Some countries, such as the USA, have a zero tolerance policy in place for *L. monocytogenes* in RTE meat products. In 2003, the US Department of Agriculture's Food Safety and Inspection Service (FSIS) published requirements for the control of *L. monocytogenes* in postlethality-exposed RTE products. Although the intent of this article is to provide options (Alternative 1, Alternative 2, and Alternative 3) to meat processors for controlling *L. monocytogenes* in their meat and poultry products, it also provides incentives for processors of RTE meat and poultry products to use postlethality treatments such as antimicrobial ingredients in formulation and other intervention technologies in order to reduce or eliminate the presence of and/or suppress or limit the growth of *L. monocytogenes* on these products. These control measures can include a myriad of postlethality treatments (e.g., radiant heating, steam pasteurization, and high hydrostatic pressure), and antimicrobial agents (e.g., organic acids and/or their salts) used singly or in combination.

Thermal Technologies

In-Package and During Packaging Thermal Pasteurization

As previously discussed, contamination of processed meat and poultry products such as frankfurters, hams, deli meats, and sausages often occurs following a lethality process such as cooking, drying, or fermentation, and before packaging. This contamination is typically limited to surface contamination and is often due to exposure with the environment and associated handling or contaminated equipment and surfaces. Postpackaging heat treatments have long been used for whole muscle products that are unavoidably handled after initial heat processing in order to increase shelf life and safety of these products. Pasteurization of the product surface is achieved by exposing the surface of the product to hot water or steam for a specified amount of time necessary to eliminate the target organism. The original postpasteurization systems designed for whole muscle products were applied to products packaged in their final packaging at temperatures of 70–96 °C (~160–205 °F) for dwell times of up to 20 min and continue to be used today for larger products such as turkey breasts, hams, and roast beef. Although the technology has success for larger diameter products and singly packaged small diameter meats, this approach has limited value for smaller diameter products such as sausages or frankfurters that are often packaged with multiple pieces per package in a single or double layer. For the inactivating heat to reach all surfaces for all pieces in a package, these products required extended dwell times of exposure to elevated temperatures that often resulted in cooking the product in the package. This led to the development of an application method that involves applying a burst of steam or hot water to product just before packaging in order to eliminate pathogens such as *L. monocytogenes* from the surface. The integration of surface pasteurization into a commercial vacuum packaging system often minimizes any negative effect of heat on food quality by reducing treatment (exposure) time from minutes to seconds and also reduces the risk of product recontamination with pathogens by applying the intervention immediately before sealing the package at the very last step in packaging before the end user. There are currently no regulations or special labeling requirements for surface pasteurization of cooked meat products. The process needs to be established and validated for each product, based on the desired level of destruction of the target organisms at the product surface and based on maintaining desirable quality characteristics, particularly color, purge (yield), and flavor. Product shape is an important consideration as the smoother the surface, the more efficient the pasteurization process. Crevices or cuts in product, net marks, and/or wrinkles may be more impervious to heat treatments. Spacing of product, and avoiding product overlap, during the process, whether hanging in a batch house or continuous process or loaded on a carrier designed to move product through a pasteurization system, must allow for all sides (surfaces) of the product to be treated evenly. Additional factors which complicate this process include the package configuration and packaging materials that will need to withstand the extended dwell times at higher temperatures during pasteurization and the rechilling required for the longer postpasteurization treatments.

Infrared Heating

The infrared pasteurization process is an effective means of reducing contamination from meat surfaces immediately before packaging. Products are exposed to high temperatures as they pass through a tunnel of heated coils on a stainless steel conveyor. The process is currently used in commercial applications for processed RTE meat products such as hams, corned beef, and roast beef. The process may be applied, for instance, to products that are removed from their packaging following a lethality step for portioning, sectioning, and repackaging in order to pasteurize product surfaces that have been exposed to incidental contamination from equipment and handling. As with previously mentioned heat treatments, product characteristics such as the size and shape of the product and uniformity of the surface need to be taken into consideration as the heat generated by this process does not penetrate into wrinkles in product ends or cuts or crevices on product surfaces.

Nonthermal Technologies

Irradiation

Nonthermal technologies such as irradiation may inactivate pathogens by destroying or damaging their cell membranes

without producing a significant negative effect on product quality. Commercially available irradiation technologies, such as electron beam, gamma, and X-ray technologies, are well established as effective microbial interventions and a substantial amount of research has been performed on meat and poultry products in particular to demonstrate the reduction of pathogens on these products. Additional research has shown that certain common food additives, such as a combination of acetic acid salts and lactic acid used in processed meat formulations, make pathogens such as *Listeria* more sensitive to radiation, thus allowing a significant reduction in the dose of radiation needed to inactivate the pathogen and hence maintaining product quality attributes. Several limiting factors in the use and application of irradiation processing technologies have included widespread consumer acceptance of the technology and regulatory approval for the use of irradiation on RTE products. Irradiation was approved by the U.S. Food and Drug Administration (FDA) in July 1985. Since then, the USDA's FSIS has issued rules to allow the use of irradiation to only treat refrigerated or frozen raw meat and meat products to control parasites and pathogens. In 1999, the FDA was petitioned by an industry coalition to allow the use of irradiation to treat RTE meats