improve aspects of meat quality in value chains. In pork, pH and color at 24 h postmortem are related to several different aspects of meat quality, including consumer acceptability, color, and water-holding capacity or drip in the retail case. A number of gene variants have been shown to have a significant effect on these traits. The best known example is the Halothane gene (RYR1 or calcium release channel 1 – CRC1: see above) associated with pale, soft, exudative (PSE) meat. Panels of markers have been used to select for reduced drip in case-ready product in the retail case. Boars are selected based on these markers to improve the water-holding capacity of the product in retail stores. Selection for improved pork quality has also focused on increasing pork intramuscular fat (see Section Marbling) as it is associated with increased sensory acceptability when present at levels less than about 3.5% wet weight. Within pork genetic line the relationship has not been as clear, so further work within and between genetic lines will be needed to elucidate the interaction between pork marbling and genetics.

Poultry

As for pork, a series of problems have been identified in poultry meat. For example, muscle myopathies, PSE meat, and the reduced cohesiveness of meat can be poultry meat quality problems. Studies have shown that the heritability for breast meat quality traits such as ultimate pH, color, drip loss, and shear-force are low to moderately heritable (h^2=0.06–0.31). Again, as in pigs, the rate of decrease in pH postmortem and ultimate pH of the meat have been shown to be the key factors of chicken meat quality; lower pH leads to paler, more exudative, and tougher breast meat. As for the other species, the amount and type of fat in the carcass and muscle is of interest for quality and especially flavor and succulence. Not surprisingly, quantitative trait loci (QTL) for all meat quality traits have been identified for chicken and turkey. The availability of genomic tools means that these QTL are now available for dissection for the development of deoxyribonucleic acid marker panels to improve the quality of poultry meat.

Marbling

SNPs have been sought for marbling of the loin muscle in both cattle and pigs because cattle carcass value is contingent upon loin marbling, whereas pork loin eating quality is strongly associated with increased marbling. Enhancement of intramuscular fat has been complicated by the discovery that different genes appear to drive fat deposition in different carcass areas and muscles. For example, in pigs, a QTL on SSC7 is related to intramuscular fat deposition in the gluteus medius muscle (a muscle of the ham), but this does not appear to influence the intramuscular fat within the longissimus thoracis et lumborum muscle of the loin. Importantly, the correlation with back fat is less than 1 (typically x in pigs and y in cattle). This means that there is great potential to use genetic markers to help select for increased marbling without increasing the exterior fat, which is undesirable in terms of today's consumers.

Muscle Fiber Biochemistry

The effects of muscle fiber type on pork meat quality are well known and well described as the metabolic characteristics of the fiber types are critical to the characteristics of meat. Differences in the percentage of specific fiber types exist both among muscles of the same animal and among breeds. Genomic tools have been developed to quantify fiber types in muscle samples. Selecting for rapidly growing, heavily muscled animals led to an indirect selection for white muscle fibers, which rely specifically on glycolysis, the Krebs cycle, and the electron transport chain for generation of energy. With this

fiber type, glycogen stores are high and the decline of muscle pH within the early postmortem period is rapid, lowering the pH dramatically while the carcass and muscles are warm. The combination of low pH and high muscle temperature produces meat with significant denaturation, so that the meat has a low water-holding capacity, a pale color and is soft, characteristics similar to that of the PSE condition produced by other mutations. The decline of intramuscular pH in muscles that are primarily composed of white fibers is also extensive, with ultimate pH values often being below pH 5.5. This is also because the metabolism of the white muscle fibers favors glycolysis. Muscles that consist of primarily white fibers also tend to have little intramuscular fat. The reduction of intramuscular fat in pork led to reduced eating quality and acceptability of pork, and, therefore, breeding strategies in the pig industry have focused within the last 10 years on increasing the proportion of intramuscular fat or 'marbling' in pork. This selection indirectly increased the proportion of red oxidative muscle fibers that have a metabolism focused on lipolysis and fatty acid utilization. With the shift in muscle energy metabolism toward fatty acid utilization, early postmortem pH decline slowed and the ultimate pH increased to a value at or above pH 5.5. With the interest in increasing intramuscular fat, the peroxisome proliferator-activated receptor-gamma coactivator-1α gene has become of interest in the selection of pigs for increased intramuscular fat as this gene is involved in energy and fat metabolism.

In the porcine loin, transcriptome analysis indicated that cooking loss, a* (redness) value, and pH at 45 min postmortem were affected by variation in the transcription of genes associated with the onset of apoptosis, glucose metabolism, and cat-ion channel activity, respectively. How expression of these genes specifically affects each meat quality characteristic is yet to be examined; however, early onset of apoptosis may lead to increased cooking loss through increased protein denaturation due to extensive proteolysis. Moreover, the redness of pork (a* value) may be affected by the transcription of glycolytic enzymes because decreased glycolytic enzyme transcription can be associated with reduced oxidative muscle fiber population, which has increased myoglobin concentrations.

Candidate Genes

Initial research following the identification of the Halothane gene was based on the so-called candidate gene studies, where information on gene function, for example, from biochemical studies, enabled researchers to look for gene variants in the genes coding these proteins and ask if they explained variation in meat quality. The CAPNs and CAST are good examples of this approach. Although information can transfer well across species (CAST has been shown to impact tenderness in several species including sheep as well as cattle and pigs), this approach is sometimes called comparative genomics. Even so, this approach has been criticized over the years as being like a 'needle in a haystack,' however, it has generated some very interesting results. The main drawback is that it depends on 'what is known,' whereas genetic approaches, such as QTL mapping, or its modern equivalent called 'genome-wide association studies' (GWAS; see Section Genome-Wide Association Studies), allow the researcher to find novel genes. The RN gene was an example, as this subunit of PRKAG was first identified through such studies on pigs. Once a region of the genome has been identified, researchers can now conduct fine-mapping or resequencing to identify variations that might explain the trait variation. This then takes researchers back to candidate gene studies using the latest bioinformatic approaches to exploit information on genomes and gene networks (see Section Gene Expression Analysis).

Genome-Wide Association Studies

With the advent of high-throughput sequencing methods, it has become relatively straightforward to generate large numbers of SNPs for populations of interest and to drive forward GWAS for all species. These panels are available at 50 000 and 600–800 000 for cattle, and 60 000 for pigs and chickens. Different designs are used from the classical F2 cross between different lines to within population studies using commercial genotypes. Associations between the traits of interest and many regions of the genome are found for all traits studied. These studies require large numbers of observations, typically more than a thousand. In the case of meat quality, the traits most commonly measured are ultimate pH and color, as well as drip loss and water-holding capacity. In the case of beef and pork, shear force is also commonly measured. It is also possible to include sensory traits. Performance data are also collected on the same animals allowing the identification of negative associations between the traits to be identified. This is a very important aspect of commercial implementation of these tools. Breeders and producers need to understand the net value of marker effects in their population and system. It does not necessarily help if improved tenderness comes at a large cost in terms of lost growth rate or feed efficiency. Fortunately, markers can help select for the desired outcome of improved meat quality at an affordable production cost.

Gene Expression Analysis

Another approach for the identification of genes and gene products involved in meat quality is to study gene expression in muscle tissues. This is the transcription of DNA into messenger RNA (mRNA), which is then translated into proteins, for example, enzymes (CAPNs) and structural proteins (myosins, titin, etc.) that the authors are interested in with respect to meat quality. The hypothesis is that the phenotype of the muscle is related to the genes being expressed in the tissue, and that differences in expression between muscles of different quality will explain some of that difference. The timing of sampling is very important as expression varies over time; in general, muscle is sampled as soon as possible postmortem. Alternatively, some studies have looked at embryonic muscle because muscle fiber type is determined at this stage of development. It is also possible that the important genes are expressed externally, such as hormones that lead to changes in muscle function or performance – these genes would not be identified by expression analysis of muscle samples, although their impact on muscle gene expression will be observed.

Ultimately, genes that are expressed differentially between muscles or muscle states (i.e., PSE vs. dark, firm, dry muscle) become candidate genes for further studies. The genes are sequenced from interesting species of animals to identify genetic variants that are then used in association studies. This can be done with individual genes, or panels of genes up to high density SNP sets of 10 000, 60 000, or even 700–800 000 as now being done in cattle.

Next-generation sequencing technologies are now being used to generate much greater depth of information for gene expression studies (RNAseq) and are beginning to replace microarray studies. The latter use known genes (or sequences) and are, therefore, more targeted, whereas RNA-seq provides much more power to look at gene variants (such as alternate splicing of mRNA) and will rapidly become the preferred method for such approaches as it allows researchers to explore the unknown (see Section Candidate Genes). This is an exciting development and it is also possible to analyze samples for other RNA species such as microRNA, which are expressed in different tissues and might explain variation b among muscles as well as among animals.

Linkage Disequilibrium

This term describes the association between DNA markers and genes. It is important as it determines the utility of DNA markers in different populations and situations. Essentially, markers (or genes) that are more often inherited together than would be expected by chance are in linkage disequilibrium, or more simply they are linked such that the analysis of one can predict the state of the other. This means that in some cases it is not necessary to identify the underlying causative gene (or even the causative mutation – sometimes called the quantitative trait nucleotide). If a DNA marker can be shown to be associated with the trait in a population, then it can be used to help select for that trait. Most commonly, this is now achieved by combining the genomic information with the phenotypic information to produce a genomic estimated breeding value (gebv). The utility depends, at least in part, on the distance between the marker (acting as a signpost) and the causative gene. However, population history and genetic background as well as other factors also play a role in this. For example, though markers can usually do a good job of predicting a trait within a population, their impact is often very disappointing across populations. This has made implementation of marker-assisted selection relatively difficult in cattle compared with pigs and poultry. However, a difference in the structure of the beef industry compared with the others is also a major factor. The identification of the causative mutations or use of denser marker panels, so that the distance between markers and the causative genes are smaller should help. Even so, one of the hurdles remains access to the phenotypic data on which to train or discover the associations between the markers and the traits of interest.

Proteomics

Increasingly, proteomics is being used to investigate the interaction between genomics and environment so that the actual expression of proteins is verified in the physical context of the animal and its genetics. Protein expression has been characterized in both antemortem and postmortem muscle in order to relate the animal's physiological state to that of meat and its subsequent meat quality. The investigation as to how protein expression or degradation affects meat quality is still nascent, but results realized to date portend the power of proteomic methods when coupled with genomics.

Much of the work in meat quality proteomics began to appear in the literature around 2005, and few proteins were identified, most likely because high-throughput protein identification systems were just becoming available. Moreover at that time, the potential for intellectual property development from these studies was still being assessed and understood, so most studies focused on the success of the application of proteomic techniques rather than the actual impact of protein differences on meat quality. Subsequent studies identified that phosphorylation of AMPK at threonine-172 was associated with increased glycogen accumulation and decreased intramuscular fat in the longissimus muscle of beef steer carcasses. In addition, the study of bovine proteins in postmortem muscle indicated that increased detection of proteins from the inner and outer membranes of the mitochondria was indicative of increased beef tenderness, suggesting that early or extensive apoptosis in early postmortem muscle might be conducive to the tenderization of beef. Proteomic studies offer the potential for direct protein markers that might predict meat quality or, like gene expression studies, information that can be used to identify DNA markers that can be used to improve quality.

Traceability

Having generated products with improved meat quality, there might be a need to be able to 'identity preserve' such products to help protect their value, helping give consumers confidence in products and preventing other lower quality products substituting for them. DNA traceability offers a useful way to help verify the origin or quality of the products. A sample of meat, even from a cooked product, for example, in a restaurant, can be traced back through the production system, back to the farm, and even individual animal, as the DNA of an animal is unique (except for twins or clones) and available for analysis long after the product has been separated from physical traceability, such as the radio frequency identification tags.

Glossary

Adipocytes Fat cells.
Anabolic lipid metabolism The synthesis of fatty acids or fats.
Brown adipose tissue A tissue that is rich in mitochondria and is involved in thermogenesis.
Catabolic lipid metabolism The breakdown of fats or oxidation of fatty acids.
Leptin A hormone secreted by adipocytes involving regulation of body composition.
Lipogenesis The synthesis of fats in adipocytes and liver cells.
Lipolysis The breakdown of a triacylglycerol into fatty acids and glycerol for further metabolism.
Thermogenesis The generation of heat.
Uncoupling protein 1 The protein involved in thermogenesis.
White adipose tissue A tissue that is both a storage site of excessive energy and a dynamic endocrine organ.

Introduction

Adipose tissue (AT) comprises the largest energy depot and provides energetic fuel for mammals. The major physiological role of AT is to store energy and to mobilize it depending on metabolic needs. Insulation is another important function of AT, particularly subcutaneous AT. Adipocytes or fat cells are the primary AT cell types. Blood vessels, nerves, connective tissues, and other cell types also reside in AT. There are two types of AT – brown and white, which are distinct in cell structure and functionality. Brown AT (BAT) confers the ability for nonshivering thermogenesis. White AT (WAT) is the common site to store excess energy in the form of triglycerides (triacylglycerol or TG). Both BAT and WAT are controlled by endocrine and neural molecules to maintain the proper shape and size under normal health conditions. Therefore, understanding the underlying molecular mechanisms regulating AT development provides important implications to improve meat quality and ameliorate human diseases, such as obesity and diabetes.

Brown Adipose Tissue

Physiologically, BAT, which is rich in mitochondria, plays an important role in dissipating heat from chemical reactions (thermogenesis). Most mammalian newborns and hibernating mammals have BAT and it regresses during the first weeks postpartum. In newborn ruminants, most of the AT is BAT, with only small amounts of WAT. Newborn lambs and calves retain highly active BAT after birth when the need for thermogenesis is high. Adipocytes in BAT of most species store lipid in multiple small droplets instead of one large droplet, as seen in WAT. An exception is brown adipocytes of newborn calves that contain a large central lipid vacuole and only a few peripheral lipid inclusions. The total amount of BAT is approximately 1.5–2.0% of body weight of newborn calves. Recently, the identification of small amounts of BAT in human adults suggests that this BAT may be a therapeutic target site for obesity and diabetes because of its high capacity to perform adaptive thermogenesis to dissipate excessive fat storage through heat production.

Master Regulator of Adaptive Thermogenesis in Brown Adipose Tissue

Uncoupling protein 1 (UCP1) is abundantly expressed in the inner mitochondrial membrane of mammalian BAT. In BAT, fatty acids (FA) from lipolysis (degradation) of BAT TG or from lipolysis in WAT with the released FA delivered from the plasma are substrates for FA oxidation and heat production. In mitochondria, electrons from oxidative metabolism travel along an electron gradient (electron transport) to terminally combine with oxygen. Energy dissipated in the gradient is trapped in the synthesis of adenosine triphosphate (ATP), the primary energy storage molecule. UCP1 uncouples O_2 consumption from ATP synthesis to short-circuit the mitochondrial process and generate heat.

Thyroid hormone and the neurotransmitter, norepinephrine, released from the sympathetic nervous system activate the β-adrenergic receptor signaling pathway to activate triacylglycerol lipase. The lipase converts TG into free FA that activate UCP1. Although the role of UCP1 in BAT mitochondrial function is clear, the physiological role of UCP1 in BAT thermogenesis was gradually discovered and evidenced through recent studies using UCP1-ablated mice. Absence of UCP1 in mice does not influence the development of BAT and the basal respiration of brown adipocytes. However, brown adipocytes from UCP1-ablated mice are unable to elevate heat production in response to noradrenergic stimulation. High fat feeding increases thermogenesis and thus UCP1 is required. Cold-induced nonshivering thermogenesis and inhibition of body weight gain in response to injected leptin both require UCP1. Activation of rodent adrenergic receptors through injection of norepinephrine or a β_3-adrenergic receptor agonist requires the presence of UCP1 to stimulate thermogenesis under thermoneutral (30 °C) and cold (5 °C) conditions. The 129 Sv mouse strain, well known for antiobesity characteristics, requires UCP1 to exert the obese-resistant properties under high fat feeding. In conclusion, the absence of UCP1 does not influence the development and differentiation of mammalian BAT but influences cold/noradrenergic-stimulated thermogenesis and also the ability to increase energy expenditure during high fat feeding.

Molecular Mechanisms Regulating Brown Adipose Tissue Development

The molecular mechanism controlling BAT development has not been fully revealed. Generally, BAT and WAT share some adipogenic transcription factors to induce differentiation. In the early differentiation process of BAT, CCAAT/enhancer-binding proteins β (C/EBPβ) and C/EBPδ are induced and contribute to the expression of peroxisome proliferator-activated receptor γ (PPARγ) and C/EBPα. PPARγ is the key driver of fat cell differentiation, whereas C/EBPα coordinates with PPARγ in the enhancement of adipogenesis. PPARγ coactivator 1-α (PGC1α) is more highly expressed in BAT than in WAT and increases the thermogenic program of FA oxidation, mitochondrial biogenesis, oxygen consumption, and UCP1 expression during cold acclimation. PPARα agonists also induce UCP1 expression. Overexpressing FOXC2 activates BAT development and the β-adrenergic signaling pathway to counteract diet-induced obesity. However, PGC1α, PPARα, and FOXC2 are not master regulators to determine the specific commitment to a brown adipocyte fate.

A common origin, previously assumed, for brown and white adipocytes has recently been challenged. Currently, BAT has been shown to be more closely related to skeletal muscle than WAT because both brown adipocytes and muscle express some of the myogenic factors, such as myogenic factor 5 (Myf5). A zinc finger transcription factor (PRDM16) is selectively expressed in brown versus white adipocytes and contributes to control the differentiation of brown adipocytes. Activating PRDM16 in WAT or white progenitor cells induces the switch to the phenotype of brown fat, including elevation of PGC1α, UCP1, and uncoupled respiration. Depletion of PRDM16 in BAT yields a nearly total loss of the characteristics of brown adipocytes. Other striking results demonstrated that PRDM16 controls a switch between skeletal myoblasts and brown adipocytes. Loss of PRDM16 in BAT precursors results in their differentiation into skeletal muscle. Conversely, ectopic expression of PRDM16 in myoblasts converts them into brown adipocytes. These results imply that white and brown adipocytes are derived from different cell lineages. BAT and skeletal muscle can both be derived from the same Myf5-positive precursor cells, whereas WAT adipocytes are not. PRDM16 complexes with C/EBPβ to induce PPARγ expression and this coactivation can convert naïve fibroblasts into brown adipocytes. These results suggest that intervention in this signaling pathway may be used to manipulate the proportion of WAT, BAT, and muscle to benefit meat production and to obliterate human diseases.

White Adipose Tissue

Originally, WAT was conceived as a stationary storage site for excessive energy. Today, WAT is recognized as a dynamic endocrine organ with active anabolic and catabolic metabolism maintaining an animal's energy balance. Moreover, adipocytes can secrete numerous adipokines that exert paracrine or endocrine functions. These adipokines, including leptin, adiponectin, visfatin, omentin, resistin, retinol-binding protein 4, and inflammatory mediators such as tumor necrosis factor-α, interleukin-6, and interleukin-10, regulate food intake and energy expenditure and mobilization. The most well-known adipokine is leptin, which reduces feed intake through inhibition of appetite in the hypothalamus of the brain. Dysregulation of leptin is closely associated with insulin resistance, obesity, and diabetes.

White Adipose Tissue Development in Newborn Mammals

At birth, most mammalian newborns have little depot fat and develop WAT rapidly with increasing TG biosynthesis. The developed WAT serves as an energy storage organ when energy intake exceeds requirements and also provides energy to other tissues when nutrients are scarce. Thermoinsulation is another role of WAT, particularly subcutaneous AT deposited under the skin. Perirenal WAT is deposited near the kidneys. Omental and mesenteric WAT are deposited in the mesenteries

suspending the gut. Perigonadal WAT, such as periovarian or periuterine, depots in females or the epididymal depot in males is around the reproductive organs. Intermuscular WAT is between skeletal muscles and intramuscular WAT is inside individual muscles. The proportion of WAT deposited in the various depots is species specific. In beef cattle and particularly in pigs the subcutaneous depot is large. Dairy cows have large mesenteric depots. Growth of WAT consists of three processes: hyperplasia, differentiation, and hypertrophy. Hyperplasia or the increase in cell number occurs in undifferentiated precursor cells (preadipocytes) but not in differentiated adipocytes. The differentiation process involves an initial increase in the transcription factors C/EBPβ and C/EBPδ followed by an increase in PPARγ and finally C/EBPα. The promoter region of a number of genes characteristic of the adipocyte phenotype contains response elements that specifically bind and are activated by PPARγ or C/EBPα. Hypertrophy is the increase in size of already differentiated adipocytes. The process involves synthesis and deposition of TG in the adipocyte. Preadipocytes are derived from embryonic mesoderm and maintained in the fibroblast-like shape until differentiation is initiated when the cells are presented with appropriate stimuli.

Hyperplasia

The increased number of preadipocytes can occur both in WAT and *in vitro* system. The stromal vascular fraction containing preadipocytes can be obtained by collagenase digestion from WAT. Preadipocytes have been successfully isolated from cattle, dogs, humans, pigs, rodents, and sheep. In the common culture medium of Dulbecco's Modified Eagle Medium/F12 with 10% fetal bovine serum, primary preadipocytes can proliferate rapidly and proceed to differentiation in cell culture dish. Several clonal preadipocyte cell lines have also been established from rodents. The most common one is 3T3-L1. This cell line and *in vitro* culture system provides researchers with convenient tools to understand adipocyte biology, such as adipocyte differentiation and accumulation of TG in lipid droplets. Recently, determining the ^{14}C content incorporated into deoxyribonucleic acid in adipocytes is a new technique developed to evaluate the age of fat cells in the body. The results from the technique show that there are approximately 10% of adipocytes renewed each year and the turnover rate of adipocytes is increased with obesity.

Differentiation

Primary preadipocytes presented with appropriate stimuli differentiate into adipocytes. Preadipocytes from different species or clonal cell lines require diverse factors. Generally, three major factors or hormones are indispensible in adipocyte differentiation – insulin, dexamethasone, and 3-isobutyl-1-methylxanthine (IBMX). Several other factors are also required for differentiation in some species, such as transferrin, thyroid hormone, and the PPARγ ligand thiazolidinedione. Treatment of preadipocytes with dexamethasone activates C/EBPβ. IBMX functions as a phosphodiesterase inhibitor to raise intracellular cAMP levels in order to increase expression of C/EBPδ. Activation of C/EBPβ and δ in preadipocytes reenters the cell cycle and undergoes several rounds of mitosis, known as mitotic clonal expansion. C/EBPβ and δ further induce the transcription of C/EBPα and PPARγ. On this stage, adipocytes with activation of C/EBPα and PPARγ promote adipogenesis and adipocyte-specific target genes, such as fatty acid-binding protein (aP2) and adiponectin, known as terminal differentiation markers. Insulin activates PI3-kinase/Akt signaling pathway to promote PPARγ activity and increase adipocyte differentiation.

Hypertrophy

During the adipocyte differentiation, activation of adipogenesis increases TG biosynthesis. Mature adipocytes have the capacity to store TG in lipid droplets with increase of its size. Lipid droplets are conceived as a dynamic cellular organelle specialized in the storage of neutral lipids, such as sterol esters and TG to prevent lipotoxicity of unesterified lipids. Lipid droplets comprise a neutral lipid core surrounded by a phospholipid monolayer made up of free cholesterol and several proteins, such as perilipin, diacylglycerol acyltransferase 2 (DGAT2), and caveolin. There are high activities of mobilizing lipids from lipids droplets (lipolysis) or synthesizing newly formed TG into storage (lipogenesis) on feeding or excessive energy state in mammals.

Adipocytes have multiple small lipid droplets in early phase and then they fuse into a large lipid droplet accompanied with accretion of TG storage. Lipid droplets occupy majority of cell volume of adipocyte with signet-ring morphology (Figure 1). TG accounts for more than 90% of the mass of AT in the later stages of growth (depending on the species, depot, and diets). Adipocyte size is largely varied in different depots and growing periods. Generally, adipocyte size in newborn pigs is approximately 20 μm in diameter and increase to more than 200 μm in older pigs. Bovine adipocytes can increase to 500 μm in diameter.

Anabolic Lipid Metabolism

De Novo Lipogenesis

When dietary energy is in excess of the requirements, the energy from dietary lipids and nonlipid precursors can be converted into lipids and stored in AT. *De novo* lipogenesis (DNL) is the metabolic process that converts nonlipid carbon precursors into lipids (Figure 2). Glucose is the primary carbon source in nonruminant mammals, whereas acetate is the primary carbon source in ruminant mammals. Glucose is converted to pyruvate in the glycolytic pathway and then to citrate in mitochondria. Citrate transported to the cytoplasm yields cytosolic acetyl-CoA. Acetyl-CoA is carboxylated to malonyl-CoA by acetyl-CoA carboxylase, the first key enzyme in DNL. Malonyl-CoA is then used as a two-carbon donor for the complex multienzyme fatty acid synthase. A series of sequential reactions – decarboxylation, reduction, and dehydration – lead to the synthesis of the 16-C saturated fatty acid palmitate. Production of longer chain FA and polyunsaturated FA requires elongase and desaturase enzymes, such as stearoyl-CoA desaturase 1. Amino acids can be transaminated or

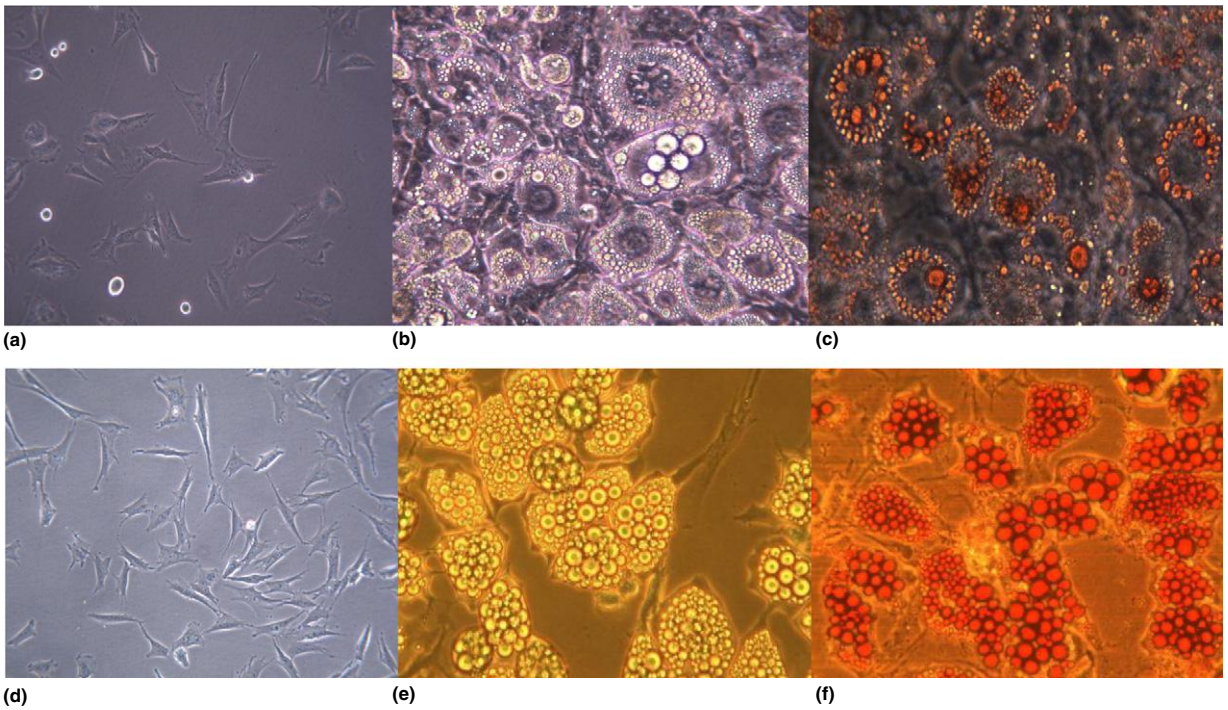

Figure 1 Morphological changes of 3T3-L1 mouse cell line (a–c) and pig primary preadipocytes isolated from stromal vascular fraction (d–f) during adipocyte differentiation. 3T3-L1 and pig primary preadipocytes maintain the fribroblast-like shape (a and d). On differention process with appropriate stimuli, preadipocytes begin to synthesize and accumulate triglycerides in lipid droplets and differentiate into adipocytes (b and e). Adipocyte genes, such as fatty acid-binding protein 4 (aP2) and adiponectin, are highly expressed in mature adipocytes. Lipid dropletes are stained and characterized by Oil red O staining (c and f).

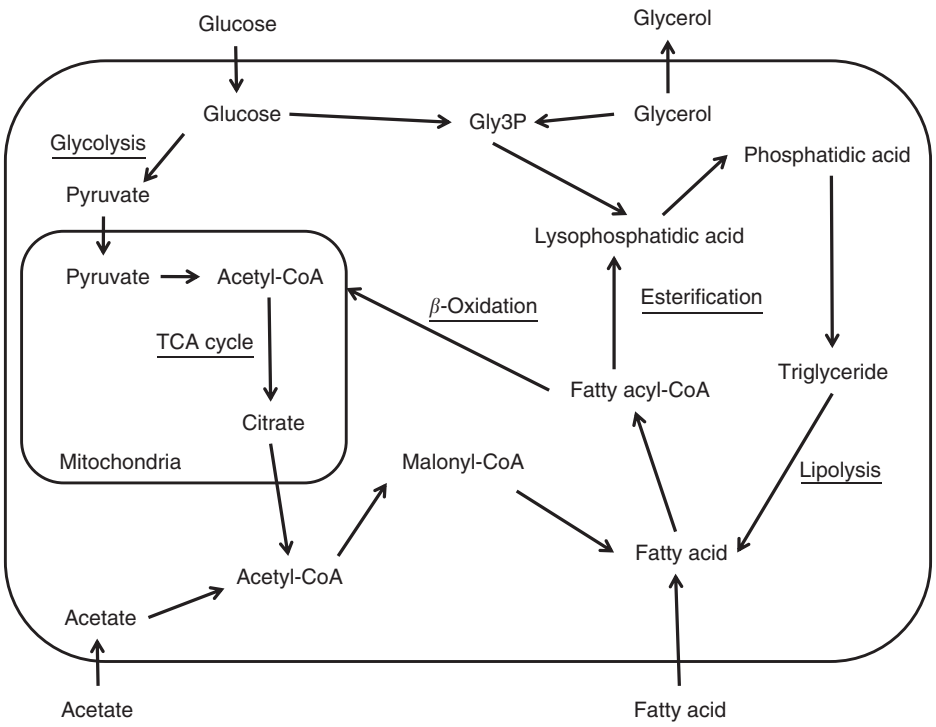

Figure 2 Outline of metabolic pathways in adipocytes.

deaminated to carbon compounds and acetate, the main product of bacterial fermentation in the rumen of ruminant mammals, which may also contribute carbon for fatty acid synthesis.

Two tissues are mainly responsible for DNL in mammals – liver and WAT. The relative contribution of these tissues is different for different species. In humans, the liver is the major site for DNL, whereas in pigs, adipocytes are the main site and in rodents both tissues are involved in DNL. In ruminants, the liver is the major site before ruminal development, but after development WAT is the major site. Suckling mammals have a diet rich in fat so there is little DNL until after weaning. However, lipoprotein lipase (LPL) must be available after birth to supply FA to the adipocyte from the circulating lipoprotein triacylglycerol. Lipolysis is also necessary for the newborn mammals to respond to periods of dietary insufficiency and to cold stress; the capacity for lipolysis is increased rapidly after birth.

Lipoprotein Lipase

FA are detergent molecules and thus toxic to cells. To avoid toxicity, FA are bound to albumin or esterified into complex lipids like phospholipids or TG. In plasma, the TG is part of various lipoproteins, particularly the chylomicrons containing exogenous dietary lipids and very low-density lipoproteins (VLDL) secreted from the liver. These two lipoproteins constitute more than 90% of blood FA. Elevated free FA in plasma contribute to metabolic diseases, such as obesity or diabetes. Ruminants produce VLDL but not chylomicrons. Uptake of FA from the plasma into adipocytes requires the enzyme LPL. LPL is produced and exported by the WAT and also by other peripheral tissues, including BAT, skeletal muscle, cardiac muscle, and mammary gland that utilize FA for storage or energy. LPL after synthesis and translocation resides on the endothelial lumen of capillaries, where it is active in hydrolysis of TG-rich lipoprotein to release free FA, 2-monoacylglycerols, and lipoprotein remnants. LPL activity is regulated in different physiological conditions (fed, fasting, and exercise). During the postprandial period, insulin and glucose upregulate LPL activity in WAT or other tissues to cleave the circulating TG into FA that are absorbed by the adipocyte or other tissue cells. FA that are not oxidized for energy are mostly esterified into phospholipid and TG.

FA hydrolyzed from lipoprotein by LPL or dissociated from albumin enter adipocytes by diffusion or by the facilitated transporter system including an FA translocase (CD36), an FA transport protein, and a membrane-bound FA-binding protein. FA inside adipocytes are bound to cytosolic transport proteins, cytosolic FA-binding proteins, and acyl-CoA-binding protein, which binds FA-CoA. FA-CoA are then esterified or oxidized. Excessive energy from carbohydrate, amino acid carbon skeletons, or lipids are converted to TG and then stored in cytosolic lipid droplets. An important intermediate is glycerol-3-phosphate (Gly3P), which forms the backbone on which the FA are esterified. Gly3P can be derived from glycerol, glycolysis, or glyceroneogenesis. Glycerol uptake from the plasma and phosphorylation by glycerol kinase is quite low in WAT. An FA-CoA is esterified to Gly3P by glycerol-3-phosphate acyltransferase to form lysophosphatidic acid (LPA). Another FA-CoA is esterifed to LPA by 1-acylglycerol-3-phosphate acyltransferase to yield phosphatidic acid (PA). The phosphate is removed to form diacylglycerol (DG) and finally a third FA-CoA is esterified to DG by diglyceride acyltransferase to form TG for storage in lipid droplets. Many tissues have the capability to synthesize TG, but AT is the major site for TG storage. The liver is another major site for for TG synthesis with the TG largely becoming part of the VLDL lipoproteins. To sum up, the anabolic processes of WAT involve activation of LPL, uptake of FA from capillary into adipocytes, activation of DNL (in many species), and promotion of FA esterification to TG.

Catabolic Lipid Metabolism

Catabolic and anabolic metabolism are well-controlled and sophisticated processes. The catabolic pathway, termed lipolysis, hydrolyzes TG with the release of FA (Figure 2). Three lipase enzymes are involved in the hydrolysis of TG. The initial step activates the rate-limiting enzyme adipose triglyceride lipase (ATGL), which removes an FA from TG to produce DG. ATGL has 10-fold more specificity for TG than for DG. ATGL is highly expressed in WAT and BAT. Its expression increases as adipocyte differentiation progresses and overexpression of ATGL increases basal lipolysis. Inhibition of ATGL reduces hormone-stimulated lipolysis, suggesting that ATGL is crucial in the basal and hormone-stimulated lipolysis. Hormone-sensitive lipase (HSL) removes another FA, primarily from DG, but the substrate specificity is lower with hydrolysis of TG, monoacylglycerol, cholesteryl esters, and retinyl esters. The third lipase, monoacylglycerol lipase, is a hormone-independent lipase responsible for the removal of the last FA from TG.

Lipolysis is controlled in different energy states, primarily by insulin to inhibit and by β-adrenergic agonists, adrenaline (epinephrine) and noradrenaline (norepinephrine), to stimulate. The catecholamines, noradrenaline and adrenaline activate lipolysis through β-adrenergic receptor signaling coupled to G-protein activation. This signaling activates adenylyl cyclase, an enzyme that converts ATP to cyclic AMP, which then activates cAMP-dependent protein kinase A (PKA). PKA then phosphorylates HSL and perilipin A, the most abundant protein associated with lipid droplets in adipocytes. The phosphorylation of perilipins and HSL is necessary for the dispersal of the lipid droplets resulting in full lipolytic activity. Lipolysis is stimulated during fasting to provide energy to adipocytes and other tissues. ATGL is also regulated by nutritional status (increased during fasting and reduced during feeding or by insulin).

In sum, AT is currently recognized not only as a stationary site for storage of excess energy or as a site to mobilize lipids for utilization in other tissues but also as a dynamic organ with comprehensive control of lipolysis and lipogenesis under feeding or fasting states. Understanding the underlying molecular mechanisms regulating AT development and fat deposition becomes a prominent issue in treating human metabolic diseases and improving animal production. The appropriate increase of intramuscular AT depot especially

provides a desirable flavor for consumers in the production of high-quality meats.

Glossary

Chondrogenesis The process by which cartilage is formed and developed.

Chorionic binucleated cells Cells located in the placental layer called the chorion; it is suggested that the normal function of mature chorionic binucleate cells at all the stages of bovine and ovine pregnancy is migration into the uterine epithelium to release its granules and subsequent condensation to a cell remnant, which is phagocytosed by the chorionic epithelium.

Cotyledon A lobule of a mammalian placenta.

Glucocorticoids A class of steroid hormones that bind to the glucocorticoid receptor, which is present in almost every vertebrate animal cell. These hormones help the body respond to stress and to environmental change and guide fundamental processes associated with converting sugar, fat, and protein stores to usable energy; inhibiting swelling and inflammation; and suppressing immune responses.

Lactogenic Inducing lactation, the onset of milk synthesis, and secretion, and includes all of the changes in the mammary epithelium necessary to go from the undifferentiated mammary gland in early pregnancy to full lactation sometime after parturition.

Proteomic Relating to the structure, function, and interactions of the proteins produced by the genes of a particular cell, tissue, or organism.

Somatogenic Originating in or relating to the cells of the body.

Somatotroph A cell of the anterior pituitary that produces somatotropin (growth hormone).

Somatotrophic Having a stimulating effect on body growth.

Transcription factor A protein or molecule that binds to specific DNA sequences or regions, thereby controlling the flow (or transcription) of information from DNA to form specific messenger RNAs.

Introduction

Growth of meat-producing animals is a complex, interactive set of processes initiated at or just after conception that can have effects until death. The expansion of genomic and proteomic techniques and studies has resulted in the discovery of numerous new factors that control the growth and carcass composition of livestock. The endocrinology of growth encompasses the biosynthesis, storage, chemistry, biochemical and physiological function of hormones, and the cells of the endocrine glands and tissues that secrete them. Hormones are secreted directly into the blood stream rather than into a duct system and have a variety of functions or actions on target organs or tissues. One hormone might affect more than one organ or tissue, and conversely, one organ or tissue might be affected by more than one hormone. Hormones and growth factors acting on the same cell type as those in which they are produced are said to have autocrine actions. Hormones and growth factors that act on other cell types in the same tissue or organ in which they are produced are said to have paracrine actions. This brief review will focus on the main hormones and growth factors, with an emphasis on growth of muscle and fat, the main constituents of meat. Commercial growth promotants are covered elsewhere and are not included in this article.

The article is divided into two sections: hormones and factors controlling embryonic and fetal growth and hormones and factors controlling postnatal growth. A number of the hormones and growth factors are active on growth before and after parturition, although in some cases they have different functions. This article will deal in greater depth with particular endocrine factors at the developmental time considered to be most important.

Embryonic and Fetal Growth

Regulation of embryonic and fetal growth is directly related to tissue differentiation and organogenesis. Imprinting of genes has been strongly implicated in fetal and placental growth. An example relevant to meat production is the imprinting of the insulin-like growth factor II (IGF-II) gene. A change in imprinting of the IGF-II gene resulting from embryo culture used in *in vitro* systems can result in the large calf or lamb syndrome. It is also reasonable to suspect that nuclear–cytoplasmic interactions within a cell, which can be altered by external growth factors around conception, can influence subsequent growth and development. These early effects on growth might be achieved by altering the degree of methylation of growth-related genetic loci, which are under the control of growth factors, which in turn are under in utero environmental influences. After conception, the growth of the embryo depends on cell hyperplasia and hypertrophy, differentiation, and also on cell survival or death by programmed cell death, called apoptosis. These cellular systems can be controlled by extracellular growth factors, although the response to a specific growth factor is to some extent dependent on the physiological state of the cell. An example is insulin-like growth factor I (IGF-I), which can stimulate, through the type I IGF receptor, both hypertrophy and hyperplasia via the phosphoinositide-3 kinase (PI-3) kinase or mitogen-activated

protein kinase pathway, or cell survival through the PI-3 Akt/Bad signaling pathway. Apoptosis – programmed cell death – is also controlled by extracellular factors, such as morphogens like Sonic Hedgehog.

Morphogens are factors that act at a distance from their site of secretion, are dose-dependent, and induce specific cell type development. Transcription factors such as Bicoid and Hunchback also act like morphogens before cellularization by producing specific concentration gradients that determine the orientation of the embryo by controlling the anterior–posterior and dorso–ventral developmental gradients. In lambs, retinoic acid activates the expression of bone morphogenic protein 2 and Sonic Hedgehog, and these two factors in concert control directly or indirectly the anatomical differentiation and growth of limbs. Maturation of organs and tissues does not occur simultaneously, but progresses along the anterior–posterior/distal–proximal axes displaying 'early to late' gradients of development in the embryo. As already mentioned, patterning signals are probably set up before the first cell divisions. These gradients are then maintained by subsequent morphogens produced by different cell types. The development of tissues and organs along these gradients can be modified by nutrient availability through nutritionally sensitive hormones and growth factors, although the developmental sequence remains unchanged.

Undernutrition of sheep at different periods of gestation leads to disproportionate growth of various organs, such as the heart and liver. This is not, as has often been assumed, limited to a particular stage of gestation. Endocrine changes reflect the original intention programming for a future postnatal lifestyle of the animal, if conclusions from epidemiological studies on starved human populations are accepted. Therefore, altered body proportions at birth might reflect complex metabolic adaptations as well as an altered hormonal environment that influence postnatal patterns of growth. Insults or negative influences during gestation that cause significant developmental changes in fetal growth and in organs and tissues are now considered to program permanent changes in the structure and function of the endocrine systems. Some changes resulting from early fetal manipulations are considered to cause permanent endocrine changes that are thought to predispose the mature animal to adipose cell hyperplasia, obesity, and endocrinological problems such as type II diabetes.

Myogenesis

The growth of a specific tissue such as muscle is dependent on endocrine, paracrine, and autocrine factors. Muscle cells – myoblasts during fetal development – are initially formed from the segmental mesodermal somites. A number of morphogens from surrounding tissues induce myogenic differentiation; examples include Wnt-1 and PAX3. Wnt-signaled transduction is crucial for maintaining the balance between proliferation and differentiation throughout embryogenesis and postnatal life. PAX3 is a gene that belongs to the paired box (PAX) family of transcription factors. This gene was formerly known as 'splotch' and has been identified with ear, eye, and facial development. PAX3 is also responsible for controlling the migration of myogenic cells into the limb buds to form the muscles of the limbs.

Insulin-Like Growth Factors

The determination of the myogenic progenitor (precursor) cells and their subsequent proliferation to form myoblasts, which fuse to form myotubes, and continue to fuse with existing myotubes to form muscle fibers, is controlled by myogenic regulatory factors. The expression of the myogenic regulatory factors is in turn controlled by other positive and negative growth factors. IGF-I and IGF-II both increase when myoblast proliferation is increasing during muscle development in cattle, swine, and sheep. Recently, a local muscle IGF-I variant, mechano growth factor (MGF), has been associated with stretched muscle. The role of MGF during muscle development is at present uncertain. However, IGF-II is the dominant IGF during fetal development, and IGF-II messenger ribonucleic acid (mRNA) has been shown to increase when myogenic progenitor cells are proliferating, migrating, and fusing in regenerating muscle. Regeneration often appears to follow similar developmental pathways as found in developing tissues. IGF-I, which is also expressed during fetal muscle development, might also be involved in these early stages of muscle fiber formation. However, growth hormone (GH), the pituitary hormone that controls the majority of circulating IGF-I, is not necessarily involved in muscle growth during gestation: mice overexpressing GH do not show increased muscle growth at birth. However, in pigs, GH treatment during certain developmental stages during gestation has been reported to have different long-term effects on muscle development. If GH is administered to pregnant sows early in gestation, at a time when myoblast proliferation is at a maximum, the number of secondary myotubes in fetal muscles results in more muscle fibers in piglets at birth. Administration of GH in midgestation delays muscle maturation, whereas administration in late gestation results in an increase in muscle fiber size.

Myostatin

Unlike IGF-I, myostatin, a member of the transforming growth factor (TGF)-β superfamily, is a negative regulator of muscle cell proliferation. Mutations in the myostatin gene result in double-muscled cattle, a condition that results from a doubling of the secondary myotubes during fetal muscle development and an increase in total number of muscle fibers, but not an increase in muscle fiber size (fiber hypertrophy) at birth. The myogenic regulatory factors have been linked with myostatin during secondary myotube formation in cattle, indicating that myostatin has a coordinating role in the terminal differentiation and fusion of myoblasts to form secondary myotubes. It has been shown in tissue culture that myostatin stimulates expression of P21, which prevents the phosphorylation of retinoblastoma (prb), a transcription regulatory protein, allowing prb to bind to the E_2F transcription factor and so blocking myoblast proliferation. Myostatin, like other TGFs, is produced as a precursor protein that is cleaved before secretion to yield the *N*-terminal associated peptide (LAP) and the *C*-terminal processed peptide. The pro-peptide has been

shown to antagonize the biological activity of myostatin, by binding to myostatin and preventing myostatin binding to its receptors. Follistatin, which inhibits follicle-stimulating hormone, has also been shown to be capable of binding to myostatin and inhibiting its actions. Mutations in the propeptide region of myostatin in mice generate the compact hypermuscular mouse, which increases muscle mass postnatally and particularly in the hind-quarter muscles. In general, these results show that myostatin can inhibit muscle growth in various ways during fetal development.

Adipogenesis

Adipogenesis, the formation and growth of adipose tissue (fat) during fetal development, is controlled by local paracine/autocrine factors, which are themselves controlled by the overall hormonal status of the fetus and the mother. The effects of changes in these hormones or factors are dependent on the stage of development, with the proliferation of preadipocytes, adipocyte differentiation and formation of mature lipid-filled adipocytes, all being sensitive to changes in the endocrine system of the fetus.

Insulin

Insulin, which controls glucose supply to and/or uptake by tissues within the fetus and the mother, seems to be a major controller of fetal adipose tissue lipogenesis (lipid synthesis); experimentally induced diabetes in pregnant sows increases fetal adipogenesis and lipogenesis. Fetal hypophysectomy and replacement therapy have revealed that a number of fetal hormones controlled by the pituitary are important in adipocyte hyperplasia and lipogenesis. Fetal GH treatment decreases the lipogenesis associated with hypophysectomy and antagonizes thyroxine-stimulated lipogenesis. Thyroxine, which is under the control of thyroid-stimulating hormone, appears to control both adipocyte hyperplasia and fat deposition in the fetus. Glucocorticoids, from the adrenal gland, are among the major hormones controlling adipocyte development and differentiation. This appears to be dependent not only on the hormone concentrations in the blood, but also on the number of adipocyte glucocorticoid receptors (GRs). In pigs, the number of GRs is low at 50 days of gestation and increases to a maximum at 105 of gestation. Birth occurs at about 114 days of gestation. The number of GRs in adipocytes can be manipulated by insulin, which may indicate that glucocorticoids are a major factor in the action of insulin on fat deposition in the fetus.

Tumor necrosis factor-α regulates adipose cell differentiation by decreasing the peroxisome proliferator activated receptors (PPARα). Members of the TGF-β superfamily have been shown to block adipocyte differentiation. Myostatin, a member of that family, has been shown to inhibit pre-adipocyte differentiation by controlling PPARα. Thus, myostatin, as previously discussed, not only inhibits pre-adipocyte differentiation, but also inhibits myoblast hyperplasia, and as a result, reduces muscle fiber number. This clearly indicates a close, coordinated physiological link between muscle and fat growth during fetal development.

Placental Growth Factors

Fetal growth is dependent not only on fetal hormones and growth factors but also on the balance of nutrients between the mother and the fetus. There may be a trade-off between the growth of the fetus and the mother's future rebreeding potential, depending on plane of nutrition of the mother. The placenta is the interface between the mother and the fetus. The placenta is not a passive organ: it secretes an array of hormones and growth factors that regulate placental growth and fetal growth, and maintains a homeostatic balance between mother and fetus. This includes control of nutrients passed on to the fetus from the mother. The placenta also protects the fetus from infections as well as preparing the mother for parturition and lactation.

The placenta secretes placental growth hormone (PGH) and placental lactogen (PL), which probably have a common ancestry. PGH has high homology with pituitary GH and can bind to both somatogenic and lactogenic receptors, but it is a weaker lactogen than pituitary GH. PGH is the dominant maternal GH during the later stages of pregnancy and down-regulates maternal pituitary GH. Although the placenta expresses growth hormone-releasing hormone (GHRH) and the hypothalamic GH inhibitor somatostatin, and somatotropin release-inhibiting factor (SRIF), these do not appear to be major controllers of placental GH. PGH appears to be regulated by glucose, which controls maternal IGF-I. The effect of maternal treatment with GH on fetal growth is dependent on the gestational age and species.

PL has both lactogenic and somatotrophic activity, although the lactogenic effects are more prominent. This is an example of a placental hormone having a significant indirect effect on postnatal growth by affecting mammary development and future milk production, and as a result, preweaning growth of her progeny. There are species differences; PL is found in ruminants but it has not been found in pigs. PL is mainly restricted to the maternal circulation and appears to exert a metabolic effect that stimulates maternal lipolysis, and thereby increasing maternal insulin, which causes insulin resistance and inhibition of gluconeogenesis. This makes more glucose available for the growth and development of the fetus. PL may also increase the flow of amino acids to the fetus by restricting maternal utilization. In sheep, PL is produced by chorionic binucleated cells of the placenta and is found in both the maternal and the fetal circulation. Maternal ovine PL (OPL) is first detected at 40–60 days of gestation and reaches its peak at 120–140 days. Recent studies from Israel have shown that ewes immunized against OPL have higher birth weights of lambs resulting from multiple births, and all immunized ewes produced more milk than nonimmunized ewes. The antibody response is an immuno-potentiating effect not an antibody-inhibiting effect.

The roles that placental GHRH and SRIF play in controlling fetal growth are unclear. The effect of SRIF on fetal growth has been tested by direct injections of SRIF into the placental cotyledons of cows: fetal GH was reduced. Injections of GHRH and thyroid-stimulating hormone increased fetal GH but not PLs. SRIF injected into the mother showed only a rebound effect when the infusion stopped; an effect on the fetus was not seen.

Administering SRIF directly to the fetus suppresses fetal GH but not placental GH or PL. Maternal immunization against SRIF has been shown to affect fetal growth: passive immunization increased birth weight; active immunization showed an increase in fetal protein in pigs and increased litter size, but had no overall increase in birth weight. In lambs, there was no effect on birth weight, but postnatal growth was increased. The results from maternal SRIF immunization are variable, and if the effects of SRIF are to be fully understood, the SRIF treatments will have to be administered to specific sites to determine the local effects.

In summary, the endocrinology of fetal growth is complex and highly interactive, with the same or similar hormones from the maternal pituitary, placenta, and fetus often having different functions and these different functions themselves often being dependent on gestational age. This interactive complex set of maternal–fetal hormone and growth factor effects has not been the main focus of growth endocrinologists, yet it is the foundation from which postnatal growth and endocrine control of growth are derived. Recent human epidemiological studies have resulted in the formulation of the Barker hypothesis (fetal origin of disease). This claims that nutritional deprivation of a fetus during critical developmental periods results in the metabolic/endocrinological balance of the fetus being reset so that postnatal metabolism, physiology, and endocrinology are permanently changed. These changes become maladaptive if the nutritional levels differ between the fetus and the adult. The change results in obesity, type II diabetes, hypertension, and so on. This hypothesis, although emanating from human studies, may have direct applications to management systems of meat animal production.

Postnatal Growth

Growth Hormone

Postnatal growth, although no longer dependent on maternal/placental nutrient supply, is still dependent in mammals on the mother's milk supply, which is under the control of GH and prolactin. Postnatal growth after weaning is controlled by appetite, feed conversion efficiency, and repartitioning of nutrients to various tissues. Appetite and nutrient repartitioning are under endocrine control.

The somatotrophic axis, centered around GH synthesis and secretion, is the most important cascade of hormones controlling postnatal growth and is related to the appearance of somatotrophic receptors in the liver during postnatal development in lambs, calves, and pigs. GH, as indicated by its name, is considered to be the most important pituitary hormone associated with postnatal growth. GH has direct anti-insulin effects on fat by decreasing lipogenesis and increasing lipolysis and on carbohydrates by increasing blood sugar. GH has indirect effects through IGF-I, which controls skeletal growth by stimulating chondrogenesis and muscle growth by stimulating satellite cell division and fusion with existing muscle fibers causing hypertrophy. GH also interacts with other hormones, such as cortisol, to produce synergistic effects that enhance the individual diabetogenic and lipolytic effects of GH and cortisol, whereas cortisol can block some of the anabolic effects of GH.

The main effects of GH on growth have been considered to be indirect. The classical somatomedin hypothesis proposed that GH acted on the liver to increase synthesis of IGF-I, with hepatic IGF-I mediating those anabolic effects. This was initially challenged by the idea that there also existed local tissue IGF-I produced in response to GH. The somatomedin hypothesis has been revisited recently because, when hepatic IGF-I was deleted by genetic engineering, circulating IGF-I levels fell to 25% of normal, but there was no immediate effect on growth. These experiments challenged the concept that circulating hepatic IGF-I is crucial for normal GH-controlled postnatal growth.

GH has been administered to meat-producing animals to stimulate lean growth. Dose–response studies in which growing pigs were administered from 50 to 200 micrograms of recombinant porcine GH per kg live weight per day from 25 to 90 kg body weight contained 28–38% more muscle mass and from 40% to 80% less adipose tissue mass. Studies in which GH or GHRH were administered daily also improved growth rate, efficiency, and carcass composition of growing lambs and pigs. In some studies in which overfat lambs were treated with GH, a heavyweight lean lamb could be produced with 6 weeks of GH treatment. Similar effects have been produced in experiments in which growing cattle were administered GH. This indicates that GH treatment not only stimulates growth but repartitions nutrients from fat to muscle by reducing lipogenesis, increasing muscle protein synthesis, as well as stimulating lipolysis to varying degrees.

Growth Hormone-Releasing Hormone

GH itself is controlled by the hypothalamic factors GHRH and somatostatin (SRIF). GHRH stimulates GH secretion through a G-protein-coupled receptor that initially increases cyclic adenosine monophosphate (cAMP), which stimulates GH secretion. A reduction in GHRH leads to a marked decrease of normal postnatal growth, as well as obesity, which is associated with hyperphagia. Daily administration of GHRH increases growth rate, improves feed efficiency and improves carcass composition in growing lambs and pigs.

Somatostatin

Somatostatin (SRIF) is found not only in the hypothalamus but also in the gut. SRIF inhibits the release of GH from the pituitary somatotrophs, as well as inhibiting a number of gastrointestinal and pancreatic hormones. SRIF acts through several G-protein-coupled somatostatin receptors. In the pituitary somatotrophs, SRIF decreases cAMP, inhibits Ca^{2+} channels and activates K^{+} channels. These effects inhibit both the basal and the stimulated release of GH.

Insulin

Insulin, secreted from the pancreas, in addition to its primary role of regulation of carbohydrate homeostasis, also stimulates growth. Insulin deficiency results in poor growth pre- and

postnatally. This suggests that insulin has a role in somatic growth that might be permissive and controls the uptake and utilization of carbohydrates and amino acids. In pigs, a lack of insulin inhibits normal growth by up to 50%, but in other studies administration of insulin did not increase muscle growth or live weight gain of well nourished pigs. In addition to controlling blood glucose, insulin also controls some aspects of amino acid transport into tissues, such as muscle, and inhibits protein degradation, so increasing protein deposition. Carcass fatness is also controlled, to some extent, by insulin, with a reported positive correlation between plasma insulin concentrations and carcass fatness. GH administration to growing pigs reduces adipose tissue/cell sensitivity to insulin, thereby reducing lipogenesis and carcass fat content. In abnormal clinical situations, such as hyperinsulinaemia, insulin may stimulate growth through the type I IGF receptor, as well as acting through the insulin receptor.

Pubertal Growth

Growth in both females and males increases around puberty – the 'pubertal growth spurt.' This growth spurt occurs at different ages between sexes and has different effects on overall growth and growth of muscle and fat. Sex differences in growth rate and carcass composition have been associated with testicular androgens (testosterone, dihydrotestosterone, and androstenonedione) in the male, and with ovarian hormones (estrogens and progestogens) in the female.

Male hormones

In the male, testosterone and dihydrotestosterone are the main testicular hormones that control growth and increase lean muscle mass. Testosterone appears to have two modes of action. Its direct action on striated muscles is through specific intracellular receptors. Testosterone circulates in blood bound to sex steroid binding proteins that assist the entry of testosterone into the cell. The indirect effect of androgens on lean muscle growth is thought to be in association with GH. When androgens were administered to hypophysectomized rats, the animals failed to grow and required GH to achieve a normal growth response to testosterone. However, although the natural testicular androgen testosterone might promote lean growth by requiring GH for maximum stimulation, synthetic androgens, such as trenbolone acetate (TBA), stimulate growth by binding directly to muscle fibers and their androgen receptors, although details of the mechanism of action are not clear. Treatment of feedlot cattle with a combined implant of estradiol and TBA increases muscle satellite cell number, increases expression of muscle IGF-I mRNA and increases circulating levels of IGF-I. Treatment of bovine satellite cell cultures with either estradiol or TBA increases expression of IGF-I mRNA, increases rates of proliferation and protein synthesis, and decreases rates of protein degradation.

Female hormones

The female hormone estrogen has been shown to stimulate growth in sheep and cattle, with a greater response found in older lambs and castrated male cattle. High doses of estradiol, however, inhibit growth and antagonize the actions of GH. This clearly indicates that the growth-promoting effects of estrogens are dose-dependent; as a consequence, when estrogen-based growth promotants are given to livestock on high-phytoestrogen pastures, very limited growth promotion is observed.

The effects of estrogens on growth are thought to be mediated in part through an increase in GH, although as mentioned in the preceding section, the direct effects on bovine satellite cells in culture have been shown to be mediated at least in part through the classical estradiol receptor, estrogen receptor-alpha (ESR-1), the IGF-I receptor, and the G protein-coupled estrogen receptor (GPER-1). Therefore, direct actions on the IGF-I axes independent of GH have been identified, and estrogens do have direct muscle satellite cell and tissue effects. Muscle growth might be directly stimulated by estrogens by direct binding to estrogen and androgen muscle receptors. It is now clear that a complex interaction of numerous pathways and receptors is involved in anabolic steroid-enhanced bovine muscle growth.

Progesterone is another ovarian hormone that has been shown to stimulate growth. Progesterone is naturally produced by the corpus luteum under control of luteinizing hormone. Progesterone might bind directly to muscle through the androgen receptor, so having a direct effect on lean growth. The actions of the synthetic progestagen, melengestrol acetate, however, might be indirect through blocking ovulation, so increasing ovarian estrogen production from immature ovarian follicles, which then stimulates growth.

Anabolic agents, mainly based on androgens or estrogens, are routinely used in the North American cattle industry during the finishing of steers on feedlots. These products have been commercially used for over 40 years, with new combinations developed recently, and will not be dealt with here beyond the information provided above.

Glucocorticoids

Glucocorticoids produced by the cortex of the adrenal gland have effects opposite to those of insulin. They decrease the uptake of glucose, so increasing blood sugar levels, and increase protein breakdown and lipolysis. Although these effects are growth-inhibiting rather than growth-stimulating, corticosteroids at physiological concentrations are necessary if the efficient stimulation of GH secretion is to be achieved by GHRH. The use of glucocorticoids such as dexamethasone to treat inflammation impairs growth by reducing the local tissue stimulation of IGF-I by GH by reducing both the IGF-type 1 receptor and GH receptor.

Catecholamines

Catecholamines, such as adrenaline (epinephrine), produced and secreted by the adrenal medulla and noradrenaline (norepinephrine), released by specific types of nerve endings, are under the control of the sympathetic nervous system. These hormones are normally released under acute stress or excitement, such as fear, and are important in the regulation of heart rate, blood flow, and metabolic adaptation to provide more energy to critical tissues. However, a number of synthetic

catecholamines, including ractopamine hydrochloride and zilpaterol hydrochloride, are used as muscle growth promotants in livestock.

These feed additives are absorbed into the blood and act on the β-adrenergic receptors of muscle and other tissues. These anabolic actions do not appear to involve IGFs. Studies conducted with growing steers demonstrated that continuous infusion of small amounts of cimaterol into the hind limb directly causes increases in amino acid uptake, increased protein synthesis and muscle growth without significant changes in GH, insulin, IGF-1, or thyroid hormones.

Recently Identified Factors Controlling Growth

With the advent of genomics and proteomics a number of new factors that control tissue growth have been identified. Two such factors that are produced by adipose tissue are leptin and adiponectin.

Leptin

Leptin is produced by adipocytes, although its receptors are found in numerous tissues including the brain. Leptin appears to be involved in the central control of energy balance regulation, achieved by controlling appetite and fat deposition though the manipulation of or feedback to neuropeptide Y in the brain, which controls appetite. Leptin also has local effects on peripheral insulin resistance. Resistance to leptin leads to obesity, which can be the result of defects in the leptin receptor and/or in downstream signaling or in the leptin carrier protein.

Adiponectin

Adiponectin is a protein that is only produced in adipose tissue but which circulates at relatively high concentrations. Adiponectin enhances insulin sensitivity and glucose tolerance and appears to increase free fatty acid oxidation in muscle. Adiponectin, like leptin, appears to be involved in regulation of energy homeostasis, which indirectly controls the repartitioning and utilization of nutrients.

Myostatin

Myostatin, already discussed with reference to muscle fiber formation during fetal development, has a role in both muscle and fat growth in the adult. Myostatin has been shown to control cell division of myoblasts during muscle fiber formation during fetal development and growth. The extension of the time period during which this occurs, leading to daughter myoblast fusing into the muscle fiber, allows ongoing muscle fiber formation. Myostatin can, therefore, reduce or block the potential for postnatal muscle growth if it appears sooner or is present at higher levels when myotube formation is occurring. Removal of myostatin has been shown to lead to partial suppression of fat accumulation and abnormal metabolism of glucose.

Summary

The endocrine regulation of growth can occur in two main ways. The first is via hormones acting through receptors and growth factors that are directly implicated in growth overall and in repartitioning of nutrients, bringing about differential tissue/organ growth. These hormones and factors are often involved in nutrient homeostasis, and therefore can be altered by level of nutrient intake. The second is an endocrine dysfunction that causes a clinical imbalance and reduced growth (i.e., reduced GH synthesis and secretion). In addition, growth appears to be sensitive to many clinical illnesses. This article has focused on some of the hormones and growth factors involved in growth, especially the growth of muscle and fat. Known GHs/factors are now very numerous and undoubtedly more will be identified. It is apparent that hormones and growth factors are highly interactive (i.e., GH markedly reduces the sensitivity of adipose tissue to insulin and steroid hormones act through several receptor pathways), and control nutritional homeostasis as well as specific growth and development of tissues and organs.

Growth factors are an integral part of growth and development from the first cell divisions after conception to the mature adult. Postnatal growth is dependent not only on the hormones and growth factors during that growth phase, but on growth and development from conception. This is most clearly seen in the determination of muscle fiber numbers that occurs before birth.

The future for growth and endocrinology in meat science is the identification of the early growth factors that determine the future growth and carcass composition of the animal, which can be used as selection markers, or for generating management strategies or genetically engineered animals.

Growth Patterns

SJ Jones, University of Nebraska, Lincoln, NE, USA

Glossary

Allometric growth The growth rate of a tissue or organ in relation to its whole.
Callipyge sheep A natural genetic mutation that produces extremely muscled hindquarters in sheep.
Double muscling An inherited condition in cattle, characterized by hyperplasia (increase in number) and, to a lesser extent, hypertrophy (enlargement) of muscle fibers.
Intermuscular fat The fat located in the seam between muscles.
Intramuscular fat The fat interspersed between muscle fibers within the muscle.
Myostatin A secreted growth differentiation factor protein that is a member of the transforming growth factor beta protein family that inhibits muscle differentiation and growth in the process known as myogenesis.

Introduction

Growth in meat animals is often described as an increase in the size (weight or dimensions) of the animal. An animal can increase in weight with the accumulation of fat (lipid), but this is not considered true growth. The growth of animals can be monitored in several ways, including measurements of length, width, girth, and weight. Generally, live weight has been the most important and most commonly measured parameter, probably because of the ease in obtaining weight information and the importance of weight in marketing animals for use as meat. If weight is recorded over time, it is possible to construct a graph that illustrates the growth pattern of an animal; the growth curve or line will be 'sigmoid,' so called because of its resemblance to the shape of the letter S (Figure 1). The zero time of the curve is in most instances the point of conception, with the curve reaching a plateau when the animal reaches mature size. Mature size can be defined as the point at which the weight change with time is only slight and there is little or no change in the fat content of the animal.

Most animals have very similar growth patterns, varying only in terms of the time it takes to reach mature size. For example, a mouse will reach mature size in several weeks, but an elephant may take 50 years to reach mature size. Because of differences in mature size and growth rate, it is difficult to compare between species and even within breeds of the same species. To make a more relevant comparison, growth is expressed as a percentage or fraction of gain of the present size of the animal instead of absolute gain. Fractional growth rates of organs and tissues vary from conception to maturity. This variation in growth is referred to as differential growth. Because the growth of each organ and tissue occurs at different times, this differential growth will be exhibited by changes in shape and proportions of parts of the animal.

The driving force behind expression of differential or proportional growth in an animal species is evolution. The 'function' of the animal kingdom is to survive and reproduce to sustain the species. As animals grow they will develop organs and tissues that are most critical for life before those organs and tissues that are a lower priority for survival. For example, at birth the brain, heart, and liver are more fully developed than bone, skeletal muscle, or fat. Understanding this fact helps to comprehend the patterns in which animals grow. Granted, in the past century, humans have altered animals to fit their needs for food, power, and fibers, but these changes are minor when compared to those of a millennia of evolutionary pressure.

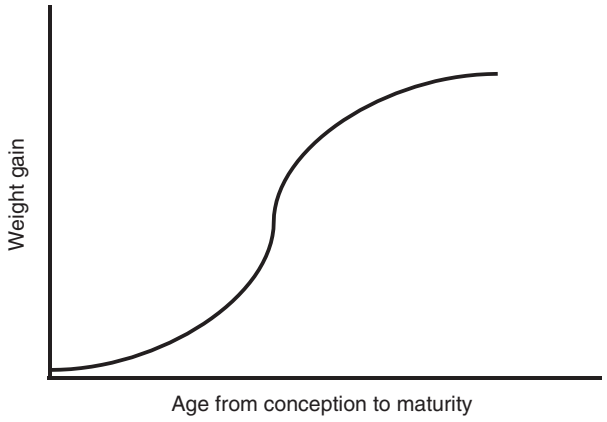

Figure 1 Illustration of the cumulative growth based on weight gain of an animal from conception to maturity.

Measuring Patterns of Growth

There is vast body of literature documenting growth patterns of tissues in animals. Two researchers who contributed to this knowledge are Sir John Hammond and the zoologist Julian Huxley. Both provided the basis of understanding proportional growth. Huxley found that proportional growth could be measured as the weight of a tissue, an organ, or a subdivision, such as an individual muscle, in relation to the whole animal or tissue. This methodology became known as growth allometry and has been used by researchers to examine growth patterns in tissues such as muscle, fat, and bone. Huxley was able to develop a mathematical method to detect the changes in growth impetus of various tissues in relationship to the whole animal or tissue. It is possible to compare

 doi:10.1016/B978-0-12-384731-7.00008-8

the relative growth of a unit of the whole animal or tissue on a logarithmic scale using eqn [1]

$$y = bx^k \quad [1]$$

where y is the weight of the tissue, x is the weight of the body, b represents the y intercept, and k is the slope or growth impetus.

This can also be expressed in terms of logarithms as eqn [2]

$$\log y = \log b + k \log x \quad [2]$$

The slope of the resulting regression (k) is called the allometric growth ratio. If $k=1$, then the unit of body being compared to the whole is growing at the same rate and is referred to as having average growth impetus. If $k>1$, then the unit of the body is growing faster than the whole and is referred to as having high growth impetus. If $k<1$, the unit of the body is growing slower than the whole, commonly referred to as low growth impetus. Using allometry, it is possible to compare the growth of various tissues in relationship to the whole body throughout the lifespan of the animal.

Organ and Tissue Growth Patterns

Comparative patterns by which organs and tissues develop follow the principle that the tissues or organs most essential for survival develop first. The relative order of growth of different tissues is similar for all species of farm animals. As illustrated in Figure 2, nervous tissue is the first to develop, followed by bone, muscle, and fat. During the growth and development of the embryo, the first noticeable tissue is the notochord. This develops in a process called neurulation and will eventually become the nervous system. The nervous system begins very early to direct the development of the other tissues in the body. For example, neurulation in the pig is complete by 15 days after fertilization. At approximately 35 days the cerebral hemispheres of the brain have achieved a relatively high degree of development and the midbrain is large and overhangs the developing cerebellum. Examining the allometric growth curve of the brain, it is observed that k is less than 1 throughout the postnatal life of the animal. The reason for this is most likely that the accelerated growth prenatally is critical for proper brain function at birth for survival.

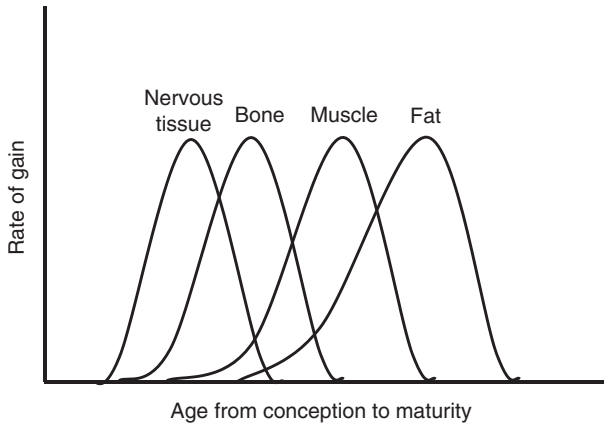

Figure 2 Growth rate of nervous tissue, bone, muscle, and fat in the animal body as a function of age from conception to maturity.

Patterns of Carcass Growth

One of the primary reasons for raising livestock is for meat production. Muscle, fat, and bone are the major components of a dressed carcass derived at harvest. A quality carcass is characterized by a large amount of lean muscle, a minimal amount of bone, and an adequate amount of fat. Figure 3(a) illustrates the percentages of tissues in the carcass as the animal grows. Muscle needs to be functional at birth therefore it comprises a high percentage of the body at birth, and as fat increases then muscle percentages decrease. At birth most animals have limited fat depots but fat becomes a major factor in carcass composition as the animal matures. Bone begins to develop in prenatal life to allow the animal to function at birth but has very little effect on carcass composition during postnatal growth.

Carcass composition can vary due to gender, frame size, and several genetic conditions. In general, intact male cattle will have an increased muscle mass and less fat than females and steers (Figure 3(b)). Animals that reach mature weights earlier have an increased fat percent (Figure 3(c)). However, if later maturing animals are allowed to grow they will reach similar composition but at a greater weight. Cattle with the genetic condition of double muscling will have increased percent muscle with a subsequent decrease of fat and a slight decrease in percent bone (Figure 3(d)).

Patterns of Bone Growth

Growth of bone determines the ultimate length of individual muscles and therefore is a major determinant of muscle growth. Obviously, as bones increase in length, muscles will also grow. For example, as the limb of an animal lengthens, it stimulates the longitudinal growth of muscle; not until bone lengthening slows is there a substantial increase in the radial growth of muscle.

There is a tendency for the distal extremities or appendicular skeleton of the animal to complete the growth cycle first, followed by the proximal and axial parts. Early observations showed that the growth pattern of animals follows a definitive sequence, i.e., metacarpals, radius–ulna, and humerus in the fore limb; and metatarsals, tibia–fibula, and femur in the hind limb. The only bone in the appendicular skeleton lagging in development is the scapula. The bones of the head generally develop early, which can be observed by the increase in head size compared to the rest of the body in young animals. The possible reason for this is to protect the brain and also to provide the animal with the ability to obtain food that is essential for survival and growth. The pattern in which bones and limbs develop is referred to as 'centripetal' growth or center-seeking growth which is characterized by the early development of bone at the extremities, with waves of growth moving to the center of the body. Besides growth beginning at the extremities and moving to the center of the animal, there are waves of growth moving along the vertebral column from

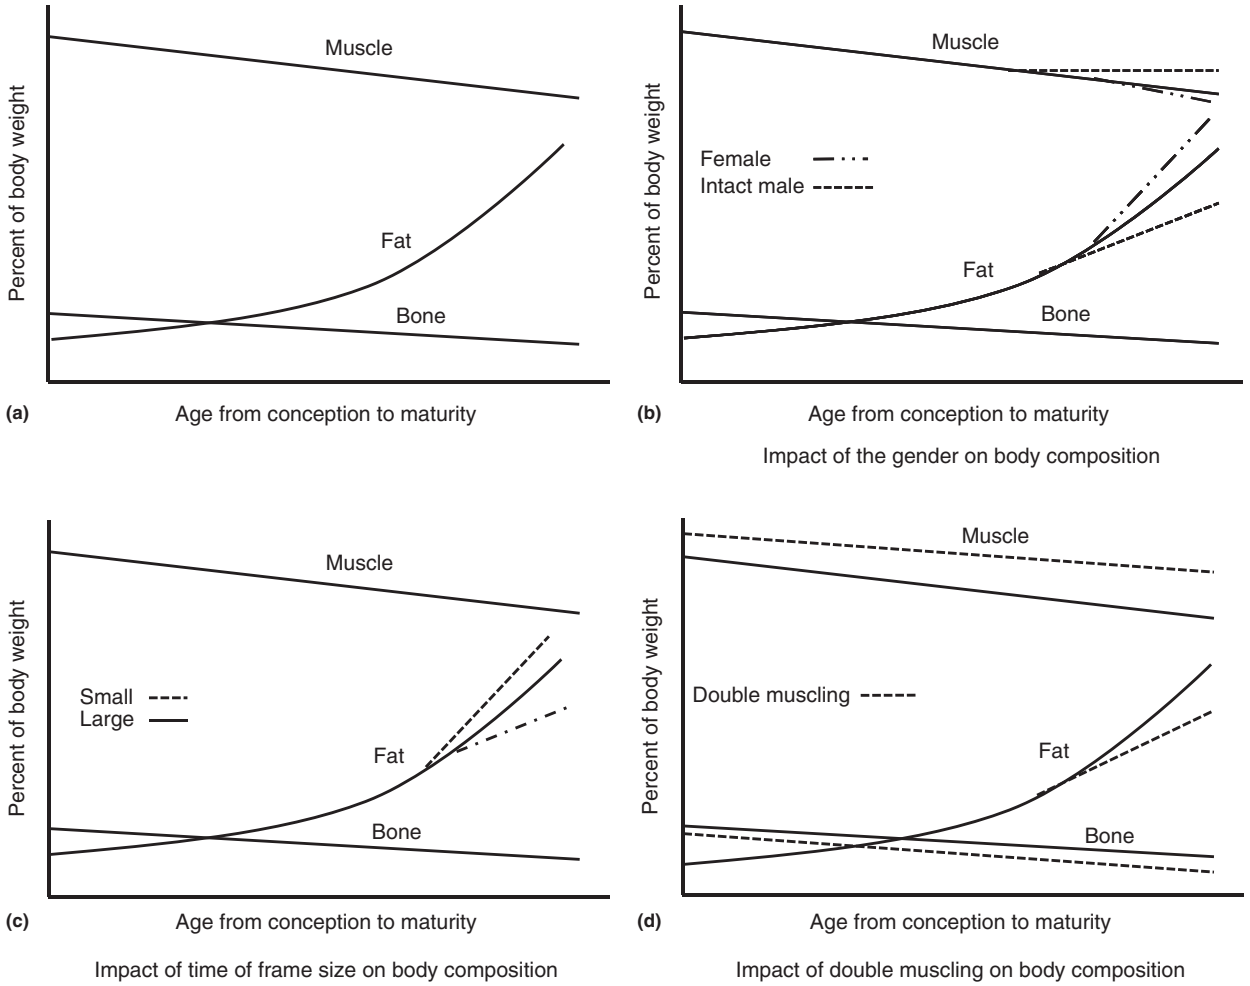

Figure 3 (a) Relative changes as a percentage of body weight of muscle, fat, and bone as a function of age from conception to maturity. (b) Relative changes as a percentage of body weight of muscle, fat, and bone as a function of age with the variation due to gender. (c) Relative changes as a percentage of body weight of muscle, fat, and bone as a function of age with the variation due to frame size. (d) Relative changes as a percentage of body weight of muscle, fat, and bone as a function of age with the impact of the double muscling genotype.

the posterior to the anterior of the animal. This can be observed by the ossification of the bone in the sacral area first; as the animal matures, the cartilage located on the distal portion of the thoracic spinous processes ossifies beginning on the most posterior vertebrae and proceeding to the anterior vertebrae.

Growth of bone slows relative to the body during the postnatal growth period. This is particularly true for bones in the distal limbs, which as explained earlier, may be due to the survival needs for early prenatal bone development.

Patterns of Muscle Growth

Many researchers have examined the growth patterns of muscle in livestock species to determine whether they could be altered to increase the amounts of muscles of higher value. This has met with limited success but, in the process, a vast amount of knowledge on growth patterns has been obtained. Most data were obtained primarily from postnatal animals, and little work has been done in understanding the growth patterns of muscle in prenatal animals. Some muscles may have already exhibited an increase growth impetus, but it is not observed in most studies.

The concept of functional demand, which is muscles develop based on their need, may help in understanding the pattern of muscle development. For example, if a newborn animal is to survive, it must be mobile so that it can stay close to its dam and nurse. To accomplish these two functions, it must have well-developed muscles in the distal portion of its limbs and the jaw. Muscles that perform these functions have been called 'early-developing' muscles because they have completed their development before birth. Other muscles that have minimal function at birth have completed only a small part of their total development at birth. Muscles of the abdominal wall would be classified in this category. As a calf begins to consume roughage and the rumen develops the muscles of the abdominal wall develop to support the gut and its contents.

Muscles can be divided into categories of low, average, or high growth impetus. These muscles are referred to as having a monophasic growth pattern. Other muscles may exhibit a

changing pattern during the time growth is monitored. For example, growth impetus may be low then change to average. These muscles are said to have a diphasic growth impetus.

The low and low-average muscles are very critical for movement of the animal. These muscles probably had a high impetus prenatally but this is difficult to determine. As mentioned earlier, these muscles are located in the distal portion of the limb and the deep muscles of the thicker part of the body. They comprise approximately 33% of the total musculature at birth but decline to approximately 25% in the animal at market weight. It is interesting to note that these muscles lose the least amount of weight during periods of body weight loss.

Muscles classified with an average growth impetus may be expected to perform uniform function throughout the life of the animal. Most of these muscles are located in the proximal part of the fore limb. These muscles provide support for a newborn during suckling and will support the adult animal when the center of gravity of the animal shifts to the fore limb.

Muscles classified as having a high growth impetus might be expected to grow more rapidly to meet functional demands placed on them, such as increased weight of the animal. Most muscles in this group are termed weight-supporting, such as the serratus ventralis, which provides a direct line of force for the weight of the thoracic portion of the trunk of the animal to the fore limb. Two muscles in the abdominal wall, the internal oblique and the rectus oblique, play a role in supporting the additional weight of the abdominal contents.

Also included in muscles that have high growth impetus are muscles of the hind limb and loin. These muscles are rather light at birth, which is fortuitous because this eases the birthing process. The development of the hind limb muscle postnatally is important for the maximum locomotive performance of the animal. In males there is an increase in muscles of the shoulder and neck during puberty. These muscles assist in survival and reproduction, more especially reproductive competitiveness.

Patterns of Fat Depot Deposition

Fat does not have the same functional activity as muscle or bone, yet it is very important in the survival of the animal. Without some type of energy store, the animal would not be able to survive. As mentioned earlier, a newborn piglet has only 2% body fat and, unless nourishment is provided shortly after birth, it will not survive. Fat clearly is the most variable tissue in the body in terms of percentage of body weight. Not only does the amount of body fat vary, but also the partitioning between depots within the body changes during growth.

The accumulation of fat in the various depots of the body generally follows a constant pattern, with the perirenal fat being the first deposited. Perirenal fat can be observed in the newborn animal, and even if the animal is severely restricted in energy a residual amount of fat is present.

Intermuscular fat, which is located between muscles and subcutaneous fat, located between the body and skin, follows perirenal fat, with intramuscular fat (located within muscles) being the final fat depot to develop. To illustrate this, growth allometry research in pigs revealed that mesentery and cavity fat increased faster than body weight the first 40 days of life, indicating early development. From 60 to 120 days there is a rapid increase in subcutaneous fat indicating development later. Similar growth patterns have been observed in cattle. When nutrients are restricted, the first depot to reduce in size is the depot that was deposited last, i.e., there would be a loss in intramuscular fat followed by subcutaneous and intermuscular fat respectively.

There are differences between species in relative proportions of subcutaneous versus intermuscular fat. For example, pigs have a greater proportion of total fat as subcutaneous fat compared to cattle. In cattle the pattern of deposition of subcutaneous fat shows that fat deposition is most rapid in the ventral portion of the animal during the fattening stage, with the most rapid location in the flank area, followed by the brisket. Early in the finishing phase, there is an increase of fattening in the loin area, but this diminishes later. The area showing the slowest fattening is in the round and chuck region. A possible reason for the reduced fat deposition in the moving limbs is that the mechanical movement of the limbs precludes the deposition of fat.

Gender Differences in Growth Patterns of Body Constituents

Gender of animals has a profound effect on muscle and fat growth patterns. This can be observed in the differences between males, females, and castrated animals. Most of the research in this area has focused on cattle because these animals are generally marketed after they have gone through puberty. The most apparent growth pattern difference that can be observed is, as a bull matures sexually, there is an increased development of the muscle in the neck and thoracic region. This probably serves two purposes: it provides support as the center of gravity shifts to the forelimbs of the animal, and it also allows an increase in the animal profile to provide for more success in the competition for and breeding of cows. This shift in muscle growth may also be explained by the observed reduction in the percentage of muscle in the posterior or pelvic limb of bulls compared to steers. In reality, muscles in the pelvic area of both animals are the same but, in bulls, the muscles are a lower percentage of the total muscle mass. There are no differences in growth patterns observed between steers and heifers in the thoracic and pelvic limbs.

Several studies have indicated there is a slight increase in the allometric growth of the abdominal muscles of heifers. These slight differences may be due to weight changes in heifers, where change in function is observed with the need for additional support for weight gain during pregnancy. Abdominal fat also increases, possibly to provide energy for fetal growth and subsequent lactation.

Fat deposition is also slightly different between genders. The most observable difference is that heifers increase in fatness sooner, followed by steers and then bulls. This difference may be readily observed if animals are slaughtered at constant weights. With the difference in the rate of fattening, the time at which animals are marketed for slaughter is important. Heifers fatten sooner and will produce lighter carcasses when compared to steers or bulls.

The amount and location of intermuscular fat is slightly different between genders. In a comparison of the amount of intermusclar fat in the forequarter, keeping the amount of intermuscular fat in the hindquarter constant, it is observed that heifers and steers have more fat in this depot than bulls. The difference in the growth patterns of the muscles in the neck and thorax between males and females is also observed in pigs. Intact males have larger muscles in the neck and thorax than do females. Gender effects on fat deposition are also observed in pigs. Several studies have shown boars have less total fat than females, whereas castrated males have more fat than females. There were also differences in the distribution of fat, with boars having lower amounts of total subcutaneous fat and higher amounts of intermuscular fat than females. One area in which boars have slightly higher amounts of subcutaneous fat is the neck and thorax region.

Genetic Variation in Growth Patterns of Carcass Components

Researchers have examined whether genetic selection can alter the growth patterns of carcass constituents. In most instances, it is difficult to identify differences in growth patterns of components of the typical carcass. For example, no differences have been identified in the growth impetus of bone due to genetic selection. There are differences in the weight of bone in large-framed versus small-framed cattle, but the development follows a very similar pattern in both.

In most livestock no differences have been observed in the relative distribution of muscle growth patterns among parts of the body. When comparing muscle growth patterns of cattle with widely diverse genetic backgrounds, there is striking similarity in the relative weight of individual muscles and in the various groups of muscles. This has led scientists to conclude that the muscles considered to be the expensive portion of the carcass (proximal muscles of the pelvic limb and muscles surrounding the spinal column), irrespective of the breed, constitute 56% of the muscle in a carcass.

There are some genetic differences among fat deposition patterns. The most obvious is observed between cattle from dairy versus beef breeds. It is widely accepted that dairy breeds have a larger percentage of total fat as perineal fat and less subcutaneous fat, and a slightly greater propensity for increased intramuscular fat whereas beef breeds have a higher percentage of subcutaneous fat. Differences are also observed when comparing *Bos taurus* and *Bos indicus* breeds. *Bos taurus* breeds generally have a higher amount of subcutaneous fat than *B. indicus* breeds. This difference is theorized to be caused by the differences in the thermal environments in which they have evolved. There are differences in fat content within the *B. taurus* breeds, with British breeds generally being fatter than Continental breeds when animals are slaughtered at the same weight. Several studies have shown the amount of subcutaneous fat can be altered in pigs when they are compared at the same weight or age.

Recently researchers have identified two genotypes that have a profound impact on muscle growth. Double muscling, a condition mentioned earlier is the result of a mutation of the myostatin gene which stimulates an increase in muscle mass. Double muscled cattle generally exhibit a higher muscle to live weight ratio, a high proportion of muscle in the carcass, higher muscle to bone and muscle to fat ratio compared to cattle selected for 'traditional meat characteristics.' The callipyge genotype in lambs is unique in that it causes a differential growth with an increased growth of muscles in the pelvic and torso regions of the animal. This condition does not manifest itself until several weeks after birth, however, at slaughter, lambs with the callipyge gene have heavier hind limb muscles with no differences observed in the muscle of the shoulder.

Nutrition Effects on Growth Patterns

In most instances, nutrient restriction slows the growth of muscles, but they compensate when adequate nutrition is restored. Consequently, because of this fact, it has been difficult to alter the distribution of muscles within the animal body. The tissue most affected by nutrient restriction is adipose tissue. As mentioned earlier in the Section Measuring Patterns of Growth, the loss of fat depots follows a pattern similar to fat deposition, but in reverse. For example, if cattle are restricted in feed, the depot that will lose the greatest total amount of weight will be the subcutaneous depot, followed by intermuscular fat, and then kidney fat. When cattle are placed on a recovery diet after energy restriction, the intermuscular fat depots have priority over the subcutaneous depots. The response of depletion and recovery is the same, irrespective of age.

Glossary

Anabolic A class of hormones such as anabolic steroids (technically known as anabolic–androgenic steroids) that are drugs with a steroid ring system with similar effects of testosterone. They stimulate protein synthesis and muscle growth, and insulin and have androgenic and virilising properties.

Androgenic/androgen Androgenic is the broad term for any natural or synthetic compound (usually steroid hormones) that stimulates or controls the development and maintenance of male characteristics by binding to androgen receptors.

Beta-adrenergic agonists (BAA) β1- and β2-agonists are the primary agonists studied, which act on beta-adrenergic receptors. A β_1-agonist is ractopamine; a β2-agonist is clenbuterol and zilpaterol hydrochloride.

Estradiol A sex hormone about 10 times as potent as estrone and about 80 times as potent as estriol in its estrogenic effect. Estradiol may be presented as E_2 or as estradiol benzoate.

Estrogens/estrogenic The primary female sex hormones. Natural estrogens are steroid hormones, whereas some synthetic ones are nonsteroidal.

Genomic/nongenomic steroid actions The genomic pathway of steroid actions involve hormone binding to cytosolic receptors and subsequent modulation of gene expression followed by protein synthesis. Nongenomic steroid actions involve alternative pathways that do not act on the genome.

Ractopamine A drug used as a feed additive to promote leanness in animals raised for meat. Pharmacologically, it is a β_1-agonist.

Testosterone Manufactured as testosterone propionate.

Trenbolone A steroid supplied as trenbolone acetate. It is used to increase muscle growth and appetite.

Zilpaterol Zilpaterol hydrochloride primarily is a β_2-adrenergic agonist.

General Effects of Metabolic Modifiers

Steroid Hormones in Animal Production

Steroid implants are used in nearly all beef cattle in North America and are commonly used in most intensive production systems worldwide. In general, implants increase feed consumption and skeletal muscle protein deposition, resulting in improved performance, increased production efficiency, and greater lean mass. Steroids have minimal effects on total carcass fat content but may have some depot-specific effects on fat deposition. Bone density and thickness may be increased by steroid implants and long-bone length can be increased or decreased, depending on the dosage of the steroid and the sex and maturity of the animal at exposure.

Several compounds have been approved for use as implants and different dosages are available for each of the compounds. Efficacy can range from modest growth enhancement, with minimal effects on quality grade, to large increases in growth and efficiency, often with reductions in quality grade (Figure 1). Typical use of implants will increase weight gain by 18–25%, improve efficiency of feed utilization by 12–18%, and increase carcass weight by 9–35 kg, depending on the length of the feeding period.

Steroid hormones are not used in food production in the European Union (EU), and importation of meat from animals that have received the products is banned in EU countries.

Classification of compounds

Steroid compounds used in food animal production include androgens, estrogens and progestins. Commonly used compounds can be classified as naturally occurring or synthetic as described below.

- Estrogens
  Naturally occurring: estradiol
  Synthetic: zeranol
- Androgens
  Naturally occurring: testosterone
  Synthetic: trenbolone
- Progestins
  Naturally occurring: progesterone
  Synthetic: melengestrol acetate (MGA)

Estradiol may be presented as E_2 or as estradiol benzoate, which is approximately 71% estradiol by weight. Trenbolone (TBOH) is manufactured as trenbolone acetate (TBA), which is approximately 80% TBOH by weight. Testosterone is manufactured as testosterone propionate.

Estradiol is more anabolic than zeranol, meaning that a dose of estradiol will stimulate growth more than the same quantity of zeranol. Because of this, zeranol-containing products contain more active compound (by weight) than estradiol-containing products, yet have less anabolic activity. Estradiol is also more estrogenic than zeranol. TBOH is much

Mechanisms by which metabolic modifiers alter growth rate and carcass composition of meat animals. Proceedings of the 53rd Annual Reciprocal Meat Conference, pp. 31–35. Savoy, IL: American Meat Science Association.

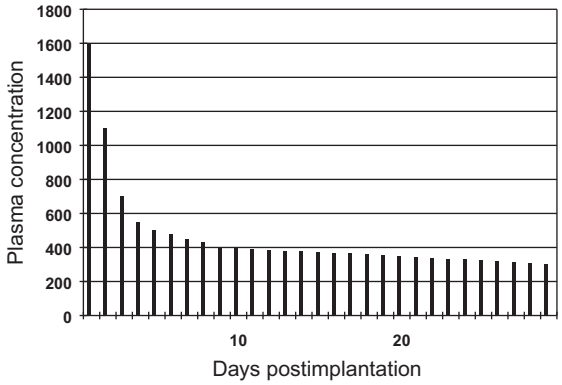

Figure 2 Idealized steroid concentration following implantation.

more anabolic than testosterone and only slightly more androgenic. Some products for heifers contain testosterone, but it is impractical to produce a steer product with enough testosterone to be economically favorable for the producer, so TBA is the more significant androgen in animal production. A significant difference between TBOH and testosterone is that TBOH cannot be aromatized (converted to estradiol).

Delivery to target cell types

Most steroids are administered as subcutaneous implants, placed in the middle third of the ear. Implant products are either compressed pellets, with a high concentration of compound and a small portion of inert ingredients such as lactose or cholesterol, or silastic rods impregnated with estradiol. Estrogenic implants range in dosage from 10 to 72 mg, TBA-containing products range from 40 to 200 mg. Many products contain both an androgen and an estrogen. MGA, an orally active steroid, is sold as a feed additive but is not sold in implant form. MGA dosage ranges from 0.25 to 0.50 mg per head per day.

Dissolution from compressed pellet implants is a first-order function, with payout (release of compound from the implant) diminishing as the physical size of the implant decreases. These products dissolve completely over time, typically in the range of 100–150 days. Use of coating materials to delay release of drug from a portion of the pellets in a dose and thereby extend the effective life of the implant is a recent innovation.

Payout from silastic products approaches zero order with products designed to payout for approximately 100, 200, or 400 days, depending on the product chosen. The silastic does not dissolve and remains in the ear indefinitely. After implantation, the product enters local circulation around the implant site. Organic components, such as the benzoic acid in estradiol benzoate are cleaved as soon as the product enters the bloodstream. The insoluble steroid binds reversibly to specific carrier proteins (steroid-binding globulins) for delivery to target cell types.

Plasma concentrations of exogenous steroid will look like the idealized data in Figure 2. There is a biphasic release of compound from the product that results in high blood levels for 24–48 h postimplantation, followed by a slow decline in concentration over the remaining life of the implant, usually 50–150 days. The initial high concentration of compound in the blood may be due to several factors: the physical insult of implanting causes increased blood flow to the implant site; the product may have some adherent compound that dissolves rapidly; and the animal likely has limited ability to clear the compound from the bloodstream at first exposure. Following this initial period, the compound is absorbed according to the physical characteristics of the implant and the blood volume and other characteristics of the animal. Circulating hormone levels will decrease over time as the implant is depleted. This reduction in circulating hormones accompanies a reduction in growth stimulus, suggesting a threshold level of circulating steroid required to maintain maximal performance.

If TBA is implanted in combination with E_2, the circulating E_2 levels can be maintained for approximately 100 days; however, implantation with E_2 alone resulted in baseline E_2 levels after 60 days postimplantation. Once E_2 enters the circulation it is cleared rapidly. E_2 has a rather short half-life in circulation. Infused E_2 has a half-life of approximately 8–42 min. High circulating E_2 following implantation is most likely the result of a transient high release rate from the implant rather than a slow clearance rate from plasma. However, the animal can adapt to high levels of E_2 exposure. Increasing the dose of E_2 had no significant effect on circulating E_2 in heifers implanted with either one or two E_2 implants, indicating that clearance rate had been altered.

The pattern of circulating TBOH is similar to that of E_2. Administration of a single TBA implant (300 mg) resulted in elevated plasma TBOH (over 900 pg ml^{-1}) in heifers the day following implantation. The circulating levels then gradually decreased to 400 pg ml^{-1} on day 90 postimplantation. In bulls, circulating TBOH concentrations increased to approximately 1000 pg ml^{-1}, were sustained at that level until week 8, and then began to decline until week 11 when the bulls were reimplanted and the circulating TBOH rose again.

Circulating TBOH concentrations are affected by the presence of other steroids. Circulating TBOH levels in

TBA + E_2-implanted steers were twice as high as those in steers implanted with TBA alone. Additionally, serum TBOH levels have been shown to be higher, especially the first few days after implantation, in implanted heifers fed MGA compared to implanted heifers not fed MGA. Apparent differences in circulating TBOH levels in the presence of other steroids may be due to E_2 or MGA competition with hepatic TBOH metabolism. Furthermore, it has been suggested the half-life of one steroid is often influenced by simultaneous administration of another steroid. Finally, synergism between TBOH and E_2 most likely is more important than individual serum hormone concentrations.

Circulating hormone concentrations are not valid for assessment of duration of implant product payout and such values are often misinterpreted. The circulating level is a function of the difference between two rates – the rate at which compound enters the animal's bloodstream, and the rate at which it is cleared by the liver or kidneys – rather than simply of the payout from the implant. The minimum effective concentration is not known for all animal types and production situations, so assessing the concentration in the blood does not provide sufficient information to assess the function of the implant. Performance is not highly correlated with circulating steroid concentration. The correlation between weight gain and serum TBOH concentration has been reported to be no greater than +0.29. Other studies have reported little to no relationship between circulating steroid hormone levels and rate and efficiency of gain in animals treated with steroid hormones. In growing bulls, circulating steroid concentration had little correlation with growth rate.

Receptors for estrogens, androgens, and progestogens are located in most cell types, but in vastly different proportions. The concentration and binding affinity of these receptors affect the ability of the steroid to elicit a response in that cell type.

Genomic steroid actions

Steroid hormone receptor proteins act as transcription factors. These receptors recognize specific *cis*-acting deoxyribonucleic acid (DNA) sequences, referred to as hormone response elements (HREs), on target genes. The HREs are located on the 5′ promoter region of hormone-responsive genes. A general schematic of classical genomic steroid action is as follows:

1. Steroid hormones, which are lipophilic, gain entry into a target cell by simple diffusion.
2. Receptors are often associated with other cytosolic proteins such as chaperone and heat-shock proteins that help to stabilize the receptor.
3. Once the steroid binds to the receptor, these heat-shock proteins dissociate.
4. The above transformation results in increased affinity of the receptor for the HRE.
5. Some receptors are found in the cytosol and translocate to the nucleus after ligand binding (glucocorticoid and mineralocorticoid receptors), whereas others (estrogen, androgen, and progesterone receptors) are located in the nuclear region.
6. Following ligand binding, the ligand–receptor complex binds to palindromic DNA sequences in the promoter regions of hormone-responsive genes.
7. Binding of the ligand-activated receptor to HRE on hormone-responsive genes either initiates or upregulates transcription or can cause a downregulation of transcription.

Nongenomic steroid actions

The above sequence is often referred to as genomic steroid action because gene transcription must be upregulated or downregulated as a result of hormone action. This process can take many hours after initial exposure to the steroid.

Recently, nongenomic mechanisms of steroid hormones have been investigated. A nongenomic steroid action is a rapid intracellular response caused by steroids that is inconsistent with the classic genomic model. These changes can occur within seconds to minutes following steroid administration and are insensitive to transcription and translation inhibitors, suggesting that this signaling pathway may involve a classical second-messenger cascade such as phospholipase C, cAMP/cGMP changes, protein kinase C, etc. Nongenomic effects may be mediated by a receptor type other than the classic steroid hormone receptor since anti-steroid molecules – such as RU 486, a potent anti-glucocorticoid and anti-progesterone – do not block these nongenomic effects.

Steroid excretion

When implants are administered in the approved location (subcutaneous; middle third of ear), the risk of detectable residue levels that could be harmful to human health is negligible. Circulating steroid levels in implanted ruminants are influenced by the release rate of the steroid from the implant and the metabolic clearance rate of the steroid in the animal's body. Metabolism of both estrogens and androgens occurs in the liver through a series of hydroxylation and reduction steps. The liver is also the site of steroid conjugation. Once conjugated, the metabolites are water-soluble and can be excreted through the kidneys and eliminated from the body in the urine. In ruminants, it appears that a significant (45%) amount of steroids, specifically diethylstilbestrol, can be eliminated through the feces.

Once released from the implant, steroid hormones have a short half-life in the circulation. After administration of an intravenous bolus of E_2 to steers, the estimated half-lives were 1 min and 20 min in the fast and slow clearance pools, respectively. These data suggest that steroids, specifically E_2, are metabolized very rapidly once released from the implant.

Effects of steroids in food-producing animals

Steroid implants influence growth through two general mechanisms: effects on feed consumption, and effects on tissue growth not specifically related to nutrient intake. In growing cattle, estrogenic implants increase feed consumption by 6–8%. Stimulation of feed consumption is dose-dependent, continues for the effective life of the implant, and has been observed within 24 h of implantation. The increased caloric intake accounts for approximately one-half of the increased growth when estrogenic implants are used.

TBA dose titration studies indicate that TBA causes a 1–2% decrease in feed consumption in feedlot cattle. When estrogens and TBA are used in combination, feed consumption is increased. Pasture studies have not been designed to test the

effects of implants on consumption of forage or carrying capacity of pastures.

Effects of steroids on skeletal muscle

Muscle tissue contains both androgen and estrogen receptors, but the concentration of these receptors in muscle is often 1000 times less than in reproductive tissues. However, the relative binding affinities for the androgen receptor in skeletal muscle and prostate are identical. Androgen receptors in muscle tissue have been characterized in several species including rat, porcine, bovine, ovine, and human. Similarly, estrogen receptors in muscle tissue have also been characterized in rat and bovine.

The level of circulating steroid has been reported to be an important determinant in the amount of unoccupied steroid receptors. In sheep, implantation with TBA appeared to reduce the number of detectable androgen receptors as compared to those in nonimplanted lambs. TBA implantation decreased the binding affinity of cytosolic androgen receptors. Implantation of calves with TBA + E_2 reduced the number of free estrogen receptors approximately 83% as compared to nonimplanted calves. Upregulation or downregulation of steroid receptors may occur via gene transcription. Androgen withdrawal, via castration, for 4 days resulted in 1.5-fold to 3-fold increase in androgen receptor mRNA in the rat prostate. Testosterone propionate injections in castrated rats 24 h before tissue removal reduced androgen receptor mRNA to the level of intact males.

Steroids have both direct and indirect effects on muscle growth. In the case of estrogens, the direct effects are thought to be secondary to indirect effects mediated by changes in other hormone profiles. The primary effect of estrogens is through an altered somatotrophic axis. estrogens increase pituitary size and increase the proportion of somatotrophs in the pituitary. The pituitary is also more responsive to somatotropin releasing factor (SRF). Production of insulin-like growth factor-1 (IGF-1) is increased and both somatotropin (ST) and IGF-1 binding characteristics are altered. These changes work together to produce higher circulating ST, a more efficacious release pattern, and a more responsive muscle, resulting in stimulus of muscle growth.

Increased ST does not explain all of the effects of estradiol. Exogenous ST has been shown to increase growth of estradiol-implanted cattle, and estradiol and SRF are additive in affecting circulating metabolites and growth factors. Effects of estradiol and ST are nearly additive when energy consumption is restricted to the level of cattle without estradiol implants. Other hormones such as insulin and thyroid hormones are also altered, supporting the increased muscle growth.

The direct effects of androgens are significant. TBOH works directly on the muscle cell to stimulate muscle protein synthesis and deposition. The specific gene products that respond to TBOH have not been fully characterized.

Androgens have significant indirect effects as well, primarily through altered glucocorticoids. Circulating cortisol is reduced in TBA-implanted steers, and both cortisol binding and response to adrenocorticotrophic hormone (ACTH) are also diminished. Androgens also produce an altered ST profile (higher, more frequent peaks and lower troughs). These changes make the circulating hormone profile of TBA-implanted steers more like that of bulls, and result in increased muscle deposition.

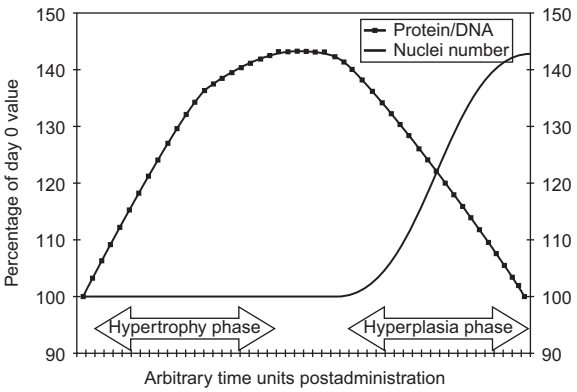

Figure 3 Idealized effects of TBA + E implantation on hypertrophy and hyperplasia of skeletal muscle.

The effects listed above can be observed within days after implantation. Early muscle growth stimulus is primarily hypertrophic in nature, which has been shown by depressed DNA–protein ratios (Figure 3). Prolonged exposure (weeks) to combined estrogenic–androgenic implants produces hyperplasia (increase in satellite cell nuclei) as well. In this case, the quantity of muscle protein is increased but normal DNA–protein ratios are observed, indicating that proliferation of satellite cells results in increased quantity of DNA in the muscle. Cell culture studies have shown that the mitogenic activity of sera from implanted steers is increased, providing support for the idea that implants initially increase hypertrophy and ultimately increase hyperplasia to support increased muscle mass.

Combined TBA + E_2 implants increase carcass protein by approximately 10% compared to nonimplanted steers. Much of this increase occurs for the first 40 days postimplantation (Figure 4). Increases in circulating and locally produced IGF-1 have been reported during this period of rapid muscle growth in TBA + E_2-implanted steers. Because IGF-1 is known to be a potent stimulator of both proliferation and differentiation of satellite cells, locally produced IGF-1 could act through autocrine or paracrine mechanisms to promote the proliferation and differentiation of muscle satellite cells, thus enhancing skeletal muscle hypertrophy. In fact, satellite cells isolated from the semimembranosus muscle of TBA + E_2-implanted steers after 35 days of steroid exposure exhibited a shorter lag phase and began proliferating sooner when placed in culture than cells from nonimplanted steers. TBA + E_2 either directly or indirectly activates quiescent satellite cells *in vivo* or maintains them in a proliferative state, supporting muscle hypertrophy.

Effects of steroids on adipose tissue

Steroid hormones are not thought to have significant direct effects on adipose tissue. Estrogen receptors are present in low concentrations and the presence of androgen receptors in adipose tissue has not been demonstrated. Indirect effects are due in part to altered ST, and increased energy consumption, which would enhance fat deposition. The net effect is that fat

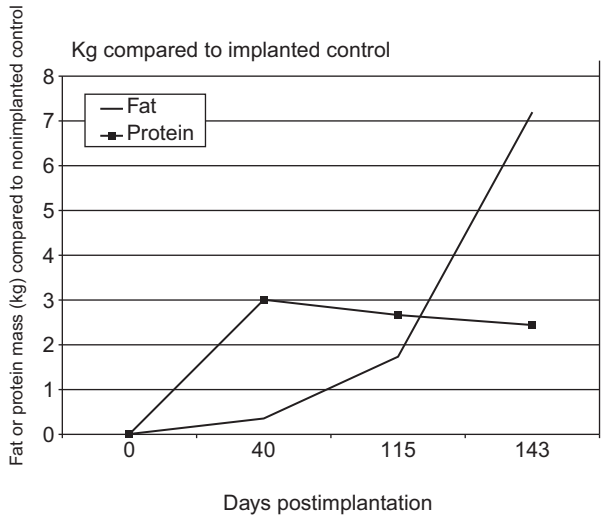

Figure 4 Changes in carcass protein and fat accumulation over time between carcasses obtained from implanted steers (120 mg TBA and 24 mg E_2), compared to carcasses from nonimplanted steers. Adapted with permission from Johnson, B.J., Anderson, P.T., Meiske, J.C., Dayton, W.R., 1996. Effect of a combined trenbolone acetate and estradiol implant on feedlot performance, carcass characteristics, and carcass composition of feedlot steers. Journal of Animal Sciences 74 (2), 363–371.

deposition rate in food-producing animals is not greatly altered by exogenous steroids. Carcasses from treated cattle may be leaner, but this is due to increased quantity (and concentration) of muscle, not to decreased quantity of fat.

There may be some fat depot specificity because many studies have shown reduced intramuscular fat (marbling) in implanted cattle, especially males. This could be a true effect of the steroids but it could also be an artifact. Most studies have harvested implanted and nonimplanted cattle at similar time end points. In these studies, chemical composition usually differs between treatments, with carcasses from implanted animals leaner, so marbling would be expected to differ as well. Investigators who chose end points other than time have typically observed less marbling reduction.

Effects of steroids on bone growth

Sex steroids are vitally involved in control of skeletal growth. Adult levels of sex steroids are required for a pubertal growth spurt (velocity) to occur in both males and females. Prolonged exposure to these adult steroid levels results in closure of the epiphyseal growth plate (cessation). Thus, steroids can be positive (velocity) or negative (cessation) in bone growth. As a practical matter in animal agriculture, the effects of implants on bone growth are modest. Limited work has shown that long-bone growth of females can be increased by exogenous estradiol, either preweaning or postweaning. Theoretically, excess steroid levels could limit bone growth by hastening growth plate closure, but there is no research to prove that this has occurred and steroid levels required are likely greater than those used in production agriculture. Exogenous steroids appear to have little effect on bone growth of steers.

Melengestrol acetate

MGA suppresses estrus in cycling females and the resulting behavioral change is favorable for animal performance. In addition, MGA induces a hyper-estrogenic state in the static ovary, which in some ways mimics the use of an estrogenic implant. Some studies have shown estrogenic implants and MGA to have additive effects, but others have not. Differences in these results may be based on dosage or animal characteristics such as maturity or genetic potential for growth. MGA effects are additive with those of TBA, and MGA appears to ameliorate negative effects of TBA on marbling in some production situations.

Practical considerations of steroid use

Because dosage and duration of implant products are not ideal for some production situations, cattle may be implanted more than once during the feeding period. Use of these reimplant programs typically improves performance compared to use of a single implant, but may further reduce quality grade (Figure 1). Implants may increase sexual or aggressive behavior of confined cattle. To properly design implant programs, dosage, duration, and desired outcome of the production situation must be considered. MGA may also be situation-specific, because a mature ovary is the primary target tissue, so immature or spayed heifers may not respond.

Because implants are administered in a nonsterile surgical procedure conducted under field conditions, abscessation of the implant site is common. Even skilled personnel using excellent technique and sanitation will observe abscesses in 3–5% of implant sites. Under poor conditions, rate of abscessation can be much higher. Data from quality assurance surveys conducted by implant manufacturers indicate that approximately 1% of implants are expelled owing to pressure from the abscess resulting in substantial missed economic opportunity. Proper technique and sanitation can minimize these problems, but there is a risk of infection after implantation regardless of sanitation. Implant products are available with a pellet of tylosin tartrate added as a local antibacterial to minimize implant site infections. Owing to improved health of the implant site, inclusion of the tylosin pellet results in increased weight gain compared to implants without tylosin, even with excellent sanitary technique and a low rate of abscessation.

Beta-Adrenergic Agonists in Animal Production

Beta-adrenergic agonists (BAA) are phenethanolamine compounds approved for use in food animal production in several countries. In the United States, ractopamine is used in both swine and cattle production to improve growth rate and efficiency of lean-tissue deposition. Zilpaterol was approved for use in cattle production in the United States in 2007 after extensive study and both ractopamine and zilpaterol had significant market uptake. Sale of zilpaterol in the United States was suspended in 2013 because of reports by beef processors of hoof problems of cattle in holding pens. The FDA has determined that zilpaterol use is safe for cattle and consumers and zilpaterol remains available in other countries. Other BAA, such as clenbuterol and cimaterol, have been widely used as

research compounds but are not approved for use in food animals.

BAA are orally active and are presented as feed additives, in contrast to steroid hormones, which have minimal oral activity (except MGA). BAAs are dosed in ppm, mg per head per day, or $g\,t^{-1}$. Typically, BAAs are administered only to animals consuming a high-energy (finishing phase) diet at the end of the finishing period during the final 3–6 weeks of production. Zilpaterol is typically withdrawn for three or more days prior to slaughter, whereas ractopamine requires no withdrawal. Typical effects of BAAs in food-producing animals are shown in Table 1.

BAA can be generally classified as β_1 or β_2, on the basis of their receptor affinity. Ractopamine is a selective β_1-agonist, while zilpaterol and other widely studied compounds are β_2-agonists. BAA are used to improve live performance and carcass leanness of cattle, sheep, swine, or poultry. There are species differences in responses to the various compounds (Table 1) and both dosage and duration of treatment affect response. In ruminants, feeding β_2-agonists for 20 days can produce effects on live weight gain and feed conversion efficiency that are as great as the effects produced by 150–200 days of steroid implant exposure, with greater increases in carcass leanness. Both β_1- and β_2-agonists affect carcass leanness and muscularity in cattle but β_2-agonists are more efficacious.

Mechanism of Beta-Adrenergic Agonists Action

Use of BAA increase carcass leanness by increasing the quantity of muscle mass and by decreasing the quantity of fat. These compounds are often called partitioning agents because they appear to divert dietary energy from fat deposition toward muscle deposition. In nonruminants, use of BAA results in mobilization of energy already stored as fat for use in muscle growth and in cattle, zilpaterol does the same. In this case, they may be called repartitioning agents. BAA can dramatically increase protein deposition and cause net fat deposition to cease or become negative, even in rapidly growing cattle consuming high-energy diets. There are indications that zilpaterol use in cattle can mobilize nutrients from non-carcass tissues for deposition in the carcass. This partially explains why zilpaterol use results in greater carcass weight gain than live weight gain and a much larger increase in the proportion of live weight that is carcass than ractopamine. Effects of BAA are realized in administration periods as brief as 20 days.

BAA directly affect both adipose and skeletal muscle tissue. BAA actions are mediated by a class of membrane-spanning receptors called beta-adrenergic receptors (β-AR), of which three subtypes exist: β_1-AR, β_2-AR, and β_3-AR. A fourth type, β_4-AR has been proposed but not confirmed and may be an artifact. These receptors function by binding to G_s proteins. Following coupling to G_s proteins, adenyl cyclase is activated, which converts ATP to cAMP. Cyclic AMP in turn regulates activity of protein kinase A. In skeletal muscle, β_2-agonists increase muscle mass by increasing protein synthesis and decreasing protein degradation, whereas β_1-agonists increase synthesis but do not affect degradation, except when very high doses are fed (Table 2). The β_1-agonist ractopamine has been shown to increase the abundance of skeletal muscle-specific mRNAs in experiments both *in vivo* and *in vitro*. Administration of β_2-agonists increases muscle mass by 8–40% with later maturing muscles affected the most. Longissmus muscle cross-sectional area is increased by 11–39%. Increased muscle fiber cross-sectional area accounts for these differences, with the greatest increase in Type II fibers and some studies indicating that the proportion of Type II fibers may be increased as well.

These changes in muscle hypertrophy occur with no apparent change in DNA content of muscle, implying that muscle satellite cells are not activated to fuse into the existing fibers to support this rapid increase in muscle hypertrophy. The lack of DNA accretion in existing muscle fibers limits the ability to sustain muscle hypertrophy, long term. Administration of β_1- or β_2-agonists reduces circulating and local IGF-1 as well as IGF-1 mRNA in skeletal muscle, which could explain the lack of effect on DNA, as IGF-1 is a stimulator of satellite cell proliferation. BAA-induced stimulation of muscle hypertrophy could be enhanced if BAA dampening of IGF-1 could be impeded.

In adipose tissue, activation of the β-AR and the subsequent intracellular signaling cascades result in activation of hormone-sensitive lipase, which facilitates lipolysis. Furthermore, receptor activation has inhibitory effects on enzymes responsible for *de novo* synthesis of fatty acids and triglycerides. Specifically, several key steps in the conversion of glucose to triglycerides are inhibited by the activation of β-AR. The net

result is that this energy substrate is then available for deposition in other tissue such as skeletal muscle, a result which could be called repartitioning.

Practical Considerations for Beta-Adrenergic Agonists Use

β-AR are found in all cell types studied but their proportion varies widely so it is the relative and absolute proportion that determines effects on specific tissues, rather than simply presence or absence. For example, bovine skeletal muscle contains β_2-AR in much higher concentration than β_1-AR, typically 10X or more. This is one reason that β_2-agonists are more efficacious in the bovine. Comparative effects of β_1- and β_2-agonists are shown in Table 2.

The intracellular mechanisms that control protein turnover *in vivo* are in some ways similar to postmortem changes which improve beef tenderness. Use of β_2-agonists, such as zilpaterol reduce tenderness in some situations, likely because the reduction in turnover that increases skeletal muscle growth alters postmortem changes as well. For example, administration of an experimental β_2-agonist, L-644,969, increased calpastatin in skeletal muscle. Calpastatin is an specific inhibitor of calpains and thus reduces tenderness by diminishing postmortem protein degradation. At high doses, the β_1-agonist ractopamine binds to β_2-AR as well. This cross-reactivity could mimic the effects of administration of a β_2-agonist, explaining both increased efficacy of ractopamine at higher doses and negative effects on tenderness that have been noted at these doses.

Effects of BAA appear to be related to animal maturity, with younger animals less responsive. For example, fetal bovine skeletal muscle cells have minimal β-AR present, although they do have β_2-AR mRNA. Comparative growth effects in young versus old rats and calves versus yearling cattle, indicate greater production responses in the older animals. In yearling cattle, as days on feed increase, β_1-AR mRNA decreases in skeletal muscle, whereas β_2-AR mRNA increases. This progression was not noted in younger calf-fed cattle.

It appears that β-AR in growing animals can become slightly refractory to prolonged (days) exposure to BAA. This should not be surprising, given the close structural similarity of BAA to epinephrine, which produces rapid effects but is cleared from circulation quickly as well. A practical means to supply growing animals with ever-increasing doses of BAA through the administration period could enhance productivity.

Comparative Efficacy of Steroids and Beta-Adrenergic Agonists

Since there are no restrictions on use of steroid implants and BAA in the same animals, questions will arise about the absolute and comparative efficacy of these two classes of growth promotants used concomitantly. In theory, steroid implants and BAA should be additive in stimulating lean-tissue growth in beef cattle due to their distinct mechanisms of action. Limited research has confirmed this with each class of compounds eliciting a typical response in the presence or absence of the other.

Earlier research evaluating the effects of bovine somatotropin (bST) and steroids revealed additive effects of these two growth promotants on weight gain and protein deposition in beef cattle. The conclusion that each had distinct mechanisms of action in stimulating growth was surprising, because E_2 use increases circulating ST levels. In fact, research suggests that E_2 and bST were not additive in the effects on circulating ST. Taken together, these data suggested that the growth-promoting effects of estrogens were not fully mediated by the increase in ST secretion.

Steroid implants stimulate skeletal muscle growth through increases in muscle hypertrophy as well as through activation of muscle satellite cells to provide the critical DNA to sustain muscle hypertrophy. It appears that locally produced IGF-1 can mediate many of these effects. Since BAA do not increase the DNA content of skeletal muscle, administration of a steroid implant 60–90 days prior to feeding BAA should have additive effects on lean-tissue deposition in beef cattle because of the different mechanisms of action. However, some research has shown that clenbuterol (a β_2-agonist) increased local expression of IGF-1 in skeletal muscle of rats. If the effects are the same in beef cattle, there might be some overlap in potential mechanism of action in which the two classes of compounds would not be completely additive.

Effects of Growth Promotants on Palatability

The effects of steroid implants on the palatability of the end product have been studied, but results are not conclusive. In most studies, implants did not significantly affect tenderness, juiciness, or flavor. Negative effects on tenderness were observed in some studies in which higher dose implant products were used. Labels on some higher dose implants state that if tenderness is of primary importance that they should not be used late in the finishing period. These negative effects can be as great as 0.6–0.8 kg increase in shear force. Interactions exist between steroid dosage and animal type. For example, negative effects on tenderness are more likely to be observed when multiple doses of androgens are administered, especially in more muscular breeds of cattle. In most other production situations, the effects of implants on tenderness are either nonsignificant or not of practical importance.

The effects of BAA on tenderness depend on the compound studied. Ractopamine has not affected tenderness of beef unless fed at the highest dose studied (300+ mg per day) for at least 28 days. In contrast, zilpaterol, which is more efficacious, typically does increase toughness when electrical stimulation and adequate aging (at least 21 days) are not used.

In an extensive study involving five universities and Merck Animal Health, involving both beef cattle and Holstein cattle that were fed zilpaterol for 20 days as part of a typical finishing diet, tenderness of several muscles was reduced unless a minimum of 21 days of wet aging was used. Feeding zilpaterol for more than 20 days resulted in toughening of all muscles, particularly the *gluteus medius* muscle from heifers, even with 21 days of aging. In 2013, some beef processing plants observed hoof damage of zilpaterol-fed cattle while those cattle were in holding pens prior to harvest. While FDA reiterated the

safety of the product, Merck Animal Health suspended marketing of the product until further studies are conducted.

Summary

Metabolic modifiers, including steroid hormones and BAA, increase production and improve efficiency of food-producing animals. This results in economic benefit to livestock producers and influences the relative price competitiveness of protein sources for consumers, favorably influencing market share for those species in which they are used. Consumers benefit from reduced costs and, in some cases, improved nutrient content of the meat. Additionally, fewer resources are required for production of meat and environmental impact is lessened. Most consumers accept product from animals produced with prudent use of metabolic modifiers. The variety of compounds and dosage choices available to producers allows for specific 'targeted outcome' programs to fit the production and marketing objectives of individual operations. The next decade of research will likely focus on production aspects of concurrent use of steroids with BAAs and the influence of these products on consumer acceptance of meat.

Glossary

Fasciculus Bundle of myofibers.
Hyperplasia An increase in number of cells.
Hypertrophy An increase in size of cells.
Intrafascicularly terminating myofibers End in fasciculus, do not reach both ends of muscle.
Mesoderm The embryonic layer from which muscle is derived.
Myoblast Single cell-forming muscle.
Myofiber Muscle fiber.
Myotube The immature myofiber formed from fused myoblasts.
Secondary fiber An alternate form of immature myofiber.
Somite A block of mesoderm.

Introduction

Principles of muscle growth in meat animals help us understand how meat yield and quality are interrelated. Meat is derived from muscles that once pulled on parts of the skeleton for body movements in locomotion, respiration, and chewing. Myofibers make up skeletal muscles, and often are many centimeters in length but only a small fraction of a millimeter in diameter. Each myofiber is a single cell with many nuclei.

Regulation of myofiber numbers is largely genetic and prenatal, provided the fetus is well nourished. Later, animal nutrition and exercise have a strong effect on the longitudinal and radial growth of myofibers, adding to their length and thickness. Myofibers adapted for repetitive activity tend to have aerobic metabolism, needing abundant oxygen from the blood stream, and are supported by large numbers of mitochondria and lipid droplets. Mitochondria release energy whereas lipid droplets store energy. Lipid droplets enhance the taste and juiciness of meat. Other types of myofibers are specialized for strong, rapid contraction but are easily fatigued. These myofibers tend to be anaerobic, using stored carbohydrates (glycogen) if blood vessels cannot supply enough oxygen. Anaerobic myofibers bulging with contractile myofibrils are particularly important in rapid muscle growth.

Rapid muscle growth and profitable meat production are often achieved by rapid growth of anaerobic myofibers, but these are not the ones with the best tenderness, juiciness, and taste. Conversely, traditional breeds may produce high-quality meat but only slowly and uneconomically. Thus, how commercial pressures to increase meat yield may detract from meat quality is seen.

A few pointers might be useful for readers unfamiliar with histological terminology. The prefixes myo- and sarco- both indicate muscle. Myo- tends to be an optional prefix used if there is a risk of confusing myofibers (i.e., muscle fibers) with some other types of fibers, such as connective tissue fibers. The suffix -blast indicates a cell that forms something. Thus, a myoblast makes myofibers, wheras a fibroblast makes connective tissue fibers. But the mechanisms involved differ radically. Myofibers are very large cells made by the fusion of small cells (myoblasts). Connective tissue fibers are cables of protein assembled outside cells (fibroblast) exuding the formative materials.

The suffix 'mere' indicates a part. Thus, a sarcomere is a small contractile unit along the length of a muscle. Chains of sarcomeres form myofibrils within myofibers. Note the diminutive ending indicating a fibril is much smaller than a myofiber. The sarcomeres along the hundreds of myofibrils inside a myofiber are neatly in line with each other. The alternating dark (myosin) and light (actin) portions of sarcomeres result in whole myofiber appearing to be transversely striated.

To complete this hierarchy of somewhat confusing terms, they are listed from largest to smallest: (1) myofasciculus – visible by eye, a bundle of myofibers; (2) myofiber – visible with a microscope, a very large cell; (3) myofibril – a contractile organelle composed of chains of sarcomeres, and located inside a myofiber; and (4) myofilament – a protein filament, part of a sarcomere. The prefix 'myo' can be dropped from any of the above terms if not needed.

Allometry

Differences in growth rate (allometry) occur among various muscles. Along the vertebral axis, a wave of growth proceeds from head to tail, starting prenatally. In the limbs, growth waves proceed from the distal extremities proximally toward the trunk of the body. Vertebral and hindlimb growth waves, having passed along the loin and up the hindlimb, eventually combine in the rump (pelvic region). Thus, the most valuable cuts of beef, pork, and lamb tend to develop late.

Muscle allometry is measured using Huxley's equation, $y = bx^k$, where k is the allometric growth ratio, the slope of a log:log plot. The log of a muscle's weight is plotted against the log of body weight. If $k > 1$, the muscle is growing faster than the remainder of the body, and vice versa. If $k = 1$, individual muscle yield remains constant as the body grows. Sometimes the log:log plot may give a curve rather than a straight monophasic line, thus showing k is changing. In these cases, the curve might be divided at a suitable point and treated as a biphasic system.

It is important to match the units of measurement on both axes, weight with weight, or length with length. When comparing results from different studies, the term on the x-axis must be the same to make a valid comparison. The allometric

 doi:10.1016/B978-0-12-384731-7.00011-8

equation can be used to analyze carcass conformation without knowing animal age. Allometric analysis can reveal subtle but important changes in muscle and body growth, such as the late growth of throat muscles to counterbalance the elastic ligament suspending the bovine head, or the late growth of abdominal muscles to cope with the bulging rumen.

Myogenesis in Embryonic Development

Mesoderm

Mesoderm is the middle of the three layers forming an embryo. Most of the meat on commercial carcasses originates from somites. Somites are blocks of mesodermal cells along left and right sides of the developing spinal cord. Adipose and connective tissues also originate from mesoderm. The two other embryonic layers are ectoderm (giving epidermis and nervous system) and endoderm (giving digestive glands and gut). Muscles developing from blocks of somitic mesoderm can be invaded by connective tissues from elsewhere in the embryo (from somatic mesoderm – in sheets, not blocks). Invading connective tissues provide vital guidance in establishing the arrangement of myofibers.

Myoblasts and Myotubes

Myofibers have a far greater volume than other body cells because of their great length. A single nucleus cannot service such a large volume of cytoplasm, so myofibers have many nuclei (i.e., they are multinucleated). Theodore Schwann, who in 1839 first proposed that animal bodies are composed of countless cells, also discovered how the multinucleated state of myofibers originates. Multinucleated myofibers are formed by the fusion of mononucleated myoblast cells, often via an intermediate stage – the myotube. A myotube has an axial core of sarcoplasm (muscle cytoplasm) surrounded by a tubular arrangement of myofibrils (contractile organelles). The first myofibers pass through a myotube stage, whereas myofibers formed later in prenatal development directly acquire a central axis of myofibrils and peripheral nuclei (as in most mature myofibers). Myofibers passing through a myotube stage may be called primary myotubes or myofibers, to distinguish them from secondary myofibers missing the myotube stage.

New nuclei are formed by mitosis. New deoxyribonucleic acid (DNA) copies existing DNA, followed by separation of two daughter nuclei. Completion of mitotic activity in mesodermal stem cells and commitment to myogenesis are controlled by the MyoD family of gene-regulating proteins (MyoD, Myogenin, myf5, and MRF4). Before commitment to become myoblasts, dividing mesodermal cells later to form muscle may be called premyoblasts (Figure 1(a)). Only after commitment can they be called myoblasts. This helps us remember that only the cells leading up to the myoblast are capable of mitosis. Myoblasts are not capable of mitosis.

The brand new myoblasts, having given up mitosis and turned to the synthesis of ribonucleic acid (RNA) instead of DNA, now exhibit many of their new proteins. They develop two long cytoplasmic extensions (Figure 1(b)). Their cytoplasm with high levels of RNA is basophilic (readily stained with basic dyes). Myoblasts explore their environment using the tips of their cytoplasmic extensions. If they contact suitable partners, myoblasts fuse together to form a multinucleated cell (Figure 1(c)). Fusion is mediated by cyclic adenosine monophosphate and protein phosphorylation. Transverse striations develop as new myofilaments self-assemble into sarcomeres and as myofibrils grow and proliferate. Between the myofibrils are many mitochondria. Tapered or fusiform structures (Figure 1(c)) occur where myotubes grow by incorporating new myoblasts.

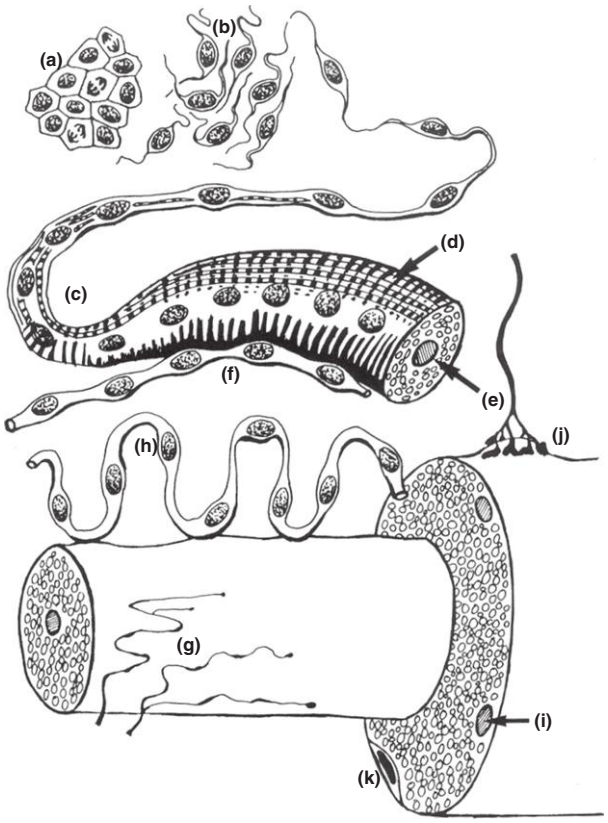

Figure 1 A composite sketch of various stages of myogenesis and muscle growth. (a) Mitotic cells, (b) myoblasts, (c) fused myoblasts forming a multinucleate future myofiber with contractile myofibrils, (d) addition of new myofibrils under the plasma membrane to form a hollow tube of myofibrils, (e) nuclei in the axis of the myotube, (f) fusion of myoblasts temporarily located on an original primary myotube to form a new secondary myofiber, (g) initial innervation of a myotube, (h) secondary myofiber thrown into snake-like folds by contraction of the myotube on which it is located, (i) true myofiber nucleus, (j) en plaque neuromuscular junction, and (k) satellite cell pressed into the surface of the myofiber but not fused with it.

Secondary Myofibers

Successive generations of myoblasts accumulate in developing muscle. The later myoblasts cling by pseudopodia pushed into the surfaces of existing myotubes. Instead of fusing with the myotube, these new myoblasts fuse with each other to form a secondary myofiber (Figure 1(f)). By this time, myotubes are innervated by axons invading from the spinal cord (Figure 1(g)). Innervation causes slow

contractions. Myotube contractions accelerate the side-by-side contact and fusion of myoblasts. Once secondary myofibers develop their own myofibrils, their uncontracted stiffness causes secondary myofibers to form snake-like folds along their supporting myotube (Figure 1(h)). Secondary myofibers then separate from the myotubes, freeing spaces on myotube surfaces for other secondary myofibers to form.

In summary: (1) myotubes function as contractile templates accelerating development of secondary myofibers, (2) myotubes establish myofiber arrangement within a muscle, and (3) myotubes are located centrally within bundles of myofibers. Only approximately 20% of myofibers originate from myotubes.

Degeneration

Cellular degeneration often occurs during myogenesis. Nuclei can be disrupted and myofibrils appear to be fragmenting rather than assembling. Perhaps this is what happens to myofibers failing to attach to connective tissue and, therefore, unable to develop tension when stimulated to contract.

Innervation

All surviving myofibers are innervated by terminal axons of motor neurons. Starting in the spinal cord, axons grow into developing muscles, partly by following connective tissues stretched by skeletal elongation, and partly by chemical attraction. Initial neuromuscular junctions are diffuse and irregular. On fast-contracting myofibers, the neuromuscular junction consolidates to a compact en plaque junction (Figure 1(j)). Junctions on slow-contracting myofibers show less consolidation, especially on poultry slow myofibers.

Prenatal muscle contraction is essential for the complete formation of secondary myofibers. Factors inhibiting prenatal muscle movements (such as plant toxins or loss of amniotic fluid) cause hypoplastic muscles (reduced myofiber numbers). Prenatal muscle movements also are essential for the shaping of articular cartilages on joint surfaces. The development of motor neurons, myofibers, and articular joints is completely integrated. A defect in one system affects the other two, often resulting in conditions such as congenital articular rigidity (arthrogryposis).

Double-Muscling – Myofiber Hyperplasia

What beef producers usually call 'double muscling' is caused by myofiber hyperplasia (an increased real number of myofibers) originating from an increased number of myotubes. Developing animals have a system to inhibit excessive muscle development controlled by a protein, myostatin (GDF8). This inhibitor itself is inhibited by another protein, follistatin. Thus, a defective gene for myostatin or high levels of follistatin will both act to increase muscle mass. Myofiber hyperplasia is widespread in the bodies of double-muscled animals. But the first three somites of the embryo, which give rise to muscles rotating the eye-ball, do not develop extra myofibers, although muscles growing into the head region later in development may become hyperplastic, such as the enlarged tongue muscle (macroglossia). This is because trunk and limb muscles differ genetically from extraocular muscles, especially in their Pax3 and Pax7 genes.

Double muscling is quite common in some beef breeds. In sheep it is rare. Myofiber hyperplasia might have occurred in the ancestral stock of broad-breasted turkeys. In cattle, double muscling is inherited as a simple Mendelian trait with incomplete dominance. Double-muscled cattle have a generalized deficiency of connective tissue, including a paucity of adipose cells. Thus, their meat is lean and relatively tender (unless cold-shortened). Obstacles to commercial exploitation of double-muscling include deleterious pleiotropic effects on male and female reproductive systems, difficult natural copulation, difficult calving, and structural problems.

Postnatal Development

Hyperplasia versus Hypertrophy

Whereas myofiber hyperplasia (increase in myofiber number) dominates prenatal development, postnatal development is dominated by myofiber hypertrophy (increase in size). Hypertrophy occurs in two dimensions – radial and longitudinal. At birth, the axial nuclei of myotubes move to a peripheral position beneath the plasma membrane (Figure 1(i)), although poultry myofibers sometimes retain axial nuclei.

Satellite Cells

Stem cells or residual premyoblasts capable of mitosis remain on the surfaces of myofibers as very small satellite cells. Endomysial connective tissue sheaths trap them below the basement membranes of myofibers (Figure 1(k)). Satellite cells have very little cytoplasm and the plasma membranes separating them from myofibers are seldom seen by light microscopy. For many years, therefore, it was difficult to explain the origin of increasing numbers of myofiber nuclei as myofibers grew in length and diameter.

When myofibers are growing or regenerating after injury, satellite cells divide by mitosis controlled by IGF-1. Typically, one daughter cell remains as a satellite cell capable of further mitosis whereas the other fuses into the myofiber to provide a new nucleus no longer capable of mitosis but switched on for producing RNA for muscle protein synthesis. Most dividing cells reveal themselves by showing chromosomes, but chromosomes cannot easily be seen when satellite cells undergo mitosis – simply because the chromosomes have no space to separate in such a small cell. Why such a complex system? Most likely to protect the sources of new nuclei in a damaged myofiber – which is a very unusual giant, multinucleated cell.

Histochemistry

The concentric arrangement of secondary myofibers around myotubes mirrors the distribution of fast-contracting, anaerobic myofibers (=white, Type II, or αW) around slow-contracting, aerobic myofibers (=red, Type I, or βR). This is

seen clearly in pork, but can require statistical testing to demonstrate in other species where myofiber arrangement changes during growth. In general, myotubes typically become slow-contracting, aerobic myofibers whereas secondary myofibers become fast-contracting, anaerobic myofibers. However, few muscles maintain the 20:80% ratio of myotubes to secondary myofibers when they become specialized for different activity patterns, and most muscles show transformations from one myofiber type to another as they grow. Thus, myofiber-type ratio is a snap-shot at a particular age and position within a muscle.

The last secondary myofibers formed prenatally are grouped around their primary myotubes, but are beneath older secondary myofibers. The last secondary myofibers typically become dual purpose myofibers capable of fast-contraction and strong aerobic activity. They may transform to become fast-contracting, anaerobic myofibers or to become slow-contracting, aerobic myofibers. The direction of the change depends on muscle activity patterns. Sometimes, myotubes start as slow-contracting, aerobic myofibers but make a major transformation to become fast-contracting, anaerobic myofibers. For example, chick breast muscle starts with many myotubes but finishes with nearly all white myofibers.

Body weight increases as a cubic function of linear body dimensions, while muscle strength increases only as a squared function (muscle cross-sectional area). Hence, postural muscles working against gravity as animals grow heavier might adapt by myofiber-type transformations from fast-contracting to slow-contracting, and (or) from anaerobic to aerobic. This adaptability of skeletal muscle has been shown in countless experiments. The type of innervation of a myofiber determines its balance of MyoD versus myogenin, its contractile properties and its predominant energy source (aerobic vs. anaerobic). When experimentally cross-reinnervated, a myofiber tends to follow the dictates of its new axon. Patterns of activity are particularly important, mediated by calcium ions acting on genes in the myofiber nucleus.

Tapered Myofibers

Myofibers are grouped into bundles (fasciculi) by perimysial connective tissue. In short fasciculi, myofibers can extend from one end of the fasciculus to the other. But in long fasciculi, many individual myofibers are much shorter than the length of the whole fasciculus and have a tapered ending anchored in connective tissue. Tapered myofibers may be called intrafascicularly terminating myofibers.

Within a myofiber, the Z-lines of adjacent myofibrils are linked laterally by a meshwork of desmin filaments and are attached to the plasma membrane by proteins such as vinculin and dystrophin. Outside the myofiber, the plasma membrane is covered by a basement membrane in which are embedded finely branched reticular fibers (Type III collagen) of the endomysium. When a tapered myofiber contracts, the tension it generates is transferred to the fibrous framework of the whole muscle. This integrates the all or nothing contraction of an individual motor unit (myofibers innervated by one motor neuron) into a smooth response by the whole muscle.

In transverse sections, tapered endings appear as small-diameter myofibers, although they can easily be missed by light microscopy. Detection of tapered myofibers is enhanced by delineating each myofiber with a silver stain. Tapered endings can confound attempts to measure the radial dimensions of myofibers in transverse sections. Furthermore, when histochemical myofiber-type ratios are determined during growth or adaptation of a muscle to a particular pattern of activity, a change in ratio has two possible explanations. First, the innervation of a myofiber might have changed its histochemistry. Alternatively, there might have been a change in the relative lengths of myofiber types, with one type growing more rapidly than another.

Several relays of tapered myofibers might extend along the length of a long fasciculus. Furthermore, several relays of fasciculi might extend along the length of a whole muscle. At no point along such a muscle will all its myofibers appear in the same plane. Thus, it is important to distinguish between the real number of myofibers in a muscle (obtained by total muscle dissection in nitric acid to loosen connective tissue) and the apparent myofiber number (obtained by sampling from muscle transverse sections).

Radial Growth of Myofibers

Skeletal myofibers are prismatic (with sides flattened by compression), but are generally treated as cylindrical in growth studies. Caution is needed when attempting to measure a mean radius or diameter from a prismatic structure, especially when it has not been sectioned perpendicularly. This is why cross sectional area is more reliable than diameter as an indicator of radial growth. Myofibers often grow >0.1 mm in mean diameter.

Within myofibers, individual myofibrils grow radially by the peripheral incorporation of new myofilaments. This lengthens the diffusion pathway along which calcium ions are released or re-sequestered by the sarcoplasmic reticulum for the control of muscle contraction. A buildup of calcium ions in the axis of myofibrils might initiate proteolysis by calpains. Continued activity can then cause myofibrils to shear longitudinally like a split log, giving an increase in the apparent number of myofibrils. Thus, the radial growth of myofibers occurs with an increase in the apparent number of myofibrils.

Radial growth of myofibers lengthens the oxygen diffusion pathway from capillaries on the myofiber surface inwards to the axis of myofibers. There is a concern this might alter myofiber metabolism when radial growth is pushed too far. Differences in myoglobin concentrations between histochemical myofiber types make this a complex problem. Mapping of a mitochondrial enzyme, succinate dehydrogenase (SDH), shows where oxygen is abundant. Strong aerobic activity in myofibers is usually peripheral, near to the capillary source of oxygen on myofiber surfaces. Fast-contracting, anaerobic myofibers exhibit the greatest radial growth. Their axes become devoid of SDH and, especially in pigs, can store massive amounts of glycogen, accompanied by phosphorylase activity. It is suspected but not proven this might contribute to rapid or extended postmortem glycogenolysis leading to pale, soft, exudative pork.

Fast-contracting muscles generally show positive allometric growth of their fast-contracting myofibers, whereas slow-contracting or postural muscles generally show positive allometric growth of their slow-contracting myofibers.

Longitudinal Growth

Longitudinal growth of myofibers occurs by the formation of new sarcomeres at the ends of the myofibrils where they attach to the inner surface of the plasma membrane. Myotendon junctions (between myofibers and collagen fibers) have numerous invaginations allowing myofibrils to attach laterally to the plasma membrane. Tension generated by a contracting myofibril is transferred laterally through the Z line, desmin, and vinculin to the myofiber beyond. This lateral transfer of tension is of fundamental importance because it allows new filaments to be added parallel to those already formed. If it were not for this lateral transfer, incorporation of new filaments in series with those already formed would be extremely difficult, like attempting to add an extra link to a chain already under tension. Thus, the length of myofibrils can be increased by the lateral addition of new sarcomeres without the end of the myofibril detaching from the plasma membrane.

With the progressive formation of new sarcomeres, the older ones are behind the new ones. The process of adding a new sarcomere might take as little as 20 min in a rapidly growing muscle. This activity matches the high level of polyribosomal RNA at the ends of myofibers, which often are more basophilic than the remainder of the myofibers.

The arrangement of myofibers in a muscle determines where increments from longitudinal myofiber growth are added. In the longissimus dorsi, for example, myofibers are at approximately 45° to the vertebral axis and longitudinal myofiber growth contributes to the depth of the longissimus dorsi. Longissimus dorsi width, however, is the product of apparent myofiber number multiplied by the radial growth of myofibers.

Changes in Myofiber Numbers

Most, if not all, myofibers are formed prenatally. Postnatal muscle growth is accomplished solely by radial and longitudinal hypertrophy to give thicker and longer myofibers, respectively. However, myofiber numbers in a standardized plane half way along a muscle might sometimes appear to increase postnatally. This is most likely caused by the longitudinal growth of intrafascicularly terminating myofibers (tapered myofibers not reaching the end of their muscle). Toward the end of commercial growth in cattle, some muscles show a reverse effect, with considerable reductions in apparent myofiber numbers. Thus, when the number of myofibers at a particular point along the length of a muscle are counted, only those running through this point can be counted. Many other myofibers not reaching the point (i.e., the tapered, intrafascicularly terminating myofibers) are missed. Fast growth of tapered myofibers might increase the apparent number of myofibers, whereas slow growth of tapered myofibers might decrease the apparent number of myofibers.

Endocrinology

Somatotropic hormone (STH) added to myoblasts *in vitro* has little effect. But STH stimulates liver cell mitosis. If myoblasts are cultured together with liver cells, myoblasts then respond to STH. Thus it was discovered that STH activates mitosis by causing the liver to produce a polypeptide hormone, known for a while as somatomedin but now called insulin-like growth factor (IGF). IGF has two forms (IGF-1 and IGF-2), and each form has a specific cell surface receptor. Acting in the opposite direction to IGF is transforming growth factor-β. This inhibits differentiation of myoblasts and their subsequent fusion to form multinucleated myotubes. Fibroblast growth factor is a heparin-binding polypeptide. It stimulates proliferation of premyoblasts and inhibits their differentiation to become myoblasts.

Amino acid uptake by myofibers is enhanced when myofibers contract or are stretched. Cortisol blocks amino acid incorporation into myofibrillar proteins. When muscles are growing: (1) STH and insulin facilitate movement of amino acids to the polyribosomes assembling muscle proteins, (2) steroid hormones enhance messenger RNA activity, and (3) thyroid hormones facilitate DNA accumulation and formation of RNA. Stimulation of the immune system, however, can cause the release of monokines and reduce muscle growth.

Glossary

Allometric growth Growth of a portion of an organism relative to or in comparison with growth of the whole organism.
Basal lamina The membrane that surrounds a cell membrane and defines the outer boundary of a cell.
de novo An expression meaning 'anew.'
Glycogen The storage form of carbohydrate, a polysaccharide consisting of branched-chain connected glucose molecules.
Hypophysectomy Removal of the pituitary gland.
Metabolism Chemical reactions or changes in living cells by which energy is provided.
Postprandial Following a meal.
Thyroidectomy Removal of the thyroid gland.

Introduction

The physiology of growth of meat animals has been actively studied for more than a century, and new, more detailed information is gathered each year as new methods are developed to study the physiological processes regulating the muscle, bone, and adipose tissue growth. Although nearly all aspects of physiology are important to growth, the focus of this article is on endocrine (hormonal) influences on growth. When nutrition is adequate and other physiological functions are normal, endocrine influences on skeletal muscle, adipose tissue, and bone are critical determinants of rate of growth and composition of the entire meat animal. These three tissues plus the supportive connective tissue (tendons, ligaments, and cartilage) comprise the 'carcass' derived at harvest, from which meat and meat products are produced. Growth of the skeletal muscle, adipose tissue, and bone is of primary importance because these tissues represent approximately 46–54%, 25–31%, and 12–15%, respectively, of the total weight of meat animal carcasses at typical market weights.

The goal of this article is to describe the important aspects of the physiology of and hormonal influence on the skeletal muscle, adipose tissue, and bone growth and to discuss briefly how nutritional modulation of growth is mediated through the endocrine/growth factor axis. The nervous system also plays an important role in hormonal regulation of growth, and an explanation of these interactions will be presented. Emphasis is placed on endocrine regulation of growth and development after birth of the animal. The number of muscle cells (muscle fibers) is 'set' at birth of meat animals, so the growth of muscle occurs primarily through an increase in cell size (length and radial area). The growth of adipose tissue, however, reflects the summation of effects of increasing cell number and increasing cell size after birth. In normal adipose tissue growth, increases in cell size contribute more than increases in cell number. Growth of the long bones in the skeleton involves a complex pattern of cell division, synthesis of cartilage-like material, and remodeling of that material and replacement with more calcified matrix to increase length, width, and thickness. Focus on the growth phase following birth is also justified because this is when functional hormone-receptor populations increase rapidly, and maturation of the gonads during adolescence adds new hormonal influences coinciding with the onset of puberty and influence patterns of tissue growth.

Growth Physiology Concepts

The physiology of growth of meat animals involves a complex of hormone and growth factor influences on the metabolic processes in cells responsible for growth of those tissues. These influences are regulated by the rate of synthesis and secretion of hormones and growth factors; the number of receptors present in a tissue; and the age, gender, genotype, and nutritional status of animals. Some hormones act quickly and stay in the circulating bloodstream for short times (short half-life); others act over longer periods, largely because they stay in the blood for a longer time (long half-life). Although hormone action is similar in most animals, subtle variations in the hormonal control of growth and metabolism are found among different mammalian and avian species. The concepts of a chemical messenger initiating a response in a cell and the use of the term 'hormone' to describe that messenger were stated in 1905 by Starling. The concept of activation through a receptor or in a cell was first put forward in 1906 by Langley. Today, the complexity of hormonal interactions across tissues and the means by which hormones coordinate and exert their influences on growth is still unraveling.

The major endocrine gland secretions that provide chronic positive influences on growth include insulin, thyroid hormone, somatotropin (ST, growth hormone), the female hormones known as estrogens, the male hormones known as androgens, and the glucocorticoids. Several other hormones are involved in the regulation of synthesis and secretion of these 'growth-supporting' hormones, the regulation of energy or mineral balance, and the sensitivity of cells to metabolic hormones or growth factors. For example, the glucocorticoids produced by the middle layer of the adrenal gland are critical in modulating response to stress (i.e., heat and cold stress) and increasing the sensitivity of cells to other hormones. The catecholamine adrenaline (epinephrine) is produced by the inner part of the adrenal gland, the medulla, and regulates the heart

rate and blood flow in an acute fashion (in seconds). However, when transient nutrient intake deficiencies occur, adrenaline stimulates the release of glucose from stores of glycogen in muscle and the liver or stimulates the release of fatty acids from stored lipid in adipose cells to provide a source of energy to support essential or basal metabolism and highest-priority growth processes.

Age effects

The relative growth rates of the skeletal muscle, adipose tissue, and bone change with time in the growing animal, resulting in changes in the percentage of live weight represented by each tissue from birth to market weight or mature size. This is called allometric growth, and it results from changes in the priorities for use of nutrients by these tissues that occur from birth to market weight or maturity. When the plane of nutrition is high (adequate or excess amounts of nutrients being consumed), rates of bone and skeletal muscle growth are relatively high at birth and slowly decline toward achievement of sexual maturity or market weight. In contrast, adipose tissue growth is very slow for several weeks after birth, but accelerates at an increasing rate with increasing age and body weight, achieving exponential rates of growth as the animal approaches or exceeds normal market weight. Although muscle cell number (fiber number) is already at maximum by birth in meat animals, adipose cell number increases manyfold between birth and market weight or mature size through differentiation (or recruitment) of new or dormant cells. Accordingly, the capacity for adipose tissue growth from birth to mature size is greater than that of muscle, but we do not yet know which hormones and growth factors determine how many fat (adipose) cells an animal will have during the different phases of growth. Excess levels of fuel energy consumption increased the rate of lipid synthesis and storage in adipose cells. Insulin is the major hormone that is facilitating these processes.

Gender effects

Gender influences involve maturation of the gonads during adolescence, which leads to increased synthesis and secretion of the primary female hormone estradiol, and the primary male hormone testosterone. Androgen secretion is high in the fetus, declines after birth, and then increases dramatically at puberty, further complicating the dynamic patterns of muscle growth that are also influenced by other hormones. This coordinated action of hormones creates age-related, gender-specific differences in growth patterns of the bone, skeletal muscle, and adipose tissue that result in carcass composition differences. Carcasses from intact males contain larger muscles, a higher percentage of muscle and lower percentage of fat than those from females, and carcasses from castrated males tend to fall between the two. One exception to this general rule is that castrated male swine (barrows) contain more fat on average than females (gilts) at the same age or weight. Gender influences also determine differences in mature size. Estrogenic hormones are known to initiate slowing and cessation of bone growth, leading to smaller skeletal stature and smaller mature size and weight of females as compared with intact or castrated males. The physiology of bone growth in cattle is interesting because castration of intact males (bulls) to produce steers allows continued bone growth to occur, and steers over 2 or 3 years of age are significantly larger and will achieve a heavier mature weight than bulls or normal females. Castration of males in all meat animals causes lower testosterone concentrations in the blood during growth, and this leads to fatter pigs, cattle, and lambs when compared with their intact male counterparts.

Genetic effects

Experimental work has demonstrated that meat animals can be selected for increased mature size, greater muscularity, and lesser amounts of carcass fat at a similar weight. Increased mature size usually results from selection for greater growth rates and leaner animals at a typical harvest weight. Animals can also be selected for increased muscularity and decreased fat, independently or in combination, at a given weight. This selection process causes a reduction in the percentage of energy consumed being converted to stored fat, and these animals are considered less physiologically mature than the unselected cohorts. They will grow to achieve the same percentage of fat in the body or carcass, but that is achieved at higher body weights. Environmental conditions such as heat and cold, nutrient availability, and the desired carcass or meat composition all provide the rationale for selection criteria used in the production of meat animals. The genetic potential for growth determines the animal's nutrient requirements for maximum growth rate.

Growth is influenced by a multitude of genes, and an interesting one is the myostatin gene. Myostatin controls muscle fiber formation during fetal muscle growth. The timing and extent of increased myostatin present during fetal development determines when muscle fiber formation stops. A condition exists in a few breeds of cattle, called the 'double-muscled' condition, in which muscles are much larger (up to 40–50%) than the same muscles in most other breeds or compared with normal animals of the same breed. Most muscles in 'double-muscled' cattle contain up to 40% more muscle fibers before birth and beyond. The application of molecular techniques has demonstrated that the 'double-muscled' phenomenon is caused by small changes in the deoxyribose nucleic acid (DNA) base-pair sequence that lead to functional changes in the gene that produces myostatin. These changes lead to a reduced production of myostatin during fetal development, and this leads to greater rates of muscle fiber formation and higher muscle fiber number. As the muscle fibers are not larger, a greater muscle fiber number is responsible for faster muscle growth after birth leading to larger muscles.

Metabolic effects

One hormone known to be critically important in partitioning of nutrient use for growth among the main tissues is the growth hormone or ST. ST stimulates bone and skeletal muscle growth, but it reduces or inhibits adipose tissue growth. Rates of synthesis and secretion of ST decline from birth to market weight, in parallel with decreasing rates of muscle and bone growth and accelerating rates of adipose tissue growth. Circulating concentrations of ST also respond to changes in the level of energy and protein nutrition, altering the sensitivity of cells to insulin to help direct use of nutrients in an appropriate fashion. Elevation of ST in the circulation redirects nutrients toward increased muscle and bone growth and decreased

Table 1 Effects of somatotropin (growth hormone) on animal tissues, hormone regulation, and metabolism in growing animals

Tissue	*Physiological effect*
Adipose tissue	Decreased sensitivity to insulin and decreased glucose uptake
	Decreased lipid synthesis
	Decrease in adipose tissue mass (all depots)
	Decreased glucose oxidation
	Increased lipolysis if animal is in negative energy balance
Skeletal muscle	Increased protein synthesis
	Increased protein accumulation in muscle
	Increased muscle growth rate and muscle mass
Bone	Increased synthesis of bone matrix
	Increased bone growth rate
Liver	Increase in liver growth rate and liver mass
	Increased glucose output
	Decreased ability of insulin to inhibit gluconeogenesis
Intestine	Increased absorption of calcium and phosphorus absorption
	No change in intestine weight
Metabolic indices	Decreased circulating concentration of blood urea nitrogen
	Decreased amino acid oxidation
	Decreased glucose clearance from blood
	Decreased glucose oxidation
	Increased synthesis and secretion of insulin-like growth factor-1 (IGF-1)
	Increased circulating concentration of IGF-1-binding protein (IGFBP-3)

adipose tissue growth. A summary of the effects on metabolic activities in various tissues and on overall metabolism is presented in Table 1. Although the relative rates of bone and muscle growth decline as mature size is approached, if energy intake exceeds requirements for maintenance and growth of muscle, bone and other tissues, adipose tissue growth is stimulated and both the relative and absolute rates of fat deposition are increased at a stage of growth where muscle and bone growth rates are declining. This leads to obesity and less efficient use of feed for growth of meat animals. Bone growth is more complex in that it involves several different cell types and synthesis of cartilage that is later replaced by hard or 'compact' bone. Several hormones control this process of continued formation of new cells and replacement of older cells throughout growth. Changes in cell number and size of these cell types cannot be used to characterize bone growth in the manner that they are used to describe muscle and adipose tissue growth.

Physiology of Skeletal Muscle Growth

Hormonal control of skeletal muscle growth after birth involves two primary targets of control: (1) rates of proliferation and incorporation of satellite cells into existing muscle fibers and (2) independent or concurrent changes in rates of muscle protein synthesis and degradation. Muscle fibers are long tubular-shaped cells that contain many nuclei, the total number of which depends primarily on muscle fiber length and radial area. Each nucleus in a muscle fiber provides information for the synthesis and maintenance of a specific amount of cytoplasm, primarily muscle proteins, in the cell. Growth of the multinucleated muscle fibers is characterized by a several-fold increase in their length, the number of myonuclei (total DNA) and total ribonucleic acid (RNA) and protein present. As the number of fibers in each muscle remains constant, increases in each of these components leads to a proportional increase in the total protein content and weight of the muscle. The number of fibers in each muscle does not increase by hyperplasia after birth in meat animals and humans, but the total number of nuclei, total amount of protein, and the total muscle weight do. Muscle fiber nuclei are the site of transcription of the DNA that defines the specific messenger RNAs that are translated into individual proteins. Skeletal muscle growth is regulated by activation of transcription in the nucleus. ST, testosterone, and estradiol increase the rate of muscle protein synthesis, and this is initiated through hormone-receptor binding and a cascade of intracellular signaling events that lead to increased protein synthesis. These signal-transduction elements will not be discussed here.

As myonuclei cannot divide, the source of the multitude of nuclei that accumulate in muscle fibers during growth after birth is attributed to the 'satellite cell' population. These cells reside between the sarcolemma (plasma membrane) of each muscle fiber and the basal lamina that surrounds each fiber. Muscle growth by hypertrophy should not be confused with growth by hyperplasia. The strict definition of hyperplasia is the increase in muscle fiber number that occurs with terminal differentiation and fusion of myoblasts to form myotubes (immature muscle fibers) during embryonic and fetal muscle growth. The regulation of myoblast proliferation, differentiation, and formation of muscle fibers is a complex process called myogenesis, and it will not be discussed here. Anabolic hormones, such as testosterone and ST, do not directly stimulate myoblast or satellite cell proliferation and fusion and the stimulatory effects probably result from the production of insulin-like growth factor-1 (IGF-1) and other growth factors. IGF-1 is produced in the liver and enters the general circulation of the blood, providing availability to skeletal muscle and other tissues, but it is also produced by skeletal muscle cells. Whether effects are mediated via an endocrine influence through the circulation or whether effects are mediated locally via paracrine influence is not certain and is under current investigation.

Farm animal muscle growth exhibits a positive association between increasing total DNA mass, total RNA mass, and total weight or protein content of individual skeletal muscles during growth, without any change in muscle fiber number. This is true for normal postnatal growth in pigs, sheep and cattle, and most other mammalian species as well. A strong association also exists between muscle weight, DNA mass, and RNA mass when nutritional restriction is imposed to slow muscle growth. Likewise, the lesser muscle size and weight observed when small birth weights are compared with heavy ones during early postnatal growth, and when surgical removal of an endocrine gland or the source of the hormone is removed (i.e., hypophysectomy or thyroidectomy), and when hormone

administration is used to stimulate skeletal muscle growth. Characterizing changes in endocrine status that occur with changes in rates of DNA, RNA, and protein accretion during growth and nutritional manipulation provide useful information for determining how changes in nutritional status mediate control of skeletal muscle growth.

Effects of Somatotropin on Muscle Growth

Insufficient amounts of ST synthesis and secretion from birth to maturity slow muscle and bone growth, and replacement therapy can restore normal growth rates. Circulating concentrations of ST vary according to the episodic pattern of secretion, a phenomenon that was not known to be present until the late 1960s and early 1970s. The effects of ST on the animal must be determined by frequent sampling and integration of concentration changes over time. Circulating ST concentrations exhibit positive correlations with carcass muscle and total RNA in the muscle of growing steers, but too many factors influence ST status to make this a reliable index for muscle growth potential.

Daily administration of ST allows a growing animal to achieve its genetic potential for muscle growth. Dose-dependent increases in absolute mass and percentage of muscle in carcasses of pigs, lambs, and cattle provide compelling evidence for the importance of the influence of ST on skeletal muscle growth. Relative increases in total muscle mass at the same live weight range from 28% with a low dose of 50 μg per kg live weight to 38% with a high dose of 200 μg porcine ST per kg live weight in animals fed an adequate diet. Smaller responses are observed if nutritional adequacy is not provided. Results from recent studies demonstrated a 27% increase in the composition of skeletal muscles in the half-carcass of 360 kg beef steers treated for 157 days with 160 mg bovine ST per week. Variation in growth response between muscles is quite small in pigs. Percentage increases of individual muscle weights were dose dependent but were similar across anatomical locations at the same dose. The chronic protein anabolic effect of ST on skeletal muscle growth appears to be achieved exclusively through enhancement of protein synthesis, with little or no difference in protein degradation rate.

The demonstrated effects of ST on protein accretion and metabolism in skeletal muscle appear to involve the IGF system. The degree to which increased circulating concentrations or locally produced IGF-1, IGF-2, and the IGF-binding proteins (IGFBPs) are involved is still in question. Administration of ST to growing pigs and ruminants beyond the first several weeks of age markedly increases plasma concentrations of IGF-1, IGF-2, and the major binding protein, IGFBP-3. IGF-1 stimulates protein synthesis and reduces protein degradation in muscle cell cultures, and circulating IGF-1 concentrations are positively correlated with protein gain in growing steers.

It is presumed that the major source of circulating IGFs and IGFBPs is the liver, as ST stimulates transcription of IGF-1, IGFBP-3, and the acid-labile subunit of the complex in the liver. Skeletal muscle and other tissues may also be a significant source, however. Increased levels of dietary protein intake in pigs and growing steers increase muscle IGF-1 messenger RNA (mRNA) abundance and whole-animal protein gain.

Relationships between growth rates, circulating concentrations of endogenous metabolic hormones, IGF-1, and IGF-1 mRNA concentrations in skeletal muscle and liver were compared in growing bulls, steers, and heifers. Bulls had higher mean ST and ST peak amplitude than heifers, whereas values for steers were intermediate. Bulls also had 1.6-fold and 3.0-fold greater liver IGF-1 mRNA concentrations than steers and heifers, respectively, whereas steers had 1.8-fold greater IGF-1 mRNA concentrations than heifers. Bulls had 1.3-fold higher plasma concentrations of IGF-1 than steers, and values for steers were 1.8-fold higher than those for heifers. Liver IGF-1 mRNA concentrations, liver slice IGF-1 production, and plasma IGF-1 concentrations were all significantly correlated with average daily gain and mean ST peak amplitude, but not with ST baseline concentrations, peak frequency, or plasma thyroid hormone (thyroxine (T_4) and triiodothyronine (T_3)) concentrations. These results suggest a relationship between sex steroid status and an endocrine influence of IGF-1 in growing cattle, but more definitive information is needed.

Effects of Estrogenic Steroids on Skeletal Muscle Growth

A recent study provides additional information regarding independent and combined estrogenic steroid and ST effects on composition of gain, skeletal muscle growth, and other growth responses. Daily administration of bovine ST (bST) alone and in combination with administration of estradiol-17β via the commercial estrogenic steroid implant Synovex (Syntex Animal Health, West Des Moines, IA, USA) increased average daily gain by 16% and 28%, respectively, without significant effect on feed intake, over a 56-day treatment period. Weights and rates of weight gain were determined for skeletal muscles taken from various parts of the carcass. The combination of Synovex plus bST resulted in additive effects on carcass protein gain, individual muscle weight gain, and muscle fiber size in the rectus femoris, triceps brachii and semitendinosus muscles. Although it is known that administration of estradiol increases ST secretion rate and plasma concentrations of ST, results from this experiment and others clearly show that estrogenic treatment and bST treatment exhibit additive effects on skeletal muscle growth.

Chronic estradiol alone and bST administration alone increase circulating insulin concentrations in growing cattle. The suggestion that increased insulin secretion is part of the pathway for the estrogenic or bST response is uncertain. Chronic insulin administration in young, rapidly growing pigs has no effect on growth rate, growth efficiency, and muscle or adipose tissue weights. Insulin serves an important role as a homeostatic (over acute time intervals) regulator of nutrient metabolism, and chronic alterations in nutrient partitioning are mediated by changing tissue sensitivity to insulin.

Effects of Androgenic Steroids on Skeletal Muscle Growth

Entire males in most species grow faster and contain greater absolute mass of skeletal muscle and less fat than castrated males. These differences are attributed to the presence of greater concentrations of testosterone in circulation. Intact males exhibit greater rates of protein gain at equal feed intakes.

Episodic testosterone administration (9 mg day^{-1}) in wether lambs increased nitrogen balance by 2.9 g day^{-1} (96%) during three successive 5-day treatment periods. Rates of muscle protein synthesis were not different between treatment and pre- and posttreatment periods.

Testosterone is known to invoke biphasic muscle growth patterns in neck muscles of intact male cattle and sheep, whereas most other muscles or muscle groups exhibit only a single-phase or linear growth pattern. It is during the latter part of the growth period to market weight (approximately 4–9 months of age in sheep and 12–18 months of age in cattle) that this divergence is noted. It is difficult to conclude just how testosterone influences muscle growth, but cautious speculation would include the possibility that the protein anabolic effect is expressed through decreased protein degradation. Similar conclusions were drawn from studies with a synthetic androgen, trenbolone acetate, administered in cattle.

Effects of Insulin on Skeletal Muscle Growth

Insulin is the metabolic hormone most responsible for facilitating nutrient uptake by tissues, organs, or cells, and thus plays a critical essential role in protein synthesis and muscle growth as well as lipid synthesis and adipose tissue growth. As mentioned earlier in the Section Growth Physiology Concepts, insulin is considered an acute-acting metabolic hormone and as such it exhibits concentration changes in the blood that follow feed ingestion patterns. After feed is consumed and digested, nutrients are absorbed into the bloodstream and insulin release from the pancreas is triggered. Synthesis of skeletal muscle proteins is sensitive to this cyclicity of nutrient intake and insulin concentration changes. Insulin stimulates glucose and amino acid uptake by muscle, and it has been shown to stimulate protein synthesis and decrease protein degradation in muscle in short-term *in-vitro* and *in-vivo* experiments. When compared with nonruminants, ruminants exhibit slower rates of insulin secretion, smaller postprandial changes in plasma concentrations, and less effectiveness in glucose removal from the blood because the volatile fatty acids (acetate, propionate, and butyrate) are the primary substrates of energy metabolism.

Physiology of Adipose Tissue Growth

Adipose Tissue Form and Function

Adipose tissue is sometimes referred to simply as fat. One of its major functions is to store energy for the body through the synthesis of lipid and its accumulation in adipocytes (fat cells). When feed intake is restricted, adipose tissue undergoes a process called lipolysis. Lipolysis is the separation of fatty acids from the stored form of fat (triglycerides), and release of the fatty acids into the blood so that they can be used by tissues and organs as a source of energy. These fatty acids are commonly called 'free fatty acids' or 'nonesterified fatty acids'. Adipose tissue is a specialized type of connective tissue found in most animals to accumulate around visceral organs, just under the skin, between skeletal muscles, and, to a small degree, within skeletal muscles. These locations where fat deposits appear are called adipose depots or fat depots. They begin as areas of loose connective tissue containing many very small blood vessels and fibroblast-like cells, where differentiation of adipocytes (fat cells) occurs and leads to the processes of synthesis of fatty acids and accumulation of lipid droplets in the cells. Fat cells are present before birth, but many new fat cells are formed during growth to puberty and beyond. Both the number of fat cells and the size of these spherical cells determine the size of a fat depot or the total amount of fat in the carcass of meat animals. Some animals, such as pigs, contain only 2–3% fat at birth and may have as much as 25–30% fat at market weight. As is the case with muscle growth, the rate of fat accumulation and ultimate fatness of meat animals is also influenced by age, gender, genotype, and nutrition.

Age effects

The composition of adipose tissue changes with age. The percentage of water and protein decline and the percentage of lipid increases with increasing age. Growth of adipose tissue with age includes hypertrophy of existing cells through lipogenesis (the metabolic processes involved in the accumulation of lipid) and hyperplasia, the formation of new cells. As long as the nutritional status provides excess energy intake, both processes will occur, leading to increasing fatness. A wide range of fat cell size exists during all phases of growth, but the number of largest cells is greater at market weight. The ability to continue fat accumulation explains why older animals that are 'overfed' become obese. There are species differences with regard to the biochemical pathways of fatty acid formation, and these differences explain the variation in fatty acid composition of adipose tissue between species.

Genetic effects

Different breeds or strains within a species of meat animal vary in their rate of fat deposition at typical market weights. Breed differences also exist in the proportion of fat stored in the different depots in the body. Dairy breeds of cattle contain far less subcutaneous fat (the depot under the skin) and more fat between muscles and in the visceral region than beef breeds. Genetic selection for decreased thickness of subcutaneous fat has been used very successfully for decades to reduce carcass fat in meat animals. This type of genetic selection results in fewer cells and smaller average cell volume at a given live weight.

Gender effects

Gender differences in fatness of meat animals are similar across species. In ruminants, intact males contain the least fat, females generally contain the most, and castrated males fall in between. Boars (intact males) contain less fat than barrows (castrates) or gilts (females) in swine, but barrows are usually fatter than gilts. These differences become most pronounced at puberty and beyond when testosterone in males and estrogens in females exert strong influences on growth and metabolism. Testosterone reduces fat synthesis and deposition, whereas estradiol enhances fat synthesis and deposition in female cattle and sheep. Gender differences result

in female ruminants being marketed at lighter weights than castrated males.

Nutritional effects

Following ingestion and digestion of a meal, insulin secretion into the blood is stimulated, leading to activation of receptors on cell membranes. Insulin stimulates or accommodates uptake of fatty acids and glucose by adipose cells. Glucose and fatty acids (predominantly acetate in ruminants) are the substrates for *de-novo* synthesis of fatty acids and triglycerides, respectively. Triglycerides are the stored form of fat in adipose cells. The greater the excess of nutrients absorbed following a meal, the greater the rate and extent of triglyceride synthesis and fat storage. To counter fattening of dairy heifers, which impairs milk production later, and breeding animals of other species, restricted feed intake is used to control fat content of these animals.

Hormonal effects

ST is known to have direct effects on lipogenesis and the rate of lipid accumulation in fat cells (adipocytes) in meat animals. This hormone blunts the sensitivity of fat cells, but not of skeletal muscle cells, to insulin. Hence, adipocytes are directed by ST to reduce uptake of glucose and fatty acids and reduce formation of triglyceride for storage. This is a potent and dynamic effect that depends closely on the amount of ST in circulation. The effects of ST are consistent in all genders and breeds of meat animals. The gender effects of testosterone and estradiol are still present, and are generally additive to the effects of ST.

Special conditions, such as onset of lactation and acute shortage of feed intake, will reverse the lipid accumulation processes through reduced synthesis and secretion of insulin and increased synthesis or action of adrenaline to stimulate lipolysis. This leads to release of fatty acids from the triglyceride molecules in fat cells and can lead to overall weight loss if sustained over a significant period.

These examples show how sophisticated monitoring of nutritional status and changes in nutrient demands are coordinated through actions of the endocrine system to accommodate the highest-priority physiological function present at any given stage or phase of growth.

Intervention strategies

Research into the complexity of growth processes led to the discovery of compounds that can be fed safely to growing meat animals to improve carcass composition and feed efficiency. The United States Food and Drug Administration, Center for Veterinary Medicine approved ractopamine, a synthetic beta-agonist compound, for use as a feed additive for growing-finishing swine (Paylean), cattle (Optaflexx), and turkeys (Topmax). More recently, zilpaterol (Zilmax) was also approved by the FDA as a feed additive to be fed the last 20 days before harvest of beef cattle. These orally active compounds fed during the latter part of the finishing period enhance skeletal muscle growth and reduce the relative amount of fat in the carcass, without altering quality characteristics of meat.

Physiology of Bone Growth

Bone Form and Function

Bone formation occurs through transformation of connective tissue during fetal development and growth following birth to the time when mature size is achieved. Five or six distinct cell types are involved in this intricate process. The complex series of events involving these cells determine not only growth rates but also the strength of the bones as well. Complexity is also added by the presence of three different types of bones throughout the body, and growth processes are slightly different for each type. The discussion presented here focuses on long bones, those responsible for locomotion and support of the animal, which determine the ultimate stature or height and mature size.

Long-bone growth centers on activities in the growth plate, or epiphysis, located in the enlarged end or ends of long bones. When activity here ceases, growth stops. This is sometimes referred to as epiphyseal 'plate closure,' the benchmark for cessation of long-bone growth and achievement of mature size. Once plate closure occurs, long bones grow only in diameter and thickness. Again, as with growth of muscle and adipose tissue, bone growth is influenced by age, gender, genetics, and nutrition. In contrast to the importance of nutrition for muscle and adipose tissue growth, nutrition has the least impact on bone growth, primarily because most normal diets for meat animals provide adequate nutrients to sustain bone growth.

Age and gender effects

Bone is the most mature tissue at birth in comparison with muscle and adipose tissue. A higher priority exists for viable bone form and function to assure survival at birth than for adipose tissue growth. Accordingly, bone represents a higher percentage of total weight at birth, and a declining percentage as the animal grows to maturity, whereas the pattern of adipose tissue growth is opposite. Significant age effects are associated with the onset of puberty. In meat animals, the estrogenic influence is responsible for earlier reduction of activity of the cells in the growth plate and ultimate conversion of this to compact bone, as compared with intact or castrated males. The females of most mammalian species are of smaller stature and lighter weight at mature size than intact males. Castrated males represent an interesting contrast to intact males or females. These animals exhibit delayed plate closure and longer times of bone growth, presumably related to lower testosterone production, than either females or intact males.

Endocrine and nutritional effects

ST exerts positive stimulatory effects on long-bone growth. Stimulation of cell division in the growth plate may involve local production of IGF-1 as a critical influence. ST stimulates bone growth in all genders and all common genotypes. Other hormones are associated with mineral balance and cartilage and bone matrix formation. A very high concentration of calcium salts is present in bone and endocrine influences on mineral absorption and incorporation into matrix material are essential for normal growth and maturation. Calcitonin, secreted by the thyroid gland, and parathyroid hormone,

secreted by the parathyroid gland, are key regulators of calcium metabolism in bone and other tissues.

Vitamin and trace mineral deficiencies can result in abnormal bone growth. Most meat animal diets contain supplements to ensure adequate availability of minerals for normal bone growth. Amounts of nutrients contributed from each individual feed source must be known for the determination of appropriate levels of supplementation for each species. Feed formulations must accommodate a balance of nutrient availability that meets the needs of bone, muscle, organs, and other metabolic tissues. Stage of growth, gender, and genotype contribute to the variation in nutrient requirements of meat animals.

Conclusion

The physiology of growth in meat animals is an orchestrated process characterized by the sophisticated coordination of cell proliferation (hyperplasia) and increase in cell size (hypertrophy) in organs, skeletal muscle, bone, and adipose tissue from birth to market weight or mature size. Total cell number is a primary determinant of skeletal muscle size and propensity to accumulate fat. Although the total number of skeletal muscle fibers present in each muscle is achieved by birth in meat animals, the number of cells in adipose tissue depots exhibits several-fold increase during postnatal growth. Organ, bone, and skeletal muscle growth exhibit a higher priority for use of absorbed nutrients than adipose tissue because they support survival functions and mobility. Adipose tissue growth results from excess energy produced from feed consumed in amounts greater than that required to support the genetic potential for organ, muscle, and bone growth. Metabolic hormones and sex hormones control metabolic pathways affecting the cellular processes that lead to cell growth and maturation (protein synthesis and degradation in skeletal muscle and lipogenesis and lipolysis in adipose tissue). Genetic blueprints exist in each animal for control of gene expression in each tissue or organ that culminate in phenotypic characteristics defining complex traits such as muscle fiber number and size, long-bone growth and mature size, and propensity to deposit fat at differential rates among the four major fat depots. These growth patterns determine the overall body growth rate, feed efficiency, and body composition. Comparisons of factors that influence growth must be made under carefully controlled conditions and at constant live weights (to remove confounding effects of allometric growth) if we are to understand the mechanisms that create differences and their impact on the relative amounts of muscle, fat, and bone that exist at any point during the various phases of growth. Animal well-being, product quality characteristics, environmental impacts, and economics ultimately determine which management strategies are used in meat animal production.

HAM PRODUCTION

Contents

Cooked Ham

J Arnau Arboix, Institut de Recerca i Tecnologia Agroalimentàries (IRTA), Girona, Spain

This article is a revision of the previous edition article by J Arnau Arboix, volume 2, pp 562–567, © 2004, Elsevier Ltd.

Glossary

Delta-T Delta-T (ΔT) cooking means that the oven temperature rises to remain constant at a temperature above that of the food core (monitored by a core probe). The constant difference between the core temperature and cooking chamber is user-definable. The food temperature increases gradually until it reaches the end-of-cooking temperature set on the probe.

Tenderization Tenderization is a mechanical process used in the manufacture of cooked ham, which produces cuts in the muscle that break the structure of the connective tissue and puncture the brine collection areas between muscles, facilitating brine distribution and increasing the extraction surface. It therefore eliminates the necessity of thorough trimming, and reduces the effect of retraction of the connective tissues during cooking.

Tumbling Is a fall massage where meat pieces are lifted by baffles to the upper part of the machine and then fall onto the meat mass below, producing an intense mechanical action that softens the meat. This type of massage results in considerable cellullar breakage and a high extraction of proteins.

Introduction

Cooked ham is the complete ham, or part of the ham, cooked at a temperature high enough to coagulate the meat proteins, ensuring that, once packed, the product remains unchanged in normal storage conditions at refrigerated temperature.

The most important criteria to bear in mind for cooked ham production are: selection of raw material, trimming, brine composition and injection rate, tenderization, type and duration of mechanical treatment, stuffing or placing in molds, the cooking process, chilling, and preparation for marketing.

Selection and Preparation of the Raw Material

Raw material selection is of paramount importance for products of optimal quality. It is important to follow good manufacturing practices during slaughtering and cutting to avoid high bacterial counts, which decrease shelf-life and can produce color defects. It is also important to select hams with a good water-holding capacity (WHC). Hams with a pH less than 6.0 at 45 min postmortem will ultimately lead to high moisture loss, paler color, binding problems, and softer texture, and it is advisable to avoid this in the production of high-quality cooked hams. The optimal pH at 24 h postmortem for cooked ham

 doi:10.1016/B978-0-12-384731-7.00226-9

production is between 5.8 and 6.2. Pale, soft, and exudative (PSE) meat has a lower WHC, whereas meat with pH > 6.2 is termed dark, firm, and dry (DFD). Even though DFD meat has a higher WHC, it is more prone to bacterial deterioration, and reduces nitrite to nitric oxide more slowly, which can produce discoloration problems, especially when nitrite content is reduced or ascorbate/erythorbate is not added. The selected pork legs should be chilled to an internal temperature between 2 and 4 °C, and classified according to weight.

Traditionally, hams were prepared with bones included, but nowadays most hams are boned. This operation is done manually due to the lack of appropriate machinery. Sometimes the original muscle structure of the ham is retained, but in order to trim out the intermuscular fat and connective tissue surrounding the muscles, hams are often separated into several pieces that can reproduce the entire ham if they are put together before cooking. Subcutaneous fat and rind are sometimes left on to give a more traditional appearance. A piece of cured rind with a standardized shape and subcutaneous fat layer is sometimes added during stuffing close to the m. biceps femoris, but fat and rind are usually trimmed off to obtain a leaner appearence. Trimming of fat and connective tissue facilitates the extraction of salt-soluble proteins, which increases the binding of muscles, improves the cohesiveness of the slices, and decreases the risk of formation of brine pockets during injection and of formation of gelatine between muscles during cooking.

Brine Preparation and Injection

The process of curing meat requires the addition of a number of ingredients and additives that are necessary to obtain the desired color, texture, and flavor. These substances are dissolved in water to form the brine. Traditionally, hams were submerged in brine and the curing salts diffused slowly into the meat. This process took several weeks and the hams were not homogeneous. Brine can be injected into the arteries, but the process is labor-intensive and the brine distribution is not uniform. Nowadays, brine is injected in such a way that the meat tissue is not torn and the brine is distributed evenly into all parts of the muscles, reducing the process time to one or two days.

To prepare the brine, it is necessary to decide the percentage to be injected. The water used must be potable. To ensure a complete solution, polyphosphates should be dissolved in the water first, followed by the nonmeat proteins, sugars, nitrite and nitrate, salt, carrageenan, and finally ascorbate. The final temperature of the brine should be adjusted to 2–5 °C. Some proteins foam when added to agitated brines; to prevent this, the use of edible antifoaming agents is advised, if allowed by local legislation; otherwise the brine should stand until the foam disappears. The amount of brine injected should be as close as possible to the target. The weight after injection is checked and adjusted by adding the required amount of loose brine to the tumbler in the process that follows the injection. An uneven distribution of brine will result in a deficiency or an excess of ingredients and additives in various areas, resulting in cooking loss and uneven coloring, binding, and flavor. The accuracy of the injection, a good brine distribution, and a low drip loss after injection are particularly important for products that are not subjected to a massaging process. Brine added during tumbling/massaging to adjust the injection weight gain should be at a minimum (< 2%) to prevent the hams swimming about in the brine, which hinders the desired tumbling effect. It is important to filter the brine to avoid blocking of the injector needles and to clean and check the filters and needles to guarantee a uniform injection.

The percentage of brine injected is determined by the desired quality of the finished product. The concentration of each ingredient in the brine depends on the amount required in the injected ham and the injection weight gain. Equation [1] relates the concentration of an ingredient x in the ham to the concentration in the brine.

$$\%B = \%P \cdot (100 + \%I)/\%I \qquad [1]$$

In eqn [1], %B = percentage of ingredient x in the brine; %P = percentage of ingredient x in the product; and %I = percentage of injection: (g of brine per 100 g of uncured meat).

The brine is injected into the muscles by means of a multineedle injector. Uniform distribution of brine in the muscles is important to reduce to a minimum the time required for the brine to migrate to the uninjected areas. This improves the color homogeneity and final product yield and prevents visible color variation along injection lines. A good brine distribution allows a better brine retention and consequently reduces the drip loss. This effect is improved when the brine penetrates deeply between the meat fibres and more muscle volume is covered with brine.

A precise injection rate ensures a minimum standard deviation of the brine content in different meat pieces and thus increases finished product quality. In some statutory requirements, the injection rate is regulated according to quality categories. The lower the standard deviation, the lower the number of under-injected pieces (which could cause sensory problems and a lower water-holding capacity) and the lower the number of overinjected pieces that would be above the statutory limit, thus producing a cooked ham with more attractive sensory characteristics.

It is important to be able to achieve the desired injection gain, ranging from a very low level such as 5%, which presents difficulties in distribution, up to a rate of 100%, which presents capacity problems.

Thorough cleaning of equipment is necessary at the end of each working day in order to avoid risk of contamination. Mechanical reliability and low maintenance requirements of the equipment used are also important in avoiding production stoppages.

Injection can be carried out with low-pressure or high-pressure injection machines. During the needle stroke, low-pressure injectors deposit the brine through the meat with needles that each have several holes more than 1 mm in diameter. This process forms brine deposits, which must then be distributed by mechanical action. High-pressure injectors (0.6–1.2 MPa) introduce a specific volume of brine when the needles have completely penetrated the meat and have stopped at the end of their downstroke. This system improves the uniformity of the injection rate from piece to piece compared to continuous pumps for brine injection, with which the pressure can change owing to variation in resistance offered by the meat.

The brine is distributed more homogeneously (particularly when pieces with bone are injected), because the needle holes are distributed along the needles and the diameter of each hole is approximately 0.6 mm. High-pressure injection, which is also called 'spray injection,' has a higher precision and gives a more uniform brine distribution with lower drip loss.

Tenderization

Tenderization is a mechanical process producing cuts or punctures in the muscles, increasing the extraction surface and eliminating the necessity of thorough trimming, as the structure of the connective tissue is broken down and consequently the effect of retraction of the connective tissue during cooking is reduced. The cuts also puncture the brine collection areas between muscles, facilitating brine distribution. Tenderization reduces cooking loss, binding defects, and holes. The degree of tenderization depends on the desired characteristics of the product. Products in which the fibrous structure of the meat is to be preserved do not undergo tenderization and the products go directly to the massaging process. For products where the primary objective is to improve tenderness, the tenderization will be light; in general, the higher the yield desired, the greater the required degree of tenderization.

There are three types of tenderizing machines available on the market:

- Tenderizer with needles: this consists of a head with needles that penetrate the meat, producing a series of small punctures in the muscles.
- Tenderizer with rollers: this consists of two sprung rollers between which the meat is passed. Some have knives that make superficial cuts; some have rollers with prongs. For rind-on products, one of the rollers is replaced with a plastic roller, which leaves the rind structure intact.
- Presses: These consist of two rollers that flatten the meat, breaking its intramuscular structure and brine pockets. This is especially useful for large pieces that do not need a great degree of binding between them.

Tumbling-Massaging

Extraction of salt-soluble proteins is important to bind the individual muscles together during cooking. The formation of exudate depends on the action of the brine ingredients and additives (NaCl, polyphosphates), the tenderization treatment, and the massaging process. The muscular structure is loosened as a result of the mechanical treatment, facilitating distribution and absorption of brine. There are two main systems: tumbling and massaging. The tumbling system provides an intense mechanical action on the meat that facilitates extraction of the salt-soluble proteins. The meat pieces are lifted by baffles to the upper part of the cylindrical machine and then fall onto the meat mass below, producing an intense mechanical action, suitable for high-yield products. This type of massage results in considerable cellullar damage and therefore an optimum extraction of proteins. The friction massaging system is smoother and acts through a stirring action that produces friction between the different muscles and with the walls and baffles of the massaging machine, producing a much gentler effect than the tumbling system. This type of massage is particularly suitable for products in which the pieces and the structure must be kept intact.

These two systems of mechanical treatment correspond to different types of cooked hams. Some of the parameters of the tumbling/massaging that influence the final result are:

- Meat characteristics: aging time before curing, age of animal, and degree of removal of fat and connective tissue.
- Brine composition: NaCl and polyphosphates contribute to the extraction of proteins, and their effect is increased by massaging.
- Massaging time: The longer the massaging time, the greater the extraction of myofibrillar proteins. However, an excessive massaging time could negatively influence the slicing quality.
- Rotation speed: A higher speed results in a greater extraction of proteins but also in greater damage to the muscle structure. For this reason, it is necessary to find an appropriate balance for each product.
- Vacuum: It is important to have a high level of vacuum to avoid foaming, which can cause air bubbles to appear between and inside the muscles. Vacuum enhances protein extraction and development and stabilization of color.
- Temperature: The mechanical action increases the temperature of the meat. Although the massaging efficiency is greater at a higher temperature, there is also a risk of bacterial growth. For this reason, it is advisable to have a cooling circuit in the equipment to control the temperature. If the tumbling equipment does not have a cooling circuit, vacuum is recommended only during tumbling, so as to avoid foaming. The temperature of the meat during tumbling should be 3–6 °C to minimize bacterial growth and allow enough protein extraction.
- Maturation period: A combination of massaging and maturation will result in the desired extraction of proteins. A minimum time of 24 h is recommended for good results. In the high-injection process it is important to reduce the processing time. In these cases the maturation is reduced to 4–6 h.
- Tumbler size: When using tumbling, the result will depend on the height from which the meat falls, and therefore the size of the batch in the machine is a relevant factor. The smaller the amount of meat, the shorter the tumbling time should be. However, it is advisable to prevent hams from falling directly onto the steel surface of the tumbler because the hams may be damaged excessively. Good results are achieved if tumblers are filled at approximately 40–50% of their capacity.

Stuffing and Molding

The matured muscles are stuffed and placed into molds to give the product the desired shape during cooking. Regardless of the material used for the mold, a polyethylene layer must be used to prevent the meat from sticking to the mold if the

product has to be repacked after cooking. If it is cooked in the bag, the shrinkable or thermoformed plastic provides protection. When thermoshrinkable multilayer plastic is used, the plastic can sometimes act as a mold through its ability to shrink. The product is clipped and placed, without a mold, between metal plates that exert pressure on the meat pieces during cooking. In this case the bags should have low oxygen permeability to prevent superficial green discoloration during cooking.

When thermoforming is used, the lower thick film is first thermoformed and then filled with the cured meat and lidded under vacuum. This system, which can also be used in combination with a rigid mold, gives the finished product a less regular shape than when using a rigid mold and shrinkable plastic, but is suitable for products for which a more traditional appearance is desired.

Molds of several shapes are used, sometimes resembling the original pear shape of the natural ham and sometimes rectangular or cylindrical, especially if the ham is to be sold sliced. The uniform cross-section of the rectangular or cylindrical shapes allows almost a complete use without waste.

The shape of the mold depends on whether or not one is attempting to reconstitute the original shape of the ham. In this case, it must be molded manually with care. Careless molding can result in products with a higher cooking loss and cavities inside the ham. A prevacuum is applied after molding to eliminate air locked between muscles. This increases the intramuscular binding and eliminates the spherical holes that are produced by expansion of the trapped air during cooking. When the air removal is completed, the bag must be vacuum-sealed either by a clipping system or by thermosealing. For thermosealing, the bags must be very clean in the seal area to avoid leaking seals.

Cans are sometimes used for cooked hams. The hams are then hermetically sealed under vacuum.

If it is not necessary to reconstruct the natural shape of the ham, the process of filling the molds can be done automatically with a stuffing machine, reducing the operations on the production line. Products that are stuffed automatically under vacuum do not require air removal and can go directly to the clipping stage. In this case, the muscles will be distributed at random in the finished product.

Cooking

One of the aims of the cooking process is to eliminate the vegetative forms of the microorganisms, but spores are not destroyed. The time required for thermal processing should be equivalent to heating the center for 40–60 min at a constant temperature of 70 °C. The heat coagulates the muscle proteins, gives the finished product consistency and firmness, and binds the muscles together. The red pigment in cured meat (nitrosylmyoglobin) is denatured into the pink pigment characteristic of cooked hams (nitrosylmyochromogen). Endogenous muscle enzymes such as proteolytic and lipolytic enzymes are inhibited and new compounds are formed that contribute to the flavor.

The packaged and/or molded hams are usually placed in cooking trolleys or baskets and cooked in steam cookers or water baths. When using steam cookers it is important to allow a good distribution of the steam; recirculation is advisable in water baths. Water baths are quicker than steam cookers. The forced and diffuse convection cooking/cooling system increases thermal efficiency and homogeneity in temperature distribution and reduces time-consuming processes by performing cooking and cooling in a single location.

Three types of cooking can be used:

- Cooking at a constant temperature: in this case the temperature is maintained constant from the beginning to the end of the thermal processing. The cooking is completed when the center of the ham (core temperature) reaches a defined temperature (between 65 and 72 °C). This is the most common method and gives acceptable results.
- Cooking at increasing temperature can be of two types: step-by-step cooking and Delta-T cooking. In step-by-step cooking, the applied temperature is increased in stages. This type of cooking produces good results, specially in cook-in systems, although the cooking time is longer than in the system using a constant temperature. In Delta-T cooking, the temperature is increased continuously in relation to the increase in temperature at the core of the product (e.g., Delta-T 25 °C, meaning that the cooking temperature in increased to maintain a 25 °C differential). When the cooker temperature reaches a certain value, it is maintained constant, as in the constant-temperature heating method. In this system, overcooking of the surface is minimized and the yield is improved, but the cooking time is longer.
- Cooking at decreasing temperatures begins with a high initial temperature (e.g., 80–90 °C) until the center reaches a predetermined temperature. The temperature is then reduced (to 70–75 °C) for the rest of the cooking process. This process is rapid, but it may result in overcooking of the surface, lower yield, and poor cohesion of the slices.

Cooling

The cooling process is important because it influences the level of pasteurization and can influence the yield and slice quality. At the end of the cooking process, the product is showered with cold water or immersed into water before being transferred to a refrigerated room in order to minimize growth of surviving microorganisms. The time taken to chill the product from 40 to 15 °C is considered critical, and should be restricted to a maximum of 4 h where possible.

Preparation for Marketing

The hams are removed from the molds and vacuum-packed. The product can be recontaminated as a result of the handling in this process. To decrease the surface flora after repacking, thermal processing of the surface (postpasteurization) is advisable. This is not necessary if the hams are cooked in their final packaging (cook-in-ham). The final products should be stored in refrigeration at 2–4 °C until they are supplied to the customer.

Nowadays, cooked hams are often marketed sliced and vacuum-packaged or packaged in a modified atmosphere. In vacuum-packaged ham, plastic film is sometimes placed between slices to ease their separation. The shelf-life depends on the bacteriological characteristics of the final product, the additives used in the brine (e.g., sodium or potassium lactate), and the packaging method. Recently, some companies have begun to treat sliced, vacuum-packed cooked ham at high hydrostatic pressures (>400 Mpa) to increase the shelf-life.

Modified-atmosphere packaging is used to improve the shelf-life of sliced cooked ham and to ensure ease of separation of slices. The gases used are mixtures of nitrogen and carbon dioxide. Oxygen concentration should be reduced less than 0.15% in the headspace to maintain the typical pink color; for this reason it is important to use packaging materials with a low oxygen permeability.

Dry-Cured Ham

J Arnau Arboix, Institut de Recerca i Tecnologia Agroalimentàries (IRTA), Girona, Spain

This article is a revision of the previous edition article by J Arnau Arboix, volume 2, pp 557–562, © 2004, Elsevier Ltd.

Glossary

Bayonne hams Bayonne ham is a 'protected geographical indication' (PGI) dry-cured ham that takes its name from the ancient city of Bayonne in the South West of France.

Iberian ham Iberian ham is a type of dry-cured ham produced in Spain and Portugal. It is made from pure black Iberian pigs or cross-bred pigs, which must be at least 75% Iberian.

Parma ham Parma ham is a 'protected designation of origin' (PDO) dry-cured ham from the Italian region Emilia-Romagna (Parma Province) made from pigs that are born and bred only there. The production is regulated by a quality consortium that recognizes qualifying products with a distinctive label. Curing uses relatively little salt and no nitrate or nitrite is used in the process.

Quick-dry slice The QDS process is an accelerated drying process for sliced meat products that is applied to the sliced product directly after the fermentation step before the long drying phase. This process results in a dramatically reduced total processing time.

Serrano ham Jamón Serrano is a 'traditional speciality guaranteed' (TSG) type of dry-cured ham produced mainly in Spain. The majority of Serrano hams are made from white pigs and should not to be confused with Iberian ham, which is entirely different.

Water activity (a_w) Water activity is defined (for practical purposes) as the ratio of the vapor pressure of water in a material (p) to the vapor pressure of pure water (p_o) at the same temperature. When vapor and temperature equilibrium are obtained, the water activity of the sample is equal to the relative humidity of air surrounding the sample in a sealed measurement chamber. Multiplication of water activity by 100 gives the equilibrium relative humidity (ERH) in percentage $a_w = p/p_0 = \mathrm{ERH}(\%)/100$.

Introduction

The production of cured ham has been established since time immemorial as a process of preservation through salting and subsequent drying. Nowadays, efforts are made to obtain a product with added value that is safe, of high quality, and appreciated for its typical sensory characteristics.

The product quality at the end of the process is influenced by the raw materials and the technological processes. There are various production technologies for cured hams, but the basic aim of all of them is to furnish a product that can be kept at room temperature without jeopardizing health, without the risk of deterioration, and to facilitate the development of the desired sensory characteristics. (Spain, Italy, Germany, and France are the main producers of dry-cured hams. In 2010 the production in the European Union was over 600,000 Tm.)

This article reviews some aspects of the production process and compares different technologies.

Raw Material

Effect of the Quality of Raw Material

The age of the pigs providing the meat has to be taken into account as this can affect, among other things, the activity of the proteolytic enzymes, the color, the amount of fat, and the influence of the muscles on the drying process. It has been shown that meat with a high proteolytic potential is less suitable for the production of dry-cured hams, especially if a low salt content is desired. The selection of the raw material can be improved by evaluation of the activity of cathepsin B, which is one of the proteolytic enzymes thought to be responsible for the development of soft texture. The current methods of production are not adapted for online measurements of proteolytic activity. However, new technologies in the field of molecular genetics, such as genetic markers, show promise for the prediction of the proteolytic activity of the raw material.

The legs of mature pigs are considered to be the most suitable for the production of traditional dry-cured hams, because they have more pigmentation, greater fat content, and less proteolytic potential.

The fat content and the weight of the ham are the main criteria used in the selection of the raw material, and they also determine the processing time of the ham. The weight of green hams ranges from 9 to 14 kg. Whereas in northern European countries consumers prefer lean hams, in some countries in the Mediterranean region there are consumers who prefer a certain amount of intramuscular fat in this product, which prolongs the maturation time; this results in certain sensory characteristics, for which the product is highly valued. In Iberian hams and dry-cured hams that have undergone a long aging process, the presence of interior fat and a certain amount of superficial fat slows down the drying process and impregnates the musculature, so that mastication produces an oily sensation in the mouth and an aged flavor that is highly appreciated (a pleasant flavor associated with the oxidation of the fat). Hams that contain almost no subcutaneous fat must be avoided, as in these hams the salting and drying process in the rind area is greater than in the rest of the ham. This results in a product with a saltier taste, a higher weight

loss, and lower quality, and therefore it is rejected by the majority of consumers.

The pH of the meat is another important parameter affecting the maturation of the ham. For microbiological safety, the majority of authors recommend avoiding hams that have an ultimate pH (pH_u) > 6.2. A pH_u lower than 6.2 also leads to improved salting, a lower percentage of deteriorated hams, fewer appearance problems (such as a shiny appearance of the lean meat and phosphate precipitates), and an undesirable soft texture in the internal part of the ham (when water content is still high), as well as crust development at the lean surface (when water content is low) due to the lower proteolysis at high pH during the aging of ham. This type of problem is greater in larger hams. Furthermore, the pH values in a ham will vary considerably between muscles. Consequently, in order to obtain a pH measurement that is representative of the ham as a whole, it is advisable to carry out the measurement on an external muscle of considerable size, such as the m. semimembranosus. Hams with a $pH_u < 5.6$ show higher proteolysis especially at low salt content and consequently more incidence of pastiness occurs. PSE (pale, soft, exudative) hams absorb more salt than normal hams when dry-cured, which increases the variability in salt content among dry-cured hams.

Elimination of residual blood from the blood vessels of the hams, manually or by mechanical systems, before curing is advisable to reduce possible microbiological problems and to improve the appearance. The best time to carry out this operation is during the cutting process, as the blood is easier to remove. When there is no assurance that this operation has been carried out, it should be done when the raw material is received.

Shape of the Hams and Types of Cut

Cured hams are produced using whole joints or parts of the leg. The whole legs can be presented in different ways. In Spain, presentation with the hoof is common for Iberian and 'Serrano' hams. Parma and Bayonne hams, as well as the majority of the hams that end up boned, are produced without the hoof. The presence of the hoof can reduce the incidence of color fading of the shank, caused by the entrance of air, although the reason for producing hams with hooves seems to be mostly cultural.

In Spain, unlike other countries, it is usual to make a cut in the rind in the shape of a V. Possibly this facilitates the use of the rind and part of the fat for other purposes. In addition, greater standardization of the thickness of the subcutaneous fat is achieved, the retraction of the lean meat is facilitated during the drying process, and the slicing of the ham is also facilitated.

In Spanish hams, the aitch bone is left in, which means that the morphology of the muscles remains intact; in French (jambon de Bayonne) or Italian hams (Parma and San Danielle), this bone is eliminated, leaving a small part ('anchetta') in place in order to avoid cavities that hinder the drying process. The elimination of the bone allows a more rapid absorption of salt and faster water loss, especially in the biceps femoris muscle.

Pieces of ham muscles are used instead of whole hams for the production of jambon d'Ardennes, for Culatello and Fiocchetto in Italy, or bayona in Spain.

In all cases, it is important to avoid damaging the surface structure, as this could lead to the entrance of microorganisms, causing deterioration of the product.

Refrigerated versus Frozen Raw Material

The use of refrigerated raw material is usual in areas where there are abattoirs and cutting rooms in abundance. Frozen hams are often used when long transport is involved because it avoids changes in temperature that could spoil the hams. The use of frozen hams facilitates the absorption of salt on the surface, its migration toward the interior, and probably the diffusion of water toward the outside as well. The use of frozen meat makes the evaluation of the quality of the raw material difficult and facilitates the crystallization of tyrosine, which is formed during the maturation process, leading to a higher number of white crystals on the surface of the hams. If there are many cycles of temperature during the storage process, or if the frozen storage period is prolonged, superficial dehydration of the rind and the lean meat of the ham can occur. This causes surface `freezer burns.' Freezer burns can hinder the salting process and can damage the final appearance of the product. To prevent this, it is advisable to cover the ham with a close-fitting protective plastic film while freezing. To avoid problems with the growth of undesirable microorganisms, it should be ensured that no point of the surface of the ham reaches a temperature above 5 °C during the thawing stage. However, if several days are required to prepare a batch of hams for curing, which is frequent in small cutting rooms with low production capacity, it is preferable to freeze the hams rather than keep them refrigerated for excessively long periods.

Classification Methods

Classification of hams is common practice in most companies. However, if the hams are classified in batches, the individual information of each one is lost. At present, classification systems that identify each ham by means of a bar code or electronic identification are being commercialized. This individual identification signifies an extraordinary advance, as it means that the information on each ham can be stored (supplier, pH, impedance, weight, data, etc.) and it ensures traceability. Moreover, the suppliers can be classified, the return of the hams can be recognized, losses can be more easily standardized, and variability can be reduced.

Salting

Massaging

To facilitate the penetration of curing salts, to eliminate blood that is present in the veins and arteries, and to mold the ham, a massage is carried out with a mixture that contains salt, nitrate, nitrite, ascorbate, and sugars. Although the massaging can be done manually, it is normally carried out continuously by

machines or in drums. In this way, the absorption surface is increased and the penetration of the salt is enhanced. Similarly, moderate pressing done by pressing machines, to reduce the thickness of the hams and to facilitate the penetration of the salt into the deepest internal muscles, is recommended.

Covering in salt must be done as soon as a temperature between 1 and 3 °C is reached in order to inhibit the growth of undesirable bacteria to reduce the percentage of rejected hams at the end of the process due to off-flavors.

Salting Methodology

In Mediterranean countries, the dry-salting process is used; in northern Europe this process is also used, as well as salting in brine. In the dry-salting process, a higher level of osmotic dehydration is obtained, whereas curing in brine reduces the amount of salt, which would have a positive environmental impact.

The dry-salting process can be carried out by two different methods. The hams may be covered with salt. This can be done by individual salting of the hams (San Danielle) or by stacking them in stainless steel containers for a period of approximately 1 day kg^{-1} for the refrigerated hams and 1–3 days less for the frozen ones (typical of Serrano and Iberian hams). The salt has a moisture content of approximately 4–5% to allow correct salting, and the atmospheric humidity is high to avoid drying out and to facilitate the formation of saturated brine on the surface of the ham. The level of atmospheric humidity should not be below 75%, as this results in dehydration of the salt. The stacking of the hams creates pressure, which is especially high in the lower strata, facilitating water loss.

Salting can also be achieved using a quantity of salt that is calculated in proportion to the weight of the ham. The best-known example of this method is for Parma hams, where the relative humidity is maintained between 70% and 75% minimum and 85–90% maximum. With this method, salting of the areas covered in salt is achieved, at the same time allowing the drying of those areas that are not covered with salt. In this case, the hams remain in a horizontal position for a period of 3–4 weeks, which results in the thickness being less than it would be if the hams were left hanging. Penetration of the salt and evacuation of water from the inside is enhanced.

In other cases, the salting takes place in salting drums, with a subsequent resting period in containers, where the hams are in contact with the exuded brine. It is important to perform two applications of salt, so that the parts of the hams that have received little salt during the first treatment are treated again a second time. In this type of process, it is better not to excessively prolong the resting period in containers as the exuded water can be reabsorbed and encourage the growth of undesirable microorganisms in areas that are not covered in brine.

Ingredients and Additives

Salt is essential for the production of cured hams and is the only substance that is permitted for the production of Parma ham. Nitrate is present at very low levels in pork, and has been the preferred nitrifying agent in products for long aging, as it is transformed into nitrite by bacterial action. The cured color due to nitrosylmyoglobine is obtained faster with nitrite than with nitrate, which is preferable in rapid production processes. Ascorbate accelerates the transformation of nitrite into nitric oxide; it prevents the development of greenish discoloration resulting from the reaction of nitric oxide with oxygen, and inhibits the formation of nitrosamines in the lean meat. Zn-protoporphyrin IX complex is the pigment formed during aging that is responsible for the color of hams without the addition of nitrite and nitrate. Sugars, on the one hand, favor the establishment of the surface flora and lend a light, sweet flavor, but on the other they can bring about acidic flavors, when the lactic flora develops in the internal parts of the hams.

Parma hams usually have pepper added to the head of the femur or in the fat that is used to cover the ham, whereas spices are hardly ever added in Spanish Serrano and Iberian hams. For pieces of ham produced by a short-duration process, it is usual to add spices to improve their sensory quality.

Washing

In the past, hams were desalted by immersing them in running water to eliminate the excess salt picked up during the long salting process. However, nowadays, because the temperature can be maintained between 1 and 5 °C during the stabilization phase, it is possible to reduce the quantity of added salt; in the industrial production of Spanish hams, washing is done only to remove any salt crystals remaining from the salting process.

Italian hams are usually washed after the resting period, and at this stage it is possible to maintain a lower water activity at the head of the femur. The washing cleans the ham of slime that has formed on the piece, and phosphate crystals and salt are eliminated. In addition, this method ensures that a later drying process can be accomplished more quickly, because drying is carried out at a higher temperature than can be used after the washing of Serrano hams. In Parma hams the temperature varies from 25 to 28 °C during the first 8 h and is then reduced to 16–20 °C. The relative humidity is approximately 60%.

The use of tepid water allows a more effective washing than the use of cold water. The ideal time to carry out the washing is also determined by the cost of the handling involved and the dehydration capacity of the resting drying rooms.

At the end of the salting process, the blood vessels usually contain a certain amount of brine and it is advisable to perform a light pressing operation to eliminate this, along with any residual blood. By pressing and forming the ham, it is also possible to improve the evenness of the cut of the product. However, this should not damage the ham's structure, which could lead to the entrance of microorganisms that could cause spoilage. At whatever stage the washing is performed, it is always recommended to carry out a quick drying of the lean meat of the ham to prevent the growth of undesirable flora. However, it must be taken into consideration that fast drying reduces the water activity of the surface to values lower than 0.75, which will cause local crystallization of salt. This could lead to drying of the lean meat or cause white-colored stains on the rind and result in deterioration of the appearance.

Smoking

In countries with cold damp climates, hams have traditionally been smoked. The smoke provides the typical smoked color and flavor, increases antioxidant activity and impedes growth of surface bacteria and molds.

Resting Period

The aim of the resting period is to achieve an even distribution of the salt while at the same time achieving a slight dehydration. On the surface of the hams, the flora will be affected by the environmental humidity, and often a growth of molds is observed. In the interior of the ham, Gram-positive, catalase-positive cocci become the dominant flora. At this stage, it is advisable to carry out a more energetic drying during the first and second weeks, as it is important to reduce the surface water activity to impede the growth of undesirable microorganisms that can give the hams a slimy appearance. The accumulated weight loss at the end of this phase usually varies between 10 and 15%.

For a regular drying process, the quantity of water that evaporates must be compensated by the diffusion of water from the inner part to the outer part of the ham. The temperature at this stage must be less than 5 °C until a water activity lower than 0.96 has been reached in all parts of the ham. To avoid whitening of the rind, brought about by the crystallization of the salt, relative humidity above 75% is recommended. Once the majority of the salt from the rind has penetrated through the fat to the lean part of the ham, the relative humidity can be reduced below 75%. This facilitates a slight oil drip of the external subcutaneous fat, which in turn facilitates flavor development.

The duration of the resting period varies according to the size of the piece, the surface of the exterior lean part, the type of trimming, and the intermuscular and intramuscular fat, among other factors. In small hams, a minimum period of 1 month is recommended. For Parma hams it is necessary to prolong this period, sometimes for 3 months, due to the low salt content and absence of nitrite. For Serrano hams this period should be longer than 40 days (In Iberian hams the resting period lasts 2–3 months because of the high fat content, which hinders salt diffusion.).

Drying-Maturation and Cellar Phase

During the drying-maturation phase, the hams continue to dehydrate (e.g., for a minimum of 110 days in the case of Serrano hams), and the processes of proteolysis and lipolysis, which provide the aroma, continue. In Spanish Serrano hams, the temperature is slowly increased from 10 to 12 °C until it reaches a maximum of 28–34 °C, with a relative humidity between 60 and 80%. However, in recent years there has been a decrease in the length of time at high temperature in order to reduce the incidence of hams with a soft texture and a white film, which can be problematic for the selling of sliced products. When the temperature is increased, the fat melts and impregnates the muscle tissue, which provides one of the typical characteristics of Serrano hams.

During this phase, a fine layer of fat is frequently applied to prevent surface cracking, excessive drying, and mustiness, and to slow down the growth of mites. This application of fat can be preceded by washing with water and drying of the ham surface. For long processes, Serrano hams are subjected to a final phase termed the 'cellar phase' at temperatures from 12 to 20 °C and a relative humidity of 50–80% to dry the ham until the desired texture is obtained. This phase begins after the drying period and lasts up to a minimum processing time of 7 months. However, high-quality Serrano hams may have a processing time of up to 18 months.

For Parma hams, the drying phase takes place at a temperature of approximately 15 °C and a relative humidity of approximately 65–80%. After 6–8 months, the drying phase is slowed down as a result of several applications of a mixture of fat, flour (to make the paste more permeable), pepper, and salt. This paste is added several times as the ham becomes drier. Matured hams are stamped with the Parma ham brand after at least 10 months of processing for pieces weighing between 7 and 9 kg, and after at least 12 months for pieces more than 9 kg; pieces less than 7 kg cannot be branded (After the resting period, Iberian hams are kept for approximately 90 days in a chamber where the temperature is slowly increased until reaching 18–20 °C. Subsequently, the temperature is again slowly increased for a period of approximately 1–1.5 months until it reaches approximately 30 °C with a relative humidity of 60–80%. Finally, the hams are held for 12–18 months at temperatures ranging from 10 to 22 °C and with relative humidity of 65–80%.).

The Development of New Quick-Maturation Products

To obtain quicker maturation processes, it is necessary to accelerate the movement of the salt toward the inside and of the water toward the outside of the ham. This can be achieved by eliminating the fat (subcutaneous and intermuscular), injecting a brine, and reducing the thickness of the pieces by pressing. For sliced products, the slices can be dried by the Quick-Dry Slice System in a period of only 30–60 min when the salt content is uniform in the whole piece.

For whole pieces, if the original structure of the ham is not maintained, microorganisms can grow inside the hams. This causes acidification of the product or development of an odor that is typical in fermented products. To ensure a good final aroma of the product, it is necessary to select the raw material properly (reject dark, firm, dry (DFD) and boar-tainted hams and use slightly marbled hams). During production, the final aroma can be influenced by the addition of flavorings, spices, and/or smoke, the use of a selected microbial flora, and optimization of the relative humidity at the different stages of the aging process.

Commercial Presentation

The commercial presentation of dry-cured ham has traditionally been as whole pieces. However, in recent decades there has been an increase in the selling of boned and vacuum-packaged products. Vacuum-packaging facilitates the slicing process and even texture of the ham, and prevents problems with mites or excessive drying. Prolonged vacuum packaging causes

re-moistening of the surface, which can result in an unpleasant aroma. If the water activity is high, undesirable microorganisms can proliferate; in this case, it is necessary to keep the product refrigerated or to freeze the vacuum packages. Although the storage of hams by freezing permits the preservation of the flavor for long periods and slows down the formation of white film in sliced products, it also facilitates the formation of white crystals. Freezing of unpacked pieces causes a loss of volatile substances, which decreases the aroma of the product.

Before slicing, hams are partially frozen in order to obtain a uniform texture to facilitate the cutting process. To increase the ham microbial stability, high-pressure treatment at 400–600 MPa may be applied to hams packaged under vacuum or in modified atmosphere with flexible packaging.

Packaging in a modified atmosphere allows a more natural presentation of the slices as it reduces their adhesion as well as the waxed appearance of slices typical in vacuum-packaged hams. To prevent the deterioration of color and aroma, the gas mixture must not contain oxygen. The gas most frequently used is nitrogen, although carbon dioxide can be useful to improve the shelf-life of hams with high water activity. The plastic used must be high barrier type to prevent the gas mixture being altered. In this type of packaging, abrupt change of temperature must be avoided, as this can result in condensation on the inside of the packaging, causing a local increase in water activity and a reduction of the microbial safety of the product.

HAZARD ANALYSIS CRITICAL CONTROL POINT AND SELF-REGULATION

S Eglezos, Niche Food Microbiology Pty Ltd., Brisbane, QLD, Australia
GA Dykes, Monash University, Bandar Sunway, Malaysia

This article is a revision of the previous edition article by M Upmann, P Jakob, volume 2, pp 547–557, © 2004 Elsevier Ltd.

Glossary

Failure mode and effects analysis (FMEA) A procedure that involves reviewing as many components, assemblies, and subsystems of a process as possible, to identify failure modes and their causes and effects.

FAO/WHO Codex Alimentarius Commission The Codex Alimentarius Commission harmonizes international food standards, guidelines, and codes of practice, to protect the health of consumers and ensure fair practices in food trading.

Good manufacturing practices (GMPs) A system for ensuring that all aspects of production, from the starting materials, premises, and equipment to the training and personal hygiene of staff, meet with recognized standards.

Hazard analysis and critical control point (HACCP) system A systematic approach to identifying biological, chemical, and physical factors in production processes that can give rise to health hazards in finished products; and to implementing measures to reduce the risks from the identified hazards to acceptable levels.

Introduction

Terms, such as self-regulation, self-control, and quality assurance, are widely used to indicate ways in which food manufacturers take responsibility for the safety of their products. In recent years, food laws in many countries have been amended to require companies to take a systematic approach to self-regulation, to ensure the hygienic/toxicological status of food products is safeguarded. Many management systems for safeguarding the quality and safety of outputs from manufacturing facilities have been devised. Total quality management (TQM) is a well-established, wide-ranging management approach that is applied horizontally across an operation and extending backward and forward to include both suppliers and customers. TQM is only one of many systems that focus on quality. Other systems include continuous quality improvement, statistical quality control, quality function deployment, quality in daily work, and fault tree analysis (FTA). FTA, for example, is a top-down deductive failure analysis system which, like many top-down systems, might identify only major failure modes in a system because it does not systematically identify many lower level causes and failures or incorporate them within a preventive framework. Three types of systems commonly used by the food industry for the purpose of ensuring product safety are good manufacturing practices (GMPs), hazard analysis critical control point (HACCP) systems, and failure mode and effect analysis (FMEA). GMP systems have been used for many years and often provide a basis for more recent systems. HACCP systems are widely regarded as the preferred means of ensuring food safety; implementation of HACCP systems for food production processes is now required by many regulatory authorities. FMEA is a more recently developed system that is increasingly seen as having application for assurance of food safety. The aim of all of these systems is to prevent, and counteract when necessary, loss of control over product quality that could lead to consumer illness. Each of these systems will be described and their application illustrated by reference to a process for production of Vienna sausage (Figure 1).

Self-Regulation

Good Manufacturing Practices

GMPs are general rules for the safe production and handling of food products, including meats. The principles of GMP, developed over a number of years, provide a foundation on which the production of safe food is based. To be successful, any quality assurance system implemented in a meat processing plant must adhere to the fundamentals of GMP.

Although GMPs are not product- or process-specific, they can be adapted to provide detailed instructions for handling food items. GMPs appropriately modified for different kinds of food, and different steps in food production chains,

including those related to meats, are available as guidelines from various professional organizations and associations. In addition, numerous product-specific legal regulations specify GMPs, especially those with relevance to meat production and trade. Both the Codex alimentarius commission and the United States Food and Drug Administration have published collections of GMP-based regulations for food.

Basic information and documentation

In GMP systems, as for other self-regulatory systems, records of all manufacturing and controlling activities must be maintained, so that the methods of control can be assessed for appropriateness and, when possible, improved. These records also provide a basis for establishing external quality credentials and for quality audits.

Documentation should record at least the type and volume of production; staff, with identification of functions, responsibilities, and working relationships; a list of contractors providing services, such as cleaning; and a list of suppliers. Building plans of the working area, in which water supply and sewage pipes, temperature zones, clean and unclean processing areas, product flow, and personnel routes are identified, which are also required. A detailed process flow diagram of the type shown in Figure 1 must be available for every product. This basic documentation should be integrated with or used with other systems of quality control, such as

ISO 9001 quality management systems, HACCP systems, or FMEA.

Fundamental requirements

Fundamental requirements for GMP are related to control of structural, environmental, and personnel resources. The production of wholesome and safe food requires a sanitary processing environment. Therefore, companies must follow appropriate rules for design, utilization, and maintenance of facilities and equipment. Generally, buildings should be sufficiently large and constructed in ways that facilitate not only sanitary processing but also cleaning and sanitizing procedures. Personnel and material flows must be arranged so that manufacturing areas do not become thoroughfares. Cleaning and sanitizing procedures must be carried out as often as is necessary according to a documented cleaning and sanitation plan (Figure 2). The cleanliness of the facility must be checked daily, by visual inspection, before production starts (the so-called preoperation checks) as well as microbiologically at intervals appropriate to the facility's production capacity. Furthermore, pest control measures must be used and their efficacy must be regularly checked and recorded. Rules for the health, cleanliness, training, and supervision of personnel must be developed and maintained. Rules for waste storage, treatment and removal, water supply, and wastewater removal must be implemented.

Manufacturing conditions

Implementation of GMP requires procedures to ensure the appropriateness of raw materials and ingredients entering the facility. To achieve this, material specifications should be detailed and material checks should be performed at delivery to establish compliance with the specifications.

All manufacturing operations should be performed in ways that prevent product contamination as far as possible. Written standard operating procedures for each operation should be prepared. Flow diagrams for processes are very useful, because these are easy to understand. Instructions for processing operations must identify factors that might affect product safety as well as measures that should be taken when misprocessing occurs. All food-handling activities, from raw material delivery to packaging, labeling, and distribution, must be covered in a GMP system.

Adjuncts to good manufacturing practice

A facility's documented GMPs can be augmented by adjunct control systems. Some definition of an adjunct control system is needed. For example, *Listeria* that persist in chillers and

contaminate ready-to-eat meats can be controlled by use of a chiller heat treatment as an adjunct to an existing GMP program. For GMP adjuncts to be effective, a multidiscipline approach needs to be taken at the facility level. Engineering, operations, and quality assurance personnel need to be involved in the planning as well as the implementation of adjunct systems.

Hazard Analysis Critical Control Point Systems

HACCP systems are used to identify, evaluate, and control hazards that are significant with respect to food safety. HACCP is a concept of science-based control of hazards that might arise during processing. HACCP systems are both product and process specific. This specificity makes it almost impossible to transfer a HACCP system developed for one product or processing line to another without modification. The HACCP concept has been adopted by the FAO/WHO Codex Alimentarius Commission. It is considered to be the quality management tool applied in food production that is most effective for systematically safeguarding the hygienic and toxicological quality of food.

Approach to implementation

The principles of HACCP require examination of every single product in detail (i.e., they are product specific) and matching of the principles to the actual production process (i.e., they are process specific).

Seven principles must be applied when establishing and maintaining a HACCP system (Table 1). Application of the principles requires detailed and documented knowledge of the production processes in question. Each principle includes a number of subprinciples.

Table 1 Stages in the implementation of hazard analysis and critical control point (HACCP) concepts according to the principles given in Alinorm 97/13 A

Alinorm principle no.	*HACCP implementing procedure: Product and process description*
1	*Hazard analysis* ● Hazard identification ● Risk assessment
	Risk management 1. Prevention analysis
2	a. Determine critical control points (CCPs)
3	b. Establish critical limits
	2. Create process monitoring system
4	a. Establish monitoring procedures for CCPs
5	b. Establish corrective actions when monitoring indicates that a particular CCP is out of control
6	c. Establish verification procedures to confirm that the HACCP system is working effectively
7	d. Establish a documentation system concerning all procedures and records appropriate to these principles and their application

Source: Reproduced from Codex Alimentarius Commission, 1997. General Principles of Food Hygiene. Supplement to vol. 1B, Revision 3. Rome: Food and Agriculture Organization of the United Nations and World Health Organization.

Company requirements

Before implementation of HACCP, some organizational requirements have to be fulfilled. A clear commitment by the management to implement HACCP is required. The HACCP team should together have comprehensive knowledge of relevant fields, such as epidemiology, chemistry, microbiology, toxicology, processing technology, veterinary medicine, and quality management.

Product and process description

A detailed description of all products and technological processes to be included in the HACCP system is required. For a single product, the description must include the formula and ingredient specifications, as well as a detailed description of all process parameters. Companies developing a HACCP system will benefit from existing documentation for a GMP and quality management system. The product's intended use, its target market, and its distribution must be detailed.

Hazard analysis

A hazard is defined as 'a biological, chemical, or physical agent in; or conditions of food with the potential to cause an adverse health effect.' All possible occurring hazards should be listed, including those inherent in the ingredients as well as those derived from the processing environment. A hazard must be designated specifically. General terms like 'pathogenic microorganisms,' 'foreign bodies,' or 'heavy metals' are not sufficient.

After hazard analysis, a risk assessment must be performed. Not all hazards are equally important as some occur often, others seldom; some cause severe illness, others are associated with only mild symptoms; and some are distributed worldwide, others are regional. The probability of each hazard's occurrence (i.e., the risk) varies depending on a broad range of factors, such as its innate characteristics (e.g., growth requirements of microorganisms and reactivity of chemicals), consumers' eating habits, sensitivities and health, the rates of exposure, and the maximum damage to health that might be caused. Unfortunately, epidemiological studies are lacking for many hazards, and statistical data are often limited. Frequently, only a rough estimate of the real situation is feasible; but this is often sufficient for HACCP risk assessment purposes. Risk assessment should allow the hazards list to be reduced to only hazards relevant to the product in question. As an example, for the Vienna sausage production process, an outline characterization for HACCP purposes of the hazard *Salmonella* spp. and evaluation of its relevance to the process is shown in Figure 2.

Risk management

After risk assessment, the frequency and degree to which each relevant hazard can occur must be assessed at every step of the process. Points at which the process can be controlled to reduce the hazard's probability of occurrence and magnitude in the finished product (i.e., the hazard can be prevented, eliminated, or reduced to an acceptable level) are called critical control points (CCPs). Decision trees have been developed to assist with the CCP identification procedure.

A proper identification and exploitation of CCPs requires:

- detailed knowledge of the processing technology;
- detailed knowledge of the hazard characteristics;

- the possibility of establishing a critical limit for safe operation for at least one process parameter (i.e., principle 3);
- the possibility of continually monitoring the critical process parameter (i.e., principle 4); and
- the possibility of adjusting the process on-line (i.e., principle 5) to prevent production of unsafe product.

Table 2 Characterization and judgement of the relevance of the hazard '*Salmonella* spp.' in a hazard analysis and critical control point concept for Vienna sausage production

Hazard characterization		
Disease		
Occurring worldwide		
Very common (epidemic)		
Serious incapacitation with moderate duration Symptoms		
	• Nausea	
	• Stomach cramps	
	• Vomiting	
	• Diarrhea	
	• Fever	
Mostly not life threatening		
	• Fatality rate $<1\%$	
	• Fatality rate for young and elderly: *Salmonella enteritidis* in hospital/nursing homes outbreaks approximately 4%	
Sequelae infrequent		
	• Reactive arthritis (Reiter's syndrome) in $<2\%$ of the cases	
Infectious dose		
	• <100 cells, depending on strain virulence, health status, and age of host	
Potential control measures[a]		
	• Temperature >55 °C	
	• pH value <3.8	
	• Water activity <0.94	
	• Preservatives (e.g., *D*-value propionic acid 0.5 mol l^{-1}: 0.8 h)	
	• Irradiation (*D*-value: 0.5–1.1 kGy)	
Occurrence during Vienna sausage production (**Figure 1**)		
No.	*Processing step*	*Source*
1	Preparing/weighing raw material	Pork: approximately 10% positive Beef: approximately 3% positive
6	Slow cutting	Spices: approximately 5% positive
All	Generally during manipulation	Persons: intestinal carrier rate up to 5%
Conclusion: *Salmonella* spp. = relevant hazard		

[a]Deviations might occur owing to summation and differences between strains.

For example, when applying these requirements to the control of *Salmonella* spp. in Vienna sausage production, the cooking step (processing step 12) can be identified as a CCP because the cooking temperature of 72 °C exceeds the minimum temperature of 55 °C needed for *Salmonella* destruction (**Table 2**). Establishing critical limits for cooking temperature and time requires knowledge of the rates of inactivation of *Salmonella* spp. at temperatures attained during cooking. According to **Table 3**, the minimum thermal treatment needed for adequate destruction of salmonellae would be 45 s at 70 °C. Product heated for shorter times or to lower temperatures must be regarded as unsafe with respect to salmonellae.

The procedure described above is repeated for all hazards recognized as relevant to identify a number of CCPs. Not all identified hazards are necessarily controllable without changing the process. Sometimes additional measures are needed to control a specific hazard. An example is the insertion of metal detectors in a processing line to allow items containing metal objects or fragments to be identified and removed.

If more than one hazard can be controlled at the same CCP, the most rigorous of the critical limits for the hazards must be adopted. With respect to Vienna sausage production, elimination of *Listeria monocytogenes* requires a cooking time of 1 min at 70 °C provided that the contamination level is the same as for salmonellae. Therefore, for safety with respect to both *Salmonella* spp. and to *L. monocytogenes*, the products should be cooked to a minimum core temperature of 70 °C for at least 1 min.

Monitoring procedures that are related to the critical limits for CCPs should then be introduced. It is necessary to list the

Table 3 Practicable approach for establishing critical limits for the cooking process for control of *Salmonella* in a hazard analysis and critical control point system for Vienna sausage production

Establishing critical limits		
Estimated requirements		
• Estimated contamination level of sausage meat: <100 cells g^{-1}	$\geq$100 000-fold reduction ($=10^{-5}$) of *Salmonella* cells required	
• Security factor: 1000		
Destruction of Salmonella spp.		
Thermal sensitivity of Salmonella senftenberg (most heat-resistant strain)[a]:		
• 10-fold reduction in cell numbers within 0.15 min at 70 °C, D_{70}: 0.15 min		
Critical limit		
Required core time–temperature combination for 100 000-fold reduction:		
• Minimum 45 s (5×0.15 min $= 0.75$ min) at 70 °C		
Actual process parameters		
No.	*Processing step*	*Actual process parameter*

[a]In glucose solution of water activity 0.98 and pH 5.5–6.2.

process parameters to be checked, the methods to be applied, the frequencies of monitoring each parameter and who is responsible for the monitoring. Monitoring of the Vienna sausage production process should include a continuous time–temperature surveillance system, ideally with automatic regulation of cooking (see principle 5). Monitoring is only useful when appropriate actions follow detection of deviation from the critical limit, as required by principle 5.

Principle 6 requires that effective working of the HACCP system is verified. This includes measures, such as periodic checks of monitoring equipment calibration, laboratory testing of product, and collection of data that confirm the absence of hazards. Onsite auditing procedures can be used for verification.

As with other self-regulation and quality management systems, HACCP systems require documentation (principle 7). This must include basic descriptions of the products and processes covered by the system, a list of hazards dealt with, a list of CCPs where hazards are controlled and a monitoring plan that specifies the critical limits, corrective measures, and verification procedures.

Failure Mode and Effect Analysis

FMEA is generally performed during product development to avoid costly failure during full-scale processing. FMEA is widely used in the nuclear, aviation, and automobile industries. Its use in the food industry is currently limited, but growing.

Practical approach

FMEA is used to assess the significance of potential product failures and to identify appropriate measures to prevent them. Issues identified by FMEA lead to immediate and specific actions. Two types of FMEA can be distinguished:

- A 'product FMEA' regards each raw material as a potential source of failure. The consequences of the failure with respect to end product safety and quality are identified and evaluated.
- A 'system FMEA' looks for weak points in the production process. A step-by-step approach is used to identify and evaluate potential causes of product failure.

As for other self-regulatory systems, FMEA requires a detailed description of the product and the processing technology.

Structured failure analysis

A failure analysis is usually present in the form of a table. By following the processing line, stepwise potential failures and their resulting effects as well as their potential causes are identified. Thus, for the Vienna sausage production process, the FMEA can be represented as in Figure 3.

The potential 'failure' of undercooking the product will cause softness, discoloration, and color instability as well as reduced storability due to microbial spoilage. In addition, pathogenic microorganisms might survive to pose health risks for consumers.

P: Production

Figure 3 Excerpt from a FMEA for Vienna sausage production.

Table 4 Classification system for assessing the probability of occurrence (O), the importance (I) to consumers, and the probability of detection (D) in failure mode and effect analyses

Risk assessment no.	*O*	*I*	*D*
1	Unlikely	None	High
2	Very low	Minor	Moderate
3	Very low	Minor	Moderate
4	Low	Medium	Moderate
5	Low	Medium	Moderate
6	Low	Medium	Low
7	Moderate	Serious	Low
8	Moderate	Serious	Low
9	High	Very serious	Very low
10	High	Very serious	Unlikely

Risk assessment

The significances of failures are evaluated based on their probability of occurrence (O), their importance (I) with respect to the client, and their probability of detection (D) before distribution of the product. These parameters are assessed on scales from 1 to 10 (Table 4).

In Vienna sausage production, the lack of water might result in the product being undercooked. This might occur with moderate frequency, for which a risk assessment number of seven would be appropriate. The consequences for consumers, however, might be very serious because of the survival of pathogenic microorganisms. The risk assessment number for client importance is then 10. Although marked undercooking will be detected through deviations in consistency, borderline cases might be difficult to detect so, the risk assessment number for the probability of detection is six.

The three risk assessment numbers (O, I, and D) are multiplied together resulting in a risk priority number (RPN), which indicates a failure ranking within the potential failure list. For Vienna sausage production, lack of water results in a RPH of 420. High RPNs indicate a need for urgent action to improve control in this area.

Optimization measures

After assessment of the potential risk of failure, measures are suggested that will optimize the processing conditions for control of potential failure. This might be achieved by reduction of one or more of the probability of occurrence or detection, or of the importance to clients. Ideally, all three parameters should be reduced. Suggested improvements are identified, and responsibilities and schedules for implementation are developed. To determine the effects of the measures, a new RPN is calculated using the reduced O, I, and D numbers.

For Vienna sausage production, there is a high probability that the lack of water will be detected by installation of a water level alert system. This should be done by technical support staff by a fixed date. Although neither the risk of occurrence of the failure nor its importance to consumers will be changed, the RPN is reduced to 70 because of the high probability of detection ($D=1$). Performing the same procedure for all processing steps will result in a process optimized with respect to safety and quality.

Future Prospects

As responsibility of food manufacturers for the safety of their products increases, self-regulatory systems that effectively control food safety risks will undoubtedly be applied to a greater extent. Cooperation between food processors and food inspection authorities will be needed for the systematic application and implementation of these systems.

The systems described here, namely GMP, HACCP, and FMEA are only a small selection from the large number of quality management tools potentially applicable for safeguarding food. Because some concepts are complex, food processors should initially only use a single, well-understood concept, and should seek expert advice. In addition, implementation should begin with a single product or process and take account of only a limited number of control parameters or hazards. All self-regulation systems must grow progressively.

Glossary

Carcinogenesis The collection of processes that allow cells to undergo uncontrolled cell division and prevents the normal removal of damaged cells, resulting in cancer formation.

Heterocyclic amines (HCAs) A class of chemicals that include compounds that are formed during high temperature or open-flame cooking of meat.

Mutagens The chemicals capable of causing deoxyribonucleic acid mutations.

***N*-Nitroso compounds** These compounds include nitrosamines produced from heme-iron and nitrates in meat in the presence of an acidic environment (e.g., processed meat or in the stomach).

Polycyclic aromatic hydrocarbons (PAHs) A family of chemicals which can be produced during high-temperature cooking of meat, for example, while grilling.

Introduction

The morbidity and mortality associated with cancer is a major health concern in most of the world, with the primary sites of cancer being dictated based, at least in part, on where individuals live and/or their socioeconomic status. In the USA, one in four deaths is attributed to cancer, even though the incidence rates over the last 5 years in which data are available (2004–08) has remained stable in women or has decreased slightly in men. Even though incidence rates are not increasing, approximately 1 660 290 new cases of cancer are expected to be diagnosed in 2013, which does not include noninvasive cancers (except bladder) or basal and squamous cell skin cancers. More importantly, long-term projections that include the impact of aging population suggest that by 2030 there will be 2.3 million cases of cancer in the USA, which is a 40% increase above current estimates.

The transition from normal tissue into a cancerous tissue involves multiple stages – from the initiating event that causes genetic mutations to promotion of cell transformation and the final stage of progression during which the potential for metastasis develops. Initiators of the transformation process include those factors which are capable of causing deoxyribonucleic acid (DNA) mutations, such as radiation, viruses, and chemicals. However, a single mutation is not sufficient to cause a cancer. Multiple insults must occur before sufficient modifications to the DNA exist for cells to attain the capacity for tumor development. These changes eventually allow cells to escape normal controls on growth and proliferation, which is characteristic of all known neoplasms. The eventual tumor mass that forms contains a variety of cell types, all of which contribute to an environment capable of supporting carcinogenesis and the eventual capacity for metastasis to other sites.

Several experimental approaches have been used to determine factors that might be involved in promoting or reducing cancer incidence. Among them are population studies that attempt to understand the disparities in cancer rates observed in various regions of the world. Others monitor cancer incidence rates among genetically identical groups that migrate from areas of low incidence to a part of the world with higher rates of specific cancers. All these approaches have

 doi:10.1016/B978-0-12-384731-7.00176-8

demonstrated that environment is a major contributor to cancer development. Aspects of the environment that have been linked to carcinogenesis include chemical exposures, radiation, pollution, infectious agents, tobacco use, and diet.

Diet and Cancer

Approximately one-third of the cancer deaths predicted during 2012 were linked to overweight, obesity, physical inactivity, and poor nutrition, suggesting that modifications to these characteristics and environmental inputs would contribute to a reduction in cancer deaths. A systematic review of the literature performed by an expert panel convened by the World Cancer Research Fund (WCRF) and the American Institute for Cancer Research (AICR) determined the relationships between meat and cancer overall and importantly, defined the relationships between meat intake and specific cancer types. This systematic review found that there was convincing evidence that red meat and processed meats contributed to increased risks of colorectal cancer. Limited evidence was found to support an increased risk of cancers in the esophagus, lung, pancreas, and endometrium with red meat consumption and for esophagus, lung, stomach, and prostate cancer with processed meat consumption. The group also found evidence to suggest a probable increase in risk for cancer of the nasopharynx with consumption of Cantonese-style salted fish. Data were only suggestive for the link between iron-containing foods and an increased risk of colorectal cancer and between smoked meats or meats that were grilled or barbecued and stomach cancer. Limited evidence exists to suggest a decrease in colorectal cancer with the consumption of fish or foods containing vitamin D. More recent analyses and reviews have also found evidence to suggest that diets with greatly elevated intakes of meat, extensively cooked red meat in particular, may be associated with an increased risk of some forms of cancer.

As the strongest evidence for a link between meat intake and cancer incidence is found for colorectal cancer, a greater extent of discussion will occur for this cancer. However, a discussion of data for other cancer sites will be presented as well. Processing of meats, such as salting, smoking, curing, and the addition of preservatives, as well as the methods used for cooking contribute to chemical exposures that may promote carcinogenesis. As a result, a presentation of the compounds developed during meat processing and/or cooking and their potential for contributing to carcinogenesis is provided.

Cancer Sites

Colorectal Cancer

When the data are combined for men and women, there will be an estimated 102 480 new cases and 50 830 deaths from colon cancer in the USA during 2013. The WCRF/AICR review found that red meat, processed meat, body fatness, abdominal fatness, and alcoholic drinks ($>30\ g\ day^{-1}$ in men) produce the most convincing link with colorectal cancer. The consumption of alcoholic drinks by women is probably linked with colorectal cancer, and there is limited, but suggestive, evidence of a relationship between consumption of foods containing iron, animal fats, or sugars and colorectal cancer. There are also limited data to suggest that consumption of fish may protect against colon cancer, whereas the data to support a link between consumption of poultry, total fat, and cholesterol and colon cancer are insufficient to support a conclusion. Inclusion of additional studies in the continuous update project by WCRF/AICR led to a relatively reduced risk of colon cancer with elevated red and processed meat consumption, but the relationship remained. One of the studies used in the continuous update report was from the UK Dietary Cohort Consortium, where mean intakes of meat were relatively low ($38.2\ g\ day^{-1}$ for men and $28.7\ g\ day^{-1}$ for women). This study found little evidence for an association between the consumption of red meat, processed meat, poultry, white fish, or fatty fish and colon cancer. A paper published after the continuous update project reports on the relationship between red meat intake and the risk of colon cancer in Japan, a population who also has a low intake of red meat (median $=46\ g\ day^{-1}$ for men and $43\ g\ day^{-1}$ for women). An increased risk of colon cancer was found with the highest level of red meat intake in women and the highest intake of total meat in men. This group found no association between colon cancer and the intake of processed meat. These observations suggest that red meat might induce a modest increase in the risk of colon cancer among populations consuming otherwise low levels of red meat, but as the level of intake approaches that observed in Westernized cultures, the risk of colon cancer is increased. Part of the relationship is more likely due to the confounding effects of increased body and abdominal fatness that are prevalent in those who are consuming diets with elevated energy densities and reduced level of foods thought to protect against colon cancer, for example, fruits, vegetables, and whole grains that contain high levels of dietary fiber and chemopreventive bioactive compounds.

As mentioned earlier, processing, both for preservation purposes and for cooking, has the potential to incorporate or develop mutagens and carcinogens in meat. The components of fresh meat that may promote carcinogenesis include fat, protein, heme iron, and the mutagens developed during high-temperature or open-flame cooking – heterocyclic amines (HCAs) and polycyclic aromatic hydrocarbons (PAHs). The HCA found in meat include 2-amino-3,8-dimethylimidazo [4,5-f]quinoxaline (MeIQx), 2-amino-3,4,8-trimethylimidazo [4,5-f]quinoxaline (DiMeIQx), and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP). The most prominent PAH in meat is benzo(a)pyrene (BaP). Processed meats also contain these compounds as well as added nitrite, nitrate, and salt. One class of potential carcinogens formed in the gastrointestinal tract is *N*-nitroso compounds, which can be formed from heme iron and nitrite. The relative risks of colon cancer are typically higher with consumption of processed meat than with fresh meat, although this observation is not true for all studies. The disparity between studies may be due to designs that combine fresh red meat and processed meats into a single red meat category, as opposed to determining their independent effects. One animal study found that nitrite-treated cured meat increased formation of early lesions of colon cancer and the effect occurred in parallel with an increase in fecal levels of total *N*-nitroso compounds.

Esophageal Cancer

Although the estimated incidence rate in 2013 for esophageal cancer was relatively low (17 990 new cases) in the USA, the estimated number of deaths from this cancer was high (15 210). The most convincing relationships between cancer of the esophagus and diet found in the WCRF/AICR review was with elevated body fatness (due to excess energy intake and/or reduced physical activity) and alcoholic drinks. At the time of that review, there were limited data to establish a link between red meat or processed meat and esophageal cancer incidence. However, subsequent publications have found positive relationships (odds ratios of 1.79–3.15 for the highest red meat intake) between red meat intake and esophageal cancer incidence. Analysis of data from the large NIH-AARP Diet and Health study detected a positive association between red meat intake and squamous cell carcinomas in the esophagus, but this study did not detect a relationship between BaP, nitrate, or nitrite consumption and cancer incidence. Another study conducted in Ireland found an increased risk of esophageal cancer in subjects with elevated intakes of total, saturated, and monounsaturated fats and fresh red meat intake. Together, these results suggest that a dietary pattern containing an excess of total and saturated fats and diets enriched in animal-based foods and low in plant foods may promote cancer in the esophagus.

Stomach Cancer

According to current estimates there will be 21 600 new cases and 10 990 deaths from stomach cancer in the USA in 2013. Although an infection with the bacterium *Helicobacter pylori* is prevalent in most cases of stomach cancer, it is thought that the incidence rate of stomach cancer can be reduced through dietary means. The WCRF/AICR review found the most convincing links between stomach cancer and diets that include elevated intakes of salt and salted or salty foods. There is only limited evidence suggesting an increase in risk with elevated intakes of chili, processed meats, smoked foods, and grilled or barbecued meats; moreover, there is limited evidence linking the consumption of unprocessed meats and stomach cancer. One recent study found no association between processed meat, nitrate, nitrite, or BaP intake and stomach cancer, yet the study did note an increase in stomach cancer with the highest intake of DiMeIQx.

Pancreatic Cancer

Overall, pancreatic cancer incidence rates are relatively stable, but there will be an estimated 45 220 new cases and 38 460 deaths from this disease in the USA in 2013. The most convincing link between pancreatic cancer and lifestyle is an increase in body fatness. However, in the WCRF/AICR review, there was only limited evidence to suggest a link between red meat consumption and pancreatic cancer. Recent data suggest that pancreatic cancer may be linked with the consumption of well-done meat that has been cooked at high temperatures, which is more likely due to the elevated levels of mutagens (MeIQx and DiMeIQx) produced with this form of cooking.

Kidney Cancer

In the USA, there will be an estimated 65 150 new cases of kidney cancer and 13 680 deaths in 2013. The most convincing evidence for an enhanced risk of renal cancer is associated with elevated body fat. The data linking meat consumption and kidney cancer were deemed insufficient to support a conclusion by the WCRF/AICR review team. However, data from a case-control study provide some evidence to suggest that the polycyclic hydrocarbon BaP formed during barbecuing is associated with an increase in kidney cancer. Interestingly, that study found a negative relationship between broiled meat intake and kidney cancer and found no association between total or individual meat types and kidney cancer incidence. These observations suggest that cooking style, and the formation of BaP, is more likely to be the base of the relationship rather than meat itself.

Bladder Cancer

Bladder cancer occurs more frequently in men than in women, and in 2013, there will be an estimated 54 610 and 17 960 new cases and 10 820 and 4390 deaths in men and women, respectively. The WCRF/AICR review concluded that there was insufficient evidence to support a conclusion concerning the association of any food and bladder cancer risk. Two newer studies have produced conflicting results, with the large European Prospective Investigation into Cancer and Nutrition study finding no association of meat, nitrosamines, or heme iron intake on bladder cancer. In contrast, data from the NIH-AARP Diet and Health Study found modest support for a positive relationship between the consumption of dietary nitrate or nitrite in processed meat and bladder cancer, as well as a borderline significance for the relationship between both red meat and PhIP intake and bladder cancer.

Lung Cancer

The most prevalent form of cancer in the USA is lung cancer, with 228 190 new cases and 159 480 deaths being estimated to occur in 2013. Fruits, as well as foods containing carotenoids, are probably capable of reducing the incidence of this disease. Although the evidence is limited, data suggest a positive relationship between lung cancer and the consumption of high levels of red meat, processed meats, and total fat. Outcomes from the European Prospective Investigation into Cancer and Nutrition suggest that no relationship exists between consumption of red meat, processed meat, white meat, or fish and lung cancer incidence. A study of Chinese women who had never smoked found that there was no association between lung cancer and the consumption of processed meats or heterocyclic amines and lung cancer. In this population, most of the meat consumed (72%) was white meat (chicken or fish) and they did note an inverse relationship between consumption of meat (total) or fish and lung cancer, suggesting white meat or fish consumption may be protective against lung cancer in those who have never smoked.

Endometrium Cancer

In the USA, the estimated number of new cases and number of deaths from endometrial cancer in 2013 are 49 560 and 8190, respectively. The most convincing and probable evidence for factors with an association to endometrial cancer risk are body fatness and abdominal fatness, respectively. The most recent publication describing the relationships between meat consumption and endometrial cancer was based on the Canadian Study of Diet, Lifestyle, and Health prospective cohort. This study found a nonsignificant increase in the risk associated with increased consumption of red meat, processed meat, and all meat combined. However, there were no clear associations found with poultry or fish consumption.

Breast Cancer

Breast cancer is the most frequently diagnosed cancer in women, with the exception of skin cancer. In 2013, there will be an estimated 232 340 new cases of invasive breast cancer diagnosed in women and 2240 in men, and 39 620 women and 410 men will die from the disease. The factors identified as having the greatest impact on breast cancer risk are consumption of alcohol, body fatness, adult attained height, with abdominal fatness, and adult weight gain having a probable role in an increased risk of breast cancer. Conclusions derived by the WCRF/AICR review, as well as the continuous update project by the same group, indicate that there are limited data to suggest a relationship between red meat or processed meat and breast cancer incidence. Studies since that review have found marginal increases in risk of breast cancer among postmenopausal women and total meat intake, whereas others have suggested no association. An evaluation of the relationship between meat, meat mutagens, and iron and the risk of breast cancer in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial failed to find a dose response relationship for red meat, processed meat, or heme iron. The most recent review of the literature concluded that red meat and processed meat intake were not associated with an increased risk of breast cancer, but the author cautions that effect modifiers, such as hormone receptor status in the breast, should be considered in order to determine whether these factors would influence the lack of association.

Prostate Cancer

Prostate cancer is the most frequently diagnosed cancer in men and is the second leading cause of death from cancer in men. In 2013, there will be an estimated 238 590 new cases and 29 720 deaths from prostate cancer in the USA. There is limited evidence to suggest that processed meats are associated with an increase in prostate cancer. It is more likely that the nitrates, nitrites, and salt found in processed meats may contribute to prostate cancer. Two studies published after the WCRF/AICR review have demonstrated an increase in aggressive/advanced prostate cancers with elevated intake of processed meat, meats cooked at high temperatures, or well-done red meat and the resulting mutagens (PhIP, MeIQx, and DiMeIQx), but one study found no association between white meat consumption and prostate cancer. Therefore, meat consumption may not be associated with localized and nonaggressive tumors, but consumption of highly processed meat or meat cooked at high temperatures might promote development of more aggressive forms of the disease.

Summary

Data suggest that diets with greatly elevated intakes of meat, extensively cooked red meat in particular, may be associated with an increased risk of some forms of cancer. The associations may be due to the fat contained in meat, the processing methods used to preserve meats, or the mutagenic/carcinogenic compounds developed during cooking where high temperatures or open flames are used. Although causation has not been established, individuals with the highest intake of cured meats and red meat have a modest (20–30%) increased risk of colon cancer. The relationship between meat intake and other cancers is not well defined, even though where data exist, they tend to suggest that processing may be in part responsible for the effects observed. Another putative indirect cause for the association between elevated intakes of meat and cancer may be the reduction of other dietary components including plant foods containing elevated levels of dietary fiber and other biologically active compounds that may be protective against cancer. These observations suggest that it might be possible to modify current processing or cooking conditions, as well as overall dietary pattern, in order to reduce the potential for meat to contribute to carcinogenesis in most tissues.

Glossary

Beef in an Optimal Lean Diet (BOLD) Study A controlled clinical study that demonstrated cholesterol lowering effects of a heart healthy diet containing lean beef.

Cardiovascular disease (CVD) It includes diseases of the heart and blood vessels.

Dietary Approaches to Stop Hypertension (DASH) A recommended dietary pattern for reducing risk of CVD, that includes fruits, vegetables, low-fat/fat-free dairy products, and foods low in sodium and saturated fat.

Low-density lipoprotein (LDL) A lipoprotein fraction that transports cholesterol into blood; which is a major risk factor for CVD.

Therapeutic Lifestyle Changes (TLC) A recommended diet for decreasing LDL-C, that is low in saturated fat and cholesterol.

Introduction

According to the World Health Organization (WHO), the leading causes of mortality worldwide in 2008 were major chronic diseases, including heart disease, stroke, cancer, chronic respiratory diseases, and diabetes, accounting for 63% of all deaths. Of the 36 million deaths from chronic disease, 25% were premature deaths (less than 60 years of age).

Cardiovascular diseases (CVD) are the leading cause of death globally. In 2008, approximately 17.3 million people died from CVD, which accounted for 30% of all deaths. Approximately 7.3 million deaths were due to coronary heart disease, and stroke accounted for 6.2 million deaths. By 2030, the WHO's projections are that 23.6 million people will die from CVD, primarily from heart disease and stroke.

Overweight and obesity are a major public health problem globally (ranked as the fifth major risk factor for deaths). In 2008, 1.5 billion adults, 20 years and older, were overweight, and 10% of the world's adult population was obese. In addition, in 2010, approximately 43 million children less than 5 years of age were overweight. Excess body fat beginning in childhood markedly increases risk of overweight and obesity later in life and the accompanying comorbidities associated with it. There are at least 2.8 million deaths each year due to overweight or obesity. Overweight and obesity contribute to the development of chronic diseases, including CVD, diabetes, musculoskeletal disorders, and cancers. For example, 44% of the diabetes burden, 23% of the ischemic heart disease burden, and 7–41% of certain cancer burdens are due to overweight and obesity.

Good nutritional practices are the foundation for reducing risk of many major chronic diseases. Dietary guidance has been issued by many government agencies and health organizations worldwide to decrease the risk of developing chronic diseases and associated morbidity and mortality. Because red meat is an important part of the diet in many populations, it is vital to discuss how it can be incorporated in a healthy diet that reduces risk of major chronic diseases, with emphasis on CVD and overweight/obesity.

Cardiovascular Disease

CVD represents many disorders of the heart and blood vessels that include: coronary heart disease, cerebrovascular disease, peripheral arterial disease, heart failure, arrhythmias, heart valve problems, rheumatic heart disease, congenital heart disease, deep vein thrombosis, and pulmonary embolism. Many CVDs develop over decades. CVD is a chronic inflammatory disease that frequently begins with endothelial damage that leads to inflammation of the vessel wall, with the consequent formation of atherosclerotic lesions that cause myocardial infarction and stroke. The underlying pathogenesis also involves dysregulated lipid metabolism and a pathological immune response.

An elevated cholesterol level and, in particular, elevated low-density lipoprotein cholesterol (LDL-C) are contributing factors to atherogenesis. Oxidative modification of LDL facilitates cellular uptake via the scavenger receptor and promotes atherogenesis via a process involving the production of macrophages and inflammatory cytokines. This sequel of events results in conversion of activated macrophages to foam cells, resulting in the formation of a fatty streak. In an abundance of atherogenic lipoproteins, the activated macrophages or foam cells endocytose until death by either apoptosis or necrosis. The death of the foam cells catalyzes the inflammatory process. In addition, there is smooth muscle cell proliferation and migration into the intima in response to inflammatory cytokines secreted by the damaged endothelium. This leads to the formation of a fibrous plaque that covers the fatty streak. Plaques that have a thin fibrous cap are susceptible to plaque rupture, resulting in a blood clot that is either released into the circulation or resides in place, thereby impeding blood flow to organs and tissues. In contrast, stable plaques tend to be asymptomatic, and over time they progressively occlude blood flow.

Cardiovascular Disease Risk Factors

The major modifiable and nonmodifiable CVD risk factors are presented in Table 1. There are other CVD risk factors that

Table 1 Modifiable and nonmodifiable risk factors for atherosclerosis

Modifiable	*Nonmodifiable*
Overweight/obesity	Age
Abnormal lipid/lipoproteins (elevated low-density lipoprotein cholesterol and triglyceride; low HDL-C)	Sex
Hypertension	Family history/genetics
Elevated blood glucose	Race/ethnicity
Endothelial dysfunction	
Chronic inflammation	
Cigarette smoking	
Physical inactivity	

have been identified recently (referred to as emerging CVD risk factors). Targeting these risk factors is central to reducing CVD.

Overweight and obesity are defined as a BMI of 25–29.9 kg m^{-2} and >30 kg m^{-2}, respectively. The optimum total cholesterol level is <200 mg dl^{-1} and the optimum LDL-C is<100 mg dl^{-1}, and less than 70 mg dl^{-1} for individuals with coronary disease. A high triglyceride (TG) level is ≥150 md dl^{-1}. Hypertension is defined as a blood pressure (BP) of greater than 140/90 mm Hg, and prehypertension is defined as a BP of 120–129/80–89 mm Hg. An elevated blood glucose level is >100 mg dl^{-1}. Having any one of these CVD risk factors increases the risk of coronary morbidity and mortality. The presence of two or more risk factors increases risk markedly. A condition known as metabolic syndrome in which individuals have three of the five following criteria (elevated waist circumference – >40 inch for men and >35 inch for women; elevated TG; low high-density lipoprotein cholesterol (HDL-C) – <40 mg dl^{-1} for men and <50 mg dl^{-1} for women; elevated BP – >130/≥ 85 mm Hg; and elevated blood glucose – >100 mg dl^{-1}) significantly increases CVD risk. Approximately one-quarter of the world's adult population has metabolic syndrome. These individuals are at two times greater risk of a fatal heart attack and three times as likely to have a stroke as healthy individuals. Healthy lifestyle behaviors are the first line of therapy for treating modifiable CVD risk factors and are central in preventing the onset of one or more of these risk factors.

Diet Effects on Cardiovascular Disease Risk Factors

Nutrition is the cornerstone for the prevention and treatment of CVD by reducing modifiable risk factors. The Therapeutic Lifestyle Changes (TLC) Diet is the gold standard dietary intervention for decreasing LDL-C, and the Dietary Approaches to Stop Hypertension (DASH) Diet is recommended for BP lowering. The TLC Diet recommends decreasing saturated fat (<7% of calories) and cholesterol intake (<200 mg day^{-1}), controlling calories to achieve a healthy body weight and increasing physical activity. The DASH Diet is low in saturated fat, dietary cholesterol, and sodium and high in fruits and vegetables (8–10 sv day^{-1}) and low-fat dairy products (2–3 sv day^{-1}). Both diets advocate a food-based approach that integrates all nutrient recommendations, including sodium reduction (<1500 mg day^{-1}). Because of the cardioprotective effects of fish consumption, two servings per week (preferably fatty fish) are recommended.

Red Meat and Cardiovascular Disease

Epidemiologic studies have linked red meat consumption to increased total CVD and cancer mortality, acute myocardial infarction, and metabolic syndrome. However, a number of epidemiologic studies have not reported an association between red meat consumption and CVD. It is important to note that epidemiologic studies typically do not adequately account for fat content, meat processing, and cooking methods. These factors can modify the health effects of lean red meat (i.e., specifically, beef) in the diet. In addition, red meat as a classification group may not just contain beef but also lamb, which is significantly higher in total and saturated fat. In one study in which the saturated fatty acid (SFA) content of the red meat was taken into consideration, the increased disease risk was no longer statistically significant. In another study in which increased red meat consumption was not associated with an increase in CVD mortality, individuals with higher red or processed meat intake also had lifestyle behaviors that increased their risk of CVD and mortality.

Clinical trials have shown that the cholesterol-lowering effects of a National Cholesterol Education Program (NCEP) Step-I diet or American Heart Association (AHA) diet containing lean red meat are equivalent to diets containing poultry and fish. In these studies, hypercholesterolemic subjects consumed 4–6 oz of lean beef or lean chicken/fish as part of the NCEP Step-I diet. Importantly, subjects in the lean red meat group were more compliant with the cholesterol-lowering diet.

There is little information about the effects of incorporating lean red meat into the DASH diet. Because the DASH diet is a recommended diet for reduction of CVD risk, and because beef is a popular food, it is important to determine whether inclusion of lean beef in the DASH diet elicits the same effects on CVD risk factor response.

The Beef in an Optimal Lean Diet Study

The Beef in an Optimal Lean Diet (BOLD) Study was conducted to examine the effects of a cholesterol-lowering diet containing lean beef (BOLD 4.0 oz day^{-1} and BOLD+5.4 oz day^{-1}) on LDL-C compared with a Healthy American Diet (HAD) and a DASH diet. Because beef often is avoided by individuals following a cholesterol-lowering diet as a means of controlling saturated fat, the authors sought to evaluate a healthy dietary pattern that contained lean beef and met food-based dietary recommendations for heart health and achieved the SFA goal of <7% calories on multiple CVD risk factors.

In the BOLD Study, 36 moderately hypercholesterolemic individuals (LDL-C >110 mg dl^{-1}) completed a randomized crossover-controlled feeding study. Participants were fed four intervention diets: HAD (33% total fat, 12% SFA, 49% carbohydrate (CHO), 19% protein (PRO), and 0.7 oz beef per

day); DASH (27% total fat, 6% SFA, 50% CHO, 19% PRO, and 1.0 oz beef per day); BOLD (28% total fat, 6% SFA, 54% CHO, 19% PRO, and 4.0 oz beef per day); and BOLD+ (28% total fat, 6% SFA, 46% CHO, 28% PRO, and 5.4 oz beef per day) for five weeks with a 1-week washout between diets. This design was employed to evaluate a 'dose-response' effect of lean beef on lipids, lipoproteins, apolipoproteins, and BP.

There were significant reductions ($p < .05$) in total cholesterol (TC) and LDL-C in response to the DASH (-19.0 ± 4.3 and -14.4 ± 3.7 mg dl^{-1}), BOLD (-18.6 ± 4.1 and -13.5 ± 3.6 mg dl^{-1}), and BOLD+ (-19.6 ± 4.1 and -13.5 ± 3.8 mg dl^{-1}) diets versus the HAD (-8.5 ± 4.1 and -5.5 ± 3.9 mg dl^{-1}). The BOLD and BOLD + diets reduced HDL-C by approximately 6%, and DASH also decreased HDL-C comparably. Systolic BP (SBP) was significantly reduced following the BOLD+ diet compared with HAD (-4.24 mm Hg). Compared with the HAD, the BOLD+ diet was the only treatment diet that significantly decreased apolipoprotein B. Apolipoprotein B is the predominant protein in non-HDL particles (i.e., the atherogenic lipoprotein particles). Significant reductions were also observed for apolipoprotein A1 (the major protein in HDL), apolipoprotein C-III, and apolipoprotein C-III bound to apolipoprotein A1 particles following the BOLD and BOLD+ diets ($p < .05$). Changes in total apolipoprotein C-III in lean beef diets reflected a decrease in a subfraction (apolipoprotein C-III HS), which represents the number of apolipoprotein C-III molecules bound to apolipoprotein A1-containing particles. It has been suggested that apolipoprotein C-III bound to HDL inhibits the antiinflammatory properties of HDL. Although total apolipoprotein A1 was decreased in the BOLD and BOLD+ diets, the decrease in apolipoprotein C-III bound to apolipoprotein A1-containing particles suggested that the anti-inflammatory capacity of the apolipoprotein A1-containing particles was improved. Collectively, the test diets with lean beef had beneficial effects on lipids and lipoproteins and BP as well as potential antiinflammatory responses.

The BOLD Study demonstrated that lean beef can be included in a cholesterol-lowering diet that is low in SFA and meets contemporary food-based recommendations. This dietary pattern elicited reductions in TC and LDL-C that were equivalent to heart-healthy plant protein-rich diets, such as the DASH diet. Of note was that increasing lean beef while controlling SFA (<7% calories) did not attenuate the decrease in LDL-C. The study also showed that increasing total dietary protein by including lean beef and other animal proteins was an effective strategy for reducing BP. Thus, the decrease in two major risk factors for CVD would be expected to correspond to a lower overall CVD risk in response to a heart-healthy diet that includes lean beef.

The Role of Lean Beef in a Healthy Diet

The 2010 Dietary Guidelines for Americans recommend three healthy, food-based dietary patterns that meet food-based and nutrient recommendations (Table 2). A variety of protein foods is recommended, including lean meat; poultry; eggs; fish/seafood; beans and peas; and nuts, seeds, and soy products. The US Department of Agriculture (USDA) Food Patterns recommends 1.8 oz lean meat daily. Including lean beef in a lipid-lowering, heart-healthy diet plan contributes to the intake of essential nutrients, such as iron, zinc, and B-vitamins. Specifically, beef is the number one food source of zinc in the diet, providing 39% of the daily value (DV) per 3-oz portion. It is also an excellent source of vitamin B_{12} (37% of the DV per 3-oz serving) and selenium (24% of the DV per 3-oz serving) and a good source of vitamin B6 (16% of the DV per 3-oz serving) and iron (14% of the DV per 3-oz serving). Compared with other protein sources, it would take 13.5 3-oz servings of salmon (2363 kcal), 7.5 3-oz servings of chicken breast (1050 kcal), 4.5 3-oz servings of tuna (491 kcal), or 6 tbsp peanut butter (570 kcal) to match the zinc, vitamin B_{12}, riboflavin, and protein in one 3-oz serving of lean beef, respectively.

Lean beef contains less than 10 g total fat, no more than 4.5 g of SFA, and less than 95 mg of cholesterol per 3-oz serving, a nutrition profile that readily fits into a heart-healthy diet. Based on the dietary fat recommendations of the AHA, individuals following a 2000-cal diet are advised to consume between 56 g and 78 g of total fat and 16 g or less of SFA. A 3-oz serving of lean cooked beef contains amounts of total fat and SFA well below these limits and cholesterol levels well below the AHA recommendation of <300 mg day^{-1}. There are currently 29 cuts of beef that meet the USDA's guidelines to be labeled lean. To select a lean cut, choose those with Loin or Round in the name labeled as Select or Choice. Some examples are listed in Table 3. Portion control and cooking technique are also important to control calories, total fat, and saturated fat.

Like most other foods containing fat, beef comprises a variety of fatty acids. Despite the common reference to animal fats as 'saturated,' less than half of all fatty acids in meat fat are saturated. For example, in lean beef, 54% of the fatty acids are monounsaturated (MUFA) or polyunsaturated (PUFA). In addition, one-third of the SFA in beef is stearic acid, which has a neutral effect on blood cholesterol levels unlike the other long-chain SFAs, which increase LDL-C.

The American Council on Science and Health concludes that 'lean beef, in moderate servings, fits well in a heart-healthy diet.' As a naturally nutrient-rich source of many nutrients, including high-quality protein, iron, zinc, and many B-vitamins, incorporating lean beef in the diet can help individuals meet their nutrient needs, as well as provide variety and flexibility in their diet, which may improve long-term adherence to a healthy dietary pattern.

Understanding Meat Labeling

According to a US Department of Agriculture Food Safety and Inspection Service (FSIS) ruling, nutrition labels are required on all single-ingredient raw meat and poultry products, including ground meats, sold in supermarkets. This information will assist individuals in meeting the 2010 Dietary Guidelines recommendations to include lean meat and poultry products as part of a healthy balanced diet. The meat and poultry industry has long awaited this ruling, which will now highlight the 29 cuts of beef, pork, and lamb that are considered lean.

Table 2 Eating pattern comparison: Usual US intake, Mediterranean, Dietary Approaches to Stop Hypertension (DASH), and US Department of Agriculture (USDA) Food Patterns, average daily intake at or adjusted to a 2000 cal level

Pattern	*Usual US intake (adults)*[a]	*Mediterranean Patterns*[b] (Greece (G) Spain (S))	*DASH*[b]	*USDA Food Patterns*

Commonly approved claims to be aware of when purchasing meat and poultry include: raised without added hormones, raised without antibiotics, not fed animal by-products, free range, free roaming, grass fed, corn fed, grain fed, and certified organic (by certifying entity).

According to the FSIS, hormones are only approved for use in beef cattle and lamb production. They are not approved for use in poultry, hogs, veal calves, or exotic, nonamenable species. Therefore, the phrase 'no hormones administered' on a chicken label cannot be approved unless it is followed (directly) with the statement 'Federal regulations prohibit the use of hormones in poultry.'

Antibiotics may be given to prevent or treat disease in cattle. A washout period is required from the time antibiotics are administered until it is legal to slaughter the animal so that any residue can exit the animal's system. The FSIS randomly samples cattle at slaughter and tests for residues. Animal-raising claims, such as these, may be approved for labeling if the animal production information submitted with the label application supports the claims being made and the claim is truthful and not misleading.

Thus far, the USDA has not adopted an official definition of grass-fed beef. There are two terms, often used interchangeably, that are found on labels: grass-fed beef and grass-finished beef. Grass-fed beef generally means beef from cattle that have eaten only grass or forage throughout their lives; however, some producers market their beef as grass fed but then finish the animals on grain for the last 90–160 days before slaughter. A more specific definition is grass-finished beef. Finishing is another term for the time that cattle grow to market weight during the last few months before processing. Typically, feed lots finish cattle for 90–160 days on a total mixed ration (TMR), whereas grass-finished cattle are fed grass only, until they are processed.

Most beef cattle raised in a contemporary production system, as well as most organic and natural beef, are finished with a TMR. The only distinction between organic or natural is that the grain is certified organic or natural. Although some grass-fed beef is organic, not all organic beef is grass fed or finished. In fact, many of the organic and natural products are TMR fed, in feedlots; it is just that the ration that is fed is certified organic or natural.

Can the Composition of Meat be Modified?

Feeding practices implemented can modify the total fat and fatty acid profile of meat from ruminant and nonruminant animals. For ruminants, the change is less than for non ruminants. Grass-fed beef has a lower total fat content compared with conventionally fed cattle. In addition, it is higher in conjugated linoleic acid (CLA), *trans* vaccenic acid (a precursor of CLA), and long-chain omega-3 fatty acids. The total SFA content is similar; however, grass-fed beef is higher in stearic acid (a cholesterol-neutral SFA) and lower in myristic and palmitic SFA (hypercholesterolemic fatty acids). Conventionally fed beef is higher in total fat, which reflects a higher content of monounsaturated fat. Because of the lower fat content, appropriate cooking techniques are necessary for grass-fed beef. For nonruminant animals (such as pigs and chickens), the fatty acid content and profile of the meat reflect diet composition more closely. Consequently, feeding techniques have been used to increase PUFA and MUFA and decrease SFA content specifically to help consumers to meet current dietary guidelines.

Obesity and Weight-Reducing Diets

Obesity is a complex physiological state and the underlying etiology is poorly understood. Obesity and overweight are related to the amount of body fat (i.e., adipose tissue). The two important adipose tissue depots are subcutaneous (located beneath the skin) and visceral (around internal organs). The distribution of adipose tissue is dependent on many factors, including sex, age, race, ethnicity, genotype, diet, physical activity, hormone levels, and medication. Although both subcutaneous and visceral fat are important, visceral adiposity has been the focus of attention because of its association with multiple comorbid conditions, such as impaired glucose and lipid metabolism, insulin resistance metabolic syndrome, CVD, and several malignancies, including prostate, breast, and colorectal cancers.

Given the ongoing obesity epidemic, there is interest among the general public and health professionals in effective treatment strategies. For the most part, weight loss programs tend not to be successful over the long term, although there are many 'success stories.' Nonetheless, there is great interest in identifying effective weight loss programs. There are countless diet programs available, many of which are fad diets or lack scientific support for efficacy. A key focus of different weight loss diets has been the macronutrient profile. A popular strategy over the years has been to decrease carbohydrates and increase protein (and also fat). In these diets, meat has been a focal point. Another popular strategy is a very low-fat diet. As noted in the Dietary Guidelines Advisory Committee 2010 Report, there are no differences in weight loss with differing macronutrient proportions, if diets are followed for longer than 6 months. In shorter term studies, high-protein diets tend to result in greater weight loss than low-fat diets; however, these differences are not sustained over time. Moreover, with diets that restrict many foods and food groups, adherence is a problem.

In summary, there is no optimal proportion of dietary fat, carbohydrate, and protein that is recommended to maintain a healthy body weight, to lose weight, or to avoid weight regain after weight loss. Thus, lean beef can be part of a healthy weight loss diet. Of importance are the total calories consumed and the nutrient quality of the diet. The three eating patterns (i.e., Mediterranean, DASH, and USDA Food Patterns) presented in **Table 2** all offer a healthy food-based strategy that can include lean beef to achieve weight loss and maintenance of reduced body weight.

Conclusion

CVD and obesity continue to be major public health problems. Both can be prevented and treated with healthy dietary practices. Healthy eating patterns include the Mediterranean

Diet, DASH Diet, and USDA Food Patterns. Research has shown that lean beef can be incorporated into each of these eating patterns and confer many health benefits, especially for CVD risk reduction and weight control. Lean beef is a nutrient-dense food that facilitates the achievement of nutrient adequacy. Advances in beef production and available consumer information have made it easier to procure lean beef and to enjoy it in a heart-healthy diet that is designed to achieve and maintain a healthy body weight.

Macronutrients in Meat

RK Tume, CSIRO, Animal, Food and Health Sciences, Queensland, Australia

This article is a revision of the previous edition article by W Chan, volume 2, pp 614–618, © 2004 Elsevier Ltd.

Glossary

α-Linolenic acid Long-chain polyunsaturated fatty acid.
Monogastric Animals having a stomach with one compartment.
***n*-3 Polyunsaturates** The first double bond appears at the third carbon–carbon bond from *n*-terminal.
***n*-6 Polyunsaturates** The first double bond appears at the sixth carbon–carbon bond from *n*-terminal.
Oleic acid Long-chain monosaturated fatty acid.
Palmitic acid Long-chain saturated fatty acid.
Phospholipids Phosphorus-containing lipid.
Ruminant Animals having a stomach with four compartments (rumen, reticulum, omasum, and abomasum).
Saturated fatty acid Fatty acid with no unsaturated bonds.
Stearic acid Long-chain saturated fatty acid.
Trans fatty acids Trans-isomer (E-isomer) fatty acids.

Introduction

The macronutrients of foods, proteins, lipids, and carbohydrates are the major components that provide essential nutrients for growth, body maintenance, and other body functions. That is, they supply energy through metabolism and provide essential chemical subunits such as amino acids, fatty acids, phospholipids, and sugars.

Boneless meat is composed of skeletal muscle fibers, connective tissue, and adipose tissues and has a water content of approximately 70–75%. It is these main cellular and extracellular components that contribute to the macronutrients of meat.

Macronutrient Content of Meat

Unlike with most food types where, within a food, the composition is quite similar, for example, eggs, the macronutrient content of meat can be highly variable because of different fat contents of the individual meat cuts, different animal species, effects of animal age, or feeding regimen. Because lean muscle cells have moisture contents of approximately 70 g/100 g, compared with just 10 g/100 g for adipose tissues, as more adipose tissue is deposited in a lean muscle, the moisture content decreases markedly as the fat content increases. In fact, the relationship between fat and moisture content is so strongly negative that it is possible to estimate fat content of meat based on its measured water content. In addition to changes in moisture content, for a given weight of meat, an increase in fatness also leads to a small reduction in protein contents because muscle cells are the main providers of protein. In lean raw meat, the protein content may be 25 g/100 g but this may be reduced to less than 20 g/100 g in more fatty meat.

Although in nutritional terms the content of carbohydrates is very low in meat (~1 g/100 g), it does play an important role in the conversion of muscle to meat, with postmortem metabolism of glycogen enabling the meat to attain an ultimate pH of 5.5–5.7. However, carbohydrates in meat are usually not considered in terms of overall energy contribution, except perhaps where a cereal has been added to a processed meat product. In this article, only raw, whole muscle foods are considered. The important macronutrients of meat are, therefore, proteins and lipids.

Meat Consumption and Macronutrients in Meat from Various Countries

The per capita consumption of meat is largely dependent on the level of a country's socio-economic development, with developed countries usually being higher consumers. Meat consumption, particularly the type of meat, is also affected by religious and ethical beliefs. In certain countries, such as in Africa and Central and South America, pork consumption may be depressed due to fears of trichinosis infestation. Table 1 shows meat consumption data for the main meat species for some of the major meat-consuming countries. Countries such as Argentina, Australia, and Brazil tend to consume a greater percentage of beef compared with other meats whereas European and Asian countries consume more pork. In some countries, the consumption of chicken meats has continued to increase over the past 30 years at the expense of red meats.

In line with previous findings from the UK, the fat content in retail cuts of meat for most meat types has continued to fall. For example, in Australia, the fat content of pork loin chops decreased from 31% in 1984 to 9% in 2005, and in the same period, lean meat increased from 55% to 75%, largely as a result of consumer demand for leaner meat products in line with current health recommendations. This has been achieved through genetics, selective breeding, feed types, weight at slaughter, and level of trim.

The macronutrient composition of relatively lean meats from various species obtained from a number of developed countries is presented in Table 2. Lean raw meat cuts were chosen to avoid the huge variation in fat contents that can exist in some muscles/meat cuts, which could have been confusing and induced large variations in energy, protein, and moisture

Table 1 Meat consumption in selected countries (kg/capita)

Country	*Beef and veal*[a]	*Pork*[a]	*Broiler chickens*[a]	*Total meats*[b]
Argentina	55	7	37	91
Australia	36	22	36	123
Brazil	38	13	49	80
Canada	30	23	29	98
China	4	36	10	53
European Union 27	15	40	18	85

South Africa	14	4	33	49
United Arab Emirates	21	–	71	85
USA	35	27	43	123

[a]*Source*: USDA, estimate for 2012.

[b]2007 data from Food and Agriculture Organization of the United Nations (FAO) 2010, Livestock and Fish Primary equivalent, 02 June 2010, Available at: http://faostat.fao.org/site/291/default.aspx (accessed 31.10.13).

contents. Instead, a selection of meats having higher fat contents is presented separately in Table 3. It is likely, however, that differences observed in fatness between the meat from various countries only reflects differences in the mean slaughter weights of the animals in those countries and the level of trim. However, for the majority of the lean cuts, where the fat content was less than approximately 6 g/100 g raw meat, the energy content ranged from approximately 450–600 kJ/100 g. In the UK, this equates to approximately 17–18% of the daily energy intake for adults between 19 and 64 years.

Of all the lean meats selected, beef steak/fillet from each country consistently had the highest, but modest, fat content (4.0–8.3 g/100 g). Beef round steak (from leg) was generally very lean. The lean meat originating from Australia, Canada, and the UK (1.7–2.7 g/100 g) was lowest in fat, possibly reflecting the predominant pasture grazing systems used in these countries. The content of fat in lamb steak/fillet was in a similar range to that found for comparable cuts of beef (3.7–6.0 g/100 g). Over the past 20–30 years, there has been a move toward lowering the fat content through breeding and production, and this has been particularly effective in pork; although perhaps at the expense of optimal eating quality. With some exceptions, it is apparent (Table 2) that pork loin/fillet is very lean (mainly approximately 1–2 g fat/100 g), somewhat lower than that observed for beef and lamb fillet.

The white breast meats from chicken and turkey were consistently very low in fat irrespective of country of origin. Skinless breast meat contained approximately 1–3 g fat/100 g whereas with skin-on breast meat, the fat content increased to 6–7 g/100 g meat.

The preceding discussion shows that lean meat is a high protein, low fat food; however, the fat and energy content of meat can be very high depending on the production process, meat cut, and extent of fat trimming. Table 3 shows the macronutrient contents in a selection of meat cuts with high fat content from a number of species.

Meat Proteins

Raw muscle contains approximately 20–25 g protein/100 g meat, which with loss of moisture and fat on cooking may attain a value of 28–36 g/100 g cooked meat. Protein from muscle tissue is an excellent source of essential amino acids and it has a high net protein utilization (NPU 0.75–0.8) (FOA/WHO 1985) and high digestibility. The high content of lysine in particular makes animal proteins attractive compared to cereal proteins. The nutritional quality of protein derived from connective tissue is somewhat lower than that from muscle tissue, although as it is present at only approximately 1–2 g/100 g meat, it is of little concern nutritionally. The main protein components of connective tissue, collagen, and elastin have lesser contents of the sulfur-containing amino acids and are, therefore, regarded as inferior. Further, because of their structure, they are less heat-susceptible to breakdown during heating and digestion.

Although it is the macronutrients of meat that contribute to energy intake, the physical/chemical forms of the meat as consumed affect the net energy intake. The energy required to digest raw or rare meat appears to be greater than that required when meat has been well done or over cooked. In controlled studies with pythons fed raw and cooked meat, it was determined that oxygen consumption was greater when the pythons had been fed raw meat, suggesting that there had been greater energy expenditure during the digestion process. Similarly there were differences in oxygen consumption dependent on whether the meat was intact or ground. Thus the degree of cooking and/or processing may be a factor to consider in terms of overall macronutrient content with respect to energy contribution.

The effect of cooking on the nutritional quality of proteins may also be important in some situations. Generally, this is not an issue at lower cooking temperatures but at higher temperatures ($>100\,^{\circ}C$) it is possible that some essential amino acids, such as lysine may interact with other chemical components (sugars) and become unavailable following digestion. Under similar cooking conditions it is also possible for the sulfur-containing amino acids to become modified and, therefore, nutritionally unavailable.

Humans require approximately 0.8 g protein kg^{-1} body weight day^{-1} to maintain skeletal muscle and organ tissue turnover. Thus a 70 kg person requires approximately 56 g of protein daily. Given the average consumption of meat for a

number of developed countries is in the range 140–300 g day^{-1}, this would equate to 28–65 g protein day^{-1}, thus accounting for the majority of the daily protein requirements. However, in individuals where there has been muscular inactivity as a consequence of an illness or trauma, a loss of muscle mass and muscle weakness usually results, and this is known as sarcopenia. This is particularly an issue with the aged population where the rate of muscle loss is believed to reach approximately 1% per year. A recent study has shown that, compared with an iso-nitrogenous amount of soy protein, beef protein was more effective in synthesizing myofibrillar proteins when fed to middle-aged men, either when at rest or after a resistance exercise. This is thought to result from relative differences in rates of protein digestion, as well as dietary meat proteins supplying the specific amino acids required for myofibrillar protein synthesis.

Meat Lipids

Lipids in meat are located predominantly in fat cells (adipocytes) in a number of cellular sites, including subcutaneous (under skin), intermuscular (between muscles), and intramuscular (within muscles). Small lipid droplets are also located within muscle cells and are more prevalent in red muscles than white muscles.

Lipids in meat consist primarily of triacylglycerols (TAG) (mainly located in adipocytes) and phospholipids (in muscle and adipocyte cell membranes), with lesser amounts of cholesterol (in cell membranes and adipocytes). The lipid content of meat can vary widely depending on the fatness of the animal and the fat content of the actual meat cut and extent of trimming. Very lean meat may contain just 1 g fat/100 g meat, but for optimal eating satisfaction, a lipid content in the range of 4–7 g fat/100 g meat has been suggested. Extremely highly marbled and expensive meats from Wagyu beef may approach 40 g fat/100 g meat. Fat as a macronutrient is also important as it is a carrier for, and an aid in the absorption of, a variety of fat-soluble vitamins and various biologically active components such as carotenoids.

As the fat content of meat increases, the proportion of TAG (neutral lipids) increases and phospholipids decreases (**Figure 1(a)**). Because most lipids present in very lean meat are located in cell membranes, the total lipids consist primarily of phospholipids, and thus contain a relatively high percentage of polyunsaturated fatty acids (PUFA) (**Figure 1(b)**). As the fat content increases, the level of polyunsaturation decreases, being replaced with increased amounts of saturated and monounsaturated fatty acids.

Compared with other lipid fractions, cholesterol comprises only a very small part of the total fat content. Independent of meat species and country of origin (**Table 2**), the cholesterol content for lean meats was predominantly in the range of 50–60 mg/100 g raw meat. Thus the contribution of a lean meat meal portion to the total suggested maximum daily intake of cholesterol (200–300 mg) is approximately 20–30%.

The composition of fatty acids of meat is important in terms of its contribution to overall nutrition. Given current health recommendations that fat intake should be reduced to less than 30% of total energy intake, the PUFA:saturated ratio should be increased to above 0.4 and that the ratio of *n*-6:*n*-3 PUFA should be less than 4, it is possible that animal diets can be manipulated and meats can be selected to achieve these more favorable fatty acid compositions. However, apart from their role in nutrition, fatty acid composition is also important in terms of meat quality, with different fatty acid compositions affecting fat hardness/softness. This has implications for the following:

- carcase boning (hard carcase fat at chiller temperatures is difficult to bone and carcases are sometimes warmed to soften fat for ease of cutting – negative impact of meat quality),
- functionality in processed meats,
- visualization of marbling for chilled assessment (saturated fats are more visually evident),
- carcase fat color (yellow pigment is less evident with higher percentage of saturated fatty acids as fat tissue is more opaque at chiller temperatures), and
- susceptibility of the meat to oxidize, leading to meat color and flavor deterioration.

At a given level of meat fatness, the composition of TAG can affect its cooking and eating properties. This is very much dependent on the specific fatty acid composition of individual TAG and on the animal species from which the meat was obtained. Not only are the melting properties of the fat affected by the level of fatty acid unsaturation, but also by the individual fatty acids' positions in the TAG molecule (*sn*-1, *sn*-2, or *sn*-3). In beef fat, as with other ruminants, the *sn*-2 position is predominantly occupied by monounsaturated fatty acids whereas in the monogastric pig, the *sn*-2 position contains mainly saturated fatty acids. Such different configurations result in large differences in melting properties of TAG having the same fatty acid compositions. Placement of stearic acid, a saturated fatty acid, in the outer position of TAG can increase lipid melting points by as much as 10 °C relative to TAG with stearic acid solely in the *sn*-2 position.

The positional distribution of fatty acids in TAG also affects the absorption process in the small intestine and the resynthesis of absorbed lipids into TAG and phospholipids, and therefore can impact on their nutrient value. Before absorption, TAG is subjected to pancreatic lipase, which results in fatty acids being hydrolyzed from the *sn*-1 and *sn*-3 positions leaving the *sn*-2-monoacylglycerol intact. This *sn*-2-monoacylglycerol is readily absorbed by passive diffusion into the enterocyte where it is resynthesized into TAG or phospholipids and then transported to other sites as chylomicrons. Thus, the stereospecific structure of the ingested TAG is retained. However, for the long-chain fatty acids from the other two positions, a protein-mediated transport process is required which is somewhat slower than the passive diffusion process. Again, once absorbed by the

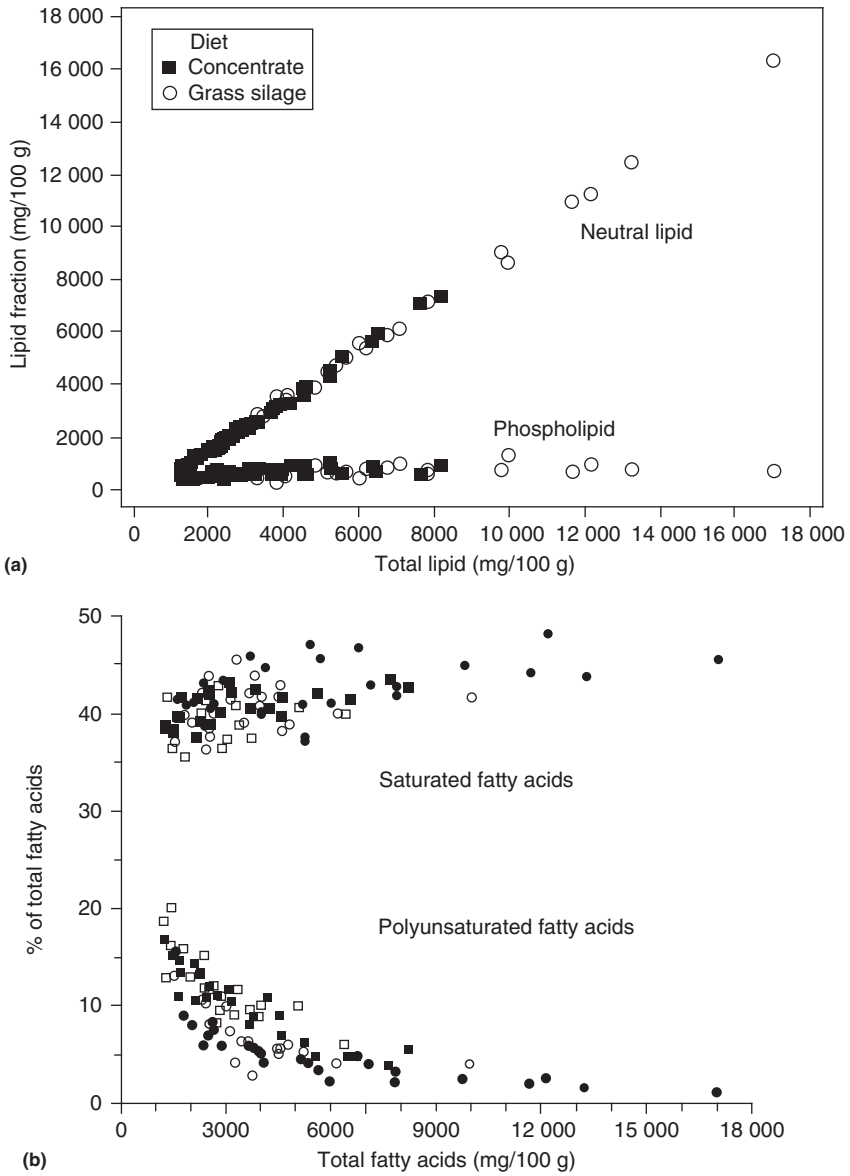

Figure 1 Lipid fractions (a) and fatty acid compositions (b) of beef *longissimus* muscles with increasing levels of fatness. Adapted from Wood, J.D., Enser, M., Fischer, A.V., *et al.*, 2008. enterocyte, the fatty acids are reassembled into TAG but without retaining any regio- or stereo-specific structure.

Fatty Acid Composition of Meat

The fatty acid composition of meat adipose tissues from monogastric animals such as pigs and chickens can be highly variable as it is largely dependent on the feeds consumed. Inclusion of polyunsaturated oilseeds in feeds has been shown to result in high contents of polyunsaturated lipids in muscles and adipose tissues. Meat quality can then be affected as a result of a more rapid development of rancidity during chilled storage and other processing treatments. For ruminants, such as cattle and sheep, the composition is likely to be more constant among individuals because dietary unsaturated fatty acids are largely hydrogenated by microorganisms in the rumen before their absorption from the intestine. In ruminants, a significant amount of fatty acids is produced by *de novo* synthesis with palmitic acid being the end product of fatty acid synthase and stearic acid then produced by an elongase. This saturated fatty acid can then be desaturated by a Δ9-desaturase to produce the monounsaturated oleic acid, which is present in high amounts in adipose tissues. The extent to which this occurs depends on the genetic expression of stearoyl-CoA desaturase and it is this activity that largely accounts for the significant differences in unsaturation that exist among ruminant species and also among breeds. An outstanding

example of high desaturase activities and high levels of monounsaturated fatty acids in ruminant subcutaneous and intermuscular fat is that observed in Japanese Wagyu cattle where oleic and palmitoleic acids can account for more than 55–60% of the total fatty acids.

The major fatty acids present in meat (muscle and fat) from various species are indicated in Table 4. Irrespective of whether the meat is from monogastrics or from ruminants, palmitic and stearic are the main saturates and oleic the predominant monounsaturate. The percentage of the other fatty acids is generally low, except for some polyunsaturates, particularly linoleic, which vary markedly between ruminant and non-ruminant species, and this is most obvious in adipose tissue.

The ratio of *n*-6:*n*-3 polyunsaturates in meat is largely related to animal feed, with pasture-feeding resulting in a greater uptake and incorporation of *n*-3 fatty acids such as α-linolenic acid, and grain-feeding higher proportions of *n*-6 acids such as linoleic acid. These PUFA are also precursors for the *n*-3 long-chain fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) and the *n*-6 arachidonic acid found in meat. In beef, mean ratios of 1.5 and 7.7 have been reported for meat from grass and grain-fed cattle, respectively. Overall, lean meats from all species provide a valuable source of essential long-chain PUFA, even though the amounts present are usually quite low (< 200 mg/100 g muscle).

In addition to the fatty acids mentioned, two additional groups of fatty acids of nutritional interest are commonly present in ruminant fats; *trans* fatty acids and conjugated linoleic acids (CLA). The predominant *trans* fatty acid formed is vaccenic acid (18:1 *trans*-11), which is a product of incomplete biohydrogenation of linoleic acid (18:2*n*-6) in the rumen. Unlike the *trans* isomers of fatty acids formed synthetically by chemical hydrogenation of polyunsaturated oils, and which are of concern for human consumption, the naturally formed 18:1 *trans*-11 present in ruminant fat appears to be of little concern health-wise, particularly at its concentration of approximately 1–4 g/100 g fat. CLA is also produced in the rumen and the major isomer present is *cis*-9, *trans*-11 conjugated linoleic acid that may be present in amounts of 0.5–1 g/100 g fat. The content of CLA is generally higher in meat from pasture-fed animals. CLA isomers have received considerable interest for their anticancer, anti-inflammatory properties and potential to reduce cardiovascular disease. Although CLA is a product of rumen biohydrogenation, it appears that a more important source is via the desaturation of 18:1 *trans*-11 present in adipose tissue by stearoyl CoA desaturase.

Macronutrients and Oxidation

The nutritive (and functional) value of meat may be compromised by oxidation of protein and lipid components. Generation of reactive oxygen species by processes such as storage, freezing/thawing, grinding, and cooking, etc., can result in structural covalent modifications to proteins such as aggregation, which can result in reduced susceptibility to proteolytic digestive enzymes and, therefore, lead to reduced uptake of amino acids. Further, this aggregation may be enhanced indirectly by the aldehydic products of lipid oxidation that are also generated by the various processing practices employed. In addition, the nonhydrolyzed peptides are not absorbed in the intestine and then pass on into the colon where they are fermented by flora, producing a range of potentially carcinogenic compounds.

Nutritive implications for ingestion of oxidized lipids mainly relate to their toxicity. Products of lipid oxidation such as hydroperoxides are known to damage DNA, and many secondary oxidation products are potential carcinogens (e.g., malondialdehyde), whereas carbonyl compounds may affect cellular signal transduction processes. Although lean meat has low lipid content, it does contain a higher proportion of the more susceptible PUFA, but their overall level of ingestion would likely be low compared with other fatty foods. Meats having high levels of the antioxidants α-tocopherol and ascorbic acid (provided by pasture-feeding or by supplementation) are better protected from oxidation than meats with lesser amounts of these compounds.

Summary

The macronutrient content of meat is highly variable, because of the large range of fatness that is possible in animals and

muscles. However, for lean meats across a wide range of species, breeds, and muscle cuts, there is little variation in the macronutrient content with protein and water making up more than 95% of its weight. Lean meat, therefore, provides an excellent source of high nutritional-quality protein supplying all the essential amino acids. Medical sources have recommended that wherever possible, fat should be trimmed from those cuts where fat is visible, preferably before cooking. This not only reduces the overall calorific value of the meat but removes a significant amount of the saturated fats, resulting in a higher proportion of PUFA in the total fat. Although the amount of *n*-3 PUFA contributed by meat is quite small when compared with oily fish, it still remains a significant and important source of these essential fatty acids.

Meat and Human Diet: Facts and Myths

V Santé-Lhoutellier, INRA, Saint Genès Champanelle, France

Glossary

Bioactive peptide A peptide able to display a physiological function including antihypertensive, antioxidative, opioid agonistic, immunomodulatory, antimicrobial, prebiotic, mineral binding, antithrombotic, and hypocholesterolemic effects.

Carnosine (beta-alanyl-L-histidine) It is a dipeptide of the amino acids beta-alanine and histidine. Carnosine is able to scavenge reactive oxygen species as well as alpha, beta unsaturated aldehydes formed from peroxidation of cell membrane fatty acids during oxidative stress. It is highly concentrated in muscle and brain tissues.

Caseinophosphopeptides These are bioactive peptides derived from the tryptic digestion of casein, which possess physicochemical properties that enable the chelation of various bi- and trivalent minerals, thereby enhancing mineral solubility in the lower small intestine.

Digestion rate of proteins It corresponds to the rate of peptides and amino acids released during digestion in the gastric or intestinal compartment.

Fructooligosaccharides These are oligosaccharide fructans, sometimes also called oligofructose or oligofructan, used as an alternative sweetener. They also have prebiotic characteristics.

Glutathion (GSH – L-γ-Glutamyl-L-cysteinyl-glycine) A tripeptide with a gamma peptide linkage between the amine group of cysteine and the carboxyl group of the glutamateside chain. It is an antioxidant preventing damage to important cellular components caused by reactive oxygen species such as free radicals and peroxides.

Sarcopenia It can be defined as muscle wasting.

Thermolysin It is a thermostable neutral metalloproteinase enzyme. It specifically catalyzes the hydrolysis of peptide bonds containing hydrophobic amino acids.

Introduction

Meat has been an important part of the human diet for a very long time. Its consumption started approximately 1.9 million years ago by *Homo erectus*. The prehistoric discovery of cooking food is reported to result in a higher net energy value intake by human ancestors and probably also a higher food digestibility. As a consequence, it is believed that the increased ease of chewing cooked meat resulted in the molar teeth size reduction.

In the modern era, and especially in the developed Western societies, meat is often an object of a controversy if one refers to the number of epidemiological studies associating consumption of meat and meat products with the risk of developing diseases such as colorectal cancer. However, many controlled studies have not found such a close association when the various risks factors were correctly adjusted – admittedly difficult to do. This article focuses on balanced positive and negative aspects of meat from a human nutrition point of view, although the diverse aspects of the use of sodium or nitrites in processed meats associated with human health will not be addressed. In particular, it covers the positive nutritional aspects of meat in a diet that includes components like essential amino acids. Other articles in this encyclopedia cover aspects such as cardiovascular and obesity health concerns and cancer health concerns. Such studies should not be seen as being in conflict with this article. The way humans use meat, especially in excess, together with excesses of other food components appears to have a large bearing on health outcomes.

Proteins

The classic criteria for evaluating the quality of a protein source are based on amino acid composition and digestibility of the protein fraction. These basic criteria can only assess the ability of a food to provide available amino acids. It is now known that the definition of the quality of dietary proteins needs to integrate new concepts such as:

- The capacity of dietary proteins to release, during the digestion, peptides having a local or systemic biological impact;
- The rate of digestion which may, in some cases, have a direct influence on whole body assimilation of amino acids.

Classical Criteria for Evaluating the Quality of Protein Sources

Meat is a heterogeneous food with a composition that varies according to the origin of the muscle (ruminants, pigs, and poultry), the type of muscles, (which are themselves complex in terms of structural and biochemical properties), and the preparation used to process them into various dishes (curing, drying, sausage making, and fermentation). Yet, meat still presents some common nutritional features. Meat is protein rich compared with other foods. In addition, those proteins which are particularly rich in essential amino acids (i.e., amino acids that the human system cannot synthesize, such as lysine and histidine), are present in a balanced way meeting human requirements right through from childhood to adulthood. This means that proteins from meat products are efficiently used by the human body to remodel or create new proteins during growth. This arises because metabolically it is not necessary to supply surplus amounts of unnecessary proteins merely to meet the requirements for individual indispensable amino acids. Furthermore, the high concentrations of lysine in meat

 doi:10.1016/B978-0-12-384731-7.00178-1

proteins are useful to improve the quality of other proteins from cereals in diverse human diets. Because meat proteins are easily digested in the small intestine, they do not induce any notable adverse reaction in the digestive tract, which could increase endogenous losses as might occur with high-fiber feedstuff.

Because of the favorable balance of indispensable amino acids, very high digestibility, and high bioavailability of amino acids, meat proteins have a high biological value. Thus, as part of a well-balanced diet, meat consumption does not need to exceed 120 g d^{-1} for healthy adults without any specific health requirements (i.e., 0.8 g kg^{-1} d^{-1} needed). With a 120 g d^{-1} protein supply situation, the part of the daily supply regarding other nutrients can exceed 60% for indispensable amino acids, vitamin B_{12}, and zinc; 40% for vitamin B_3 and cholesterol; and 20% for iron, selenium, riboflavin, vitamin B_6, and pantothenic acid as well a variable quantity of saturated fatty acids.

Bioactive Peptides

Currently, there is abundant available data that have described the physiological effects of certain food-derived peptides on the activity of the digestive tract and other physiological functions (i.e., antihypertensive, opioid, immunomodulatory, or antianxiolitic activities). Among the peptides found in meat, some are already abundant in the original feedstuff, and their synthesis does not follow the classical metabolic pathways of protein synthesis and degradation. These are, for instance, carnosine and glutathion present in meat products. Other peptides that are present in the proteins can only be released during the various processes of meat transformation or during digestion.

Carnosine is a dipeptide (β-alanine-L-histidine) present only in animal tissues. It is particularly abundant in brain and skeletal muscle from mammals. Its concentration is more elevated in glycolytic muscles, but it can also vary according to animal species, age, and/or food intake. The carnosine concentration in meat is not much affected by the type of meat aging or cooking processes.

The main biological activity of carnosine appears to be related to its buffering activity that allows, for instance, offsetting the decrease in intracellular pH linked to lactic acid production in muscles where anaerobic glycolysis is particularly active. Carnosine also has antioxidant properties by its ability to bind divalent metallic ions and its ability to trap free radicals. Moreover, carnosine seems able to reduce aldehydes formed from unsaturated fatty acids during oxidative stress and it has been suggested that carnosine also plays a prominent role in protection against glycation and crosslinking of proteins. Protein crosslinking interferes with tissue function and can, therefore, lead to aggregation of cellular material in the form of plates. Thus, carnosine may play an important role in preventing secondary complications in diabetes and in the protection against neurodegenerative disorders such as Alzheimer's disease. Carnosine-rich diets could, therefore, become increasingly important in geriatric human diets.

Glutathion is a tripeptide (GSH – L-γ-Glutamyl-L-cysteinyl-glycine) whose concentration is very high in the liver and is also present in the skeletal muscle. In contrast to carnosine, GSH is not specific to animal products and is also present in significant quantities in vegetables such as broccoli and spinach. It seems that a portion of the dietary glutathion can be absorbed intact, and it participates in the intracellular glutathion store in peripheral tissues. Because of the thiol function of cystein radical, glutathion exists as either a reduced (GSH) or an oxidized (GS-SG) form. GSH is the major hydrosoluble antioxidant in animal cells. It is an efficient free radicals scavenger, protecting cells from reactive oxygen species' (ROS) attacks. Any changes in GSH and GS-SG concentrations directly reflect alterations of their redox state. Glutathion also plays a role in xenobiotics detoxification, metabolism of various molecules (leucotriens, prostaglandins, formaldehyde, methylglyoxal, and nitric oxide), and the regulation of expression and/or activation of 'oxidation-sensitive' transcriptional factors that are necessary for the antioxidant response. Glutathion deficiencies contribute to the oxidant stress, which plays a key role in the aging process and the establishment of various pathologies (Alzheimer's, Parkinson's, and inflammation of the digestive tract). Studies in humans and animals show that an adequate protein intake is essential to maintain glutathion homeostasis. Moreover, GSH plays an important role in maintaining the integrity of the intestinal mucosa. Finally, dietary GSH, in addition to biliary GSH, participate in reduction of lipid peroxides present in the intestinal lumen.

Very few studies have described the ability of meat proteins to be a potential source of bioactive peptides. The most studied biological activity is the antihypertensive activity based on the inhibition of the angiotensin-converting enzyme (ACE). Several ACE-inhibiting peptides have been evidenced in controlled studies of muscle protein hydrolysates These studies have included a skeletal muscle hydrolyzed with thermolysin (i.e., myosin hydrolyzed with thermolysin), troponin C hydrolyzed with pepsin, and sarcoplasmic proteins hydrolyzed with a mixture of thermolysin, proteinase A, and protease type XIII. An *in vivo* study of an animal model shows that, following the ingestion of beef meat, numerous peptides are reproducibly released during the digestive process (Table 1) and many of them contain an amino acid sequence known to present an ACE-inhibiting potential. To be active at the peripheral circulation, these sequences will still need to be released intact by mucosal peptidases in order to enter the blood circulation and be resistant to the peptidases present in the blood plasma. The possibility of absorption of antihypertensive peptides has been demonstrated in humans after an oral administration of the dipeptide Val-Tyr, but the occurrence of such an absorption following the ingestion of dietary proteins containing bioactive sequences has so far not been reported. However, it was shown that a partial substitution of dietary carbohydrates by red meat can lower blood pressure in hypertensive patients.

Digestion Rate

It has been shown that the kinetics of the digestion of dietary protein determines the effectiveness of their assimilation, although optimal kinetics is not necessarily the same for all

Table 1 Peptides reproducibly released in duodenum and jejunum digestive contents during digestion of cooked beef meat in pigs

subjects. For instance, for elderly people, it seems preferable to concentrate the daily protein supply on a single meal, or to ingest rapidly digested proteins, in order to accentuate the postprandial increase in plasma amino acids and stimulate protein synthesis. From these observations, nutritional strategies are now developed to counteract aging-related muscle wasting (sarcopenia). The meat in this context could be a very interesting food because of its high concentrations in highly digestible proteins allowing the concentration of the protein supply in one meal.

A recent study in old human subjects has shown that meat can be considered as a source of rapidly digested proteins. However, the rate of digestion depends on the chewing capacity of elderly people and more precisely on the level of boli disruption before swallowing. Being slower in subjects with reduced chewing efficiency (complete dentures) than among subjects of the same age normally toothed, it induces a lesser increase in postprandial protein anabolism. The interest of meat consumption to counteract muscle wasting in the elderly, especially when associated with physical activity, would require to take into account the decline in chewing efficiency associated with aging and to develop new and adapted meat preparation techniques, allowing one to benefit from meat's full nutritional potential.

Micronutrients

Meat is an essential source for key micronutrients because either it is the only source of them or it is characterized by their high bioavailability.

Iron

Iron plays an important role as an oxygen carrier in hemoglobin in blood, or myoglobin in muscle, and it is also required for many metabolic processes. Iron has a higher bioavailability when derived from meat as heme iron than plant-derived iron. Approximately 30% of heme iron is

absorbed in the intestines, against only 7% of nonheme. Concentration of heme iron in meat depends on the animal species. For example, 100 g of red meat supplies approximately 3 mg of iron, i.e., 30% of the daily recommended intake, whereas the same quantity of white meat provides only 0.4 mg of iron. In modern societies, meat and meat products provide approximately 20% of the iron actually used by the body. Iron is an essential micronutrient in human nutrition and its deficiency is a world nutritional problem. Owing to the high prevalence of anemia in developing and industrialized countries, almost two-thirds of the world's population, it is necessary to maintain a suitable iron intake through diet in order to achieve an appropriate status of iron in the body. For this reason, accurate knowledge of iron availability of foods is essential in order to plan intervention strategies that improve deficient situations of this nutrient. With regard to the two forms of iron present in foods, heme iron has greater bioavailability than nonheme iron. Beside this, nonheme iron bioavailability is conditioned by several dietary factors such as classical factors (meat, ascorbic acid, fiber, phytic acid, and polyphenols) and new factors (caseinophosphopeptides and fructooligosaccharides with prebiotic characteristics).

Furthermore, heme iron has been pointed as a major prooxidant agent in food or in the digestive tract. The Fenton reaction leads to HO formation and lipoperoxidation propagation as well protein oxidation in the product, which can affect the organoleptic properties. In the digestive tract, heme iron is suspected to promote adenoma in rat studies. However, this effect is reversed in the presence of calcium, suggesting calcium could act as a chelator of iron.

In addition, some epidemiological studies postulated a possible role of this food component in carcinogenesis. In numerous studies, the prevalence of cancer risk associated to meat intake often includes processed meat, i.e., meat cooked with nitrites forming nitrosomyoglobin. Therefore, it remains difficult to assess the difference between iron alone and iron added with nitrites.

Zinc

Zinc is associated with the reactivity of a wide variety of enzymes. By binding zinc, phytate decreases its bioavailability. Hence, meat is a better source of this compound than vegetables. Thus, 100 g of bovine meat supplies approximately 5 mg of zinc, i.e., 40% of the daily recommended intake. Meat contributes 17% of the total zinc intake in France and 31–34% in Denmark, the UK, and New Zealand. In the USA, the contribution of meat to total zinc intake is 56%. In some human populations, the serum levels of zinc are below the deficiency threshold, especially in children and in the elderly.

Selenium

Selenium plays a central role in human antioxidative defense systems and it has been suggested that high selenium intakes reduce the risk of cancer and cardiovascular diseases. Meat and meat products are a good source of selenium as 100 g of meat supplies 6–8 μg of selenium, i.e., approximately 10% of recommended intake. The liver is particularly rich in selenium (40–100 μg for 100 g).

Meat and meat products are also important sources of copper, cobalt, chromium, manganese, and nickel and greatly contribute to the recommended intakes of these compounds.

Vitamins

Two important micronutrients occur only in meat: vitamins A and B_{12}. Both cannot be compensated for plant-derived provitamins. Provitamin B_{12} does not exist and the provitamin A, β-carotene, has to be taken in high amounts due to a poor conversion rate (1:12).

Vitamin A

Vitamin A is involved in bone growth, eye pigment synthesis, and prevention of respiratory diseases. Meat is a better source of vitamin A than vegetables. Meat contains retinol or retinol esters, which are directly usable by the body, whereas vegetables contain β-carotene, a precursor of retinol, and the conversion rate of β-carotene into retinol is only 1:12. The concentration of vitamin A in meat ranges widely among species (2–100 μg per 100 g of meat). With 20 000 μg per 100 g, the liver is the best source of vitamin A in the human diet, and its contribution to the recommended intake is approximately 75%.

Vitamins B_9 and B_{12}

The B vitamins work as cofactors in different enzyme systems in the body and their deficiency is linked to many diseases. Meat and animal-derived foods are the only foods that naturally provide vitamin B_{12}, a water-soluble component. Meat contains 0.3–2 μg of vitamin B_{12}, oxidative muscle having the highest content, whereas the liver contains 65 μg. A daily consumption of 120 g of meat or a monthly consumption of 120 g of the liver supplies recommended intakes. Similarly, folic acid has a nearly 10-fold higher bioavailability from meat (especially liver) and eggs than from vegetables.

Vitamin D

Vitamin D is essential for the development and maintenance of bone. Although most vitamin D comes from the action of sunlight on 7-dehydrocholesterol in the skin, some human populations are particularly reliant on a dietary supply of vitamin D. With a level of 0.1 μg per 100 g, the contribution that meat makes to vitamin D dietary intake is important. In general, meat products contribute 20–30% of daily intake of vitamin D.

Vitamin E

There are small amounts of vitamin E in meat, but the recent trend to include seed oils or vitamin E in animal diet contributes to an increase of vitamin E content in meat.

Fat

Meat, like other animal products, is a source of lipids, mostly of phospholipids, triglycerides, and cholesterol. The proportion of

lipids in lean meat lies between 2% and 6%, according to species and muscle type. For example, in white meat such as deskinned poultry breast meat, the amount of lipid barely reaches 2%. The hydrolysis of triglycerides releases three fatty acids. These can be either saturated or unsaturated (monounsaturated fatty acids (MUFAs) or polyunsaturated fatty acids (PUFAs)). Because of its high saturated/unsaturated fatty acid ratio, beef consumption suffers unfairly from a poor image in terms of nutritional quality. To increase the amounts of PUFAs, and especially of *n*-3 PUFAs, in bovine meat, several strategies including diet have been implemented to reverse this ratio and achieve perceived positive health effects. Because PUFA and MUFA are highly reactive to oxidation in meat storage or during processing, addition of antioxidants in the diet of ruminants is recommended.

Meat Intake and Cancer

Several epidemiological cohort studies either have suggested a positive association between meat intake and colon/prostate cancer or have failed to detect such an association. However, the majority of the studies were not adjusted for total energy intake. It is more or less generally suggested that animal fat, rich in saturated fat, is closely associated with cancerogenesis and it is, therefore, implied that plant-derived mostly unsaturated fat (PUFA) is more protective. In animal models, the tumor-promoting effect of fat intake has been observed primarily for PUFA.

The suggestion that consumption of red meat as a source of dietary fat increases the risk of colon cancer is based on the premise that dietary fat promotes excretion of bile acids, which can be converted into carcinogens. However, this may not be true as fat derived from red meat might be less absorbed due to either its composition (stearic acid) or matrix (muscle) interactions. Also, it has been suggested that heterocyclic amines produced in barbecued meat might contribute to carcinogenesis.

The role of heme iron as a promoter is often suggested. Like many other transition elements, iron possesses unfilled atomic orbitals that allow it to coordinate electron donors and participate in redox processes. Iron can cause oxidative stress and DNA damage, and heme iron can catalyze endogenous formation of N-nitroso compounds (NOCs), which are potent carcinogens. Studies of chemically induced colon carcinogenesis in rats demonstrated a dose–response relationship between heme iron and promotion. The way in which the heme iron could promote cancer is described in Figure 1 via the fat peroxidation and the N-nitroso pathways. There is

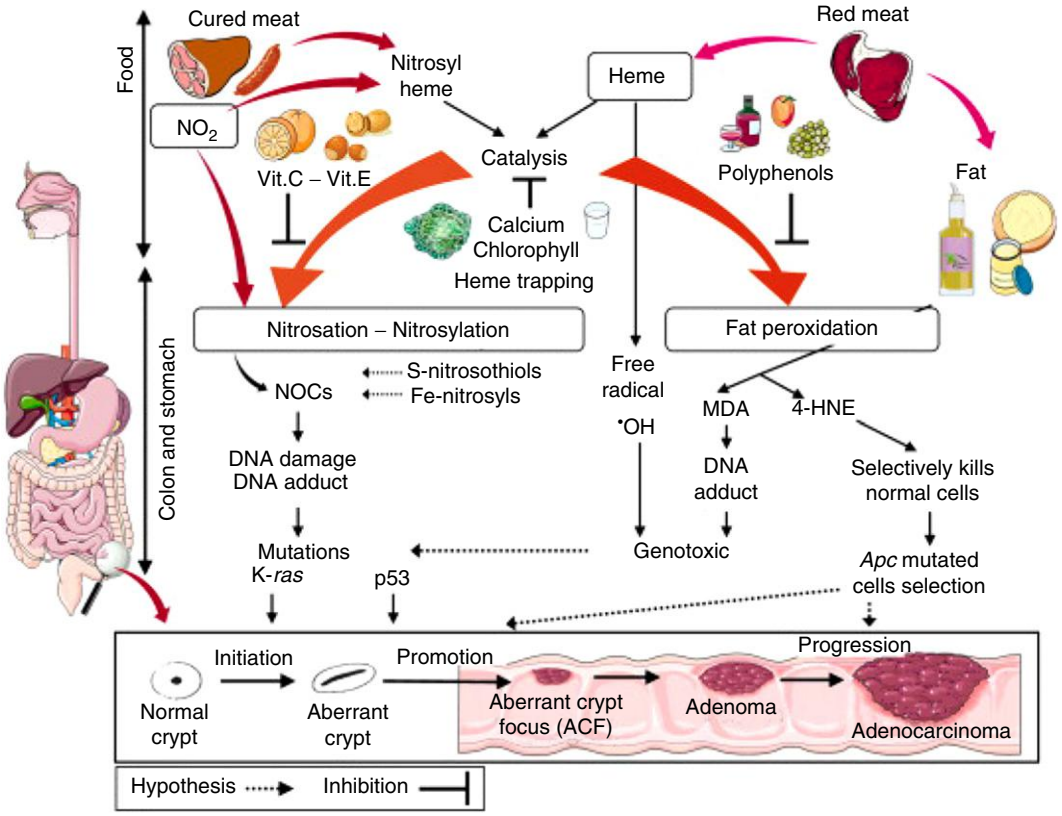

Figure 1 Catalytic effect of heme iron on fat peroxidation and N-nitrosation, and their inhibition by dietary means. Consequences for the development of colorectal cancer – Reprinted with modifications from Cancer Prevention Research – Bastide, N., Pierre, F., Corpet, D., 2011. Heme iron from meat and risk of colorectal cancer: A meta-analysis and a review of the mechanisms involved. Cancer Prevention Research 4, 177–184. Heme iron catalyzes nitrosation and fat peroxidation. End products are NOCs, malonaldehyde (MDA), and 4-hydroxynonenal (4-HNE). These pathways explain, at least in part, the promoting effect of red and cured meat on colorectal cancer. The catalytic effects of heme iron can be inhibited by trapping heme with calcium carbonate or chlorophyll. The endogenous formation of NOCs is inhibited by vitamin C and E. Ongoing studies suggest that specific polyphenols can inhibit fat peroxidation and/or nitrosation.

some evidence that carcinogenesis promotion by dietary heme iron is associated with the urinary excretion of a fat peroxidation biomarker, 1,4-dihydroxynonane mercapturic acid, the major 4-HNE – end products of lipoperoxidation of ω6 fatty acid – urinary metabolite. 4-HNE and MDA are toxic and bind DNA, forming mutagenic adducts. Those metabolic events could explain tumor promotion. Interestingly, in a study on rats, intake of beef meat with added calcium decreased the risk of tumor formation. The chelation of calcium by the heme iron complex would prevent the iron to act as a catalyst of lipoperoxidation. The N-nitroso pathway would mainly explain the hypothesis that nitrite-cured meat favors cancer. But this pathway is not limited only to cured meat, because a diet high in fresh red meat (600 g d^{-1} compared with 60 g d^{-1}) induces a 3-fold increase in fecal nitrosocompounds.

Conclusion

Although meat presents beneficial nutritional properties due to its essential amino acid composition, it is also very important to understand the function of biologically relevant peptides it contains, and its high digestibility. Therefore, there is a strong rationale for reassessing the processing that affects proteins in terms of their impact on the nutritional quality of meat. These postmortem changes (aging, processing treatments, etc.) affect the meat structure, which can decrease the bioavailability of essential amino acids, not only by changing the type of digestive end products (more or less resistant peptides) produced but also by affecting the digestion rate. New insights into the field of bioactive peptides make it possible to reexamine current concepts of the nutritional quality of dietary proteins, which to date have only been based on essential amino acid composition and digestibility. Thus, by integrating other properties having a known impact on health, the position of these foods within the framework of a balanced human diet can be revised.

Through its carnosine content and the potential of meat proteins to release bioactive peptides, especially antihypertensive peptides, meat could offer new nutritional benefits. Furthermore, the high protein content and fast rate of digestion of meat makes it the first-line choice in nutritional strategies designed to counteract aging-related sarcopenia. Digestion in the small bowel (rate and end products), which to date has been relatively unexplored, remains a key point to deeper insight into whether nutritional quality is positively or negatively impacted by the biochemical and structural changes of the major compounds that are caused by food processing procedures. There is clearly a need for more work in this area, given the uncertainties over the definition of meat and processed meat.

The increase in meat consumption has been associated with an increased risk of cancer (in societies where there is adequate food available), but there is also a concomitant increase of other foods almost to excess, a reduction of exercise and an increase in obesity, so meat is unlikely to be solely responsible. At the other end of the scale, addition of relatively small quantities of meat to a diet will have a positive effect, for the reasons indicated in this article, and certainly outweigh any disadvantages associated with its absence. It would be fair to say that the currently available epidemiologic evidence is not sufficient, on its own, to support an independent positive association between reasonable (i.e., not an excess) levels of red meat consumption and increased risk of colorectal cancer.

Micronutrients in Meat

B Mulvihill, Timahoe, Co. Laois, Republic of Ireland

This article is a revision of the previous edition article by B Mulvihill, volume 2, pp 618–623, © 2004 Elsevier Ltd.

Glossary

Bioavailability The amount of a nutrient which is absorbed and used/metabolized by the body. Techniques for assessing bioavailability include radioactive tracers, *in vivo* and *in vitro* studies.

Heme and nonheme iron Food iron is classified as heme and nonheme iron. Heme iron is derived from hemoglobin and myoglobin and its food sources are meat, fish, and poultry. Main food sources of nonheme iron include meat, cereals, fruits, vegetables, and nuts. Heme iron is more bioavailable than nonheme iron.

Irish Universities Nutrition Alliance (IUNA) IUNA is made up of four academic nutrition units from University College Cork, University of Ulster, Trinity College Dublin, and University College Dublin. Since it was established, IUNA has conducted a series of food consumption surveys among different age groups in Ireland. In addition to collecting information on habitual food and drink consumption, they also record, health and lifestyle characteristics and anthropometric measurements. The wealth of data is a valuable resource and is used to guide and develop nutrition policies and health promotion campaigns.

Meat factor Meat promotes the bioavailability of nonheme iron and the mechanism which is responsible for the enhanced absorption/bioavailability remains unknown. It is commonly referred to as the 'meat factor.'

Recommended dietary allowances The level of intake of nutrients that, on the basis of scientific knowledge, are judged to be adequate to meet the known nutrient needs of practically all healthy persons.

Introduction

This article examines the role that meat and meat products play in supplying iron, zinc, selenium, sodium, vitamin D, and the B vitamins to the diet. Data on the content of these nutrients in meat are taken from publications of McCance and Widdowson's 'The Composition of Foods.' These values should be used as a general guide; they are for raw meats and, therefore, may vary for processed and cooked meats.

Recommended dietary allowances (RDAs) are the level of intake of nutrients that are judged to be adequate to meet the known nutrient needs of practically all healthy persons. In this article, the RDA is cited for adult males and females. In the case of many nutrients, the RDA varies for age and special conditions (such as pregnant and lactating women). A full listing of the RDA values for each nutrient in Ireland is available from The Food Safety Authority of Ireland.

To put a figure on the contribution that meat makes to the micronutrient intakes, data will be taken from four food consumption surveys conducted in Ireland by the Irish Universities Nutrition Alliance (IUNA). The surveys were conducted among nationally representative samples of:

- Children: 5–12 years, 594 children, data collected between 2003 and 2004, used 7-days weighed food record.
- Teenagers: 13–17 years, 441 teenagers, data collected between 2005 and 2006, used 7-days semiweighed food record.
- Adults: 18–64 years, 958 adults, data collected between 1997 and 1999, used 7-days estimated food record. A second survey, 1274 adults, data collected between 2008 and 2010, used 4-days semiweighed food record. With the exception of selenium, adult micronutrient intake data will be taken from the most recent survey.
- The elderly: those aged 65 years and older, 226 persons, data collected between 2008 and 2010, used 4-days semiweighed food record.

A nutrient analysis software package, WISP©, analyzed the data, which uses the sixth edition of the UK compositional figures. It was added to using Irish food composition data for composite dishes, generic Irish foods and supplements. All foods were categorized into food groups, including a 'meat and meat products' food group.

Meat and meat products' food group contains fresh meat (beef, veal, pork, lamb, chicken, turkey, and game), meat dishes (offal and offal dishes; beef and veal dishes; and lamb, pork, and bacon dishes), and cured and processed meats (bacon, ham, burgers (beef and pork), sausages, meat products, meat pies, and pastries). Results from the surveys are summarized in Table 1.

Minerals

Iron

Iron deficiency is the most common nutritional disorder in the world (in both developed and developing countries) and it is estimated that nearly a quarter of the world's population is deficient in iron. Groups at greatest risk of iron deficiency include infants, children, adolescent girls, and pregnant women. For instance, iron deficiency is the most common nutritional disorder during early childhood and meat is recommended in

the weaning diet and has been shown to make a significant contribution to the iron status of toddlers. Inadequate intake of iron can lead to varying degrees of deficiency; from low iron stores to iron-deficiency anemia. Conditions associated with iron deficiency include defective psychomotor development in infants, impaired education performance in school children, adverse perinatal outcome in pregnancy, and a diminished work capacity.

Bioavailability of iron refers to the proportion of ingested iron that is absorbed and utilized by the body. Low bioavailability of dietary iron is a major contributing factor to iron anemia. There are three elements in meat that make it so valuable in terms of iron nutrition.

1. Meat is a rich source of iron. A fillet steak contains 2.1 mg iron per 100 g. Fillet steak is an expensive cut of meat, but irrespective of the price, all meats are rich in iron. For instance, rib roast contains 1.7 mg iron per 100 g and liver contains 8–17 mg iron per 100 g. A 100-g portion of lamb and pork contains approximately 1.4 and 0.7 mg of iron, respectively.
2. There are two types of iron in meat – heme and nonheme iron. Dietary iron exists in two forms, heme and nonheme. Heme iron is found in foods that contain hemoglobin and myoglobin, that is, foods of animal origin and therefore meat and fish. Approximately 50–60% of the iron in meat is heme. In contrast, plant foods contain only the nonheme form. Heme iron is readily absorbed (20–30%) and utilized by the body and therefore is said to be highly bioavailable. The effect of cooking meat on heme iron is not fully understood; it is suggested that high temperatures convert heme iron into nonheme.
3. Meat promotes the absorption of nonheme iron. Meat also contains nonheme iron, and it is this iron that makes the largest contribution to the body's iron pool. Meat promotes the absorption of nonheme iron, not only from itself but also from other foods eaten with it in the same meal. For instance, it has been estimated that the amount of nonheme iron absorbed from cereals, fruits, and vegetables when eaten alongside meat can be as high as 15–25%. In contrast, when these foods are eaten on their own, nonheme iron absorption is between 1% and 7%. Nonheme iron absorption is inhibited by fibers (phytate and oxalate), phenolic (tannins) compounds, and other minerals (zinc, calcium, and copper) and enhanced by only two food components – vitamin C (ascorbic acid) and meat. The component in meat that enhances the absorption of nonheme iron is referred to as 'meat factor.' The 'meat factor' mechanism remains to be elucidated. Cooking meat does not impair the 'meat factor.' A functional food has a health benefit above and beyond the nutrients the food provides. Thus, presence of the 'meat factor' may, in the future, allow meat to be marketed as a functional food.

Meat makes an important contribution to iron intakes. Irish food intake survey data show that meat and meat products contribute 13%, 17%, and 18% of dietary iron in the diets of children (5–12 years), teenagers (13–17 years), and adults, respectively. The contribution that heme iron and the 'meat factor' makes to iron intake and status is not known. A thorough understanding of the bioavailability of both heme and nonheme iron from the diet is required to fully appreciate the role of meat in iron nutrition. Low intakes of meat are routinely associated with low iron stores and anemia. Therefore, the role of meat in iron nutrition cannot be overstated and including at least some meat in the diet guarantees an assured source of easily absorbable iron.

Zinc

Zinc is an essential nutrient required for numerous metabolic functions, including synthesis of proteins, nucleic acids, and insulin and sexual maturity in males. Deficiency of zinc results in growth retardation, high rates of infection, skin lesions, and impaired wound healing.

People readily associate meat with iron, but what they do not appreciate is that meat is an even better source of zinc and contributes twice as much zinc as iron. Data from the Irish nutrition surveys show that meat and meat products contribute 28%, 34%, 36%, and 35% of the zinc intakes in 5–12-year-old children, teenagers, adults, and the elderly, respectively. A general rule of thumb is that a third of humans' zinc intakes come from meat and meat products.

Similar to iron, meat also promotes the absorption of zinc and therefore the zinc in meat is classed as highly bioavailable. It is estimated that 20–40% of zinc is absorbed from meat. The mechanism by which meat promotes the absorption of zinc is not known. Zinc present in other foods such as plants (cereals, grains, legumes, and nuts) has a low bioavailability due to the presence of phytates, which are thought to bind the zinc and inhibit its absorption. The elderly, vegetarians, toddlers, and people with renal disorders are at risk of zinc deficiency.

Beef is the richest meat source of zinc; for example, a 100-g portion of trimmed lean beef contains approximately 4-mg zinc. The RDA for zinc is 9.5 mg day^{-1} for males and 7 mg day^{-1} for females. Therefore, a typical 100-g portion of beef provides approximately half its daily requirement. Lamb is also rich in zinc, with a typical 100-g portion containing approximately 3.3-mg zinc; lower levels are found in pork (2.1-mg zinc per 100 g). Red meats are generally better sources of zinc than white meats; for instance, chicken breast contains less than 1-mg zinc per 100 g. Zinc is stored in the liver and the zinc content of lamb and pork liver is 4–8 mg per 100 g and that of calf liver is 14–16 mg per 100 g.

Selenium

Selenium is a constituent of the enzyme glutathione peroxidase, which inactivates toxic hydrogen peroxide and hydroperoxides. Evidence suggests that selenium may protect against coronary heart disease and certain cancers, in particular prostate cancer. The RDA for selenium is 55 μg day^{-1} for adults. Meat and meat products contribute approximately 30% of selenium intakes.

Of the red meats, pork (13 μg per 100 g) contains the highest levels of selenium, followed by beef (7 μg per 100 g) and lamb (2 μg per 100 g). Organ meats such as kidney (150 μg per 100 g) and liver (42 μg per 100 g) are rich in selenium. The interest in selenium as an essential antioxidant nutrient is relatively new and research is required to find out more about selenium in meat, including its bioavailability.

Sodium

Fresh meat is low in sodium. Data from Irish nutritional surveys indicate that as a food group, meat and meat products supply approximately a quarter of sodium intakes and make the largest contribution of any food group (Table 2). Sodium is added to fresh meats as a curing agent to extend their shelf life by acting as a preservative; it also adds flavor and improves their color, taste, and texture. The Irish survey data separated the 'meat and meat products' food group into 'fresh meat and meat dishes' (beef, veal, pork, lamb, chicken, turkey, and game; offal and offal dishes; beef and veal dishes; and lamb, pork, and bacon dishes) and 'cured and processed meats' (bacon, ham, burgers (beef and pork), sausages, meat products, meat pies, and pastries). 'Cured and processed meats' contribute a fifth of total sodium intakes (Table 2). The contribution that meat and meat dishes make to sodium intake is 6% in children and teenagers, 9% in adults, and 7% among the elderly. Meat is indeed low in sodium, and it is the contribution of sodium by processed and cured meats that is having such a large impact.

Countries are looking at ways to reduce the amount of salt in processed foods and considerable inroads have been made. In Ireland, the Food Safety Authority of Ireland implemented the Salt Reduction Programme. Its aim was to reduce the intake of salt to 6 g day^{-1} by 2010 (the RDA is 4 g day^{-1}). The program worked with food processors to look at strategies to reduce salt, such as simply lowering salt in the formulations and using alternative ingredients such as low sodium salts, salt replacers, and other ingredients that may mask the effects of reducing salt. The program did achieve success but it did not reach its target of 6 g day^{-1}. Many processors have reduced the salt they use during processing but have indicated that they cannot reduce salt any further as it would negatively affect the taste, color, shelf life, texture, and safety of their products.

Vitamins

Vitamin D

Until recently, meat was not recognized as a valuable source of vitamin D – the sunshine vitamin. However, recent data indicate that meat and meat products are the richest natural dietary source of vitamin D. Children in Ireland aged between 5 and 12 years receive 31% of their dietary vitamin D from meat and meat products. Moreover, this food group contributes 35% dietary vitamin D in teenagers, 30% in adults, and slightly lower levels (22%) in the elderly. Vitamin D is fat soluble and higher quantities are found in meat fat than in lean meat.

The main source of vitamin D is sunlight. The endogenous synthesis of vitamin D begins when ultraviolet light converts dormant 7-dehydrocholesterol in the skin to cholecalciferol. Cholecalciferol is subsequently hydroxylated in the liver to 25-hydroxycholecalciferol ($25(OH)D_3$) and in the kidney to its most biologically active form, $1,25(OH)_2D_3$ (dihydroxycholecalciferol). $1,25(OH)_2D_3$ acts as a hormone and stimulates calcium absorption and maintains healthy bones.

Table 2 Contribution of meat and meat products to sodium (salt) intakes in Ireland among different age groups

	5–12 years old	*13–17 years old*	*18–64 years old*	*>65 years old*
Meat and meat products[a]	24	26	27	24
Meat and meat dishes[b]	6	6	9	7
Cured and processed meat[c]	18	20	18	17

[a]Meat and meat products – refers to all meats (beef, veal, pork, lamb, chicken, turkey, and game), meat dishes, and cured and processed meats.
[b]Meat and meat dishes – offal and offal dishes; beef and veal dishes; and lamb, pork, and bacon dishes.
[c]Cured and processed meats – bacon, ham, burgers (beef and pork), sausages, meat products, meat pies, and pastries.
Source: Data taken with permission from Irish North–South Food Consumption Surveys – Irish Universities Nutrition Alliance (www.iuna.net).

Historically, cholecalciferol was the only vitamin D metabolite in meat to be measured. Research indicates that $25(OH)D_3$ is five times more potent than cholecalciferol and this potency factor is included in Irish compositional data and the food intake surveys. Meat also contains $1,25(OH)_2D_3$ and it is suggested that it is 25 times more potent than cholecalciferol. This is not included in vitamin D analysis as further research is required to shed light on this issue.

In the 1920s, meat was shown to protect against rickets, a fact that has long been forgotten. Rickets (softening of the bones) occurs in children; its adult equivalent is osteomalacia. Rickets was endemic in industrial cities in Britain in the nineteenth century, whereas today it is practically nonexistent. The reason for this is thought to be the early introduction of meat into the diet of toddlers. It is hypothesized that there is a 'magic factor' in meat, which protects against rickets and it may be related to vitamin D. In Ireland, babies are recommended to take a vitamin D supplement up to their first birthday. In addition to maintaining bone health, vitamin D aids the immune system and it may protect against tuberculosis, muscle weakness, diabetes, certain cancers, and coronary heart disease.

B Vitamins

Meat is a significant source of many B vitamins. The B vitamins in meat are thiamin (vitamin B_1), riboflavin (vitamin B_2), niacin, pantothenic acid, vitamin B_6, and vitamin B_{12} (cobalamin). As the B vitamins are water soluble, lean meat contains higher amounts of them than meat fat. They are not very stable and some losses of B vitamins occur during cooking. The amount of B vitamins lost during cooking depends on its duration and temperature. One way of replenishing the lost B vitamins is to use the juices of meat to make gravy or to make a casserole or a stew where the juices are eaten as part of the meal.

Vitamin B_{12} (Cobalamin)

Vitamin B_{12} was the last vitamin to be isolated; it has a complex structure and the largest molecular weight of all vitamins. Vitamin B_{12} is exclusively of animal origin as it is made through bacterial fermentation in the gut. Natural food sources of vitamin B_{12} are limited to meat, fish, milk, and eggs. Fortified foods such as breakfast cereals also contribute to intakes of this vitamin. The RDA for vitamin B_{12} is 1.4 μg day^{-1} for adults (males and females). Organ meats are the richest food source; examples include liver (23–110 μg per 100 g) and kidney (15–54 μg per 100 g). Beef, lamb, and pork contain 1–3-μg vitamin B_{12} per 100 g. Therefore, a 100-g portion of meat provides most, if not all, of the daily requirement of this vitamin. In Ireland, meat and meat products contribute approximately a quarter of vitamin B_{12} intakes in teenagers and adults and a fifth in children (5–12 years).

Vitamin B_{12} acts as a cofactor for many enzymes. It plays a role in red blood cell formation and a deficiency causes megaloblastic anemia. Vitamin B_{12} also plays a role in maintaining a normal central nervous system and another clinical syndrome of vitamin B_{12} deficiency is neuropathy (e.g., spinal cord disease).

As vitamin B_{12} is limited to foods of animal origin, vegans and strict vegetarians are at risk of deficiency and are advised to take vitamin B_{12} supplements. In addition, infants breast-fed by a vegan mother are also at risk of deficiency. Another vulnerable subgroup is the elderly, as they have a diminished capacity to absorb dietary vitamin B_{12}.

Vitamin B_6

The RDA of vitamin B_6 for adult males and females is 1.5 and 1.1 mg day^{-1}, respectively. Meat is a valuable source of vitamin B_6. Beef, lamb, and pork contain between 0.3- and 0.5-mg B_6 per 100 g. Calf (0.89 mg per 100 g), lamb (0.53 mg per 100 g), beef (0.52 mg per 100 g), and pig (0.64 mg per 100 g) liver contain higher amounts of vitamin B_6. In Ireland, meat and meat products contribute 18% of dietary vitamin B_6 in children (5–12 years) and 23%, 24%, and 22% in teenagers, adults, and the elderly, respectively. Vitamin B_6 is present in plants; however, it cannot be absorbed from some vegetables because of the presence of glycosides; this does not affect the vitamin B_6 in meat.

The term 'vitamin B_6' includes three pyridines: pyridoxine, pyridoxal, and pyridoxamine and their 5′-phosphorylated derivatives, which are interconvertible. In the liver, pyridoxine and pyridoxamine are converted into pyridoxal 5′-phosphate, which acts as a cofactor for many enzymes, including those related to protein metabolism and amino acid interconversion. Vitamin B_6 also plays a role in red blood cell formation and supplies energy by converting fat to energy.

The Role of Vitamins B_6 and B_{12} in Lowering Homocysteine

Homocysteine is an amino acid metabolite, and a raised plasma level is an independent risk factor for heart disease. Both vitamins B_6 and B_{12} act as cofactors for enzymes that break down potent homocysteine to innocuous amino acids.

Research shows that vegans and strict vegetarians who have habitually low intakes of vitamins B_6 and B_{12} have higher circulating levels of plasma homocysteine. This shows the important role that vitamins B_6 and B_{12} play in lowering plasma homocysteine and highlights the fact that meat and meat products are valuable sources of these vitamins.

Niacin

The RDA of niacin for adult males and females is 16 mg day^{-1}. Meat is the richest food source of niacin. A 100-g portion of meat contains approximately 5–7 mg of niacin. There are two sources of niacin in the diet – the vitamin nicotinic acid and the amino acid tryptophan. Half the niacin provided by meat is derived from tryptophan, which is more readily absorbed by the body than that from plant sources, which is bound to glucose. In Ireland, teenagers and adults get 39% of their niacin intakes from meat and meat products and this is 30% in children (5–12 years).

Niacin supplies energy to the body by converting carbohydrates and fat into fuel. It also promotes a normal appetite, healthy skin, and aids in digestion.

Vitamin B_1 (Thiamin)

The RDA of thiamin is 1 mg day^{-1} for adults. Thiamin is found in useful amounts in meats, particularly in pork. Pork and its products, including bacon and ham, are the richest meat sources of thiamin (1 mg thiamin per 100 g). Beef and lamb contain 0.1 mg thiamin per 100 g and the liver, kidney, and heart contain approximately 0.5 mg thiamin per 100 g.

Thiamin acts as a cofactor for enzymes, which convert fats and carbohydrates into fuel, thus supplying energy to the body. Thiamin also helps in promoting a normal appetite and normal nervous system function.

In Ireland, approximately a fifth of thiamin is provided by meat and meat products in teenagers and adults. Among children (5–12 years), slightly lower levels (16%) are supplied by meat and meat products.

Vitamin B_2 (Riboflavin)

Riboflavin acts as a cofactor for enzymes of the Krebs cycle, which supplies energy. It also promotes healthy skin, eyes, and vision and may prevent against cataracts. A deficiency of riboflavin reduces appetite, causes anemia, and impairs the conversion of tryptophan to niacin.

The RDA of riboflavin for adults is 1.6 mg day^{-1} for males and 1.3 mg day^{-1} for females. Offal meats are good sources of riboflavin; for example, kidney contains 2–3.3 mg per 100 g and liver contains 2–6 mg per 100 g. A 100-g portion of beef, lamb, and pork contains approximately 0.2-mg riboflavin. Meat and meat products provide 10% dietary riboflavin among children, this rises to 15% for teenagers and 16% for adults and the elderly.

Pantothenic Acid

The liver and kidney are rich sources of pantothenic acid. Although most of this vitamin is leached into the drip loss associated with frozen meat, this is unlikely to be of any nutritional consequence as pantothenic acid is universal in all living matter. There is no RDA for pantothenic acid, although it is suggested that an intake of 4–7 mg day^{-1} is required. All meats contain pantothenic acid, such as pork (1.46 mg per 100 g), beef (0.75 mg per 100 g), and lamb (0.92 mg per 100 g).

Pantothenic acid is involved in energy production and aids in the formation of steroid hormones. It is often referred to as the 'antigray' hair factor, as it is thought to prevent hair becoming gray. In Ireland, meat and meat products provide 17% dietary pantothenate among children, 23% to teenagers and the elderly, and a quarter of an adult's intake.

Summary

Iron is the main nutrient that people associate with meat, and it may come as a surprise to many people that meat is a valuable source of many other nutrients. In fact, meat and meat products contribute double or more than double the dietary intakes of zinc, selenium, vitamin D, and niacin than that of iron. The iron and zinc in meat are highly bioavailable. Meat enhances the absorption of iron from nonmeat sources and its contribution to iron nutrition has still to be quantified. Over the past 50 years, the contribution that meat makes to selenium intakes has grown. Recent advances in compositional analysis reveal that meat and meat products are the richest natural dietary source of vitamin D. In the past, little attention was given to the contribution that meat makes to the intake of the B vitamins. Recently vitamins B_{12} and B_6 have attracted much interest as they reduce plasma homocysteine and meat contributes between a fifth and a quarter of their dietary intakes. Meat is the richest food source of niacin. Vitamin B_{12} is exclusively of animal origin. The majority of sodium supplied by meat and meat products comes from its addition to processed meats.

Meat and meat products make a significant contribution to the dietary intakes of iron, zinc, selenium, vitamin D, vitamin B_{12}, vitamin B_6, niacin, vitamin B_1, thiamin, vitamin B_2, riboflavin, and pantothenic acid. In many cases, their offal meats contain even higher quantities of these micronutrients. However, nutritional science is relatively new and many mysteries have still to be unraveled about meat and its nutrients.

Nutraceuticals

AW Brown, University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

The importance of foods and food products in the prevention and treatment of diseases has moved beyond the simplicity of essential nutrients. Food and food products are now divided into many different categories based on the purposes of the food. Apart from conventional foods that are simply meant for sustenance, four categories of food or food products intended to improve or support health are medicinal foods, functional foods, supplements, and nutraceuticals. Although there is considerable overlap among these categories, there are distinct differences as well as nuances that determine which particular category a product belongs to. Medicinal foods are considered prescribed diets to treat medical conditions, such as diets designed to circumvent genetic abnormalities or severe allergies. Functional foods are foods thought to supply an additional benefit beyond meeting micronutrient or macronutrient needs, such as reducing oxidative stress, improving longevity, or lowering some disease risk factor.

Dietary supplements and nutraceuticals are distinguished from the other categories in that they are composed of extracts or components of foods meant to be consumed separate from food rather than as ingredients or whole foods. Dietary supplements are meant to supplement nutrient deficiencies in normal diets, such as vitamins and minerals. Some dietary supplements, such as herbal supplements, can also be used to introduce compounds not generally considered to be nutrients but that may still contain functional compounds that affect health.

The word nutraceutical itself is a portmanteau of the words 'nutrient' and 'pharmaceutical.' Thus, the concept of a nutraceutical is a component of food that has pharmaceutical properties. Nutraceuticals can therefore sometimes be considered a subset of dietary supplements in that eliminating a nutrient deficiency can cure or prevent some ailments (e.g., vitamin D and rickets). Often, however, nutraceuticals are considered components of foods that are given at pharmaceutical or superdietary doses to elicit responses beyond the effects known to be sufficient to prevent deficiencies (e.g., vitamin D and cancer prevention).

Definitions of these classifications of food are not clearly established, and vary among countries, researchers, and commercial operations. In particular, some consider nutraceuticals to be intact foods with health-promoting properties (defined as functional foods above). Thus, it is imperative that the chosen definition be made clear whenever discussing these categories of foods. The definition used herein corresponds to that of the Bureau of Nutritional Sciences of the Food Directorate of Health Canada:

> "A nutraceutical is a product isolated or purified from foods that is generally sold in medicinal forms not usually associated with food. A nutraceutical is demonstrated to have a physiological benefit or provide protection against chronic disease."

The former part of the definition gives rise to the commercial reality that any compound or extract from food can be considered a nutraceutical. The latter part of the definition restricts nutraceuticals to products that can be demonstrated to improve health or impede disease. However, it can be difficult to prove that a purported nutraceutical improves health, which results in regulatory challenges discussed below.

Government Regulations

Regulation of categories of foods and food components varies from nation to nation, but generally there are no clear legal divisions or definitions for the use of such terms as 'functional foods,' 'nutraceutical,' or 'dietary supplement.' For instance, the Dietary Supplement Health and Education Act from the US essentially defines a dietary supplement as a product intended to supplement the diet that contains at least one dietary ingredient and is not to be consumed as conventional food, such as in capsule or liquid form. In addition, the product needs to be labeled as a dietary supplement. However, there is no regulatory definition of 'nutraceutical.' In Japan, food supplements are considered food, and need to comply with regulations for one of two categories: Foods with Nutrient Function Claims, such as the functions of vitamins and minerals, or Foods for Specified Health Uses, which are officially approved health claims. This is similar to 'structure/function' versus 'significant scientific agreement' health claims in the US.

Regulations divide medicines and foods. In the US, for example, compounds intended to treat or cure diseases that are not caused by nutrient deficiencies are considered drugs, with the exception of a few food components approved in the Code of Federal Regulations. For example, certain vitamin D- and calcium-containing foods or supplements can be advertised as lowering osteoporosis risk, which means these formulations are meant to prevent a disease. This differs from structure/function claims, in which compounds can be implicated in supporting health but not treating or preventing disease. Again using vitamin D as an example, a company marketing a vitamin D-containing supplement could suggest that vitamin D 'supports normal blood pressure' because there is some (but not conclusive) scientific evidence that vitamin D helps maintain normal blood pressure (a structure/function claim), but because strong scientific evidence does not exist they cannot claim that vitamin D lowers the risk of hypertension (a disease claim). Many individual countries, as well as the European Union, make analogous distinctions.

A common theme with nutraceuticals is that their efficacies are uncertain. Their functions go beyond the essentiality of nutrients where deficiencies result in clearly identifiable maladies. Moreover, the rigorous scientific investigation, fiscal backing, or dramatic phenotypic changes demonstrated by pharmaceuticals are often lacking. Therefore, the understanding of nutraceuticals' functions and effects are constantly being

 doi:10.1016/B978-0-12-384731-7.00236-1

evolved. Because of the difficulty in establishing the strength of scientific evidence required to make legal disease claims, most dietary supplements and nutraceuticals are not approved to treat diseases or disease risk factors. Reaching a scientific consensus requires a significant financial investment. Often, however, a company cannot own the rights to a compound in food, but can merely own the rights to the methods of extracting or preparing the compound. Thus, the amount of time and money required to convincingly prove that a nutraceutical cures or prevents a disease is insurmountable for most companies.

Generalizability is often limited in nutraceutical research because of variability in the nutraceutical itself, such as differences in the exact chemical structure of the nutraceutical, the matrix in which the nutraceutical is supplemented, the dosage and frequency of administration, and the route of administration. For instance, glucosamine may have a sulfate or chloride counter ion; poorly preserved omega-3 fatty acids can oxidize; mineral absorption can be affected by the presence of other minerals; administration schedules affect absorption and functionality; and although nutraceuticals by definition should be orally administered, some studies administer them through alternative means, such as intramuscular and intraarticular injection of glucosamine. Understanding these details is imperative to elucidating the effects of nutraceuticals, as well as their potential contraindications. Therefore, even if a compound does amass the scientific consensus required to establish disease claims, companies that prepare the compound in a different way are not guaranteed to be able to use the approved disease claim because the preparation may alter the efficacy. That is, one proprietary formula may alter the efficacy of a nutraceutical compared to other preparations.

Examples of Animal-Derived Nutraceuticals

As described, any extract of food or food components may be considered a nutraceutical. The nutraceuticals discussed herein are restricted to a few of the more well-studied compounds that are found in animals or animal products, regardless of whether they are actually or commonly commercially isolated from animals.

Bile Acids

Hydrophilic and hydrophobic interactions drive important characteristics of the absorption of nutrients in the gastrointestinal tract. Lipids do not appreciably dissolve in aqueous environments such as the intestinal lumen. Bile secreted from the gall bladder contains chemicals such as bile acids that are important in solubilizing lipids and lipid-soluble nutrients for absorption. Thus, bile acids are integral to the efficient solubilizing and absorption of lipids in the intestines.

Chemically, bile acids are synthesized from cholesterol to be more hydrophilic by adding hydroxyl groups to a number of positions on the ring structure, as well as a carboxylic acid to the tail. The pattern of hydroxylation defines the chemical structure of the bile acid and gives rise to a variety of trivial names of bile acids, such as cholic, deoxycholic, lithocholic, chenodeoxycholic, hyodeoxycholic, ursocholic, and muricholic acids. Some of the trivial names are actually derived from animals, such as ursocholic acid for bears and muricholic acid for mice. Bile acids can also be conjugated to glycine or taurine, or remain in the nonconjugated state. For example, using cholic acid as an example, there are glycocholic, taurocholic, and nonconjugated cholic acids. Although bear bile has been used in traditional Chinese medicine for a long time, most bile acids commercially available today are highly purified from slaughterhouses.

Bile acids, particularly chenodeoxycholic acid and ursodeoxycholic acid, have been used as an alternative to surgery in gallstone patients, with an approximately 40% success rate in dissolution of gallstones in patients with symptomatic, small, radiolucent gallstones in otherwise functioning gall bladders. However, gallstone recurrence occurs in approximately half of those treated with bile acids within 5 years, though with a much lower recurrence thereafter. These recurring gallstones can usually be dissolved again following additional treatment with bile acids. The gallstones are typically crystalized cholesterol in the gall bladder, and therefore bile acids improve gallstones by resolubilizing the cholesterol in bile.

Bile acids have also been implicated in altering insulin sensitivity in diabetes and obesity. Most research up to this point has been conducted in animal and cell culture models, demonstrating beneficial metabolic effects, but very little work has been conducted in humans. One promising study in obese humans in which tauroursodeoxycholic acid was administered for 1 month demonstrated improved markers of systemic glucose tolerance driven by increases in muscle and liver insulin sensitivity, but not in adipose tissue. Other suggestions from animal, cell culture, and some human research indicate improvements in longevity, fatty liver diseases, and diet-induced atherosclerosis. However, more research needs to be conducted in humans to confirm these results.

It is important to note that bile acids play a key role in cholesterol homeostasis, and bile acid sequestrants that increase the excretion of bile acids have been used to decrease whole body cholesterol by requiring more bile acids to be synthesized from cholesterol. Rather than a benefit from supplementation, this is a benefit from a physiological decrease in bile acids.

Carnitine

Cells shuttle fatty acids into mitochondria through a carnitine-coupled transport system to utilize them for energy and metabolism. Fatty acids are coupled to carnitine through the carnitine-palmitoyl transferases, and can then enter the mitochondria for energy production through β-oxidation.

Humans are capable of synthesizing carnitine, and thus it is not an essential nutrient. In addition, most Western diets are sufficient in carnitine because of high contents in red meat, dairy, poultry, and fish, with the highest quantities found in red meat. In certain medical conditions, carnitine deficiency can occur, such as genetic primary carnitine deficiency, chronic renal failure, or specific disorders with intestinal absorption. In these cases, carnitine supplementation is used to fulfill a

nutrient deficiency rather than a nutraceutical function as defined above.

Tissue carnitine concentrations tend to decrease with age. In older adults, carnitine supplementation in the form of acetyl-L-carnitine reduced cognitive deterioration in individuals who had mild cognitive impairment or mild/early Alzheimer's disease. Benefits were detected as early as 3 months, with both clinical and psychometric measurements improving over time compared to a placebo. Carnitine has also been implicated in improving vitality in cancer patients low in carnitine. Carnitine supplementation in carnitine-deficient cancer patients appeared to improve signs of Cancer Related Fatigue, such as increasing vitality, decreasing fatigue, and improving quality of life scores. However, at least one randomized study failed to reproduce this effect.

Several studies have implicated carnitine in improving male fertility, such as by improving sperm quality, motility, fatty acid oxidation, and mortality in the testes.

One nutraceutical function attributed to carnitine is the boosting of athletic performance; however, the results of human studies have been inconclusive. In addition, using carnitine to alter body composition or as a weight-loss aid is not strongly supported by research in humans.

Conjugated Linoleic Acid

Conjugated linoleic acid, commonly called CLA, is a series of 18 carbon, doubly unsaturated fatty acids. The two most common isomers are *cis*9 *trans*11 and *trans*10 *cis*12, which are considered natural *trans*-fatty acids and are generally regarded as not having the same deleterious properties as artificial *trans*-fatty acids.

Interest in CLA blossomed when it was identified as an antitumorigenic compound found in beef. It is produced in ruminant animals through rumen biohydrogenation of unsaturated fatty acids. In addition, humans can synthesize some forms of CLA from specific precursors, such as *trans*-vaccenic acid (tVA), which is a naturally occurring monounsaturated *trans*-fatty acid. Through a delta-9 desaturase enzyme, humans can convert tVA into *cis*9 *trans*11 CLA.

Grass-fed cattle contain more CLA in their meat and milk than grain fed cattle, particularly in times of rapid grass growth. Feeding fish oil and flax seed to cattle has been shown to increase the CLA content of meat and milk as well. However, most studies looking for health effects in beef and dairy products enriched in CLA have shown no or modest health benefits. Most research showing benefits of CLA have demonstrated the effects in nutraceutical form.

Although it was originally investigated for potential antitumorigenic properties, human studies have not demonstrated clear results regarding the effects of CLA and cancer. One case-control study demonstrated a strong negative correlation between dietary and serum CLA and tVA and breast cancer in postmenopausal women; however, CLA content of breast adipose tissue appeared to be a modest risk factor. In addition, total CLA and tVA exposure was modestly associated with an increase in breast cancer in a cohort study in the Netherlands. Several other studies have demonstrated no association, and thus the effects of CLA on *in vivo* tumorigenesis are still inconclusive.

CLA has also been thought to affect attributes of the metabolic syndrome, such as body composition, body weight, and insulin sensitivity. These effects are purportedly from CLA acting on a transcription factor known as Peroxisome Proliferator Activated Receptor gamma (PPAR-γ), which is involved in regulating energy homeostasis. However, studies of overweight Caucasian males supplemented with approximately 3 g of CLA daily for several months have demonstrated decreases in insulin sensitivity. However, one meta-analysis concluded that CLA may induce a modest (0.05 kg per week) decrease in body fat mass. Although the effects of CLA on health appear to be isomer specific, too little data exist in humans to adequately characterize these effects.

Glucosamine and Chondroitin Sulfate

Glucosamine and chondroitin sulfate are two nitrogen-containing carbohydrates found as part of the extracellular matrix in joints. Two polymers of glucosamine are chitin and chitosan, which are components of crustacean exoskeletons; hydrolyzing these polymers is one source of glucosamine for dietary supplement preparations. The two common forms of glucosamine found in supplements are glucosamine sulfate and glucosamine hydrochloride. Chondroitin sulfate, however, is composed of a polymerized, variably sulfated disaccharide of glucuronic acid and acetylgalactosamine. The disaccharide unit can be sulfated at three different positions, which affects the overall structure and function of chondroitin sulfate. Although the sulfate in glucosamine preparations serves as a counter ion to the positive charge on the amine, the sulfate in chondroitin is covalently attached at the various positions. Two common sources of chondroitin sulfate are bovine and shark cartilage.

Glucosamine has been researched in terms of impeding the progression of osteoarthritis and decreasing associated pain. A number of studies have demonstrated a decrease in several measurements of osteoarthritis pain, including Lequesne's severity index, the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), and reports of daily pain. In addition, some studies have shown trends toward or significant slowing of joint space narrowing in patients with osteoarthritis. Although some studies demonstrated no improvements over placebo, glucosamine is well tolerated and resulted in fewer adverse events than ibuprofen administration for pain. One point of controversy is whether there is a difference in efficacy between the sulfate and chloride counter ions of glucosamine. Glucosamine sulfate has been more thoroughly studied than glucosamine hydrochloride, and although there is still some evidence that glucosamine hydrochloride may decrease pain outcomes, the evidence is less convincing than for the sulfate form.

Chondroitin sulfate has been evaluated for the same endpoints as glucosamine. Similarly, a number of studies have shown decreases in pain as measured by Lequesne's index, decreases in functional impairment, and retardation of joint narrowing. Again, although some studies demonstrated no improvements over placebo, chondroitin sulfate was as well tolerated as placebo.

The combination supplementation of chondroitin sulfate and glucosamine has also been investigated for osteoarthritis.

The Glucosamine/Chondroitin Arthritis Intervention Trial, a rigorous randomized clinical trial, did not demonstrate an improvement in joint pain; however, an exploratory analysis demonstrated that glucosamine plus chondroitin improved pain measurements in individuals who started with moderate-to-severe pain. Another study of middle-aged to elderly women showed improvements in WOMAC scores and subjective measurements of joint function. In addition, the combination of chondroitin sulfate and glucosamine resulted in a decreased need for nonsteroidal antiinflammatory drugs. Thus, the efficacy and effect size of glucosamine and chondroitin sulfate regarding osteoarthritis progression are still not certain.

Heme Iron

Iron is an essential mineral required for a number of functions in the body. When an iron atom is embedded in a porphyrin ring structure, it is called heme iron. Heme iron is the molecule responsible for the oxygen- and carbon dioxide-carrying capacity of hemoglobin in red blood cells; myoglobin serves a similar function in muscle. Heme iron is also an integral part of the cytochrome P450 system, which is responsible for a vast number of enzymatic oxidation reactions.

Dietary iron can be found either complexed to heme or in other forms. Heme iron is absorbed more efficiently than nonheme iron; furthermore, unlike nonheme iron, the absorption of heme iron is not negatively affected by dietary components known to chelate minerals, such as phytate, or in the presence of other minerals, such as calcium.

Individuals who have low intakes of iron, have iron deficient anemia, or in other ways have an insufficient iron status will benefit the most from taking iron. Extreme or intense athletes who otherwise have normal iron absorption can become iron deficient from increased iron requirements, blood loss, rhabdomyolysis, or hemolysis. Therefore, iron supplementation may support athletic performance in those at risk of becoming iron deficient through exercise. However, iron supplementation to individuals who are deficient does not necessarily impart nutraceutical properties beyond those of basic dietary supplementation.

As a nutraceutical, iron has not been shown to boost athletic performance beyond relieving a deficiency, and most other research on iron beyond basic requirements generally tends toward concerns regarding oxidative damage, coronary heart disease, and other maladies, although the results have generally been inconclusive. Because the human body does not have a mechanism to get rid of excess iron, supplementing the diet with excess iron could lead to toxicity.

Omega-3 Fatty Acids

Omega-3 fatty acids, also called n-3 fatty acids, are lipids that are characterized by an unsaturated bond three carbons from the end of the acyl tail. This contrasts with omega-6 (or n-6) fatty acids, which have the double bond six carbons from the end. Other positions of double bonds are possible, but omega-3 and omega-6 fatty acids are often discussed together, with some uncertainty as to whether it is the total quantity of omega-3 fatty acids in the diet that leads to their health-modulating effects, or the ratio of omega-3 to omega-6 fatty acids in the diet. Both omega-3 and omega-6 fatty acids are essential nutrients, meaning that the double bonds that define omega-3 and omega-6 fatty acids cannot be synthesized by humans. Very long chain, highly unsaturated omega-3 fatty acids are often considered more active in health promotion, including eicosapentaenoic acid ((EPA), a 20 carbon fatty acid with 5 double bonds) and docosahexaenoic acid ((DHA), a 22 carbon fatty acid with 6 double bonds). Humans can synthesize very long chain omega-3 fatty acids from long chain omega-3 precursors, such as α-linolenic acid (ALA), but cannot create the omega-3 bond itself.

One of the greatest sources of omega-3 fatty acids in human diets is fish and fish oil. Often, DHA and EPA are considered fish oil fatty acids, although the fish accumulate these fatty acids most often from consuming algae. Therefore, aquaculture in which fish are fed grains such as corn results in fish with lower omega-3 fatty acids. The greatest terrestrial source of omega-3 is flax seed, which has spurred the supplementation of animal diets with flax to increase the omega-3 fatty acid content of the meat. The omega-3 in flaxseed, as well as what little there often is in other terrestrial animal sources, is predominantly ALA, which is not considered as bioavailable or as health promoting as DHA and EPA. Therefore, livestock animals are not likely to be a good source of omega-3s for nutraceutical supplementation.

Omega-3 fatty acids decrease blood triglycerides in a dose-dependent manner. Elevated triglycerides are common in type II diabetes, and although omega-3 fatty acids decrease triglycerides, little convincing evidence exists regarding the effects of omega-3s on other hallmarks of diabetes, such as insulin resistance or blood glucose. Omega-3 fatty acids do, however, improve all-cause mortality related to cardiovascular diseases, particularly for EPA and DHA. To a lesser extent, evidence suggests that omega-3s modestly improve blood pressure.

A number of observational studies have linked increased EPA and DHA to decreases in prostate and breast cancers, with some of these studies focusing on an increased omega-3/omega-6 ratio. However, just as many studies have shown no effect, although there is little to no evidence of increased risk of these cancers with omega-3 consumption.

Omega-3s have also been implicated in improving joint tenderness in rheumatoid arthritis, but not necessarily joint pain. Other conditions studied include inflammatory bowel disease, renal disease, lupus, and bone fractures, but the evidence of improvement in these morbidities is much less certain.

Vitamin D

Vitamin D is a sterol-derived, lipid-soluble vitamin that can be synthesized endogenously or acquired through some foods, such as fish oil, egg yolk, beef liver, and fortified foods such as dairy products. There are multiple forms of vitamin D. Vitamin D_3, or cholecalciferol, is created from 7-dehydrocholesterol (a precursor in cholesterol synthesis) when skin is exposed to Ultraviolet (UV) light; it is also found in some foods. Vitamin D_3 is then processed in the liver to create 25-hydroxy vitamin D_3, or calcidiol. Calcidiol is further hydroxylated to

create 1,25-dihydroxy Vitamin D_3, or calcitriol, primarily by the kidneys. If the starting sterol is ergosterol instead of 7-dehydrocholesterol, the series of compounds are known as vitamin D_2; because these are primarily derived from non-animal sources, they will not be discussed further here. The vitamin D_3 used to fortify milk and other products can come from extraction of 7-dehydrocholesterol from animal hides, followed by exposure of the extract to UV light.

Calcitriol is generally considered the active form of vitamin D_3, functioning to facilitate calcium absorption from the intestines, as well as to act as a hormone in controlling calcium balance within the body, such as altering bone resorption and renal calcium filtration. These functions contribute to vitamin D's status as a vitamin, leading to the two well-known vitamin D deficiency diseases of rickets and osteomalacia.

Vitamin D has been linked to decreased risk of cardiovascular disease, stroke, hypertension, diabetes, metabolic syndrome, and cancer. Beyond the clear benefits to bone health, the US Institute of Medicine determined that all other health claims were inconclusive, inconsistent, and insufficiently characterized. However, a number of studies point to future potential for nutraceutical properties of vitamin D. For instance, observational studies have demonstrated an inverse relationship between diabetes risk and vitamin D status, although only in certain populations. Conversely, when individuals were supplemented with vitamin D in controlled studies, there appeared to be little if any improvement in diabetes risk. With regard to stroke, recent findings suggest that vitamin D supplementation may improve stroke risk, possibly by altering hypertension.

The relationship between vitamin D and cancer is more complex. Although some data exist to suggest that vitamin D may increase the risk of certain cancers, such as an increase in pancreatic cancer risk in a cohort of Finnish smokers, most evidence points to vitamin D having either beneficial or no associations with cancer risk, particularly regarding colon, breast, prostate, and overall cancer risk.

Vegetarianism

MB Ruby, Universität Hamburg, Hamburg, Germany

This article is a revision of the previous edition article by NG Gregory, volume 2, pp 633–640, © 2004, Elsevier Ltd.

Glossary

Ferritin An intracellular protein that stores and releases iron.
Hypercholesterolemic Having high levels of blood cholesterol.
Implicit association An automatic association between different concepts.
Socioeconomic status A measure of one's social standing or social class, typically based on education, income, and occupation.
Visceral Relating to or perceived as if in the viscera (internal organs).

Introduction

This article reviews the current literature on vegetarianism, exploring what motivates people to choose a vegetarian diet and how vegetarians and meat eaters often differ in their attitudes toward meat consumption, as well as how they tend to differ in their broader attitudes, values, and worldviews. Furthermore, this article provides an overview of the potential health benefits and health risks associated with vegetarian diets. Ethical and spiritual concerns have motivated vegetarianism since the time of Pythagoras, and these concerns were further expanded in the twentieth century to include specific concerns for animal rights, environmental welfare, and world hunger. In contrast, scientifically grounded arguments for the health benefits of a vegetarian diet are more recent, only emerging in the nineteenth century. Recent polls indicate that approximately 3% of the US Americans and 8% of Canadians identify themselves as vegetarian. Additional polls estimate rates of 3% in the UK, 1–2% in New Zealand, and 3% in Australia, with considerably higher rates of 6% in Ireland, 9% in Germany, 8.5% in Israel, and 40% in India. Although vegetarians are a minority in most cultures, they are not always small minorities, and the popularity of vegetarian diets is on the rise in many countries. As the popularity of vegetarianism has grown, so too has the number of scholars formally investigating the practice of vegetarianism.

Definitions of and Motivations for Vegetarianism

Although the most common definition of vegetarianism is the avoidance of red meat, poultry, and fish; considerable inconsistency among people's self-identifications arises within the literature, such that many people who claim to be vegetarian do not actually follow a strict vegetarian diet. In a 1997 Canadian survey, 78% of self-identified vegetarians reported that they sometimes consumed fish or seafood, 61% sometimes ate poultry, and 20% sometimes ate red meat. In 2001, 34% of self-identified Canadian vegetarians sometimes consumed red meat. Similarly, among a 2004 survey of self-identified vegetarians in the USA, only 30% said that they never ate fish, 36% said that they never ate poultry, and 64% said that they never ate red meat, and comparable discrepancies have emerged among Swiss and British populations. This inconsistency is not solely limited to lay people – among a 1990 survey of women physicians in the US, 38% of self-identified vegetarians had eaten fish, poultry, or red meat at least once in the past week.

A more precise way of assessing vegetarianism is along a continuum. At one end of this continuum are omnivores, who consume all manner of animal products. Further along the continuum are partial vegetarians, who avoid red meat but still consume poultry, fish, eggs, and dairy. Further along the continuum are pescatarians, who are similar to vegetarians but eat fish and shellfish in addition to an otherwise vegetarian diet. Further still along the spectrum are lacto–ovo vegetarians, who eat no meat, fish, or poultry but do eat eggs and dairy, followed by lacto-vegetarians, who also avoid eggs. At the end of the spectrum are vegans, who consume no animal products whatsoever. For the sake of parsimony, the term vegetarian will be used in this article to describe those who are following a lacto–ovo-, lacto-, or vegan diet, unless otherwise indicated.

Just as people's definitions of vegetarianism vary, so do their motivations for following a vegetarian diet. In Indian cultural contexts, family traditions and religious beliefs about the spiritually polluting effects of meat consumption emerge as the predominant motivations for vegetarianism, whereas in the majority of recent studies conducted in Western societies, the most common motivation for vegetarianism is concern that meat consumption is not consistent with animal welfare. Secondarily, people report concern for health and the environmental impact of meat consumption, followed by spiritual concerns and disgust at the taste and texture of meat (see Tables 1 and 2).

Research has uncovered a series of major differences between people whose vegetarianism is chiefly motivated by ethical concerns and those who are primarily motivated by concern for health. Compared with health vegetarians, ethical vegetarians consume a smaller range of animal products,

Table 2 Summary of the most common motivations for vegetarianism

Reason	*Summary*
Animal welfare	Avoidance of meat due to the belief that modern meat production is unethical. Some avoid all meat products to alleviate this concern, whereas others consume meats only from sources whose animal welfare practices they find acceptable, such as local family farms
Environment	Avoidance of some or all types of meat out of the concern that meat production has negative effects on the environment and is unsustainable (e.g., carbon dioxide emissions, soil erosion, and resource use). This particular motivation is relatively new and its associations are largely unknown
Health	Avoidance of meat out of concern for their health. This motivation has three main components: (1) avoiding cholesterol and saturated fat, (2) avoiding substances in the meat that one considers harmful (e.g., hormones, antibiotics, and pathogens), and (3) attempting to reduce the risk of specific health problems that one believes to be associated with meat consumption (e.g., cancer, hypertension, and heart disease)
Disgust	Avoidance of meat due to disgust at the sight of it, especially visible blood or bodily juices. Some find the taste and/or smell of meat disgusting or dislike its texture and springy mouth feel
Religion	Avoidance of some or all meats for spiritual or religious reasons. Eating meat is sometimes believed to be spiritually polluting or to exert undesirable influences on one's character, such as increased levels of aggression. Religions that encourage vegetarianism include some branches of Hinduism, Jainism, and Buddhism

transition more swiftly to a vegetarian diet, are more concerned with animal welfare, and respond to meat consumption with stronger feelings of disgust. At present, little is known about those whose vegetarianism is primarily motivated by other factors, such as concern for environmental sustainability.

After adopting a vegetarian diet, people often add and drop motivations over time. In general, people are more likely to add than to drop motivations, especially among those who are originally motivated by concern for animal welfare. Furthermore, there is evidence that people tend to move along a trajectory – in a 2002 study of women in Vancouver, Canada, most current vegetarians consumed a smaller range of animal products than when they first became vegetarians. Nonvegetarians hold relatively similar beliefs about why one might wish to follow a vegetarian diet, although they prioritize motivations in a different order than vegetarians do. In a 2003 South Australian study, nonvegetarian participants most commonly cited potential health benefits of a vegetarian diet, such as eating less saturated fat (65%) and controlling one's weight (40%), whereas concern for animal suffering (36%) and environmental welfare (22%) were cited less often.

Just as people identify common motivations for adopting a vegetarian diet, people also exhibit high levels of agreement on common deterrents to vegetarianism. In a 2003 study of Australian adults, the most commonly cited deterrent to vegetarianism was the enjoyment of eating meat (78%), followed by an unwillingness to change one's eating habits (56%), beliefs that humans are meant to eat meat (44%), and insufficient knowledge about vegetarian diets (42%). As with much of the literature on vegetarianism, pronounced gender differences emerged, such that more men than women believed that humans are meant to eat meat (49% vs. 39%) and that women were more likely than men to report the unwillingness of their family, spouse, or partner as a significant deterrent to adopting a vegetarian diet (39% vs. 18%). Although research on former vegetarians is rare, a 2002 study of formerly vegetarian women in Vancouver, Canada found that the most common reasons for resuming meat consumption were health concerns such as anemia and fatigue (29%), missing the taste of meat (23%), a change in living situation (such as moving in with a meat-eating family, 17%), and the perception that following a vegetarian diet was too time consuming (17%).

Attitudes toward Meat

Alongside fundamental differences in their eating practices, vegetarians and omnivores tend to hold very different attitudes toward meat. A 1998 study of teenage British girls revealed that vegetarians had strongly negative attitudes toward meat, linking it with the killing of animals, cruelty, the ingestion of blood, and visceral disgust. The nonvegetarian girls, however, had very positive attitudes toward meat, linking it with the concepts of luxury, social status, good taste, and special occasions such as holiday dinners. In recent years, several studies have found evidence for changing attitudes toward meat-based and vegetarian foods among omnivores in many Western societies. In a 2005 Canadian survey, 40% of respondents indicated that they sometimes seek out meatless meals; retail grocery sales of tofu and plant-based meat substitute products increased by 50% in Canada between 2000 and 2003; and in 2006, the US market for processed vegetarian foods (e.g., meat substitutes and nondairy milks) was estimated to be approximately US$1.17 billion. This trend also appears to hold outside the home – in a 2007 survey conducted by the National Restaurant Association, 71% of surveyed chefs in the USA considered vegetarian dishes to be 'hot' or 'a perennial favorite,' 63% described vegan dishes in the same terms. One reason cited for this shift is concern for animal welfare. A 2004 Canadian survey revealed that approximately 20% of respondents had boycotted food products out of concern for the treatment of the animals on the farm or during processing. Animal processing appears to be an area of particular concern – in a 1993 study of meat eaters in the UK, when presented with the hypothetical prospect of having to personally kill the animals that they wished to eat, the majority said that they would stop eating meat altogether. Obviously, an extremely high percentage of people would neither have access to a facility nor have the knowledge or skill to kill and process animals.

Values and Vegetarianism

A growing body of research indicates that, within Western populations, vegetarians and omnivores tend to endorse different sets of values, with endorsement of liberal values more common among vegetarians and endorsement of conservative values more common among omnivores. A 1990 study of women physicians in the USA found that those who self-identified themselves as 'very liberal' were two times more likely to be vegetarian than those who self-identified themselves as 'conservative.' Similar results emerged in a 1995 study conducted in the northeast USA, such that those endorsing 'traditional values' (e.g., social order, family security, and obedience) were more likely to be omnivores, whereas those who endorsed 'altruistic values' (e.g., equality, social justice, and environmental welfare) were more likely to be vegetarians. Concordantly, a 2004 Dutch study found that vegetarians were more concerned than omnivores with the impact of their food choices on the environment, and in a 2000 New Zealand study, those with a more pronounced omnivore identity more strongly endorsed right-wing authoritarianism and social hierarchies. A 2006 UK study found that, compared with omnivores, vegetarians reported greater opposition to capital punishment, and this antiviolence stance was especially strong among ethically motivated vegetarians. Similarly, in a 2008 study of the US Americans, vegetarians reported greater human-directed empathy than omnivores, and in a 2010 study conducted in Italy, ethically motivated vegetarians reported more concern for human suffering and showed increased recruitment of empathy-related areas of the brain when viewing scenes of human and animal suffering.

Perceptions of Vegetarians

Perceptions of vegetarians and vegetarianism have changed over time. Up through the early twentieth century, public and professional attitudes toward vegetarians remained very negative – indeed, in a 1946 paper on the psychology of vegetarianism, drawing on personal anecdotes, a prominent New York psychiatrist claimed that vegetarians were domineering and secretly sadistic, possessed little regard for their fellow human beings, and avoided eating meat in order to make difficulties for others.

In more recent times, people appear to hold common stereotypes about the personalities of vegetarians. In a 1986 study conducted in Arizona in the USA, meat eaters thought of vegetarians as typically pacifist, weight conscious, drug using, and liberal, and a similar pattern emerged among vegetarians who saw themselves as relatively intellectual, weight conscious, and sexy, with a tendency toward using recreational drugs. Further studies conducted in the US in the 1990s found that attitudes toward vegetarians were generally positive, especially among women, teenage girls, and self-identified liberals. A 2007 study of the US Americans obtained more nuanced results, in that meat eaters viewed vegetarians as more highly moral but relatively weak; parallel results emerged in a 2011 study of Canadian students, in which both meat eaters and vegetarians considered vegetarians to be more moral but less masculine than their omnivorous counterparts.

Vegetarianism and Health

Although research conducted in Western societies reveals that concern for animal welfare is often the most common motivation for vegetarianism, concerns for personal health are a notable and increasingly prevalent reason why people reduce or cease meat consumption. The most common concerns are about cardiovascular disease, cancer, obesity, high cholesterol, and the consumption of hormones and antibiotics. However, strict vegetarianism can introduce health risks, especially in the earlier stages of life. Although it was long maintained that meat was essential to human nutrition, recent research questions this stance. In their 2009 position paper, the American Dietetic Association holds that "appropriately planned vegetarian diets are healthful, nutritionally adequate, and may provide health benefits in the prevention and treatment of certain diseases. Well-planned vegetarian diets are appropriate for individuals at all stages of the lifecycle, including pregnancy, lactation, infancy, childhood, and adolescence, and for athletes." That said, proper planning is critical, as a poorly planned diet runs the risk of nutritional inadequacies and subsequent negative health outcomes.

Vegetarian diets are generally associated with lower body mass index (BMI) and lower rates of obesity. This pattern of results was found in a large cross-sectional study of 34 192 Seventh Day Adventists living in California in the USA, as well as in the Oxford Vegetarian study, a prospective study of 6000 vegetarians and 5000 omnivores from the UK. Similarly, in the European Prospective Investigation into Cancer-Oxford (EPIC-Oxford) study involving a cross-sectional study of 37 785 adults, meat eaters had the largest age-adjusted mean BMI, followed by vegetarians, and then by vegans. Furthermore, among a health-conscious subset of EPIC-Oxford, weight gain over a 5-year period was lowest among those who reduced their consumption of animal-based foods.

In both the EPIC-Oxford and the Adventist Health Study, as well as a 1999 meta-analysis of studies conducted in the USA, the UK, and Germany, vegetarians and vegans had a lower risk of death from ischemic heart disease than meat eaters. Notably, these differences held even after controlling for BMI, smoking habits, and socioeconomic status. Concordantly, studies indicate that vegetarians typically have lower levels of total blood cholesterol and low-density lipoprotein (LDL) cholesterol than meat eaters have. Among several cross-sectional and cohort studies conducted in the USA, the UK, and Barbados, vegetarians have lower rates of hypertension than meat eaters, and rates among vegans are even lower. Some research also suggests that vegetarians have lower rates of cancer. Within the Adventist Health Study, after controlling for age, gender, and smoking behavior, vegetarians had substantially lower risk of prostate and colorectal cancer but no significant difference in risk of lung, breast, stomach, or uterine cancer.

The exact mechanisms underlying differences in health outcomes between vegetarians and omnivores are yet unclear. These differences in outcomes are often confounded by differences in lifestyle and habits, and vegetarian diets tend to be lower in saturated fat and cholesterol, higher in dietary fiber, vitamins C and E, folate, magnesium, potassium, and various phytochemicals, and have a higher polyunsaturated to saturated fat ratio. Meta-analyses suggest that milk consumption reduces rates of colorectal cancer, and some vegetarians largely replace meat in their diets with milk products. These differences, rather than the presence or absence of meat per se, are often thought to underlie the various health benefits associated with vegetarian diets. Furthermore, most studies compare health outcomes of participants already following omnivorous or vegetarian diets, and experiments directly testing the health effects of meat consumption are rare. A series of studies conducted in Australia placed meat eaters on a lacto–ovo vegetarian diet for a period of time, then returned them to their normal diet. Among both healthy and hypertensive meat eaters, blood pressure dropped during the vegetarian diet phase and rose on return to the previous diet. The authors were unable to isolate the mechanisms underlying the change, but it was neither linked to changes in sodium, potassium, saturated fat ratio, fiber, or caloric intake, nor to body weight. A recent study comparing different types of omnivorous diets reveals that changes in the type and amount of meat one consumes can also lead to similar changes in health indicators. Among a sample of 36 hypercholesterolemic patients in the USA, participants following a diet with $<8\%$ of calories from saturated fat and 113 g of lean beef per day were able to significantly decrease their LDL cholesterol levels, compared with those following a standard Healthy American Diet. In a case control study of 8724 participants in Uruguay from 1988 to 2000 (6892 cancer cases and 1832 controls), researchers found a positive relationship between total meat intake and risk of several cancers including those of the stomach, esophagus, and colorectum, nervous system, and thyroid, but due to the correlational nature of the study, causality cannot be concluded.

In stark contrast to potential health benefits, some vegetarians and vegans will be at risk for several nutritional inadequacies, particularly calcium, iron, omega-3 fatty acids, vitamins B_{12} and B_6, and vitamin D. Although lacto–ovo vegetarians typically consume similar levels of calcium as nonvegetarians, vegans sometimes have lower intakes than both groups and could fail to meet recommended intakes. Indeed, in the EPIC-Oxford study, vegan participants' risk of bone fracture was approximately 30% higher than that of lacto–ovo vegetarians and meat eaters, more likely due to their lower calcium intake.

There are two forms of iron: that found in plant-based foods is nonheme iron and that in animal-based foods is heme iron. As nonheme iron is more difficult for the body to absorb than heme iron, vegetarians have an increased risk of iron deficiency anemia, especially for milk-fed infants and women who either have reduced iron intakes from dieting or a tendency to lose more iron than usual during menstruation. Indeed, research from Australia and New Zealand has found that vegetarian adults had lower average serum ferritin levels than meat eaters.

Although vitamin B_{12} deficiency is relatively uncommon among lacto–ovo vegetarians due to the consumption of eggs and dairy products, some vegans have markedly lower intakes of vitamin B_{12}, as no known unfortified plant-based food contains reliably high levels of vitamin B_{12}.Vitamin B_{12} is a critical nutrient, as it is required for the synthesis of myelin (the insulation sheath for nerves) and thereby helps maintain a healthy nervous system. Given this, the period following weaning can be especially risky if the parents do not provide adequate supplementation. Among some subgroups of vegans, resistance to supplementation is common, thus increasing the risk of vitamin B_{12} deficiency. As with vitamin B_{12}, a 2005 study of adults in California in the USA suggests that vegans might not consume sufficient levels of vitamin D, which plays an important role in bone health.

A commonly held belief is that vegetarian and vegan diets do not provide adequate levels of quality protein. However, a 1994 review indicates that by eating an assortment of plant-based foods throughout the day, vegetarians and vegans can obtain all essential amino acids, and a 2003 meta-analysis uncovered no significant difference in protein needs as a function of protein source. Vegetarians and vegans typically meet or exceed protein requirements, and a 2004 review indicates than plant-based diets can provide adequate levels of protein for athletes. That said, some plant proteins are more easily digested than others, for example, isolated soy protein is more easily digested than isolated wheat protein. Hence, a 2002 World Health Organization report recommends that those vegetarians whose protein comes mainly from sources that are more difficult to digest, such as legumes and cereals, should consume somewhat higher levels of protein.

Gender and Vegetarianism

One factor that routinely arises in the research and writings on vegetarianism is gender. There is broad evidence across a large array of cultural contexts that men and women approach meat on fundamentally different levels. The idea that meat is predominantly a man's food emerges within many geographical regions – from Europe and North America to Africa and Southeast Asia. A series of experiments conducted in the USA, the UK, and Western Europe in the past decade support claims for strong associations between meat and masculinity. Across a variety of studies and measures, participants both demonstrated implicit associations between meat and maleness and explicitly rated a variety of red meats as especially 'male' foods. These associations are echoed in broader relations to food – those activities which are associated with acquiring and preparing food (e.g., shopping, cooking, and serving) are often considered feminine tasks. Furthermore, a 1995 UK study revealed that men know considerably less about the nutritional properties of the foods that they eat, reporting a larger proportion of high-calorie foods and a lower proportion of fruits and vegetables, and are more likely to have suspicions about the benefits of healthy eating, insisting on large, 'masculine' meals that typically center around meat. In a 1993 study of the US Americans, women consider more nutritious meals to be more pleasurable, convenient, and healthy than men do and are more likely to report that they avoid eating red meat. Similar findings emerged among a 1999 study of Norwegians, such that men are more likely to believe that 'a healthy diet should always include meat.' Given this pattern of results, it is unsurprising that among Western societies, vegetarian women outnumber vegetarian men, and across most surveyed societies, women consume less meat than men do. Concordant with large gender differences in vegetarianism, research within Norwegian and British populations reveals that women are more likely than men to actively reduce their meat consumption.

Summary

In recent years, the prevalence of vegetarianism expanded in many cultural contexts, primarily due to concerns about animal welfare, personal health, and environmental sustainability. The current psychological literature suggests that omnivores and vegetarians tend not only to hold divergent attitudes toward meat consumption but also differ in their broader values, worldviews, and moral intuitions. Vegetarian diets have been associated with some potential health benefits and also with the risk of potential nutritional inadequacies.

Glossary

Food irradiation Process of exposing foodstuffs to a source of energy capable of stripping electrons from individual atoms in the targeted material.

Gray (Gy) 1 J kg^{-1} – a physical quantity. 1 Gy is the deposit of a joule of radiation energy in a kilogram of matter or tissue. Such energies are typically associated with ionizing radiation, such as X-rays or gamma particles or with other nuclear particles. It is defined as the absorption of one joule of such energy by one kilogram of matter.

Ionizing radiation Radiation composed of particles that individually carry enough kinetic energy to liberate an electron from an atom or molecule.

Irradiation The process by which an object is exposed to radiation originating from various sources other than background radiation and usually excludes the exposure to nonionizing radiation, such as infrared, visible light, microwaves, or other electromagnetic waves.

Nonionizing radiation Any type of electromagnetic radiation that does not carry enough energy to ionize atoms or molecules. It has sufficient energy only for excitation of atoms to a higher energy state and can produce effects in biological tissue that can lead to burns (e.g., UV radiation to cause sunburn), or accelerate some chemical reactions.

Pasteurization A process by which the microbial population present on food is reduced to improve the shelf life and safety of the food product. Pasteurization often consists of heating food to a specific temperature, for example, 72 °C and immediately cooling it, but can include any physical, chemical, or biological process that reduces the subsequent microbial growth.

Radiation Radiation is a process in which electromagnetic waves travel through a vacuum or matter. This spectrum of radiant energy can be divided into ionizing and nonionizing radiation.

Sievert (Sv) 1 J kg^{-1} – a biological effect. 1 Sv represents the equivalent biological effect of the deposit of a joule of radiation energy in a kilogram of tissue. A derived unit is used for radiation dose quantities such as equivalent dose, effective dose, and committed dose. It is a measure of the effect of low levels of radiation on the human body.

Introduction

Food irradiation is the process of exposing foodstuffs to a source of ionizing radiation emitted by a radioactive substance or generated by high-energy accelerators including X-rays. Radiation can also be used for nonfood applications, such as medical devices or even for examining tubes for gas pipelines, plastics, hoses for floor heating, and even automobile parts, wires and cables, and even gemstones.

Ionizing and Nonionizing Radiation

This spectrum of radiant energy can be divided into ionizing and nonionizing, according to whether it ionizes or does not ionize the atoms in ordinary chemical matter. Both ionizing and nonionizing radiation can be harmful to organisms. In general, however, ionizing radiation is far more harmful to living organisms per unit of energy deposited than nonionizing radiation, even at low radiation doses. Random effects in a

 doi:10.1016/B978-0-12-384731-7.00135-5

cell can result in anything from harmless reactions to degradation of important structures in the cell; to killing it outright or triggering suicide (apoptosis); or modifying the deoxyribonucleic acid (DNA) in harmful, but yet temporary ways. By contrast, most nonionizing irradiation is harmful to organisms only in proportion to the thermal energy deposited (a prime example is microwaves generated in a microwave oven). Broiling and toasting use high radiant energies to cook food.

The radiation of interest in food preservation is ionizing radiation, also known as irradiation. These shorter wavelengths are capable of damaging microorganisms, such as those that contaminate food or cause food spoilage and deterioration. Due to the capability of microorganisms to contaminate foods and the fact that much of our food supply is lost due to spoilage and insects each year, scientists have been experimenting with irradiation as a method of food preservation since 1950. They have found irradiation to be a controlled and very predictable process.

Only certain radiation sources can be used in food irradiation. These are the radionuclides cobalt-60 or cesium-137 (used very rarely); X-ray machines having a maximum energy of 5 MeV (million electron volts); or electron machines having a maximum energy of 10 MeV. Energies from these radiation sources are too low to induce radioactivity in any material, including food. In addition, the radioactive source is never in contact with the foodstuffs and this also ensures the energy of radiation is limited below the threshold of induction of radioactivity (Figure 1).

Radiation dose is the quantity of radiation energy absorbed by the food as it passes through the radiation field during processing. The units used are Gray (Gy), which is the unit of 'absorbed dose' (1 J kg^{-1} – a physical quantity) or in rad (1 Gy = 100 rads). This differs from the Sievert (Sv): which represents the 'equivalent dose' (1 J kg^{-1} – a biological effect). The Sievert is generally used as a measure of the effect of low levels of radiation on the human body. International health and safety authorities have endorsed the safety of irradiation for all foods up to a dose level of 10 000 Gy (10 kGy).

As the energetic particles or waves pass through the target material, chemical bonds are broken and, in particular, they can damage DNA, affect reproduction of microorganisms and other organisms such as insects, and thus preserve food. In this way, it can reduce the risk of foodborne illness, prevent the spread of invasive pests, and even eliminate sprouting or ripening.

Irradiation Compared to Pasteurization

As in the heat pasteurization of milk, the irradiation process greatly reduces but does not eliminate all bacteria. Irradiated poultry, for example, still requires refrigeration, but would be safe longer than untreated poultry. Strawberries that have been irradiated will last 2–3 weeks in the refrigerator compared to only a few days for untreated berries. Irradiation complements, but does not replace, the need for proper food handling practices by producers, processors, and consumers.

Two things are needed for the irradiation process:

- a source of radiant energy, and
- a way to confine that energy.

For food irradiation, the sources are radioisotopes (radioactive materials) and machines that produce high-energy beams. Specially constructed containers or compartments are used to confine the beams so that personnel will not be exposed.

Machines that produce high-energy beams offer greater flexibility. For example, they can be turned on and off unlike the constant emission of gamma rays from radioisotopes.

Regulation of Food Irradiation

Since 1986, all irradiated products must carry the international symbol called a radura, which resembles a stylized flower.

Treated with irradiation or Treated by irradiation

The United States Food and Drug Administration (FDA) requires that both the logo and statement appear on packaged foods, bulk containers of unpackaged foods, on placards at the point of purchase (for fresh produce), and on invoices for irradiated ingredients and products sold to food processors.

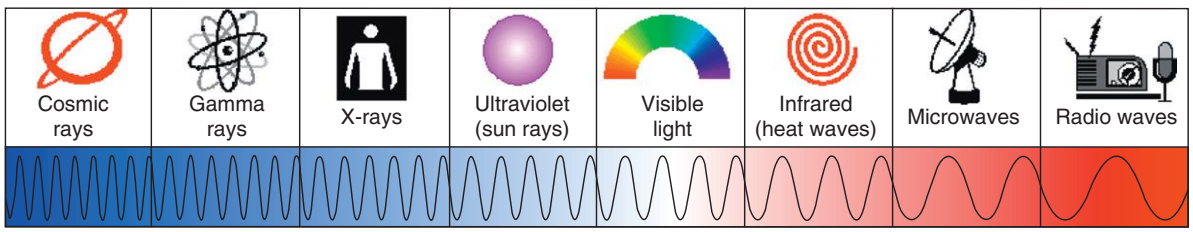

Figure 1 A diagrammatic representation of the energy spectrum. UW Food Irradiation Education Group (http://uw-food-irradiation.engr.wisc.edu/Process.html).

Processors may add information explaining why irradiation is used; for example, 'treated with irradiation to inhibit spoilage' or 'treated with irradiation instead of chemicals to control insect infestation.' Accurate plant records are essential to regulation because there is no way to verify or detect if a product has been irradiated, or how much radiation it has received.

The Food Irradiation Process

Irradiation is known as a cold process, and is sometimes called cold pasteurization. It does not significantly increase the temperature or change the physical or sensory characteristics of most foods. An irradiated apple, for example, will still be crisp and juicy. Fresh or frozen meat can be irradiated without cooking it. During irradiation, the energy affects unwanted organisms but is not retained in the food. Similarly, food cooked in a microwave oven, or teeth and bones that have been X-rayed do not retain those energy waves.

Irradiation of Muscle Foods

Irradiation Effects on Meat Flavor

Processing of meat, with exposure to ultraviolet (UV) light, heat, and oxygen can cause flavor changes and irradiation is no different. The changes due to irradiating fresh meat, even at low doses, therefore can result in off-odors and off-flavors (which have been described as rotten egg, bloody, fishy, barbecued corn, burnt, sulfur, metallic, alcohol, or acetic acid). The changes, however, are exacerbated by the other factors also known to have effects, such as oxygen exposure during and after the irradiation process. Methods to decrease any detrimental effects of irradiation include oxygen exclusion (vacuum packaging), replacement with inert gases (nitrogen), addition of protective agents (antioxidants), and postirradiation storage to allow flavor to return to near-normal levels (repackaging or double packaging in oxygen impermeable film). The changes through irradiation result from initiation or promotion of lipid oxidation or formation of free radicals from unsaturated fatty acids at double bond positions.

Quality

Irradiation might affect the quality of meat by processes other than those attributable to microorganisms. Radiation dose, dose rate, temperature and atmosphere during irradiation, and temperature and atmosphere during storage can all affect the outcome of specific foods. Radiolytic products can cause oxidation of myoglobin and fat, leading to discoloration and rancidity or other off-odor or off-flavor compounds. Ozone, a strong oxidizer, is produced from oxygen during food irradiation and may oxidize myoglobin, causing a bleaching discoloration.

Some scientists have observed that irradiated raw meat developed an off-odor compared with the nonirradiated control and the threshold dose for irradiation odor ranged from 1.5 kGy for turkey to 6.25 kGy for lamb. In some studies, an irradiation odor was detected but not objectionable in raw beef irradiated at low dose. Cooking appears to reduce or eliminate any irradiation-induced odor. Odor resulting from irradiation might thus be important only in raw meat. Further investigation would enable full characterization of irradiation-induced odor and better understanding of the conditions that affect its development.

Irradiation of frozen grass prawns at 10 kGy reduced levels of polyunsaturated fatty acids (C20:5 and C22:6) by 25–32%, possibly due to oxidation and decomposition of lipids into volatile compounds. The threshold dose for development of irradiation flavor in the frozen grass prawns was 4.5 kGy.

Color

Irradiation can also cause some color changes in meat that are greatly influenced by the packaging environment, just the same as in other processes. For example, irradiated vacuum-packaged meat can develop a fairly stable brighter red or pink color in pork, beef, and turkey breasts. In the presence of oxygen, however, irradiation can cause discoloration. The extent of chemical changes that occur in the frozen state is less than that in nonfrozen food due to decreased mobility of free radicals. With less mobility in the frozen state, free radicals tend to recombine to form the original substances rather than diffuse through the food and react with other food components. Irradiating foods at appropriate doses and under certain conditions, such as in a reduced oxygen or oxygen-free atmosphere, packaging, and the frozen state, can minimize or avoid the development of objectionable off-odors and off-flavors. The product quality (color and odor) issues can be controlled with proper processing conditions.

Four Areas in Which Irradiation Is Most Useful

- Preservation: Irradiation can be used to destroy or inactivate organisms that cause spoilage and decomposition, thereby extending the shelf life of foods. It is an energy-efficient food preservation method that has several advantages over traditional canning. The resulting products are closer to the fresh state in texture, flavor, and color, with the caveats of ensuring other processing factors are under control. Using irradiation to preserve foods requires no additional liquid, nor does it cause the loss of natural juices. Both large and small containers can be used and food can be irradiated after being packaged or frozen.
- Sterilization: Foods that are sterilized by irradiation can be stored for years without refrigeration just like canned (heat sterilized) foods. With irradiation, it will be possible to develop new shelf-stable products. Sterilized food is useful in hospitals for patients with severely impaired immune systems, such as some patients with cancer or acquired immunodeficiency syndrome. These foods can be used by the military and for space flights.
- Control sprouting, ripening, and insect damage: In this role, irradiation offers an alternative to chemicals for use with potatoes, tropical and citrus fruits, grains, spices, and seasonings. However, because no residue is left in the food, irradiation does not protect against reinfestation like insect sprays and fumigants do.

- Control foodborne illness: Irradiation can be used to effectively eliminate those pathogens that cause foodborne illness, such as *Salmonella*.

Nutritional Quality of Irradiated Foods

Scientists believe that irradiation produces no greater nutrient loss than what occurs in other processing methods, such as canning.

Effects of Irradiation on Biological Organisms

Irradiation exposes food to a source of ionizing radiation sufficient to create positive and negative charges. Depending on the dose of radiation energy applied, foods can be pasteurized to reduce or eliminate pathogens, or they can be sterilized to eliminate all microorganisms, except for some viruses. For example, low (up to 1 kGy) to medium doses (1–10 kGy) kill insects and larvae in wheat and wheat flour and destroy pathogenic bacteria and parasites. Low to medium doses also inhibit sprouting of potatoes and other foods and slow the ripening and spoilage of fruit. Higher doses (10–50 kGy) sterilize foods for a variety of uses, such as for astronauts during space flight and immune-compromised hospital patients who must have bacteria-free food.

When molecules absorb ionizing energy, they become reactive and form ions or free radicals that react to form stable radiolytic products. The Council for Agricultural Science and Technology (CAST, 1989) estimated that a dose of 1 kGy would break fewer than 10 chemical bonds for every 10 million bonds present, an extremely small percentage. Cooking, or applying infrared radiation to foods, produces similar changes in chemical bonds.

Microbiology Effects

As with cooking and thermal processing, higher radiation doses kill greater numbers of bacteria. The D values (decimal reduction, or dose required to destroy 90% of the microorganisms present) of several pathogenic bacteria that can be associated with raw meat and poultry. *Salmonella* is the most resistant non-spore forming pathogen, with a D value of approximately 0.6 kGy. The radiation doses approved for poultry (1.5–3.0 kGy) would destroy approximately 99.9% (3 logs) to 99.999% (5 logs) of *Salmonella*. Except for spores of *Clostridium botulinum*, all other pathogenic bacteria would be controlled within this dose range. A minimum dose of 1.5 kGy would destroy at least 6 logs of *Escherichia coli* O157:H7, which has a D value of approximately 0.24 kGy. Irradiation, therefore, would be extremely effective at eliminating this pathogen that was declared an adulterant in ground beef in 1994. The parasites *Toxoplasma gondii* and *Trichinella sprialis* are inactivated at doses of 0.25 kGy and 0.3 kGy, respectively.

Although the primary objective of irradiation of muscle foods is destruction of pathogenic bacteria, substantial reduction of spoilage microorganisms also occurs. Levels of aerobic and anaerobic bacteria were reduced by over 4 logs and almost 5 logs, respectively, in chilled ground beef irradiated at doses to 2.5 kGy. Shelf life of the ground beef stored at 4 °C was extended by 9 days before counts reached 7 logs. Studies showed that the refrigerated shelf life of vacuum-packaged beef sirloin cuts irradiated to 2 kGy more than doubled, from approximately 4 weeks for nonirradiated product stored at 0 °C to 10 weeks for irradiated product stored at 4 °C with a 3 log reduction in psychrotrophic aerobic bacteria in ground beef irradiated at 2.5 kGy. The irradiated ground beef had a shelf life of 10 days before counts reached 7 logs compared with the nonirradiated control which lasted only 1 day. Other studies on pork loin slices packaged under nitrogen and irradiated to 1 kGy had a 26-day shelf life (21 days more than the control) stored at 5 °C, and uninoculated ground pork, irradiated at 1.9 kGy, had no surviving bacteria when stored at 2 °C for up to 35 days.

The predominant food spoilage organisms are Gram-negative psychrotrophic microorganisms that are very susceptible to radiation. Several researchers have shown that irradiation of food at doses of at least 1 kGy virtually eliminate Gram-negative microorganisms, but has a much smaller effect on Gram-positive, lactic acid-producing microorganisms. *Pseudomonas* species and Enterobacteriaceae (common spoilage bacteria) are easily eliminated even with low doses of radiation. However, in all of these studies at doses in the range of 1–5 kGy, Gram-positive microorganisms survived and caused spoilage after prolonged refrigerated storage.

Approved Uses for Food Irradiation

Irradiation has been approved for many uses in approximately 40 countries, but only a few applications are presently used because of consumer concern and because the facilities are expensive to build.

In the United States, the FDA approved irradiation for eliminating insects from wheat, potatoes, flour, spices, tea, fruits, and vegetables. Irradiation also can be used to control sprouting and ripening. Approval was given in 1985 to use irradiation on pork to control trichinosis. Using irradiation to control *Salmonella* and other harmful bacteria in chicken, turkey, and other fresh and frozen uncooked poultry was approved in May 1990. In December l997, FDA approved the use of irradiation to control pathogens (disease causing microorganisms, such as *E. coli* and *Salmonella* species) in fresh and frozen red meats, such as beef, lamb, and pork.

Applications for Food Irradiation

Because the irradiation process works with both large and small quantities, it has a wide range of potential uses. For example, a single serving of poultry can be irradiated for use on a space flight. Or, a large quantity of potatoes can be treated to reduce sprouting during warehouse storage.

However, irradiation cannot be used with all foods. It causes undesirable flavor changes in dairy products, for example, and it causes tissue softening in some fruits, such as peaches and nectarines. Irradiated meat will be successful in

the market place only if consumers are satisfied with its sensory quality and most recent evidence suggests that this is a viable technology.

Industry Adoption of Meat Irradiation

There are several reasons to explain in the United States why irradiation is not widely used for meat:

- First, there is no strong consumer demand for the process because: (1) consumers are, in general, quite confident that food is safe and do not see a burning need for irradiation, (2) they are not familiar enough with irradiation to be comfortable about it, and (3) anti-irradiation activists have successfully raised consumer doubts about the process. Several studies have shown that once consumers are properly educated about irradiation, they will be willing to accept it and will purchase irradiated foods.
- Second, most companies in the industry are reluctant to assume the risk of being first with a controversial process, so they are holding back until there is strong demand or reduced controversy related to irradiation.
- Third, added cost for irradiated products is a barrier without distinct demand to justify the cost. Large-scale irradiation facilities require substantial financial investment and meat processors have not had strong enough economic signals to invest in such facilities. This assumes that not every processing plant would construct a facility and that means that products would need to be transported from some processing plants to an irradiation facility before transporting to retail or food service facilities and this adds extra cost.
- Fourth, there have also been some studies that show potential for some off-flavors or off-odors when products are held longer than ideal time periods.

Accreditation A process in which competency, authority, or credibility is certified.
Accreditation body Organization auditing compliance with the requirements to fulfill.
Codex Alimentarius Collection of internationally recognized standards, codes of practice, guidelines, and other recommendations relating to foods, food production, and food safety.
Equivalent By procedures of mutual evaluation and acceptance between accreditation bodies accreditation systems may be recognized as equivalent.
ISO 17025 standard Standard on general requirements for the competence of testing and calibration laboratories. Fulfilling the Requirements assures the quality of analytical test results.
Notification Process, in which laboratories are empowered to conduct official analyses of public responsibility.

Introduction

Food samples are generally analyzed in order to decide whether they are acceptable with respect to safety, quality, and regulatory requirements. For this decision to be made, the analytical results have to reflect the real condition of the sample. However, every analytical procedure is influenced by numerous external and internal factors, and confidence in analytical results is only justified if the laboratory performing the work (1) uses an appropriate analytical method and (2) controls all factors potentially influencing the accurate run of the analytical procedure. In other words, a quality assurance program for laboratory testing is essential.

Having introduced a system to assure the quality of test results, laboratories may subsequently strive for an official approval of their competence to perform specific tests or types of tests. This official approval of competence is called 'accreditation.' The term is derived from the Latin word *accredo*, which means 'to yield one's belief to another,' i.e., to believe unconditionally, to trust, and to accept wholeheartedly. Hence, this term in connection with laboratory work indicates that the client may trust the analytical results delivered.

Laboratories entrusted with tasks in the public food control sector are obliged to go through the trouble of a 'notification' procedure. Derived from the Latin expression *notum facere*, meaning 'to make well known,' this essentially means an administrative procedure resulting in the public listing of laboratories that have been state inspected and found to be competent to take over legally prescribed state control tasks.

Accreditation and Notification System

Development

One of the earliest approaches to promoting laboratory quality systems dates from 1947 in Australia, when the Australian National Association of Testing Authorities (NATA) was founded. The intention was to organize a national testing service by identifying what was important for the reliability of test results and by developing standards to be met. In the 1960s, many countries developed their own laboratory standards, the application of which became increasingly prescribed by legislation during the 1970s. However, it was recognized that the prescription of methods alone – without the exclusion of interfering factors during testing – did not result in a uniformly high level of laboratory performance. As a result, from the 1980s there was a general move toward the

prescription of a general quality system within which the laboratory must operate. This is best illustrated by Article 12 of regulation (EU) 882/2004: laboratories involved in official controls must "... operate and are assessed and accredited in accordance with the following European standards: (a) EN ISO/IEC 17025 on 'General requirements for the competence of testing and calibration laboratories'; …". Although these requirements apply only to laboratories involved in public food control, this also affects food laboratories in the private service sector. For the results to be accepted as equivalent, the latter are advised to voluntarily adopt the same standards.

Standards to be Met

To guarantee the quality of test data, a system of quality standards has to be implemented in the laboratory. Such a system must comply with generally accepted and standardized norms.

As early as 1978, the International Laboratory Accreditation Cooperation (ILAC) provided a statement of technical criteria for accreditation of laboratories to the International Organization for Standardization (ISO). Published as ISO Guide 25:1984, this standard formed the basis for laboratory accreditation worldwide, and also for the European Standard EN 45001, which was adopted by the joint European Standards Institution (CEN, Comité Européen de Normalisation/European Committee for Standardization; CENELEC, Comité Européen de Normalisation Electrotechnique/European Committee for Electrotechnical Standardization) in 1989. The further sophistication of laboratory quality system requirements necessitated several revisions of ISO Guide 25. The last extensive revision finally resulted in the ISO 17025 standard, which brought the terms and requirements of laboratory quality systems in line with the quality management and quality assurance standards of the ISO 9000 series. This standard also replaces EN 45001.

Figure 1 shows the hierarchical structure of the private-law accreditation system as well as the relevant standards to consider. Since the term 'accreditation' is not limited to testing laboratories, calibration laboratories and inspection and certification services are also included in the figure. Some relevant norms for laboratory accreditation are further detailed in Table 1.

Organizations auditing compliance with the accreditation demands are called 'accreditation bodies.' Most accreditation bodies have adopted ISO/IEC 17025 as the basis for the accreditation procedure, which is crucial for safeguarding a uniform approach for determining laboratory competence. By procedures of mutual evaluation and acceptance between accreditation bodies according to ISO/IEC Guide 68:2002 accreditation systems may be recognized as equivalent and a mutual recognition agreement (MRA) may be signed. This helps test data that accompany exported goods on overseas markets to be more readily accepted, although it does not guarantee it.

Notification is a similar process, in which laboratories are empowered to conduct official analyses of public responsibility. Herein, competence assessment will be performed by public authorities, mostly requiring accreditation according to ISO/IEC 17025 as a prerequisit and demanding several additional requirements. Table 2 compares briefly accreditation

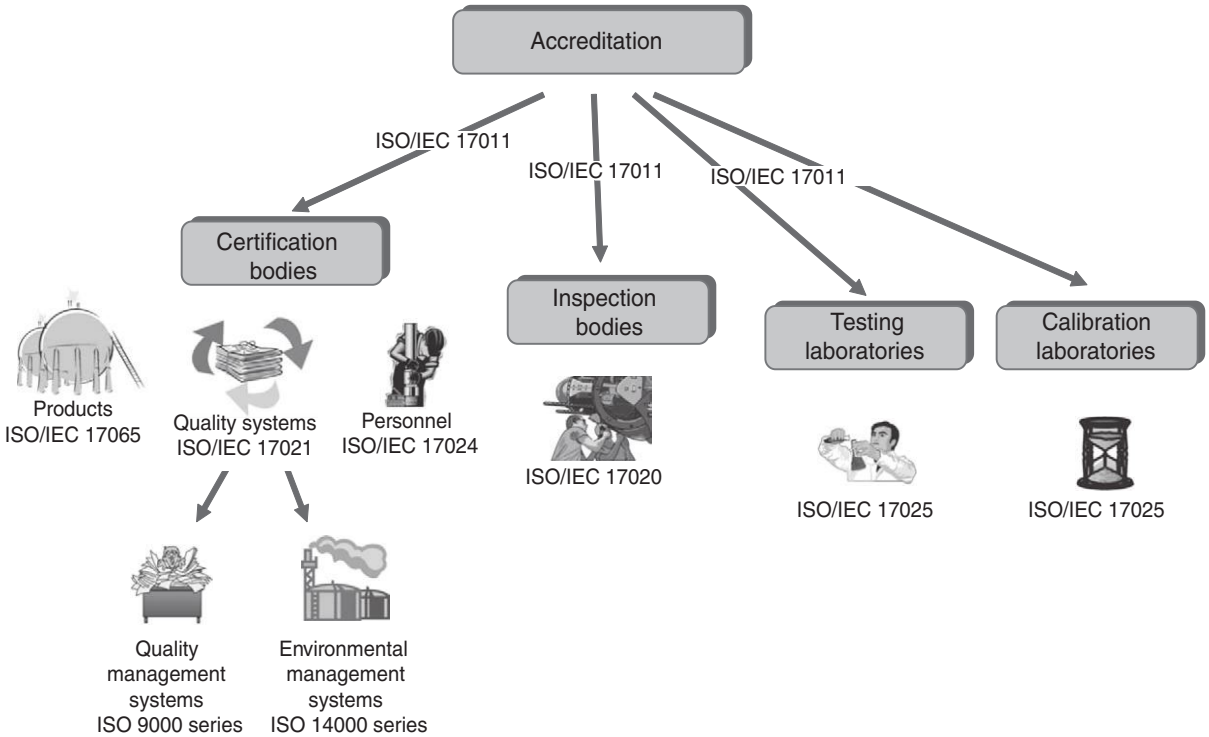

Figure 1 Accreditation system and relevant European and International standards in the privately organized sector. Adapted from Wessel, H., 1998. ...ierungen – Begriffe der Qualitätssicherungen. DACH-Zeitung 63 (10), 57, with permission from Reichenberger & Co. GmbH.

Table 1 Standards referring to accreditation and certification of analytical laboratories

Standard	*Description*
Terms	
● EN 45020:2006	Standardization and related activities – general vocabulary
● ISO/IEC Guide 2:2004	Standardization and related activities – general vocabulary
● ISO/IEC 17000:2004	Conformity assessment – general vocabulary
Laboratory requirements	
● ISO/IEC 17025:2005	General requirements for the competence of testing and calibration laboratories
● ISO/IEC 17043:2010	Conformity assessment – general requirements for proficiency testing
● ISO 15189:2012	Medical laboratories – requirements for quality and competence
● ISO 10012:2003	Measurement management systems – requirements for measurement processes and measuring equipment
● ISO 9000:2005	Quality management systems – fundamentals and vocabulary
● ISO 9001:2008	Quality management systems – requirements
● ISO/TR 10013:2001	Guidelines for quality management system documentation
Accreditation body requirements	
● ISO/IEC 17011:2004	Conformity assessment – general requirements for accreditation bodies accrediting conformity assessment bodies
● ISO/IEC 17040:2005	Conformity assessment – general requirements for peer assessment of conformity assessment bodies and accreditation bodies
● ISO 19011:2011	Guidelines for auditing management systems
● ISO/IEC Guide 68:2002	Arrangements for the recognition and acceptance of conformity assessment results

Table 2 Comparison between accreditation and notification systems

	Accreditation	*Notification*
Aim	To document the competence to perform specific tests for private clients	To carry out state control tasks
Basis	Private contract between laboratory and accreditation body	Specific legal regulation
Extent	Free choice of the applicant laboratory (a single method would be possible)	All methods fixed in the legal regulation concerned
Requirements	Testing environment and accommodation	Testing environment and accommodation
	Personnel	Personnel
	Technical equipment	Technical equipment
	Quality system and manual according to ISO 17025	Quality system and manual
	Participation in proficiency testing schemes desirable but not imperative	Successful participation in proficiency testing schemes imperative
	Subcontracting possible at any time	Subcontracting only exceptionally

and notification requirements. The Codex Alimentarius Commission Guideline CAC/GL 27–1997 concerning the 'assessment of the competence of testing laboratories involved in the import and export control of food' additionally laid down the use of internal quality control procedures, such as duplicate analysis or inclusion of particular reference materials into the analytical procedure. Owing to the formal acceptance of Codex standards in the World Trade Organization's SPS (sanitary and phytosanitary measures) and technical barriers to trade agreements, the significance of these Codex standards has dramatically increased over the past few years.

Procedure

In the private laboratory sector, accreditation is a voluntary procedure that a laboratory may choose to undergo. Nevertheless, since the beginning of the 1990s a strong movement toward conformity assessment has developed, resulting in a huge number of conformity assessment bodies for multiple purposes in nearly all economic areas (Figure 2). Some websites that are useful for finding information on laboratory accreditation are given in section Relevant websites.

Testing laboratory accreditation is usually restricted to defined testing procedures, for example, determination of dioxin in meat. By contrast, a notification demands the application of all analytical methods regulated in the legal norm applied, for example, Council Directive 98/83/EC of 3 November 1998 on the quality of water intended for human consumption.

Generally, the assessment of competence includes the following five steps:

1. preparatory steps
2. application for approval of competence
3. auditing procedure
4. accreditation/notification
5. surveillance

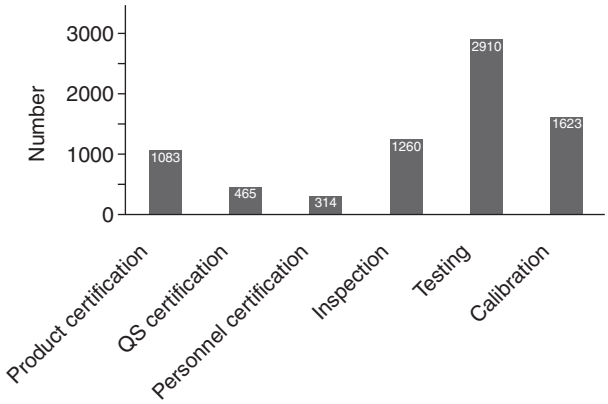

Figure 2 Fields of activity of 3535 conformity assessment bodies in 29 European countries organized in the European Organisation for Conformity Assessment (EOTC) in April 2002.

Preparatory steps

As a first step, it is necessary to become thoroughly informed about the requirements, so that it is clear what the accreditation's or notification's subject matter (analytical methods, testing procedures, and legal norms) is, and what the demands of the accreditation body are. Furthermore, the current laboratory's status quo must be established.

Since a quality system according to an appropriate norm (in general ISO/IEC 17025) is demanded, a concept for its implementation or revision must be prepared. It is necessary to determine which organizational and technical structures must be introduced, modified, or eliminated, and which documents must be produced (responsibility, schedule). This is the main area where resources are required. Depending on the existence and state of any current quality system, as well as the level of support provided by the laboratory's management, this preparatory phase may last from 6 months for well-organized laboratories to 3 years for institutions that have more changes to implement.

Application for approval of competence

For private laboratories, the application for accreditation must be directed toward the accreditation body chosen by the laboratory and a civil law contract is made. In the case of notification, the state authority responsible for the legal norm in question should be contacted.

Auditing procedure

The accreditation body or state authority assigns appropriate assessors and reviews in a first step the application and quality documentation. An on-site assessment is performed including review of the quality documentation, records, and sample handling. In addition, interviews with technicians may be held, demonstrations of tests or calibrations may be requested, and equipment and calibration records may be examined.

The assessor's findings will be summarized in a written report. Any deficiencies must be remedied before the next step can be taken.

Accreditation/notification

After elimination of deficiencies, the accreditation body or state authority decides – usually by a council vote – on the accreditation/notification. Where the accreditation/notification is granted, competence to perform the specific tests is testified by the issue of an official accreditation certificate and publication in the register of accredited organizations.

Surveillance

Subsequently, the laboratories are supervised according to the rules of the accreditation body or the state authority. Document reviews and periodical re-audits are a standing part of the surveillance activities.

Costs

The costs for accreditation and notification are considerable. The establishment and implementation of the quality system is responsible for about 90% of the total expenses, which is the focal point of each approval of competence. These costs result mainly from release of personnel in order to establish the documented quality system and to train the staff involved. Technical upgrading or reconstruction may be necessary. However, the latter is mostly the removal of shortcomings that already existed.

The fees charged by the accreditation body for the document review and auditing procedure, as well as the accreditation certificate, vary widely. They are different from country to country and depend on the size of the laboratory and the number of tests accredited. Laboratories in Germany, for example, must expect costs of €10 000–25 000. Costs in other countries may be lower. Owing to mutual recognition, private laboratories may choose foreign accreditation bodies. However, it should be recognized that accreditations that involve border crossing may incur considerable travel, translation, and shipment costs.

Benefits

The primary benefit of accreditation is obvious: the laboratory is formally recognized as being competent to carry out specific tests or specific types of tests and receives a written proof of this. This may be an effective marketing tool when laboratories are invited to tender for analyses. From the point of view of a client who wants a product to be checked, the availability of a list of accredited laboratories makes it easier to select a service, which is able to deliver accurate and reliable results.

Additionally, notification as well as accreditation in combination with the concept of mutual recognition will reduce costs in international trade. Once the principle 'once tested, accepted everywhere' is recognized all over the world, expensive resampling and retesting, as well as multiple second-party audits, will be avoided for the most part.

Furthermore, the laboratory itself will enjoy some internal advantages. The unbiased evaluation of the laboratory's work by a science-based and experienced third party counteracts the organization's natural myopia. The required quality system will result in clearly stated procedures and responsibilities.

This will make it easier for new personnel to become familiarized with their work, facilitate mutual substitution between staff members, and help to increase confidence when carrying out rarely applied analytical methods.

Laboratory Requirements

The main objective of a laboratory quality system is to ensure the consistency of laboratory results day to day and their conformity with defined criteria. Therefore, sample handling and all methodical procedure steps have to be documented, and all data relevant for the test as well as the test results have to be recorded in order to guarantee traceability.

There is no generally applicable plan for establishing a laboratory quality management system. Each organization will have its own idiosyncrasies and problems that require special consideration and treatment. However, the general principles and requirements are laid down in the International Standard ISO 17025. The requirements are grouped into two main categories, i.e., management and technical aspects.

Management Requirements

To guarantee objective analysis and data reporting, the laboratory has to ensure its integrity and independence from any undue internal and external commercial, financial, and other pressures. Also, the staff's duties and responsibilities must be specified and documented in order to avoid faults due to unclear organizational structures. In this respect, the role of the laboratory's senior management is very important: it maintains the general accountability, establishes the marketing strategy and the quality policy, and commits the required resources. Therefore, a quality system cannot be established without the senior management's support. Additionally, review and assessment of the quality activities and assurance of a continuous improvement are aspects of the management's duties.

Further management requirements are the establishment of a system for approval, issue, change, and access for documents and records, as well as rules for the review of requests, tenders, and contracts and for the service to clients including handling of complaints.

Standards for subcontracting work and for purchasing services and supplies must be set, in order to guarantee the fulfillment of the laboratory's own quality standards. Furthermore, rules for dealing with nonconforming work including corrective and preventive actions are required.

Technical Requirements

Technical requirements concern personnel, environment, equipment, reagents, culture media and reference materials, sampling and sample handling, test methods, and quality of performance. For laboratories carrying out microbiological testing of materials, products, and substances, the joint EA/EURACHEM working group document EA-04/10 Accreditation for Microbiological Laboratories provides detailed and specific guidance on the interpretation of ISO 17025. The guidance is applicable to the performance of all objective measurements, whether routine, nonroutine, or as part of research and development.

Personnel

Testing has to be either performed or supervised by an experienced person, qualified to degree level. Furthermore, staff should have relevant practical work experience before being allowed to perform work covered by the scope of accreditation. If the laboratory includes interpretation of test results in the report, this has to be done by authorized personnel with suitable experience and relevant knowledge of the specific application, including, for example, legislative and technological requirements. The laboratory management has to ensure that all personnel have received adequate training for the competent performance of tests and operation of equipment.

Environment

A typical laboratory is comprised of the testing facilities and ancillary facilities. In general, there are specific environmental requirements for the testing facilities, for example, to construct the premises according to the 'no way back' layout principle, to designate areas for sample receipt and storage, to separate the areas of sample preparation, examination of samples, media and equipment preparation, and sterility assessment and decontamination. Reduction of contamination may be achieved by having smooth surfaces on walls and minimal opening of windows and doors while tests are being carried out. Laboratory clothing appropriate to the type of testing being performed should be worn and removed before leaving the area. This is particularly important in the molecular biology laboratory, where movement from an area of high deoxyribonucleic acid (DNA) load to one of low DNA load may unwittingly introduce cross-contamination. Moreover, there should be a documented cleaning program for laboratory fixtures, equipment and surfaces. In addition, an appropriate environmental monitoring program should be devised, including all factors potentially influencing the test results. In microbiological laboratories, for example, the microbial counts of the air and the working surfaces should be monitored.

Equipment

As part of the quality system, a laboratory is required to operate a documented program for maintenance, calibration, and performance verification of its equipment. The maintenance has to be carried out at specified intervals determined by factors such as the rate of use. A calibration and performance verification program of equipment directly influencing the test results (e.g., scales and pH meters) has to be established. Even for rather simple equipment items this may be a sophisticated affair. For microbiological incubators, for example, the time required to achieve temperature equilibrium conditions, temperature stability, and uniformity of temperature distribution have to be established and documented, in particular with respect to its typical use. Subsequent to the initial validation of the equipment, the constancy of the characteristics should be checked and recorded after each significant modification. Moreover, the laboratory has to monitor the operating parameters during each use and retain records of the results.

Reagents, culture media, and reference material

The suitability of each batch of reagents, culture media, and diluents, critical for the test has to be verified initially as well as during its shelf life. Furthermore, all reagents, media, and diluents have to be labeled adequately to indicate identity, concentration, storage conditions, preparation date, validated expiry date, and recommended storage period. Reference materials, certified reference materials, and reference cultures have to be used, for example, to demonstrate the accuracy of results, to calibrate equipment, to monitor laboratory performance, or to validate methods.

Sampling and sample handling

While testing laboratories are responsible for primary sampling to obtain test items, for example, sampling of drinking water in food establishments, the sampling procedure also has to be covered by the quality assurance program. Transport and storage conditions have to maintain the integrity of the sample. The conditions should be monitored and records should be maintained.

The laboratory has to establish sample delivery and sample identification procedures. All relevant information such as date and time of receipt, and sample condition on receipt, have to be recorded. Samples have to be stored under suitable conditions in order to minimize changes, and storage conditions have to be defined and recorded.

Testing methods and quality of performance

All methods used in a laboratory have to be validated. The validation process should reflect the matrices and test conditions used in the laboratory. The specificity, relative trueness, positive and negative deviation, detection limits, matrix effects, repeatability and reproducibility of the method should be determined. Additionally, the uncertainty of measurement has to be estimated and the laboratories should be aware of the incidence of false positive and false negative results associated with qualitative tests used.

A program of periodic checks is necessary to demonstrate that variability (e.g., between analysts and between equipment or materials) is under control. The program may involve internal quality controls such as the use of reference materials, spiked samples, and replicate testing. The example in Figure 3 compares the variability of two microbiological methods during replicate testing. Furthermore, it is recommended (if not prescribed; see above) regularly to take part in external proficiency testing schemes, which are relevant to their scope of accreditation and matrices used.

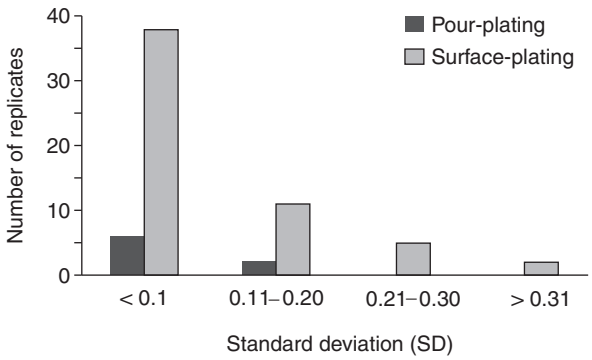

Figure 3 Variability during replicate microbiological testing for purposes of internal quality control. Standard deviations (SD) are shown for replicate testing using the pour-plating and surface-plating methods.

Prospects

As described above, laboratory accreditation and notification provide important benefits. Nevertheless, a further evolution of the whole system will support its effectiveness.

Generally, the establishment, implementation, and maintenance of a quality system in a laboratory bind relevant personnel and monetary resources, and the necessities of surveillance and documentation will usually result in an increased workload. However, the laboratory should be careful not to bureaucratize the processes. Over-organization and pure formalism only results in personnel demotivation and superfluous workload. The quality system should be a helpful tool to control factors influencing the analytical results, and not an obstacle to work!

Owing to the universal character of the standards, there may be some lack of clarity when realizing the requirements. Several organizations provide documents in order to interpret the normative text. However, this should not result in 'flooding' of the laboratory with documents of limited importance. Accreditation bodies and other organizations should restrict information to helpful and practical advice.

In the future, it is likely that the incorporation of specific analytical methods into legislation will be replaced by the specification of method performance characteristics, for example, proof of applicability, in-house method validation, specification of detection limits, determination of measurement uncertainty, etc. This will have the advantage that the analyst's expertise is emphasized, thus allowing a certain degree of freedom with respect to the choice of the method. Furthermore, laboratory automation will be furthered and administrative difficulties involved with changing a method delivering unsatisfactory or inferior results in comparison with another will be eliminated.

However, this increased degree of freedom must go hand in hand with a strengthening of the expertise of the accreditation bodies in order to ensure a uniform quality during competence assessments of laboratories. Furthermore, to overcome barriers to international trade, an international harmonization of the accreditation/notification requirements as well as the further development of mutual recognition of accreditations is mandatory. This should be a worldwide effort, otherwise accreditation itself will serve as a new barrier. Laboratories in many countries are still not in a suitable state to take part in this development since infrastructural problems such as unstable energy supply or a lack of local accreditation bodies render the establishment of an accredited quality system difficult.

MANURE/WASTE MANAGEMENT

Contents

Manure Management

JM DeRouchey, Kansas State University, Manhattan, KS, USA

Glossary

Aerobic An environment with air and oxygen.
Anaerobic An environment without air or oxygen.
Manure Combination of feces and urine excreted from animals that results in a mixture of organic matter and nutrients such as nitrogen, phosphorus, and potassium among others.
Monogastric An animal that has a simple single-chambered stomach, such as pigs and poultry, compared with a ruminant, such as cows or sheep, that have a four-chambered complex stomach.
Ruminant An animal that has a four-chambered complex stomach, such as cows or sheep, compared with a monogastric, such as pigs or poultry, which have a simple single-chambered stomach.

Introduction

Raising livestock responsibly and economically involves numerous management aspects, including genetic selection, reproductive success, adequate nutrition, and providing an overall environment that promotes proper husbandry. Although all are essential to the sustainability and viability of raising livestock, one area that continues to receive more attention is the management of the manure produced by livestock. Manure production is a natural process of excreting unused or unavailable consumed nutrients from the body. In fact, livestock generally utilize only 10–30% of the total nutrients (feed) they consume. When defining animal manure, feces and urine are the main components. Other materials or liquids can also get mixed with feces and urine and become part of the manure stream. These may include washwater of equipment used for flushing/cleaning pen floors, wastewater from drinkers, spoiled feed, bedding (straw, sand, savings, etc.), rain, runoff from pen surfaces, and soil scraped from dirt pen surfaces. Proper manure management can help to improve many aspects of livestock production, including animal growth, feed efficiency, and health. In addition to these, properly handled manure can be used to replace commercial fertilizer through the nutrients it contains and at the same time improve soil quality. However, when in storage or applied to the land, it must be done in a manner not to harm the environment, particularly surface water and groundwater. Some nutrients are volatile in storage and during land application, especially nitrogen compounds; thus, odor issues can arise and be undesirable for humans in surrounding areas. However, these challenges can be overcome through various management practices.

Manure Nutrients

The nutrients found in manure are directly related to the nutrients fed to the animal. Because livestock use feed nutrients with less than 100% efficiency, the nutrients not digested and absorbed by the body are excreted as manure through urine

 doi:10.1016/B978-0-12-384731-7.00073-8

and feces. Therefore, just as feed rations are formulated to certain levels of nutrients, manure nutrient concentrations can be predicted based on them. When valuing the economics of manure nutrients, producers consider the nutrients that they generally purchase and apply through commercial fertilizer for crop growth. Thus, the main manure nutrients evaluated for concentrations are nitrogen, phosphorus, and potassium and, to a lesser degree, micronutrients of zinc, copper, and sulfur that might be required on the basis of soil type and location. Every manure analysis should include a moisture test to help to determine the level of nutrients in either a given manure volume (liquid manure) or a given manure weight (solid/stackable manure).

Nitrogen

Nitrogen in manure can be found in multiple forms. Manure is typically characterized by three reporting values based on an analysis: (1) total (Kjeldahl) nitrogen, (2) ammonia nitrogen (NH_4^+), and (3) organic nitrogen, which is calculated from the difference between total nitrogen and ammonia nitrogen concentrations. Although total nitrogen is valuable to account for, ammonia nitrogen is the form that is the most important to understand. This is the form that is immediately available to plants as a fertilizer source. However, ammonia nitrogen is subject to volatilization loss to air at any point during storage or land application. Thus, covered storage structures and incorporation of manure directly into the soil are ideal means to capture a larger portion of the ammonia nitrogen for plant utilization in order to replace a larger portion of commercial nitrogen fertilizer. Organic nitrogen is not immediately available to plants for growth; however, through mineralization (breakdown of organic material through decomposition) while in the soil, the organic nitrogen becomes available for plant use in future years. The degree of mineralization is heavily influenced by the activity of soil microflora, especially bacteria and fungi, as well as soil temperature, moisture level, and soil type. Thus, knowing that both ammonia and organic nitrogen are critical to accurately predict the amount of nitrogen immediately available to plants, the amount that will become available in subsequent years as the organic nitrogen is mineralized to ammonia nitrogen.

Phosphorus

Phosphorus in manure can be in multiple forms; however, all are available to plants. Thus, total phosphorus should be used in an analysis of manure. However, for agronomic purposes, P_2O_5 is used for the recommended amount for land application. The conversion is: total phosphorus $\times$ 2.27 = P_2O_5.

Potassium

Potassium is a manure nutrient that may or may not be needed for plant growth. This depends on the crop to be grown and soil type. Like phosphorus, the level of potassium in manure should be analyzed on a total basis. However, for agronomic purposes, K_2O is used for the recommended amount for land application. The conversion is: total potassium $\times$ 1.2 = K_2O.

Farm Nutrient Balance

Environmental stewardship of livestock and poultry operations can be defined in many ways. One practice to achieve this classification involves properly balancing nutrient inputs for operations (fertilizer, animals, and feed) and outputs (milk, meat, crops, and manure). This concept applies to all operations, both large and small. To comply with regulatory nutrient management plan requirements, regulated operations must demonstrate that manure will be handled and applied on an agronomic basis. For most small operations, the regulatory requirements are not as strict; however, efficiently minimizing excess inputs while utilizing manure nutrients is essential for sustainability. More often than not, as farms get larger in livestock numbers, their ability to achieve a nutrient balance can be more difficult. Consequences of an unbalanced farm is overapplying manure nutrients over time, which leads directly to increased soil nutrient levels above that needed for plant uptake and growth. This not only is an uneconomical method of managing and utilizing nutrients, but it also becomes an environmental issue due to potentially increased runoff and leaching of various nutrients. Nitrogen can be transported by water, both by means of runoff from excess rainfall and by leaching downward through the soil. Phosphorus is more likely to runoff saturated soil, and once in open surface water, it can cause algae growth, which reduces water oxygen levels. The lowering of water oxygen has negative effects on aquatic animals and can lead to death in extreme cases of algae blooms.

Feed Influences Manure Nutrients

To help to minimize the level of nutrients present in manure, providing diets to livestock and poultry that meet but do not provide excess nutrients is ideal. Nutrition research to determine nutrient requirements is an ongoing process and substantial progress has been made to determine daily requirements for all species of livestock and poultry. However, although daily requirements are established, historically, dietary margins of safety above the daily needs of animals, especially for phosphorus, have been used by nutritionists to not limit performance of both market and breeding animals. However, these margins have been reduced substantially as the price of ingredients, such as supplemental phosphorus, has dramatically increased. As feeding nutrients above the animal's requirement simply increases excretion, and not absorption and utilization to any great measure, the manure level of these nutrients simply increases.

Monogastrics

Swine and poultry have digestive systems that are generally similar in overall function and absorption capabilities. Although differences in digestive anatomy exist between them, most concepts of how nutrition influences nutrient excretion are similar. Swine and poultry diets are formulated on a digestible basis for many nutrients, particularly phosphorus and amino acids (nitrogen). Amino acids are the structural

components of crude protein, which are the nitrogen containing compounds of the diet. One of the challenges to reduce excretion of nitrogen and phosphorus is to improve the availability of those nutrients for digestion and absorption.

As an example, the phosphorus in cereal grains has a very low availability for digestion, approximately 14% for corn but as high as 50% for wheat. Thus, when diets are formulated, the majority of the dietary phosphorus passes through the animal into the manure because it is not digested and absorbed. This is due to the majority of phosphorus being in 'phytic' form, in which pigs and poultry cannot break the bonds of this phosphorus complex. The main reason for this is that they do not produce 'phytase,' which is the enzyme responsible for breaking the bonds of phytic acid. However, technology has allowed the synthetic production of phytase, and it is currently used worlwide as an additive in swine and poultry diets. A diet with added phytase allows a decrease in supplemental phosphorus and an increase in overall phosphorus availability, so the total level of phosphorus excreted is reduced. The use of dietary phytase has led to reductions in phosphorus manure concentrations, resulting in less phosphorus being applied to the land. Also, crop genetic advancements have led to the production of low-phytate corn. When these varieties are fed, for example, in swine diets, excretion can be lowered 13–50% compared with pigs fed regular corn.

For diet nitrogen management, methods to reduce the overall crude protein (crude protein = nitrogen content × 6.25) are also in use in swine and poultry diets. Because monogastric diets are balanced on an individual amino acid basis instead of on a crude protein basis, synthetic amino acids can be added directly to diets to replace ingredients used specifically for their amino acid content. These are typically plant proteins, such as soybean meal. However, as more protein sources are added to the diet, the crude protein level of the diet increases as well. It is well documented that reducing dietary protein content by using dietary crystalline amino acids reduces the amount of nitrogen excreted, which lowers the nitrogen content of manure directly. A general guideline in swine and poultry is that for every 1% reduction in dietary crude protein by using crystalline amino acids, nitrogen excretion is reduced 10%. Similar results have been found with poultry, where a 1.3% reduction in dietary protein resulted in a 21% reduction in manure nitrogen content. Because nitrogen excretion is reduced when crystalline amino acids are used in the diet, more swine and poultry manure can be applied per acre, leading to a reduction in the amount of land required for manure application.

Ruminants

Ruminant animals, such as beef and dairy cattle, have a different digestive system than that of monogastric animals in that they have four compartments (rumen, reticulum, omasum, and abomasums) of their stomach. The main compartment that makes a ruminant unique is the rumen, where fermentation of feedstuffs occurs. Also, in the rumen, wide arrays of microorganisms are present to help to break down the feedstuffs for absorption in the lower digestive tract. With this, ruminant animals produce phytase naturally in their digestive system, so they can digest and absorb phosphorus in feedstuffs to a much higher extent than by monogastrics. Thus, phytase is not fed to ruminant animals.

When balancing a ruminant diet for crude protein concentration, little, if any, attention is paid to the amino acid concentration, which is in contrast to monogastric species. This is due once again to the rumen, where the microorganisms actually break down the dietary protein and form microbial protein that contains a different level of amino acids than was fed in the diet. Feeding synthetic amino acids provide no measureable benefit as they are broken down before they have the opportunity to be absorbed in the small intestine. Therefore, practices to reduce the diet crude protein level of cattle are limited, as diets are formulated to crude protein requirements to meet daily needs.

Manure Treatment

Treatment of raw manure is generally practiced when a producer wants to change the characteristics of it to make it easier to handle or to bring more value to their operation. However, many producers do not utilize treatment methods as the excreted manure form is ideal for their individual situation (i.e., static swine pit underneath the flooring). However, manure characteristics can be altered by storage method (aerobic or anaerobic), anaerobic digestion, adding additives to influence its characteristics, attempting to separate solids from the liquid stream, or composting. Although many methods are used, only the most common types will be discussed.

Anaerobic Treatment

Anaerobic treatment involves several steps in which microorganisms degrade or break down organic waste products in the absence of oxygen. Different types of manure treatment are involved with this process, with the main ones being an earthen lagoon or digesters.

Anaerobic lagoons

Anaerobic lagoons serve as liquid manure storage structures. Most often they are dug into the soil and contain an outer clay liner to mitigate leaching. Lagoons can be plastic lined to prevent absorption of moisture into the ground soil. This type of manure treatment is popular in areas of low rainfall and high evaporation. Also, where irrigation of liquid manure is desirable, this type of structure and manure treatment is desirable. Anaerobic lagoons, however, can be negatively perceived as odor from a large open surface of wastewater because they are noticeable with the correct weather conditions. The undigested material, generally the minerals, must be cleaned or removed from the bottom, which can be costly.

Anaerobic digesters

Anaerobic digesters are simply an enclosed structure where anaerobic break down of manure organic matter takes place. The anaerobic microorganisms convert the organic matter into biogas, which then can be captured and utilized for energy as a flammable gas. Methane is the most commonly captured

by-product from the digestion of organic matter, but carbon dioxide, hydrogen, hydrogen sulfide, nitrogen, and water vapor are also present. Advantages of this type of manure treatment include a reduction in odor and greenhouse gas emissions and as renewable energy source. However, the initial cost, level of labor, and continual management of the microorganism balance have prevented the widespread use of digesters.

Aerobic Treatment

Aerobic treatment refers to biological treatment in the presence of oxygen in liquid-type manure storage structures. Aerobic microorganisms break down organic and nitrogenous compounds that help to reduce odor and ammonia emissions, which are the main advantages of this type of manure treatment. However, aerobic treatment is not widespread due to operational costs related to mechanical equipment, such as motors, compressors, turbines, or fans, required to infuse enough oxygen into liquid manure to support aerobic bacteria viability.

Composting

Composting is the natural decomposition of solid manure or other organic materials by aerobic (oxygen dependent) bacteria and fungi. However, the microorganisms require certain conditions to effectively break down materials. The main conditions essential for proper composting are: (1) carbon to nitrogen (C/N) ratio, (2) moisture, and (3) temperature. Microorganisms use C and N for energy, growth, and reproduction and ideally require a C/N ratio of 25–30:1. However, manure from feedlots or pens results in a ratio of 10–20:1. To increase C, fibrous materials (straw, corn stalks, wood shavings, newsprint, rotted silage, hay bales, etc.) can be added, as they contain high C/N ratios (60–850:1). To achieve desired C/N ratios, the manure is combined with a C source.

Moisture levels should optimally be between 50% and 60%, as active composting slows when it falls below 40% or can totally cease ($<15\%$). If the level is $>65\%$, pores for oxygen transfer may become blocked and odor emissions can increase. A liquid source can be added to the mixture if moisture levels are below the preferred range. Wells, ponds, lagoons, or other water sources can be used, but if the liquid is from waste storage containments, the nutrient content will increase, which can be an advantage or disadvantage depending on the use of the end compost. As a rule of thumb, the compost is too wet if water can be squeezed out of a handful and too dry if the handful does not feel moist to the touch.

Microorganisms responsible for effective composting require an optimum range of 104–150 °F for maximum efficiency. Pathogens (135 °F or greater for 3 days) and weed seeds (145 °F) can be killed from the heat generated during composting. However, temperatures more than 150 °F can kill microorganisms and the pile should be turned. Conversely, a pile with temperature less than 104 °F may indicate an inadequate oxygen level and should be turned. If the temperature fails to rise, the pile should be allowed to finish composting for at least 1 month.

The most common method of composting is storing the composting material in windrows. When using a bucket loader to turn the piles, the initial windrows can be 6–10 ft high and 10–15 ft wide. During composting, many nutrients are lost through microorganism degradation and atmospheric loss, including N (40%) and C (60%). This loss can be seen by a decrease in pile mass, which can be one-half from start to finish. Composting time may range from 2 to 5 months, depending on the management and composting conditions.

When selecting a site, regardless of size, several considerations need to be evaluated. Some of these factors include proximity to your home and neighbors, visibility of site, drainage, runoff control, soil type, and separation distance between the composting site and water sources and streams.

Land Application

Livestock manure is used as an economical means of providing nutrients for crop growth and can provide for increased soil organic matter and fertility. When preparing to land apply manure, keys items that should be known include the nutrient content of the manure, application method to assure a uniform application based on crop needs, soil type, and what type and level of commercial fertilizer may be needed to compliment the manure application process.

As application of manure has the potential to increase odor from the volatilization of various compounds, best management practices to reduce odor and capture more nutrients in the soil for crop uptake include: (1) injecting liquid manure streams directly into the soil and (2) incorporating surface-applied solid or liquid manure into the soil within 24 h. Injecting manure directly into the soil is the most effective application method to reduce odor and retain nutrients for crop use. Research evaluating the ammonia concentrations of manure has shown that up to 90% is retained in the soil if injected compared with surface applying. Incorporating surface-applied manure within 24 h retains the majority of nutrients. However, surface-applied manure will lose almost all the ammonia nitrogen after 5–7 days. Manure should be applied at agronomic rates to match the upcoming year's plant needs, so that runoff or leaching is minimized to prevent environmental degradation to groundwater or surface water.

Air Quality

As manure contains many volatile compounds, unwanted or unpleasant odor is a potential in nearby areas of livestock production. In some situations, odors are very objectionable to nearby residents or passersby. Odors and gases are emitted into the atmosphere from all livestock and poultry operations, but the amount of emissions depend on a variety of factors. Some of the factors include weather conditions (high temperatures, moisture, and humidity all can increase odor), wind, manure storage type (open structure produces more odors than that by covered), amount of manure accumulated in open pens or in stockpiled areas, and the amount of dust

coming off the production area. Overall, manure can produce between 80 and 200 odorous compounds.

As previously discussed in the Section Feed Influences Manure Nutrients, reducing the level of nitrogen in the feed directly lowers the nitrogen level in manure. Another benefit is that the reduced nitrogen content of manure leads to less ammonia loss due to a lower overall level in manure. Ammonia is a colorless gas and has an undesirable smell. Ammonia from livestock operations mainly originates from excreted urinary nitrogen, so any decrease in the concentration of nitrogen in urine and feces will reduce the amount of ammonia that is released into the air from manure storage areas. Thus, it is not surprising that numerous research trials have shown that including crystalline amino acids in swine and poultry diets to replace protein ingredient sources, such as soybean meal, reduces ammonia emissions from manure.

Greenhouse Gases

Greenhouse gas compounds of environmental concern that contribute to global warming are carbon dioxide, methane, and nitrous oxide. Generally, carbon dioxide receives the most attention as a contributor to climate change; however, methane and nitrous oxide are significant greenhouse gases because of greater global warming potential relative to carbon dioxide. Although greenhouse gases are being contributed by numerous sources into the atmosphere, these are also emitted from animal agriculture. The gases emitted by agriculture are predominantly methane from enteric fermentation in ruminants, carbon dioxide from nutrient metabolism and respiration, and all three compounds from manure decomposition. Thus, livestock and poultry operations can make improvements in reducing greenhouse gas losses by avoiding excess diet protein levels, improving overall feed efficiency, reducing time of manure storage, and injecting or incorporating manure into soil at the time of land application.

Waste Management in Europe

W Philipp and LE Hoelzle, University Hohenheim, Garbenstr, Stuttgart, Germany

Legal Background

The directive 2008/98/EC on wastes in the European Union (EU) is aimed to improve protection of the environment and climate as well as natural resources by boosting the waste prevention and the recycling of waste. For this, a five-step waste hierarchy is defined, i.e., waste prevention, reuse, recycling, energy recovering, and disposal. In this context, reuse means that the waste is used without further treatment; recycling means any recovery operation by which waste materials are reprocessed into products, materials, or substances for the original or other purposes.

The preference is always for the best option with regard to the protection of the environment. For the consideration of the options, technical, economic, and social consequences are estimated. The recycling management is, therefore, forcefully directed to waste prevention and recycling without endangering well-established ecologically high-class disposal techniques.

In the framework of enforced recycling strategies, the waste management of municipal waste shall achieve a rate of recycling of 65% until 2020. The rate of material utilization of building waste will be 70%.

Municipal Solid Waste

Municipal waste consists of disposals derived from private households and comparable institutions, as well as of domestic waste-like material from industry, i.e., waste of surgeries, schools, kindergarten, etc. In addition, bulky refuse, waste from markets, litter, biodegradable waste, glass, paper, feces, and sludge belong to municipal waste. Until June 2005, use of untreated biodegradable municipal waste for landfilling in Germany was allowed. Now, reusable waste material has to be treated either thermally or biomechanically before it is used in a repository.

Biowaste

Biodegradable waste can be commonly found in municipal solid waste as green waste, food waste, paper waste, and biodegradable plastics. Other biodegradable wastes include human waste, manure, sewage, and slaughterhouse waste. The reutilization of biowaste is one of the most important parts of waste management today. Figure 1 shows the percentages of separately collected biowaste and green waste.

Separation of biowaste from other waste and the removal of the remaining biodegradable elements in the residual waste through pretreatment was the turning point with regards to the waste management sector's climatic impact: the annual emissions of greenhouse gases, expressed in CO_2 equivalents, have been reduced by approximately 56 million metric tons compared with 1990 levels. That represented almost 25% of the total reduction in emissions of greenhouse gases achieved in Germany until 2006.

In the context of further efforts to produce renewable energy, for example, from energy plants, whose cultivation is sometimes in competition with food and fodder production, combined material and energy recovery from biowaste and green waste is now of particular interest.

In 2007, the German Advisory Council on the Environment (SRU, 2007) established that every year approximately 100 million metric tons of 'biomass residues,' i.e., biowaste and similar materials are generated in Germany from areas such as forestry, agriculture, or sewage and waste management. Of this, approximately 65% could be technically and ecologically useful. This has a potential of 4–5% of the country's primary energy requirement. High priority should be given to exploiting this potential, a major proportion of which falls within the sphere of responsibility of local authorities.

The EU Waste Framework Directive of December 2008 also underscores the need to make better use of biowaste. Article 22 of the Directive states that member states shall take appropriate measures to encourage the separate collection of

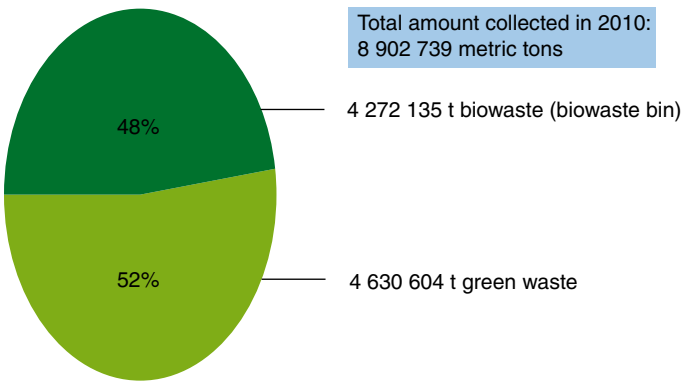

Figure 1 Percentage of separately collected biowaste and green waste of the total amount of biowaste. Reproduced from Federal German states waste inventories 2010 (NRW and Thuringia, 2009).

Utility of bio-waste in the different recovery paths

biowaste with a view to utilize it for composting and anaerobic digestion. Figure 2 summarizes the possible reutilization pathways of biowaste.

Sewage Sludge

Sewage sludge originates from municipal sewage plants that purify the wastewater derived from private households and from industry. It contains separated ingredients of the wastewater, i.e., sediments from the mechanical purification step, excess biomass from the biological purification step, and sludge from the third purification step containing precipitated phosphates. Owing to the rather high nitrogen and phosphate content, sewage sludge can be used as fertilizer on agricultural areas where the pollution burden is rather low. This usage of the sewage sludge is desirable with regard to political economy and protection of resources. Currently, approximately 50% of sewage sludge is used for fertilizing in Germany. The other part is used as refuse-derived fuels or for landfilling after biomechanical pretreatment or a treatment in a waste incinerating plant.

The application of sewage sludge as fertilizers in agriculture is administered in the EU according to the directive 86/278/EU.

Animal By-Products

All residual materials derived from animals that are not suited for human consumption are called animal by-products. They consist of entire animal bodies, parts of killed animals or animals that died, or products originating from animals that are not or no longer determined for human consumption including oocytes, embryos, and semen that are not used for breeding.

Animal by-products are considerable sources for infections and play an important role in the transmission of infectious agents, i.e., foot-and-mouth disease virus, swine fever viruses, or prions. Therefore, these materials should be utilized or depolluted without endangering the health of human beings and animals as well as the environment. Beyond this, it is to be ensured that no animal by-products end up in the food chain.

To achieve these goals, the differentiation and utilization of animal by-products in Europe is regulated by the regulations 1069/2009 and 142/2011 of the EU. These regulations deal with animal by-products and their follow-up products that are excluded from consumption. In addition, products and crude materials of animal origin that are excluded from the food chain due to the decision of producers and are, therefore, not used for human consumption are also considered in the regulation. The hygienic conditions and epidemic precautions for the collection, transport, storage, treatment, handling, usage, trading, and elimination of animal by-products are subjects of this regulation.

In accordance with the regulation 1069/2009, animal by-products are categorized into three groups with regard to origin and epidemiological risk for humans as well as animals. Based on this, the materials have to be variably treated and can be utilized in different ways.

Category 1 Material

Animal by-products belonging to Category 1 are considered to have the highest epidemiological risk potential. Category 1 material shall comprise the following animal by-products:

- Entire bodies and all body parts, including hides and skins, of the following animals:
  - animals suspected of being infected by a transmissible spongiform encephalopathy (TSE) in accordance with Regulation (EC) No 999/2001 or in which the presence of a TSE has been officially confirmed;
  - animals killed in the context of TSE eradication measures;
  - animals other than farmed and wild animals, including in particular pet animals, zoo animals, and circus animals;

  - animals used for experiments as defined by Article 2(d) of Directive 86/609/EC without prejudice to Article 3(2) of Regulation (EC) No 1831/2003; and
  - wild animals, when suspected of being infected with diseases communicable to humans or animals.
- Specified risk material, entire bodies or parts of dead animals containing specified risk material at the time of disposal.
- Animal by-products derived from animals that have been subjected to illegal treatment is defined as the use of unauthorized substances or products authorized under Community legislation for purposes or under conditions other than those laid down in Community legislation or, where appropriate, in the various national legislation (Article 1(2)(d) of Directive 96/22/EC or Article 2(b) of Directive 96/23/EC).
- Animal by-products containing residues of other substances and environmental contaminants listed in Group B (3) of Annex I to Directive 96/23/EC, if such residues exceed the permitted level laid down by Community legislation or, in the absence thereof, by national legislation.
- Animal by-products collected during the treatment of wastewater required by implementing rules adopted under point (c) of the first paragraph of Article 27 from establishments or plants processing Category 1 material; or from other establishments or plants where specified risk material is being removed.
- Catering waste from the means of transport operating internationally (international catering waste, e.g., aircraft catering). Mixtures of Category 1 material with either Category 2 material or Category 3 material or both.

Category 2 Material

Animal by-products belonging to Category 2 are considered to have the medium epidemiological risk potential. Category 2 material shall comprise the following animal by-products:

- Manure, nonmineralized guano, and digestive tract content.
- Animal by-products collected during the treatment of wastewater required by implementing rules adopted from establishments or plants processing Category 2 material; or from slaughterhouses other than those covered by Article 8(e).
- Animal by-products containing residues of authorized substances or contaminants exceeding the permitted levels as referred to in Article 15(3) of Directive 96/23/EC.
- Products of animal origin that have been declared unfit for human consumption due to the presence of foreign bodies in those products.
- Products of animal origin, other than Category 1 material, that are: imported or introduced from a third country and fail to comply with Community veterinary legislation for their import or introduction into the Community except where Community legislation allows their import or introduction subject to specific restrictions or their return to the third country; or dispatched to another Member State and fail to comply with requirements laid down or authorized by Community legislation except where they are returned with the authorization of the competent authority of the Member State of origin.
- Animals and parts of animals, other than those referred to in Article 8 or Article 10, that died other than by being slaughtered or killed for human consumption, including animals killed for disease control purposes; fetuses; oocytes, embryos, and semen that are not destined for breeding purposes; and dead-in-shell poultry.
- Mixtures of Category 2 material with Category 3 material.
- Animal by-products other than Category 1 material or Category 3 material.

Category 3 Material

Animal by-products belonging to Category 3 are considered to have the lowest epidemiological risk potential. Category 3 material shall comprise the following animal by-products:

- Carcasses and parts of animals slaughtered or, in the case of game, bodies or parts of animals killed, and which are fit for human consumption in accordance with Community legislation, but are not intended for human consumption for commercial reasons.
- Carcasses and the following parts originating either from animals that have been slaughtered in a slaughterhouse and were considered fit for slaughter for human consumption following an antemortem inspection or bodies and the following parts of animals from game killed for human consumption in accordance with Community legislation:
  - carcasses or bodies and parts of animals that are rejected as unfit for human consumption in accordance with Community legislation, but which did not show any signs of disease communicable to humans or animals;
  - heads of poultry;
  - hides and skins, including trimmings and splitting thereof, horns and feet, including the phalanges and the carpus and metacarpus bones, tarsus and metatarsus bones, of animals, other than ruminants requiring TSE testing, and ruminants that have been tested with a negative result in accordance with Article 6(1) of Regulation (EC) No 999/2001;
  - pig bristles, feathers.
- Animal by-products from poultry and lagomorphs (animals belonging to the order Lagomorpha, which includes the rabbits, hares, and pikas) slaughtered on the farm as referred to in Article 1(3)(d) of Regulation (EC) No 853/2004 that did not show any signs of disease communicable to humans or animals.
- Blood of animals that did not show any signs of disease communicable through blood to humans or animals obtained from the following animals that have been slaughtered in a slaughterhouse after having been considered fit for slaughter for human consumption following an antemortem inspection in accordance with Community legislation: animals other than ruminants requiring TSE testing; and ruminants that have been tested with a negative result in accordance with Article 6(1) of Regulation (EC) No 999/2001.
- Animal by-products arising from the production of products intended for human consumption, including degreased bones, greaves (protein containing residues of

rendering, after partial separation of fat and water), and centrifuge or separator sludge from milk processing.
- Products of animal origin, or foodstuffs containing products of animal origin, which are no longer intended for human consumption for commercial reasons or due to problems of manufacturing or packaging defects or other defects from which no risk to public or animal health arises.
- Pet food and feeding stuffs of animal origin, or feeding stuffs containing animal by-products or derived products that are no longer intended for feeding for commercial reasons or due to problems of manufacturing or packaging defects or other defects from which no risk to public or animal health arises.
- Blood, placenta, wool, feathers, hair, horns, hoof cuts, and raw milk originating from live animals that did not show any signs of disease communicable through that product to humans or animals.
- Aquatic animals, and parts of such animals, except sea mammals that did not show any signs of disease communicable to humans or animals.
- Animal by-products from aquatic animals originating from establishments or plants manufacturing products for human consumption.
- The following material originating from animals that did not show any signs of disease communicable through that material to humans or animals: shells from shellfish with soft tissue or flesh; the following originating from terrestrial animals: hatchery by-products, eggs, egg by-products (including egg shells), and one-day-old chicks killed for commercial reasons.
- Aquatic and terrestrial invertebrates other than species pathogenic to humans or animals.
- Animals and parts thereof of the zoological orders of Rodentia and Lagomorpha, except Category 1 material as referred to in Article 8(a)(iii), (iv), and (v) and Category 2 material as referred to in Article 9(a)–(g).
- Hides, skins, hooves, feathers, wool, horns, hair, and fur originating from dead animals that did not show any signs of disease communicable through that product to humans or animals, other than those referred to in point (b) of this.
- Adipose tissue from animals that did not show any signs of disease communicable through that material to humans or animals, which were slaughtered in a slaughterhouse and which were considered fit for slaughter for human consumption following an antemortem inspection in accordance with Community legislation.
- Catering waste other than as referred to in Article 8(f).

A strict separation of the three different categorized materials from the production up to the utilization or disposal is the basis for the biosafety of the whole process. In case of mixing materials belonging to different categories, the mixture is always allocated to the category showing the higher risk potential.

Waste Treatment

Composting Processes

Composting is a biological decomposition process for organic waste, in which the material is broken down by microbes and microorganisms under aerobic conditions. During the composting process, the temperature of the material increases up to 70–80 °C. This will sanitize the input material.

Input materials for composting plants can be, for example, biowaste, green waste, digestates from biogas plants, sewage sludge, and animal by-products of Categories 2 and 3 after sanitation. Composting has been used as a method of biowaste treatment on a large industrial scale in Germany since the middle of the 1980s.

As composts contain essential plant nutrients, they are good organic fertilizers and excellent soil improvers. Compost and composted solid digestates are especially suitable for humus reproduction.

The mechanical composting processes applied can be divided into various categories:

- composting in heaps (triangular, trapezium-shaped, or flat stacks),
- composting in bunkers/containers
- row/tunnel composting
- composting as briquettes
- other systems.

The processes differ in the way the heaps are constructed (open, covered, and in containers), the type of ventilation, and also the duration of the intensive rotting stage and the maturity of compost desired. If the intensive rotting system is set up for mature compost, the main and subsequent rotting phases are integrated. If the intensive rotting results in sanitized fresh compost, a second rotting stage can follow to achieve a higher degree of decomposition. In composting facilities, the second stage is carried out predominantly in flat or triangular heaps.

The following diagram provides an overview of the possible composting processes (Figure 3).

Marketing channels for compost can be found in many areas, i.e., private gardening, landscape recultivation, soil suppliers, agriculture, and horticulture.

The economic importance of using composts in agriculture is often underestimated. However, a constantly rising demand shows that compost is rapidly becoming an attractive substitute in the wake of higher mineral fertilizer prices. Whereas until a few years ago farmers were paid to accept compost and composted digestates, nowadays it is usually a source of revenue.

If one considers just the fertilizer value of compost based on mineral fertilizer prices, a metric ton of compost was worth up to 12 Euros in early 2012.

Anaerobic Digestion Processes

Unlike composting, the biological decomposition processes occur in the absence of oxygen. The most important end product of anaerobic digestion is biogas. Biogas can be used mainly in electricity and heat production. Besides this, a nutrient-rich digestate is produced during the fermentation process that can be used in liquid or solid form as a fertilizer in agriculture and related areas.

Separately collected biowaste as well as food scraps and the herbaceous parts of green waste, on the other hand, are

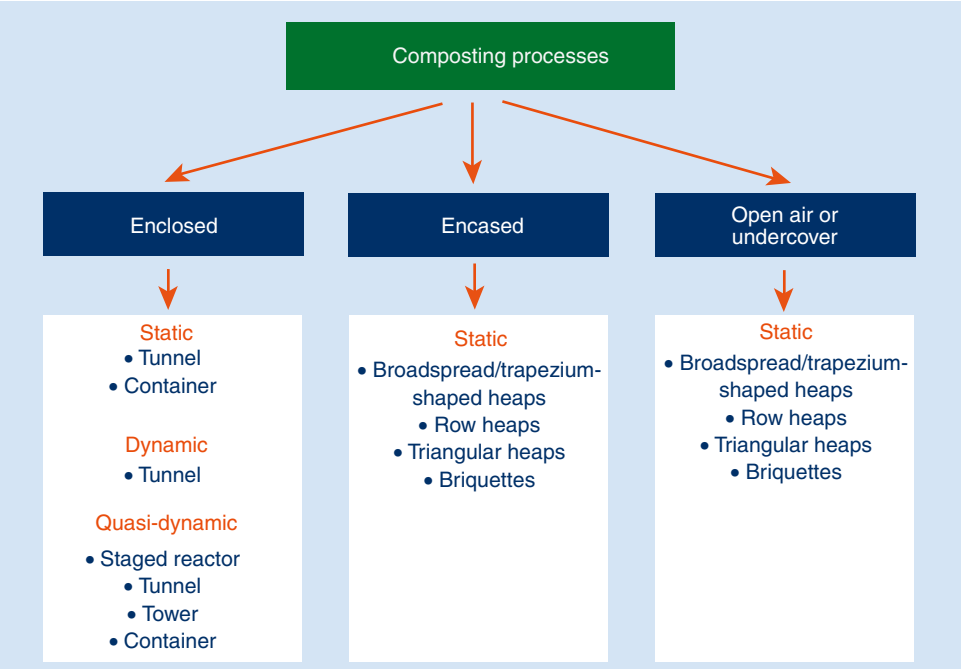

Figure 3 Overview of the composting plants.

generally well suited for anaerobic digestion. However, animal by-products can be used as input material of biogas plants, for example, manure, carcasses of slaughtered animals, etc. In most cases, biogas plants are operated using a mixture of manure and energy crops.

The digestates can be used directly in agriculture in liquid or solid form or marketed as a solid digestate product after composting. Anaerobic fermentation achieves a positive energy and climate balance due to biogas production, which can be used as a substitute for fossil fuels.

An important feature for distinguishing anaerobic digestion processes is the method of operation (Figure 4). There are continuous and discontinuous processes, which are operated at mesophilic temperature (35–37 °C) or thermophilic temperature (50–55 °C).

In the continuous process, input material is automatically fed at regular intervals into the anaerobic digestion reactor (fermenter). This process promotes continuous biogas production of consistent quality. In the discontinuous process, the digesters are filled manually, then after several weeks they are emptied and refilled (batch operation). Biogas production is not continuous, but parallel connection of several digesters working on a staggered system can largely compensate this. In addition, with regard to the dry matter of the input material, wet and dry fermentation is distinguished.

Anaerobic digestion achieves a positive energy and climate balance due to the emerging biogas and the resulting substitution of fossil fuels. With anaerobic digestion the climate credit amounts to approximately 99 kg (German average) or 194 kg (state-of-the-art facilities). For 1 metric ton of biowaste, depending on the input quality and process, between 80 and 140 m^3 of biogas with a methane content of 50–65% is produced. The energy from this equates to 50–80 m^3 of natural gas. As an example, an input of 20 000 metric tons of biowaste per year suffices to operate a cogeneration plant with a rated electrical capacity of 600 kW, producing enough electricity for 1000–1500 households. It is also possible to refine biogas to natural gas quality and feed it into the natural gas grid.

Disposal and Recycling of Animal By-Products

Animal by-products can contain infectious agents, which can infect human beings and animals. Therefore, the utilization possibilities for these very heterogeneous materials are dependent on the category to which the by-products belong. In the case of Category 1 materials harboring the highest epidemiological potential, the materials have to be sterilized (133 °C, 3 bar, and 20 min) and afterwards burned.

Materials of the Categories 2 and 3 can be recycled after sterilization and disinfection, respectively. In these cases, the materials can be composted or used as input materials in biogas plants. The production of animal feed derived from Category 3 materials is principally possible but more or less restricted to pet feed.

Waste Management and Hygiene

When using organic fertilizers in agriculture, the transmission of microorganisms infecting human beings and animals has to be considered. This is especially the case if sewage sludge, untreated slurry, and digestates are used. Therefore, the epidemiological risk of fertilizers produced during the recycling of wastes of different organic origin has to be estimated. For this, the risk assessment should include the raw material, the processing techniques, the end product, and the kind of application.

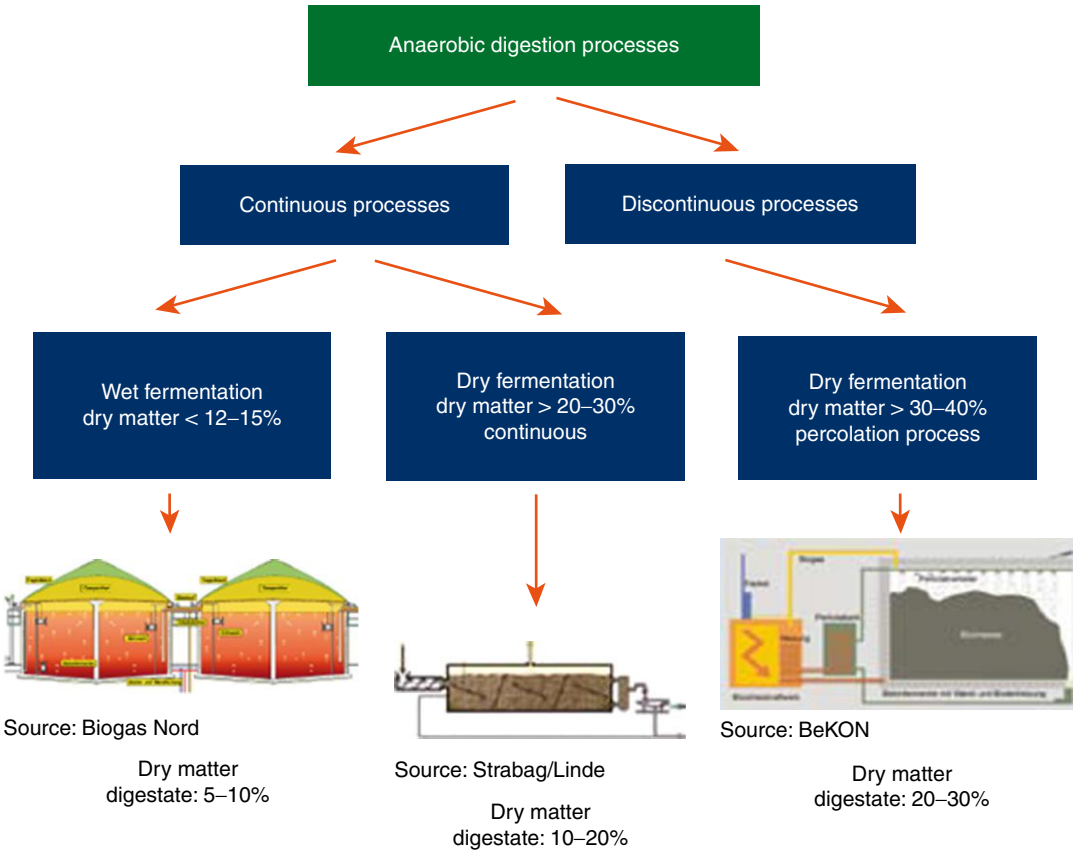

Figure 4 Overview of the anaerobic digestion plants.

In some cases the minimization of the epidemiological risk is only possible by treatment of the raw material (disinfection and sterilization), for example, animal by-products. Sometimes the treatment process is able to inactivate infectious agents leading to an epidemiologically harmless product, for example, composting. One additional possibility to minimize the epidemiologic risk is to perform microbiological investigations of the end product before application. This leads in some instances to restrictions for the scope of application.

In summary, blood, placenta, wool, feather, hair, horn, and raw milk from animals which are not suspicious for carrying agents that can be transmitted to humans and animals are allowed to be used in biogas plants after pasteurization (70 °C, 1 h according to the regulation 1069/2009). The same procedure is applied in the case of inedible fat (e.g., used fat from fryers). Fat from fat separators originating from the food industry and slaughterhouses is processed as Category 1 material.

According to Article 9(f) of the regulation 1069/2009, fetuses, oocytes, embryos, and semen which are not destined for breeding purposes as well as dead-in-shell poultry have to be disposed as Category 2 material using pressure sterilization (at least 133 °C, for at least 20 min with an absolute pressure of at least 3 bar). Male and female reproduction tracts as well as brain material that were not categorized as specified risk material are preceded accordingly.

Furthermore, high-quality soil improvers and fertilizers can be produced sustainably from biowaste and green waste by treating it in composting plants or combined anaerobic digestion and composting facilities. The material recovery of digestates is an important renewable source of plant nutrients and humus, and therefore is essential for the greenhouse gas balance.

Summary

Every year, some 2 billion tons of waste are produced in the EU, and this rate is rising steadily. Therefore, strict measures of waste management are necessary for protecting the environment and climate as well as human health and natural resources. The Directive 2008/98/EC on wastes comprises the legal background of waste management in the EU. This legislation introduces a five-step waste hierarchy where waste prevention is the best option, followed by reuse, recycling, and other forms of recovery (e.g., energy recovering), with disposal such as landfill as the last resort. The main waste categories are municipal solid waste, biowaste, sewage sludge, and animal by-products.

Animal by-products are an exception since they can be utilized for recycling only after disinfection. They must be dealt in accordance with strict regulations (regulations 1069/2009 and 142/2011 of the EU) designed to prevent harm to people, animals, and the environment. Animal by-products are categorized (Category 1–3 materials) by the risks they pose and the methods used to deal with them.

The two most important procedures for recycling of organic raw materials are composting and biogas fermentation. Composting is a biological decomposition process for organic waste, in which the material is broken down by microbes and microorganisms under aerobic conditions. Biogas can be used mainly for the production of electricity and heat. Besides this, a nutrient-rich digestate is produced during the fermentation processes that can be used in liquid or solid form as a fertilizer in agriculture and related areas.

MEASUREMENT OF MEAT QUALITY

Measurements of Water-holding Capacity and Color: Objective and Subjective

R Warner, CSIRO, Werribee, VIC, Australia

Glossary

Color space A color space maps a range of physically produced colors to an objective description of color sensations registered in the eye, typically in terms of tristimulus values. It is the terminology used to describe the mathematically derived languages for describing color, such as International Commission on Illumination (CIE) XYZ, CIE$L^*a^*b^*$, and RGB.

Diffuse reflection The reflection of light from a surface such that an incident ray is reflected at many angles rather than at just one angle.

Gloss The shine or lustre on a surface.

Isobetic A specific wavelength at which the extinction coefficients for two or more forms of myoglobin are the same.

***Lab* color space** A color-opponent space with dimension L for lightness and a and b for the color-opponent dimensions of redness–greeness and blueness–yellowness, respectively, based on nonlinearly compressed CIE XYZ color space coordinates.

RGB color space Any additive color space based on the RGB color model and defined by the three chromaticities of the red, green, and blue, the additive primary colors. It can produce any chromaticity defined by those primary colors.

Specular reflection The mirror-like reflection of light from a surface, in which light from a single incoming direction is reflected into a single outgoing direction.

Tristimulus Relates to the three levels of stimulus that color gives to the three types of cone cells in the eye. The cone cells (photoreceptors) in the eye have sensitivity peaks in three wavelengths: short, medium, and long, hence tristimulus refers to stimulation of all three types of cone cells.

Water-binding capacity The amount of water that can be added during cutting, heating, grinding, and pressing, including the use of phosphates and salts.

Water-holding capacity The amount of water that meat can hold during cutting, heating, grinding, and pressing and during transport, storage, and cooking. The water released can be variously described as drip, purge, cook loss, weep, exudate, or cook loss.

Introduction

The two most important quality traits of meat are the visual acceptability, which determines the initial impression of quality, and sensory acceptability when the meat is consumed, possibly justifying the visual impact. The surface color of meat and the weep in the tray are important for cues on visual acceptability of meat on retail shelves when it is purchased. Water-holding capacity (WHC) is related to sensory juiciness as well as the occurrence of weep in the tray. Meat color and WHC can be assessed subjectively or objectively and these methods are discussed below. In addition, the background to WHC and color measurement are briefly described along with the specifications necessary for selecting a colorimeter for meat color measurement.

This article focuses on methods that can be used in the laboratory or in the field.

Water-holding Capacity Measurement

WHC determines not only the visual acceptability but also the loss of water during transport, storage, and cooking. Muscle comprises approximately 75% water at rigor and the addition of water to meat, and the hydration of the meat after cooking, is closely related to taste, tenderness, color, and juiciness. The consequence of poor WHC is low cook yields and often 'dry (lack of juiciness)' meat, so these can also be used to indirectly measure WHC. This section describes the methods used to measure WHC.

WHC is the amount of water the meat can hold during cutting, heating, grinding, and pressing. If there has been added water, including phosphates and salts, the correct term would be water-binding capacity. The terms drip, purge, cook loss, weep, and exudate refer to the loss of water from muscle and are inversely related to WHC. Each of these traits is related to each other but do not always have a strong correlation. In particular, cooking loss can have quite different influencing factors and thus should not be inferred from measurements of the other traits.

Factors that Influence Water-holding Capacity

Water in the muscle cells (approximately 75% by weight) is bound primarily by capillary forces within the myofibrillar structure, as well as in the sarcoplasm. In the living animal, water is kept in cells by the sarcolemma (cellular membrane)

 doi:10.1016/B978-0-12-384731-7.00210-5

and maintained by various membrane pumps. Postslaughter, water is moved to the sarcoplasm by shrinkage of the myofibrils and kept in the cell until the pH falls, adenosine triphosphate becomes unavailable, and water and ions can move and pass through the sarcolemma into the extracellular space between the cells. In muscle, approximately at pH 7, of a live animal, the myofibrils take up most of the space in the muscle cell. Postmortem, the myofibrils shrink both in transverse and longitudinal directions, the intracellular sarcoplasmic space increases, and over time, water moves to the extracellular space. In a muscle at approximately pH 7, more than 95% of the water is within cells; some days postmortem, approximately 15% is in the extracellular space and the water appears as drip at the surface of the meat. From this point, proteolysis of the cytoskeletal filaments occurs during aging and further water is produced over time as drip. Dark, firm, and dry (DFD) meat with a high ultimate pH (>6.2) loses less drip. This is because the myofibrils have had minimal transverse shrinkage, as at the high pH of DFD meat, there is a net negative charge on the proteins in the myofibrils, which causes the filaments to be repulsed from each other. During rigor, as the pH of the muscle approaches 5.4 or lower, the net charge on proteins in the myofibrils diminishes and filaments can approach each other, causing transverse shrinkage in the myofibril. Thus, there is always some loss of WHC when the pH of muscle drops from 7 to 5.5. When the sarcomere shortens, due to rigor, cold, or heat shortenings, the myofibril shortens longitudinally, with water being expelled to the intracellular space. Thus, meat from stretched muscles, with long sarcomeres, has higher WHC as measured by drip loss, purge, and cooking loss. In muscle prone to the pale, soft, and exudative (PSE) condition, the high temperatures shortly after slaughter (35–42 °C) and the already low pH lead to myosin denaturation, which causes additional transverse shrinkage in the myofibril, along with early membrane destruction. In PSE muscles, the three conditions of low pH, denatured myosin, and damaged membranes cause drip loss to occur virtually without any time lag. The strongest increase occurs in the first 2 days. This seems to be less of an issue in beef and lamb, although increased drip has been observed in beef muscle going through high temperature rigor. The WHC, therefore, can be influenced by the prerigor myosin denaturation, sarcomere shortening, decline in muscle pH from 7 to 5.5, and the release of water from the muscle cell as a result of cytoskeletal protein degradation postrigor during tenderization.

Weight loss during storage, cooking, freezing, and thawing are related to how much water is available and how easily it can leave the muscle structure network.

Methods to Measure Water-holding Capacity

The measurement of WHC usually involves the application of force to measure the water released. The force can either be natural, through gravimetric means, or be applied externally as pressure, through centrifugation, compression, or taking advantage of capillary action.

Methods applying no external force

1. Gravimetric (drip loss): This method involves the measurement of weight loss in free drip, bag drip, or cube drip, where the meat is left to itself under different environmental conditions. The most commonly used method involves using a standard size and weight block of meat (approximately 30–100 g) and suspending it in a bag, for 1–2 days at 1–4 °C, ensuring that the meat does not touch the sides of the bag (Figure 1). Variations of this method include chopping the meat and placing it in a tray, so that all the drip can be collected in the bottom of a tray, which is not in physical contact with the meat. Each method involves weighing the meat at the start and end, and the drip loss is expressed as a loss in weight of the sample over the defined period, expressed as a percentage of the initial weight. The surface area of the meat can influence the results. This method is widely used because of its simplicity and is often called the Honikel bag method.

   The EZ-DripLoss method has been developed as a simplified, convenient, and standardized variation of the procedure. A 25-mm slice is removed at a right angle to the muscle fiber direction. The sample is immediately cut using a 25-mm cork borer in the fiber direction. It is then placed in a special preweighed container equipped with a lid to avoid evaporation and loss of meat juice. This container contains lamellas with a minimum area touching the sample's surface. The container is stored for 24 h at 4–6 °C, and then the meat is removed and weighed from the container and carefully dried with absorbent paper and weighed.
2. Weep or purge: Purge, or weep, is defined as water lost from meat or muscle during storage postrigor, including during storage in trays (overwrap or modified atmosphere packs) on retail shelves. Measuring purge, or weep, involves measuring the loss in weight of meat over a defined period. Thus, the meat is weighed before being placed in the bag or tray, then weighed again once the bag is opened or the packaging is removed, at the end of the storage or display period. The fluid is mopped up and the meat reweighed at the completion of the storage period. This is a method that can be used when the meat is stored in a vacuum bag or retail-ready tray. The appearance of weep or purge is unsightly and implies an inferior product.

Figure 1 Illustration of the gravimetric method for measuring drip loss, involving suspension of a meat sample in an inflated bag and storage at 2–4 °C for 1–2 days. Credit: Kaufman, R., University of Wisconsin–Madison.

3. Subjective scoring of exudate: Visual scores for exudate have been used to assess the surface muscle of beef and pork carcasses. The score can be a simple 'yes' or 'no,' or a score from 0% to 100%, similar to that used for the rapid filter paper method discussed in the Section Methods Applying External Force under point 4.

Methods applying external force

1. The press method or compression: This was the first method developed to measure WHC. A predefined circular piece of meat (approximately 30 g) is placed on filter paper, between two plastic sheets, and a defined pressure is applied to the meat. The water squeezed out is absorbed by the filter paper and is related to the amount of 'loose' water in the sample. The amount of water released is either measured (1) indirectly as the area of the ring of expressed juice or (2) directly by weighing the filter paper. This method is no longer widely used as the results are variable and are dependent on the texture of the meat.
2. High-speed centrifugation: This involves subjecting samples of 1–20 g to centrifugal forces of 6000–40 000*g*. Water release is determined by weighing the water or the sample before and after centrifugation. This method removes more water than most of the other methods, due to the high centrifugal forces involved. But due to the elastic nature of meat, some of the water is reabsorbed once the centrifugal force is removed. Similar to the press method, the results obtained are influenced by the texture of the meat. This method has had very limited use.
3. Low-speed centrifugation: This method involves subjecting 3–15 g samples at 200–5000*g* for 15–30 min (or even longer) and measuring the weight loss of the sample or weight of the exuded fluid. The advantage of this method over high-speed centrifugation is that it uses specially designed centrifuge tubes with a perforated disc in the middle (e.g., Mobicols from MoBiTec). This disc allows moisture to spin down to the bottom while leaving the tissue on the top, thus preventing reabsorption of the fluid. One of the problems with this method, which has introduced inaccuracies in the results, has been the blocking of the pores in the membrane. This can be overcome by using superglue to glue the piece of meat to the bottom of the lid of the tube. Figure 2 shows the effects on water loss during centrifugation by gluing, or not gluing, the meat sample to the lid of the tube before centrifugation. This method has become very popular as it correlates well with drip loss measurements, is relatively simple to conduct, and samples can be centrifuged regularly (e.g., every 15 min) to follow changes in WHC.
4. Rapid filter paper method: This method relies on capillary suction forces of the filter paper applied to the meat surface. It is extremely rapid and involves placing a filter paper on a freshly cut surface at a defined time postcutting (e.g., 10 min), smoothing it out, then either scoring the filter paper for wetness (0–100% wet) or weighing the filter paper (Figure 3). Figure 4 shows the relationship between the filter paper score and temperature at rigor.
5. Other capillary suction methods: Other methods that utilize capillary suction rely on suction potential generated via different analytical filter papers and previous calibration of the filter papers or gypsum blocks combined with

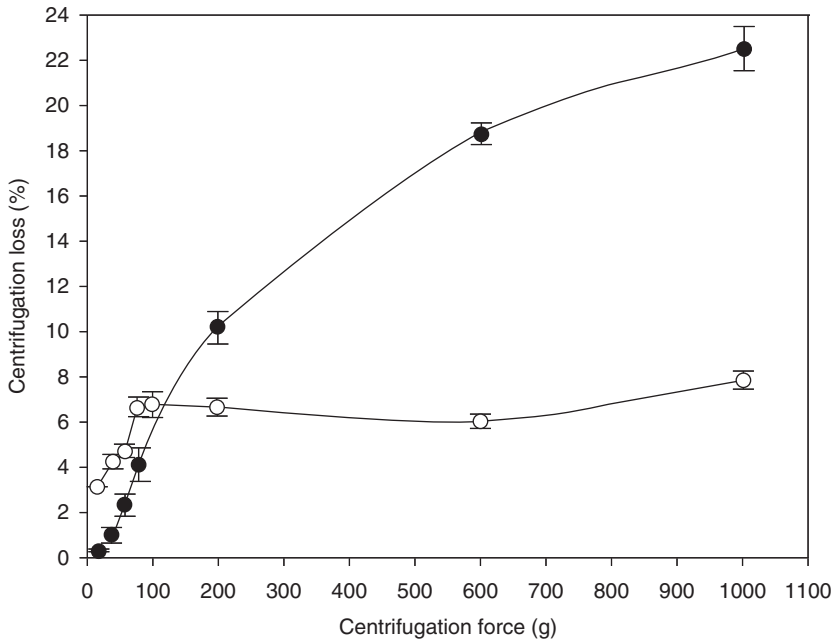

Figure 2 Water loss from meat samples (centrifugal loss %), as a result of 30-min centrifugation as a function of centrifugal force. Filled circles: samples glued to the bottom of the lid. Open circles: nonglued samples. Bars indicate the standard error of the mean. Ten replicates at each time point. Reproduced from Kristensen, L., Purslow, P.P., 2001. The effect of ageing on the water-holding capacity of pork: Role of cytoskeletal proteins. Meat Science 58, 17–23.

compression. These two methods are time consuming and have not gained widespread use.

6. Application of heat (cooking loss): Cooking loss is defined as the loss in weight as a result of cooking, being expressed as a percent of the precook weight. A common method is to combine a measure of weight loss during cooking with the objective measurement of tenderness. Thus, samples destined for objective measurement of cooked meat are weighed before cooking, and then after cooking, the samples are cooled before removal from the bag, are blotted, and reweighed in order to determine cooking loss. Cooking loss is strongly related to degree of aging, cooking temperature, and cooking conditions and is quite an ill-defined property of meat. Of all the WHC measurements, cook loss has the highest correlation with the sensory trait juiciness, which is a complex and ill-defined trait in itself.

Figure 3 Illustration of the rapid filter method for measuring weep or exudate on a beef loin surface. The filter paper can either be weighed, for amount of fluid absorbed, or be scored for percentage of wetness. Credit: Athula, N., Department of Primary Industries, VIC, Australia.

Indirect methods

1. Protein solubility: Protein solubility is a good indirect indicator of WHC, which has been used to quantitate the low WHC of PSE meat muscle for a number of years. Measurement of sarcoplasmic and myofibrillar protein solubility of muscle involves homogenizing 1–2 g of meat in a low ionic strength and high ionic strength buffer, for sarcoplasmic and total protein solubility, respectively, then measuring the protein concentration in the supernatant after centrifugation at 1500*g* and 4 °C for 20 min. Myofibrillar protein solubility is determined by the difference between the protein concentration in the low and high ionic strength buffers. Alternatively, myofibrillar protein solubility can be determined by subjecting the pellet left, after centrifugation of the low ionic strength solution, to a high ionic strength buffer in order to solubilize the myofibrillar proteins.
2. Cook yield: This method is used to predict the yield of cooked meat products. Samples are weighed, homogenized in a food processor, placed into containers, cooked to a defined internal temperature, cooled, and then weighed for cook yield determination.

Color Measurement

Factors Contributing to Meat Color

The concentration and chemical state of the pigment myoglobin in the meat surface, as well as the texture of the meat and light scattering within the meat structure, determine the perceived color. The concentration of pigment in the meat surface, which determines the lightness and redness, usually varies with muscle and also with species (pork and chicken having low muscle myoglobin content relative to beef and sheep meat) and animal age. Young animals, such as veal, have less muscle myoglobin and thus the meat appears paler and less red. The main chemical states of myoglobin in a fresh meat surface are the reduced, purple deoxymyoglobin, red

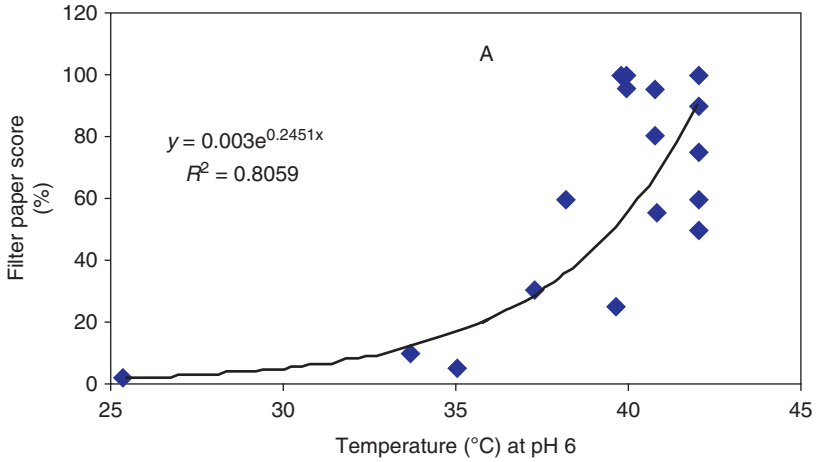

Figure 4 The relationship between filter paper score (rapid filter paper method) and temperature at pH 6 (rigor temperature) in the beef loin muscle. Reproduced with permission from Robyn Warner, Department of Primary Industries, Victoria, Australia.

oxymyoglobin with a bound oxygen molecule, and brown, reduced metmyoglobin. The consumer acceptability of the meat deteriorates rapidly when metmyoglobin starts accumulating in the meat surface. If deoxymyoglobin is the predominant form in the meat surface, the meat appears dark, purple red, and also has less consumer acceptability. Light scattering within the muscle structure occurs when the meat has undergone rapid pH fall prerigor at a high muscle temperature, muscle proteins have denatured, and there are only small gaps between myofibrils. These conditions are thought to cause increased scattering of incident light within the muscle structure and the muscle surface appears 'pale' or 'less light' to detectors (human or machine). This is particularly evident in the condition known as PSE pork.

These variations in pigment and structure will cause variations in the color of the meat surface, which can be visually seen and also measured by a machine.

Theory of Color Measurement

In the study of color perception, one of the first mathematically defined color spaces is the International Commission on Illumination (CIE) 1931 XYZ color space, created by the CIE in 1931. Owing to the distribution of three different types of cone cells, with different sensitivity peaks, in the eye (sensitivity to short, medium, or long wavelength light), the tristimulus values depend on the observer's field of view. To eliminate this variable, the CIE defined the standard (colorimetric) observer. Originally, this was taken to be the chromatic response of the average human viewing through a 2° angle, due to the belief that the color-sensitive cones resided within a 2° arc of the fovea in the retina. Thus, the CIE 1931 Standard Observer is also known as the CIE 1931 2° Standard Observer. A more modern and valid alternative is the CIE 1964 10° Standard Observer. Color spaces and color models of Yxy (derived from XYZ) and RGB (primary colors) have been described. A *Lab* color space is a color-opponent space with dimension L for lightness and a and b for the color-opponent dimensions of redness–greenness and blueness–yellowness, respectively, based on nonlinearly compressed CIE XYZ color space coordinates. The coordinates of the Hunter 1948 L, a, b color space are L, a, and b. However, *Lab* is now more often used as an informal abbreviation for the CIE 1976 (L^*, a^*, b^*) color space (or CIELAB). The difference between Hunter and CIE color coordinates is that the CIE coordinates are based on a cube root transformation of the color data, whereas the Hunter coordinates are based on a square root transformation. Thus, the CIE $L^*a^*b^*$ and Hunter Lab values are not directly comparable and the CIE $L^*a^*b^*$ is the preferred color space for meat measurement as it puts more emphasis on the red part of the spectrum.

In comparison to XYZ, Yxy, and RGB color spaces, the *Lab* color space is designed to approximate human vision. It aspires to perceptual uniformity, and its L component closely matches human perception of lightness, although it has its limitations.

Edge loss occurs when light that scatters through a translucent material, such as meat, which originally would be seen by the eye, is simply not measured by the instrument due to the configuration of the illuminant, sensor, and aperture. This occurs during conventional reflectance measurements of translucent materials when both the illumination and observation light paths travel through an aperture. Generally, the L^* value decreases when the window decreases in size from infinity to 3 mm. Thus, more accurate and valid measurements are obtained if a large aperture is used.

When incident light strikes a surface, the reflected light is described as $<4\%$ specular and $>96\%$ diffuse. Specular reflection is reflected from the surface at right angles to the incident light, whereas diffuse reflection is scattered. Color is seen in the diffuse reflection and gloss is seen in the specular reflection. If samples have the same color, but different surfaces, they will be perceived as a different color. Instrument geometry refers to the angle the light source and the detector make with the sample. Thus, geometries can be diffuse (sphere) or directional (45°/0° or 0°/45°). Directional geometry machines are recommended for meat as they exclude specular reflection, whereas sphere geometry includes specular reflection.

Instrumental Measurements of Meat Color

Surface measurements of color are difficult to make in a well-defined manner unless working under strict laboratory conditions. This is due to the blooming process that begins as soon as a fresh cut has been made in a piece of meat as well as due to the anisotropic characteristics of meat. However, standardized blooming conditions where the temperature and time are specified assist in obtaining accurate and representative measurements. Anisotropy means that the results obtained are different for measurements in different directions on the same material. Thus, the orientation of the fibers in a piece of meat will determine the color measured, showing the necessity for standardizing the fiber orientation in a meat surface being used for color measurement. A standardized measurement procedure is of utmost importance for reliable results. The recommendations for standardizing meat color measurement are for a minimum blooming time of 30 min, for the blooming to occur at 1–4 °C, duplicate measurements and preparation of the surface of the meat so that the fibers are always oriented the same way. The recommendations for the color machine are to calibrate it using standard color tiles and to use a constant (and recorded) degree of observer, size of aperture, and illuminant/viewer angle (Table 1).

Meat mainly reflects light in a diffuse way from the surface, thus the texture of the surface can influence the measurement. The texture or grain in the meat can influence the color measurements, emphasizing the need for standard procedures to be used. In addition, weep, exudate, or water on the meat surface, such as with PSE, can cause variable spectral reflectance to occur, again influencing the color measurements made. Because meat is partially translucent, a portion of the incident light is transmitted below the surface and reflected internally. Thus, samples must be sufficiently thick to ensure no light is reflected from the background. Ideally, the sample should be at least 2.5 cm thick. For high pH dark cutting (DFD) meat, the dark color is thought to be caused by internal reflection of light, thus preventing light from being reflected back to a detector (human or machine).

Table 1 Recommended specifications for preparation of meat for color measurement and for colorimeters, including alternatives and comments

Specification	*Recommended*	*Alternatives*	*Comments*
Time of blooming	30–60 min		Too short can result in inaccurate measurements
Thickness of sample	>2.5 cm		To ensure no effect of background color
Temperature of blooming	1–4 °C		Cold temperature allows better bloom due to higher solubility of O_2 at low temperature
Illumination/viewing angle	45/0 or 0/45	d/8 (diffuse/8)	45/0 allows exclusion of specular reflection
Degree of observer	10°	2° or 0°	Revolves around understanding of cones in eye
Aperture – Size of measuring port	As large a possible >8 mm		Small size can result in 'edge loss'
Light source (illuminant)	D65 (daylight at noon)	C (average daylight) A (Incandescent) F2 (Cool white fluorescent) U30 (Ultralume)	
Calibration tiles	Black and white	Color similar to sample	

Important specifications for any color machine are the angle of the viewer, size of the measuring head, presence of a glass or plastic plate in the measuring head, and type of incident light, as summarized in Table 1. As the color measurements obtained are not absolute, and are reliant on the viewing conditions and specifications of the machine used, the values that are obtained with different machines cannot be compared. An example of this is when color measurements of *L*, *a*, *b* are made with a Hunter Lab Mini Scan 4500 XE Plus; the size of the measuring head (large, 25 mm or small, 5 mm) has a substantial influence on the values obtained.

Lab or $L^*a^*b^*$, along with the calculation of hue and chroma/saturation, is one of the two main systems generally used to describe the color of fresh meat. The other system is percentage reflectance, which is described below along with CIE $L^*a^*b^*$.

1. CIE L*a*b* or Hunter Lab: The CIE $L^*a^*b^*$ or Hunter Lab systems report values for lightness (L^* and L), redness/greenness (a^* and a), and yellow/blueness (b^* and b) and are represented by a three-dimensional color space (see Figure 5). The hue and saturation (also called chroma) can be calculated from the a^* and b^* values. Hue angle = arctangent (b^*/a^*), defines the color, and also indicates the changes in the myoglobin pigment from red to brown. Saturation or chroma = $\sqrt{(a^{*2}+b^{*2})}$ indicates the intensity of the color. An increase in a^* (redness–greenness) value is predominantly related to an increase in the concentration of myoglobin in the meat surface, especially oxymyoglobin. An increase in L^* value (lightness) occurs when there is not only less myoglobin in the surface but also increased light scattering, due to protein denaturation in the muscle structure.
2. Reflectance ratios and percentage reflectance: Reflectance measurement closely relates to what the human eye and brain can see. It is a good method for examining the amount and chemical state of myoglobin in meat *in situ* and is rapid. Usually, the difference in color over time, between treatments or samples, is required and for this the calculation of the reflectance ratios is recommended. For a discussion of the analysis of the individual pigments present in the meat, using reflectance spectrometry or pigment extraction, see Further Reading. The proportions of the three major pigments in fresh meat, namely deoxymyoglobin, metmyoglobin, and oxymyoglobin, can be calculated from the spectra from a reflectance spectrophotometer. The calculations depend on wavelengths known as isobetic points, where the extinction coefficients for two or three of the pigments are the same. Isobetic points are 525 nm for all three pigments and 572 nm for the reduced pigments. The ratio of percentage reflectance at 630 nm to that at 580 nm (R630/R580) has commonly been used to measure the changes in fresh meat color,

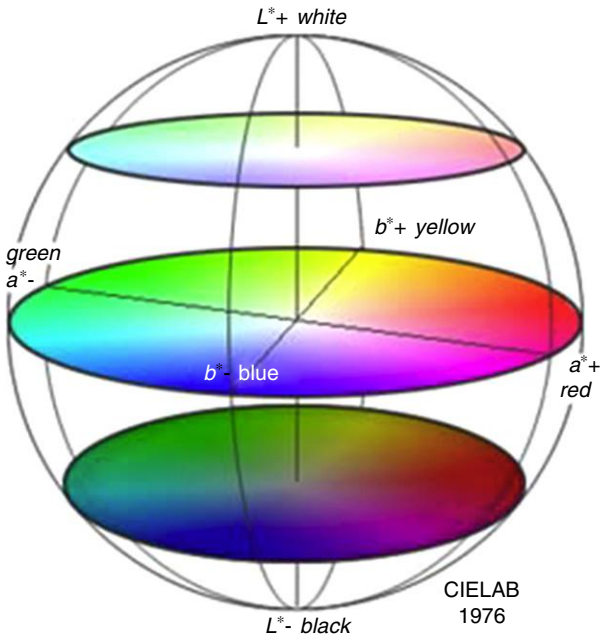

Figure 5 A representation of the CIE $L^*a^*b^*$ color space showing lightness (L^*) values, redness/greenness (a^*) values, and yellowness/blueness (b^*) values (http://www.zevendesign.com/category/glossary/browse-C/).

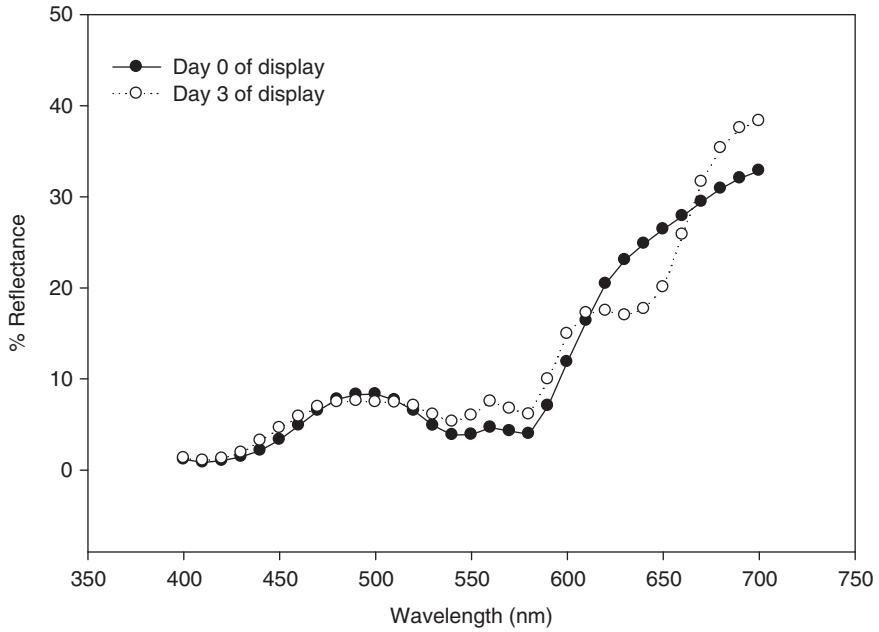

Figure 6 The percentage reflectance over 400–700 nm of lamb loin muscle overwrapped and under simulated retail display for 0 or 3 days. The shift to the brown pigment metmyoglobin is shown particularly around 550–700 nm (reproduced with permission from Robyn Warner, Department of Primary Industries, Victoria, Australia). The ratio of percentage reflectance at 630 nm to the percentage reflectance at 580 nm is recommended to monitor the change in the pigments in the meat surface during retail display.

especially during simulated retail display and shelf life studies. A decrease in ratio of R630/R580 measures a change in the predominant pigment in the meat surface from oxymyoglobin to metmyoglobin and is a measure of the 'browning' occurring in the meat surface. Figure 6 shows the change in the percentage reflectance across the visible spectrum from 400 to 700 nm, for lamb loin muscle which has been displayed for 0 or 3 days.

3. Laboratory and portable machines: The first portable color machines were produced by Minolta, which enabled easy measurement of meat surfaces in boning rooms, chillers, and in the field. They have gained considerable popularity because of their small size, cost, and ease of operation. The portable Hunter Lab color machines are also now popular and are more likely to be used for reflectance measurements in order to monitor changes from oxymyoglobin to metmyoglobin during shelf life studies (see above and Figure 7). Laboratory machines have been used for a number of years to measure spectrophotometry and color space values. The main considerations for choice of a machine are the need for portability, aperture size, illumination/viewing angle, and ease of use. A summary of the recommended specifications for colorimeters to measure the color of meat are presented in Table 1.

Figure 7 A portable Hunter Mini Scan instrument (Model 45/0-L) being used in the field to measure percentage reflectance on an exposed beef loin muscle. The muscle has been exposed to the air for 30 min and is done after rigor is completed. This machine is not used for grading purposes but certainly has potential to be used in this manner. Subjective Scoring Methods of Color Measurement

Visual assessment of color is related to the consumer and ultimately any instrumental measurement must be verified against consumer scores of acceptability and unacceptability. To conduct visual assessments using consumers rating as acceptable or unacceptable, at least 10, and ideally more than 10, consumers should be used. Pictorial standards can substantially improve a panel's consistency and validity. Color space parameters have been correlated with many subjective scales and the scales used to grade meat usually refer to the paleness or darkness of meat. Semiobjective pictorial standards have been developed by industry for grading purposes and these are widely used around the world. It is very important to standardize the conditions at the slaughter facility or

processing plant during grading for meat color. Thus, a standard lighting system as well as a standard cut must be used. In addition, where possible, a defined blooming time and minimum time postslaughter should also be specified and standardized. In the case of beef, if carcasses are graded too early, before final rigor is attained (final rigor usually attained >24 h postslaughter), the perceived color can be darker than the actual color, costing the company significant money. This is because carcasses graded as 'too dark' incur a significant economic penalty. Examples of meat color chips are the Australian meat and fat color chips for beef and the Japanese meat color chips for pork. When using these color chips, it is important that measurements are made under exactly the same lighting conditions every time, because the color blocks have spectra in the visible region that look nothing like meat spectra. In addition, the lighting used to view the meat should be in the range of 800–1600 lux at the meat surface to be graded.

Glossary

Antibiotic growth promotants Sub-therapeutic levels resulting in improved growth and reproductive performance.
Antibiotic resistance Continual use of antibiotics can involve a resistance and this resistance can be transferred to humans and other animals.
Feed efficiency A measure of an animal's efficiency in converting feed mass into increases of the desired output (meat in the case of meat animals and milk in the case of dairy cows).
Ionophore Ionophore antibiotics exert their antibiotic action by disrupting the transport of ions in the cell membranes; ionophores are absorbed in small amounts and are deposited in various tissues including liver, muscle, fat, and skin.
Sub-therapeutic Levels of antibiotic used that are below the dosage levels used to treat diseases.

Introduction

Antibiotics have now been used in livestock production for more than 60 years. Antibiotic growth promotants (AGPs) have provided a convenient dietary means of efficiently producing pork, beef and poultry meat and other animal products. AGPs are orally active at sub-therapeutic levels, resulting in improved growth and reproductive performance. Antibiotics are also used at moderate levels to prevent disease (prophylactics) and at therapeutic levels to treat a variety of diseases.

The swine and poultry industries have been the principal users of AGP, but they are also used for beef cattle, dairy calves, sheep, and companion animals. The major impediment to the use of AGP is the real and perceived risk of creating antibiotic-resistant microorganisms that can be transferred to humans and other animals. During the last 20 years, the growing consumer demand for food products with credence values such as safety, welfare friendly, healthy, and reduced environmental impact has placed even further pressure on the use of AGPs and the mandatory or voluntary removal of AGPs from a number of countries and market segments. The desire to reduce the use of AGPs in animal industries has resulted in much interest in the development of alternatives, many of these alternatives based on plant extracts, probiotics, blood and yeast based extracts, although none of these can yet provide the full efficacy of AGPs.

The Efficacy of Antibiotic Growth Promotants

The inclusion of growth-promoting antibiotics in pig feed can improve live weight gain by 5–6% and feed conversion efficiency by 3–4% (Figure 1). The most pronounced effects are

 doi:10.1016/B978-0-12-384731-7.00018-0

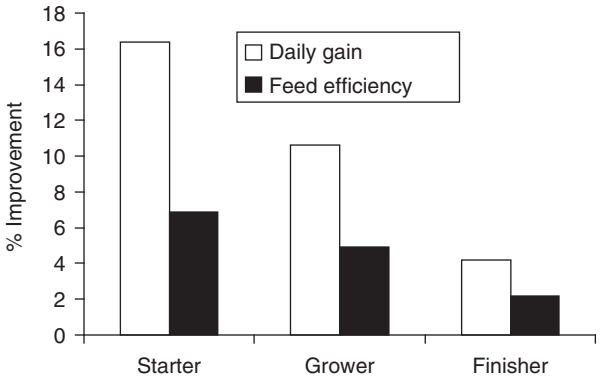

Figure 1 Effect of antimicrobial growth promotants on daily gain and feed efficiency in different classes of pigs. Data are modified from Gaskins, H.R., Collier, C.T., Anderson, D.B., 2002. Antibiotics as growth promotants: Mode of action. Animal Biotechnology 13, 29–42.

found in young pigs, with the response declining in finisher pigs. The efficacy of AGPs in broilers have also been well documented, particularly under adverse conditions such as high stocking rate, insufficient hygiene, and high pressure of infectious diseases.

The Mechanism of Action of Antibiotic Growth Promotants

The exact mechanisms by which AGPs improve growth performance have not been fully elucidated, although several have been proposed. The proposed mechanisms include (1) an inhibition of subclinical infections, (2) a reduction of growth-depressing microbial metabolites, (3) a reduction in competing microbial use of nutrients, (4) an enhanced uptake and use of nutrients through a thinner intestinal wall associated with AGP-fed animals, and (5) reduced protein turnover associated with immune stimulation and intestinal tissue synthesis. The common hypothesis is that intestinal bacteria depress animal growth and this is supported through a lack of effect of AGPs in germfree animals.

Although statistically significant differences in growth rate have never been well correlated with differences in bacterial counts, either in specific intestinal segments or in the gastrointestinal tract as a whole, several investigations have shown that AGPs do produce significant changes in the composition and activity of the gastrointestinal microbiota. The results strongly indicate that AGPs accomplish their effect in the small intestine, whereas they have little or no effect in the large intestine. It is generally accepted that the small intestinal microorganisms compete with the host animal for easily digestible nutrients and at the same time produce toxic compounds. Experiments with slaughter pigs have shown that as much as 6% of the net energy in the pig diet could be lost owing to microbial fermentation in the small intestine. However, the microorganisms in the hindgut are believed to have a beneficial effect on the host animal because they produce energy by fermentation of feed material that has escaped digestion in the small intestine. It has been calculated that on a normal Danish pig diet, 16.4% of the total energy supply for slaughter pigs is achieved by microbial fermentation in the hindgut. Zinc bacitracin, virginiamycin, and salinomycin have all been shown to reduce microbial activity in the small intestine in pigs, whereas virginiamycin, spiramycin, and salinomycin have been shown to reduce microbial fermentation of carbohydrates in the small intestine. Quantification of the results from these experiments indicates that the amount of energy saved for the animal by the reduced microbial fermentation in the small intestine almost equals the improved feed conversion. It is interesting to note that although different types of bacteria may generate one or more of the growth depression effects mentioned above, the Gram-positive bacteria such as streptococci, lactobacilli, and clostridia that predominate in the small intestine often contribute to these effects. As most of the AGPs target the Gram-positive bacteria, these observations are consistent with the involvement of small-intestine Gram-positive bacteria in the growth depression. AGPs exert no benefits on the performance of germfree animals, which also clearly points to their effect being on the microflora rather than being a direct interaction with the physiology of the animal.

Antibiotic Growth Promotants and Their Role in Resistance Development

Since the introduction of antibiotics as growth promoters in animal production in the 1950s, there has been great concern about the development of resistant bacteria. Several studies have shown that the occurrence of resistance is closely related to the use of a drug. This association has also been demonstrated for antibiotics used as growth promoters and it has been shown that food animals may serve as reservoirs of resistant bacteria or resistance genes that may spread to the human population. For these reasons, international public health organizations have recommended termination or a rapid phasing out of the use of AGPs that are also used for human therapy or that may give rise to multiple-resistant bacteria causing infections in humans. Examples include avoparcin and virginiamycin.

Antibiotics Allowed as Antibiotic Growth Promotants

Until 1969 there was almost no restriction in the types of antibiotics used as AGPs. In 1969, the Swann committee in the UK recommended tighter governmental control of the types of antibiotics used as AGPs, and stated that antibiotics used to treat human diseases should not be used in animal feed. This led in 1971 to a ban of tetracyclines and other therapeutic antibiotics as AGPs in many countries. In 1986, Sweden was the first country to ban the use of all AGPs.

Since 1995 major changes in the use of antibiotics as growth promoters have occurred in Denmark. Avoparcin was banned in May 1995, and virginiamycin was banned in January 1998. Furthermore, the food animal industries decided in 1998 to voluntarily stop all use of antibiotics as growth promoters by the end of 1999. The termination of the use of antibiotics as growth promoters in 2003 has led to a

Table 1 Timeline of the European Union (EU) withdrawal of nontherapeutic antibiotics (NTAs) in food animal production timeline

1963–1965	Epidemic of resistant *Salmonella typhimurium* in the UK
1969	Swann Committee in the UK recommends that antimicrobials for animals be divided into two groups: feed additives used without a prescription and therapeutic agents used with a prescription; recommends restricting use of antimicrobial growth promoters
1972–1974	The EU bans the use of tetracycline, penicillin, and streptomycin for growth promotion
1986	Sweden bans the use of antibiotics for growth promotion in agriculture, as requested by Federation of Swedish Farmers Sweden stops the use of all general prophylactic medications
1988	Vancomycin-resistant enterococci (VRE) is reported in food animals in the UK
1993	Denmark restricts direct sale of therapeutic antimicrobials from veterinarians and limits veterinary profits from antimicrobial sales. Denmark bans routine prophylactic use of antimicrobials
1994	Denmark bans the use of avoparcin for all purposes in agriculture. Danish Integrated Antimicrobial Resistance Monitoring and Research Program (DANMAP) is initiated. Sweden and Finland join the EU and lobby for the EU-wide ban on agricultural growth promoters
1995	Germany bans the use of avoparcin
1996	The EU bans the use of avoparcin. Netherlands bans the use of olaquindox and carbadox
1997	WHO Berlin meeting, 'The medical impact of the use of antibiotics in food animals,' concludes that use of medically important antimicrobials as growth promoters should be stopped
1998	The Copenhagen recommendations: recognition of antimicrobial resistance as a global threat; call for development of new antimicrobials and establishment of a European Surveillance System. Denmark bans use of virginiamycin.
1999	Scientific Steering Committee of the European Commission recommends phasing out antimicrobial growth promoters that are medically important and implementing disease-preventive methods. The EU bans olaquindox and carbadox; suspends authorization of bacitracin, tylosin, spiramycin, and virginiamycin. European Antimicrobial Resistance Surveillance System (EARSS) is established. Sweden bans the use of remaining AGPs: flavophospholipol and avilamycin. The UK's Advisory Committee on the Microbiological Safety of Food issues a report recommending improved veterinary training and surveillance of resistance
2001	European Surveillance of Antimicrobial Consumption (ESAC) launched to collect data on antimicrobial use in ambulatory and hospital care
2006	The EU ban on all AGPs
2008	European Surveillance of Veterinary Antimicrobial Consumption Project (ESVAC): European Commission asks the European Medicines Agency to harmonize surveillance programs collecting data on antimicrobial sales and usage

total reduction of the use of antibiotics in food animals in Denmark by 54%.

Before 1 July 1999, nine antibiotics were permitted as AGPs in the European Union (EU). In 2004, only four antibiotics remain authorized as AGPs in the EU: flavophospholipol, monensin sodium, salinomycin, and avilamycin. The distinction between the AGPs banned, and those still allowed, is based on whether the active component is used in human medicine or has similarities to a medical product used to treat human disease. It is an ongoing discussion whether AGPs really present a threat to human health. However, there is still – in spite of the fact that AGPs have been used for nearly 50 years – no convincing evidence about unfavorable health effects that can be directly linked to the use of sub-therapeutic levels of antibiotics. AGPs are nevertheless now considered politically unacceptable in the EU, and it is the plan that all AGPs were to be phased out in the EU by January 2006. In North America and many other parts of the world, the use of AGPs is still permitted, and they are used frequently. Even antibiotics used to treat infectious diseases in humans are allowed as AGPs in the United States.

Global Anitibiotic Growth Promotant Use Status

Growing concerns about antimicrobial resistance have caused a number of countries including the EU, New Zealand, and South Korea to implement restrictions or bans on the use of AGPs. These bans apply to both domestic production as well as imported products. The first ban on farm use of AGPs was enacted in 1986 in Sweden. Since then Denmark, the UK, and finally the EU banned the use of AGPs in food animal production. It is worth noting that initially, some of these bans were closely monitored from the outset, whereas others were not fully enforced at first (Tables 1 and 2).

Ionophore Antibiotics (Coccidiostats)

Ionophore antibiotics are fermentation products of different *Streptomyces* species and other fungi. They are polyether antibiotics, which exert their antibiotic action by disrupting the transport of ions in the cell membranes. In contrast to AGPs, ionophores are absorbed in small amounts following ingestion and are deposited in various tissues including liver, muscle, fat, and skin. To prevent antibiotic residues in the carcass, ionophore antibiotics are withdrawn from the diets before slaughter.

Ionophore antibiotics are used as coccidiostats to prevent coccidiosis in poultry, a disease caused by protozoa of the genus *Eimera* that may pass from one bird to another through contamination of the litter. The protozoa cause serious damage to the intestines of the animals, thus inhibiting the absorption of nutrients and growth. Infections are often fatal and can spread rapidly. Ionophore anticoccidials are mostly used in broilers, but also to some extent in turkeys and laying hens. To prevent residues in eggs, laying hens may only be fed with ionophore antibiotics during the rearing period.

Table 2 Country policies on AGP use in animal production. A summary of the country policies on AGP use in animal production

Country	*Overview of policies*
Australia	Allows use in feed of some drug classes that are important in human medicine, but is reviewing its policies for approved uses. Establishing a comprehensive surveillance system. Limited information is available on its data collection system
Brazil	Limited information suggests that Brazil does not currently restrict the use of these drugs in feed. Information is not available to determine if Brazil has surveillance and data collection systems in place
Canada	Allows use in feed of some drug classes that are important in human medicine, but is reviewing its policies for approved uses. Establishing a comprehensive surveillance and data collection system
China	Limited information on current activities, as well as information on existing surveillance and data collection systems
European Union (EU)	Prohibits use of antibiotics in feed for growth promotion. Most of the EU members have established surveillance and data collection systems. In 2011, the EU passed a resolution calling on its member states to 'ensure a better control over the implementation of the ban (2006) on antimicrobials being used as growth promoters,' and to 'work toward an international ban on antimicrobials as growth promoters in animal feed,' and to bring this matter up in its bilateral negotiations with other countries such as the United States
Hong Kong	Limited information on current activities, as well as information on existing surveillance and data collection systems
Japan	Some unconfirmed media reports indicate that Japan has increased or is considering increasing restrictions on antimicrobial use in food animal production, whereas other reports indicate it is continuing its review. Has established surveillance and data collection systems
Mexico	Limited information suggests that Mexico does not currently restrict the use of these drugs in feed. Limited information also suggests that Mexico is developing a surveillance and data collection system
New Zealand	Prohibits use of antibiotics in feed for growth promotion. Has established surveillance and data collection systems
South Korea	Effective in 2011, prohibits 'eight antibiotics (enramycin, tyrosine, virginiamycin, bacitracin methylene disalicylate, bambermycin, tiamulin, apramycin, and avilamycin) and one antimicrobial agent (sulfathiazole) in animal feed as feed additives,' effective in 2011. Limited information is available on its surveillance and data collection systems
Thailand	Some unconfirmed reports indicate that Thailand has increased or is considering increasing restrictions on antimicrobial use in food animal production. Information is not available on its surveillance and data collection systems
United States	Allows use in feed of some drug classes that are important in human medicine, but is reviewing its policies for approved uses. Has established surveillance and data collection systems

Source: Reproduced from Johnson, R., 2011. Potential trade implications of restrictions on antimicrobial use in animal production. Congressional Research Service Report 7–5700.

Compared to most chemical coccidiostats, the situation of coccidial resistance against ionophores does not seem to be a cause for alarm. However, following long-term application, a clear reduced efficiency of ionophore anticoccidial drugs has been observed.

Besides their anticoccidial effect, ionophore antibiotics inhibit the growth of Gram-positive bacteria and have been shown to effectively reduce the numbers of *Clostridium perfringens*, thus preventing necrotic enteritis. In this respect, ionophores seem to be able to substitute AGPs. The continued use of ionophores in broiler feed, after the AGP ban in Denmark, is very likely the reason why the removal of AGPs was not being followed by increased problems with necrotic enteritis, for example, increased mortality and liver condemnation at slaughter.

The antibacterial property of ionophores is the reason why some of these substances are also used as AGPs in animal feed. The ionophores salinomycin and monensin are applied as feed additives in the production of pigs and cattle, respectively. However, when used as AGPs, the concentration allowed for the use of salinomycin, for example, in pigs is lower (40 mg kg^{-1} feed), compared to the concentration allowed for use as an anticoccidial in broiler production (60 mg kg^{-1} feed).

Managing without ionophores will not be easy. Apart from their efficiency, the low price of these compounds is an advantage in favor of their continued use. A number of efforts have been made to prevent infection or to moderate intestinal lesions related to coccidioses by dietary means. However, at the present time the only real alternative to anticoccidial drugs in broiler feed seems to be the application of vaccines, which are now commercially available. However, use of vaccines will not solve the problems with necrotic enteritis caused by *Clostridium perfringens*. Despite these problems, the use of ionophores as anticoccidials is being discussed in the EU, and they will probably be phased out as feed additives by January 2012.

Impact on Resistance of Termination of the Use of Antibiotic Growth Promotants

A continuous national monitoring program for antibiotic resistance has been carried out in Denmark since the ban of AGPs in 1999. The data from this monitoring program show that it is possible to reduce the occurrence of antibiotic-resistant bacteria in a national population of food animals when the selective pressure is removed. This observation is supported by investigations carried out in Germany, Holland, and Belgium.

The termination of AGP usage has resulted in a marked reduction in the presence of resistant bacteria in food animals, but resistant bacteria have not completely disappeared. Several investigations have shown that, although the probability of randomly picking up an AGP-resistant enterococcus from an animal or a food product has been reduced, the resistant strains are still present in the farm environment, in the food animals, and even in the animal products. Removal of the selective pressure has thus reduced the population density of resistant bacteria and accordingly the possibility for transfer of resistant bacteria from animals to food, but the seeds of resistance remain in the farm environment for many years after

the termination. A readmittance of antibiotics for growth promotion would mean a quick increase in resistant strains to pretermination levels.

Managing without Antibiotic Growth Promotants

So far, only a few studies have investigated the effect of terminating the use of AGPs on animal health and productivity. To investigate whether and how removal of AGPs affected production results and mortality in Danish broiler flocks, data covering the period before and after the termination of AGPs were extracted from a database administered by the Danish Poultry Council. This database provides information about each broiler flock including parental flock, stocking rate, mortality, and feed consumption. The results of this study showed no evidence of decreased productivity (kg broiler per m^2) or increased mortality following the removal of AGPs. However, a minor increase in feed consumption was reported corresponding to 16 g feed per kg broiler. This decreased feed efficiency is, however, offset completely by saving the cost of AGPs. Necrotic enteritis was at most a minor broiler health problem following the termination of AGPs in Denmark, probably because producers continued to use ionophores for prophylaxis against coccidiosis.

In Danish pig production, there was a significant increase in therapeutic antibiotic treatments for diarrhea in the post-weaning period following the complete elimination of AGPs. The termination of AGPs also resulted in some loss of productivity in weaners. In finishers, however, no effect of the termination of AGPs was observed on productivity or feed efficiency. Similar results for pig production were observed earlier after elimination of the use of AGPs in other countries.

Beta-Agonists

DH Beermann, University of Nebraska, Lincoln, NE, USA

This article is a revision of the previous edition article by DH Beermann, volume 3, pp 1026–1030, © 2004, Elsevier Ltd.

Introduction

Meat animals are managed to produce safe, nutritious palatable food in various forms ranging from retail cuts of beef, pork, lamb, veal, and poultry to a variety of fresh ground items and further processed products. The latter are produced using one or more of various processing technologies such as curing, smoking, fermenting, blending or chopping, and cooking. The fresh meat provided by each species varies in eating characteristics and composition according to the influences of management factors such as age, gender, genetics (breed or strain), and portion of the animal from which it is derived. Nutrition and other production strategies or practices also influence these characteristics.

Management strategies used in meat animal production are selected to maximize the efficiency of production, yield, and quality of meat with minimal impact on the environment and with accommodation of good health and welfare of the animals. One recently developed management strategy that increases efficiency of growth, improves the amount of meat, and improves carcass composition is the use of a class of feed additives called beta-agonists. These compounds have been intensively studied during the past two decades, and a few specific beta-agonists, but not all, have been approved for use in meat-producing animals in several countries. They are not used in dairy animals because they do not alter milk production, and they are also not to be used in breeding animals. At present, only one product is approved for use in turkeys, but not in chickens.

These compounds act to repartition the use of nutrients consumed by animals toward increased muscle growth and reduced amount of fat gain. These growth-regulating compounds are administered as a feed ingredient because they are orally active. They are usually fed at concentrations of 5 to 30 ppm (ppm) (g per tonne) near the end of the finishing period for 20 (zilpaterol hydrochloride) or up to 42 (ractopamine hydrochloride) days just before the harvest. Their use, therefore, requires careful planning to determine their start.

Currently, only four products are approved by the US Food and Drug Administration (FDA) for their commercial use in the US. Three products contain the beta-agonist ractopamine hydrochloride, which is produced by Elanco Animal Health, Indianapolis, IN, USA. These three products are marketed as Paylean® (approved in December 1999), Optaflexx® (approved in June 2003), and Topmax™ (approved in April 2009) for their use in swine, beef cattle, and turkeys, respectively. Paylean® is also approved for its use in 14 other countries around the world. Another compound, zilpaterol hydrochloride, is manufactured by Merck Animal Health, Whitehouse Station, New Jersey, USA. It is sold commercially as Zilmax® for its use in beef cattle and is fed during the last 20 days, with a 3-day withdrawal required before harvest. It is approved for its use in Canada, Mexico, South Africa, South Korea, and the US. The FDA approved its use in the US in 2006. Approval is being considered by other countries also. Specific guidelines for feeding animals with these commercial beta-agonist products are provided by the manufacturer. None of the beta-agonists are approved for their use in production of meat animals within the European Union.

Nature of Beta-Agonists

Beta-agonists are naturally occurring and synthetic organic compounds that share a common base chemical structure distinctive to a class of compounds called phenethanolamines. The general structure of a phenethanolamine is shown in Figure 1. It consists of a phenyl group ring structure attached to the ethanolamine group. Different substituents attached at the A, B, C, and R positions denote differences among the family of phenylethanolamine compounds called beta-agonists. These substituents influence how long the beta-agonist stays in circulation in the blood, which tissues are influenced, and what specific actions or effects they promote. Two naturally occurring beta-agonists are adrenaline (epinephrine) and noradrenaline (norepinephrine), but neither compound has beneficial effects on animal growth. Adrenaline is synthesized and secreted by the medulla of the adrenal gland, and noradrenaline is released by specific types of nerve endings in the body. These two phenethanolamines, called catecholamines, play important roles in the regulation of heart rate, blood flow, and other physiological and metabolic functions in humans and animals.

Synthetic beta-agonists such as clenbuterol (Figure 2) have been used in human and animal medicine for many decades to relieve respiratory distress symptoms associated with asthma, to treat pregnant women to control premature parturition (uterine smooth muscle relaxant), and as a cardiostimulant to treat cardiac irregularities. These compounds have no antibiotic activity.

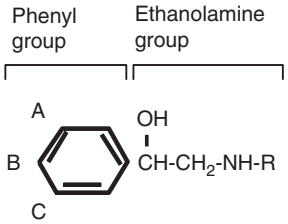

Figure 1 The base chemical structure of phenethanolamines. All contain the phenyl group coupled to the ethanolamine group, but they differ in substituents attached at positions A, B, C, and R.

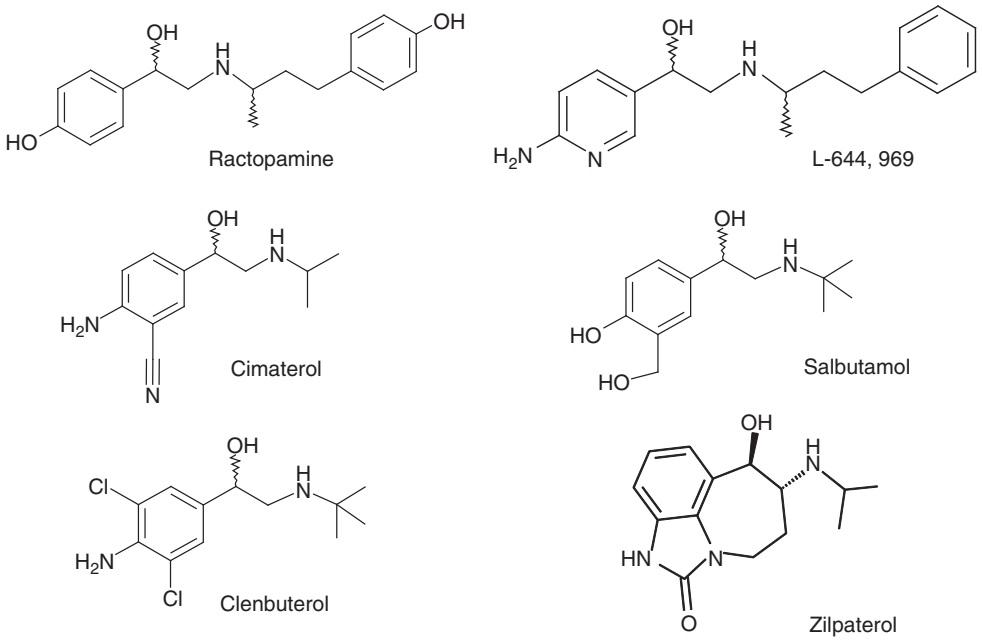

Figure 2 The chemical structures of beta-agonists, also called phenethanolamines, that have been studied in meat animal species. These compounds exert their influence by binding with receptors on the plasma membrane of cells in skeletal muscle, adipose tissue, and other tissues and organs.

During the past three decades, several beta-agonists including ractopamine, cimaterol, clenbuterol, L-644 969, salbutamol, and zilpaterol (Figure 2) were evaluated for their potential muscle growth enhancement and antiobesity effects. All were found to increase muscle growth rate and reduce the amount of fat in laboratory animals, meat animals, broiler chickens, and turkeys. However, these compounds, other than ractopamine and zilpaterol, are not approved for their use in meat animals or poultry and it is illegal to administer them to food-producing animals unless approved for therapeutic use by a veterinarian. For several reasons, the naturally occurring beta-agonists adrenaline and noradrenaline do not have significant effects on efficiency or composition of growth of meat animals or poultry. They tend to be cleared from the blood very rapidly, and certain tissues exhibit diminished responses or lack of response to continuous presence of their elevated concentrations in the blood or to continuous stimulation of cells by them.

Beta-Agonists as Feed Additives

Beta-agonists or phenethanolamines are often referred to as repartitioning agents because they redirect nutrients used for growth toward increased rates of muscle protein synthesis, leading to larger muscles, and away from deposition in adipose tissue (fat). It is more efficient to grow muscle than fat, so feeding meat animals with beta-agonists results, on average, in reduced feed intake at equal or greater rates of body weight gain (improved efficiency). The increased leanness of animals resulting from greater weights of individual muscles and the reduction in the amount of adipose tissue or fat also improves the meat yield of the animals. Experimental research has demonstrated that lambs and cattle fed with cimaterol or clenbuterol contained muscles in the hind leg that were up to 25–30% larger, whereas the amount of fat in the carcass was reduced by 15–25%. These two compounds would more likely reduce the 'value' of the carcasses because of decreased quality grade and greater incidence of 'dark cutters.'

Finishing pigs can be fed Paylean® at 4.9–9 g t^{-1} of complete feed from 68 kg to market weight, and it is required that the feed contains 16% protein. The muscle growth response depends on adequate nutrient availability (primarily amino acids) to produce larger muscles. Inadequate protein nutrition will preclude a positive muscle growth response. There is no withdrawal period required when feeding animals with Paylean®.

Paylean® fed to finishing swine for 30 days at 20 g t^{-1} (20 ppm) has been shown to increase average daily gain by up to 10%, decrease feed intake by 3–5%, increase carcass yield by 1 kg, and improve percentage of muscle in the carcass from 52% to 58%. This equates to an increase of 4.3 kg in the absolute amount of lean or muscle yield. Separable fat was reduced from 27% to 23% of carcass weight, equivalent to 3 kg less fat. These changes enhance the economic value of pork carcasses in addition to the positive impact of improving the efficiency of live animal production. Research results demonstrate that meat quality characteristics (muscle color, pH, degree of marbling, and moisture retention) and sensory traits of cooked pork (flavor, tenderness, and juiciness) were not different from pork derived from pigs not fed Paylean®. Caution should be exercised to strictly adhere to manufacturer's feeding directions to avoid the risk of reduced tenderness that has been observed with higher doses or longer feeding times. Nutrient composition of pork is also unaffected when it is fed Paylean®. Responses to Paylean® were smaller at the approved lower

Figure 3 Fresh pork loins (a) and hams (b) from market hogs fed Paylean® (left) and not fed Paylean® (right). Photographs provided by and reproduced with permission of Elanco Animal Health, Greenfield, IN, USA.

doses of 5 g t^{-1} and 10 g t^{-1} (5 and 10 ppm, respectively). The size of the growth responses varies among the individual beta-agonists studied, the species to which beta-agonists are fed, and the dose at which the beta-agonist is fed. The enhanced lean growth response to feeding with Paylean® appears to be proportional to the genetic potential for lean growth. One study observed a reduction in marbling in Berkshire pigs, which are known to contain a higher propensity for marbling than for most other breeds. Figure 3 illustrates the effects of feeding with Paylean®.

Finishing beef cattle can be fed Optaflexx® at dietary levels of 10–30 ppm for the final 28–42 days of feeding, but the recommended level of feeding is 200 mg per head per day. Studies involving more than 4000 cattle demonstrate 15–25% improvement in average daily gain and no change in feed intake, resulting in significant improvement in feed efficiency. Carcass yield is increased by 2–8 kg, and carcasses contain less fat and more muscle and protein on a relative basis. Optaflexx®-fed cattle contain approximately 10 kg more lean muscle with equal amounts of feed, compared with control animals. Meat quality factors and sensory panel characteristics (taste, tenderness, texture, and juiciness) of beef from cattle fed Optaflexx® are not consistently different from those of control cattle. Some data suggest statistical reduction in tenderness when the highest level of 300 mg per head per day is fed. Nutrient composition of the meat is not different. No withdrawal period is required.

Zilmax® improves growth performance, carcass yield, and the yield of muscle from carcasses when fed to finishing cattle. Studies involving more than 40 000 finishing cattle fed Zilmax® at 7.56 g t^{-1} dry matter (60–90 mg per head per day) for 20 days with a 3-day withdrawal period demonstrated that feed efficiency improved by 3%, carcass weights increased by 11–15 kg, and gross return to the feeder was increased. Zilmax® had no negative effects on meat quality when fed for 20 days, and meat was aged at least 21 days in studies conducted in the US. Because length of feeding may vary and some genotype by beta-agonist interactions may exist, caution must be exercised to avoid increasing the risk of reduced tenderness, particularly when a beta-2 agonist like Zilmax® is fed.

Mode of Action of Beta-Agonists

Beta-agonists that exhibit repartitioning effects act through receptors (beta-adrenergic receptors) on skeletal muscle and adipose cell membranes and generate signals that control metabolic activities in the cells. When ractopamine or other beta-agonists bind to the beta-adrenergic receptors on fat cells, biochemical signals are created throughout a pathway involving activation of several enzymes that lead to reduced rates of fat synthesis and storage (lipogenesis) in the cells, and at the same time stimulate fat mobilization from the cell (lipolysis). These changes result in a slower rate of fat accumulation in animals, and the magnitudes of the changes are influenced by the dose or amount and the length of time for which the beta-agonist is consumed.

Skeletal muscle cells, called muscle fibers, also contain beta-adrenergic receptors on their surface. The interaction of the beta-agonist with the receptor affects similar pathways of signaling events as in fat cells. In muscle, however, these signaling events increase the rate of synthesis of ribonucleic acid (RNA), which leads to increased rates of synthesis of muscle proteins in the cells. The effects on muscle result in an increase in cell size (hypertrophy) without an increase in cell number. The total number of muscle fibers in a muscle is generally set by birth in most domestic animal species. Growth occurs by increase in the length and radial dimensions of the cells. These are the same changes that occur with vigorous weight-lifting or isometric exercise, which lead to muscle enlargement (growth) in humans. When beta-agonists are fed, a shift in metabolic properties does occur in some muscle fibers to increase percentage of fibers with glycolytic metabolism, thereby reducing the percentage exhibiting aerobic metabolism. Ultimately, feeding with beta-agonists results in approximately 20–30% greater rates of muscle cell growth in pigs fed Paylean® for 28–42 days. The changes that occur in muscles of animals fed beta-agonists are not progressive, nor do they continue to occur over longer periods of time. Hence, the recommended time of feeding is near the end of the finishing period. Longer feeding has little or no benefit on growth performance or output and would result in markedly reduced economic benefit.

Because less energy is required to grow muscle than to grow adipose tissue or fat, use of feed for growth in animals fed beta-agonists for short periods (20–42 days) is more efficient overall. The beta-agonists stimulate muscle growth and reduce the rate of nutrient use for adipose tissue growth, resulting in less feed required to produce an animal of the same weight. Ultimately, there is less animal waste produced and less environmental impact when beta-agonists are fed to meat-producing animals.

Safety of Feeding Beta-Agonists to Meat Animals

Stringent safety criteria and extensive testing to address the safety of feed additives and animal health products are used to assure that approval of a product is warranted. The human food safety of beta-agonists approved for use in the US has been determined through a series of evaluations to satisfy the safety criteria. Ractopamine hydrochloride, the active ingredient in Paylean®, Optaflexx®, and Topmax™, has been

extensively tested in laboratory animals and meat animals to establish the safety of the approved use levels and conditions under which they are produced and used. The same testing was conducted in association with approval of Zilmax®. Assessments of chronic toxicity, mutagenicity, lifetime carcinogenicity, and effects on reproduction over two generations of laboratory animals are required by the FDA in the US. Approval of these compounds in other countries is often based on approval by this agency.

Ractopamine and zilpaterol were similarly evaluated for possible effects on animal welfare, and no adverse effects were found. Animal health, behavior, and well-being were extensively evaluated at usage levels at least 10 times higher than approved for use in meat animals. Studies revealed that clenbuterol and cimaterol have much longer half-lives in meat animals. These differences may contribute to problems of significant residues in edible tissues and associated possibilities of toxicity in humans when clenbuterol or cimaterol are fed to meat animals.

The European Union had banned all beta-agonists for use in meat animals in 1989; however, full scientific evaluation of beta-agonists has been conducted and it does not support the ban, of those approved for use elsewhere. Illegal and unsafe use of beta-agonists was a problem in many parts of the world, and this may have contributed to the ban by the European Union. Thorough review and approval of ractopamine use by FDA followed the ban, and safe use of approved commercial products such as Paylean®, Optaflexx®, Topmax™, and Zilmax® is assured when adherence to use guidelines is followed. Beta-agonists are not all alike. Differences in chemical structure and biological activity are significant; they determine where the use of beta-agonists is appropriate and allowed. Some beta-agonists, such as clenbuterol, are approved for use in human medicine but have not been approved for use in meat animals. The unique structure of specific beta-agonists and the way they are metabolized in the body influence safety considerations. Ractopamine and zilpaterol are approved for their use in meat animals. It is safe to consume food from them.

Glossary

β-agonist An adrenalin-like compound that binds to and stimulates β-receptors to have similar effects to adrenalin.
Average daily gain (ADG) The amount of live weight that an animal gains each day.
Growth hormone releasing factor (GRF or GHRH) A hormone produced in the hypothalamus that increases the release of somatotropin from the pituitary.
Intramuscular (IM) fat The fat, that is found within muscle, that is often referred to as marbling.
Somatostatin (SS or SRIF) A hormone produced in the hypothalamus that decreases the release of somatotropin from the pituitary.
Somatotropin (ST) A growth hormone (GH) that is slightly different for cattle (e.g., bovine ST) and pigs (e.g., porcine ST). Regulators are GH-releasing factor and Somatostatin or ST release-inhibiting factor.

Introduction

In the 1920s, it was discovered that a crude pituitary extract stimulated growth in rats, and this extract was referred to as growth hormone (GH) or somatotropin (ST) after the Greek derivation meaning tissue growth. Results were extended to farm animals when ST was shown to enhance growth rates in pigs and stimulate milk production in lactating ruminants. For many years, it was not possible to apply this knowledge to practice because of the limited supply of ST. However, this has changed, with the development of recombinant DNA techniques, and porcine ST (pST, pGH) has been approved since 1995 for commercial use as a daily injectable in growing pigs, first in Australia and then in other countries. Recombinant bovine ST (bST, bGH) is, since its commercial introduction in 1990, approved in many countries (including the United States) for stimulating milk production in dairy cows. However, bST is not approved for use as a growth promoter, possibly because of relative differences in the value of the different bovine products (i.e., meat vs. milk) and the potential for crossover of product applications. Use of bST and pST is not allowed in the countries of the European Union.

The main objective of this article is to review the effects of ST, or GH, on performance and meat quality in farm animals, with special emphasis on the use of bST and pST to growing cattle and pigs, respectively.

Somatotropin

ST is a single polypeptide chain consisting of 191 or 190 amino acids, although the amino acid composition varies somewhat between species. The bovine, porcine, and human growth hormones are rather different, whereas the bovine and ovine forms are almost identical. ST is a naturally occurring protein hormone produced by the anterior pituitary gland and secreted into the circulation. ST has several important roles in the regulation of development and growth of skeletal muscle, bone, adipose tissue, and the liver in growing animals and plays an integral role in the coordination of lipid, protein, and mineral metabolism in mammalian species. Elevation of plasma ST redirects nutrients toward increased muscle and bone growth and decreased adipose tissue growth in meat animals. It appears that the ST-induced shift in nutrient partitioning is mediated, in part, through inducing insulin resistance in adipose tissue. Other hormones and peptides regulate the secretion, but the main physiological regulators of ST release are growth hormone-releasing factor (GRF or GHRH) and somatostatin (SS or SRIF (somatotropin release-inhibiting factor)), both produced in the hypothalamus and with quite distinct upstream and downstream points of regulation.

Because ST is a protein, it cannot be administered orally but has to be administered by injection. In most early experiments, ST was administered by daily injection. However, sustained-release vehicles have also been developed for commercial application in dairy cattle as either biweekly or monthly implants (e.g., subcutaneously as oleaginous suspensions). In commercial pig production, pST dissolved in sterile water, is injected daily using a propane-powered applicator. However, daily injection with pST is problematic and so alternative injection regimes with less frequent injections have been investigated and demonstrated to have similar efficacy to daily injections.

Performance, Carcass Quality, and Health

Cattle and Sheep

In the late 1950s, the first published paper documented that the administration of exogenous pituitary-derived bST to growing heifers (female calves) resulted in a 10% increase in average daily gain (ADG). Similarly in the late 1970s, the first report with a positive effect of ovine ST (oST) treatment on growth rate in sheep was published. Following this, responses of the same magnitude have been observed using both pituitary-derived and recombinant ST. The increase in ADG of heifers has been as high as 25%. In males, the growth responses have varied: for example, an 18% increase in bull calves, a zero effect in young bulls. In general, the effects on

ADG are rather small in finishing feedlot steers, which may relate to their higher degree of fatness and the opposing effects of ST on lean and fat deposition. In wether lambs, improvements of ADG of approximately 10–20% are typical, but increases in ADG as high as 36% have been observed.

Feed intake may increase slightly in young cattle (e.g., calves), whereas a slight reduction may be seen in finishing animals (e.g., steers). This difference suggests that the changes in feed intake depend on the balance between the increase in protein accretion and the reduction in fat accretion. Thus, with a minor effect on feed intake and often an increased growth rate, ST treatment generally results in improved feed efficiency, ranging from 2% to 25%.

The effect of ST on absolute carcass weight is dependent on the growth response obtained, the length of the treatment period, and the developmental stage of the animals, because these factors influence the relative changes in deposition of protein, fat, and bone in animals. In general, there is a small positive effect on carcass weight, but increases as large as 8–9% have been observed in heifers. However, reduced carcass weights have been observed in some studies, perhaps where the increase in protein deposition is offset by a decrease in fat deposition.

The increase in protein deposition in ST-treated animals is generally considered to be due to an increase in protein synthesis rather than to a reduction in protein degradation, although the responses may differ between species, physiological age in the same species or even between different tissues within the same animal. Given the high rate of protein turnover in skeletal muscle, only subtle changes in either protein synthesis or degradation are sufficient to account for the differences in protein deposition. Although ST increases protein deposition in most muscles in the body there appears to be some variability in how different muscles respond. Also, the increased protein deposition is not restricted to skeletal muscle as ST increases protein deposition in all tissues including skin and visceral organs. Indeed, the proportional increases in protein deposition in skin and viscera may be greater than that in skeletal muscle contributing to a reduction in dressing rate ($\sim$1% in pigs). Also, ST can increase bone deposition impacting on boneless meat yield percentage. Therefore, the increases in growth rate observed with ST treatment need to be offset against the decreases in dressing and boneless meat yield percentage.

It is a consistent finding that ST administration increases the lean-to-fat ratio of carcasses. This is due to the previously mentioned increased protein deposition and a reduced fat deposition comprising subcutaneous fat, intermuscular, and intramuscular (IM) (i.e., marbling) fat. The longissimus dorsi area is increased in some but not all studies. In spite of the reduced carcass fat content and backfat thickness, carcass conformation is usually not changed by ST treatment of cattle. In sheep, the effects of exogenous ST on carcass weight and carcass composition are similar to those observed in cattle and the maximum observed changes are a 30% reduction in carcass fat accretion and a 36% increase in protein accretion.

The magnitude of growth response and changes in carcass composition following ST treatment is influenced by nutritional factors, such as feeding level and protein and amino acid levels and supply. Interactions between feeding level and ST treatment have been demonstrated and suggest that the response to ST in young growing cattle in many situations may be impaired by limitations in amino acid supply from microbial and ruminal escape protein. Thus, the effect of ST on performance can be enhanced by increasing the level of escape protein (e.g., a fish meal–rich diet); also, the effects of ST and abomasal-infused casein seem to be additive. There are still no definite and complete data available for estimation of energy and protein requirements of ST-treated cattle. However, amino acid availability and amino acid composition may in fact have limited the protein-anabolic response in some of the earlier ST experiments. It is also likely that nutrient density (i.e., protein, energy, and some minerals) of the diet should be increased in order to compensate in feeding situations where ST administration reduces feed intake and to ensure there are sufficient nutrients to support the increased protein and bone deposition.

Other possible sources of variation in the growth responses to ST include dose and pattern of administration. Using the maximum increase in ADG and/or decrease in plasma urea as criteria for optimizing the response, the optimum dose for cattle has been estimated at 41–64 μg per kg bodyweight per day. In sheep, the optimal dose seems to be higher (100–200 μg per kg bodyweight per day). The effect of pattern of administration is less clear, but injections four times a day seem to be more potent than injection once a day or continuous infusion. A possible explanation might be that a regimen of several injections per day resembles the normal episodic secretory pattern more closely than injection once a day or continuous infusion. Furthermore, the most effective dose is lower for daily than for weekly administration. The biological effect of ST does not seem to be attenuated with the length of the treatment period, and the marginal effect of ST does not diminish with time. In fact, the maximum reduction in carcass fat is obtained after a long treatment period (months).

ST seems to act additively with other growth promoters, such as β-agonists and sex steroids. This has been observed in experiments in which ST has been given together with zeranol (a steroid-like compound with female sex hormone activity) or implants of estradiol (female sex steroid) or estradiol, progesterone, and trenbolone (with male sex hormone activity) combined. Similarly, the effects of ST and a β-agonist (clenbuterol) seem to be additive.

Pigs

Exogenous pST treatment consistently improves ADG, feed conversion efficiency and protein deposition, and reduces fat deposition in pigs. Dose-dependent increases in lean deposition and reductions in feed intake, fat deposition, and carcass fat have been observed (Figure 1). Occasionally, no growth responses are observed because the reduction in fat deposition may offset the increase in protein deposition.

Despite the accelerated protein deposition, feed intake usually always decreases in ST-treated pigs under *ad libitum* conditions, with a 5–15% reduction being common. The increased ADG and the simultaneous reduction in feed intake are virtually always associated with a substantial improved feed efficiency, which can amount to 40%.

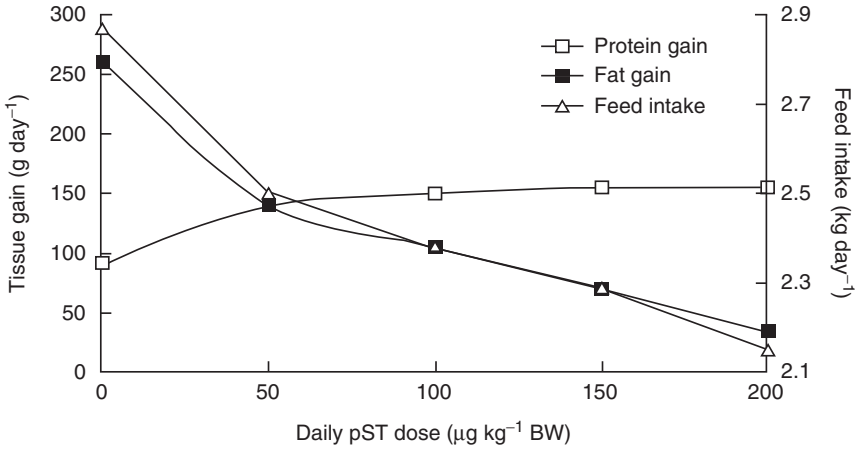

Figure 1 Relationship between porcine somatotropin (pST) dose and parameters of growth performance. Reproduced from Krick, B.J., Roneker, K.R., Boyd, R.D., *et al.*, 1992. Influence of genotype and sex on the response of growing pigs to recombinant porcine somatotropin. Journal of Animal Science 70, 3024–3034.

Table 1 Effects of growth hormone on performance in cattle and pigs. All means expressed relative to the control mean as 100

	Cattle	*Pigs*
Feed intake	90–110	70–96
Daily gain	93–127	95–130
Gain/feed	103–125	115–150
Dressing percentage	95–103	96–99
Carcass lean	100–102	110–150
Carcass fat	80–90	26–85

The reason for the reduction in feed intake is related to the mechanism of action of ST on adipose tissue metabolism. The ST-induced shift in nutrient partitioning is mediated, in part, through inducing insulin resistance in adipose tissue. This insulin resistance results in a reduced uptake of glucose in adipose tissue and a reduction in fat synthesis as well as accumulation of glucose in the circulation. Consequently, the ST-treated pig will reduce feed intake and fat deposition. All animals treated with ST contain less carcass fat with reductions in subcutaneous fat of up to 70% having been observed. Reductions in IM, belly, and leaf fat are also generally observed during pST treatment.

In contrast to adipose tissue, the amount of muscle tissue is generally increased in carcasses from ST-treated pigs. The magnitude of this increase is typically 5–20%. Also, animals that do not show an overall increase in growth show increased amounts of carcass lean. As in ruminants, protein-rich tissues other than muscles, such as visceral tissue, also increase after pST treatment. Thus, ST treatment generally causes a slight decrease in dressing percentage (1–2 units) (Table 1).

The large variation in response to ST treatment can, as in ruminants, be explained by (1) ST dose and mode of administration, (2) diet composition, (3) the animal's potential for tissue accretion, (4) the developmental stage, and (5) the breed or genotype of pigs. Concerning dose, carcass protein accretion increases with up to 150 μg pST per kg bodyweight per day, whereas lipid accretion continues to decrease up to a dose of 200 μg pST per kg bodyweight per day. It has been calculated that 94% and 84% of the maximum theoretical responses in ADG and feed efficiency, respectively, are met at 100 μg pST per kg bodyweight per day.

Owing to the increase in protein accretion, dietary levels of essential amino acids have to be elevated in order to maximize the ST response in pigs. For this reason, the full potential of ST was not revealed in some of the earlier studies in which relatively low levels of lysine (0.7–0.8%) were applied. Most likely the lysine requirement with ST treatment is 1.0–1.2%, which is 20–30% above the requirement for contemporary pigs.

Variation in growth response to ST treatment can also be attributed to the pig's potential for growth. For example, it has been shown that differences in protein accretion rate between gilts, barrows, and boars largely are eliminated by ST treatment. Thus, the magnitude of response was highest for animals with the lowest growth potential (i.e., gilts and barrows), and lowest for animals with the highest growth potential (i.e., boars). In line with this, the effect of ST on lean tissue gain seems to be inversely related to the animal's inherent potential for lean tissue growth. Furthermore, it has been reported that pigs with relatively low capacity for lean growth require a higher dose of ST than pigs with relatively high capacity. However, factors other than lean growth potential are probably important for the response to ST. One such factor might be muscle fiber size and, consequently, the number of fibers, because the relationship between muscle fiber size and response to ST suggests that pigs with relatively large muscle fibers will show smaller improvements in lean deposition rates than pigs with relatively small muscle fibers.

Health Aspects

In the large majority of studies concerning the effects of ST on performance, there have been no reports of adverse health or welfare aspects. However, only a few studies have specifically examined health aspects. Thus, it has been reported that ST treatment may increase the incidence and severity of osteochondrosis and cartilage unsoundness in pigs although this may be because insufficient dietary calcium and phosphorous were provided to support the increase in bone deposition.

Stomach ulcers may also be a problem in ST-treated pigs but this only appears to occur when very high doses of ST are used resulting in a large reduction in feed intake or where finely milled maize-based diets are used

In one dose–response study in steers, a higher incidence of abomasal ulcers and liver abscesses was observed in the groups receiving very high ST doses compared with the control group or a group receiving a low dose. In a second study, where five low-to-moderate doses were applied, there were no systematic differences in incidences of abomasal ulcers and liver abscesses in steers. These observations suggest that very high doses of STH probably may cause health problems in cattle.

Muscle Characteristics and Meat Quality

Because of the general improvement of growth performance after ST treatment, it is most relevant to examine the response in muscle and meat quality characteristics. The following discussion focuses on muscle fiber types, muscle metabolic potential, and physicochemical and sensory aspects of meat from ST-treated animals. The effects on chemical composition (e.g., fatty acid composition) of edible tissue will also be discussed.

Muscle Fiber Type Properties and Metabolic Potentials

Treatment with ST does not seem to affect the number of muscle fibers in a given muscle. Consequently, the increase in carcass meat content after ST treatment of pigs and cattle is reflected in increased muscle fiber hypertrophy. Studies in pigs have shown that the response to ST is dependent on the anatomical location, with muscles located in the hindquarter region and the loin responding most to ST.

The majority of studies have also reported no effect of ST on fiber type distribution. The major effect of ST administration is on increasing muscle fiber size which can result in increased shear force, an objective measure of tenderness. Also, the use of pST has also been reported to reduce calcium-activated proteolysis in the Longissimus muscle, thereby preventing improvements in tenderness during the aging process. In both heifers and pigs, an increased number of capillaries per fiber has been observed after ST treatment. These changes are probably not a direct consequence of ST treatment per se, but are probably secondary to the muscle fiber hypertrophy. Only small changes in the activities of citrate synthetase, hydroxyacyl-CoA dehydrogenase, and lactate dehydrogenase were found. These findings indicate that muscle function is not compromised by ST treatment and the hypertrophy only indicates a higher degree of muscle maturity.

Physicochemical Characteristics

The postmortem rate (pH measured in 45 min postmortem, pH_{45}) and extent (ultimate pH measured either 24 or 48 h postmortem, pH_u) of muscle pH changes affect several meat quality aspects, for example, water-holding capacity, color, tenderness, and juiciness. However, results for pH_u and pH_{45} are not consistent. Thus, the pH_u of the longissimus muscle was unaltered after ST treatment in some studies in pigs and cattle but not in others. A meta-analysis has shown that while there was a significant difference in pH_u in pST-treated pigs, the magnitude of the difference was negligible (5.63 vs. 5.64). The pH_{45} has been reported either to decrease or to be unaltered.

Meat color is also largely unchanged after ST treatment of pigs, heifers, and lambs of different breeds. A meta-analysis has shown that there was no difference in the L*(reflectance) value, but there were significant, but small, differences in a* ($+2.1\%$) and b*(-5.7%), indicating slightly redder and less yellow pork from pigs treated with pST. In agreement with relatively unchanged color, the heme pigment content of the longissimus muscle was unchanged after ST treatment in heifers and pigs.

Drip loss and cooking loss influence meat yield and the juiciness of meat, respectively. A meta-analysis has shown that there was a small, but significant, decrease in drip loss (4.8 vs. 4.5%) in pork from pigs treated with pST. Cooking loss seems to be unaffected by ST treatment in both pigs and cattle. Therefore, treatment with ST has little effect on these important quality characteristics.

Subjective fat marbling scores and chemically extractable IM fat in the loin are consistently reduced by ST. Although a reduction in IM fat would likely reduce the intake of saturated fats in the consumed portion of meat, low levels of IM fat can impact negatively on sensory perceptions of meat quality. The poly- and monounsaturated fatty acid composition of both subcutaneous and IM fat are significantly increased by pST treatment. The reduction in IM fat coupled with the favorable fatty acid profile in pork from pigs treated with pST should result in a more healthy product, although this may be offset against reduced eating quality. Furthermore, the dramatic reduction in *de novo* fatty acid synthesis means that proportionately more of the fatty acids incorporated into newly formed lipids would be of dietary origin and this offers the opportunity to further manipulate fatty acid composition through dietary intervention.

In general, it appears that pST causes a small increase in shear force ($\sim +9\%$) and sensory perceptions of toughness in pork but it is unsure whether this would be consistently detected by consumers as there is no difference in perceptions of flavor or juiciness. There are far fewer studies in ruminants but those that have been conducted suggest similar findings as for pigs. Most of the observed increase in shear force of pork chops with high doses of pST seems to be accounted for by the first yield of the force–distance curve, which indicates a change in tenderization of the myofibrillar proteins. In agreement with this, the ratio between noncollagen protein and collagen deposition rates was 49% greater in the carcasses of ST-treated pigs. In lambs, the ratio of collagen to noncollagen synthesis seems to be unchanged, and in young cattle, collagen content and solubility were found to be unchanged after treatment with ST.

Sensory Aspects of Meat from ST-Treated Animals

The limited data on consumer preferences would suggest that there is a decrease in tenderness ($\sim -9\%$), although there is no effect on juiciness or flavor. Importantly, there may be some interactions between muscle types, processing, gender, and genotype. For example, chops from pST-treated pigs

received significantly lower scores for initial tenderness, initial juiciness, sustained juiciness, and flavor than chops from control counterparts. However, there was no effect of pST on the sensory characteristics of the cured and processed semimembranosus obtained from these same pigs.

Final Remarks

GH clearly has potential as a growth promoter in pigs and ruminants. The general effects of ST are increased or unchanged growth rate, improved feed efficiency, and increased protein deposition concurrent with reduced rate of fat deposition. The net result is increased lean-to-fat ratio of the carcass. The response is known to depend on many factors including the dose of ST, the pattern and mode of administration, the developmental state of the animal, and nutritional factors, such as feeding level and amino acid supply. There are still many questions that remain unanswered concerning optimal doses, diet composition, and animal nutrient requirements.

Existing evidence indicates that muscle function is not compromised by administration of ST. The effects on meat quality are negative but generally marginal. There may be a slight decrease in meat tenderness, but most sensory panels do not detect this effect. Furthermore, it is possible that postmortem handling of the meat has been suboptimal in these experiments owing to the lean carcasses of ST-treated pigs, which may require less severe chilling.

Disease Control and Specific Pathogen Free Pig Production

JP Nielsen, University of Copenhagen, Frederiksberg C, Denmark

Infectious and Noninfectious Diseases

Diseases of pigs may have infectious or noninfectious etiologies. Infectious diseases are caused by pathogens, such as viruses, bacteria, or parasites. Noninfectious diseases may be hereditary, or of metabolic, nutritional or injury origin.

In intensive production systems, where large groups of relatively young animals are kept in confinement with limited airspace and in close contact, infectious diseases tend to predominate. Under such conditions infections may spread easily through direct contact, short-distance airborne transmission, or fecal uptake. This means that diseases may from time to time become a problem for animal welfare and production economy. Therefore, a number of strategies have been developed to eliminate or control the risk of infectious disease development.

The immune response of the animals is the major defense mechanism against infection. When the balance between immunity and infection is disturbed disease may develop. The severity of disease outbreaks may also be influenced by the environment, management procedures, hygiene level, and the nutritional status of animals.

Methods for Reduction of Infectious Diseases

Infectious disease limiting systems may be categorized into two main types:

1. Disease control systems that rely on a balance between infection, immunity, and management resulting in the absence of clinical disease.
2. Disease eradication systems that rely on the absence of specified infectious agents.

The first category includes changes in management, such as improved hygiene, immunization programs, and treatment with antibiotics. Hygiene measures and immunization are relevant for all types of infection, whether it is viral, bacterial, or parasitic in nature, whereas treatment with antibiotics is directed only against bacterial infections.

The second category includes specific pathogen free (SPF) production, national eradication campaigns, and programs for elimination of infections from herds.

Independent of disease control strategy a strict biosecurity program should be established in order to keep new infections out of herds. This is important for infections, which are endemic to a given region, and for transboundary infections that may spread from other parts of the world.

Infectious Disease Control

Infectious disease control is defined as an effort to live with the pathogens in a balance with immunity and management. This means that the infection may still be present in a subclinical form, but a mixture of immunity, antibiotic treatments, and low infection pressure will keep it under control.

Vaccination Programs

Vaccination is a commonly used method for the control of infections. Most often vaccination will protect against clinical disease, but not prevent animals from becoming infected carriers. In pig production there are three main vaccination strategies:

1. protection of piglets by immunization of sows and transfer of passive immunity via colostrum,
2. vaccination of individual animals in order to induce immunity to subsequent infection, and
3. vaccination of breeding animals in order to induce immunity to infections, which may impair the reproductive performance.

Typical vaccines in group 1 include *Escherichia coli* neonatal diarrhea, erysipelas, necrotizing clostridial enteritis, porcine reproductive and respiratory syndrome (PRRS), and postweaning multisystemic wasting syndrome (PMWS). Typical group 2 vaccines include pleuropneumonia, *Lawsonia intracellularis*, *Haemophilus parasuis*, PMWS, and PRRS. Typical group 3 vaccines include Porcine Parvovirus, PRRS, and PMWS.

Antibiotic Treatment Programs

Treatment with antibiotics is another important method for control of infections in pig herds.

For many years antibiotic growth promoters, in so-called subtherapeutic doses, were included in feed in order to enhance growth and control subclinical disease. The European Union banned this use in the year 2006, due to risk of resistance development and transfer of bacterial resistance to human bacterial pathogens. Antibiotic growth promoters are still used in other parts of the world, although the use is controversial.

Therapeutic treatment programs in pig herds must be based on a precise diagnosis, including herd history, clinical signs, and laboratory findings. Depending on the prevalence of disease and the risk of spread, it may be decided to use batch medication or individual animal treatment. It is important to follow approved guidelines for doses and treatment periods in order to reduce development of resistance. Certain antibiotics that are critical for human treatment should be avoided in pig production. These antibiotics include Quinolones and Cephalosporins. Development of resistance against these first-line antibiotics in zoonotic bacteria, such as *salmonella* and *campylobacter*, may cause life-threatening treatment failure in humans.

The main routes of administration of antibiotic compounds to pigs are medicated water or feed and individual

 doi:10.1016/B978-0-12-384731-7.00020-9

animal injections. An advantage of injections is that the individual animal dose is well defined. The disadvantage of this administration is the amount of work involved, and the diagnostic difficulties in identification of animals suffering from subclinical infections.

Water and feed medication programs will result in a much more variable dosing of the individual pigs due to variation in disease severity, mobility, and social rank. Unfortunately, the most severely affected animals tend to stop eating and eventually also drinking, which means that the diseased animals will receive lower doses than the healthy ones.

Infectious Disease Elimination

National Eradication Programs

Several important transboundary pig diseases have been eradicated nationwide, especially in Europe and the United States. Such infections include classical and African swine fever, foot-and-mouth disease, and Aujeszky's disease. More recently Enzootic pneumonia caused by *Mycoplasma hyopneumoniae* has been eradicated from countries like Switzerland, Finland, and Norway. So far, the important viral infection PRRS has never been eradicated when established in a country. However, Sweden succeeded in stamping out the first outbreaks, and thereby prevented further spread of the disease in the country.

Successful national programs require that spread and transmission of infections is arrested and that diagnostic procedures for correct distinction between infected and non-infected herds are available. Strategies for national eradication include 'stamping out' where all animals in a positive herds are culled, or 'test and slaughter' where single animals are tested and culled. Stamping out has been used in Europe for infections such as foot-and-mouth disease and classical swine fever. Test and slaughter has been used for eradication of Aujeszky's disease. Eradication programs with culling and slaughtering of large numbers of animals will probably not be acceptable for the public in the future. Therefore, more focus is put on vaccination strategies where vaccination zones are used to create barriers for spread of infection. For this purpose so-called DIVA (differentiating infected from vaccinated animals) vaccines are useful in eradication programs because they allow destruction of infected animals while animals protected by vaccines may be slaughtered and consumed.

Eradication Programs at the Herd Level

Individual herd owners may decide to eradicate infections due to economic losses or welfare problems. In herds selling breeding animals, a high health status is particularly relevant. It is important to consider the risk of reintroduction before investing time and money in a herdwise eradication program. Herds located downwind within a distance of 2–3 km should be considered a risk factor for windborne infections such as *M. hyopneumoniae* and PRRS.

Eradication with Total Depopulation

Eradication based on total depopulation may be achieved by removal of all animals followed by cleaning, disinfection, and an empty period of 2–3 weeks. After this down period new animals with a well-defined SPF status may be inserted. By this method it is possible to obtain freedom from several infections in a single process.

Eradication with Remaining Breeding Stock

More recently, protocols for eradication of infections where the breeding animals remain at the farm during the program have been developed. The advantage of such programs is that the period with economic losses due to reduced production is shorter.

Eradication of *M. hyopneumoniae* has been a model for eradication programs where the breeding animals are retained on the farm. Eradication of this infection is facilitated by a strong immunity that develops in convalescent animals which in practice means that they clear the infection. The initial programs were developed in small herds in Switzerland in the 1970s. In Denmark the same principles have been used in herds with 1000 sows or more.

The original principles for herd eradication consisted of:

1. stabilization of herd by vaccination or development of natural immunity,
2. removal of all animals younger than 10 months,
3. two weeks farrowing stop,
4. cleaning and disinfection of infected premises, and
5. medication of remaining animals >10 months.

During the years these principles have been simplified, and it has been shown that eradication may be successful even without removal of piglets from the farrowing unit.

At present eradication herdwise programs with success rates between 80% and 100% exist for *M. hyopneumoniae*, PRRS, *Brachyspira hyodysenteriae*, and Mange (*Sarcoptes scabei*) in Denmark. Programs with higher risk of failure have been developed for *Actinobacillus pleuropneumoniae*, toxigenic *Pasteurella multocida*, and *Lawsonia intracellularis*.

Specific Pathogen Free Production

The term SPF is an abbreviation for 'specific pathogen free.' 'Specific' means that certain well-defined pathogens among numerous more or less well-defined causes of disease are included. 'Pathogen free' means that herds are free, not only from clinical disease or subclinical infection, but also from the infectious pathogen as such. The number of pathogens that a given SPF herd is free from may differ according to the ambitions of the farmer. SPF production may be used for all animal species, but it has been developed for pig production in particular.

The early SPF techniques were inspired from research on cesarean sections and germ-free rearing of pigs. This research showed that freedom from pathogens in pig populations could be maintained after establishment of a clean source.

The first commercial farms were established in the 1950s in the United States and since then several systems have been developed in North America and Europe. The Danish SPF program was established in 1968 and is, by far, the largest

system with 250 breeding and multiplying herds and 3500 herds producing pigs for slaughter. The impact of SPF production on Danish pig production and export is huge because more than 75% of the sows delivering slaughter pigs and more than 90% of the breeding and multiplying animals have SPF status.

The advantage of SPF production is that animals with a guaranteed freedom from specific infections may be obtained. Freedom from infection and subsequent disease leads to increased growth rate and feed conversion ratio and reduced mortality. This leads to improved economic results and to a more stable production. Improved animal welfare and reduced antibiotic consumption are additional benefits from improved health status.

SPF production is based on the following principles:

1. Herds are established after careful cleaning and disinfection.
2. A strict biosecurity program preventing reintroduction is established.
3. Transport of animals between herds is carried out in special trucks with filtered air-inlets.
4. Openness about information on reintroductions of infections.
5. Monitoring by farmers, vets, and by laboratory testing.
6. Quarantine of visitors and vets coming from herds with lower health status.

Specific Pathogen Free Diseases

It is expensive to monitor, test, and declare freedom of pathogens. Therefore, it must be carefully considered which pathogens are relevant to include in the SPF system. Only infections with considerable economic impact and a well-defined and preferably cheap diagnosis should be included. It is also important that the infections are predominately transmitted by pigs. Infections transmitted by humans, rodents, feed, or bedding should be avoided. In Table 1 the infections included in the Danish SPF system are given.

A 'perfect' disease in an SPF program has a well-defined causal pathogen that may be laboratory confirmed by low-cost diagnostic tests with a high sensitivity and specificity. Such tests are most often serological testing of blood samples or automated polymerase chain reaction (PCR) tests.

Biosecurity and Introduction of Infections

Strict rules on biosecurity are cornerstones in SPF production, and have been advantageous for pig production in general. Biosecurity rules of the Danish SPF system are presented in Table 2.

Although biosecurity rules are enforced, approximately 20% of Danish SPF herds will experience introductions of unwanted infections each year (Figure 1). The highest number of introductions is experienced for *M. hyopneumoniae* and PRRS. It is well known that these infections are spreading by wind over distances as far as 2–3 km, and it is, therefore, assumed that the main route of infection is airborne from infected herds in the neighborhood.

Table 1 Major infections in pig herds that may be controlled by specific pathogen free production

- *Mycoplasma hyopneumoniae*
- *Actinobacillus pleuropneumoniae*
- Porcine reproductive and respiratory syndrome virus
- Toxigenic *Pasteurella multocida*
- *Brachyspira hyodysenteriae*
- *Haematopinus suis*
- *Sarcoptes scabiei*

Table 2 Biosecurity specifications and procedures in the Danish specific pathogen free (SPF) system

Entry of animals
Semen from controlled boar studs
Pigs from herds with equal or higher SPF status
Piglets from non-SPF herds after C-section
An 8-week quarantine period for pigs before entry in breeding herds
Only neutered cats from urban communities
Pest controlled properly
Bird entry avoided
Entry of humans
Twelve hours quarantine after contact with pigs of lower health status
No quarantine after contact with pigs of equal or higher SPF status
Change of footwear
Change of cloth to the level of underwear
Washing of hands
Minimum distance to neighboring herds
100 m for production herds
500 m for breeding and multiplying herds
Perimeter of production facilities
Well-defined borders of the production area
Entrance must be marked with SPF status
All external doors must be locked up
Special compartments for pigs leaving the farm
No direct contact between trucks and the production facilities
Safe procedures for entry of feed and bedding
Transport of pigs between herds
Only approved transporters with especially designed trucks
Air inlet filters to avoid infection by air under transport
Health monitoring in SPF herds
Clinical inspection
Fifteen weeks intervals in production herds
Monthly intervals in breeding herds
Testing for Ap, Myc, and PRRS in blood samples
Yearly in production herds
Monthly in breeding herds
Clinical suspicion of infection
Six weeks investing period
Openness to the public
All information on SPF status may be accessed on www.spf-sus.dk

Actinobacillus pleuropneumoniae is also among the more prevalent causes of infections in the Danish SPF program. Although this infection may also spread by airborne transmission over short distances, it is believed that this is rarely the case. The monitoring of this infection by blood testing is complex because more than 12 serotypes exit, which may partly contribute to the spread of this infection.

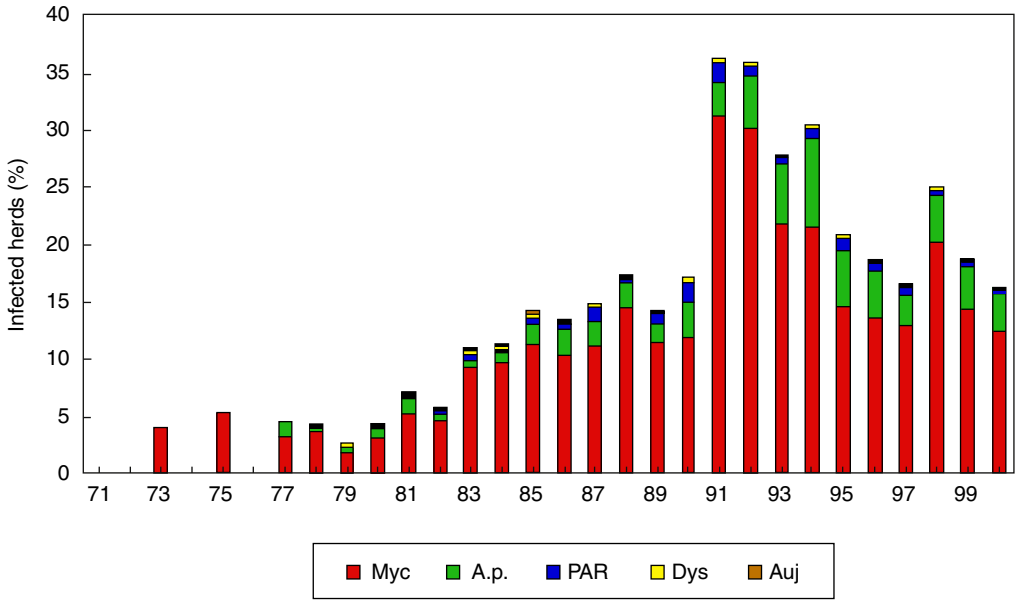

Figure 1 Infection episodes in Danish SPF system, including approximately 3500 production and breeding herds in the period 1985–2000.

Infections with *B. hyodysenteriae*, *Sarcoptes scabei*, and toxigenic *P. multocida* are very infrequent in the Danish SPF system.

Conclusions

Infectious disease reduction in pig herds may be based on a control strategy (living with the infection) or an eradication strategy (SPF). The strategy must be chosen by individual farmers, regions, or nations based on the pig density in areas, the structure of the pig production, and the cost and consequences of disease.

The advantage of the control strategy is that a balance between infection, immunity, and management may be obtained leaving the herd well protected against new infections. The disadvantages are that this strategy may require permanent costs for vaccination, treatment, and eventually disease outbreaks when the balance is disturbed.

The advantage of the eradication strategy is that once the infection is totally eliminated, there will be no more cost or losses as a result of the corresponding disease. This is a very rewarding situation. Disadvantages include that monitoring efforts may be costly and that such herds always are at risk of introduction of the infections they are free from, in particular those that may be transmitted through air.

Glossary

Carcass weight The weight of an animal that remains after slaughter once the head, feet, skin, and internal organs have been removed.
Cottage industry A small-scale industry, often home based rather than factory based, with relatively few employees or a limited customer base and low economic impact.
Doe An adult female in some animal species.
Dressing percentage/dress out The percentage of an animal's live weight that becomes the carcass weight at slaughter, determined by dividing carcass weight by live weight and multiplying by 100.
Extensive production/farming An agricultural production system which, relative to the land area being farmed, is characteriseized by small capital and labor inputs, as well as limited reliance on technologies (e.g., pesticides and fertiliseizers).
Feral Refers to an animal that has changed from being domesticated to being wild or untamed.
Ghee A class of clarified butter that originated from South Asia.
Hind or Doe A female deer, especially a red deer.
Inanition A lack of adequate nutrition or food (starvation).
Intensive production/farming An agricultural production system which, relative to the land area being farmed, is characteriseized by high capital and labor inputs, as well as substantial use of technologies (including pesticides and fertiliseizers).
Kit or kitten A young rabbit.
Parturition The act of giving birth.
Pâté de foie gras A food product made from the livers of ducks or geese that have been specially fattened, typically by force feeding.
Poikilothermic A term used to refer to an organism whose internal temperature varies considerably.
Rut The mating season of ruminant animals.
Stag or Buck A male deer, especially used when referring to large deer species.
Ungulate A mammal with hooves.
Velvet antler Refers to the entire cartilaginous antler (in a precalcified stage) of certain deer species that is used in a dried and powdered form in many traditional Chinese medicines.
Venison The meat of a game animal.
Weaner A young animal that has been weaned from mother's milk and has been introduced to an adult diet.

Introduction

With the rapid global advances in transportation and infrastructure, individuals from different ethnic groups frequently find themselves in regions of the world which are far from home. Nonetheless, such individuals often retain the desire to consume those foods with which they are traditionally accustomed. To be able to address these desires, a more formal scientific approach is required for the production of the specific species comprising this ethnic food, which includes aspects such as genetic selection (for specific paternal or maternal characteristics), advanced nutritional interventions, as well as disease control. However, it is not only the production systems that need to be of a first-world standard, but also the entire supply chain leading to the market. The latter may include the supply of live animals that would need to pass through a suitable abattoir and processing plant, as well as the transport and distribution of the resultant products to the end consumer – who may be local or international. Consequently, the production of many exotic species has developed in two different directions. The first direction follows older traditional systems, where small-scale production and low numbers of certain species are maintained. Meat is a secondary product in such cases and the products are generally sold locally and for cash. The second direction involves the production of exotic species in a more scientific manner, with the supply of meat frequently being the main output.

Species that are well-established as meat producers include birds (ratites and game birds), buffalo, camels, deer, game animals (ungulates and other African wildlife species), goats, rabbits, rodents, reptiles, kangaroos, and yaks. With some species, meat may be a lower-valued coproduct of other activities or from the sale of alternative items derived from the animals, such as hides, fur, or oil. For example, crocodile farms usually acquire the majority of their revenue from the public display of the animals in pens and from the sale of the skins. Depending on market conditions, rabbit and possum fur can be an economically important coproduct and antler velvet can provide deer farmers with approximately one-third of their annual revenue. The oil pressed from the preen gland of the emu can be more valuable than the meat. Water buffaloes are kept in some countries mainly for draught purposes, with milk production being of secondary importance and the meat serving only as a supplementary product when there is surplus stock or when the animals have to be culled. Goats represent an important food source in many poorer communities in

 doi:10.1016/B978-0-12-384731-7.00029-5

Africa. Typically, several goats will be kept per household, one or more of which may be slaughtered for meat consumption on a special occasion or as the family's needs dictate. In such countries, livestock are often used for draught, as an investment, and as a source of manure, rather than as a primary source of meat. In other regions of Africa, multispecies game reserves and combined livestock/game enterprises are replacing monocultures of domestic livestock. Consumptive practices (culling by hunting) are often combined with nonconsumptive options (tourism) on such wildlife ranches, because the returns from meat production alone normally do not justify the substantial investment in fencing required to contain the animals on the reserve. Nonetheless, with the growth in consumer awareness on the health and ethical aspects linked to production practices, a market has grown for meat products that are perceived to be derived from animals raised as 'natural,' 'wild,' or 'free range.' Against this backdrop, game (wildlife) species from South Africa and Namibia have been harvested in a sustainable manner and exported worldwide.

Birds

Of the birds that are well established as meat producers, the ratites (large, flightless birds) and game birds are among the most important.

Living ratites include the ostrich (Struthionidae) of Africa, the rhea (Rheidae) of South America, the emu and cassowaries (Casuariidae) of Australasia, and the kiwis (Apterygidae) of New Zealand. Ratite species are closely related and share common physical characteristics, such as underdeveloped pectoral muscles, the lack of well-developed wings, and keeled sterna, which prevent them from flying, and an adaption to rely on their strong leg muscles for locomotion.

Of all the ratites, ostriches are produced in the largest numbers. Although there have been numerous attempts at rearing emu (mainly in Australia and New Zealand, but also in India and the Americas), the lack of a suitable market for its products has largely hindered the growth of this industry. The female emu normally lays between 5 and 15 eggs in a season. The adult birds are omnivorous and can be fed on lucerne pellets supplemented with grain, whereas the chicks are usually started on a grain-based crumb. Where the primary purpose is to produce emu meat, the birds can be slaughtered as 1 year olds. Nevertheless, the low muscle yields limit the suitability of this species for commercial meat production. Furthermore, emu feathers and skin are of little commercial value. There has, however, been some interest in the medicinal properties of the oil derived from the retroperitoneal and subcutaneous adipose tissue sites of the emu. The kiwi and rhea species are bred artificially primarily for conservation purposes.

The capture and domestication of ostriches for feather production began in the mid-1860s in the Karoo and Eastern Cape regions of South Africa. The income generated by feather production stimulated the rapid development of ostrich farming in this country (mainly around the Oudtshoorn area in the Little Karoo), which reached a climax in the early twentieth century just before the onset of World War I. In 1913, farmed ostrich numbers were approximated at 770 000; however, this number dropped rapidly to 23 000 by 1930 due to the collapse of the market for ostrich feathers. Feathers are now a secondary product of ostrich farming, whereas leather and meat has gained greater prominence since the 1980s. The current income proportions generated from ostrich meat, leather, and feathers in South Africa are 60%, 30%, and 10%, respectively.

An indication of how rapidly the ostrich industry developed in South Africa and also worldwide can be attained by considering global ostrich slaughter figures over the past two decades. In 1993, 152 000 ostriches were slaughtered in South Africa, which accounted for 84.5% of the global ostrich production. In 2002, however, the 340 000 ostrich slaughtered in South Africa constituted only 60.7% of the global ostrich-slaughter market, due primarily to competing ostrich production in Europe, Australia, Namibia, and China.

The increasing demand for ostrich meat throughout the world is mainly due to the low intramuscular fat content and the favorable fatty acid profile. Most of the marketable meat components of the ostrich carcass are concentrated in the posterior limbs and these are normally sold as individual muscles, such as the Musculus iliofibularis (fan fillet), M. iliofemoralis (side strip), M. iliotibialis cranalis, M. femorotibialis accessorius, M. fibularis longus, M. flexor cruris lateralis, M. obturatorius medialis, M. gastrocnemius (big drum), and the M. iliotibialis lateralis.

The ideal habitat for ostriches is the open, short-grass plains and semidesert areas of Africa, but they also inhabit the hot deserts of the Western Sahara and Namibia. They tend to avoid dense woods and tall grass areas. Although little is known about their natural diets, ostriches are believed to feed on low-growing, green vegetation such as forbs, green grasses, seeds, berries, and succulents in arid, semidesert to grassland environments. The mating season of ostriches in the Little Karoo is normally between June and January, and this is also the egg-laying period for female ostriches. A good producing hen will lay 8–10 eggs per month. Once the breeding season has begun, eggs are collected every day, preferably early in the morning or in the late afternoons. The eggs then undergo a process of sterilization and preparation to enter an artificial incubator in the next few days. Almost all commercial ostrich farms in South Africa use artificial incubators to increase hatching numbers.

In South Africa, the three phases of ostrich rearing between hatch and slaughter include: immediately posthatch, rearing to 4–6 months of age, and finishing (most often in feedlots). Posthatch, the chicks are usually maintained indoors for 2–7 days in a temperature-controlled (30 °C) room or enclosure with adequate ventilation. Thereafter, rearing can be conducted in two ways, namely, foster- or artificial rearing. In the former case, young ostriches are raised by experienced breeders that serve as foster parents and each parent is able to shelter 1015 young birds on irrigated lucerne pastures. Alternatively, farmers that have yearling hens as foster parents may move the young birds to a shelter at night (with adequate enclosure and heat) and return them to the foster parents the following morning. In the case of artificial rearing, chicks are maintained in groups of 30–50 in a temperature-controlled building in cold weather and/or at night. These buildings are

usually coupled with an outside run or small paddock of kikuyu grass or lucerne, where the birds are placed during the day. The birds stay in-house at night for the first 2 weeks posthatch. As they become better adapted to regulating their body temperatures, they are kept in the paddocks at night, provided with shelter. The growing birds are kept under such conditions until 16 weeks of age. During the finishing phase of rearing, the ostriches spend 7–8 months in a feedlot or on lucerne and natural veldt camps. In a feedlot, there is zero-grazing and the birds are dependent on a grower ration and chopped lucerne for nutrition. Other ingredients used in ostrich feeds include maize, soybean, and sunflower oilcake, lupines such as full-fat canola and canola oilcake, fishmeal, hay, and salt bush. However, birds are able to graze when kept on lucerne or natural veldt and receive a grower ration as a supplementary feed. In the Little Karoo, approximately 80% of the ostriches destined for slaughter are reared in feedlots from 3 months of age, whereas the remainder are raised on pastures. Ostriches in South Africa are usually slaughtered at an age of 8–14 months in order to obtain high-quality meat, optimal leather quality, and skin size and a single feather harvest, and at this age can yield up to 35 kg of meat from a 55 kg carcass.

The game birds, classified broadly as land fowls and water fowls, have long been hunted for recreational reasons. They, however, also represent an important food source due to their ability to endure continuous harvesting. Game bird meat forms an integral part of the culinary customs of numerous countries, such as Britain and France. Species of the following orders are regarded as game birds: Galliformes (including guinea fowls, partridges, quails, francolins, and pheasants), Anseriformes (including ducks and geese), Columbiformes (including doves and pigeons), Pterocliformes (including sandgrouse species), and Charadriiformes (including snipes).

Game bird hunting is believed to have originated with the ancient Egyptians, who used falcons, dogs, and other weapons and techniques in order to capture the birds. With the invention of the shotgun, game bird hunting later developed into a major sport in Europe, with many traditional, prestige, and ethical aspects involved. The game bird hunting industry contributes to the economy in the UK by providing employment for approximately 26 000 individuals and generating an annual revenue of €0.5 billion. Game bird hunting is also popular in the USA, where more than 38 million game birds are shot each year.

Captive-bred birds form a key part of the international industry, especially in Europe, where large numbers of game birds are bred on an annual basis specially to be released into the wild. In the UK, these captive-bred birds predominantly include pheasants, although red-legged partridges, gray partridges, and ducks are also reared for this purpose. The UK Game Farmers Association estimates that around 20–30 million birds are reared for release into the wild each year. Apart from the financial advantages afforded to landowners by this practice, it is also believed to reduce pressure on wild game bird populations.

Goose production is well established as a cottage industry in many parts of the world, whereas in other regions it has developed into a large-scale business venture. In France, Muscovy ducks and European geese are used for producing *pâté de foie gras*. On many farms, this involves force-feeding the birds with a tube 2–3 times daily while they are caged in a cramming shed for the purpose of producing an enlarged fatty liver. Forced feeding is considered unethical treatment and is illegal in several countries. Goose farming is also well developed in central and eastern Europe, where Rhenish and Italian breeds are well represented, along with the Muscovy duck. The guinea fowl (*Numeda meleagris*) is another game bird that may be farmed as a cottage industry in Africa or may be produced under intensive production systems similar to those used for broiler production. In Africa, both live guinea fowls and their eggs are traded, whereas the meat is produced under more formal marketing systems in Europe. Squats (pigeons) are also produced in numerous countries as part of the cottage industry. Pigeons are grown in pens or cages on rooftops in urban areas of Asia.

Buffalo

Water buffaloes are large animals belonging to the family Bovidae, which are an important livestock species in southern Asia, as well as in South America, southern Europe, and northern Africa. It is estimated that there are approximately 158 million water buffalo in the world, 97% of which inhabit tropical and subtropical parts of Asia, where there is at least one buffalo for every three heads of cattle. Water buffaloes are particularly suited to the marshland conditions in East and Southeast Asia, but high mortality due to calf drowning can occur during the wet season.

The classification of the water buffalo currently remains unresolved. Certain authorities list a single species, *Bubalus bubalis*, with three subspecies: the river buffalo (*Bu. bubalis bubalis*), the swamp buffalo or carabao (*Bu. bubalis carabanesis*), and the wild water buffalo or arni (*Bu. bubalis arnee*). Others consider these to be closely related, but separate species. In 2003, the International Commission on Zoological Nomenclature ruled in favor of classing the wild buffalo as a separate taxon. As a result, the wild forms are now usually referred to as *Bu. arnee* and the domestic forms as *Bu. bubalis*. The former usage, however, remains acceptable for those authors who regard them as conspecific. Both the river buffalo and swamp buffalo are considered to be derived from the wild water buffalo, being the products of thousands of years of selective breeding in Asia. The river buffalo has 50 chromosomes, whereas the swamp buffalo has 48. The two do not readily interbreed, although fertile offspring can occur. Buffalo–cattle hybrids have not been observed to date, and the embryos of such hybrids reportedly do not reach maturity in laboratory experiments.

In paddy-farming regions, swamp buffalo are traditionally raised for draught purposes, whereas river buffalo are kept for fresh milk and ghee production. At present, there is no organized buffalo meat industry. Rather, the animals are slaughtered for meat consumption once they reach the end of their working lives and are often in a poor condition when this occurs. Male calves that are not needed as replacements are not always used for meat production and the surplus stock are normally allowed to die from inanition. Water buffalo feature as a source of meat in countries neighboring the Caspian and Black Seas, where they are slaughtered at approximately

18 months of age at 300–360 kg live weight and dress out at approximately 55%.

Camelids

Camelids belong to the biological family Camelidae, which comprises the genera *Camelus* (including true camel species), *Lama* (including the guanaco and Ilama), and *Vicugna* (including the vicuña and alpaca). The term 'camel' is, however, often broadly used to describe all of the aforementioned camel-like animals. Of the true camel species, the one-humped dromedary or Arabian camel (*Camelus dromedarius*) represent approximately 91% of all the camels found, whereas the two-humped Bactrian camels (*Cam. bacterium*) make up the remainder. Some authorities, such as the International Union for Conservation of Nature (IUCN), apply the binomial name *Cam. ferus* to the wild forms of Bactrian camel, while reserving the name *Cam. bactrianus* for the domestic forms. Although there have been attempts at crossing the dromedary and Bactrian camels, weak and infertile offspring have most often resulted.

Of the estimated 15 million camels in the world, approximately 80% are found in Africa, with the greatest concentration being kept as dairy animals in Somalia. Dromedaries occupy the northern half of Africa, the Arabian peninsula, Iraq, Iran, Afghanistan, Turkmenistan, Pakistan, and western India, where they are used primarily for milk production. Bactrian camels are found to the north of this range, extending into western China. They are kept in considerable numbers in Kazakhstan, Uzbekistan, and Turkmenistan for the purposes of milk, meat, hair, and hide production. A population of approximately 0.2 million largely feral dromedaries inhabit Australia, from where live camels are exported as breeding stock or for the supply of the Middle East meat market.

Camels exhibit a slower growth rate than cattle. The live weights of yearlings can reach 200 kg and these weights can increase under good conditions to 350–400 kg by the end of the second year. Compensatory growth can occur up to the age of 3.5–4 years and the camels reach mature body size at approximately 8 years. They have a lower reproductive rate and higher calf mortality compared to other livestock; thus, young females are usually retained for breeding. Within Africa and the Middle East, many of the animals presented for slaughter are cull breeding stock.

Because the camels are frequently found in harsh environments, the meat is of particular value in the dry seasons when beef is in short supply. However, the demand for camel meat generally exceeds supply and the meat from young stock is particularly sought after. In the eastern region of Ethiopia, camel meat is regarded as high quality and socially acceptable. The dromedary dresses out at approximately 56% of live body weight (average slaughter weight of mature, fattened desert camels is 456 kg) and 64% of empty body weight, yielding 56% meat, 19% bone, and 13.7% fat. In comparison to other red meats (beef, lamb, goat, and chicken), dromedary meat has been found to contain more moisture, less fat, less ash, and similar protein contents.

The majority of the camel's fat reserves are deposited in the hump, which constitutes approximately 8% of the carcass weight (1–5% of live weight). It is thought that the hump serves to insulate the camel from solar radiation, because fat conducts heat more slowly than water. Analysis of the adipose tissue of the hump has revealed that this contains approximately 84% lipid, 139 mg cholesterol per 100 g (wet weight), and 166 mg cholesterol per 100 g lipid. The hump frequently forms part of the sirloin cut and can result in the latter having a high lipid content (49% fat).

Of the genera *Lama* and *Vicugna*, the llama (*Lama glama*) and alpaca (*Vicugna pacos*) are domesticated, whereas the guanaco (*L. guanicoe*) and vicuña (*V. vicugna*) are wild, and commercial farming of the latter two remains limited. The llama is produced for both its meat and fiber, whereas the alpaca is primarily farmed for its fiber. Numerous attempts have been made to cross the alpaca with the llama in order to improve the quantity, but not necessarily the quality of this highly priced species.

Young (9–12 month old) male llamas reared in Chile are often heavier than their same-aged female counterparts (104 kg vs. 68 kg, respectively), but gender differences become less pronounced in older (>3 years) animals (101 kg vs. 105 kg, respectively). Male llamas have slightly heavier dressing percentages (approximately 56%) than females (approximately 54%). However, llamas reared extensively in the mountains of Peru are generally lighter and have lower dressing percentages than those from Chile, likely due to genetic differences between the two populations. Alpaca from Peru are smaller (46.1 kg) than the llama from the same region, although they have a higher dressing percentage (53%). When farmed, fiber, and meat are the most important commodities obtained from the wild guanaco. Adult guanaco weigh 88–120 kg, with little differences in gender, and dress out at approximately 60%. The wild vicuña is the smallest of the camelids, but produces the finest and most valuable wool.

Deer

Deer are ruminant mammals belonging to the family Cervidae. Of the cervid species farmed in Europe, the red deer (*Cervus elaphus*) and fallow deer (*Dama dama*) are the most common. The national deer herd numbers in the UK are estimated at approximately 36 000, and have been relatively stable since 1995. Deer production is a very well-established industry in New Zealand, developing from the point where deer were regarded as pests, to original capturing of wild animals (a pioneer's business) and finally to an important export industry. Red deer comprise approximately 85% of the total farmed deer numbers in New Zealand. Approximately 680 000 yearlings, hinds, and stags are slaughtered annually and more than 90% of the products (venison, velvet antler, and coproducts) are exported. Venison from red deer is high in protein and has a low fat content. Red deer have been genetically selected for large antlers (mainly for velvet production), in combination with docility and fast growth rate.

Like most game species, deer require high fencing to prevent escape, which adds to the establishment costs of a deer farm. Grazing management is controlled in a similar manner as for sheep, because both are bottom-grazers that select the shorter grass species. Most farms breed and rear deer calves to

slaughter, rather than selling the calves to finishing units as weaners. The calves are usually sold for slaughter as yearlings and are transported to abattoirs in specialized deer trucks. Deer can be flighty animals and experience is required for their handling. Breeding stags also show aggression toward humans, particularly during the rut.

The most common deer species farmed in the USA and Canada are the elk or wapiti (*Cer. canadensis*), fallow deer, sika deer (*Cer. nippon*), the chital or axis deer (*Axis axis*), and the white-tailed deer (*Odocoileus virginianus*). The elk is among the largest deer species in the world, whereas the latter species are all considerably smaller in size. The sika deer is probably the best example of a deer species that has been rescued from the brink of extinction and is now farmed commercially for velvet and meat production. Reserves of the wild animals were depleted at the turn of the twentieth century by hunting for their valuable antler velvet. The last populations inhabited the Primorski territory of the former Soviet Union (now the Union of Soviet Socialist Republic (USSR)), with a smaller number in the Far East. Stocks in the USSR were protected and multiplied, and then distributed to New Zealand, Germany, and Denmark for farming and parkland purposes.

The Caspian red deer (*Cer. elaphus maral*), often referred to as the Maral or Noble deer, is one of the most recent species to be domesticated. They are valued mainly for the antler velvet, which is used in the manufacture of pantocrine (a natural drug). The mature stags weigh up to 400 kg, thus have the potential to produce large carcasses for the meat market.

Reindeer or caribou (*Rangifer tarandus*), thought to be one of the first species to be domesticated, are reared today primarily for their meat, antlers, fur, and hides and, to a lesser degree, for milk and transportation. Today, this species is found almost exclusively in the Northern Hemisphere, where there are more than 4 million reindeer (approximately 75% of these are domesticated and 25% are wild). The reindeer are likely to have been tamed in herds rather than individually, from which practices evolved the almost unique method of rangeland reindeer management. Reindeer production, particularly by the indigenous Sami people of the Arctic, changed from an intensive herding system to a more extensive system using modern aids such as trucks, helicopters, motorbikes, and snowmobiles to aid with herding. Reindeer are now mainly kept in free-range systems, not behind fences, and are dependent on the natural pastures of the mountain tundra and forests for food. Their predominant food sources include lichen, browse (especially from shrub willow and birch), sedges, herbs, and grasses. In winter, the reindeer forage by scraping away the snow and lichen comprises approximately 70% of the feed. As a ruminant feed, lichen is relatively rich in carbohydrate and low in protein.

The rutting season of the reindeer is between September and October and pregnancy lasts approximately 7.5 months. Fawns born in April and May put on approximately 60% of their mature body weight during the first summer, but stop growing during their first winter. Puberty is reached by the time of the next rut. Common reindeer breeds include the Chukotka and Nentsi. The Chukotka is well established in the Chukotka, Kamchatka, and Yakutia regions of the tundra, and the less numerous Even and Evenk breeds are found toward the south. The Chukotka has a long body with relatively short legs and the carcass weight of a large stag is typically 60 kg. Nentsi are located on the Arctic coast to the east of the Ural Mountains. Although slightly lighter in weight than the Chukotka, larger Nentsi strains exist on some of the Arctic Islands.

Game Animals

It is estimated that over 25% of the surface area of South Africa that is fit for agricultural practices is currently utilized for some type of wildlife production (either formal National and Provincial game parks or private game farms). Game animals in this country serve for both nonconsumptive purposes (tourism and photographic safaris) and consumptive purposes (hunting safaris and harvesting for export). African ungulates hold particular potential for both of the aforementioned purposes. The animals harvested commercially are mainly the springbok (*Antidorcas marsupialis*) (>80%), blesbok (*Damaliscus pygargus phillipsi*), and kudu (*Tragelaphus strepsiceros*). Other species such as zebra (*Equus burchelli*), blue wildebeest (*Connochaetes taurinus*), impala (*Aepyceros melampus*), and gemsbok (*Oryx gazelle*) are exported in smaller numbers.

There are two game production systems currently practiced in Africa. The first of these involves intensive farming (using modern livestock procedures), where game stud breeders produce highly priced, rare species for other producers or for the hunting market. The second system involves farmers who combine game farming with traditional livestock farming to produce animals for either the hunting industry (>1 million animals hunted per annum) or for harvesting for the export market. It is generally accepted that the animals are enclosed in areas that are large enough not to impede their natural movement, and that the animals can be classified as being organically raised. Not all game species require high fencing to maintain them in their enclosures. Springbok and blesbok, for example, are contained by standard sheep fencing. There are well-developed procedures for the harvesting, processing, and exporting of game meat into the European Union and Asia.

Goats

Domestic goats (*Capra aegagrus hircus*), a member of the family Bovidae, are believed to have descended from the wild goat or bezoar (*Cap. aegagrus*) of southwest Asia and Eastern Europe. The domestication of these small ruminants over 9000 years ago led to numerous phenotypic changes and the development of multiple goat breeds, which soon became widely distributed around the world due to their great ability to adapt to varying environmental conditions. Global goat numbers are estimated at approximately 869.1 million, almost 60% of which are found in Asia and 24% in Africa, where the ratio of sheep to goats is approximately equal. In countries such as India, Pakistan, and Nigeria, goats outnumber sheep by almost two to one.

Goat farming represents a small niche in developed countries, but contributes substantially to the livelihoods of rural populations in developing countries across the globe. Goats may be farmed for their meat, milk, hides, fiber, and manure.

Most of the world's goat meat is supplied by Asia (71%) and Africa (22%). Goat meat is recognized for its low fat content.

The production of goats may be extensive (reliant on goat grazing on large areas) or intensive (farming on small plots with daily management), for subsistence or for profit. Although not customary, goats can be finished off in feedlots before slaughter. In subSaharan Africa, goats are typically kept by crop farmers, who allow them to browse the scrub bushland. In more productive regions, they are tethered on pasture and kept in kraals or huts at night. The interchange of breeding stock may occur when people look after the animals of neighbors. The goat population in parts of Africa is often infested with the tapeworm *Stilesia hepatica*, which occupies the bile duct, but does not appear to cause jaundice.

Although a limited number of breeds have been improved for meat production, specific meat breeds have been developed in South Africa and the USA. The most well-known improved meat breed is the Boer goat from South Africa, which was bred following scientific selection criteria to improve carcass conformation. The Boer goat has now been exported and is being produced in the Americas, Australia, New Zealand, and China. In Australia, large numbers of feral goats are harvested for export and for local meat markets.

Rabbits

Rabbits comprise eight genera in the family Leporidae and are found in several parts of the world. They are simple-stomached, herbivorous animals with a relatively fast growth rate and high feed conversion efficiency. Leporids such as the European rabbit (*Oryctolagus cuniculus*), as well as the hares (*Lepus* spp.), are an important food meat in Europe, South and North America, and certain parts of the Middle East. In addition, the wool and skin/fur of rabbits is of commercial importance. Rabbit production is particularly well developed in China, where approximately 700 000 tons is produced per annum. Within Europe, rabbit production is strongest in Italy (230 000 tons per annum), Spain (74 161 tons per annum), and France (51 400 tons per annum). Today, fresh rabbit meat is sold in the butcheries and markets of some countries, whereas certain supermarkets sell frozen rabbit meat. The meat is highly palatable, high in protein and low in calories, fat, and cholesterol.

When rabbits first became available for sale to the public, many rabbit farms started to increase in size to accommodate the demand for the meat. Not only did the number of does increase, but also the breeds, housing conditions, feeding, and management techniques were developed accordingly. Nonetheless, the industry was badly affected by myxomatosis in the 1950s and 1960s, whereas the spread of rabbit calicivirus, which originated in China, had a detrimental effect in the 1990s. Coccidiosis and cysticercosis have also been difficult to control.

Rabbit farms are classified as small, medium, and large. Regardless of the size, however, the main goal of rabbit farmers is usually to improve the reproductive performance of rabbit does. Stocks of lower productivity are improved by crossing with intensive breeds. A better nutritional status of both fetuses and suckling kits has a positive effect on their later productivity. The gestation period of rabbits is 30–32 days. Does are not prone to lactational anoestrus and can be remated shortly after parturition. Under intensive conditions, a 42 day reproductive rhythm (remating 11 days after parturition) is practiced. Under extensive conditions, the 18 or 25 day mating interval with 35–42 day weaning is more suitable. On small farms, natural mating is favored, whereas artificial insemination is commonly employed on large farms. The number of doe teats and reproductive ability are positively correlated. Does with 10 teats kindle higher numbers of kits (5–10% more) than does with 8 teats. Synthetic rabbit breeds may have 10–12 teats and cross-fostering is common in large breeding units.

In most commercial rabbitries, the animals are housed in flat-decked or stepped wire cages, with the provision of nesting boxes for kindling and for the protection of the young rabbits. Complete pelleted feeds form the main part of the rations, and automated feeding and watering equipment are utilized.

Intensive selected rabbit breeds are most suitable for medium and large rabbit farms due to their good reproductive and productive performance, as well as good maternal ability. Medium-weight breeds (4.0–5.4 kg at maturity) and heavyweight breeds (6.3–7.2 kg at maturity) are most suited for meat production. The New Zealand White and Californian are the leading commercial breeds, with a high proportion of muscle for their size. Synthetic rabbit breeds originated from the crossing of two or more intensive breeds to introduce higher reproductive and productive characteristics, greater adaptability to different environmental conditions or traits preferred by certain groups of consumers. The Californian is the best known of these synthetic breeds, which originated from the crossing of the Himalayan and Chinchilla rabbit breeds, with subsequent crossing of the offspring therefrom with New Zealand Whites.

Certain native rabbit breeds are used in countries with extreme climatic conditions and, even if their reproductive performance is suboptimal, they are well adapted to the local environment and keeping conditions. Colored breeds are kept in some countries to produce meat for own consumption or special markets. Some colored breeds are used in Europe in organic farming or alternative systems. The productivity of colored breeds is between those of native and intensive breeds, and their reproductive ability is sufficiently suitable to make them common on small farms. For backyard rabbit husbandry or home meat production, breed choice is not of critical importance. Rather, under such circumstances, inexpensiveness and resistance to the environment and diseases may be the more important characteristics. The Angora is the primary rabbit breed for wool production, whereas the Rex and Satin breeds have been raised for their pelts for the fur market.

Rodents

Rodentia make up the largest order of mammals, comprising over 440 genera and over 2000 different species. The five main families within this order are Muridae (rats and mice), Sciuridae (squirrels), Echimyidae (spiny rats), Heteromyidae (pocket mice and kangaroo rats), and Dipodidae (jerboas and jumping mice). The Muridae represent approximately 66% of all the rodent taxa. Representatives of the Rodentia are

widespread and, with the exception of Antarctica, occur on all continents and on many oceanic islands. In a number of these regions, rodents are prized items in the diets of local people, with approximately 89 species serving as a food source.

Apart from their ability to survive on diverse diets, the success of rodents is attributed to their large litter sizes, short gestation periods, and early sexual maturity. All of these characteristics make them ideal meat producers. The guinea pig (*Cavia porcellus*), for example, has been a stable meat source for many of the poorest people in the Andes for over 3000 years and 20 000 tons of meat (64 million edible carcasses) is produced from this species annually. Farm-raised guinea pigs have a dressing percentage of approximately 65% and the meat contains approximately 21% protein and 8% fat.

Four types of rodents have production potential in Latin America, namely, the capybara (*Hydrochoerus hydrochaeris*), paca (*Cuniculus* spp.), agouti (*Dasyprocta* spp.) and the coypu or nutria (*Myocastor coypus*). The capybara is believed to have been domesticated in Brazil as early as AD 1565. This species is the largest of the Rodentia and adults typically weigh 35–66 kg. Licensed ranches in Venezuela harvest approximately 85 000 capybara per year. Although capybara meat is considered to be very tasty, most recipes for its preparation require the removal of fat by successive stages of boiling in fresh water. Capybara meat is also traditionally processed in Columbia and Venezuela by salting and drying. Of the closely related pacas and agoutis, the former is particularly regarded as a luxury food source by inhabitants of Guyana, Mexico, Trinidad, and Nicaragua. Coypu are native to South America, but also exist today in Europe, Asia, and North America, where they may be commercially farmed. They are fairly large semi-aquatic rodents (adult weights of 5–9 kg); however, they do show sexual dimorphism and the males are generally heavier than the females. Although the marketing of coypu meat has shown varied success, fresh, frozen, and processed products are now appearing on the commercial market in Uruguay. Coypu has a carcass yield of 52% relative to live weight, resulting in the following meat yields (after cutting up the eviscerated carcass): back (25.0%), two hind legs (23.7%), two front legs (14.7%), and belly flaps (12.9%). The remainder (23.7%) is referred to as 'small meat.' The meat from farm-reared coypu has a lipid content of 1.4–1.8%, and a cholesterol content of 70.1–72.7 mg 100 g^{-1}wet tissue.

Cane rats or grasscutters (*Thryonomys swinderianus* and *T. gregorianus*) are widely eaten in some African countries, but are also regarded as pests on many crops. Research has been carried out over the past 15 years to select stocks for improved adaptability to a restricted life in captivity, as well as to develop rearing programs in rural and periurban areas of Africa. In West Africa, approximately 80 million cane rats are hunted per year, with an equivalent of 300 000 metric tons of meat. With a carcass yield of approximately 64%, comprising 22% protein and 4% fat, these species are highly sought after for meat production in Africa.

Reptiles

Reptiles belong to the class Reptilia, within which the four recognized orders include the Crocodilia (crocodiles, alligators, gavials, and caimans), Squamata (lizards and snakes), Testudines (tortoises, turtles, and terrapins), and Sphenodontia (tuataras). Humans have exploited reptiles in many global regions and for many centuries, mostly as a food source. This, coupled with the use of their skins and their incorporation into many traditional Asian medicines, has led to the overexploitation of certain species. Turtles presently suffer the greatest human predation, particularly in China, where many local populations are now depleted. The exploitation of snakes for food and for medicinal purposes, also mostly in China, has raised concerns for those species involved in the trade. In addition, tegu lizards (*Tupinambis* spp.) have been exploited in Paraguay mainly for their skins, but this has not been on a sustainable basis. Crocodilian species were hunted extensively during the 1950s and 1960s, largely for their skins, and the decimation of many populations resulted in the institution of worldwide conservation and management efforts. In 1975, all populations of the Nile or common crocodile (*Crocodylus niloticus*) were listed by Convention on International Trade of Endangered Wild Fauna and Flora (CITES) in Appendix I, which includes species that are threatened with extinction and for which commercial harvesting and trade is generally prohibited. Between 1983 and 2004, a number of African countries successfully transformed their national *Cro. niloticus* populations from Appendix I to Appendix II, with the latter including species which are not necessarily considered to be threatened, but for which trade is strictly controlled (mostly through quota systems) to prevent overexploitation. The transformation of many of these *Cro. niloticus* populations was largely attributed to the incorporation of ranching into the crocodile management regimes.

Crocodiles have been ranched in Zimbabwe since the early 1960s; however, the number of farms increased during the late 1980s. Lucrative crocodile farms also exist in South Africa, as well as in Asia and Australia. Crocodiles are farmed primarily for their skins, whereas the flesh is a secondary product. The skin represents nearly 20% of the live weight of the Nile crocodile and a dress-out of approximately 56.5% is derived from this species. This dressing percentage is lower than that obtained from the American alligator (*Alligator mississippiensis*) (63.3%) of similar length. The crocodile tail comprises 18% and 33% of the live weight and empty carcass weight, respectively. The carcass weight can be further apportioned as 60.8% lean meat, 12.2% fat, and 26.6% bone. The protein content of raw crocodile meat is approximately 22.1% and the fat content varies with muscle proximity from 0.91% to 2.94%.

With captive crocodile breeding, eggs are regularly harvested from brood stock pens and are thereafter incubated and hatched under controlled conditions (relative humidity of 97–99% and temperature of approximately 31 °C). Crocodiles do not have sex chromosomes. Rather their sex is determined by a process called environmental sex determination (ESD), with the most common form of ESD being temperature-dependent sex determination (TSD). Females are produced at low and high temperatures, whereas males are produced at intermediate temperatures (often called the female–male–female (FMF) pattern). In the wild, nest site selection combined with TSD may enable the female to control the sex of her offspring. The incubation temperature not only influences the sex of the crocodiles, but also the growth rate before and after hatching,

the metabolic rate, optimal thermoregulatory temperatures, and sexual characteristics such as pigmentation pattern and intensity. Commercial breeders may make use of this strategy to ensure that males are predominantly produced. Eggs should hatch within 73 days when the incubation temperature is maintained at 31 °C; however, this may take as long as 95 days. After hatching, average growth rates of 3.1–3.95 mm per day are achieved in commercial production systems. Crocodiles are poikilothermic and are, therefore, reared in heated buildings. Young crocodiles normally reach 1 m in length at 8–10 months, and are then moved to growing or rearing ponds. Crocodiles reared in artificially heated environments (approximately 32 °C) reach a suitable commercial size after 18–30 months (1.5–2.5 years). As crocodiles are mainly produced for their skins, the size (measured across the belly) determines when the reptile is ready for slaughter. Average belly width at slaughter is 27 cm and attained between 24 and 30 months of age.

Kangaroos

Kangaroos are marsupial species of the family Macropodidae, which also includes wallabies, wallaroos, tree kangaroos, pademelons, and forest wallabies. Kangaroos are endemic to Australia and their meat and skins have contributed to the survival of the aboriginal people in this region for tens of thousands of years. Although Australian law prohibits hunting of many of the approximately 50 macropod species, the 3 largest kangaroo species are particularly abundant in rural areas of Australia and are regarded as pests due to their competition with cattle and sheep for valuable pasture resources. As a result, a number of Australian states have determined that kangaroos may be sustainably harvested for commercial purposes, albeit under strict regulatory control. Quota systems determine the maximum number of kangaroos that can be harvested from the wild and the animals may only be killed for commercial use by licensed, skilled marksmen.

The production of kangaroos under intensive conditions has limited feasibility not only due to the high costs of establishing a kangaroo farming enterprise, but also due to the slow growth rate of the animals, their mobility, and ability to jump stock fences, as well as their behavioral patterns which impede mustering or herding. In addition, the market for kangaroo meat and skins can be adequately supplied by the existing rangeland harvesting (hunting).

Approximately 70% of the Australian kangaroo harvest is currently exported, supplying more than 55 countries worldwide. The species that are most commonly harvested for commercial export include the red kangaroo (*Macropus rufus*), eastern gray kangaroo (*M. giganteus*), western gray kangaroo (*M. fuliginosus*), and the common wallaroo or euro (*M. robustus*), with the former three species comprising approximately 90% of the commercial harvest. Meat for human consumption and skins for the leather industry represent the most important kangaroo-derived products. Kangaroo meat is strong in flavor, high in protein, zinc, and iron, while being relatively low in fat (approximately 2%) and cholesterol. Some kangaroo meat may also be processed into pet food.

Yaks

Yaks (*Bos grunniens* or *Bo. mutus*) are used for meat consumption in the mountainous regions of central Asia. They are kept principally for milk and wool production, but there are specialized meat strains that have a relatively large mature body size in Kirgizia. The average birth weight is between 9 and 16 kg and they may be slaughtered at 3 years of age, or when they reach approximately 300 kg live weight. At that weight, they dress out at approximately 57%. The conformation of the yak is quite different from that of cattle. They have a short neck, a thoracic hump, deep chest, short forelegs, and well-developed hindlegs that are adapted to grazing steep slopes. Musk-ox inhabiting the margins of the ice sheet in the northern hemisphere has been used for meat consumption in the past, but numbers are now too low to allow regular cropping. Their unusual feature is their compact but large size.

Various Other Species

A number of other domesticated species are used for meat production, not all of which are farmed. Approximately 470 000 tons of horse meat, derived from domesticated and wild horses, is used annually for human consumption. Both feral and domesticated horses are slaughtered in dedicated abattoirs, and much of the meat is exported to France. The major horse meat consumers are France, Japan, Belgium, Luxembourg, the Netherlands, and Italy. Italy uses horse meat in delicatessen sausages. The major exporting countries are the USA, Argentina, and Canada.

The consumption of frog's legs is popular in many parts of the world. There has been an overall increase in the global trade of frog's legs over the past 20 years, and the industry is valued at approximately $40 million per year. More than 100 000 metric tons of frog's legs were imported between 1996 and 2006 from both farmed and wild sources. France, the USA, Belgium, and Luxembourg are the largest importers of this culinary curiosity.

Meat from dogs is consumed in certain regions of East Asia, and in particular in the Philippines.

At least three species of snail are eaten in Europe as a delicacy: *Helix pomatia*, *H. lucorum*, and *H. aspera maxima*.

Meat Production in Organic Farming

JE Hermansen, K Horsted, and AG Kongsted, Aarhus University, Blichers Allé, Tjele, Denmark

This article is a revision of the previous edition article by JE Hermansen, K Jakobsen, volume 3, pp 1046–1051, © 2004, Elsevier Ltd.

Introduction

Worldwide, there has been a significant growth in certified organic agriculture since the 1990s, and this now takes place in more than 100 countries. Organic agriculture has been one of the fastest growing sectors of agricultural production and the global market for organic products tripled from 2000 to 2009. In 2009, countries like Australia, Argentina, the USA, China, Brazil, Spain, India, and Italy each had 10^6 ha or more under organic management. In Europe, the proportion of organically managed land in 17 of its countries exceeds 5%.

Although other large agricultural areas throughout the world are managed without the use of fertilizers, pesticides, or feed additives without being labeled organic, it is important to make a distinction between the two types of farming. Organic agriculture not only is based on minimizing the use of external inputs but also follows a system and process-oriented approach in directly aiming to promote agroecosystem health including biodiversity, biological cycles, soil biological activity, and prevention of animal diseases instead of curing them. Livestock often plays an important role in obtaining some of these principal aims in organic farming. Thus, livestock production, especially ruminant livestock, forms an integral part of many organic farms. However, the market share of organic meat products – in contrast to milk and egg products – is still very limited.

This article highlights some of the problems and challenges as well as some results obtained in organic meat production, but first some basic aspects of certification and regulation are mentioned.

Guidelines and Regulations in Organic Production

The basic principles and standards for organic farming are formulated by The International Federation for Organic Agricultural Movement (IFOAM). This is an international umbrella organization of organic movements in more than 100 countries. These basic principles are not very detailed but form the basis for legal regulation in local, national, or international bodies. The IFOAM basic standards state, in relation to livestock, that the farming practice should facilitate production of high-quality food in sufficient quantities; interaction with natural systems and cycles in a constructive and life-enhancing way; maintenance of genetic diversity of the production system in order to create a harmonious balance between crop production and animal husbandry; and provide all livestock conditions of life with due consideration for the basic aspects of their innate behavior.

To facilitate trade in organic products on an equal basis, as well as consumer protection, more detailed regulations have been set by national organizations such as the European Union (EU) and the US and more lately by the Food and Agriculture Organization of the United Nations (FAO)/World Health Organization (WHO). The joint FAO/WHO Standard Program and the Codex Alimentarius Commission developed guidelines in 2001 for organic animal production. These guidelines for organic food take into account the current regulations in several countries, EU regulation 834/2007 in particular, as well as private standards applied by producer organizations, especially those based on the IFOAM Basic Standards.

The EU regulation is very detailed and is a good example of how the basic standards of organic farming are implemented. It includes specifications for housing conditions, animal nutrition, and animal breeding, as well as animal care, disease prevention, and veterinary treatment. A key principle is to rely mainly on the management of internal farm resources rather than on external input and, in relation to animal health management, to rely on prevention measures rather than on allopathic medical treatment.

Livestock must be fed on organically produced feedstuffs, preferably from the farm itself. A limited proportion of conventional feedstuffs were permitted within a transitional period but expired on 31 December 2011 (recently postponed by the EU commission). A summary of the special demands is given in **Box 1**.

Disease prevention in organic livestock production is based on the following principles:

- Selection of breeds with abilities to cope with the required conditions, viability, and resistance to disease. Breeds should be selected to avoid specific diseases or health problems that prevail in conventional livestock production. Preference is to be given to indigenous breeds.
- Livestock should be raised in a manner that suits the requirements of the species and promotes a good resistance against disease and infections.
- Application of good quality feeds which, together with application of outdoor areas and grazing, strengthen the natural immune system of animals.
- Securing a suitable space in order to prohibit overcrowding and associated health problems.

Treatment of sick animals should be carried out immediately. Nonallopathic medicine should be chosen before allopathic medicine, if efficient. Preventive treatments with allopathic medicine are not allowed. Medical treatment requires instruction and diagnosis by a veterinarian. The withdrawal time for allopathic medicine is set to twice the length required by veterinary authorities.

In individual countries, the detailed regulations can differ depending on private certification bodies. An example of such

Box 1 Main EU regulations' feeds and feeding

The feeding of young mammals must be based on natural milk, preferably maternal milk, for a minimum period depending on the species

Rearing systems for herbivores are to be based on maximum use of pasturage according to the availability of pastures in the different periods of the year. At least 60% of the dry matter in daily rations is to consist of roughage, fresh or dried fodder, or silage

Roughage, fresh or dried fodder, or silage must be added to the daily ration for pigs and poultry, and for poultry in the fattening period, at least 65% of the feed formula must contain cereals

Only feed materials listed in Annex V of Council Regulation No. 834/2007 whether conventionally or organically produced can be used (a positive list). Furthermore, conventional feed materials of agricultural origin can be used only if they are produced or prepared without the use of chemical solvents. This implies that, for example, soybean meal, the most common protein source in animal nutrition, cannot be used in organic feeds

Antibiotics, coccidiostats, medicinal substances, growth promoters, or any other substance intended to stimulate growth or production shall not be used in animal feeding

No feed components may have been produced with the use of genetically modified organisms (GMOs) or GMO derivatives

Vitamins authorized for conventional animal production under Directive 79/524/EEC must preferably be derived from raw materials occurring naturally in feedstuffs or synthetic vitamins identical to natural vitamins only for monogastric animals

adjustment is the use of antibiotics. In the USA, use of antibiotics in disease treatment excludes the animal from being sold as organic and in Sweden the use of homeopathic medicine cannot be chosen by a veterinarian. Another example is the use of a ring in the sow's nose to prevent rooting. In many countries, this is allowed for environmental reasons, whereas in others (e.g., Soil Association in the UK and Sweden), this is not allowed because it is considered non-acceptable as it prevents the sows from performing their natural behavior.

Pork Production

Some main requirements within the EU as related to pig production are that pigs should have access to grazing whenever weather and ground conditions allow this. If the pigs are housed indoor in barns, access to an outdoor run and special specifications for space requirement (considerably higher than that in a conventional system) are required. The weaning age for piglets should be at least 40 days.

Depending on the prevalent conventional pig production systems, the organic systems vary between different European countries. In Spain, the traditional Dehesa systems have lent themselves to organic conversion fairly easily and the same is true for combined woodland and livestock (silvopastoral) systems in other Mediterranean Countries. Similarly, in the UK, the prevalent outdoor breeding units have been relatively easy to convert to organic production, where farm size and crop rotations have allowed adequate space. In Western Continental Europe, more intensive systems have been converted into organic production by running the breeding stock outdoors during lactation (Figure 1) and keeping finishers in barns allowing pigs access to outdoor pens.

The land required to fulfill the demand for access to outdoor areas differ between countries, often impacted by the local environmental regulation. For example, in Denmark, a farrowing outdoor pen in use during 1 year (supporting 6–7 farrowing with suckling period) requires a size of approximately 1000 m^2 and needs to be free of pigs every second year. Considering the land requirement to be available for pig farming in general due to environmental regulations, this outdoor area for pigs can easily be spaced. In situations where there is no regulation on land related to pig farming, the requirement of outdoor area may be a serious limiting factor. However, a general perception is that the establishment of an outdoor farrowing unit requires far less investment than that of a typical pig building, which must be taken into account for an economic assessment.

Figure 1 In Western continental Europe more intensive systems have been converted into organic production by keeping the SOWs outdoots during lactation.

Good production results in terms of daily gain, and pigs per litter are often obtained in intensive organic systems. However, the longer weaning period means that number of litters per sow and year is lower than that in conventional pig production. Long weaning periods have been hypothesized to impair the welfare of the sow due to heavy weight loss and/or damage to teats and udder. However, Danish experiments showed no difference between a weaning age of 5 and 7 weeks in this matter, probably because the nursing frequency and milk production have already decreased markedly after 5 weeks coinciding with an increase in the piglets' intake of solid feed.

According to surveys from the UK, Denmark, Austria, and the Netherlands, endo- and ectoparasites appear to be the most common concern for organic pig producers. Lameness, injuries, and sunburn are other common problems reported from studies on outdoor pig production. Respiratory diseases, however, seem to be less prevalent in organic than in conventional herds.

Several investigations indicate that growth rate obtained in outdoor systems with finishers on grass can be comparable to the growth rate in indoor production. However, variable feed conversion rates have been obtained. In the summer period, a feed conversion comparable to indoor conditions has been obtained in some investigations, whereas in other periods of the year, or in other investigations, a higher feed consumption per kilogram gain has been reported.

Organic pigs need access to roughage, i.e., grass and grass silage. If high-quality forage is available, pregnant sows are able to cover 50% or more of the daily energy and protein intake by roughage. Lactating sows, however, are able to rely only on fibrous roughage as energy source to a moderate extent if milk production (and the live weight gain of the piglets) is to be maintained. Several investigations have focused on the use of roughage for finishers. For instance, the effect of restricting concentrate on the *ad libitum* intake of clover grass and clover grass silage, as well as on the production results and sensory meat quality, has been investigated.

Restricting concentrate to 70% of *ad libitum* intake on a daily basis resulted in:

- a higher roughage intake (20–30%), but, nevertheless, only amounting 5–6% of total energy intake;
- a lower daily gain (12–16%);
- a lower feed consumption per kilogram gain (10%);
- an increased lean content (1–2%);
- reduced tenderness of the meat; and
- a higher content of polyunsaturated fatty acids in carcass fat depots and meat.

Few direct comparisons between organic and conventional production systems are available and the effects on daily gain and carcass quality reported in literature are conflicting, probably depending on the exact nature of the feed used, genetic factors, and rearing conditions. Combined effects of rearing the growers with access to more space and organic feedstuffs seem to result in more intramuscular fat, a higher fat thickness, and more dark colored meat. In addition, use of more oil-rich ingredients for amino acid supply than used in conventional production may result in an increased level of polyunsaturates in fat, which, in turn, may impair the technological product quality but might improve the quality from a human health perspective.

Cattle and Sheep Production

The importance and characteristics of organic beef production vary widely in different countries. In countries where organic dairy production is highly developed, the major contribution to organic beef production originates from dairy bull calves and culled cows. In other countries, the major contribution comes from extensive suckler herds.

Dairy Cattle

Organic standards require group-housing systems and adequate bedding and tend to limit stocking rates in dairy production. Milk yield per cow is often lowered due to a lower feed intake as a result of the restriction on which feed is to be used. It has been hypothesized that the restriction in feed intake might result in an increased risk of metabolic disorder and poor fertility because the same high-merit genotypes for milk production are often used in conventional and organic production. However, a number of investigations have not been able to demonstrate this. The overall picture is that no well-documented differences in reproduction and health problems (as related to mastitis, milk fever, ketosis, and lameness) exist for dairy cattle.

Beef Production

The intensive rearing of bulls is very limited in organic production. The requirement of 60% forage in the diet makes it very difficult to obtain good production results. Bulls older than 1 year can be housed in a stable with access to an outdoor run throughout the year, but this often puts high costs on the production.

In some countries, the bull calves from organic dairy breeds for these reasons are not raised as organic but sold for conventional rearing (or harvested very young). In other countries, there is tradition for grass-based rearing systems for steers, which fits very well the organic production conditions.

The main concern in such systems regarding production and health are related to infection with endoparasites because no prophylactic use of antiparasiticides is allowed in organic production. Important measures in endoparasite control include pasture management, low stocking density, and early- and late-season feed supplementation.

Extensive Suckler Beef and Sheep Production

In general, extensive suckler and sheep production complies with the aims and requirements in organic production to a wide extent. The organic producers often do not consider animal health problems in such systems significant. External parasites, diarrhea, and mineral deficiencies, although receiving low rankings, are considered the most important conditions in young beef stock.

Although organic dairy sheep production is rapidly growing in the Mediterranean countries, the bulk of organic sheep production in Europe is lamb production in France and the UK. In these countries, similar ranges of lamb mortality, lambing percentage, and ewe replacement rates as in corresponding conventional systems have been reported.

As in beef systems, restrictions on internal and external parasites control with conventional prophylactic antiparasiticides have been recognized as a major constraint to sheep health management. Therefore, establishing proper pasture management options is essential. A key issue here is a better understanding of the prospect of taking advantage of the content of condensed tannins in certain legumes and herbs for the prevention of infection and/or losses as a result of infection with gastrointestinal nematodes.

Broiler Production

For poultry production, the implementation of the organic ideals in the EU regulations includes, among others, a

maximum flock size of 3000 and 4800 for layers and broilers, respectively. These flock sizes are well below flock sizes normally seen in conventional poultry production but still much higher than what can be considered 'natural' flock sizes. The birds should have access to a hen yard corresponding to at least 4 m^2 per laying hen/broiler; coccidiostats cannot be included in the feed; and beak trimming is not allowed.

In organic broiler production, coccidiosis is no longer a major problem due to the fact that vaccination is now allowed. However, prophylactic uses of anticoccidials is banned, but recently, focus on medical plants such as *Artemisia annua* has received attention as supplement to the feed to prevent or control coccidiosis in free-range broilers. The effect of medicinal plants on, for example, parasitic infections such as coccidiosis in poultry still needs to be investigated further.

In those countries where free-range layer flocks have been common, establishment of organic egg production has been relatively rapid, whereas organic broiler production has been much slower to develop, possibly due to the considerable higher price for organic broilers compared with that of conventional broiler products. As the difference in price between organic and conventional is particularly high in broiler products, this might probably deter consumers from buying organic broilers, unless quality of the product is correspondingly higher than that of the conventional broiler products.

According to the EU legislation, ages at slaughter for broilers depend on the growth rate and whether the parent stock is organic or not. In general, the use of slow-growing strains is preferred due to the fact that high growth rates often are positively correlated with different kinds of health problems such as dermal lesions and gait abnormalities. However, the regulation seems paradoxical in the way that a higher harvest age is required for fast-growing than for slow-growing broiler strains in order to motivate producers to use slow-growing strains. Broilers should be of at least 81 days if they are not slow growing, whereas slow-growing broilers can be harvested at 70 days of age. If the parent stock, in addition to the slow growth, is organic, then there is no age limit. In practice, there might be a risk that the use of broiler genotypes with high growth rates compromises animal welfare, which is in contrast to consumer expectation for organically produced broilers.

In the original form, the EU regulations for organic broiler production have been very much inspired by the French Label Rouge concept for broilers, despite the fact that Label Rouge not necessarily needs to be organic. However, the Label Rouge concept still maintains the demand for very slow growing, hardy broiler breeds, which are harvested between 81 and 110 days of age, whereas the EU regulations for organic broiler production allow another definition on slow-growing broilers, which, in practice, means that a slow-growing broiler will still grow faster than broiler strains in the French Label Rouge system. This also means that organic broiler production may vary between the EU member states. For example, organic producers of broilers in France, until now, use similar broiler genotypes as those used in the Label Rouge concept and other free-range systems, whereas other countries, such as Denmark and Sweden, use broiler strains with faster growth that have lower harvest ages and weights. These strains are even sometimes restricted in protein in the diet as they otherwise would grow too fast. This feeding strategy can, in some cases, lead to feather pecking or even cannibalism among the broilers and increase cost of production.

Product Quality

The term product quality as seen from the consumer's perspective covers a range of topics from nutritional, sensory, and functional properties of the product to food safety and the perception of the production methods used in the production process. Because trade with organic products is predominantly market driven, the attitudes and expectations of consumers are very important. Many studies and surveys carried out in Europe have shown that consumers choose to buy organic food because they think that this food is safer and organic production practices are better for the environment and animal welfare.

Nutritional, sensory, and functional properties of meat are very much dependent on the very specific feeding that takes place and the genotypes of the animals. Because these conditions vary much within organic production and within conventional production, the results of different comparisons vary accordingly and there is no evidence of essential and consistent differences in flavor or nutritional qualities between organic products and conventional ones. However, due to a more pronounced reliance on homegrown feed in organic production – a tendency to use other genotypes/strains that may be more adopted to the local environmental – and a less developed framework for management of traditional carcass quality parameters, the variation in organic products is more pronounced, and it is more difficult to obtain a defined carcass quality beforehand.

Perceptions of meat quality of consumers are, among others, strongly related to the geographical and cultural background, and consumers often prefer the meat quality they are familiar with. It has been suggested that long-term exposure to, for example, conventional broiler meat may be an obstacle to the liking of meat from other broiler products. Thus, conventional broiler meat is traditionally very tender, whereas meat from slow-growing broiler breeds used in organic systems may be less tender. However, some studies indicate that some slow-growing broiler genotypes reared in extensive organic production systems develop more tender and juicy meat when slaughter age is close to or has reached sexual maturity. In addition, new studies indicate that other sensory attributes like some taste and aroma attributes are more important to assessors in a sensory panel. Slow-growing broiler breeds with higher harvest ages are often associated with more intensive flavors, which many people perceive positively.

In regard to consumers' health, no epidemiological studies are available. With respect to chemicals, organic agriculture differs from conventional agriculture as it refrains from using synthetic agricultural inputs such as synthetic pesticides, herbicides, fertilizers, fungicides, veterinary drugs (antibiotics and growth promoters), synthetic preservatives, and additives. Thus, potential hazards posed by synthetic input residues are prevented to the extent possible.

Studies carried out to investigate the relative presence of pesticide residues in organic as opposed to conventional products show lower presence of pesticide residues in organic food, although organic food may not be defined as pesticide free. However, the health risk related to pesticides and veterinary drugs are generally considered much lower as compared with microbiological hazards. Also, there is no clear evidence to indicate that organic food is more prone to mycotoxin contamination than conventional food, and there is no evidence, at present, to support the assertion that organic animal food is more or less microbiologically safer than conventional food.

In conclusion, the most central quality parameter is the way of production, which offers some animal welfare and environmental benefits. The quality of individual products per se will be determined by the individual producer and processor.

Conclusion and Perspectives

Comparative production, product quality, and disease and welfare data from conventionally managed and organic livestock farms are scarce. Owing to their limited nature, results are often contradictory.

However, it appears that there are grounds to conclude that many of the concerns predicting serious health problems in organic livestock production have been overstated. However, the fact that animal health situation does not appear to be consistently better on organic than on conventional farms raises further questions to the extent of management and system changes that are actually implemented on livestock farms during a conversion to organic production.

The rearing of pigs and especially poultry is very different in organic systems compared with conventional ones. It seems that the idea of using better-adapted genotypes in organic production, is not really being explored and implemented.

All livestock production is land based in the sense that land is needed to supply feed for the livestock. However, a challenge for the organic production is that more land is needed to support a given meat output due to lower yield of fodder per hectare and often a slightly lower feed conversion compared with conventional production. Although the higher cost related to this in a farmer's perspective is compensated by a higher selling price, which in many cases, in fact, results in a higher net return to the farmer, the increased land use is a concern in a resource perspective.

Glossary

Broiler A meat chicken usually killed at 5–8 weeks.
Brooding Caring for very young chicks often with a heat source.
Commercial enterprise A poultry farm that produces poultry in large numbers using modern methods.
Formulated feed A diet fed that meets the nutrient needs for meat production.
Grower diet A diet fed to meat chickens between 21 and 39 days or longer.
Hygiene The act of maintaining cleanliness.
Insecticides Chemicals that kill insect pests. It should be used with caution by following the instructions.
Litter A material placed on the floor to soak up excreta from chickens in order to keep the ground dry.
Medication A medicine or the act of treating with medicine.
Starter diet A formulated feed given from day 1 to 21.
Virus Minute organisms that can infect chickens and make them sick or lead to death.
Vitamins The essential organic elements in poultry diets for chick growth.

Chicken Meat Production Systems

The commercial intensive chicken meat industry is vertically integrated, incorporating company-owned feed mills, breeder farms, hatcheries, and processing plants. In this model chickens are produced under a contract in which the farmer provides the housing, equipment, litter, utilities, and labor, whereas the company provides the chicks, feed, medication, transportation, and technical/veterinary supervision. A modern intensive farm can comprise 8–40 houses, with each house growing 30–45 000 birds per batch, and birds reaching market weight within 5–6 weeks (Figure 1). Each house will grow 5–5.5 batches of birds annually, with each batch separated by a clean out and rest period.

Over the past several years demand for free-range chicken meat has risen markedly in many developed markets and as a result free-range farms have evolved from small mobile or fixed houses producing 500–10 000 birds/batch (Figure 2) to large sheds of more than 2000 m^2 housing approximately 35 000 birds that have access to shaded and vegetated outdoor areas via hatches or popholes that are open during daylight hours when feathering and weather conditions are appropriate.

Intensive meat bird houses are clear-span structures with litter on the floor and birds running free; cage systems are uncommon in meat bird production. The types of housing for growing meat birds includes controlled-environment houses that are designed to exhaust different volumes of air through the house depending on the weight and density of birds and internal temperature and humidity. Modern houses have full automation that links fans, evaporative coolers, and heaters to appropriate sensors to maintain the required house environment. Some intensive systems do not use evaporative cooling or heaters to control temperatures but do control ventilation.

 doi:10.1016/B978-0-12-384731-7.00028-3

Older free-range chicken meat houses where birds are given access to forage pastures (Figure 2) are often naturally ventilated, relying on the farmers' experience to use heaters or fans to control the house environment. More recent free-range houses incorporate automatic mechanical ventilation and heating. Organic free-range production systems often require that meat birds not have access to forage areas where manufactured fertilizers, herbicides, or insecticides have been used, and not be provided with supplementary feed that contains synthetic additives.

The main management concerns and activities in intensive meat chicken production systems are biosecurity (keeping diseases out), preparing the house for placing chicks, assessing and monitoring chick and bird quality and health during their brooding and growing periods, vaccination, waterer and water management, ventilation, lighting, feeding, catching and transport, dead bird and waste disposal, and improving carcass quality.

Free-Range Systems

The free-range house provides dry litter, food, water, and protection from predators. Incandescent or fluorescent light (up to 12 h per day) is provided to birds to supplement the natural day length according to market specification for the product. Stocking rate in the house and for the range is defined by the prevailing Code of Practice, or determined by members of the local and national free-range associations in conjunction with welfare groups and government authorities. Chickens are reared on litter mostly in houses with open-sides or hatch doors, using gas or electric brooders, and birds will not leave the house to forage for 2 or 3 weeks until they are fully feathered and weather conditions are appropriate.

Free-range allows birds to forage (Figure 3) but there are risks to bird health and welfare, such as predation, fear of predation, exposure, diseases, cannibalism, and poor pasture management.

Adequate natural or artificial overhead cover is provided in the foraging areas to offer birds conditions akin to their native natural habitat, protection from overhead predators (e.g., hawks), and shelter from extreme weather conditions. Pasture is normally rested from poultry for 2 months between each batch and every third year in order to prevent parasitic build up and allow revegetation. If the free-range system is also an organic system, forage may need to be grown without use of manufactured fertilizers, herbicides, and insecticides.

In some organic systems, no synthetic additives are permitted in their manufactured feed and birds supplement their diet by foraging outdoors. 'Organic' is a term defined by law in some countries and organic meat producers are governed by a strict set of guidelines, relating to registration and certification, permitted and nonpermitted ingredients, the environment and conservation, processing and packing.

Sourcing breeds that are suitable for organic or free-range conditions can be difficult due to the underdeveloped nature of these systems, resulting in the use of breeds intended for intensive production. Slaughter age for organic birds may be 8–12 weeks but most modern breeds develop musculoskeletal problems at that age. There are some producers using slower-growing meat strains under contract to poultry companies; these modern strains of birds are often more active and grow slower in free-range systems and it is often claimed they develop a more distinctive meat flavor from consuming flavor-producing grasses, herbs, and insects.

Free-range foraging areas must provide continuous vegetation, shade, and protection from weather and predators, and must drain adequately. Portable houses must be continually moved. Grain crops, legume pastures, grasses, and herbs are good sources of forage for birds. Birds are reared in batches and processing commences by removing the most advanced birds at 5 weeks of age and then finishes with removal of the remaining birds at approximately 8–12 weeks, depending on the market requirement.

Intensive Systems

Housing

For intensive housing of meat birds, considerable thought and planning are required to establish a house and its surrounding infrastructure (Figure 4). Suitable sites must comply with local planning rules, and consideration has to be given to driveways, loading area, feed silos, work room, water supply, power and water supply, electrical systems, lighting,

Figure 3 Free range meat birds resting under shade of tree. Courtesy of Australian Chicken Meat Federation (ACMF).

Figure 4 Intensive chicken meat house. Courtesy of Australian Chicken Meat Federation (ACMF).

building type, insulation, cooling pads, roof system, curtains, sidewall inlets, placement of doors and ramps, computer systems with back-up alarm warning systems, back-up generators, feeders, waterers, heaters, and fans. There are three common house types: naturally ventilated, fan-assisted, and fully controlled environmental houses. Fully controlled environmental houses are designed to exhaust between 0.1 and 12 m^3/h/kg average bird weight of air through a house, and have full automation that links fans to sensors to maintain the required shed environment. Producers increasingly use computerized systems to remotely check and change settings in houses. Modern intensive houses are approximately 16 m wide and can range in length from 95 to 235 m. Optimum length for efficient use of fans, good air movement patterns, and effective evaporative cooling is 10 times the width of the house. Beyond a width to length ratio of 1:12, the ventilation system can be more effective if the house length is divided into half and fans placed at both ends with inlets in the center or vice versa.

Environmental control and automated systems must be adequately alarmed and there must be appropriate back-up systems. For example, a water tank, or an alternative water supply, sufficient for a minimum of 24 h should be made available and the system must include a reliable back-up power supply for force-ventilated houses.

Many older houses are being renovated to eliminate air leaks, upgrade insulation, or to install modern tunnel ventilation and evaporative cooling systems. Many growers are eliminating energy-wasting curtains in favor of solid sidewalls with insulated panel ventilation shutters. To minimize the consequences of back-up generator failure, panels are being installed that can either be easily removed, moved to one side or lifted up to allow natural ventilation of the birds, but the safest and most common option on new farms is a second back-up generator.

Insulation

The value of insulation is generally recognized in cold climates, where it can reduce heat loss by conduction and help minimize fuel usage. However, in warm climates insulation also protects birds from heat stress caused by solar heat gain through the roof. Under-roof insulation is essential in both open-sided and fan-ventilated houses. Even with the best ventilation systems, uninsulated houses can suffer mortality rates of 10–15% or more during times of extreme heat. Types of insulation used in poultry houses include spray-on polyurethane foam, blanket batts, polystyrene sheeting, shredded paper or blown-in mineral wool or fiberglass. External reflective roof coatings or white paints can also provide some benefit. Insulated panel is most commonly used for modern poultry houses and provides the most effective insulation. These panels comprise sheets of insulation covered on both sides by painted metal.

Ventilation

Ventilation requirements for birds change during the growing period, which has an influence on the way a house is ventilated. Most modern houses have several different ventilation systems. The two most common are exhaust fans and sidewall curtains.

Adequate ventilation is vital at all times to provide the birds with a constant and uniform supply of fresh air, and to remove moisture, gases and dust, all of which can carry microorganisms that are pathogenic to birds. Although high air speeds are needed to keep birds cool in summer, the system must be capable of reducing these speeds in cold weather to protect the birds from chilling, while still expelling pollutants. Mixing fans can reduce heating costs by moving the air in the house to achieve a warmer floor and uniform air temperature. The most important indicators used to assess environmental conditions within a house are odor and litter moisture. To maintain an appropriate environment for the birds, the farmer must take into consideration the number and speed of fans, temperature, and humidity. Noxious gases including ammonia, carbon dioxide, carbon monoxide, and hydrogen sulfide need to be kept below 20, 3000, 50, and 5 ppm, respectively, for bird and worker comfort and health.

Types of fan ventilation systems

Fans ventilate poultry houses by either pushing air in (positive pressure), or pulling air out (negative pressure) (Figure 5). A poultry house should be airtight to reduce air leakages and light leakages that can occur through damaged or loose curtains, or joining gaps in sidewalls, end walls, and ceilings. A 30% saving in fuel costs can result by improving house tightness, tested by conducting static pressure measurements. Polyurethane spray-on foam is often used to repair cracks and gaps in houses.

Tunnel ventilation

Tunnel ventilation systems use large exhaust fans to pull air into the house through inlets at one end, often through evaporative cooling pads, then down the length of the house, and out through the fans at the opposite end (Figure 6). When the fans are on, the air moving over the birds helps to keep the birds cool, with the effect increased when the evaporative pads are in use. Tunnel ventilation that incorporates a good minimum ventilation system is more efficient than the fully controlled-environment housing.

Figure 5 Tunnel ventilation fans. Courtesy of Australian Chicken Meat Federation (ACMF).

Figure 6 Meat chickens in tunnel ventilated house. Courtesy of Australian Chicken Meat Federation (ACMF).

Minimum ventilation

Minimum ventilation is used when the temperature outside is more than 1–2 °C lower than that required by chickens for optimum growth and feed conversion. It uses extraction fans to bring fresh air into the house via sidewall inlets at a low rate, which is sufficient to maintain the air quality while retaining enough of the heat generated by the chickens to keep the desired house temperature.

Natural ventilation

Some older houses without fans rely on natural air currents for ventilation through sidewall curtains or shutters. Natural ventilation can be used for growing chickens (3–6 weeks of age) when the ambient temperature is between 16 and 20 °C. The curtains or shutters are opened manually or adjusted automatically with a controller in response to internal temperature.

Heating and cooling

Forced-air furnaces and radiant heating are the two common methods of providing heat to young chicks. Hot air rises and ceiling fans are used to reduce the temperature differential between the floor and the ceiling in the house. Sidewall inlets (minivents) are used to direct air from outside toward the ceiling and this movement then pushes the hot air produced by the furnace to the floor. Radiant heaters provide heat in the form of infrared light to the floor instead of the air. Chicks can locate their desired temperature by moving to the appropriate area of the floor.

Figure 7 Cooling pads and pump. Courtesy of Australian Chicken Meat Federation (ACMF).

The most effective cooling systems are those that work using the air intakes and cool the whole house, such as foggers, misters, and evaporative cooling pads (Figure 7). The pads comprise perforated absorbent materials with water running through them. Orientation and spacing of buildings is another important consideration to reduce the overall heat load. Planting trees around the facility also provides shade and has other benefits such as providing a visual barrier.

Usually chicks are restricted to 30–50% of the house in the first 2 weeks. For newly hatched chicks, the temperature below which they cannot metabolize sufficiently is approximately 26 °C; thus there is a need to provide artificial brooding temperatures of 30–32 °C. This is gradually reduced as the target temperature for older birds lowers to approximately 21 °C. High temperatures (>35 °C) can present serious problems for meat birds, especially when interacting with other factors such as high humidity and high stocking density. As the birds get older, they are more susceptible to heat and cooling becomes more important. For example, 6-week-old meat birds commence panting at 23–26 °C and experience considerable heat stress at 27–29 °C. The ways in which birds can lose heat include (1) standing erect with the wings held away from the body and raising the scapular (shoulder) feathers, (2) vibrating the floor of the mouth cavity ('gular flutter'), and (3) panting. During hot weather, foggers, misters, and evaporative cooling can very effectively reduce heat stress on birds.

Feeding system

Bulk feed storage bins (silos) (Figure 8) are located outside the house and a centerless auger or dragline moves feed to the mechanical feeders that generally consist of 2–3 lines of feeders. There are two main automated feeding systems: pan

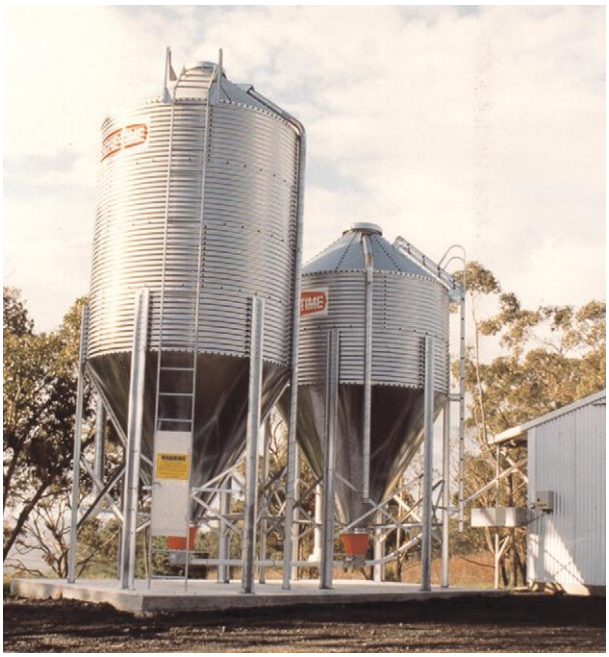

Figure 8 Bulk feed storage bins (silos). Courtesy of Australian Chicken Meat Federation (ACMF).

feeders (1 pan/65 birds) and tube feeders (1 tube/70 birds). The height of the feeders can be altered manually using feeder winches or remotely using switches. Before placement of chicks the feeders are located at ground level, with paper on the ground next to the feeders, and with a crumble feed on the paper for the first few days. This encourages birds to eat and locate feeders. At all stages of production, birds should receive diets with appropriate nutrients and particle size. Feed delivery equipment must be properly maintained and kept at the correct height, with the lip or trough of the pan level with the bird's back. The feed level within each pan is adjusted according to the age of the bird and feed requirements by using a feed flow adjustment fitted to each pan. At the end of the growing period, feeders are raised to the ceiling to allow catching and clean out. Manual feeding systems are more commonly used in older free-range systems, although farmers with newer or fixed free-range housing will use automatic feeding systems.

Drinking system

Birds must have continuous access to good quality water for optimum growth and efficiency. There are four types of waterers; nipple (with or without a drip cup); cup; bell (automatic circular waterer), and trough waterers. Troughs run lengthwise in the house and bell waterers are similar in principle to troughs. Birds drink from cup waterers by activating a small trigger that releases water into the bottom of the cup or from nipple waterers by reaching up and activating a trigger pin that releases water into the bird's mouth. To maintain the correct water pressure, a regulator is used in the drinking line and cable winches enable adjustment of the waterer height as the bird ages. Pressure in the nipple drinker system is reduced in the first few days to encourage chicks to peck at the drops on the nipple. Lighting is kept bright for the first few days to encourage birds to find water and learn to drink. Problems for waterers include air locks, leaks, uneven floors, and contaminants. Water meters can be used as a management tool to measure water intake, which can help diagnose production and health problems. Drinking water should be filtered unless prefiltered mains water is in use and kept cool in hot weather.

Lighting

There are usually two lines of dimmable lighting fixtures in a house, arranged so that light intensity at floor level is at least 20 lx for the first 3 days and 5–10 lx thereafter. The primary aim of artificial control of day length for meat birds is to increase growth rate by increasing feeding time. The lighting program determines when and for how long birds have access to the feeders. In recent years many poultry producers have changed from incandescent lamps to more energy-efficient and longer-lasting fluorescent lamps. Lighting programs vary widely from company to company and depend on the strain of bird used, housing type (naturally ventilated versus controlled environment), geographical location, and season. A small dark period is sometimes used to adapt birds to darkness in the event of a power failure. In some instances meat birds are generally given restricted access to feed to slow growth, in order to avoid physiological problems (e.g., leg weakness and heart attack) in their growing cycle. This is achieved by providing birds with a period of 4–14 h of darkness each day. To reduce power costs and improve feed conversion, intermittent lighting programs consisting of varying periods of light and darkness can be used. These light regimes tend to disrupt labor management due to the short periods of light/dark cycles and can only be used in lightproof housing. In dark-curtain tunnel houses light levels can be kept very low during the black-out periods.

Litter

Litter management is important for producing high-quality birds and for minimizing health problems. Respiratory infections resulting in lung lesions are increased by contaminants in the air; the most important being dust, bacteria, and ammonia. New poultry housing technology, such as nipple waterers with splash cups, mechanical ventilation, and moisture sensors that continually monitor litter moisture levels are providing the ability to more closely regulate litter moisture by varying air exchange rates in poultry houses. Dry litter certainly leads to easier handling at the end of the batch and less odor problems. It is common practice for broiler companies to include enzymes (mainly xylanase and lipase) in diets to minimize the possibility of wet droppings and to reduce excessive litter moisture.

A variety of litter materials are used, including wood shavings or sawdust, chopped straw, shredded paper, rice hulls, and sand. Collection by a contractor or an agreement with a fresh litter supplier or neighbor wanting manure as fertilizer for crop, viticulture and horticulture production is the normal means of disposing used litter. However, there is concern regarding heavy metals and pathogens in litter along with risk of excessive nutrients causing environmental harm, particularly to waterways. Alternative methods of utilizing the spent litter are via composting or burning. Poultry litter can be incinerated in furnaces to generate electricity either on-farm or

on a large scale at a regional location subject to local regulations concerning emissions.

The most environmentally friendly approach is to use an integrated biosystem. Methane can be generated using anaerobic digestion technology and utilized to generate power or heat, depending on economic feasibility to run such systems. *Gasification technology is* also being considered using *incomplete combustion* of litter *in a limited oxygen environment.* Stormwater *or* wastewater from house cleaning can be recycled after chlorination for use in cooling pads and for washing out.

Dust is uncomfortable for staff and birds and high levels can also lead to equipment failure and/or electrical fires. Factors that influence airborne dust levels include litter composition and moisture levels, bird activity, stocking density, and the amount of dust on surfaces and floors. Particles that affect health are generally in the invisible range (dried feces, feathers, skin, and litter) and in birds particles of 3–7 μm are deposited in the anterior region of the respiratory system whereas smaller particles are deposited throughout the rest of the respiratory system. Their adverse effects arise because they carry or incorporate bacteria, fungi, and gases. Planting trees around broiler houses has been demonstrated to effectively reduce pollutant emission and improve odor dispersion. The trees filter dust, feathers, odor, and noise and direct the pollution plumes upwards and improve dispersion. Vegetation cover around broiler farms also provides shade on buildings resulting in reduced thermal load on the sheds and a reduction in the electricity and water costs to cool the sheds in summer. Tree barriers placed in front of outgoing air plumes (especially from tunnel-ventilated sheds) can reduce the likelihood of cross-infection via airflow between different sheds, as airborne dust and pathogens attached to the dust particles will be filtered out by the barriers on impact.

House and bird management

A clean house before chick placement is an essential management task that impacts on both production and welfare. A clean house reduces levels of pests, parasites, rodents, insects, mites, roundworms, coccidia, other microbial pathogens, and dust. Grass and lawn areas surrounding the house should be cut regularly and unwanted equipment discarded to reduce build up of vermin. In commercial production, a contract cleaning crew is often used to clean and sanitize the house. After each batch of chickens, old litter is removed from the shed and cobwebs and dust are washed off walls and ceilings. An appropriate disinfectant is then used on walls and equipment. Cresols are often used as floor disinfectants, chlorine compounds for relatively clean surfaces, synthetic phenols for the floor and equipment, and quaternary ammonia compounds for walls. All feed residues are removed from the shed and the drinking lines flushed and sanitized.

Birds are placed within 8 h of hatching, depending on the distance of farms from the hatchery. Day-old birds are delicate and require gentle handling at placement. They are normally placed close to the waterer lines to encourage them to locate water as quickly as possible (Figure 9). A skilled farmer can tell from the appearance of birds whether they are healthy. Careful observation of birds in the first few days is essential to ensure their health and make sure that an appropriate thermal environment is provided. Maintaining a high-health status is essential and vaccination programs are used to prevent some diseases. During the first week there are normally 4–6 inspections per day and 2–3 daily inspections thereafter.

Figure 9 Day old chicks next to drinkers. Courtesy of Australian Chicken Meat Federation (ACMF).

To ensure that body weight is meeting the target for both growth and evenness, a sample of birds is weighed regularly after week one to determine the coefficient of variation, which is an indicator of the uniformity of the flock. An electronic scale with a weighing platform is located in the shed and records the weight of birds automatically when they stand or sit on the platform.

Recommended stocking densities for broilers vary around the world, with a range from 28 kg m^{-2} in summer to 40 kg m^{-2} in winter depending on the capability of the ventilation system. A high stocking density may place physical restriction upon movement; distance traveled decreases with age and with increasing stocking density.

Removal and correct disposal of dead/culled birds are important to prevent build up of pathogenic microorganisms, transmission of disease to healthy birds, and odors. Common methods for disposal include contained composting onsite or freezing and subsequent regular collection for off-farm disposal, burial in properly covered pits, or on-farm incineration. Composting is done in rotary or sealed containers, which are aerated mechanically, or in piles of litter.

Broilers are often caught at night for slaughter the following day. A pick-up crew comprises 6–10 catchers and a forklift driver, who load up to 7000 birds in containers onto a semi-trailer. Feeder and drinker lines are raised, lights are dimmed to keep the birds calm, and portable netting may be used to contain and minimize disturbance to birds. The catchers pick-up birds, hold them by one or both legs, and place them in containers. Some companies utilize mechanical harvesters to automatically catch birds and transfer them to containers. The lines that are raised depend on the house layout and the percentage of birds taken for processing. If it is a small pick-up, some farms may raise the center line of feeders and take the birds from the center of the house. If it is a single sex pick-up in a house where male and females are grown in separate halves of the house, the feeders and waterers in that half of the house will be raised. It is common practice to pick-up birds by 5 a.m. and to transport birds to the processing plant within 2 h; however, if the weather is hot, pick-up should be finished by dawn and birds transported immediately.

The major risk to birds from the time of pick-up are overheating or chilling. In hot weather, this is minimized by pick-ups occurring mostly in the late afternoon/evening/night when the thermal load is reduced. There are some recommendations for fully enclosed, ventilated, and alarmed trucks to allow birds

to be safely transported during the day in cold or hot weather without exceeding or going below their thermal limits.

Conclusion

The intensive chicken meat industry uses modern technology in all aspects of housing and management to produce chicken meat at least cost. Alternative production systems use some of the technical developments made in poultry housing to improve bird management and reduce cost of producing free-range meat chickens.

Glossary

Common Agricultural Policy (CAP) It is a system of agricultural subsidies existing in the European Union and available to all Member States (28 countries as of 2013).
Cysticercosis Parasitic disease caused by the larval stage of some cestodes of the *Taenia* genus.
Food and Agriculture Organization of the United Nations (FAO) A United Nations' agency aiming to improve food security, food safety, and reducing rural poverty.
Maasai Seminomadic ethnic group that is found in areas of Kenya and Tanzania.
Outdoor systems Production system also described as extensive, which requires lower capital investment for housing and where food producing animals are allowed outside access, including contact with soil and growing plants.
Pastoralism A production system widely used in areas with a low availability of natural resources (water and pastures), and usually has a nomadic component.
Trichinellosis Zoonotic parasitic disease caused by encysted larvae of *Trichinella spiralis* in striated muscle in humans.
World Organisation for Animal Health (OIE) An intergovernmental organization responsible for improving animal health, animal welfare, food safety, and biodiversity worldwide.

Introduction

The production systems currently in use for raising animals for meat production are not homogeneous across the world. Differences can be found among countries, and even among regions of a country. This variability is not influenced by a single common cause, but it is multifactorial (geography, climate, culture, and political factors).

Because some animal species are more suitable for specific terrain conditions than others, and there are space restrictions for animal production (competition for human living space, crop production, etc.), geographic conditions are relevant when analyzing production systems. For example, Argentina (pampa region) and Brazil (central states) have large and fertile areas that are used for extensive production of cattle (Table 1). However, small countries, such as the Polynesian islands, due to the limited areas available for animal breeding, rely mostly in raising pigs and small ruminants (Table 1). The same is true for some Mediterranean countries where their abrupt terrain is more adequate for small ruminants than cattle (Table 1).

Climate can also be a driver in the animal production method chosen and in the species more suitable to be raised. For example, countries located in North Africa will be able to raise mostly sheep and goats, which are considered to be more 'rustic' animals and will be able to better endure the harsh environmental conditions of the Sahara (Table 1). However, the Sahel region has higher annual precipitations, and hence grassing areas can be found that can support cattle as well as, in general, a higher number of livestock (Table 1).

Cultural factors play an enormous role in the way in which animals will be raised and in how animal products will be used. Certainly, raising cattle, pigs, or small ruminants is performed mostly with the intention of obtaining a food product for human consumption (meat or milk) as a result, but the fact that an animal will be raised for production does not necessarily mean that it is intended to be harvested.

An example of cultural differences in animal production is India, where cattle are considered sacred for the Hindu religion. Cattle in India is used mostly for milk production, and most of the owners will have only a small number of animals. Additionally, several states in India have outlawed the opening of cattle slaughterhouses. Nevertheless, in India there are a large number of people who do not profess Hindu religion and they will be open to beef consumption. This poses a problem with animal welfare, as cattle will have to stand long hours of transport in order to reach states where cattle abattoirs are allowed to exist. At the same time, because cattle have not been bred with the intention of meat production, meat quality and meat yield are poor, resulting in a low economic return.

Pig production is another example where cultural factors influence animal production. In pigs, genetic selection has improved their feed conversion, and most of the commercial production will be driven by intensive indoor production systems. However, though pigs can get a commercial weight faster than cattle and have a more desirable meat yield, due to religious factors, pig breeding is almost inexistent in some areas, such as North Africa and Middle East countries (Table 1).

Political factors have also influenced animal production. For example, the Common Agricultural Policy of the European Union (EU), as well as the subsidies given by the New Zealand (NZ) government in the 1970s, did encourage animal production and increased competitiveness of the EU and NZ in the world meat market. Though some countries still give economic incentives, these have been reduced or eliminated in the EU and NZ, pushing producers to increase profitability by

Table 1 Number of livestock (cattle, pigs, sheep, and goats) per geographical area

genetic selection or changes in management. Political decisions restricting markets can also affect production, as it happened with Argentina's restriction to beef exports in the middle of the last decade, which resulted in a change of use of land with farmers stopping beef production, thereby reducing the Argentinian cattle stock due to lower returns they received in the market.

Animal production is closely related to food security, and that concept is linked to animal welfare, animal health, and food safety. Hence, although some countries or economic blocks (such as the EU) have a strong legislation on the protection of animal welfare, these regulations are always linked to the production of safe and affordable food from animal origin for human consumption.

According to the World Organisation for Animal Health,

> "an animal is in a good state of welfare if (as indicated by scientific evidence) it is healthy, comfortable, well nourished, safe, able to express innate behaviour, and if it is not suffering from unpleasant states such as pain, fear and distress."

That definition also includes that

> "good animal welfare requires disease prevention and veterinary treatment, appropriate shelter, management, nutrition, humane handling and humane slaughter/killing."

Overall, animal welfare is a very important factor to consider for every different animal production system because high levels of welfare will reflect in a better production output. But, to decide what is appropriate welfare is not always easy and it will depend on the way in which all aspects of animal production are assessed. For example, arguably in developing countries where pastoralist production systems are in use, animal welfare might have lower standards than in developed countries because animals may not be provided with the same high level of biosecurity or animal health preventative management measures (i.e., vaccination). Nevertheless, pastoralism might allow animals to express more of their natural behavior and have lower levels of stress than animals raised in intensive production units.

Cattle Production Systems

Cattle for meat production are bred mostly in extensive production systems (Figures 1 and 2), in areas with availability of large grazing lands. Some countries use intensive systems, or a combination of both, intensive and extensive systems, where feedlots are normally used for the finishing of the animals after raising them in pastures (Figure 3).

Though most of the beef cattle are bred in extensive systems, it does not mean that beef cattle are raised only in large

Figure 1 Beef cattle grazing in the Peak District, Derbyshire, UK.

herds. Beef production is largely intensified or concentrated in many countries, and still traditional production systems are in use (Figure 4).

Figure 4 Cattle in a traditional production system, Linares, Maule, Chile.

7	Pakistan	Russia	New Zealand	Indonesia
8	Mexico	Mexico	Pakistan	Mali
9	Colombia	France	Ethiopia	Mongolia
10	Australia	Poland	South Africa	Tanzania

The total number of cattle kept in the world is over a billion animals (Table 1). Regarding distribution of cattle, the Americas have the largest proportion (36% of world total), followed by Asia (34%), Africa (17.6%), Europe (8.65%), and Oceania (2.8%) (Table 1). In fact, cattle distribution is not homogenous, and only 10 countries (6 of them in the Americas) concentrate nearly 60% of the estimated world cattle population (Table 2).

Cattle, nevertheless, are not necessarily bred for meat consumption, because in some countries cattle could have a higher economic value in dairy production, or as working animals (transport/field) (Figure 5). Nevertheless, at the end of their production life most of the dairy and working cattle will also be used for meat consumption. But, as that is a secondary use for these animals, management, feeding, genetic selection, etc. are not focusing in getting high-value meat or high yields. A clear example of that is India, which possess the world's second largest cattle population (Table 2); however, the level of beef production in India (world number 11) is below Germany (world number 10), even though the latter has a cattle herd size equivalent to only 6% of the one in India. One of the reasons for that differential is because a large segment of Indian population professes Hinduism, a religion that considers cattle as sacred, meaning that beef consumption is forbidden. Cattle in India are used mostly for milk production

and for work, and though some beef is produced for local consumption, most of it will go for the export market albeit. However, owing to the previously described factors, it will have poorer yields when compared to net beef producing countries.

Brazil, Argentina, and Uruguay are some of the most important players in beef international trade, and although part of their agricultural sector still rely on animal work, a large percentage of their economy depends on exports of agricultural products, including beef. Hence, nutrition, farm biosecurity, animal health and welfare, as well as traceability are of great relevance for them. Cattle in these countries are raised mostly in extensive systems. But, although the availability of large grassing areas gives them an advantage by allowing them to sustain large herds, for a long time they were subjected to restrictions for international trade due to problems to control notifiable diseases (specifically foot and mouth disease (FMD)), and lack of traceability. Nowadays, the progress made in herd health status, the negligible risk status for some zoonotic diseases, as well as improvements in management and animal welfare have allowed these countries to open new markets.

There are threats for beef-producing and -exporting countries. One of the most critical is the competition for the use of land. The demand for bioenergy production has resulted in many areas previously used for grazing cattle to be turned instead into areas for crops, hence reducing the animal load that the countries can sustain. The use of grains for bioenergy also pushes higher the prices of animal feeding, affecting especially intensive production systems. All that has translated into a reduced world livestock number, lower returns for the beef farming sector, and higher meat prices for consumers.

Finally, pastoralism is still an important production system used in large areas, particularly in developing countries. More than half of the cattle in Africa is located in Eastern Africa (Tables 1 and 2), where pastoralism is one of the most common cattle production systems. However, as for the case of India, a large proportion of their cattle is not necessarily kept for beef production. The reason for keeping large herds relies on cultural factors, as for some communities, such as the Maasai, ownership of cattle represents a symbol of status; hence the larger the herd, the more important the person will be in his community.

Owing to reduced human intervention when compared with commercial beef production systems, pastoralism arguably can offer a better state of welfare for the animals. However, animals in pastoralist systems are also more susceptible to environmental changes, such as droughts, which regularly affect the East Africa region (as in 2010–11). These systems are also exposed to a higher risk of diseases because of lack of immunization or due to exposure to wild reservoirs which maintain the disease (i.e., FMD in wilder beast and buffalo in some areas of Africa).

As a result, animals that do go to beef market might not have adequate conformation, have a poor yield, or they might have a high percentage of rejections during postmortem inspection.

Regardless of the problems previously described, without a doubt, pastoralism is essential for food security in isolated, impoverished communities. Keeping cattle allows them to self-sustain and gives them potentially a source of extra income in case of need. Lack of quality and safety, however, mean that cattle raised in this system cannot currently become an important player in the international beef market.

Sheep and Goats Production Systems

As for beef cattle, most of the small ruminant production is carried out in extensive systems. Sheep production for meat is especially found in extensive systems and can be found either in large grazing units (Figure 6), or small-/medium-size units (Figure 7). Regarding goat production, most of it is done in small units (mostly for milk production) and in pastoralist systems.

The total number of small ruminants in the world is approximately 2 billion animals (Table 1). Regarding distribution of sheep, Asia has the largest number (44.4%), followed by Africa (24.5%), Europe (12.2%), Oceania (10%), and the America (8.9%). For goats, Asia also has the largest number of animals (65.6%), followed by Africa (31.6%), the Americas (4.3%), Europe (1.9%), and Oceania (0.6%).

Figure 5 Cattle as working animals in Chennai, Tamil Nadu, India.

Figure 6 Sheep grazing in the Peak District, Derbyshire, UK.

Figure 7 Sheep in the Arauco province, Chile.

From the species covered in this article, the combined number of small ruminants (sheep and goats) represents the largest number of food producing red meat animals worldwide (Table 1). Owing to their more resistant nature to environmental changes and lower nutritional requirements, compared with other farm animal species, small ruminants are mostly kept in developing countries where environmental conditions are less suitable for keeping cattle, access for feeding for an intensive system is more difficult, or there are cultural issues for pig production.

Although most of the small ruminants are farmed in extensive systems, there are a large number of sheep and goats that are raised in pastoralist systems in Asia and Africa (Tables 1 and 2). In these areas, most of the small ruminants are kept as a source of milk. The production of meat is usually the result of the slaughtering of old females and males, which are surplus to the dairy herds.

Although mostly not produced in a commercial setting, sheep and goats kept in pastoral systems provide a steady source of protein for the diet of a large percentage of impoverished and transient population. This is particularly important when considering goats in Africa, where they represent, proportionally, the largest share of food-producing animals for the continent (34% of the red meat animals species in Africa are goats (Table 1)), and there is approximately one goat for every four people.

Traditional sheep and goat breeds in Africa show more resistance to the mostly dry environmental conditions where they are bred than their European counterparts. However, as with other species, a pastoralist system does have constraints in animal health, nutrition, and management. Certainly, in order to increase the availability of food for these communities as well as to increase the chances to access the markets and get better returns, genetic improvement would be needed; however, genetic improvement on its own is not enough when the other limitations still exist.

Meat production from small ruminants as a surplus of dairy production is not only restricted to pastoralist systems but it is also true for some developed countries that rely mostly on intensive and semiintensive systems for small ruminants' production. Here, housing, general management, feeding, and genetic improvement are essential. An example is Cyprus, where climatic conditions and landscape do not provide natural grass areas. In that country, the agricultural sector focuses in milk production in order to provide fresh liquid milk for human consumption as well as for cheese production for local consumption and exports. Because of cultural preferences, in Cyprus, approximately a third of the raw milk produced comes from sheep and goats. Males are used for meat and are normally harvested at a more tender age (3–5 months) than in meat production systems. Genetic selection and management interventions target better milk yields rather than meat production.

Table 3 Indigenous production of meat

Rank	*Beef*	*Pork*	*Lamb*	*Goat meat*

2	Brazil	USA	Australia	India
3	China	Germany	New Zealand	Nigeria
4	Argentina	Spain	UK	Pakistan
5	Australia	Brazil	India	Bangladesh
6	Mexico	Vietnam	Turkey	Iran
7	France	Canada	Syria	Mali
8	Russia	Russia	Algeria	Indonesia
9	Canada	Netherlands	Russia	Niger
10	Germany	France	Nigeria	Ethiopia

However, Australia, NZ, and the UK are three of the most important players in lamb production at world level (Tables 2 and 3). They have large sheep herds that are intended for meat production, and use mostly extensive sheep farming methods, with large herds, and high seasonality for their production. In the past, the profitability of sheep farmers in these countries depended largely on wool prices, but current meat prices are the drivers for sheep farming. Genetic selection, nutrition, innovation, and animal health among other factors, have been pivotal for them to keep competitiveness in the international meat market.

Although developed countries using extensive and intensive commercial production systems do not face as many challenges as pastoralist systems, because they can control better animal health risks, environmental impact, such as CO_2 print, presents new constraints. Small ruminants are not as efficient producing meat as pigs and poultry, meaning that, for similar meat yields, CO_2 production in sheep farming is higher. That is particularly critical when legislation in developed countries is targeting the reduction of CO_2 emissions, and consumers are willing to pay for environmental friendly produce.

Pig Production Systems

Pork has become a very popular meat and a very good source of animal protein for human diets. A factor associated with pork becoming so relevant in the international meat trade is that pig production cycles are shorter than the ones for cattle and small ruminants, meaning that production improvements related to changes in management and genetics can be obtained faster.

The total number of pigs in the world is approximately 1 billion animals (Table 1). Regarding distribution of pigs, Asia has the largest proportion (59.8%), followed by Europe (19.5%), the Americas (16.9%), Africa (3.3%), and Oceania (0.5%).

Several developed countries are currently using outdoor systems (Figure 8) for pig production. However, most of the world's commercial pig production is carried out in intensive large indoor units (Figures 9 and 10). Also, it is possible to find small producers, either owning small commercial units or subsistence farmers owning backyard pigs.

As with cattle and beef production, the world distribution of pig population and pork consumption is influenced by several factors, with religion being one of the most relevant. For some religious groups, pigs are regarded as 'dirty animals,' hence in some countries pork is a forbidden meat for the majority of the population. Pigs are only bred for meat production, and so the relevance of pig breeding in areas where pork is not consumed is either low or negligible.

The relevance of religion in the world distribution of pig farming can be appreciated in Table 1. The North African region accounts only for 0.09% of the total African domestic pig population. In Asia, the continent that accounts for more than half of the world pig population, the production concentrations is in the Eastern and South Eastern subregions, whereas regions with a majority of Muslim population, such as Western Asia, accounts only for 0.15%, and Central Asia represents 0.26% of the total for the continent.

Although low in numbers, pig farmers can be found in countries with a majority of Muslim population. However, pig production in these areas is generally, but not always, confined to small communities from other religious groups, with pigs bred in small, mostly backyard production units. The method of breeding pigs in these regions and the limited resources available can have a detrimental effect on animal health and welfare and also affect human health. For example, in these countries, there is a lack of veterinary professionals trained or with experience in treating/identifying pig diseases, there is not enough expertise in order to identify management problems and suggest solutions. They also lack medicines and vaccines specifically to be used in pigs; they have problems with biosecurity and poor access to genetic improvement. Also, the higher level of exposure of pigs to zoonotic diseases, linked to the lack of official ante- and postmortem inspection (home killing), can result in a higher risk of human foodborne outbreaks.

Problems in pig production related to animal health and welfare are not restricted to countries where pigs are not raised commercially. China, the world's largest pig producer, has been involved in several problems in the present year (2013). Pork has been sold from carcasses that were intended to be collected by the government for disposal after dying on farm; at the same time approximately 20 000 pig carcasses were found floating in Huangpu river in Shanghai. These situations do not only result in human health risks, but also generate public scare, and affect the pig industry as a whole as the consumer reduces the demand for pork. Additionally, it does raise concerns about the morality of pig industry and the intensive production system.

Out of the 10 countries with the largest pig herds in the world, 5 are the EU member states (Table 2); the same applies to the ranking of the largest pork producers (Table 3). These

Figure 8 Outdoor pig fattening unit, Parral, Chile.

Figure 9 Indoor pig fattening unit, O'Higgins region, Chile.

Figure 10 Sow and piglets in intensive pig production, O'Higgins region, Chile.

countries use intensive pig production systems either indoor or outdoor. The high level of biosecurity used and the strength of their veterinary services has successfully helped to eradicate most of the diseases that produce a negative impact in international trade, animal health, and human health. Diseases, such as trichinellosis and cysticercosis, do represent a negligible risk in these systems, and new cases mostly appear only in impoverished areas where backyard pigs are still kept, or associated with wild boar hunting.

To protect animal health and welfare current the EU legislation has strict requirements for breeding pigs in intensive systems. For example, piglets cannot be weaned before 28 days of birth, and males cannot be castrated without using anesthesia and veterinary supervision in piglets older than 7 days. Additionally, from 1 January 2013 there is an EU-wide ban on the keeping of sows in close-confinement stalls from 4 weeks after service.

Higher pig welfare standards result in lower loses due to diseases and a better final product. However, every intervention in the system does have an associated cost. These costs make the production of pork more expensive in highly regulated countries or economic blocks as the EU than in countries where strong legislation in animal welfare might not be available. Additionally, there is a high cost burden associated with feeding costs, and, as it has been discussed earlier in this article, the current high price for grains affects intensive production systems.

Overall, due to genetic selection, pig farming is a very efficient way to produce meat for human consumption. There are threats that can affect the industry, such as the use of grains in pig feeding when these could be used for human diet otherwise. However, the flexibility and variety of systems that can be used in pig farming in order to fit the local resources, as well as the public demands, make this species a very good choice regarding food security.

MEAT-BORNE HAZARDS, CONCEPTS AND METHODS FOR MITIGATING RISKS RELATED TO

KDC Stärk and JA Drewe, Royal Veterinary College, London, UK

Glossary

Attribute Characteristic that can be quantified during an evaluation of a surveillance system. Examples of attributes include cost, benefit, sensitivity, and timeliness.

Coverage Proportion of the population of interest (e.g., cattle on farms in a certain region, or beef carcasses at an abattoir) that is included in the surveillance activity. A high coverage is particularly important in surveillance for the early detection of exotic or new (emerging) diseases.

Evaluation Systematic and objective assessment of the relevance, adequacy, progress, efficiency, effectiveness, and impact of a course of actions, in relation to objectives and taking into account the resources used.

Hazard A pathogen, substance, or activity that has the potential to lead to adverse health consequences. In this article, only hazards relating to meat are considered. Negative health consequences in both livestock and consumers are relevant.

Representativeness Extent to which features of the population of interest are reflected in the surveillance data that are collected. Features may include: herd size; herd type (e.g., breeding, fattening, milk, and meat); age; sex; and location. A surveillance system that is representative accurately describes the distribution of a hazard in the population by place and animal. Bias reduces as representativeness increases.

Risk Probability of occurrence of an adverse event and the magnitude of the resulting consequences.

Risk-based surveillance Use of information about the probability of occurrence and the magnitude of the biological and economic consequence of health hazards to plan, design, or interpret the results obtained from surveillance systems.

Sanitary status The infection or disease status of a country, compartment, or region according to international standards and relevant for international trade. In principle, only animals and goods from areas of the same status can be traded or from units of higher status to lower status, but not the other way round.

Surveillance Resource-using activity involving the ongoing collection, collation, analysis, and communication of health-related events in order to inform decision making and to trigger targeted intervention, typically involving a defined threshold for action, with the aim to offset negative effects.

Introduction

Meat-borne hazards can have a range of negative effects. Depending on the biology and epidemiology of the hazard, they can cause subclinical or clinical disease in livestock and subsequent losses due to suboptimal growth or production. Hazards can also reduce the suitability of meat for certain products during processing or lead to cross-contamination as a consequence of hygiene failures. Perhaps most importantly, meat-borne hazards can cause illness in consumers ranging from subclinical infection to severe disease and even death. Pathways of infection might be complex if other foods are contaminated and result in indirect infection.

In order to assess such negative effects, risk analysis has become the method of choice for industries and governments, particularly in the context of international trade. A key input into the risk assessment component of risk analysis are data originating from monitoring and surveillance activities. Knowledge of the pathways of pathogen transmission and factors affecting pathogen survival, growth, and spread are essential if effective risk management strategies are to be developed. Risk management can involve a range of interventions targeted at pathogen reduction, inactivation, or elimination. To assess the success and viability of risk mitigation, surveillance and intervention have to be considered jointly because both are resource-using activities. Therefore, the most efficient balance of surveillance and intervention will include consideration of both the effectiveness and the economic aspects of a strategy.

In this article, concepts and methods of mitigating risks related to meat-borne hazards will be described and discussed. This will cover both surveillance as well as intervention. Hazards are highly diverse. Individual hazards, including microbiological hazards such as *Salmonella* or chemical hazards such as dioxin, are covered in more detail in separate articles. Here, we are considering the generic concepts and methods used in the design, implementation, and evaluation of hazard mitigation. We will use selected examples to illustrate how these may be applied in the context of meat-borne hazards.

 doi:10.1016/B978-0-12-384731-7.00217-8

Concepts of Hazard Mitigation

Mitigation = Surveillance + Intervention

Owing to the link between surveillance and intervention, decisions need to be made as to how best to divide resources between them. Limited budgets mean that resources spent on surveillance will not be available for interventions and vice versa. To dedicate more efforts to surveillance might be desirable as it may lead to early detection and, therefore, minimize costs related to interventions. Alternatively, surveillance may be costly, for example, if a hazard is very rare, and it may be preferable to save resources for interventions if and when needed. For both surveillance and intervention, there will be several options for the design and selection of technology. In the selection of the most suitable components, both effectiveness and costs need to be taken into account. Such considerations require the use of economic concepts.

A second consideration relates to the mitigation objective. Although it may be feasible to achieve a significant reduction in the risk related to a meat-borne hazard, to eliminate it entirely from the production chain might be unrealistic. For example, hazards such as *Campylobacter*, which have environmental or wildlife reservoirs, will be expensive if not impossible to eliminate. The choice of objective of mitigation, therefore, will also have to consider the biology of a hazard together with the feasibility of surveillance and the efficacy of interventions.

Responsibilities

Mitigation programs for meat-borne hazards can be managed and implemented at different levels. For some hazards, surveillance and intervention are government-led. This is typically the case for hazards of public health significance, either because of their frequent occurrence (e.g., heavy metals) or because of their severe health consequences (e.g., prions). For such hazards, mitigation will be predefined and compulsory and the responsibility for design and implementation lies with government. Depending on government structures, some mitigation activities may be delegated to health services or industry. For example, *Salmonella* surveillance in pigs is coordinated and implemented by industry in several European countries, with targets provided by governments. In case of under-performance of such programs, penalties will be implemented by governments.

Mitigation for less severe hazards is often the responsibility of meat producers themselves. Typically, such hazards pose a smaller risk to public health, are less easily transmitted by meat, or the consequences of exposure are less significant (or uncertain). For example, paratuberculosis has been discussed as a possible public health hazard but due to continuing uncertainties, mitigation programs are currently mainly industry-led. Similarly, risks related to antimicrobial resistance continue to be debated and mitigation in most countries is currently mainly based on codes of practices rather than compulsory legal interventions.

Legal Frameworks and Standards

Compulsory hazard mitigation programs require a legal basis to achieve the desired coverage. This is provided by the competent authorities in a country, typically the Ministry of Agriculture and the Ministry of Health. Legislation is also developed in an international context because meat is often traded freely between countries. In order to assure quality and safety of products, international standards are developed by the Codex Alimentarius Commission and the World Organisation of Animal Health (OIE) on behalf of the World Trade Organization. These standards define minimum levels of surveillance and the required and permitted intervention options. They also define the minimum sanitary status required for a country, compartment or zone to participate in international trade. Risk analysis is the method of choice used to establish such standards.

Both public health and animal health concerns can trigger trade restrictions. For example, foot-and-mouth disease (FMD) is highly contagious for cattle and pigs but not a zoonosis. As the virus can survive in carcasses, trade from infected zones or countries is restricted because of the animal health risks. Another example is *Salmonella* in poultry meat. Some countries have eliminated this pathogen from their poultry chains. To prevent new incursions and to assure public health, imported poultry is also required to be *Salmonella*-free.

Possibly the most stringent and comprehensive international standards ever developed in relation to meat relate to the control of prions in beef (Box 1). The relevant articles of the Animal Health Code developed by the OIE provide detailed requirements for both surveillance as well as intervention activities.

Surveillance Systems

Level of Surveillance and Mitigation

Surveillance can be implemented at local, regional, or even global level. This will be closely related to who will use the surveillance information and the anticipated method(s) of

Box 1

Bovine spongiform encephalopathy (BSE) is a severe degenerative disease of ruminants caused by prions. The disease was first identified in the late 1980s and subsequently led to major trade restrictions of beef which still persist in some regions. Clinical signs are not highly specific and cases can only be confirmed postmortem. Owing to the low incidence of BSE, risk-based surveillance designs are used. These focus on high-risk population strata such as fallen stock, emergency slaughter stock, and suspect cases. Because BSE is zoonotic, severe trade restrictions apply to countries where it is present. A system for risk classification of countries is used. The risk category is also relevant for setting surveillance targets. A point system was developed in order to encourage countries to test high-risk animals. Control of BSE focusses on removal of central nervous system material from carcasses at slaughter and incineration at high temperature and under pressure. Owing to uncertainties of complete removal of high-risk material, the feeding of animal-derived proteins was banned in many countries. However, with a decreasing number of BSE cases, discussions have begun to relax some of the testing and prevention measures because maintaining this level of mitigation is costly and appears no longer justified in all countries.

intervention. If the intervention decision is made at the farm or local level, surveillance should also be focused there. However, many mitigation decisions relating to meat-borne hazards are taken at regional or national level because of public health relevance or the risk of meat-borne spread to susceptible livestock.

International surveillance programs have gained particular attention recently following several multicountry outbreaks. For example, livestock feed was contaminated repeatedly with dioxin in Europe due to manufacturing errors. This incident led to contaminated meat and milk being marketed in many countries and a subsequent multicountry recall. Such events highlight the international connectedness of food and feed systems and the potential consequences of mistakes in one country on consumers elsewhere. As such incidents are also very costly and damage consumer confidence, more intensive surveillance programs were developed using harmonized methods. Surveillance standards developed by international organizations (see Section Legal Frameworks and Standards) as well as industry standards have an important role in preventing the spread of meat-borne hazards through trade.

Objectives of Surveillance

Surveillance for meat-borne hazards may have one or more objectives. Depending on the prevalence of a certain hazard, the objective of surveillance may be to identify cases to instigate a control measure, to demonstrate continuing absence of the hazard, to detect emergence of a new hazard as early as possible, or to estimate the current prevalence or changes in prevalence over time (temporal differences) or between locations (spatial differences). The design of the surveillance system will vary according to the respective objective.

Surveillance Activities

At the beginning of all surveillance is case definition. The case definition can be based on clinical or pathological signs or syndromes, which will typically be considered a 'suspect case.' Suspect cases in animals might be detected at farms, veterinary practices, abattoirs, or markets. Suspect cases in humans are detected by family practitioners or hospital workers. When the case definition is unspecific and describes a clinical syndrome rather than a case of a specific disease, it is referred to as 'syndromic surveillance.' This approach increases the sensitivity but results in decreased specificity. This is desirable when the surveillance objective is early detection.

Suspect cases are subject to laboratory confirmation using the most suitable test or combination of tests. The choice of test technology will be related to the objective of surveillance. For example, antibody-based tests are often not the optimal choice for early detection because of the delay in antibody production in many diseases. Antigen-based testing might be more suitable for such an objective.

Once a case is detected, a process for reporting is required. In the case of compulsory mitigation, a legal basis will define notification responsibilities. Typically, anyone owning or caring for animals is responsible for notification. The decision to notify requires basic knowledge of what reportable diseases might look like. It is, therefore, dependent on disease awareness, which is generally accepted to be the weakest link in surveillance based on case reporting. Educational programs are often used to increase disease awareness.

Reported cases can trigger mitigation steps or contribute to regular disease statistics that are used to document progress of intervention programs. Surveillance results are frequently communicated via the internet, but printed reports remain common. For some diseases, international reporting is also required. The OIE published regular reports on their website within the World Animal Health Information Database system.

Approaches to Surveillance

Surveillance can be classified according to the approach taken to case detection. As described in Section Surveillance Activities, case reporting is very common. This is also referred to as 'passive' surveillance because the central unit responsible for data collection and decision making is taking a passive stance waiting for reports to arrive. Alternatively, 'active' surveillance can be implemented by designing specific mechanisms for case searching and enhanced detection. This can, for example, consist of specific surveys that are implemented regularly. Passive and active surveillance can both be applied to all eligible units (e.g., farms, animals, and villages) or to a sample of units. When sampling is applied, measures should be taken to minimize undesired bias.

Surveillance Designs

The design of a surveillance program will require the specification of many aspects including: the surveillance objective; case definition; sampling approach; sampling frame; sample size (if applicable); methods of data capture, management, security, and confidentiality; statistical analysis; and reporting and communication channels. Potential interventions resulting from detected cases should also be defined and the necessary legal basis assured.

In some programs, the hazard is predefined, but in others there may be choices. For example, when conducting surveillance for antimicrobial resistance, a large number of pathogen-resistance–host combinations exist. The concept of risk as used in risk analysis – i.e., the probability of occurrence and the magnitude of the consequences – can be used to set priorities in such a situation. This is referred to as risk-based surveillance. Information on risk factors is systematically used to target sampling and testing activities to strata of the target population where the chances of detecting the hazard are highest. Risk factors might relate to husbandry, location or management practices, depending on the epidemiology of a hazard. See Box 2 for an example.

The objective of risk-based designs is to increase surveillance efficiency, i.e., the amount of information obtained per resource input. This means that the same efficacy should be achieved with reduced costs or an increased efficacy with the same costs. This approach has become increasingly popular over the last few years and development of enhanced methods is continuing. Risk-based approaches are also used in

Box 2

Salmonella surveillance in pig populations was systematically introduced in countries with major pig industries to prevent human salmonellosis and to maintain market confidence. Most *Salmonella* infections in pigs other than cases caused by *Salmonella choleraesuis* are subclinical. A surveillance system based on sampling pigs at harvest is commonly used following a program first developed in Denmark. A risk-based sampling approach is used such that sampling intensity is based on previous test results and the size and types of farms. Interventions against *Salmonella* in pigs consist of a combination of general measures, such as better biosecurity, changes in diet, and improved pig flow and hygiene. Specific measures such as vaccination are not yet available. When targets for *Salmonella* counts are not achieved, carcasses from affected pigs can be decontaminated or the meat can be heat treated. Trade of such meat may be restricted, mainly based on private standards.

Box 3

Avian influenza (AI) is a disease of poultry caused by viral strains of low or high pathogenicity. Some strains are zoonotic. Surveillance is required by international standards and involves systematic sampling and testing of poultry as well as reporting of increased mortality in poultry. A risk-based approach can be used by increasing sampling on farms in areas with large wild bird populations or farms with imperfect biosecurity, such as free-range poultry farms. Highly pathogenic and zoonotic strains of AI are subject to stamping-out strategies. For other strains, hygiene and general containment is applied. Improved biosecurity is an important mitigation tool. Vaccination is also available. The occurrence of AI in wild birds (often without clinical signs) and the emergence of novel strains in wildlife reservoirs pose a considerable challenge for the prevention and containment of outbreaks in poultry. Surveillance is, therefore, often extended to wild bird populations by sampling birds that are trapped, hunted, or found dead.

Table 1 Examples of combinations of surveillance approaches and designs that can be used to detect meat-borne hazards

Approach taken to surveillance	*Surveillance design*	
	Conventional surveillance	*Risk-based surveillance*
Passive	Case reporting of suspected cases Syndromic surveillance	Case reporting within risk strata Syndromic surveillance within risk strata
Active	Complete population screening (census) Random sampling	Targeted screening of and within risk strata Random sampling within risk strata

the context of inspection. Combinations of surveillance approaches and designs are shown in Table 1.

While not all surveillance designs are suitable for every surveillance objective, more than one may be applicable in any given situation. In some instances, a combination of different surveillance approaches might be the most effective and efficient way to achieve the objective. The term 'surveillance system' is used to refer to surveillance that consists of more than one component (surveillance activity), combining different approaches and designs. For example, surveillance of diseases that involve wildlife often includes several surveillance components (Box 3).

Methods for Assessing Surveillance

The key attributes of surveillance programs are their sensitivity, specificity, and representativeness. Depending on the objective of a surveillance program, the primary attribute of concern might be the probability of detecting a case (sensitivity) or the precision of the estimated level of occurrence of a disease (incidence or prevalence).

There in an increasing need for methods to assess complex surveillance systems, to establish equivalence across surveillance designs, and to identify the most effective designs. Scenario-tree analysis has been developed to assist such decisions. This quantitative approach can deal with a range of surveillance system components with varying designs. Each 'branch' in the scenario tree represents a specific design. The output of the tree is the probability of detecting a case. It is, therefore, particularly suitable for programs that are used for demonstrating freedom from infection. Scenario-tree analysis has been widely used to assess the performance of risk-based surveillance in comparison to conventional designs.

Interventions for Hazard Reduction

Endpoints

If interventions are to be applied when cases are identified, various options exist depending on the aim of intervention. The objective might be to eliminate the hazard from all animals and units in a population and thereby eliminate all related economic losses. Alternatively, the objective might be to reduce losses by reducing the frequency of occurrence or preventing severe cases. The decision regarding the endpoint will depend on the legislation, which will specify elimination targets for certain hazards. For example, brucellosis is subject to elimination objectives in many countries. However, when cases occur frequently, elimination might not be economically feasible and a reduction target might be more realistic. This is the case in many countries where brucellosis in wildlife is still common. In a situation where a hazard is generally absent (i.e., surveillance is targeted at early detection), an identification and elimination strategy is typically used. This is the case for all so-called exotic diseases. The diseases grouped in this category will depend on the sanitary status of the country or region. Huge progress toward areawide elimination of several diseases has been made, most notably the global eradication of rinderpest in 2011. For zoonotic diseases with severe consequences for humans, elimination is also desirable. An example for such a hazard is BSE for which all countries have an elimination target.

Intervention Options

Intervention strategies might form part of either preventive or corrective action, and might be specific or nonspecific for a particular hazard (Table 2).

When effective vaccination is available, this might be an economic prevention strategy in regions of significant infection pressure and for pathogens that cause substantial losses. However, diagnostic tests are often unable to distinguish infected from vaccinated animals. New vaccine technologies increasingly allow for this distinction. Vaccination has been successfully used in major eradication campaigns against diseases such as classical swine fever and FMD (see Box 4). As such programs progress, vaccination is discontinued to allow for ultimate eradication of the hazard.

Specific pathogen free programs might offer another solution. This has been very successfully used in pig industries around the world, sometimes involving entire regions and even countries (e.g., elimination of specified respiratory hazards from pigs in Switzerland). For endemic diseases, a test-and-remove strategy can be used to eliminate individual infected animals. This is used in some countries for tuberculosis control in cattle.

When there are no specific intervention strategies available, management changes might offer a solution. For example, biosecurity can be increased to reduce infection pressure. The highest risk of hazard introduction is related to replacement stock. This risk can be managed by purchasing only from certified sources, by using testing and quarantines or by operating a closed herd. Biosecurity is not only relevant to control access of visitors and livestock, but also vermin. For example, some hazards can be physically carried by insects and rodents. Measures targeted at such pathways are sometimes summarized under 'good farming practice.' This also includes hygienic management of pasture, slurry, and feed. Early separation of young stock from infected dams is effective for some pathogens. Unspecific use of antimicrobials is not considered best practice as the negative impact on resistance situation generally outweighs the benefits.

For some hazards, dietary changes may also be an option. This is most significant for feed-borne hazards, including *Salmonella*, prions or environmental contaminants, where changes in feed manufacturing and storage have significant impact. For some hazards, dietary changes can also impact the survival of hazards in the digestive tract and thereby reduce infection pressure indirectly. This is being used to reduce the occurrence of *Salmonella* in pigs. In this field, more research is needed to assess the efficacy of feed additives, such as the use of pre- or probiotics, phyotherapy, or immunomodulators.

Table 2 Examples of combinations of intervention strategies that can be used to reduce the impact of meat-borne hazards

	Specific for a hazard	*Not specific*
Preventive	Specific pathogen free animal production	Biosecurity and good farming practice
	Vaccination	Early weaning
Corrective	Treatment	General antibiotic use
	Test-and-kill	Improved husbandry and redesign of buildings
	Eradication	Cleaning and disinfection and restocking

Box 4

FMD is a highly contagious disease affecting cloven-hoofed animals. Owing to the reliable occurrence of characteristic lesions, surveillance is mainly based on clinical surveillance. In sheep, however, clinical signs might be mild. This led to a major outbreak of FMD in the United Kingdom and subsequently other European countries in 2001 causing losses of over £8 billion (~€12 billion or US$12 billion). The most widely used intervention strategies are vaccination in endemic areas and stamping-out in free areas. Vaccination is challenging due to the circulation of different serotypes and the antigenic change of viruses. Owing to the significant difference in the occurrence of FMD, severe trade restrictions are applied between countries and regions of different sanitary status. Some discussions have started to consider possibilities for a global eradication of FMD. However, costs and technical challenges of such a project appear prohibitive at the moment.

Integrated Control along the Food Chain

For some hazards, interventions in primary production, i.e., on the farm, may not be the most effective or efficient option. Alternatives are interventions at harvest and along the food chain. Often, combinations of interventions are also useful. Options for controlling meat-borne hazards can be applied at slaughter. For example, when hazards are located in specific parts of the carcass, these can be trimmed out and destroyed. This is used for BSE. Hazards that cause specific lesions detectable at harvest can also be eliminated from the food chain by removing affected organs or carcasses. This is used, for example, as part of tuberculosis control.

Freezing can inactivate some hazards, including some parasites. However, control at source on the farm should still be considered as decontamination steps might not be sufficient to sufficiently reduce the public health threat. Heat treatment is another effective measure to prevent human infection. In regions where food-borne hazards are known to be prevalent and elimination is not feasible, measures along the food chain are the only option. Ultimately, safe storage, handling, and hygienic preparation of meat by consumers are extremely important and effective measures to prevent food-borne disease. It is, therefore, important to emphasize the responsibility of consumers and to increase their awareness and knowledge of meat-borne diseases.

Economics of Hazard Mitigation

Costs of Surveillance

In order to conduct surveillance that is useful, a range of activities is required, which all incur costs. This includes the costs of investigation activities (e.g., veterinary time and travel), sampling, sample shipment and analysis, data capture, statistical analysis, reporting, and communication. Unfortunately,

data detailing the cost of surveillance are often not readily available because many activities are conducted as part of routine tasks and not easily specified or associated with specific hazards. For example, a meat inspector often collects a wide range of surveillance data on several meat-borne hazards simultaneously. How to divide the cost of manpower between different surveillance programs is not trivial.

Cost of surveillance is related to coverage. The larger the sample size, the higher the costs. Sampling is, therefore, an intuitive cost saving mechanism when compared to surveillance of entire populations. The latter is, however, still very commonly used in clinical surveillance. The assumption is that clinical observation of livestock is part of due care expected from farmers and herders. In case of unusual observations, compulsory reporting and follow-up investigations by veterinary services provide the most efficient and, therefore, most widely used surveillance design world wide. However, underreporting due to real or perceived negative economic consequences and stigmatization of affected farms is a major weakness in all general reporting systems.

Costs of Intervention

Costs of intervention vary greatly. Although generic measures such as improved biosecurity are effective for a range of hazards and can be considered part of 'good farming practice,' measures such as vaccination have a specific effect and are, therefore, comparatively more expensive. The most expensive intervention is likely to be a strategy where a pathogen is eliminated using drastic measures, such as slaughtering all animals ('stamping-out') and replacing them with healthy ones. Such interventions incur not only direct costs but also indirect costs related to loss of production during periods when farm buildings are cleaned and disinfected or a farm is subject to movement restrictions as well as loss of market shares. The latter is particularly critical in a global market. A disease outbreak in one region, such as AI in Southeast Asia, can lead to permanent loss of market to another continent.

Trade-offs and Optimization

Nobody would implement any mitigation if there were only costs. Of course there are also benefits, but these are sometimes difficult to quantify because they might be incurred not only by the individuals who implement mitigation, but by a wider group, leading to so-called externalities. Over the last decades, resources available for mitigation have become increasingly limited emphasizing the need for improved efficiency of surveillance and interventions. This has emphasized the need for trade-offs and for more integrated consideration of surveillance and intervention in economic frameworks. However, capacity to conduct such analyses is still limited in veterinary services and animal industries around the world.

Who Should Pay for Mitigation?

There are many different systems for sharing costs of surveillance and interventions among participants of meat-production chains. Solutions vary according to hazard types with highly contagious and zoonotic hazards being mostly covered by governments (e.g., tuberculosis and FMD) while less contagious or endemic hazards are left to industry to manage. Sometimes, governments set mitigation objectives, but technical solutions for efficient surveillance and intervention are developed by the industry (e.g., *Salmonella* mitigation in pigs in Denmark).

Evaluation of Mitigation

Evaluation has been defined as a systematic and objective assessment of the relevance, adequacy, progress, efficiency, effectiveness, and impact of a course of actions. In this context, we consider actions related to surveillance and mitigation. Such an assessment should be linked to the intended objectives of a program as well as to the resources used. Systematic evaluation of programs and policies has become increasingly popular as a consequence of reduced budgets. For the evaluation of surveillance, a flexible framework with specific guidance has recently been developed, including relevant surveillance attributes and illustrative examples. In addition to attributes that are regularly used to evaluate surveillance such as sensitivity, specificity, and bias, additional attributes such as feasibility, coverage, and costs are used. A similar approach is applicable to the evaluation of disease control. Ideally, surveillance and intervention targeted at a specific hazard should be evaluated jointly. Such examples are, however, currently rare.

Future Directions

Challenges for the future include improving the efficiency of surveillance and control of meat-borne hazards. Risk-based designs are likely to be increasingly applied to achieve this. Evaluation of surveillance and intervention programs should be conducted regularly to enable continued improvements to be made to the process. The ever-increasing human population and the associated demand for more safe meat means that mitigating risks relating to meat-borne hazards will remain important for a long time to come.

Glossary

Conduction, thermal A heat transfer mechanism through a solid material/medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

Convection, thermal A heat transfer mechanism through a liquid or gas by means of circulating currents caused by changes in density.

Heat transfer coefficient Coefficient used in thermodynamics to calculate heat transfer, typically by convection or phase change, between a fluid and a solid.

Pasteurization A form of heat treatment that kills certain vegetative bacteria and/or spoilage organisms in milk and other foods. Temperatures below 100 °C are used.

Radiation, thermal A heat transfer mechanism in which electromagnetic radiation is generated by the thermal motion of charged particles in matter. All matter with a temperature greater than absolute zero emits thermal radiation.

Refrigeration May be defined as the process of removing heat from any substance to (1) render colder – reduce temperature, (2) change its state – for example, water to ice, (3) maintain its state – preserving foods, storing ice.

Water activity (a_w) A measure of the available water in a substance. 'High a_w' foods support bacterial growth; 'low a_w' foods do not. This is not the same as water content. Some foods with a high water content have a relatively low a_w because the water is bound up with dissolved salts or sugar, for example, jam.

Introduction

To provide safe meat and meat products of high organoleptic quality, attention must be paid to every aspect of the cold chain. The process commences with the initial chilling and continues through to the storage of the chilled retail portion or meat product within the home. Within the cold chain are processes such as primary and secondary chilling, freezing, thawing, and tempering, where the aim is to change the average temperature of the meat. In other processes, such as chilled and frozen storage, transport, and retail display, maintaining the temperature of the meat is the prime aim.

Failure to understand the needs of each process results in excessive weight loss, higher energy use, reduced shelf life, or a deterioration in product quality.

Refrigeration is the prime process controlling the growth of pathogenic and spoilage microorganisms on meat. It is therefore very important to understand the refrigeration methodology that is required in each stage of the cold chain and the interaction between the stages.

Removing the required amount of heat from a carcass is a difficult, time-consuming operation but critical to the operation of the cold chain. Most of the subsequent processes are designed to maintain not to reduce temperature. As a meat product moves along the cold chain it becomes increasingly difficult to control and maintain its temperature. Temperatures of bulk packs of chilled product in large storerooms are far less sensitive to small heat inputs than single consumer packs in transport, open display cases, or under domestic refrigeration.

Elements of The Cold Chain

Primary Chilling

The rate of heat removal and the resulting rate of temperature reduction at the surface and within the carcass has a substantial influence on the weight loss, storage life, and eating quality of the meat produced. EU regulations require that all meat temperatures within the carcass must be reduced below 7 °C (3 °C for poultry) before the carcass is further processed or moved from the chiller. Similar legislation is applied in many other parts of the world. Careful control is required to achieve conditions that will reduce the carcass temperature in the designed time cycle. This has to be carried out in the most economic manner taking into account weight loss and energy consumption.

Conventional Chilling

The majority of carcass meat is chilled in conventional air chill rooms nominally operating at one or sometimes two conditions during the chilling cycle. Similar methods are normally used for poultry carcasses that are sold in a fresh state, i.e., chilled. Immersion chilling is sometimes used for poultry that is subsequently frozen, and spray/evaporative chilling has been used on beef, pork, and poultry carcasses.

Air temperature, air velocity, and to a limited extent relative humidity are the environmental factors that affect the cooling time of meat carcasses and sides. Cooling rate will also be a function of the weight and fat cover of a given carcass.

Air temperature is the single most important factor controlling chilling time. For example, with beef sides, cooling in air blowing at 3 ms^{-1} using a constant 4 °C compared with 0 °C will increase the time to reach 7 °C in the deep leg of a 100 kg side from 20.3 to 27.7 h (a 36% increase). With an air velocity of 0.5 ms^{-1} using a constant 4 °C compared with 0 °C to cool a 220 kg side will increase the time from 45.9 to 68.3 h (a 49% increase). In systems designed to produce fully chilled sides, with average meat temperatures of 2–4 °C, the requirement for low air temperatures becomes even more important. In air at 0 °C and 3 ms^{-1} it will take approximately 48 h to reduce the average temperature of a 220 kg side to 4 °C. In air at 4 °C it will take an indefinite amount of time.

Increasing the air velocity during chilling produces a substantial reduction in chilling times at low air velocities, but similar increases at higher velocities have a much smaller effect. At 0 °C a four-fold increase in air velocity from 0.5 to 2 ms^{-1} results in an 8 h reduction in chilling time to 7 °C for a 140 kg beef side, but requires a 64-fold increase in fan power. In most practical situations with large carcasses it is doubtful whether an air velocity greater than 1 ms^{-1} can be justified.

Decreasing relative humidity has been shown to produce a slight reduction in chilling time due to increased evaporative cooling from the carcass surface. However, unless water is added to the surface of the carcass, any increase in the rate of evaporation will be directly reflected in a higher weight loss.

In some beef, pork, and poultry chilling systems refrigerated water sprays are often used in conjunction with air chilling. The sprays are not applied continuously but in short bursts, for example, 90 s at 15 min intervals for the first 8 h in beef systems, 5 and 15 min after the start of poultry chilling. The process increases the rate of evaporative heat loss but, by replacing the water lost, reduces the overall weight loss. Although often called evaporative air chilling, it should not be confused with true evaporative chilling carried out in a vacuum chamber as used with freshly harvested leafy vegetables and salad crops. Experiments have been carried out on the chilling of poultry carcasses in a vacuum chamber and these achieved cooling rates similar to immersion systems. However, the 5% weight loss was considered too high for industrial use.

In practice, it is difficult to separate the effect of carcass weight from fat cover on chilling time. Heavy carcasses and sides tend to have more fat cover than lighter carcasses and sides. For example, little difference has been observed in the cooling times of 30 kg ram carcasses with high and low fat thicknesses. However, when the fat was completely stripped from the muscle, the cooling time to 7 °C was reduced from 10 to 8 h.

The chilling time of lean, light (16.8 kg) lambs can be under half that of 26.8 kg lambs with a much thicker fat covering. In industry, it would not be unusual for a chilling system to contain lamb carcasses covering this range of weights and fat covers. The design and operation of such a system must therefore be a compromise between overly long chilling periods for the smaller carcasses and under cooling of the larger carcasses.

Chilling rates in immersion systems are a function of the cooling medium used, its temperature, the size of the carcass being chilled, and whether it is wrapped or unwrapped. In static systems immersion in slush ice is far more effective than water immersion at the same temperature. Mechanical movement or agitation of the immersion liquid can substantially reduce chilling times. In all cases unwrapped carcasses cool far faster than those that are wrapped. In some cases there is a doubling in the cooling time. Smaller wrapped broilers will cool in 50–67% of the time required for larger wrapped fowls under the same conditions. This is most probably due to the immersion liquid penetrating the cavity and substantially reducing the effective meat thickness.

If specified cooling schedules are to be attained, refrigeration machinery must be designed to meet the required heat extraction rate at all times during the chilling cycle. Heat enters a meat chill room via open doors, from personnel, through the insulation, from lights and cooling fans, and from the cooling carcasses or sides. The product load, i.e., heat released from the meat, is the major component of the total heat to be extracted from a fully loaded chill room.

The rate of heat release from a single side or carcass varies with time. It is at a peak immediately after loading, and then falls rapidly. The peak value is primarily a function of the environmental conditions during chilling and the rate at which hot meat is introduced into the chill room. Increasing air velocity, decreasing air temperature, or shortening loading time increases the peak heat load. There is a four-fold difference in peak load between a beef chill room operating at 8 °C and 0.5 ms^{-1} loaded for more than 8 h and the same room operating at 0 °C and 3 ms^{-1} and loaded for more than 2 h.

Accelerated Chilling

Using conventional single-stage chilling regimes only relatively lean, light beef sides can be cooled to 7 °C in the deep tissue during a 24 h operating cycle, while evaporative losses are of the order of 2%. Pork is conventionally cooled overnight, whereas lamb can be transported on the same day as slaughter. There is considerable interest in methods of shortening cooling times and reducing evaporative weight loss. All accelerated cooling systems are likely to be more expensive to install and operate than conventional plants. Therefore, to be cost-effective they must offer substantial savings in terms of increased throughput and/or higher yields of saleable meat.

Most accelerated chilling systems rely on the maintenance of very low temperatures (−15 to −70 °C) during the initial stages of the chilling process, by either powerful mechanical refrigeration plant or cryogenic liquids. Because any substantial freezing would produce increased drip loss on final cutting, accelerated systems only maintain very low temperatures during the first few hours of the chilling process. One or more successive stages at progressively higher temperatures are employed, with the final stage at or above 0 °C to remove the last of the heat or to allow for temperature equalization.

Freezing

Meat for industrial processing is usually frozen in the form of carcasses, quarters, or boned out primals in 25 kg cartons. Most bulk meat, consumer portions, and meat products are frozen in air blast freezers. Some small individuals items, i.e., beef burgers, may be frozen in cryogenic tunnels, and a small amount of offal and other meat is frozen in plate freezers. It is not unusual for meat to be frozen twice before it reaches the consumer. During industrial processing frozen raw material is often thawed or tempered before being turned into meat-based products such as pies, convenience meals, and burgers or consumer portions such as fillets, and steaks. These consumer-sized portions are often refrozen before storage, distribution, and sale.

The need for fast freezing to maximize the quality of frozen meat is increasingly open to argument. Fast freezing may well be the most economical practical process, and it is very likely to reduce weight loss from unwrapped meat. Fast freezing produces smaller ice crystals than the slower processes. However, the differences in crystal size and composition do not translate to effects that can be detected by taste panels or quantitative sensory methods.

For example, in one study on hamburgers the effects of three different freezing methods, spiral freezing, cryogenic freezing (liquid nitrogen), and impingement freezing, were compared. The parameters studied were appearance, dehydration during freezing, cooking losses, meat structure by microscopic analysis, and sensory properties by sensory analysis. The time required to freeze a 10 mm thick 80 g hamburger from +4 °C to −18 °C ranged from less than 3 to more than 22 min. Weight loss in the slow process was more than three times than that in the fast process. Ice crystals were significantly larger in hamburgers frozen in 22 compared with 3 min. However, no significant difference could be seen in cooking losses. Sensory analysis revealed no difference in eating quality between the three freezing methods, even after 2 months of storage. In studies with aged beef steak no differences were found in the texture or other organoleptic qualities of the final cooked steak between frozen (to −7 °C in 1.5 or 35 h) and unfrozen steaks.

Thawing and Tempering

Although thawing is often considered as simply the reverse of freezing, there are important differences between the two operations. The majority of the microorganisms that cause spoilage or food poisoning are found on exposed surfaces. During freezing, surface temperatures are rapidly reduced to levels that slow and then suspend microbial growth. In the thawing operation, surface temperatures rise rapidly to temperatures at which growth can recommence. These temperatures are maintained for the duration of thawing, which for large slow-thawing materials, or for uncontrolled or high-temperature thawing, can result in unacceptable spoilage at the surface before center regions have thawed.

Another difference is that thawing is inherently slower than freezing. The thermal conductivity of thawed meat is approximately one-third of that of frozen meat. This means that as thawing progresses, a layer of poor thermal conductivity is formed at the surface that acts, in effect, as insulation. The freezing process in general suspends the growth of, but does not destroy, microorganisms. Above −12 °C, microorganisms begin to grow again. This limits the temperatures that can be used to thaw, as high air temperatures will promote rapid microbial growth on the surface of the food.

Air is used in the vast majority of thawing/tempering applications. Air thawers are very flexible and may be used to thaw any size of meat cut from whole carcasses to individual steaks. Use of still air is limited to thin products; otherwise thawing times are excessively long. Although little or no equipment is needed, considerable space is required to lay out individual items of product. Moving air is more commonly used, providing more rapid heat transfer as well as improved control of temperature and humidity. Two-stage air thawing with a high initial air temperature followed by a second stage at an air temperature below 10 °C has also been used. The duration of the high-temperature stage is limited to 1 or 2 h to avoid excessive bacterial growth, but the increase in heat input during this time considerably reduces the overall process time.

Immersion in liquid media allows much more rapid heat transfer, especially if pumped or agitated to avoid temperature stratification in the liquid and grouping together of products. Thawing times are therefore greatly reduced. Practical limitations are that boxes and other packaging (unless vacuum-pack or shrink-wrap) must be removed before immersion. In addition, bulk blocks are liable to break up, leaching from product surfaces can lead to poor appearance, and frequent changing of water for hygiene reasons requires disposal or treatment of large quantities of effluent.

Vacuum thawing transfers latent heat of condensation of steam onto product surfaces at low pressure and temperature. For example, if a pressure of 1704 Nm^{-2} (0.017 atm) is maintained, steam can be generated at 15 °C and will condense at this temperature onto the frozen product surfaces. This ensures that although large amounts of latent heat are

added, the product will not rise above 15 °C. The process is rapid, but evacuation to subatmospheric pressure restricts it to batch operation. This process is more effective for thin products where the heat released into the surface is quickly conducted through the product.

Microwave systems have been successfully used to temper meat, i.e., raise the temperature from −2 to −5 °C, but not to fully thaw it, i.e., raise the temperature above 0 °C. Potentially very rapid, the application of microwaves is limited by thermal instability and penetration depth. Instability results from preferential absorption of energy by warmer sections and by different ingredients, such as fat. Warmer sections may be present at the start of the process; for example, the surface temperature may be warmer than the middle, or they may be produced during the process, such as energy being absorbed at the surface rather than penetrating all of the product. In the extreme, such warming can lead to some parts of the food being cooked whereas others remain frozen. These problems, as well as the capital cost of equipment, have greatly limited commercial use.

Secondary Chilling

Any handling operation, such as cutting, wrapping, mincing, or dicing, will add heat to the previously chilled meat. It is important that a secondary chilling operation be carried out to remove this added heat before the product is bulk packed.

The aim of any precooking process for chilled foods is to ensure the destruction of the vegetative stages of pathogenic microorganisms. However, there is always the possibility that the cooking process will not kill some microorganisms that produce spores or that the food will become recontaminated. Therefore, the temperature of the food should be rapidly reduced to below 7 °C after cooking to prevent multiplication. In addition to the microbiological factors, rapid reduction in product temperature aids retention of nutrients, which is vital in systems such as cook–chill that are often used for the preparation of meals for the elderly, the infirm, and young people.

The majority of companies rely on air blast cooling systems for the chilling of precooked products or ready meals. In batch systems the products, packs, or trays of cooked material are placed directly on racks in the chiller or on trolleys that can be wheeled into the chiller when fully loaded. Continuous systems range from trolleys pulled through tunnels to conveyerized spiral or tunnel air blast chillers.

Some meals and products are chilled using cryogenic tunnels; however, care must be taken to avoid surface freezing. Sous-vide and other imperviously packed products are often chilled by immersion in cooled water or other suitable liquid. With some cooked products such as large hams in molds and sausages, chlorinated water sprays can be used in the initial stages of cooling. Increasingly, pie and ready meal fillings are pressure-cooked and vacuum-cooled. With many products an initial cooling stage using ambient air can often substantially reduce the refrigeration load in the cooling system.

Chilled and Frozen Storage

After chilling, carcass meat is often stored for a period, ranging from a few hours to two weeks, unwrapped in a chill storage room. Meat primals and consumer cuts are often placed, wrapped or unwrapped, in trays or on racks in similar rooms. Low temperatures, minimal air movements, and high relative humidities should be maintained around unwrapped meat in order to maximize storage life and minimize weight loss. With wrapped and unwrapped meat low velocities are also desirable to minimize energy consumption. Many storage rooms are designed and constructed with little regard for air distribution and localized velocities over products. Horizontal throw refrigeration coils are often mounted in the free space above racks or rails of product, and no attempt is made to minimize the air velocity over the surface of unwrapped meat. Using a false ceiling or other form of ducting to distribute the air throughout the storage room can substantially reduce variations in velocity and temperature. Maximum air velocities of 0.75 and 0.4 ms^{-1} were measured over products in two storerooms having 30 cm deep false ceilings with slits to distribute the air throughout the rooms. The maximum temperature distribution measured within the rooms was less than 2 °C. Using air socks, improved air distributions can be maintained with localized velocities not exceeding 0.2 ms^{-1}.

Increasingly, red meat is aged for 4 weeks and longer to improve its texture and taste. There are two methods of aging: unwrapped on the bone (dry aging) or as vacuum-packed primals (wet aging). In both cases aging is best achieved by maintaining the stores at a temperature close to, but not below, the initial freezing point of the meat. There has also been increased use of controlled-atmosphere retail packs to extend the display life of meat. Because the packs tend to be large and insulate the products, effective precooling before packaging is especially important if product quality is to be maintained.

The frozen storage life of meat is limited by quality changes, primarily rancidity development in the fat. The rate of rancidity development is mainly a function of the feeding of the animal, the treatment of the meat before freezing, the type of packaging, lighting, and the storage temperature.

Transport

Developments in temperature-controlled transportation systems for products have been one of the main factors leading to the rapid expansion of the chilled food market. The sea transportation of chilled meat from Australasia to European and other distant markets, and road transportation of chilled products throughout Europe, the US and the Middle East is now in common practice. Air freighting was initially used for high-value perishable products such as strawberries, asparagus, and live lobsters. However, it is now increasingly used to provide consumers with a year-round supply of once only seasonal products.

Effective temperature control during transportation is becoming increasingly important as the shelf life of products is extended and legislation increased. Shipboard transportation of chilled vacuum-packed primals to distant markets is now common practice. However, to achieve the required shelf life, meat temperatures have to be maintained at −1±0.5 °C to avoid bacterial growth or freezing.

Retail Display

Retail display cabinets for meat and meat products are designed to display wrapped or unwrapped chilled product, or frozen wrapped product. The retail display of refrigerated food is probably still the weakest link in the cold chain. It is also very energy-hungry, consuming approximately 50% of all the energy used on refrigeration in a typical cold chain. The required retail display life and consequent environmental conditions for wrapped chilled products differ from those for unwrapped products. The desired display life for wrapped meat and meat products ranges from a few days to many weeks and is primarily limited by microbiological considerations. Retailers of unwrapped meat and delicatessen products normally require a display life of one working day. In this case display life is limited by dehydration leading to changes in the appearance.

Chilled Wrapped Meat

To achieve the display life of days to weeks required for wrapped chilled meat the product should be maintained at a temperature as close to its initial freezing point (approximately −1.5 °C) as possible. Air movement and relative humidity have little effect on the display life of a wrapped product, but the degree of temperature control can be important, especially with transparent, controlled-atmosphere packs.

To maintain product temperatures below 0 °C the air off the coil must typically be −4 °C and any ingress of humid air from within the store will quickly cause the coil to ice up. Frequent defrosts are often required, and even in a well-maintained unit the cabinet temperature will then rise to 10–12 °C and the product by at least 3 °C. External factors such as the store ambient temperature, the siting of the cabinet, and poor pretreatment and placement of products substantially affect cabinet performance. Warm and humid ambient air and loading with insufficiently cooled products can also overload the refrigeration system. Even if the food is at its correct temperature, uneven loading or too much product can disturb the airflow patterns and destroy the insulating layer of cooled air surrounding the product.

Chilled Unwrapped Meat

Changes in appearance are normally the main criteria that limit the display life of unwrapped foods, with the consumer selecting newly loaded product in preference to that displayed for some time. Deterioration in appearance has been related to the degree of dehydration in red meat and is likely to similarly occur in other foods. Apart from any relationship to appearance, weight loss is of considerable importance in its own right because most meats and meat products are sold by weight.

Changes in relative humidity (RH) have a substantial effect on weight loss, with a reduction from 95 to 40% increasing weight loss by a factor of between 14 and 18. Raising the air velocity from 0.1 to 0.5 ms^{-1} has little effect on weight loss at 95% RH but increases the loss by a factor of between 2 and 2.4 at 60% RH. Temperature changes from 2 to 6 °C have a far smaller effect on weight loss than the changes in either relative humidity or velocity. Fluctuations in temperature or relative humidity have little effect on weight loss, and any apparent effect is caused by changes in the mean conditions.

Frozen Display

All frozen meat and meat products are wrapped before they are placed in retail display. The principal reason for packaging meat during frozen display is to minimize moisture loss. Moisture loss causes deleterious effects on the texture, flavor, and color of the meat. As long as the display keeps the temperature of the meat below −12 °C there will be no microbial problems. Changes to the color of the surface of the meat normally limit the frozen display life. Low temperatures, minimal temperature fluctuations, and low illumination levels will maximize display life.

Domestic Handling

After a chilled or frozen product is removed from a retail display cabinet it is outside a refrigerated environment while it is carried around the store and then transported home for further storage. In the home it may be left in ambient conditions or stored in the refrigerator/freezer until required.

In the past two decades there have been at least 15 surveys of temperatures in domestic refrigerators around the world. The results are all very similar, with overall mean temperatures in domestic refrigerators ranging from 4.0 to 7.4 °C, and maximum temperatures from 8 to 20.7 °C. These results are very worrying because they imply that the average temperature of at least 50% of domestic refrigerators is above 4.5 °C, around the world. When one looks at the percentage of temperatures measured that were above set points the results are even more worrying. In the last French and UK studies 80% and 70%, respectively, of the temperatures were above 5 °C and in Greek work 50% were above 9 °C. Comparable studies have not been carried out on domestic freezers.

Market Requirements and Specifications

M Henchion, Teagasc Research Centre, Ashtown, Dublin, Ireland

Glossary

AUS-MEAT The authority for uniform specification of meat and livestock in Australia.

Bovine spongiform encephalopathy (BSE) A fatal neurodegenerative disease in cattle commonly known as mad cow disease.

Credence attributes The product attributes that have a value but cannot be evaluated by a consumer even after 'consumption,' for example, animal welfare standards or environmental impact of the production method.

Equivalence One of the three objectives of the World Trade Organization (WTO) agreement on the application of sanitary and phytosanitary measures (SPS Agreement 1995). It is based on accepting that different sanitary measures can achieve the same level of protection and helps ensure that imported meat meets all safety standards applicable in the importing country.

(S)EUROP A European Union classification system that grades beef or lamb carcasses on the basis of conformation and fat scores.

Harmonization One of the three objectives of the WTO agreement on the application of sanitary and phytosanitary measures (SPS Agreement 1995). It relates to the establishment, recognition, and application of common SPS measures by different members. By harmonizing SPS measures with international standards, food safety and animal health protection can be achieved without unduly restricting international trade.

Institutional meat purchase specifications Specifications for meat and meat products are developed and maintained by the US Department of Agriculture. They are developed to provide a standardized system to describe traded meat products.

***In vitro* meat** An animal flesh product that has been grown in a culture and was never part of a complete, living animal.

Mechanically separated meat (MSM) Meat produced by forcing beef, pork, or poultry through a sieve or a similar device under high pressure to separate the bone from the edible meat tissue.

SPS Agreement 1995 The WTO agreement on the application of sanitary and phytosanitary measures.

World Organisation for Animal Health (formerly the Office International des Epizooties (OIE)) The world organization for animal health recognized by the WTO agreement on the application of sanitary and phytosanitary measures (SPS Agreement 1995).

Introduction

Market requirements are specified for several reasons ranging from ensuring food safety and animal health to facilitating trade and achieving market differentiation. The rationale for developing specifications influences their complexity as well as the requirements of the systems required for their verification. The reasons for developing market specifications, the main specification attributes, and methods of assessing adherence to specifications are elaborated below. A conclusion section outlines some recent developments in market specifications as a result of technological developments and changing market requirements.

Reasons for Specifications

Food Safety and Animal Health and Welfare

Specifications relating to sanitary measures are important to protect consumer well-being as well as animal health. They can also play a critical role in shaping meat trade. Given the increasingly global nature of food supply (and associated food safety and animal health implications), it is important that these specifications are in place at an international level.

An international agreement was put in place in 1995 called the World Trade Organization Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement 1995). The agreement is based on three key principles:

- Science-based risk assessment. This is a very important principle from a trade perspective; the science requirements of the agreement have minimized its potential to be used as a protectionist instrument to support domestic producers.
- Equivalence. The concept of equivalence is based on accepting that different sanitary measures can achieve the same level of protection and helps ensure that imported meat meets all safety standards applicable in the importing country.
- Harmonization. This relates to the establishment, recognition, and application of common SPS measures by different members. By harmonizing SPS measures with international standards, food safety and animal health protection can be achieved without unduly restricting international trade.

Although technical and sanitary measures may have common objectives, such as protecting human and animal health and minimizing market failure, operationalization at national level can result in trade issues due to heterogeneous requirements. Reasons for countries adopting different forms of regulations to reach similar objectives include differences in the way the product is defined and characterized, or it may be due to requirements about the production process, requirements on conformity assessment, etc.

Within the agreement, sanitary measures related to meat include hygienic, veterinary, and sanitary requirements for the maintenance and use of meat-processing enterprises. Specifications relate to construction of the plant, its operation, as well as handling of animals during transport and lairage.

Sanitary measures are important for domestic products as well as imported products. Hence, national and regional regulations exist for domestically produced meat. For example, implementation of an hazard analysis critical control point system is mandatory for food production establishments in regions such as the EU and the USA and is generally treated as a precondition of trade. Maximum permissible residue levels (e.g., of nitrofuran and nitrofurazon) in meat and freedom from contamination by relevant microbiological species (e.g., *Escherichia coli*, *Salmonella* spp., *Listeria* spp., etc.) are also specified by various national authorities.

Animal welfare is an important aspect of ensuring food safety due to the close links between animal welfare, animal health, and foodborne diseases. Hence, specifications in relation to animal welfare are often mandatory in nature. However, the link between animal welfare and product quality also means these specifications are important in terms of ensuring consumer satisfaction. For example, pigs slaughtered immediately on arrival have a tendency to produce PSE (pale soft exudative) meat and therefore for animal welfare and meat quality reasons pigs should have a rest period between transport and slaughter. At the EU level, there are directives and legislation in place to cover a range of animal species and welfare-affecting issues, including production methods, transport, and activities at the time of stunning and slaughter. Specific directives cover the protection of individual animal categories, such as calves, pigs, and laying hens. Other international organizations have also issued recommendations and guidelines concerning animal welfare, such as the World Organisation for Animal Health and the Council of Europe. These are not mandatory in nature.

Trade Facilitation

Trade is facilitated by having a common language through which products can be compared and, ultimately, prices can be negotiated. Having commonly understood product specifications means that buyers know what they are getting for a certain price and sellers know what they have to produce to achieve a certain price. For trade in carcasses, the relationship between certain animal characteristics and yield of saleable meat (and thereby profitability) are the basis of product specifications. In the EU, the relationship between conformation and fat level with yield of saleable meat is the basis of the (S)EUROP grid applied to cattle and sheep. Leaner animals with good conformation, for example, continental-type breeds such as Charolais and Limousin, are predicted to have higher yields of saleable meat. The grid consists of a 5-point scale in which each conformation and fat class is subdivided into low, medium, and high classes resulting in 15 classes (some countries have further subdivisions, for example, the UK has a 7-point scale for fatness). It was introduced, in 1981, to facilitate the application of a community scale for classifying adult bovine animals. It has since been extended to sheep and is used as a legal EU requirement for beef (but not sheep) price reporting.

The United Nations has been active in developing an 'international language' to facilitate trade use between buyer and seller and has developed standards for meat that moves beyond the carcass. It describes meat items commonly traded internationally and defines a coding system for communication and electronic trade. It has standards for beef, veal, pork, sheep, goat, llama, alpaca, chicken, and turkey. The standards generally relate to raw (unprocessed) meat. Requirements relating to food standardization and veterinary control are not addressed; they are presumed to be addressed by national or international legislation or requirements of the importing country. Specifications relate to cutting, trimming, and boning of cuts; refrigeration processes and appropriate internal temperatures reflecting whether the product is chilled, frozen, or deep-frozen; traceability; production and feed system; slaughtering system; fat limitations on certain cuts; labeling; and third-party conformity assessments. Localized systems for describing traded meat products are also available, for example, from AUS-MEAT in Australia and the Institutional Meat Purchase Specifications for meat and meat products in the USA.

Classifications based on the EUROP grid in particular, and also on the UN standards, do not provide any indication of the quality of meat from a consumer's perspective. The EUROP system has been criticized as just being a way to pay farmers and being of little value after the payment point. Thus, it is argued that payment for animals based on such a system does not adequately support the needs of modern meat processing. The lack of noninvasive methods to predict eating quality has hindered the development of payment methods for livestock based on eating quality. A number of schemes have been developed recently that attempt to predict eating quality based on various production and processing attributes. One such scheme has been developed by Meat Standards Australia. This grading system for beef, lamb, and sheep meat predicts tenderness and flavor using factors such as breeding, nutrition, environment, cooking length, and cooking method.

Product Differentiation

From a marketing perspective, the main reason for developing specifications is to be able to use key characteristics of production and processing (cues) as a basis for communicating quality attributes to consumers and hence differentiate the product from competitors. This changes the focus of the sale away from being based on the cheapest supplier and away from a 'commodity' product perspective. Such cues are needed because many quality attributes are experiential, i.e., cannot be determined until after purchase, for example, taste and tenderness. Therefore, specifications need to be developed that can provide easily identifiable quality cues for consumers. For example, color, fat levels, cut, trim level, and meat juiciness are used as quality cues for consumer demand attributes such as tenderness, taste, and juiciness. Credence attributes are another important consumer-related specification issue. Credence attributes are attributes that cannot be observed by the consumer at the point of sale or after consumption. Examples in the context of meat include organic, free range, and quality

assured. Providing quality assurance to consumers is an important source of differentiation in many developed markets following bovine spongiform encephalopathy (BSE), the more recent horse meat scandal in processed beef products and other food-related scares. These schemes have generally been related to food safety and traceability, underpinned by national animal movement schemes. However, many have expanded to include sensory attributes, animal welfare, and other credence-type attributes. Consumer interest in products with such attributes is growing with the environmental impact of meat production (e.g., carbon footprint) and its local provenance currently of interest in some markets (e.g., Canada's largest food retailer Loblaws is highlighting the sourcing of Ontario beef and is implementing a Grown Close to Home™ program). Growing consumer interest in carbon reduction due to increased government and media attention to climate change and its causes is one of the drivers of this.

Specifications developed for food safety and animal health reasons tend to be mandatory in nature and may range from national to transnational in scope. Specifications relating to trade may be mandatory or voluntary depending on the context; however, specifications for market differentiation reasons tend to be voluntary. The latter are generally retailer specific; however, national and regional schemes also exist where there is an export market focus.

Specification Attributes

In addition to sanitary, animal welfare, and other regulations that are clearly defined and mandatory in most countries, voluntary specifications relating to production and processing characteristics are specified in most markets. These are primarily based on factors known to influence eating quality and include production and processing factors. Although significant progress has been made in developing effective processing specifications to enhance quality and consistency of the final product for the consumer, the control and manipulation of animal variability is not as well understood. Furthermore, postslaughter factors are known to have a high influence on meat-eating quality because the main determinants of meat tenderness are the shortening of the muscle fibers and the extent of proteolysis of key structural proteins. Both can be optimized using electrical stimulation (and can even ensure that tenderness of *Bos indicus*-type cattle matches that of British and Continental breeds). Hence, it is considered that the postslaughter specifications are particularly important in presenting a product of acceptable quality to the consumer. This section outlines the main animal production and processing characteristics that may be specified in different markets.

Animal Production Characteristics

The final characteristics of the product are determined by the interaction of an animal's genotype with its environment (i.e., phenotype); hence, genetic as well as environmental characteristics may be specified. Specifications for live animals may include breed, sex (including whether male animals are castrated or not), age, and weight (live or dead weight) at slaughter and animal welfare practices including parasitic dosing, housing and feeding (including age at weaning) regimens, and healthcare. Breed, sex, age, and weight at slaughter influence fat and conformation levels and ultimately saleable meat yield and yield of cuts of various quality, and quality in terms of taste and tenderness. For example, Blonde d'Aquitine animals produce a higher yield of saleable meat because of lower fat levels and better conformation than other breeds. Age at slaughter is reported to effect beef tenderness; however, the impact of breed on meat quality is not clear because of the interfering influences within and between breeds, such as feed, growth rates, etc. Many of these factors are interrelated: for a given age at slaughter, bulls tend to be heavier; however, heifers of a European continental breed, for example, Charolais, may be heavier than bulls of one of the British breeds, for example, Hereford. Age at slaughter is also a food safety issue. For example, animals more than 30 months of age are not allowed into the food chain in the UK because of concerns about BSE. However, animals more than 30 months of age are allowed into the food chain in other EU countries if they have been tested free of BSE. Animal welfare practices influence consumer acceptability of the product and a priori knowledge can also bias sensory perceptions in favor of the product deemed to be from systems with higher animal welfare and greater environmental concern. However, feeding regimen also influences carcass and meat quality. Too low feeding levels increase age to slaughter, decrease the amount of intramuscular fat, darken the muscle color in the case of beef, and decrease the palatability of the meat. Too high feeding levels provide proper contents of intramuscular fat and good palatability of the meat but carcasses tend to be too fat, which has a negative effect on marketing and processing. In addition to the level of feeding, composition of the diet influences fat and muscle color. Pink beef with white fat can be produced by feeding a diet including maize silage, whereas beef that is deep red with yellow fat can be achieved on a grass-based diet. Moreover, the high level of genetically modified protein sources in animal feed has resulted in a specification that requires genetically modified feed to be excluded from an animal's diet for a specified period before slaughter in some markets.

Processing Characteristics

Specifications for carcasses include product attributes such as weight of carcass, conformation, fat levels and color of fat and muscle, and process attributes such as slaughtering, maturing/aging procedures, cutting, and packing. Process attributes are specified because they are important environmental variables that influence the final quality of the product, saleable yield, and ultimately profitability.

The most common slaughtering method is the captive bolt. However, meat destined for certain markets may require specific slaughter methods. For example, meat for the Muslim market must be from cattle slaughtered by cutting the throat to allow the meat to be sold as halal. Electrical stunning can be used. Electrical stimulation during the stunning or bleeding period can improve tenderness, so some multiple retailers specify this.

The aging process/conditioning has a significant impact on tenderness as the natural enzymes in meat (e.g., calpains)

tenderize the meat over time. In general, extending the postmortem aging period improves tenderness. Under normal industrial conditions, aging period varies by animal species with 3–5 days being the norm for pigs, 7–10 days for sheep, and 10–21 days for cattle. Moreover, the chilling regimen can influence the aging process, as activity of the enzymes is influenced by temperature. The way the carcass is suspended during the aging process also influences tenderness. For example, pelvic suspension improves tenderness and is a specification used by many Irish and UK multiple retailers. Furthermore, the addition of tenderizers (enzymes), such as papain, helps to break down the connective tissue and make the meat tender; however, this is not a commonly used specification. In practice the length of the aging period is often determined by geographical proximity of the market (meat for local markets needs to be tender within a few days, whereas meat for the export market may have the advantage of several weeks of chilled storage in which aging can take place) with other means used to achieve tenderness within the given time limit.

Cutting style affects yield and cutting time and thus profitability. Cutting specifications vary by anatomical separation location (e.g., the rib number at which the animal is quartered) and/or the level of external fat trim (whether or not various fat deposits are left on the carcass). Primal and further processed cuts are obtained in accordance with different cutting specifications. Industry cutting specifications are produced by a number of agencies. For example, in the USA, the Institution Meat Purchase Specifications/National Association of Meat Purveyors Specifications number may be specified to avoid the need to specify cutting procedures in detail. Different cuts are specified according to intrinsic characteristics of the muscle, because for example, fiber structures may be an important source of variation in meat-eating quality. BSE has influenced cutting specifications within the EU as all beef animals more than 12 months of age at slaughter are required to have their spinal column removed. This has resulted in a new outlet for animals less than 12 months of age, which is aimed at the 'T-bone market.'

The level of processing to some extent determines packing specifications. Primal cuts tend to be vacuum packaged and retail cuts packed in modified atmosphere packaging; however, other forms of packing are also available. Other quality specifications at this stage include level of marbling, total bacterial counts, bruising, pH, drip, and shelf life.

In an attempt at differentiation, some breed-specific specifications have been developed, for example, Certified Hereford Beef Specification, and some production systems based on geography and traditional methods are protected within Europe. Examples of the latter include products that use Protected Geographical Indications (PGI), for example, Ternera de Navarra (Spain) and Connemara Hill Lamb (Ireland).

In addition to the above, to comply with food safety and other requirements, modern meat production specifications include a requirement to maintain records of all activities along the chain.

Assessment of Adherence to Product Specifications

Adherence to specifications can be objectively determined in some instances; however, an element of subjectivity exists for others. This is not surprising as quality is an important factor in determining many specifications and quality encompasses both objective (e.g., carcass weight and organoleptic measures) and subjective elements (e.g., about production methods). Visual inspection is common for examining some aspects of the physical product, such as fat and conformation. However, other attributes require auditing, certification, and evaluations. For example, feeding regime and parasitic dosing regimes require detailed records, which may have to be verified by a third party. Signed declarations from producers/processors to agree to a code of practice covering issues such as stockmanship, animal welfare, feeding, etc. are fundamental to quality assurance and other credence attributes-based schemes. Random farm/abattoir visits by an independent agency are also part of the process.

Objectivity is important for all specifications but particularly for specifications that determine price. The EUROP classification scheme for beef and sheep was entirely subjective when first implemented as it was generally carried out by visual appraisal by trained graders. This often resulted in mistrust between farmers and abattoirs and between abattoirs and retailers. More recently mechanical grading systems have been developed and implemented. These are now widespread in Australia and some parts of Europe. Ireland was the first EU country to get authorization for mechanical grading and has 24 systems installed in export factories. France now have a significant number of systems, Denmark and Germany have a small number of systems, and a few countries (the UK, Spain, Sweden, and Norway) have done, or are in the process of doing, trials. These systems are generally based on video imaging analysis (VIA). They use one or more digital cameras, lights, and a large numbers of measurements at specific points of a completely still carcass to assess shape and coloration, and hence predict conformation, fat cover, and meat yield using algorithms. Such systems also have limitations with an argument that VIA is not very good for fat assessment or for assessing damaged carcasses (e.g., those damaged during hide removal). Methods to address these limitations include augmenting the system with other systems, such as near-infrared spectroscopy in the case of the fat limitation, paying based on a batch average, or engaging a human grader for the damaged carcass.

The range of objective measurements is increasing in availability and prevalence, (e.g., mechanical grading on the (S)EUROP grid and testing using single-nucleotide polymorphisms (SNPs) for PGI status). Moreover, measurement is becoming easier with the use of noninvasive live animal and carcass measurements to predict key attributes. For example, ultrasound measurements of live animals close to slaughter can be used to predict retail beef yield and thus avoid the need to individually weigh cuts. Bioelectrical impedence of primal cuts can be used to determine total skeletal muscle and total skeletal fat-free muscle weight.

Recent Developments

Technological advances result in the need to develop new specifications to protect consumer health, ensure animal welfare, etc. Such advances in the context of meat include farm animal cloning, advances in mechanical separation of meat, and

the development of *in vitro* meat production systems. Specifications in these areas are often limited by the systems that are available to assess adherence to specifications. For example, with regard to cloning, although the European Commission has proposed introducing a 5-year temporary suspension of cloning or importing of clones for food, a practical test does not exist to determine whether an animal has been produced as a result of cloning technology or natural reproduction.

Although mechanically separated meat (MSM) has been available for some time, issues around its safety arose in the 1980s and resulted in restrictions around how much can be used and the type of products in which it can be used. Clear regulations exist around how it may be described on food labels, for example, it may not be labeled as 'meat' but must be labeled as 'mechanically separated' pork, chicken, or turkey in the ingredients statement. Products such as hot dogs may contain no more than 20% mechanically separated pork. Concerns about the potential for spinal cord being mixed up with the rest of the meat during the mechanical separation process have resulted in restrictions around its application. For example, mechanically separated beef is considered inedible in the USA and is not permitted in any processed products. Concerns also exist about the calcium content of MSM so that MSM specification may require that the calcium content is not significantly higher than that of minced meat. Specifications relating to microbiological criteria are also important in the context of MSM.

In vitro meat is not commercially available; however, recent developments indicate that it could be available as a meat ingredient in the not too distant future. Although sensory and visual aspects are not clear, such a product could be attractive to consumers for animal welfare and environmental reasons. Specifications on its production will be considerably different to meat produced naturally and could include specifications relating to growth medium, origin of the 'starter' culture, etc. It could also result in a market specification regarding the origin of the meat, i.e., *in vivo* or *in vitro*.

Continued developments may be expected in this area driven by an increasingly demanding consumer (particularly regarding credence attributes) as well as technological advances in measurement techniques to verify specifications. However, fundamental to the development of a definitive, objective list of market specifications will be improved understanding of the relationship between production and processing conditions and quality and saleable yield as well as more research that identifies various noninvasive predictors of eating quality and meat yield.

Transport of Meat and Meat Products

SJ James and C James, The Grimsby Institute of Further & Higher Education (GIFHE), North East Lincolnshire, UK

Glossary

Conduction, thermal. Mechanism for heat transfer The process of heat transfer through a solid material/medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

Convection, thermal. Mechanism for heat transfer The process of heat transfer through a liquid or gas by means of circulating currents caused by changes in density.

Eutectic solution Relating to or denoting a mixture of substances (in fixed proportions) that melts and freezes at a single temperature that is lower than the melting points of the separate constituents or of any other mixture of them, for example brine (salt and water). Eutectic refrigeration systems utilize the latent heat within a frozen eutectic solution to provide heat extraction and maintain temperatures.

Heat transfer coefficient Coefficient used in thermodynamics to calculate heat transfer, typically by convection or phase change, between a fluid and a solid.

Pasteurization A form of heat treatment that kills certain vegetative bacteria and/or spoilage organisms in milk and other foods. Temperatures below 100 °C are used.

Radiation, thermal Mechanism for heat transfer. Electromagnetic radiation generated by the thermal motion of charged particles in matter. All matter with a temperature greater than absolute zero emits thermal radiation.

Refrigeration May be defined as the process of removing heat from any substance to: (1) render colder – reduce temperature, (2) change its state – for example, water to ice, (3) maintain its state – preserving foods, storing ice.

Water activity (aw) A measure of the available water in a substance. 'High-aw' foods support bacterial growth; 'low aw' do not. This is not the same as water content. Some foods with a high water content have a relatively low aw because the water is bound up with dissolved salts or sugar, for example, jam.

Introduction

Worldwide transportation of chilled and frozen meat by sea, land, and air is a well-established practice. Developments in frozen transport in the nineteenth century established the international meat market. In 1877 a cargo of frozen meat was sent from Buenos Aires to France. The following year 5000 frozen mutton carcasses were transported from Paraguay to France. In 1880 the Strathleven arrived in London with a cargo of 40 ton of frozen Australia beef, and the Dunedin followed in 1882 with mutton, lamb, and pork from New Zealand; by 1910 the UK was importing 600 000 ton of frozen meat. Further developments in temperature control have established sea transportation of chilled meat from Australia and New Zealand to European and other distant markets, and road transportation of chilled products throughout Europe, the Middle East, and the United Sates is now common practice. Air freighting is increasingly being used for high-value perishable meat products such as venison and Wagyu beef.

In the UK, transportation is considered to be the third highest sector in the food cold chain in terms of energy consumed by refrigeration systems. Under European Union legislation red meat (beef, lamb, and pork) must be kept below 7 °C, poultry below 4 °C, and offal below 3 °C during transportation.

It is particularly important that the meat is at the correct temperature before loading because the refrigeration systems used in most transport containers are not designed to extract heat from the load but to maintain the temperature of the load. In the large containers used for long-distance transportation meat temperature can be kept within ±0.5 °C of the set point. With this degree of temperature control transportation times of 8–14 weeks (for vacuum-packed meats stored at −1.5 °C) can be carried out and still retain a sufficient chilled storage life for retail display.

There are substantial difficulties in maintaining the temperature of refrigerated meats transported in small refrigerated vehicles that conduct multidrop deliveries to retail stores and caterers. During any one delivery run, the chilled product can be subjected to as many as fifty door openings, where there is heat ingress directly from outside and from personnel entering to select and remove product. The design of the refrigeration system has to allow for extensive differences in load distribution, dependent on different delivery rounds, days of the week, and the removal of product during a delivery run.

Sea Transport

Historically it was the need to preserve meat during sea transport that led to the development of mechanical refrigeration and the modern international trade in foodstuffs. Recent developments in temperature control, packaging, and controlled atmospheres have substantially increased the range of foods that can be transported around the world in a chilled condition. With conventional vacuum packing it is difficult to achieve a shelf life in excess of 12 weeks with beef and 8 weeks for lamb. Controlled/modified atmospheric packaging can extend this by many weeks. A shelf life of up to 14 weeks at −1.5 °C can now be achieved with lamb from New Zealand.

 doi:10.1016/B978-0-12-384731-7.00180-X

Table 1 Expected maximum transport duration for meat shipments for a reasonable retail display/shelf life

	Vacuum pack (0 °C; weeks)	*Vacuum pack (−1.5 °C; weeks)*
Pork	6	8
Lamb	7	10
Beef	10	14

These cuts are individually packed in evacuated bags of linear polyethylene, and then placed in a foil laminate bag that is gas flushed and filled with a volume of CO_2 approximately equal to that of the meat. Similar storage lives are currently being achieved with beef primals transported from Australia and South Africa to the EU.

Assuming good standards of preparation and prompt cooling the times given in Table 1 can be used as approximate guidelines for long-distance meat shipment. These times rely on the meat being at or below the storage temperature before loading. The 2- to 4-week advantage of transporting meat at −1.5 rather than 0 °C is lost if the meat is loaded at a temperature above 0 °C. Cooling in the center of a load of meat is very slow and the meat will be well into its journey before the desired temperature is achieved.

Most International Organization for Standardization (ISO) containers for food transport are either 6 or 12 m long, hold up to 26 ton of product, and can be 'insulated' or 'refrigerated.' The refrigerated containers incorporate insulation and have refrigeration units built into their structure. The units usually operate electrically, either from an external power supply on board the ship or on the dock, or from a generator on a road vehicle. Insulated containers either utilize plug-type refrigeration units or may be connected directly to an air-handling system in a ship's hold or at the docks. Close temperature control is most easily achieved in containers that are placed in insulated holds and connected to the ship's refrigeration system. However, suitable refrigeration facilities must be available for any overland sections of the journey. When the containers are fully loaded and the cooled air is forced uniformly through the spaces between cartons, the maximum difference between delivery and return air can be less than 0.8 °C. The entire product in a container can be maintained to within ±1.0 °C of the set point.

Refrigerated containers are easier to transport overland than the insulated types, but often have to be carried on deck when shipped because of problems in operating the refrigeration units within closed holds. Therefore, they are subjected to much higher ambient temperatures on board ship and consequently larger heat gains that make it far more difficult to control product temperatures.

For bulk transportation of frozen meat refrigerated cargo ships are commonly used. Frozen meat is generally stored and transported at −18 °C or below. Unlike chilled meat, small temperature changes during loading and unloading can be tolerated with frozen meat.

Air Transport

Perishable goods, food, and ornamental plants making up 80% by volume is one of the largest air cargo sectors, accounting for 14% by volume of total global air freight. Reports in 2005 highlighted perishables as one of the fastest growing air cargo sectors at approximately 10% per year, expecting volumes to amount to approximately 10 million tones per year by 2010. Although air freighting of foods offers a rapid method of serving distant markets, there are many problems because the product is usually unprotected by refrigeration for much of its journey. Up to 80% of the total journey time is made up of waiting on the tarmac and transport to and from the airport. During flight the hold is normally between 15 and 20 °C. Perishable cargo is usually carried in standard containers, sometimes with an insulating lining and/or dry ice, but is often unprotected on aircraft pallets.

Studies in Australia have led to the following recommendations for air transport of chilled foods:

1. Insulated containers should always be used to reduce heat gain.
2. Product should always be precooled and held at the required temperature until loading.
3. With products that deteriorate after any surface freezing dry ice should not be used.
4. Containers should be filled to capacity.
5. A thermograph should accompany each consignment.

Overland Transport

Overland transportation systems range from 12 m refrigerated containers for long-distance road or rail movement of bulk chilled or frozen products, to small uninsulated vans supplying food to local retail outlets or even directly to the consumer. Some of the first refrigerated road and rail vehicles for chilled product were cooled by air that was circulated by free or forced systems, over large containers of ice. Similar systems using solid carbon dioxide as the refrigerant have also been used for cooling of transport vehicles. However, most overland vehicles for long-distance transport are now mechanically refrigerated.

There can be a substantial difference in the ability of transport systems to cool warm meat. One particular study in the USA, for example, has shown rail containers to be more effective than road containers at reducing temperature in meat should it be loaded warm. In the study deep temperature in beef sides and quarters at the time of their loading into transport vehicles ranged from 6 to 18 °C. Maximum surface temperatures were also high and ranged from 0.5 to 6.5 °C. In rail wagons the surface temperature declined during the first 24 h and was subsequently maintained at a temperature of 0 ±1 °C. In the road vehicles the surface temperature fell slowly during the whole journey and had not attained a steady minimum value when unloaded. On average the deep temperature of sides in rail wagons reached 1 °C after 72 h. Temperatures in quarters in road vehicles were still above 2 °C after 120 h. Journey times varied from 3.8 to 6.7 days, and it was calculated that during that time pseudomonads could proliferate by between 8 and 22 generations in the meat transported by road. Adequate air movement through the load in the rail vehicles produced even temperature distributions.

In general, it is not advisable to rely on product cooling during transportation. However, in the Netherlands 'in

transport cooling' is used as an integral part of a processing system for pork carcasses, which allows the carcasses to be dispatched on the same day the animals are killed.

Types of Refrigeration System

The majority of current road transport vehicles for chilled foods are refrigerated using either mechanical, eutectic plates or liquid nitrogen cooling systems. The use of photovoltaics (solar power) to power mechanical units has been pioneered in some countries.

Mechanical Units

Many types of independent engine and/or electric motor-driven mechanical refrigeration units are available for trucks or trailers. One of the most common is a self-contained 'plug' unit that mounts in an opening provided in the front wall of the vehicle. The condensing section is on the outside and the evaporator on the inside of the unit, separated by an insulated section that fits into the gap in the wall. Units have one or two compressors, depending on their capacity, and these can be belt driven from the vehicle but are usually driven directly from an auxiliary engine. This engine may use petrol from the vehicle's supply, an independent tank, or liquid petroleum gas. Many are equipped with an additional electric motor for standby use or for quiet running, for example, when parked or on a ferry.

Irrespective of the type of refrigeration equipment used the product will not be maintained at its desired temperature during transportation unless it is surrounded by air or surfaces at or below that temperature. This is usually achieved by a system that circulates air, either forced or by gravity, around the load. Inadequate air distribution is probably the principle cause of product deterioration and loss of shelf life during transport. Conventional forced air units usually discharge air over the stacked or suspended products either directly from the evaporator or through ducts toward the rear cargo doors. Because air takes the path of least resistance it circulates through the channels that have the largest cross-sectional area. These channels tend to be around rather than through the product. If the products have been cooled to the correct temperature before loading and do not generate heat then they only have to be isolated from external heat ingress. Surrounding them with a blanket of cooled air achieves this purpose. Care has to be taken during loading to avoid any product contact with the inner surfaces of the vehicle because this would allow heat ingress during transport. Many trucks are now being constructed with an inner skin that forms a return air duct along the side walls and floor, with the refrigerated air being supplied via a ceiling duct.

The application of photovoltaics to refrigeration for the distribution of chilled supermarket produce has been pioneered in some countries such as the UK. In 1997 Sainsbury's, a major UK supermarket chain, commissioned the world's first solar-powered refrigerated trailer. Operating in the UK, it was stated that 'During most of the year there has been an excess of solar energy over daily demand.' However, few commercial systems are currently available, and it is possible that the high capital cost of current PV systems is limiting adoption. It is anticipated that with time these costs should come down and payback times shorten.

Eutectic Plates

Eutectic plate cooling systems are used in refrigerated vehicles serving local distribution chains. The system works on the principle of latent heat. The eutectic plate consists of a coil, through which a primary refrigerant can be passed, mounted inside a thin tank filled with a eutectic solution. The eutectic solution is frozen by the refrigeration system in a static, or overnight, situation. During the working day no power is required, the cooling being provided by the melting of the frozen eutectic plate. A significant amount of refrigeration power is created as the eutectic melts, due to latent heat, while keeping a constant temperature in the container. Standard eutectic solutions freeze at temperatures between −3 and −50 °C. A number of these plates are mounted on the walls and ceilings or used as shelves or compartment dividers in the vehicles. Two methods are commonly used for charging up the plates: (1) when the vehicle is in the depot the solutions are frozen by coupling the plates to stationary refrigeration plants via flexible pipes and (2) a condensing unit on the vehicle is driven by an auxiliary drive when the vehicle is in use and an electric motor when stationary.

To provide the required cooling capacity, the plates should be mounted so that air can circulate freely over both sides and over the product. Most systems rely on gravity circulation but some are equipped with fans, ducts, and dampers for temperature control.

Eutectic systems are chosen for the simplicity, low maintenance, and quietness of their operation but can suffer from poor temperature control.

Liquid Nitrogen

A typical liquid nitrogen system consists of an insulated liquid nitrogen storage tank connected to a spray bar that runs along the ceiling of the transport vehicle. Liquid nitrogen is released into the spray bar via a thermostatically controlled valve and vaporizes instantly as it enters the body of the vehicle. The air is then cooled directly utilizing the change in the latent and sensible heat of the liquid nitrogen. Once the required air temperature has been reached the valve shuts off the flow of liquid nitrogen and the temperature is subsequently controlled by intermittent injections of liquid nitrogen.

Many advantages are claimed for liquid nitrogen transport systems, among them their simplicity, low capital cost, and silent operation. It is also claimed that long hauls can be carried out, vehicles are available that will maintain a chilled cargo at 3 °C for 50 h after a single charge of liquid nitrogen, and overall costs are comparable with mechanical systems.

Problems Particular to Local Delivery Vehicles

In a 1970–71 UK survey of vehicles used to transfer chilled meat from small abattoirs to shops, almost 70% were

unrefrigerated and 20% had no insulation. Since that time the intensifying demand from legislation and retailers for lower delivery temperatures has put increasing pressure on fleet operators to improve temperature control. However, there are substantial difficulties in maintaining the temperature of chilled foods transported in small refrigerated vehicles that conduct multidrop deliveries to retail stores and caterers. The vehicles have to carry a wide range of products and operate under diverse ambient conditions. As already mentioned, during any single delivery run, the chilled product can be subjected to as many as fifty door openings, during which there is heat ingress directly from outside and from personnel entering to select and remove product. The design of the refrigeration system has to allow for extensive differences in load distribution, dependent on different delivery rounds, days of the week, and the removal of product during a delivery run. A refrigeration system's ability to respond to sudden demands for increased refrigeration is often restricted by the power available from the vehicle. All these problems combine to produce a complex interactive system.

Throughout the world sales of chilled foods are expanding. In the meat industry the traditional range of pies, sausages, and cooked meats has been rapidly expanded with the addition of many ready meal-type products. Traditional meat product manufacturers are now aiming to further extend their range of products to include items such as gourmet-style meals without artificial colors, flavors, or preservatives. Retailers are discovering that considerable quality and economic advantages can be derived from maintaining chilled products at temperatures far closer to their initial freezing point. Increasingly, fleet operators will be forced to deliver chilled meats at temperatures between 0 and 2 °C.

The rise in supermarket home delivery services, where there are requirements for mixed loads of product that may each require different storage temperatures, is introducing a new complexity to local land delivery.

Design and Operation of Local Distribution Vehicles

Refrigerated vehicles are developed and tested in carefully controlled conditions. Owing to the large number of interacting variables, as many as possible of these variables are held constant during the tests. These tests do not provide van manufacturers with data on food temperatures and van performance during commercial operation. Additionally, van operators need to know in advance whether a particular van, on a particular round, under given ambient conditions, will be able to deliver food at the correct temperature. To overcome these problems computer prediction programes such as 'CoolVan' have been produced that allow the systematic alteration of one or more variables while simulating the operation of a vehicle in a complex, realistic way.

In the following section, data from the verified model illustrate the effects of some of these variables while operating a small refrigerated delivery van over a realistic journey, during which it stops and starts, the door opens and closes, the ambient conditions vary, the refrigeration system operates under its own control, and food is removed from the vehicle. The van modeled was a 3-ton vehicle, typical of the type used for the delivery of cooked meat products. It consisted of an insulated box with a single door at the rear. A nominally 2.8 kW refrigeration unit was mounted in a pod on the front bulkhead of the van over the driver's cab. Inside, the van was equipped with racking for carrying trays of products and a reinforced floor. The type of journey for which these vehicles are used ranges from a single bulk delivery to a regional depot or supermarket, to multiple deliveries to up to 40 separate shops in a region during 1 day. The details of the standard journey used to compare factors are shown in Table 2.

Table 2 Standard delivery van schedule for assessment of effect of van and operational variables

Variable	*Value*
Mean daily temperature	16 °C
Maximum daily temperature	28 °C
Relative humidity	60%
Cloud cover	None
Month	June
Latitude	53° N
Start time	07:30
Journey length	321 km
Number of stops	20
Time halted at each stop	5 min
Time the door is open at each stop	2 min
Door protection	Strip curtains
Average speed between stops	32 km h^{-1}
Weight of food at start of journey	1000 kg[a]
Initial van temperature	4 °C
Thermostat switch-on temperature	5 °C
Thermostat switch-off temperature	3 °C

[a]An equal amount of food is delivered at each stop and no food is left at the end.

Van Insulation

To maintain meat temperatures below 5 °C in an uninsulated van the refrigeration system has to have an extraction capacity of over 10 kW. However, only a small thickness of insulation is required to greatly reduce the amount of heat that has to be extracted, the amount decreasing with the reciprocal of the thickness of insulation (Figure 1). Loading a van with precooled meat reduces the total amount of heat that has to be extracted during a journey. The load acts as a heat sink, consequently modifying the action of the thermostat and reducing the running time of the refrigeration system and the heat extracted by it. For an insulation of 75 mm thickness (which is typical for a commercial vehicle) loading the van reduced the average heat extraction rate by 26%. Increasing the insulation thickness from 75 to 100 mm produced a 33% reduction in the average extraction power required.

Infiltration

Poor maintenance and customization can have a significant effect on heat infiltration. A comparison of two vehicles, one a well-sealed van with a close-fitting door and effective door seals, the other a poorly maintained one with several gaps and

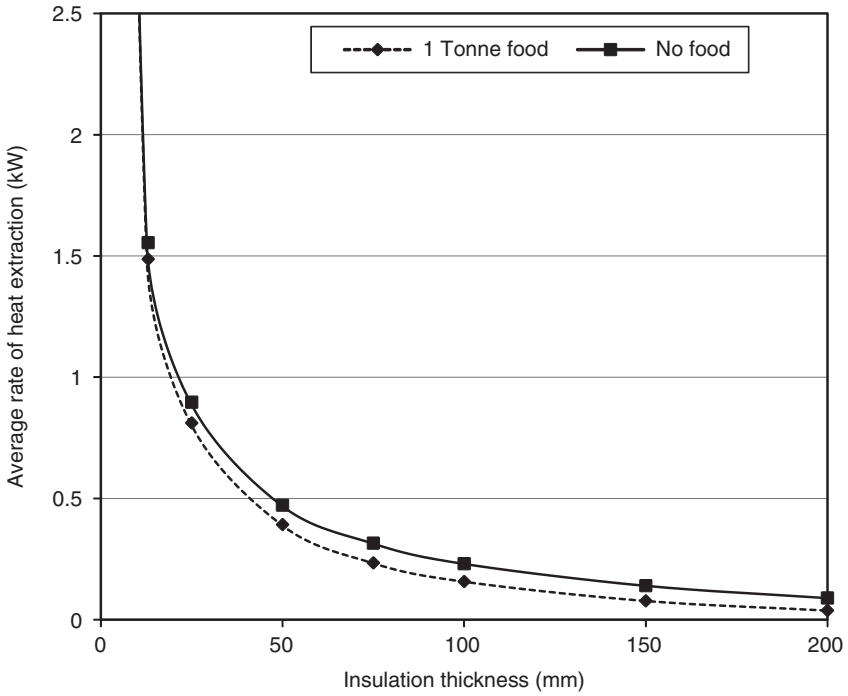

Figure 1 The effect of the thickness of insulation of a refrigerated delivery vehicle, with and without a food load, on the average rate of heat extracted by the refrigeration plant over a standard journey (details of journey shown in **Table 2**).

holes through the insulation and poor door seals, showed a difference in measured heat infiltration of 86%. However, infiltration during the time that the door is closed is a relatively small proportion of the total refrigeration load. Consequently, the vehicle, fitted with a nominal 2 kW cooling system, was found to keep the meat temperature below 5 °C during the journey.

Door Openings

The heat extracted from a closed van is very small; however, opening the door greatly increases the heat load. In vans where the engine drives the refrigeration system this extra heat must be removed during the period when the van is moving. Several factors interact when the number of door openings increases. The complete journey takes longer, and during the extended journey the ambient temperature and the solar radiation on the van is different from the early part of the journey. If the length of time that the door is left open at each stop is also increased from 5 to 10 min then the temperature of the air around the food in the van increases further during each stop (Figure 2). The refrigeration plant therefore operates at a higher evaporating temperature (and hence it has greater capacity) when reducing the temperature once the doors are closed and the vehicle starts moving again. The time during which the refrigeration plant can run remains the same as the number of drops increases, and therefore the rate of heat extraction increases approximately linearly with the number of stops.

The fitting of plastic strip curtains across the doorways can substantially reduce heat gain and consequently the heat that has to be extracted (Figure 2). However, in practice they are often damaged or tied aside because they restrict free access.

Initial Food Temperature

Delivery vans are designed to transport precooled meat. If the meat is loaded at 7 °C rather than 0 °C the heat extracted by the refrigeration system will be 7 times greater. In the predicted case, shown in Figure 3, the meat was assumed to spread out over the shelves of the van and thus cooled down quickly. If the meat were stacked with little or no air circulation through it then the heat extracted would be less, but the meat would remain warm.

Length of Journey

As the length of the journey gets shorter while the number of drops remains the same the heat entering the van during the stops must be extracted in shorter time intervals between each stop. The rate of heat extraction therefore varies inversely with the length of the journey (Figure 4). It is easier to maintain food temperatures on long journeys than when there are a large number of stops with little time spent traveling between each stop.

Combination of Factors

It is when a number of factors combine that problems occur and the temperature of the meat cannot be maintained. If an

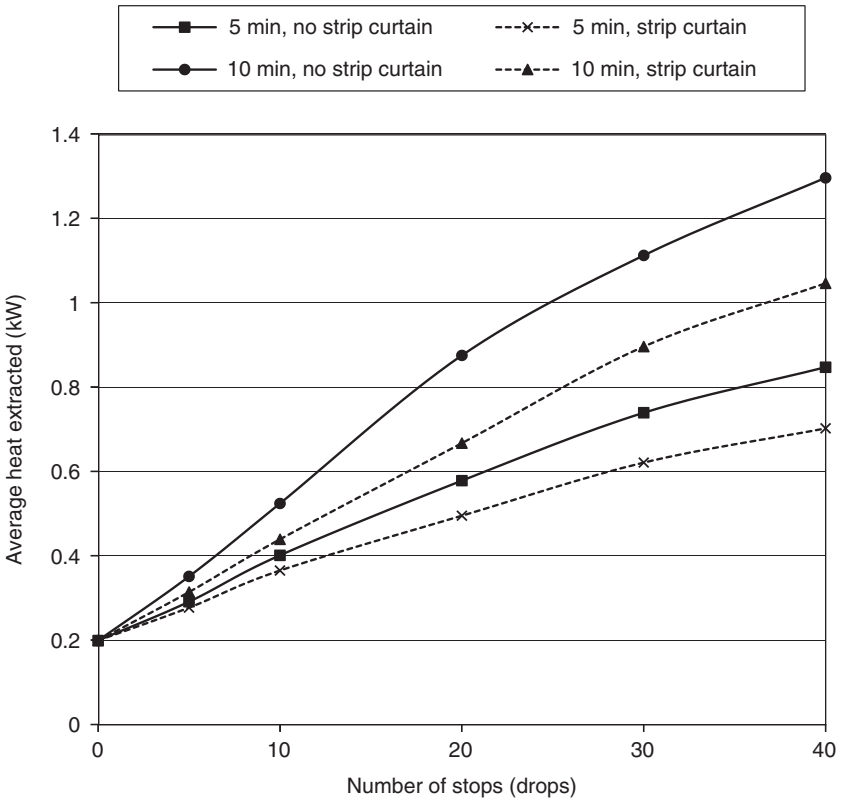

Figure 2 The effect of the number of stops (drops), and time of the stop, a refrigerated delivery vehicle makes, with and without a strip curtain, on the average rate of heat extracted by the refrigeration plant, averaged over the periods when the vehicle is moving, over a standard journey (details of journey shown in **Table 2**).

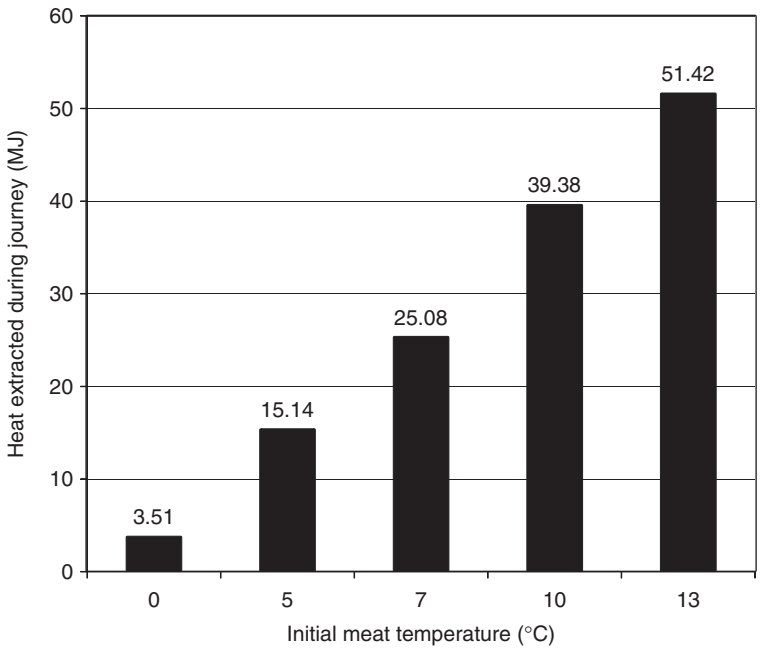

Figure 3 The effect of different initial product temperatures loaded on to a refrigerated delivery vehicle on the heat extracted by the refrigeration plant over a standard journey (details of journey shown in **Table 2**).

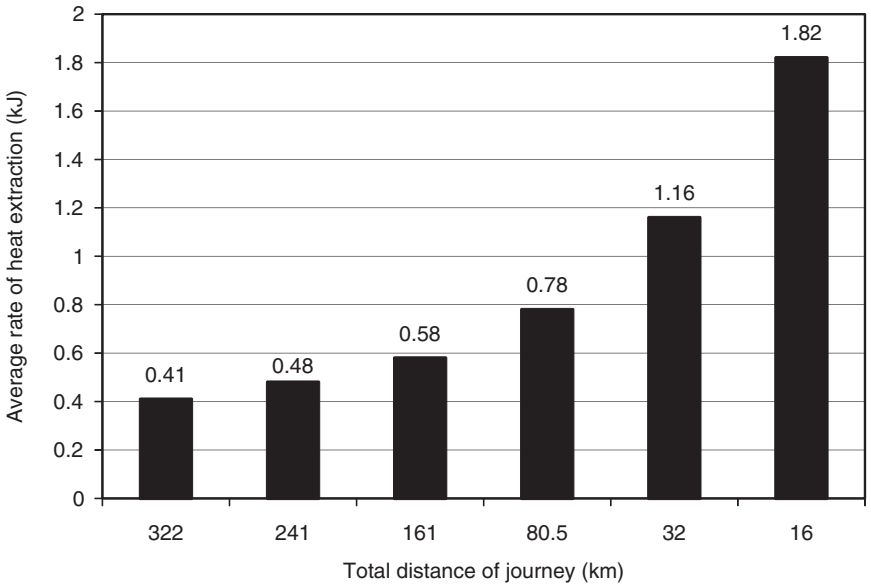

Figure 4 The effect of the total distance of a journey on the average rate of heat extracted by the refrigeration plant of a refrigerated delivery vehicle, averaged over the periods when the vehicle is moving (details of journey shown in **Table 2**).

old van were used for the standard journey described in this section and the van stopped for 10 min at each delivery with the door open for 5 of those minutes, with strip curtains in place, then the meat temperature would be 5.1 °C at the end of the journey. If the number of stops increased to 30 and the length of the journey decreased to 100 miles then it would increase to 6.4 °C. In these journeys, the refrigeration plant is not running long enough when the van is moving to remove all the heat entering the van when it has stopped.

If strip curtains were fitted over the door (and used) but the door was left open for the full 10 min that the van was stopped at each delivery, then the meat temperature at the end of the run would increase to 7.2 °C. If the operator then reduced the amount of food carried on the van to an initial load of 250 kg, the final food temperature would be 8.0 °C. This is because when the air temperature in the van increases above the food temperature the food starts to cool the air and acts as a store of refrigeration capacity. If less food is placed in the van then there is a smaller store of refrigeration capacity and temperatures increase. If the strips are not used over the door opening then the food temperature increases even more to 9.4 °C. Moreover, if the journey is started later in the day, when the ambient temperature has warmed up, then the situation deteriorates even further.

To try to rectify matters operators have moved to more powerful refrigeration units, or to eutectic systems, and they have also considered vans where the refrigeration system is driven by its own engine so that it can operate when the van is stationary. If such a system were used then it would have to have a capacity in excess of 4 kW if it were to maintain the food temperature to a maximum of 5 °C during the last journey described above. Eutectic systems have the advantage that they can deliver cooling while the van is stationary. However, their storage capacity is limited and a eutectic system would need a large number of beams (the thermal storage units) to maintain temperature during the above combinations.

Wet Markets

HF Ho, SilverPeak Pte Ltd., Singapore

This article is reproduced from the previous edition, volume 2, pp 702–705,
© 2004, Elsevier Ltd., with revisions made by the Editor.

Introduction

The traditional system of retail food marketing in Asian countries is the wet market. A wet market is a combination of poultry farmers' markets, fishmongers, and open-air butcher shops that are about the size of a large supermarket.

A wet market gets its name from floors that are soaked from being continually washed down; washed because fish intestines and blood from butchering chickens and ducks in the poultry stalls become putrid if left around for very long, and also because a wet floor is considered better than a bloody and smelly one.

Wet markets are normally divided into distinct sections: live poultry, meat (pork, beef, and mutton), fish and seafood, eggs, fruit, vegetables, rice, and dry grocery items. Naturally, the wettest parts of the wet markets are the poultry and fish sections. Stalls in the wet markets are relatively small, rarely more than a couple of square meters, and are separated by narrow aisles (Figures 1–3).

Wet market stalls are restricted in what they are permitted to sell. For instance, if the stalls are licensed to sell vegetables, they sell just that. The same goes for stalls that sell meat, fish, or poultry.

Wet markets normally operate from very early hours of morning until noon. Some wet markets, for example those in Hong Kong, also operate in late afternoon to cater to office workers who normally do some quick shopping for fresh foods before they head home to prepare dinner for their families.

Meat Stalls

In Muslim countries, such as Indonesia and Malaysia, and in multiracial societies, such as Singapore, Islamic teaching that Muslims must not come into physical contact with pigs and pork dictates the meat stalls in these countries. Hence, the meat stalls are of two distinct types: those that sell only pork, and those that sell beef and/or mutton. These two types of stalls are physically segregated in different parts of the wet markets.

In the meat stalls, large slabs of meat hang from metal hooks. Pig heads, tails, and entrails are also on display. The butchers are skillful in deboning the half carcasses or quarters that they have taken delivery (nonrefrigerated) from the abattoirs. They chop and slice selections of meat with huge metal cleavers according to the requirement of their customers.

Figure 1 A wet market Tekka Center, Singapore.

Poultry Stalls

Traditionally, live poultry (chickens, ducks, and pigeons) are kept in multitier cages for customers to inspect and choose. For a nominal fee, the vendors will slaughter the poultry

Figure 2 Indoor markets also exist under shopping areas such as this one under Lok Fu Shopping Center (Hong Kong).

 doi:10.1016/B978-0-12-384731-7.00181-1

Figure 3 A wet market in Hong Kong.

selected and purchased by the customers. Bleeding, scalding, defeathering and cleaning of the entrails, and dressing the carcasses are speedily carried out within a confined space of a couple of square meters.

Poultry droppings, feathers, and blood that inevitably splash all over the floors and walls create a high risk health environment for both poultry and humans. A perfunctory hosing down of the floors, walls, and empty cages at closing hours, without thorough cleaning and disinfecting, does not remove the disease-causing microorganisms in the fecal materials and caked blood that have accumulated over months and years.

Wet Market Strengths

Wet markets are conveniently located within residential areas. Perishable products sold in the wet markets are perceived by customers to be fresher than those offered at the supermarkets. Asian chefs are known to take pride in choosing the best cuts of meat and the healthiest chickens that are fresh from the wet markets to prepare their signature dishes.

Furthermore, in order to buy the freshest supplies to cook for their family meals, many housewives, such as those in Hong Kong and other Asian cities, go to the wet markets twice a day, firstly in the morning, and again in the late afternoon.

Customers are allowed to touch and smell the products, and to inspect the live poultry before deciding on their purchases. It is also customary for customers to bargain with the stall vendors for discounts on their purchases. Often, stall vendors also give credit and keep special cuts of meat for their regular customers.

Wet Market Weaknesses

As the space allocated to each stall is limited to a couple of square meters, the stalls in the wet markets tend to be cluttered. Furthermore, the standard of food hygiene tends to be poor and the level of cleanliness low. In addition, shopping hours in wet markets are restricted, which is the main drawback for individuals who work.

Market Forces

According to market surveys carried out by Anderson Consulting in 2000 on understanding shopping trends in wet markets in Southeast Asia, Hong Kong, and Korea, wet markets' share of retail grocery sales ranges from 60% in Singapore, 70% in Malaysia and Thailand, 80% in Indonesia to 90% in Hong Kong.

According to another report (dated March 2003) by AC Nielsen Marketing Research, between 80% and 90% of shoppers visit wet markets on a regular basis in Indonesia, Korea, Malaysia, Singapore, Thailand, and the Philippines. In Indonesia, the wet market is the main store-type frequented by nearly one-third of all shoppers. Wet markets are also the most popular store-type that meet shoppers' daily need for fresh meat, fruit, and vegetables. In Thailand and Indonesia, shoppers frequent the wet markets at least once every other day, five times more frequently than they visit the supermarkets. Fewer than 30% of shoppers turn to supermarkets for their fresh food requirements. Two out of three respondents in Singapore said they go to the wet markets seven times a month.

According to a report by the Foreign Agriculture Service of the US Department of Agriculture, there are 564 000 wet markets in Thailand for a population of 60 million. Figures for other Asian countries are not available. It is conceivable that figures for other Asian countries, if available, will be comparable to that in Thailand. This is because wet markets can be found in every village, township, and city, catering to the populations' daily need for fresh foods.

In an estimate by the Food and Agriculture Organization of the United Nations, more than 90% of the meat in Asia is marketed 'warm,' that is, without refrigeration. Pigs and cattle are slaughtered during the night and their 'warm' meat reaches wholesale and retail markets in the early morning and thereafter, the customers' kitchen, all within a day.

At first glance, wet markets may give the impression of being unhygienic. However, if properly organized, especially under the supervision of municipal authorities in accordance with a system of licensing of the store holders and products offered for sale, wet markets are generally recognized to be an acceptable marketing system well suited for the relatively poorer infrastructure in underdeveloped/developing countries. Wet markets are a good and viable source for fresh foods at affordable prices. Thorough cooking of food by consumers helps to ensure that food is safe.

It should be noted that the method of 'warm' meat distribution and marketing described above (i.e., without refrigeration) works well only where transport distance is short – it requires abattoirs to be located near urban centers where wet markets are located to ensure freshness of the meat.

Public Health Hazards

In view of the less than desirable hygiene conditions in many of the traditional wet markets, it is only a matter of time before

serious public health problems will occur. In fact, a series of widely publicized food-poisoning outbreaks in China in recent years has tarnished the image of neighborhood wet markets, resulting in consumers' perception that the meat sold in such markets is not clean and safe. The perception stems from the manner in which the meat is sold: the unprotected 'warm' meat is exposed to dust and other pollutants, and attracts flies, rodents, and other vermin. However, there is substantial upgrading of conditions in wet markets.

In Hong Kong, people traditionally buy their chickens live from dedicated poultry markets, where the selected poultry are freshly killed. Avian influenza virus (H5N1), also known as bird flu, showed up in Hong Kong in 1997 and was quickly traced to the crowded poultry markets. The virus killed 6 people and infected 18 others before it was contained, after which some 1.5 million chickens had to be humanely destroyed by the health authority. It was the first time in medical history that an influenza virus was known to have transmitted directly from chickens to humans. The influenza virus returned in 1999, resulting in 1.2 million chickens being destroyed. Since then, the virus has returned periodically, albeit on smaller scales.

A recent review and some studies have suggested that Chinese wet markets would be unique epicenters for transmission of potential viral pathogens, as new genes could be acquired or existing genes modified through mechanisms such as genetic reassortment, recombination, and mutation. Because wet markets are at close proximity to humans, there is the possibility of a high transmission efficiency of viruses to humans.

The Hong Kong authority considered how best to change the traditional way in which poultry are kept, slaughtered, and sold in the poultry markets. A proposed policy option considered by the authority was the centralized slaughter of poultry, banning slaughter of poultry in wet markets. Implementation of this proposal ushered in a new era of poultry hygiene practices in Hong Kong. In fact, a model of this seemingly revolutionary practice was already in place in Singapore.

Modern Wet Markets

Long before the unfortunate avian influenza outbreaks in Hong Kong occurred and the attendant public health implications were recognized, the Singapore government in 1993 banned the unhygienic practice of keeping and slaughtering poultry in the wet markets. Poultry stallholders and live poultry wholesale importers were encouraged to set up mechanized poultry slaughterhouses. There are now 10 chicken and 4 duck slaughterhouses strategically located in different parts of the island. The poultry stalls in the wet markets now sell chilled and dressed whole chickens and ducks supplied by these slaughterhouses. The poultry sold are also individually tagged with the name of the slaughterhouses and the date of slaughter to facilitate trace-back and enforcement of the Sale of Food Act.

After the initial outbreak of avian influenza in Hong Kong in 1999, the authorities introduced new strict guidelines on the handling and slaughtering of poultry in the wet markets. This included a requirement that chickens and ducks be kept and slaughtered separately. This technical requirement takes into consideration the nature of the avian influenza virus, which is carried naturally in ducks, and which can be passed on to chickens and humans, causing serious disease. It is interesting to note that, since 1993, chickens and ducks in Singapore have been slaughtered in separate licensed premises, a regulatory requirement premised on poultry slaughter hygiene and public health considerations.

After several years of preparation and intense discussion with, and education of, the stallholders in the wet markets, the Singapore government in 2000 implemented the cold chain system for the distribution and marketing of meat and poultry. All vendors of pork, chicken, beef, and mutton in the wet markets are now required to install display chillers to keep the meat and poultry at a constant temperature of 4 °C. This marked the disappearance of 'warm' meat from the wet markets.

New-generation wet markets in Singapore and elsewhere are better in design and construction and are spacious, bright, and well ventilated. There is also proper floor drainage resulting in dry surfaces. The health authorities also conduct regular inspections ensuring a clean and healthy environment (Figures 4 and 5).

The Future

Despite all the shortcomings of wet markets and the aggressive expansion of international supermarket chains, traditional wet markets will likely continue to exist in Asia. In fact, the wet markets have changed with the times. It has been reported that beef exporters in the United States have in recent years been very successful in penetrating the low and middle market segments in China and several Southeast Asian countries by supplying meat cuts such as short plates and chucks to the wet markets. This augurs well for the future of wet markets as a recognized channel for distribution and sale of meat in Asian countries.

Figure 4 Modernized wet markets are housed in full-structure buildings although there are numerous street-level wet markets still in use throughout Asia. Multiple floors make good use of limited commercial space.

Figure 5 Indoor markets are generally more organized than outdoors in Hong Kong.

An uninterrupted cold chain for perishable meat and poultry from the production sources (abattoirs and import consignments) to the stalls in wet markets will ensure food safety practices and enhance the image of this colorful, traditional system of meat marketing in Asia. This is already happening in Singapore, where the government is building more wet markets in new public residential areas to meet popular demand from the constituents. With other countries capitalizing on the experience of Singapore in the management of modern wet markets, the decline in the number of wet markets can be slowed, as has been reported in some Asian cities.

MEAT PRICING SYSTEMS

GT Tonsor, Kansas State University, Manhattan, KS, USA

This article is a revision of the previous edition article by WD Purcell, volume 2, pp 705–713, © 2004, Elsevier Ltd.

Glossary

Consumption The purchase of goods or services that individuals directly benefit from and do not subsequently sell to others.

Demand A term used by economists describing what quantity of goods or services buyers are willing to purchase at varied purchase prices.

Price discovery A process of determining the price of a good in the marketplace through the iterative interactions of sellers and buyers.

Supply A term used by economists describing what quantity of goods or services sellers are willing to produce at varied sales prices.

Utility A term used by economists to represent preferences over a set of goods or services.

Introduction

The retail meat supply chain is characterized by a constantly changing complex of product offerings. Accordingly, many different prices and valuations persist in the meat business. A consumer purchases a meat package only if the posted price does not exceed the value presented by the product. Economists regularly use a measure called 'utility' to explain observed consumer decision making. Ultimately, consumers will distribute their limited food budget across multiple food items in a manner that the last item purchased of each product contributes the same utility. The price of a meat package plays a critical role in guiding which consumers purchase the product. Similarly, meat prices guide how much of the product is ultimately provided by the industry. More broadly, meat prices serve an economic role in signaling how limited resources should be allocated both by the supplying industry and the consuming public. Recognizing the broader roles of price, product pricing, and price discovery as critical mechanisms to initiate and coordinate actions throughout the meat supply chain is critical for understanding the everchanging meat business.

Price Discovery

The ongoing process of an industry searching for the price level equating the quantity that suppliers offer for sale at a schedule of alternative prices (supply curve) and the quantity consumers are willing to purchase at alternative prices (demand curve) is referred to as price discovery. The price discovery process is dynamic and imprecise as neither consuming nor producing parties have complete information on factors influencing demand and supply. A sound understanding of how the meat price discovery process incorporates changing demand and supply factors in order to find a price level that clears the market for different meat products is important.

Figure 1 shows the US inflation-adjusted retail Choice beef and pork prices from 1980 to 2010. The presented prices are adjusted for inflation in the US, and a similar adjustment to prices in other meat-producing countries would be needed to allow an examination of underlying demand and supply factors without confounding this with general inflation. The general trend of declining beef and pork prices in the US in the 1980s and 1990s is evident. Additional analysis is needed to identify if decreasing demand or increasing supply is the underlying driver of these declining prices. Figure 2 suggests that increasing beef and pork supplies are not the driver of declining retail prices. Per capita retail beef consumption has dropped sharply since 1980. Although not drastic, per capita retail pork consumption has dropped considerably. In many years, particularly in the 1980s and 1990s, both real prices and per capita consumption were declining for Choice beef. This indicates that the US consumers were placing notably lower value on Choice beef over this period. Not surprisingly, this reduced retail beef demand was the trigger for a host of changes in the US beef industry, including a notable downsizing of the beef cow herd.

Figure 3 presents a demand index for Choice beef starting with 1980 as the base year. The beef demand index measures vertical shifts in beef demand over time. One way to understand the index is to note that creating the beef index involves calculating the real beef price that one would expect to observe if beef demand was the same as that experienced in the

 doi:10.1016/B978-0-12-384731-7.00182-3

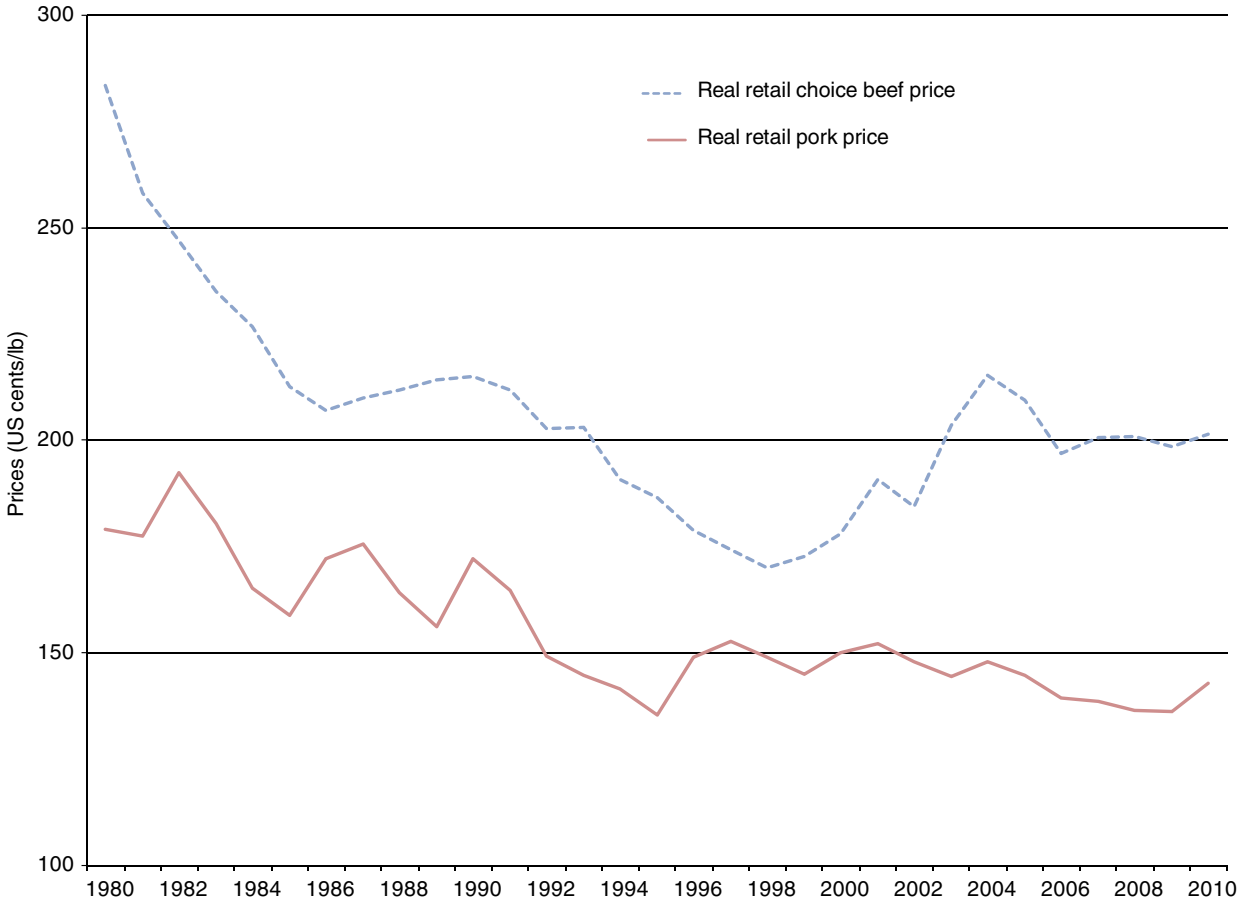

Figure 1 US inflation-adjusted (Consumer Price Index, 1982–84 = 100) retail prices for Choice beef and pork, 1980–2010.

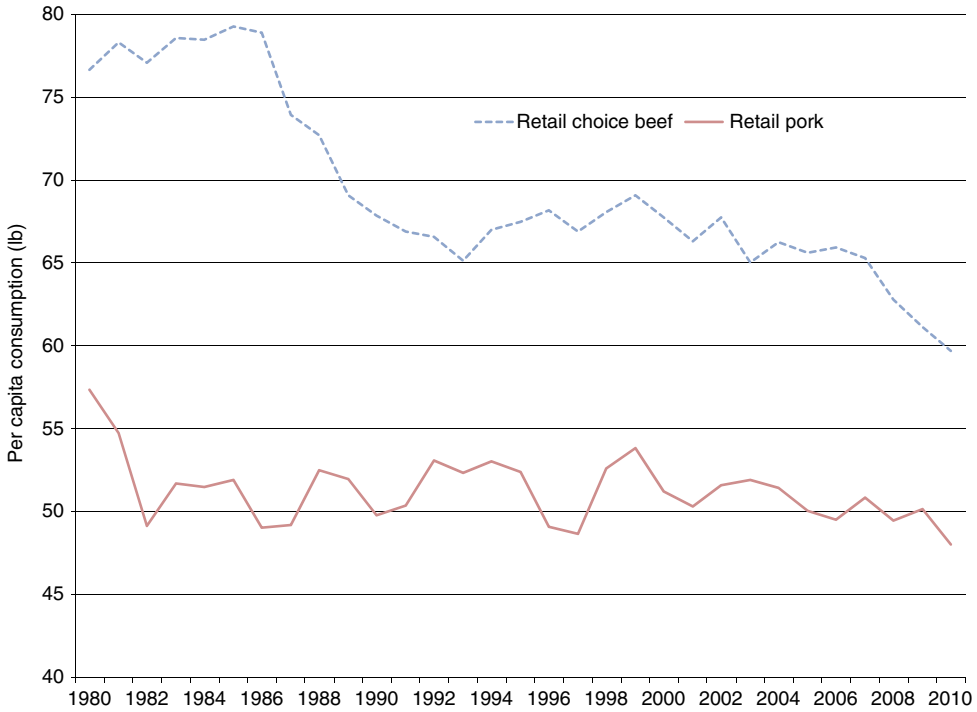

Figure 2 US per capita consumption in retail weights for Choice beef and pork, 1980–2010.

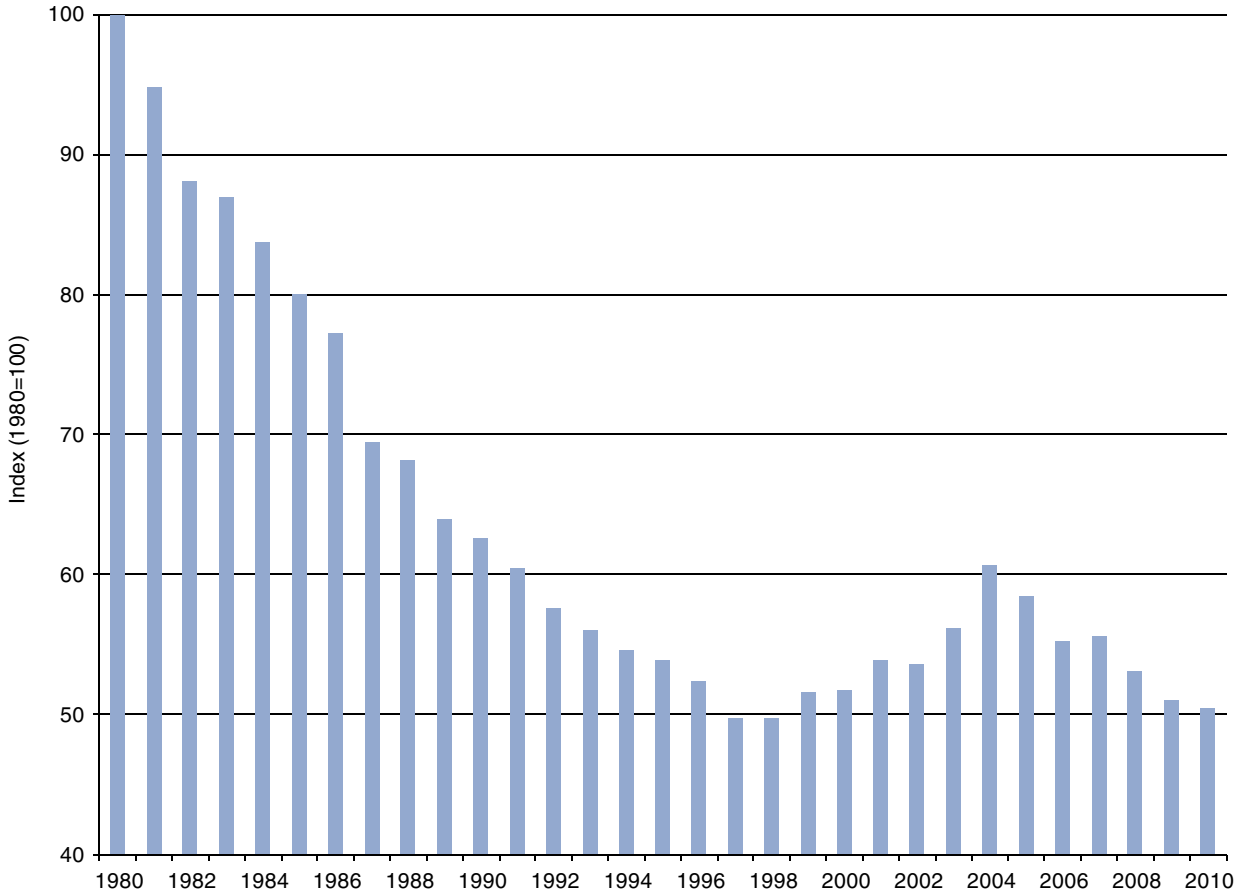

Figure 3 US Choice beef demand index, 1980–2010.

base year. With this constant demand, expected beef price is compared to the price actually transpiring in the marketplace in order to indicate changes in underlying demand. For instance, the minimum beef demand index value of 49.7 in 1998 suggests beef retail prices were 50.3% lower in 1998 than they would have been if beef demand was at its 1980 level. This example highlights that beef demand is not per capita beef consumption. Per capita consumption is simply domestic beef disappearance (net volume of domestic production, cold storage adjustments, and international trade) divided by resident population and it provides little information regarding beef demand when considered independently from prices. This example estimate of 50.3% quantifies the magnitude of demand reduction experienced by the industry between 1980 and 1998. In fact, for 18 consecutive years, beef demand declined, which presented substantial problems and resulted in downsizing of the beef industry. Although no 'magic bullet' or single dominant driver exists, a number of factors including consumer incomes, relative meat prices, food safety recalls, health and nutrition information, and product convenience influence meat demand.

Figure 4 presents a similar demand index for retail pork. The cumulative demand decline was less in magnitude for pork than for beef. However, the pattern of reduced retail prices and per capita consumption also applies to pork. In both cases, the declines suggested by calculated demand indices, particularly between 1980 and the mid- to late 1990s, indicate that the US consumers placed notably lower values on pork and beef. Deeper examination of why these demand problems developed in the US markets can provide important inferences for any beef- and pork-producing country that may face similar consumer demand concerns. Moreover, understanding the success of various response attempts by the US industries to remedy these concerns is useful both for industry leaders in the US and other producing countries.

Figure 5 shows a trend of increasing the total US per capita red meat and poultry since 1980. This largely corresponds to expanding consumption of poultry products. The observation of declining beef and pork consumption in a period of expanding total meat consumption and declining beef and pork retail prices suggests that consumers have placed higher relative value on available poultry products than on beef and pork products over this time period. Questions regarding these trends are regularly asked by industry leaders and policy makers, who at times have suggested attempting to 'solve the problem' by regulating price discovery processes throughout the US meat supply chain. To understand the impact of these regulation issues, consideration of meat prices needs to be further expanded to what economists refer to as 'pricing efficiency.'

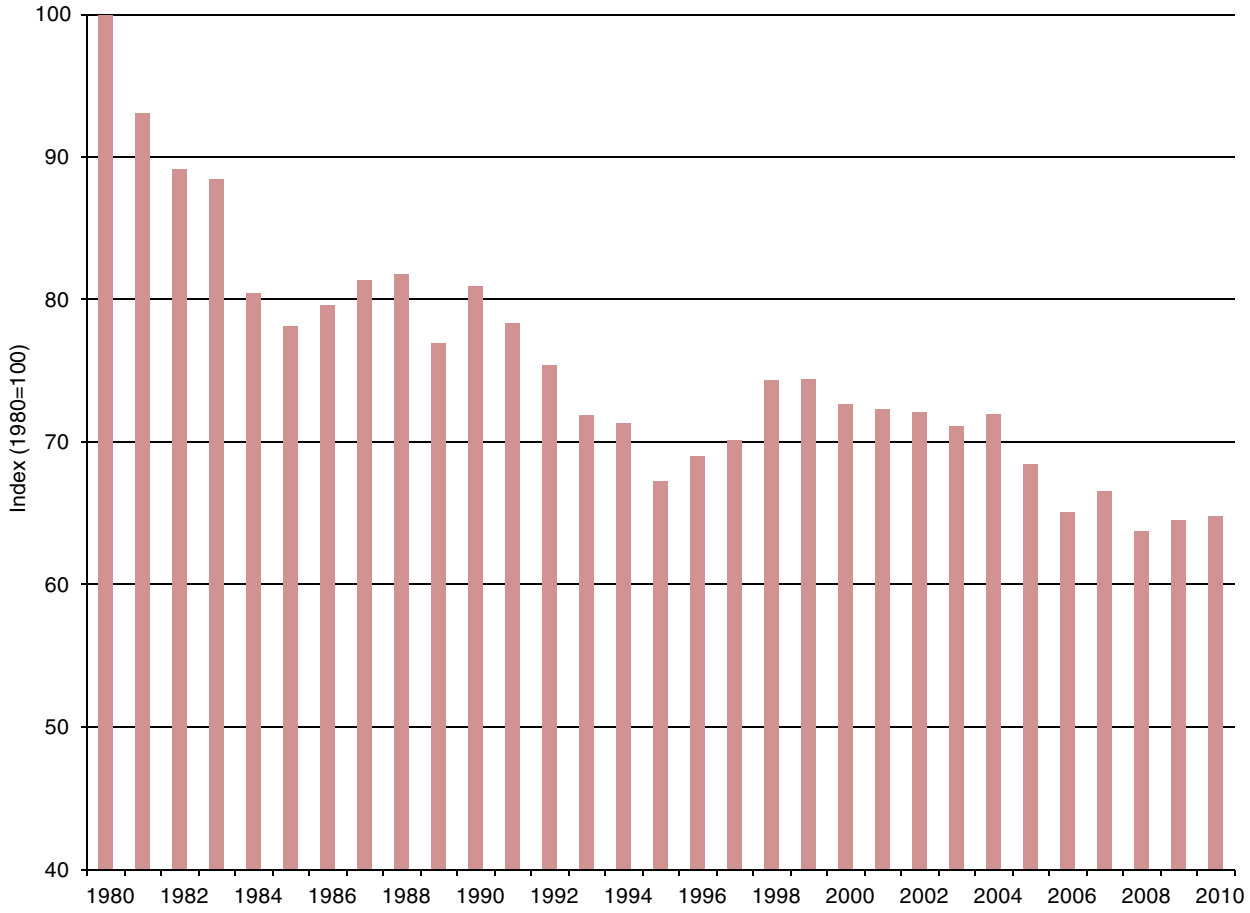

Figure 4 US pork demand index, 1980–2010.

Pricing Efficiency

The general concept of pricing efficiency refers to the effectiveness of a marketing system to clearly communicate price signals to market participants. Consumers send signals by their purchasing decisions regarding what they prefer and what they are willing to pay for different meat products. For instance, consumers may pay a price premium for meat products of a particular quality grade, brand, or carrying a desired alternative attribute. Similarly, producers throughout the meat supply chain send signals regarding what they are willing to provide to consumers at alternative prices through their production decisions. This interactive signaling process between consumers and suppliers is crucially important to effectively align scarce resources. This process is even more important in the meat industry where multiple sectors of production (e.g., cow calf, stocker, feedlot, processing, and retail in the beef industry) are involved in complicating preference and pricing signals, that is, multisector industries such as those characterizing livestock production require more extensive pricing systems and communication of pricing signals than sole-sector industries.

The price signaling processes in the meat supply chain will work effectively only if price premiums and discounts are clearly associated with different meat product types and attributes that are of interest to consumers. Some attributes such as portion size are easily observed by consumers, such that signals are effortlessly and cleanly distributed throughout the meat supply chain. Other attributes such as tenderness or food safety are typically not directly apparent from visual inspection of a product by consumers. If these attributes are important to consumer purchasing decisions, they must be measured, tracked, and conveyed on retail meat products. Several countries have systems in place providing quality grade information about meat products. The success of these systems in sufficiently conveying price signals underlying consumer purchasing decisions has been debated. For instance, the US beef quality grades are based largely on marbling and do not directly measure product tenderness. This is an example of a partial and incomplete signal that conveys imperfect information to market participants. Arguably, the above-mentioned declines in the US beef demand were at least exacerbated by this less than fully efficiency pricing system where communication of consumer desires and corresponding changes in supplied product attributes are not completely achieved.

A fair assessment of any pricing system must recognize that no panacea exists because meeting a threshold of 100% complete and accurate price signaling is impossible. Moreover, at some point, the benefits of additional enhancement in

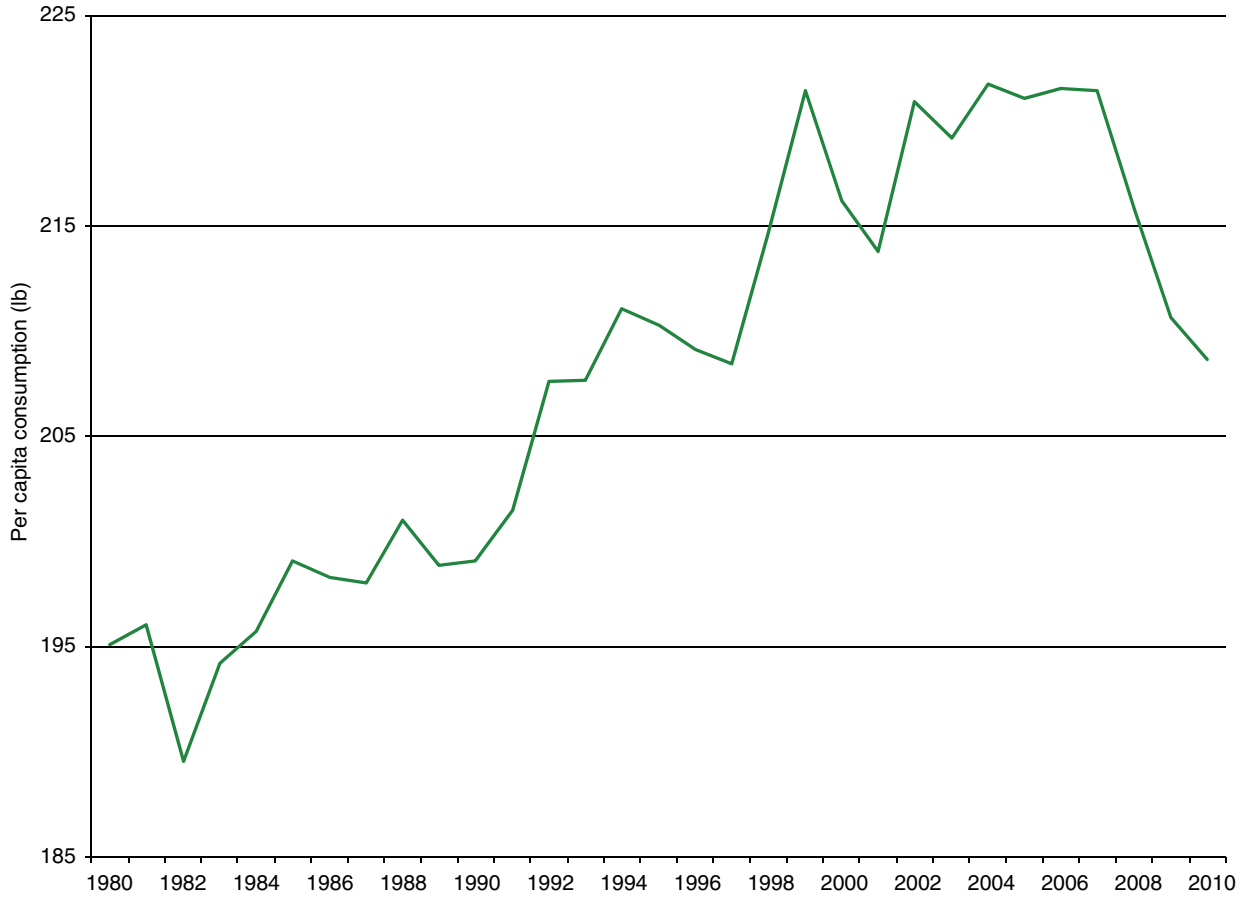

Figure 5 US total red meat and poultry per capita consumption in retail weights, 1980–2010.

pricing efficiency are no longer sufficient to cover the costs of their provision. This benefit–cost assessment process is ongoing both within meat industries and in policy discussions. These discussions, in turn, have led to a host of changes including a shift toward more vertically integrated systems away from systems comprised of separate, individual profit-maximizing centers spanning market segments. Historically, the US beef system has been less vertically integrated and less coordinated than pork and particularly poultry industries. However, over the past two decades, the beef industry has increasingly adopted use of contracts, marketing arrangements, and vertical alliances in order to improve vertical coordination. Similarly, the pork industry has moved rapidly to a model similar to the poultry industry where most production now occurs in vertically integrated systems.

The movement toward increased vertically integrated meat-producing systems has largely occurred because previously existing systems composed mainly of more independently operating businesses which failed to provide sufficient pricing efficiency. Price signals from traditional systems were basically unable to convey consumer desires regarding particular meat product attributes. This, in turn, left suppliers without clear information needed to assess whether the price they would receive for a product carrying a different set of attributes would sufficiently cover the associated increases in production costs. Ultimately, this type of disconnect leads to outcomes including those noted above regarding substantial demand declines. Although adoption of vertically integrated systems more likely provides more efficient pricing systems by more closely aligning and conveying information across market segments in the meat industry, this adjustment is ongoing and presents new challenges for public policy regarding meat pricing.

Meat Pricing Systems in Transition

The increased emphasis and use of contracts, marketing arrangements, and vertical alliances characterizing increasingly vertically integrated meat supply chains alters the role of prices. For instance, provision of many meat product attributes desired by consumers requires substantial adjustments not just in day-to-day operations and variable cost aspects of meat production but also in significant capital investments altering an operation's fixed costs. As an example, the extent to which meat tenderness can be impacted in live animals includes not only possible adjustments in feeding regimens (e.g., altering the diet and hence variable costs) but may also require changes in animal genetics (e.g., changing breed composition and hence fixed-cost investments in more expensive breeding stock). This adjustment toward increased focus on fixed-cost-altering investments highlights the changing relative role of

traditional commodity product price signals. Many contracts, marketing arrangements, and vertical alliances include nonprice aspects of coordination but importantly incorporate price components typically in the form of a price grid of premiums and discounts over a base price. However, this base price is frequently still established by transactions in the industry segments that have not moved toward additional vertical integration. Recognizing both the increased share of production occurring in vertically integrated systems and the associated reliance on price signals from outside the vertically integrated system highlights a controversial issue in the US meat supply chain. The same type of industry maturation and adjustments in pricing system requirements and roles can be expected in other meat-producing countries, particularly in countries that repeat the US case of delayed implementation of more effective pricing systems.

The retail meat case available to consumers can be characterized as increasingly complex as it offers an expanding line of product types, forms, and characteristics largely aimed at better meeting diverse consumer preferences. Perhaps the most significant of these changes, and the broader movement away from commodity-oriented pricing systems, is the substantial growth in branded products. For instance, between 2004 and 2010, the portion of retail beef products branded in the US increased from 42% to 63%. Besides expansion of branded product lines, consumers now have access to 'convenience' products that may be precooked, have been 'naturally raised,' are enhanced with flavor additives, or contain a host of other claims and attributes. This expansion in product offerings reflects the meat industry's attempt to enhance consumer demand in response to the previously noted demand struggles.

Similarly, the role of exports is increasing in many of the world's largest meat-producing countries which add further complexity to the global retail meat case. The impacts of consumers in various countries valuing products differently results in meat not being exported in carcass proportions. For instance, a notably larger portion of beef livers than ground beef products are exported from the US. This results in the meat case presented in two countries to vary notably and presents both opportunities and challenges to the livestock industry supplying these varied retail outlets.

One broad implication of these increasing meat pricing complexities is that analysts are faced by an exponentially more challenging task. For instance, the need and feasibility of scanner data-based analyses has rapidly developed. As an example, recent scanner-data based research suggests that consumers have paid more than \$5 lb^{-1} premiums for branded steak products. Only a few years ago, the ability to conduct similar microlevel research was constrained to consumer survey approaches. However, in the future, accurate identification and understanding of consumer meat preferences will increasingly rely on studies informed by scanner data and related household-level data sources that reflect actual purchasing behavior in notably more detail than previously available. Given the traditional reliance on national, aggregate disappearance-data-based analyses, which mask over variations in product types, forms, and attributes will increasingly present both notable challenges and promising opportunities for researchers and industry leaders.

Public Policy Issues in Meat Pricing Systems

The growing importance of base livestock prices as inputs into arrangements of vertically integrated systems and associated concerns with possible market power of industry segments characterized by fewer and larger entities have resulted in several public policy issues. For instance, the United States Department of Agriculture (USDA) has a long history of reporting cash prices from direct trade of slaughter hogs with similar practices in place for other US livestock. However, the portion of slaughter hogs marketed in negotiated cash markets has fallen from 43% in 1997 to less than 5% in 2010. The declining market share of livestock being transacted in cash markets has led to numerous calls for new regulation and industry adjustment. These and other related concerns ultimately led to mandatory price reporting of prices in live hogs, fed cattle, boxed beef, lamb, and boxed lamb markets under the authority of the US Livestock Mandatory Reporting Act of 1999. These mandatory price reporting systems have recently been reauthorized through 2015 and now include wholesale pork products. Broadly speaking, the introduction of corresponding mandatory price reports by the USDA has altered the pricing efficiency of the US meat industry by providing information, which in some cases at least partially replaces previously reported prices and in other cases provides entirely new insights to the industry. Although assessing the net benefit/cost of these reports is beyond the scope of this discussion, an appreciation of several aspects is needed, including the public and private industry costs underlying generation of these reports, the provision of new information such as wholesale primal level prices previously not reported publically, and the value of these reports in supplementing insights obtained directly from the reduced set of direct cash market transactions.

A related policy issue pertains to the actions of meat processors, including a particularly focused discussion on the impact of various livestock procurement procedures. Several producer groups have expressed concern that processor procurement strategies have resulted in detrimental impacts on cash market prices. This concern has led to notable public interest in the issue including an extensive Congressionally funded study completed in 2007. This interest has persisted with the USDA proposing changes, which ultimately were largely not implemented at the time of this writing, as recently as 2012. Given the underlying changes in industry structure that are expected to continue, there will remain a complex set of public policy issues to be considered and debated regarding meat pricing systems well into the future. Moreover, similar discussions can be expected in other meat-producing countries that may have similar experiences to the US and yet have alternative histories of public price information provision and expectations.

Meat Pricing Systems of the Future

Looking ahead, several issues from the past will remain worthy of focus in the future. The ability of increasingly vertically integrated systems in the US to provide efficient pricing systems will be debated for years to come and arguably the

verdict is yet to be determined as adjustments remain well underway. More broadly, the extent to which similar moves to vertically integrated systems and development of altered price discovery mechanisms occurs in other meat-producing countries is interesting to consider. As meat industries worldwide attempt to profitably operate in an increasingly complex environment characterized by higher costs of production and increased overall social interest in their production practices, at a minimum the relative success of different meat-producing countries and industries will be sensitive to the success in implementing and adopting efficient pricing systems. The lessons learned from notably delayed action in the case of the US beef industry can be very instructive for industries worldwide. This process can only be expected to be of increasing importance as multitudes of new meat consumers enter the global marketplace in coming years. Similarly, as industries outside of the developed world continue to develop, mature prudent attention is encouraged to the experiences of those in the developed world which have been briefly highlighted here, that is, although much more is known about pricing systems in the developed world, application to other countries (and even species not directly mentioned here) is encouraged. Moreover, deeper recognition of how consumer preferences vary across meat product types, attributes, and cultures (e.g., consider different values of beef tongue in Japanese and the US markets) will only exacerbate the need for more detailed and complex pricing systems and general mechanisms for information exchange to be implemented. Ultimately, the viability of meat-producing industries hinges on the ability to produce what consumers desire in order to properly align activities within supply chains, to efficiently offer these desired products, and to remain keenly aware of how 'answers' to these challenges dynamically change over time. The ability of the global meat supply chain to meet this challenge will largely determine its economic success.

MEAT RESEARCH INSTITUTIONS

RG Kauffman, University of Wisconsin, Madison, WI, USA

Introduction

Meat science and muscle biology research efforts and interests worldwide have existed only to a significant extent in the past century. These interests developed rapidly as knowledge about using domesticated animals for food increased. Many individuals, through their academic backgrounds of biochemistry, microbiology, histology, anatomy, physics, physiology, and mathematics, have studied muscle and related tissues and how they can be used for food. These scientists were either focused on the animal and food sciences or associated with private meat companies; all were attempting to improve fresh meat and find better ways to preserve, store, and process meat into consumer products.

From the initial scientific efforts by individuals, groups of individuals evolved and began to collaborate in investigations that required expertise from multiple disciplines. Some problems, such as meat tenderness, required sophisticated biological and physical approaches, whereas others, such as methods of cooking, packaging, and storage, required technological and engineering inquiries. The former have been arbitrarily identified as being more basic in nature, whereas the latter more applied. Many of the problems required combinations of these two approaches, and to resolve them in the most satisfactory way, group efforts prevailed. Therefore, individual scientists began cooperating for such complex investigations, each pursuing that part of the problem in which their expertise was required. From this obvious need, university, government, and industry organizations established groups, laboratories, sections, or independent institutes to launch complex research programs, all focused on learning more about muscle and related animal tissues (fat, bone, viscera, skin, etc.). They varied in size from just a few scientists to many, depending on need and financial support. Even though most investigations have been of biological or technological nature, some have required socioeconomic expertise (such as learning about consumer acceptance and marketing strategies).

When groups of scientists were formally assembled, they usually included some scientists trained in more basic disciplines and others in more applied ones. This combination of

scientific qualifications has proven invaluable to the ultimate success of research. Basic disciplines include subjects such as physiology, biochemistry, biophysics, microbiology, histology and histochemistry and theoretical economics, mathematics, and statistics. Applied subjects include subjects such as processing techniques (emulsification, cookery, curing, etc.), refrigeration and freezing technology, engineering, automation, computer applications (e.g., for traceability), environmental aspects, packaging, nutrition, marketing, consumer preference, slaughter procedures (stunning, electrical stimulation, etc.), sausage manufacturing, and new product formulation, ingredients, etc. At least some of these require a working knowledge of the basic sciences. However, one of the unique characteristics of some research institutions was that they chose to enroll scientists representing several areas of expertise. Through the efforts of research coordinators, the various scientists were organized to cover all aspects of a problem.

Regrettably, some small groups of scientists who function informally will be omitted from this article because they were unintentionally missed in this search. The three tables of institutions that follow have been categorized by scope and size. **Table 1** lists national meat research institutions, **Table 2** covers provincial (state and/or city) institutions, and **Table 3** lists private industrial meat research institutions. Some institutions that no longer exist have been intentionally included because of their significant contributions in the past. The word 'institution' has been interpreted to include any formally organized unit having one or more scientists. Within each category, institutions have been alphabetized by country, province (state and/or city), and institution name. When known, the address and website, primary subjects covered, species of animals used, and size of program as arbitrarily defined by numbers of staff scientists involved (small <3, medium 3–12, and large >12) are included. The size of institution does not reflect in any way the quality or significance of the research accomplished, and it should be understood that most provincial institutions conducting research also provide pedagogical and extension functions, many of which are the primary focus for that institution's existence.

MEAT SPECIES DETERMINATION

AH Teen Teh and GA Dykes, Monash University, Bandar Sunway, Malaysia

Glossary

Adulteration The act of adding foreign substances to something that makes it impure.
Authentication The process of determining whether something is what it is declared to be.
Chromatography Separating mixtures of molecules based in a mobile phase through a stationary based on different molecular characteristics.
Comminuted Reduced in size to small particles.
Electrophoresis A technique to move dispersed particles in an electric field and separate them based on different molecular characteristics.
Polymerase chain reaction A technology for amplifying specific nucleic acid sequencing from a few copies to many thousands or millions of copies.

Introduction

Food adulteration refers to the act of intentionally debasing the quality of food by either adding or replacing the food substances with undeclared alternative components, or by the removal of some valuable components. This is usually done to lower the cost or increase the bulk of a given food product. This has been a major concern among consumers as it is often undesirable from an economic, health, religious, or legal standpoint. Meat adulteration in comminuted and highly processed meat products is a widespread practice in some retail markets where meat species with higher commercial value have been replaced or substituted with lower value or undesirable alternatives. In addition, fraudulent adulteration of food products with undeclared components might cause health problems such as allergies in sensitized individuals. The 2012 horse meat scandal in Europe, in which horse meat was found in beef products has raised public concern with respect to meat authentication. Although horse meat is a consumable product in its own right and harmless to human health, the general public responded negatively to the fraudulent meat. Furthermore, several religions have strict dietary laws relating to meat animal species. For Muslims, for example, consumption of pork and other porcine derivatives is prohibited among devotees. Food authentication and, in particular, identification of component species in meat products is, therefore, important in order to control food quality and safety as well as to protect consumers' rights.

The analytical techniques commonly used for meat species identification can be broadly divided into protein-based and deoxyribonucleic acid (DNA)-based techniques. The protein-based methods include immunological assays, electrophoretic, and chromatographic techniques. These methods are fast and easy to perform and the investment in equipment is much less compared to DNA-based methods. The use of these methods for meat species identification is limited when assaying thermally processed foods due to the denaturation of proteins. More recently, DNA-based methods have been used as an alternative to protein analysis in meat species identification as DNA molecules are more stable when compared to proteins and allow analysis of processed and heat-treated products. In addition, DNA molecules are present in most biological tissues and can, therefore, be extracted from a variety of tissues. All these factors make them a good choice for differentiation and identification of components in food. Among the DNA-based methods used in species identification, the polymerase chain reaction (PCR), which involves highly specific amplification of one or more DNA fragments is the most well-developed method due to its simplicity, rapidness, specificity, and sensitivity for species identification in foods. A number of PCR techniques have been used for meat species identification and these include PCR-sequencing, PCR-restriction fragment length polymorphism (PCR-RFLP), PCR with species-specific primers, PCR-random amplified polymorphic DNA (RAPD), and real-time PCR. Protein-based and DNA-based methods currently used in meat species identification are described below.

Protein-Based Methods

Enzyme-Linked Immunosorbent Assays

The enzyme-linked immunosorbent assay (ELISA) is an immunological assay that utilizes an enzyme to detect the presence of an antibody or an antigen in a complex, mixed sample based on the specific binding of the antigen and antibody. Of the different types of ELISA available, the indirect and the sandwich ELISA are the two most commonly used types for meat species identification. The indirect ELISA entails the binding of two antibodies, namely the primary antibody (which is specific to the antigen) and the secondary antibody (which is linked to an enzyme that will produce a chromogenic or fluorescent signal when a substrate is added). In the sandwich ELISA, the antigen is bound between two antibodies, specifically the capture antibody and the detection antibody. The detection antibody can be conjugated to an enzyme that

will lead to the production of a signal when an appropriate substrate is added.

ELISA tests can be used for both the qualitative and quantitative detection of meat species. They have been used to identify meats of different species using antibodies against muscular and serum animal proteins. In addition to qualitative studies, quantitative studies such as the evaluation of levels of pork adulteration in raw ground beef have been reported.

ELISA tests used in meat species identification are highly sensitive and specific, fast and cheap, easy to perform, and do not require expensive laboratory equipment. In addition, a variety of ELISA test kits to detect low levels of contamination by meat animal species, even in highly processed meat and meat products, have been developed. These have been used by many regulatory authorities around the world to detect meat species adulteration. The simplicity and rapidness of ELISA analysis make them a suitable choice for routine analysis of a large number of samples. A major drawback of the ELISA test with respect to meat species identification is that some target proteins denatured during processing might not be detected. This limitation has, nevertheless, been overcome by the development of antibodies against specific thermostable proteins that have been applied in ELISA tests for the detection of pork in heat-treated meat products. Even with these innovations, however, ELISA assays still have disadvantages including the initial difficulty in producing antibodies specific to the target and the instability of the antibodies under extreme pH levels or with high concentrations of salt or solvent. These assays can also be hindered by cross-reactions occurring among closely related species due to the reliance on antibodies against specific protein targets.

Chromatographic Techniques

Chromatographic techniques such as high-performance liquid chromatography (HPLC) and gas chromatography have been used for meat species identification by analyzing for specific components or compounds of the meats. These techniques are based on differences in protein, peptide, or amino acid profiles between different meat species.

Chromatographic techniques are highly sensitive and reproducible and are suitable for use in routine analysis in meat authentication. One example of the application of chromatographic techniques for meat authentication is the utilization of HPLC to analyze the ratio of the imidazole dipeptide carnosine and its methylated analog anserine, which differs between different meat species. There are, however, some drawbacks to these methods. The separation of the protein peaks is often unsatisfactory. In addition, tedious extraction of the samples before analysis is required and these methods are, therefore, very time consuming. Furthermore, a single chromatographic method is unable to differentiate more than seven species simultaneously.

Electrophoretic Techniques

Protein electrophoresis is based on the separation of proteins in an electric field that are later visualized using staining. This technique has been applied to meat species identification through the separation of meat components such as sarcoplasmic and myofibrillar proteins. The principle behind these techniques is based on the presumption that every animal species has a specific protein composition that is identical within the species. The conventional electrophoretical methods commonly used in meat species identification include polyacrylamide gel electrophoresis (PAGE), sodium dodecyl sulfate-PAGE (SDS-PAGE), and isoelectric focusing (IEF) techniques. More recently, capillary electrophoresis (CE) has also been used in meat authentication.

In PAGE, the proteins are separated based on the electrical charge and sizes of the protein molecules. Individual proteins move toward the anode or cathode, depending on their charge. In SDS-PAGE, denatured protein molecules with negative charges move toward the anode only and hence they are separated based solely on their molecular weight. In IEF, separation of the proteins is carried out on a gel with a stabilized pH gradient with the proteins separated based on their isoelectric points. These conventional electrophoretical techniques offer cheap, fast, and highly reliable methods for meat species identification. In addition, they do not require a sophisticated equipment or a high degree of technical expertise. Among the electrophoretic techniques SDS-PAGE provides the highest resolution and most reproducible results and has been most effectively used in the detection and identification of foreign meat proteins in protein mixtures. It has also been used to identify meats of a wide range of species including cattle, sheep, lamb, goat, red deer, and rabbit. The major drawback of these electrophoretic methods is that the difference in the protein patterns obtained might not be species-specific as these patterns might be affected by other factors such as age, nutritional stage of animals, effects of stress, and/or other individual differences. In addition, great effort is often required in interpretation of the results. Furthermore, these techniques are unable to differentiate closely related animal species and are also not suitable for examination of samples that have been thermally treated.

More recently, CE systems have been used as an alternative to gel electrophoresis. In this method, electrophoresis is carried out in fine capillary tubes at high speed and under high voltage and the separated proteins quantified using various detectors based on fluorescence, refractive index, ultraviolet absorbance, and mass spectrometry. An example of the use of CE in identifying meat proteins is the SDS-CE method which entails separation of meat proteins based on their molecular size. These methods have been used to detect qualitative and quantitative differences in proteins in raw beef, pork, and turkey meats. In general, CE offers a powerful analytical method for meat authentication due to its high resolving power, high separation efficiency, and ease of automation. In addition, the analytical potential of CE can be further enhanced by combining it with PCR amplification-based techniques. However, the application of CE methods in analysis of complex meat matrices or heat-processed samples is restricted due to its low sensitivity and reproducibility.

Deoxyribonucleic Acid-Based Methods

Polymerase Chain Reaction-Based Methods

PCR-based methods are the simplest DNA-based method to determine the presence of a meat species in food. These

methods are based on specific amplification by oligonucleotides (primers), which hybridize to the targeted flanking regions of the DNA sequence(s) followed by amplification of the fragment and verification of the fragment size using agarose gel electrophoresis. PCR-based methods have been recognized as the most specific and sensitive technique in meat species identification. However, these methods have some disadvantages that limit their use in meat authentication. The high sensitivity of these methods could lead to false positive results, especially under low-stringency conditions, due to the nonspecific amplification of nontarget sequence, the formation of hairpin loops, or the formation of primer dimers, which will result in production of undesired fragments. In addition, the efficiency of these methods will be reduced in the presence of inhibitors sometimes present in meat products. A number of PCR-based methods have been developed for species detection in meat products and some of these are described below.

Polymerase Chain Reaction Sequencing

The PCR-sequencing method involves using a universal primer pair to generate single-band amplification products. The product of the generated PCR amplicon is then sequenced and the resulting sequence is analyzed. The results allow discrimination of even very closely related species by relying on the availability of known sequences for comparison and this method can, therefore, be used for interspecific and intraspecific identification of animal DNA in meat products. PCR-sequencing is a simple and direct method, which results in high amount of information because no complex postanalysis or enzymes are required with this method. This method has been reported to successfully identify a wide range of meat species origin, including differentiating closely related species such as goat and sheep, or cattle and buffalo.

PCR-sequencing has been established as the most accurate method for meat species identification but its application to meat authentication has been limited due to some restrictions. For example, PCR-sequencing is not suitable for analysis of cooked or processed samples with degraded DNA. This method has restricted use in meat adulteration investigations as it is not suitable for analysis of mixed-species meats due to the use of a universal primer pair. Furthermore, the need for expensive laboratory equipment means that this technique has limited use for large-scale screening. The PCR-sequencing method is generally used for verification of results obtained from species-specific and real-time PCR.

Polymerase Chain Reaction-Restriction Fragment Length Polymorphism

The PCR-RFLP technique is based on sequence variations between different species and is determined by the digestion of selected DNA fragments with one or more selective restriction enzymes. This technique generates species-specific patterns that enable differentiation between meat species, including closely related species.

PCR-RFLP is cost-effective, simple, and suitable for use in routine, large-scale studies. An example of its use is for the detection of pork adulteration of raw meats through analysis of the cytochrome *b* gene of mitochondrial DNA (mtDNA). PCR-RFLP has also been used to trace meat adulteration by game meats that might be present in meat samples. As amplification of large DNA fragments is required for enzymatic restriction in order to generate restriction patterns, PCR-RFLP is not suitable for analysis of processed foods due to DNA denaturation. In addition, this technique is not suitable for the analysis of mixed-species meats, because results might show complex restriction patterns representing all the possible species present in the sample.

Polymerase Chain Reaction with Species-Specific Primers

PCR with species-specific primers is widely applied in meat authentication studies to identify a species using specifically designed oligonucleotides under restrictive PCR conditions. The identification of the target sequence can be verified based on the amplicon size determined through gel electrophoresis without subsequent sequencing or RFLP if the complete sequence of the amplified fragment is known.

PCR with species-specific primers is a simple, fast, specific, and highly sensitive method for species identification. It is, therefore, very useful for routine analysis of a large numbers of samples, including cooked or processed products with highly degraded DNA, and also in the analysis of mixed-species food matrices. Specific primers for a wide range of animal species have been designed and successfully applied to identify the origin of species in comminuted and highly processed meat products. The use of species-specific PCR to detect pork adulteration in fresh or processed meat products has been well documented as adulteration associated with the addition of pork frequently occurs.

A major drawback of species-specific PCR is the presence of false positive results that arise due to cross-homology. This can be overcome by increasing the specificity of the designed primers in order to ensure they will not display a cross-reaction with nontarget species.

Polymerase Chain Reaction-Random Amplified Polymorphic Deoxyribonucleic acid

The PCR-RAPD technique is based on the amplification of DNA fragments using a randomly designed short arbitrary primer that amplifies multiple discrete regions on the genomic DNA under appropriate PCR conditions. This is followed by separation of amplified fragments based on their sizes using gel electrophoresis and samples are identified by comparing the DNA bands of the resulting patterns. This technique is able to detect meat species without prior knowledge of the DNA sequence of the species of interest as long as reference material for comparison is available.

The PCR-RAPD technique has been used in many meat identification studies to differentiate between domestic animals as well as among rare species of animals. Use of this technique has also been made in various authentication studies for identification of many species of animals, usually commercially important or domestic species such as pork, beef, lamb, chicken, and turkey. Furthermore, this technique can be applied to either raw or processed forms of products.

Table 1 Summary of protein-based and DNA-based methods used for species identification

Method	*Principles*	*Advantages*	*Disadvantages*
Protein-based			
1. Enzyme-linked immunosorbent assay (ELISA)	• based on an immunological technique that utilizes an enzyme to detect the presence of an antibody or an antigen in a sample based on specific binding between the two	• sensitive and specific, fast and cheap, easy to perform, and does not require expensive laboratory equipment • a variety of ELISA test kits have been developed	• initial difficulty in production of antibody specific to the target • instability of the antibodies under extreme pH levels or with high concentrations of salt or solvent • hindered by cross-reactions occurring between closely related species
2. Chromatographic techniques	• based on separation by molecular weight of proteins, peptides, or amino acids and producing patterns that differ between meat species	• highly sensitive and reproducible • suitable for routine analysis	• separation of protein peaks is usually unsatisfactory • requirements for tedious extractions and long analysis times • unable to differentiate more than seven species simultaneously
3. Electrophoretic techniques	• based on the separation of proteins in an electric field according to their molecular weight and charge by polyacrylamide gel electrophoresis (PAGE), sodium dodecyl sulfate (SDS)-PAGE, or isoelectric focusing	• cheap, fast, and highly reliable method do not require sophisticated equipment and high degree of technical expertise	• unable to differentiate closely related animal species • not suitable for examining material that has been thermally processed
	• capillary electrophoresis at high speed and under high voltage conditions in fine capillary tubes	• high resolving power, high separation efficiency, and ease of automation • has the potential to be combined with polymerase chain reaction (PCR) amplification	• restricted to analysis of complex meat matrices or heat-processed samples due to its low sensitivity and reproducibility
DNA-based			
1. PCR-sequencing	• based on using a universal primer pair to generate single-band amplification products followed by sequencing of the PCR product	• simple and direct method • known to be the most accurate method in meat species identification	• unsuitable for use in cooked or processed samples • unsuitable for the analysis of mixed-species meats • requires expensive laboratory equipment
2. PCR-restriction fragment length polymorphism (PCR-RFLP)	• based on sequence variation between different species established through digestion of selected DNA fragments with one or more restriction enzymes	• cost friendly, simple, and suitable for routine large-scale studies	• not applicable for processed foods due to DNA destruction • not suitable for the analysis of admixed meats
3. PCR with species-specific primers	• using specifically designed oligonucleotide primers under restrictive PCR conditions	• simple, fast, specific, and highly sensitive • suitable for routine analysis of large samples • can be used to analyze cooked or processed products and mixed-species samples	• false positive results due to cross-homology
4. PCR-random amplified polymorphic DNA (PCR-RAPD)	• based on the amplification of DNA fragments using a short arbitrary primer that amplifies multiple discrete regions on the genomic DNA, followed by separation of amplified fragments based on their sizes using gel electrophoresis	• fast and simple powerful technique in instances where little or no information on the DNA sequence is available	• difficulty in interpretation of the gel images and obtaining reproducible data • unsuitable for use in highly processed meats and meat mixture samples
5. Real-time PCR	• based on direct and independent monitoring of cycle-to-cycle amplification using a fluorescent-labeled signaling probe	• high sensitivity and specificity, larger dynamic detection range, and less carryover contamination • allows the detection of trace amount of different animal species in samples of complex composition • provides both qualitative and quantitative information of the targets	• high cost due to cost derived from the specific fluorescent probes • the design and availability of primers and probes are hard to meet as they must be selected according to very rigid conditions

Major drawbacks of the PCR-RAPD method include difficulty in interpretation of the gel images and also in obtaining reproducible data as the results of the analysis vary depending on PCR conditions and also intraspecies polymorphisms. In addition, its application is restricted in highly processed meat samples due to degradation of DNA and is also not suitable for identification of a target species in meat mixtures.

Real-Time Polymerase Chain Reaction

Most of the conventional PCR techniques only enable qualitative and not quantitative analysis of the animal species in meat samples. Quantification of the adulterate components plays an important role in investigation of meat adulteration because the quantitative results can be used to determine whether the adulterant is added intentionally or due to accidental contamination in the production line. One of the quantification methods commonly used for meat authentication is real-time PCR. In this technique, the cycle-to-cycle amplification is monitored directly and independently using a fluorescent-labeled signaling probe. The intensity of the fluorescent signal is directly correlated to the PCR products amplified in each cycle and enables detection in a real-time format at an early stage.

Real-time PCR allows the detection of trace amounts of different animal species in samples of complex composition. In addition, it is more precise than end point analysis as it provides quantification information of the targets originally present in the sample. Furthermore, real-time PCR offers a wide range of other advantages, including high sensitivity and specificity, larger dynamic detection range, and less carryover contamination. The real-time PCR technique is, therefore, arguably the most effective technique currently used for species identification and quantification in meat authentication.

Real-time PCR assays have been applied to detect a wide range of meat species such as beef, pork, lamb, horse, chicken, turkey, and duck, among others. These techniques have also been used to detect and quantify porcine DNA with a detection limit down to 0.1% porcine tissue in heat-treated meat mixtures, indicating high sensitivity of these techniques for detection and quantification purpose. There are, however, some disadvantages of real-time PCR techniques including high cost due to the requirement for specific fluorescent probes. In addition, the design and availability of primers and probes are hard to meet as they must be selected according to very rigid conditions.

Conclusion

A wide range of techniques are available for meat species identification and meat product authentication. Despite the wide choice of analytical techniques available for meat species identification, all have specific advantages and disadvantages that are summarized in **Table 1**. The selection of a technique for meat species identification will be governed by factors such as sensitivity, cost, reliability, and rapidity. All factors should be considered before selecting a technique for a particular purpose.

Glossary

Advanced meat recovery Machinery that removes residual meat from bones after primals have been carved off. In contrast to mechanically separated meat obtained by high pressure, bones remain intact and the miscroscopical structure of the product is that of meat.

Bovine spongiform encephalopathy (BSE) An infectious disease in cattle causing degeneration of the brain and spinal cord. The disease is closely related to spongiform encephalopathies in other animal species and humans. There is some evidence for transmission to humans via consumption of certain bovine tissues. To control or eradicate BSE, a number of measures have been implemented in pre and postharvest phase.

High pressure mechanically separated meat (MSM) Meat which is recovered from bones in a way that the structure of the bones is altered, and which contains higher amounts of calcium than minced meat. Usually this means pressing of meat from prefragmented bones at 100 bar or more.

Lean finely textured beef (LFTB) A process where trimmings are desinewed, and fat is removed by gentle heating and centrifugation.

Mechanically recovered meat (MRM) The product is obtained by removing meat from flesh-bearing bones after boning or from poultry carcasses, using mechanical force. Depending on the pressure applied, muscle fiber structure may remain or be destroyed. In the European Union, mechanically desinewed meat also falls under MRM definition.

Introduction

Meat removed from bones or fat trimmings by machines is a welcome contribution to the world's food supply. Recovery of meat from bones of filleted fish began in Japan in the late 1940s and increased as the amount of filleted fish increased. Frames from filleting operations increase yield by 10–20% and lobster bodies, crab, and undersized shrimp yield an additional 40%. Meat from underutilized fish that previously was considered too small or bony is also saved. Approximately 27×10^6 kg of imported and domestically produced minced fish was consumed in the US in 2000.

Mechanical recovery of poultry from necks, backs, and other bones with meat attached started in the late 1950s. The number of machines increased as the amount of cut up chicken and turkey increased. It was estimated that mechanically separated poultry accounts for 2–4% of the annual turnover of poultry meat in the European Union (EU).

Removal of beef and pork from irregularly shaped bones began in the 1970s. The vertebral column and other bones with meat still attached after hand boning were used. In 2003, the annual additional yield of beef was approximately 23×10^6 kg in the US. Mechanically recovered pork yield was approximately 68×10^6 kg. Large amounts of meat are also being produced in other countries. Historically, the beef and pork industries relied on skilled employees using hand-held knives to physically cut meat from bone. Power knives, also called Whizard knives, increased speed and efficiency but were still unable to harvest all of the lean for human food, so it became part of rendered products.

In addition to mechanical removal of meat from bones, mechanical recovery of lean from fat also occurs. Partially defatted tissue is derived primarily from beef and pork fatty trimmings. The trimmings contain lean meat that is difficult to recover by hand. They pass through a low-temperature rendering process followed by centrifugation to remove lean from a rendered slurry. The recovered lean contains 7–17% fat.

A modification of this low-temperature (41 °C) rendering and centrifugation process is being used to produce lean containing not more than 6% fat. Sinew and cartilage are first removed by a rotating auger that forces lean and fat through small holes in a sieve. After low-temperature rendering and centrifugation, the finely comminuted product is frozen within 90 s in a thin sheet on a drum and then shipped frozen to meat processors. This process produces large quantities of lean meat used in low-fat ground beef. The product is known as lean finely textured beef (LFTB), or lean beef trimmings. Boneless lean beef trimmings may be treated with ammonium hydroxide or citric acid to reduce microbial counts. High microbial counts and rancidity are potential problems.

This article addresses the history, utilization, composition, safety, and palatability of meat recovered from bone. Meat mechanically recovered from fat and product from automatic deboning machines that use specially designed grinder blades to remove most of the bone and cartilage unintentionally left in hand-boned meat are not addressed in detail.

 doi:10.1016/B978-0-12-384731-7.00136-7

Machines that Remove Meat from Bone

Machines that operate on a belt–drum principle, in which the bone is forced against a perforated drum by a rubber belt, were first used to recover meat from fish bones and they are still the most popular for mechanical recovery of fish. Holes in stainless steel drums range from 1 to 10 mm in diameter, but a hole size of 5 mm is most common. Meat passes through holes, while bones and skin stay on the outside of the drum and are ejected through a discharge chute. Following deboning, mince may be refined by passing it through a strainer that removes most bone particles and small pieces of belly lining. Holes in strainers typically range from 1 to 2 mm in diameter. Mince can range from a coarse texture to a fine paste depending on the source, machine type and setting, and processing method.

Another machine breaks up bones and then separates meat by a microgroove principle. Bone and meat are forced against a drum separator that allows meat to pass through microgrooves into the inner portion as broken bone is forced against it.

The auger type of mechanical deboner is also used to a limited extent in the fish industry and is the most popular machine for poultry. These machines use rotating augers inside stainless steel cylinders to force meat through orifices approximately 1 mm in diameter. In this system, bone is retained on the inside and augured out of the end of the cylinder to separate it from meat.

The most popular mechanical recovery systems for beef and pork utilize hydraulically powered presses. The steps are (1) presizing, (2) pressing, and (3) desinewing. Presizing consists of dividing the bones into sections 10–15 mm in length. Bone sections are then pressed at high pressure in a piston-like device with holes in the walls and the pressing head. As bones compress, meat is pushed off the bone, through filters and away from the machine via the product outlet. Compressed bone is then ejected from the chamber and another batch of presized bone enters. Recovered meat is transferred to a desinewing step where it passes between a belt and a drum with holes 1.0–1.3 mm in diameter. Sinew, cartilage, and bone particles are removed at this step and the product is ready for use in ground or processed meat.

Names for Mechanically Recovered Meat and Pertaining Legislation

The terminology of mechanically recovered meat (MRM) is determined, to some extent, by legislation. The EU stresses in its preamble to regulation (EC) 853/2004 that the definition of mechanically separated meat should be broad, covering all methods of mechanical separation, and be flexible in view of technological innovations. The definition given later in this regulation specifies that mechanically separated meat (MSM) is obtained from flesh-bearing bones or poultry carcasses by mechanical means altering the muscle fiber structure, meat obtained from 'soft' separators or mechanically desinewed meat (sometimes also termed 'Baader meat,' according to the brand name of commonly used machinery for that purpose) was for several years not considered as MSM. In 2010, it was decided that mechanically desinewed meat should fall under the MSM definition (EU COM(2010) 704 final). This standpoint is debatable in a view of improvements in low-pressure MSM technology. Rules for the use of MSM include: MSM must not be produced from ruminants; the addition of MSM from pork or chicken to meat products must be declared on the label. MSM with calcium contents execceding 100 mg per 100 g is considered 'high pressure' MSM, which can be used only for heated meat products.

In the US, meat recovered from bones by means of advanced meat recovery machinery can be labeled similar to hand-deboned meat, for example, beef/pork trimmings or ground beef/pork. The bones must remain intact during the process, and the maximum calcium content of the product is 150 mg per 100 g. Differences in texture and consistency of meat from press machines when compared to auger machines provided further justification for defining the advanced recovery product as meat. However, products with higher calcium levels have to be labeled 'mechanically separated' beef/pork. In contrast, for MSM produced by forcing bones with attached edible meat under high pressure through a sieve or similar device to separate the bone from the edible meat tissues, Food Safety and Inspection Service (FSIS) established a standard of identity for the food product and restrictions were made on how much can be used and the type of products in which it can be used. These restrictions were based on concerns for limited intake of certain components in MSM, like calcium. To protect consumers against bovine spongiform encephalopathy (BSE), beef mechanically separated from bones is considered inedible and is prohibited for use as human food. However, mechanically separated pork is permitted and must be labeled as such in the ingredients statement. LFTB, i.e., beef recovered from fatty trimmings under gentle heating and centrifugation, followed by acid or alkaline treatment und freezing, has commonly been added to ground beef. Recently, consumer concerns about LFTB triggered a heavy debate in the US. There are some pejorative terms used for such product, although its composition makes it nutritive food. Mechanically deboned chicken or mechanically deboned turkey is common names. Until 1995, these items were labeled as chicken or turkey when used in processed meat such as frankfurters in the US. In 1995, the FSIS of the US Department of Agriculture (USDA) amended the regulations to prescribe a definition and standard of identity and composition for poultry product resulting from mechanical separation of carcasses and parts. Requiring 'mechanically separated' on the label ensured that poultry products distributed to consumers were not labeled in a false or misleading manner. Other names that have been used for mechanically removed poultry meat include comminuted poultry, finely comminuted poultry, and finely ground poultry. The terms 'finely ground,' 'ground,' 'finely comminuted,' and 'comminuted' have also been applied to poultry products produced by hand boning.

'Minced' is the most common term for fish that has been mechanically recovered. The name is also used for meat separated from whole fish and bony fillets. In the EU, this product must be termed mechanically separated fish.

The terminology for MRM and the use of special labeling is being debated in many parts of the world. Those who support calling the product meat (i.e., pork) say that the

proximate composition is similar to that of meat and that it looks and tastes like meat. Those who prefer a specific name say that another name will help ensure that products distributed to consumers are not labeled in a false or misleading manner and are not misbranded. Concerns about false labeling relate to presence of nonmuscle tissue, for example, bone marrow and bone particles.

Uses for Mechanically Recovered Meat

Minced fish is usually frozen and then thawed and used in formulated sea foods including fish sticks, fish cakes, nuggets and added-value or specialty products such as chowders, patés, fish balls, and gefilte fish. Washed minced fish that has been blended with stabilizing ingredients is called surimi and is used in popular items such as imitation crab. Other fabricated products also use surimi as a key ingredient to improve texture.

Mechanically separated poultry exceeds 318×10^6 kg annually in the US. Approximately 182×10^6 kg is used in sausages such as frankfurters and bologna, and approximately 136×10^6 kg is used in products such as chicken patties, nuggets, and poultry rolls. In some countries, sausages have mechanically separated chicken or turkey along with beef and pork as ingredients.

In 1995, when the final rule requiring 'mechanically separated chicken' or 'mechanically separated turkey' to appear on the label was implemented, the USDA-FSIS stated that 529 labels for mechanically separated poultry existed. They estimated that labels for products containing mechanically separated poultry such as frankfurters, chilli, bologna, poultry, baby foods, chicken nuggets, or patties would number approximately 5000. This low-cost meat source has led to poultry meat products being more cost effective in the marketplace.

Mechanically recovered pork is used extensively in sausages and in many items where ground pork is used. In some countries, mechanically recovered pork must be indicated in the labeling. In other countries, only the word 'pork' needs to appear on the label.

Mechanically recovered beef is often blended with hand-boned beef. A smaller portion is sold as standalone product for use in jerky, taco meat, and pizza toppings. Uses for mechanically recovered beef and pork from hydraulic press machines change as government regulations change, but decreased costs associated with mechanical recovery increase consumer demand. The need to maximize meat yields while minimizing waste, and a reduction in repetitive motion stress-related injuries, are other reasons why mechanical recovery of meat continues to increase.

Composition

Most fish mince have a similar moisture, protein, and ash content to that of hand-boned fillets, but total fat content is slightly higher. Calcium also is higher in most minced fish, reflecting the presence of bone. Minces made from different parts of fish vary in bone content. In one study, cod bones from fillets produced 84 mg bone per kg of mince; trimmings produced 272 mg kg^{-1}, frames produced 1736 mg kg^{-1}; and backbones produced 4050 mg kg^{-1}. Some residual bones in mince from fillets of gutted whole fish are more than 6 mm long. Use of a drum with smaller perforations reduces bone size but also yields a mince of finer texture. People dislike fatty fish such as herring and mackerel because of the large numbers of small bones remaining in the hand-boned fillets. However, mince made from these fish is relatively free from bones so mince does not always contain more bone than hand-boned fish.

Tissues associated with bone may alter the composition of minced fish. When blood-rich tissues from kidney are included among raw materials, the resulting mince is higher in iron. The increase has not been a concern. Sardines contain 2.4 mg iron per 100 g, which is more iron than is found in most minced fish.

Incorporation of cryoprotectants such as sucrose, sorbitol, and phosphates allows mince to keep better than mince without additives. Washed mince is called surimi. Surimi often contains 3–4% sugar, 4–5% sorbitol, and 0.1–0.3% sodium phosphate and is almost fat free with cholesterol contents of 10–15 mg per 85 g serving. Because most of the fat is washed out of surimi during processing, ω-3 fatty acids also are removed, limiting the health benefits associated with eating fish.

Variations in composition of mechanically separated poultry result from factors such as the age of the bird, the proportion of bone and fat in the material being deboned, the type of machine, and whether the material being deboned is raw or cooked. Skin-on poultry always contains more fat before and after mechanical recovery than poultry with skin removed because most fat in poultry is associated with skin (Table 1). An indication how the proximate composition varies between the different carcass parts of chicken and about the proximated composition of turkey frames is given in Table 2.

The cholesterol content of mechanically separated poultry is higher than that of hand-boned poultry. The increase in cholesterol is associated with increases in fat, marrow, kidneys, and other tissues. Spinal cord extracted during mechanical separation of necks and backs also plays a role because the cholesterol content of spinal cord is 40 times higher (2420 mg per 100 g) than that of in lean. Inclusion of spinal cord material into mechanically separated poultry explains a cholesterol content in excess of the combined values for other tissues. In the US, the FSIS decided that cholesterol was not an issue in mechanically separated poultry as this product is primarily used as an ingredient in further-processed products where cholesterol content is declared on the label anyway. People concerned about limiting cholesterol uptake would be able to make educated decisions based on labeling.

The connective tissue content of mechanically separated poultry is lower than in hand-boned meat from comparable parts because the high tensile strength prevents its extrusion with the meat. An exception is found in cooked mechanically separated poultry because collagen is gelatinized during cooking, allowing it to be extruded.

Calcium in mechanically recovered poultry is higher than in most hand-boned products because of bone particles. Calcium, by USDA regulation, does not exceed 0.235% in MRM

Table 1 Composition of hand-boned and mechanically recovered poultry

Nutrient	Hand-boned, no skin		Mechanically recovered			
	Breast[a]	Leg[a]	Broiler backs and necks		Mature hens	
			With skin	Without skin	With skin	Without skin
Water (g per 100 g)	74.8	76.1	62.7	69.3	69.8	70.9
Protein (g per 100 g)	23.1	20.1	11.4	13.8	20.4	20.4
Fat (g per 100 g)	1.2	3.8	24.7	15.5	9.1	7.5
Ash (g per 100 g)	1.0	0.9	1.0	1.0	1.3	1.3
Calcium (mg per 100 g)	11	11	118	133	112	130
Iron (mg per 100 g)	0.7	1.0	1.6	1.7	1.3	1.3
Cholesterol (mg per 100 g)	58	80	140	120	122	110

from mature poultry or 0.175% when it is made from other poultry. These calcium values are intended to limit bone content to 1%. Iron in mechanically recovered poultry is higher than in hand-boned poultry, reflecting incorporation of marrow and other organs containing iron.

The compositions of mechanically recovered beef and pork from systems that involve presizing, pressing, and desinewing are shown in Table 3. The composition of hand-boned beef is based on a composite of trimmed retail cuts. Mechanically recovered beef figures are averages from numerous studies. It is clearly not possible to conduct analytical tests for moisture, protein, fat, and ash and to determine whether the product being analyzed is handboned or mechanically recovered. In addition to similar average values, there is a great deal of variation in proximate composition within both products.

Calcium and iron are higher in mechanically recovered red meat than in hand-boned meat because bone particles and marrow are present in mechanically recovered products. Calcium and iron deficiencies exist in many diets, so the presence of these minerals in greater amounts is nutritionally advantageous for most people. Hand-boned red meat contains approximately 0.01% calcium. MRM may contain up to 0.15% calcium by USDA regulations.

The iron content of mechanically recovered beef and pork is consistently higher than it is in hand-boned beef and pork. Some of the increase is a result of the incorporation of red marrow during pressing. Because iron in marrow varies inversely with fat content, some have suggested that the ratio of iron to protein in MRM would be a better indication of the amount of marrow present than iron alone. However, iron or iron:protein ratios may not give the correct marrow content for MRM because an increase in iron content of meat occurs even when marrow is not present. One reason for the increased iron concentration of MRM is that much of the collagen, which is almost devoid of iron, is removed. In one study, MRM contained 1.2% collagen, while comparable hand-boned meat contained 4.8%. Another reason for increased iron levels in MRM is that pressing lean remaining with the bone removes water-soluble pigments that are high in iron.

In general, cholesterol in mechanically recovered beef is higher than in hand-boned beef and at least some of the increase is due to marrow. Variability in the cholesterol content of marrow makes it impractical to use cholesterol levels as an

Table 3 Composition of hand-boned and mechanically recovered pork and beef

Nutrient[a]	Hand-boned		Mechanically recovered	
	Pork[a]	Beef[b]	Pork	Beef
Water (g per 100 g)	61.0	59.2	66.5	63.0
Protein (g per 100 g)	17.0	17.8	15.4	16.4
Fat (g per 100 g)	20.8	21.9	17.3	20.0
Ash (g per 100 g)	0.9	0.8	1.1	1.1
Calcium (mg per 100 g)	5	7	106	115
Iron (mg per 100 g)	0.8	1.9	3.0	5.6
Cholesterol (mg per 100 g)	74	69	126	115

indicator of the amount of marrow present in MRM. In the US, beef bones must have all spinal cord removed before pressing. Therefore, the higher cholesterol content of mechanically recovered beef does not reflect spinal cord contamination.

Safety

Although a large volume of data relating to chemical composition, microbiology, and toxicology of fish is available, very few safety concerns that relate only to minced fish have surfaced. Sanitation requirements that apply to whole gutted fish or fish fillets also apply to mince. Bone fragments in minced fish are of minimal concern because some minced fish contains less bone than hand-boned fillets.

Several safety concerns were raised before the final rule for mechanically separated poultry was adopted by USDA in 1995. One of these concerns related to bone particle size. The conclusion was that bone particles up to 2 mm in mechanically separated poultry do not present a health hazard. There is debate about the use of mechanically separated poultry in baby food because more fluoride is found in bones than in muscle. Some believe that fluoride contributed by foods made with mechanically separated chicken, when combined with other sources of fluoride exposure, could increase the risk of mild dental fluorosis in children less than 8 years of age. However, no documented cases of fluoride problems related to chicken or turkey in baby food are available and no restriction has been placed on the use of mechanically separated poultry in baby food. Other concerns about increased calcium from bone and increased cholesterol from marrow and spinal cord are fully disclosed in nutrition facts on labels. These are nutrition concerns and are not safety related.

Because there are microbiological concerns related to the production and use of mechanically recovered fish, poultry, and red meat, some countries have adopted specific regulations relating to source of bones, the anatomical regions from which they come, and the temperature and time under which they can be held before mechanical recovery of lean. Handling of mechanically recovered products, including room temperature, chilling, and freezing, and their use have also been specified.

Countries where BSE exists have ended mechanical recovery of beef from bones (high pressure), because of traces of the spinal cord, which has been shown to be infectious, could be present. BSE causes the variant Creutzfeld–Jakob disease. With the exception of BSE, mechanically recovered beef, like pork, poultry, and fish, offers no unique safety problems.

Palatability

Data relating to palatability of MRM centers on texture, color, and flavor. Texture is finely comminuted or pasty. Color is redder, reflecting the incorporation of heme pigments from blood and kidney in fish and poultry, and from marrow in beef and pork. Flavor changes relate to increased oxidation of fat, resulting in lower storage stability. Washing removes fat, blood, pigments, and odorous substances. It is used to produce white and attractive surimi products such as imitation crab. Washing also improves storage stability by removing enzymes and fat that result in oxidation and rancidity. Many of the problems related to oxidation in poultry and red meat are overcome commercially by rapid chilling or freezing and by using MRM in products immediately after it is produced.

The popularity of fish sticks and imitation crab from mechanically recovered fish, of frankfurters and nuggets from mechanically recovered poultry, and of ground beef and sausages from mechanically recovered red meat attest to the desirable palatability attributes of these products. Nevertheless, some trained panels have reported differences in sensory characteristics of mechanically recovered products in comparison to their hand-boned counterparts. Because some differences exist and because questions regarding product identity have been raised, mechanically recovered products are not universally accepted. For example, some fast-food restaurants avoid using mechanically recovered beef in their hamburgers.

Mechanically recovered fish and poultry have been in existence longer than mechanically recovered red meat and there is less debate about their identity and use. Because all mechanically recovered products are safe, nutritious, wholesome, and highly palatable, their acceptance and use will continue to increase. More MRM will help feed malnourished, protein-deficient people in developing countries and improve the health of meat plant workers in developed countries by reducing repetitive motion stress that is associated with hand boning.

Glossary

Antimicrobial intervention The application of an antibacterial chemical or temperature treatment to beef surfaces in order to reduce the potential presence of enteric pathogens that may contaminate tissue surfaces during harvesting/processing.

Hot water carcass treatment Treatment of meat surfaces with hot water, typically 80–96 °C, to raise carcass surface temperatures to levels capable of destroying enteric foodborne pathogens.

Organic acid carcass treatment The treatment of meat surfaces with dilute organic acids (lactic, acetic, and citric) in an effort to dramatically reduce the surface pH and destroy enteric foodborne pathogens.

Steam pasteurization A process in which beef carcasses are introduced to a pressurized, closed chamber and sprayed with steam in order to raise the surface to a temperature sufficient to destroy enteric foodborne pathogens.

Steam vacuum A hand-held device consisting of a vacuum wand equipped with a steam nozzle that can deliver a stream of steam to the carcass surface while vacuuming the area.

Introduction

When present on fresh meat products, enteric foodborne pathogens such as Shiga toxin-producing *Escherichia coli* and *Salmonella* can present significant risks to human health. These pathogenic bacteria are considered high priorities for control in food safety programs implemented within the meat processing industry. To address the risk posed by these pathogens, significant research has been directed toward reducing presence on raw meat through the implementation of various decontamination procedures, also known in the industry as antimicrobial interventions.

Currently used methods are typically based on raising the temperature of the meat surface to levels that are lethal for enteric bacterial pathogens or through the application of chemical treatments. The application of more than one treatment is common, often a temperature treatment followed by organic acid spray, in a 'multiple hurdle' approach to reducing contamination.

Temperature-Based Treatments

The use of hot water or steam as a decontamination method has been investigated extensively, and treatment of carcass surfaces with water at temperatures greater than 74 °C are often used as sanitizing interventions. Temperatures used vary between applications and often depend on the temperature of the available hot water supply or the specific spray cabinet used. Bacterial destruction due to hot water treatments is based on a time–temperature relationship and it is recommended that actual bacterial reductions be validated using microbiological testing rather than relying strictly on temperature. The benefit of applying hot water against washing carcasses with warm water was reported in the scientific literature, producing an average reduction of different pathogens on fresh meat of 0.2 $\log_{10}$ cm^{-2} after washing with water at 40 °C and a reduction of 3.1 $\log_{10}$ cm^{-2} after applying water at 80 °C. In addition, several studies have demonstrated that washing carcasses with water at

 doi:10.1016/B978-0-12-384731-7.00198-7

temperatures greater than 80 °C will not produce permanent discoloration on the carcass surface. In an early investigation on hot water decontamination, it was reported that beef carcasses treated with a steam and hot water spray (80–96 °C) for 2 min contained significantly lower bacterial numbers than untreated carcasses. A volume of 18.9 L of water was sprayed on each carcass; however, the actual temperature at the carcass surface during the treatment was not indicated. Hot water (80 °C) poured on beef and lamb samples for 10 s was reported to have caused destruction of more than 99% of *E. coli* and *Salmonella* inoculated at levels of 6.5 $\log_{10}$ cm^{-2}. Although the surface tissues of the beef and mutton were not permanently discolored by this treatment, discoloration was seen when water at 90 °C for 120 s was used. In a laboratory evaluation of a hot water cabinet, *E. coli* reductions of 3.0 $\log_{10}$ cm^{-2} were attained on artificially contaminated beef carcass sides treated with hot water that elevated the carcass surface temperature to 83.5 °C for 20 s. Early investigations also reported that lamb carcasses sprayed with hot water at temperatures above 80 °C caused significant decreases (>1.0 $\log_{10}$ cm^{-2}) in aerobic plate counts (APC). In other studies where hot water treatments were evaluated, reductions in coliform or *E. coli* counts of approximately 3.0 $\log_{10}$ cm^{-2} were reported.

Designing an appropriate method to deliver a hot water treatment to a meat surface is of paramount importance for obtaining effective reduction in bacterial populations. A successful treatment relies on the ability of the hot water to raise the temperature on the meat surface to a lethal temperature for a sufficient amount of time in order to cause bacterial destruction (several seconds, depending on the temperature). Further complicating is the design of hot water spray systems, the formation of water droplets provides increased surface area that can allow rapid cooling of water as the spray travels from the nozzle to the carcass surface, resulting in an insufficient temperature increase at the carcass surface. In an early investigation of the effectiveness of hot water treatments, hot beef carcass surface areas were sprayed with 95 °C water in an attempt to raise the carcass surface temperature to 82 °C for approximately 10 s. As a result of this treatment, the bacterial contamination on the carcass surface was reduced significantly. It was reported that problems in applying hot water included obtaining a water spray that would adequately raise the surface temperature of the carcass to a bactericidal level. The volume of the spray and the size of the water droplets were found to have a profound effect on the temperature of the water after leaving the spray nozzle and before contacting the carcass surface. Using a type of nozzle which addressed cooling of hot water due to small droplet size by producing an intact 'fan spray' of hot water, it was reported that hot water sprayed onto different hot carcass surface regions obtained average reductions of initial counts for *E. coli* O157:H7 and *Salmonella* serotype Typhimurium of 3.7 and 3.8 $\log_{10}$ cm^{-2}, respectively. Corresponding reductions for APC and counts of coliforms and thermotolerant coliforms were 2.9, 3.3, and 3.3 $\log_{10}$ cm^{-2}, respectively. In this study, the hot water spray was combined with a previous water wash at 35 °C, which significantly improved the visual quality of the carcass surfaces.

Another heat-based process that gained popularity among meat processors in the 1990s is steam pasteurization. Scientists at Kansas State University assembled an experimental pasteurization chamber for laboratory testing and reported reductions of *E. coli* O157:H7, *Salmonella typhimurium*, and *Listeria monocytogenes* by 3.4–3.7 log cycles on surfaces of freshly slaughtered beef carcass surfaces. However, in additional laboratory testing, steam pasteurization alone showed no greater reductions than other treatments such as knife trimming or steam vacuuming. In commercial testing of steam pasteurization in a beef processing plant, carcasses were subjected to a preliminary water wash, and then passed through air blowers to eliminate excessive humidity that would favor steam condensation. The carcasses were then passed through a steam chamber that was supplied by steam from a tank, followed by transfer to another section of the cabinet where cold water was applied. Applying this treatment, it was possible to reduce APCs on carcasses from initial counts of 2.1–2.2 $\log_{10}$ colony forming units (CFU) cm^{-2} to 0.6–0.8 $\log_{10}$ CFU cm^{-2}. Counts of *E. coli* were also reduced from original counts of 0.6–1.5 $\log_{10}$ CFU cm^{-2} to undetectable levels after 6 or 8 s of steam treatment.

In the 1990s, regulations requiring knife trimming of any visible fecal contamination from carcass surfaces resulted in what the industry perceived as excessive and substantial carcass weight loss. Steam vacuuming, a variation on total carcass treatment designed to provide cleaning of isolated surface areas by application of a vacuum supplemented by steam, was introduced as an alternative to knife trimming. The technology was reported to be effective in reducing contamination in some studies; however, others have questioned effectiveness. Nevertheless, steam vacuuming has been implemented in most beef processing plants in the United States.

Chemical Treatments

The application of organic acid rinses containing dilute solutions of acetic, lactic, or citric acids are among the most commonly studied and applied chemical decontamination treatment methods. The antimicrobial properties of organic acids have long been utilized by the food industry for food preservation, and the meat industry also has benefitted from the use of these antimicrobial compounds to decontaminate carcass surfaces. The antibacterial mechanism of organic acids has not been completely described; however, it is widely accepted that the undissociated molecule of the organic acid or ester is responsible for antimicrobial activity. Many weak acids in their undissociated form can penetrate the cell membrane and accumulate in the cytoplasm. If the intracellular pH is higher than the pK_a of the acid, the protonated acid will dissociate, releasing a proton and acidifying the cytoplasm of the microorganism. Some reports indicate that the antimicrobial effect of organic acids may also be due to undissociated molecules, a specific non-pH-related effect of protonated molecules or a simple decrease in pH. An obvious requirement for successful reduction of bacteria on meat surfaces using organic acids is the ability to contact the bacteria on the cell surfaces. If bacteria are hidden in small knife cuts or under tissue and the organic acid cannot contact the cell, the desired antibacterial effect is unlikely.

A concern related to spraying beef carcasses with organic acid is the reported resistance of *E. coli* O157:H7 to low pH environments. However, several studies have indicated that lactic or acetic acid sprays, when applied at 55 °C and at sufficient concentration, can effectively reduce levels of *Salmonella* and *E. coli* O157:H7.

Lactic acid is one of the most commonly used compounds in beef carcass decontamination, and its ability to reduce pathogens or other organisms of fecal origin on beef surfaces has been extensively studied. Most studies on carcass decontamination using lactic acid indicate that this acid exhibits strong antibacterial capacity. A continued antimicrobial effect has also been observed during storage of meat after spraying lactic or acetic acid solutions on hot carcass surfaces. Although the most common application of lactic acid is currently on hot carcass surfaces, it has also been reported that the treatment is effective, even though to a lesser degree, on chilled beef carcass surfaces. In addition, it has been found that APC and *E. coli* counts increased more rapidly on untreated steaks than on steaks treated with acetic or lactic acid.

Chlorine-containing sprays have been extensively investigated for effectiveness in decontaminating meat surfaces. Chlorine dioxide at concentrations of up to 20 ppm was found to be no more effective than water in reducing bacteria of fecal origin on beef carcass tissue. Likewise, no differences in bacterial reductions on meat were reported after spraying tap water or water with 200 ppm sodium hypochlorite. In contrast, other investigators found lower bacterial counts on beef carcasses treated with 200 ppm sodium hypochlorite compared with untreated carcasses. In addition, they reported some continued effect of chlorine during storage of the carcasses. In an investigation conducted at Iowa State University, after inoculating different pathogenic and nonpathogenic organisms onto lean and adipose beef tissue, investigators applied washes containing phosphate buffer, ethanol, sodium chloride, sodium hydroxide, and potassium hydroxide. Phosphate buffer, ethanol, and sodium chloride produced reductions by less than 1 log cycle, whereas sodium and potassium hydroxides effectively reduced the populations of the inoculated bacteria by as much as 4 log cycles.

Acidified sodium chlorite (ASC) solutions have also been evaluated for their ability to reduce the presence of *E. coli* O157:H7 and *S. typhimurium* on beef carcass surfaces. When phosphoric acid was used to acidify sodium chlorite, the resulting ASC solution reduced populations of both pathogens by 3.8–3.9 log cycles, whereas when ASC solutions were prepared by acidifying with citric acid, the reductions obtained ranged from 4.5 to 4.6 log cycles. ASC has been approved as a direct food additive for use in decontamination of poultry and red meats.

Several published studies have indicated that multiple treatments may be required during processing for reducing pathogen contamination, also known as a multiple hurdle treatment. Numerous carcass decontamination methods have been investigated alone and in combination for their potential efficacy in reducing pathogen numbers on meat; however, results and conclusions are varied and often contradictory. For example, one study reported that spraying beef carcasses with 2% lactic acid, steam vacuum, or trimming was ineffective and only steam or hot water treatments were shown to substantially reduce bacterial contamination. The same report indicated spraying carcasses with 200 ppm peroxyacetic acid was likely also ineffective but was difficult to determine due to subsequent steam treatment. Another investigation evaluated the effects of 0.02% peroxyacetic acid, acidified 0.16% sodium chlorite, 2% lactic acid, and 4% lactic acid on chilled beef surfaces and determined that peroxyacetic acid and ASC had negligible effect on coliforms or *E. coli* and were less effective than 4% lactic acid. It was concluded that inconsistent results in evaluating antimicrobial treatments may be attributed to different types of meat surfaces to which they are applied or may reflect the composition of the surface microflora as affected by prior antimicrobial treatments. A later investigation concluded that peroxyacetic acid concentrations up to 600 ppm were ineffective as an antimicrobial treatment applied to chilled inoculated beef carcass surfaces.

Although many options exist for decontamination of meat surfaces, none of the approved interventions is capable of completely eliminating the presence of pathogens. Currently, processors in the meat industry often utilize a variety of redundant intervention technologies in an attempt to reduce risk of foodborne pathogens but are still unable to guarantee complete elimination of bacterial contamination. Proper end user handling of meat products is required for assurance of safety. Research continues to investigate novel interventions in an attempt to assist meat processors minimize or eliminate pathogens such as *E. coli* O157:H7, other Shiga toxin-producing *E. coli*, and salmonellae, as well as unknown and emerging foodborne pathogens.

Decontamination of Processed Meat

MD Hardin, IEH Laboratories & Consulting Group, Lake Forest Park, WA, USA

Glossary

Bacteriocins The proteinaceous substances produced by one kind of bacteria in order to inhibit the growth of a similar or closely related bacterial strain.
Bacteriophages (phages) The viruses that infect bacteria.
Chemical antimicrobials The chemical interventions that include organic acids and chemicals such as ozone.
Extrinsic factors The factors associated with the environment external to the food product.
High-Pressure Processing (HPP) The process of exposing ready-to-eat meat products, such as cold cuts and hams, to very high pressures (5500–9000 bars).
Hurdle approach It is the microbial control where the synergistic effects of the combined treatments is more effective than either treatment used alone.
Intrinsic factors The inherent properties associated with a food product.
Pasteurization The process of heating a food to a specific temperature for a predefined time and then immediately cooling it to slow spoilage. For intervention technologies. pasteurization processes are often designed to reduce the number of microbial pathogens.
Probiotic bacteria These are bacteria (generally lactic acid bacteria), thought to be beneficial to the host.

Introduction

Ready-to-eat (RTE) meat and poultry products that are intended to be consumed without additional preparation by a food establishment or the consumer encompasses a wide variety of products and processes from fully cooked, not shelf stable, or dried to more complex meat processes such as fermentation and dry curing. The types and levels of microorganisms that develop on or in a meat product are influenced by the intrinsic and extrinsic factors of the ingredients, the product and production environment, as well as by the specific growth requirements of the organism. The safety and shelf life of many processed meat products often depend on a combination of several factors that may actually become hurdles that limit microbial growth. All of these variables, the characteristics of the organism(s) of concern, as well as the extrinsic and intrinsic factors that affect their growth, death, and survival must be taken into consideration when developing a product, establishing product safety and shelf life, or when validating a production process or decontamination technology.

Important controls for products in this category include raw materials of good microbiological quality, validated lethality processes designed to eliminate the organism of concern, and rapid and controlled chilling to prevent the recontamination and growth of microorganisms surviving the cook process. In addition, there must be complete physical separation of raw and RTE products and ingredients and proper hygienic control of facilities, equipment, and employees in order to reduce cross-contamination and maintain product shelf life and safety. The application of postlethality processes such as postpasteurization or high-pressure processing (HPP), and the use of additives such as sodium or potassium lactate and sodium diacetate, provide an additional level of protection against the growth of foodborne pathogens throughout the shelf life of the product.

Although numerous interventions and additives are available that preclude microbial growth, thereby enhancing the safety and extending the shelf life of processed meat products; not all are appropriate for all types of products. This may be due to the negative effects various antimicrobial processes and ingredients have on the organoleptic properties of the product and/or the prohibitive costs involved in the investment and implementation of the intervention which may be particularly challenging for small processors. The number and types of commercially available thermal, nonthermal, antimicrobial chemical, biological, and other novel treatments that may be, and are, applied to foods and which are designed to inhibit, reduce, or inactivate microorganisms has increased considerably over the past several years. The driving force behind this proliferation and development of new and novel interventions for RTE meat and poultry products has primarily been the result of both proactive and reactive responses to outbreaks of foodborne illness, recalls, and regulatory actions associated with *Listeria monocytogenes*. Food safety concerns and public health implications related to *Listeria* stem primarily from contamination of RTE meat and poultry products that receive no additional cooking by the food preparer or the consumer.

There are a number of factors that may contribute to the contamination of processed meat and poultry products with pathogens such as *Listeria*. Pathogens may be present in raw materials and product ingredients and survive the lethality process. Pathogenic microorganisms may also be present in ingredients applied postlethality, such as glazes and spices. However, contamination of RTE meat and poultry products with pathogens, such as *L. monocytogenes*, occurs primarily during postprocessing steps such as slicing, dicing, packaging, and repackaging. Therefore, in order to maintain the safety of these products during distribution and storage, and in addition to adequate temperature control and effective cleaning and sanitation, any of a number of antimicrobial treatments can be applied during the postprocessing stage. Although it is almost impossible to completely eliminate *L. monocytogenes* from raw meat, most measures to control *L. monocytogenes* in RTE meat products involve continual management and a multiple hurdle approach with measures targeting several

 doi:10.1016/B978-0-12-384731-7.00246-4

areas in the process. This includes, for the product, reducing levels of the organism in raw meat and nonmeat ingredients, avoiding cross-contamination of raw products with RTE-processed products, and preventing growth of the organism in the product itself. In the environment, limiting product contamination and proper sanitation including employee hygiene; preventing establishment of the organism in coolers, cold rooms, air-handling units, and equipment; and conveying systems of postlethality areas (RTE areas) of a processing plant or in a food preparation kitchen may reduce the risk of product contamination with this organism.
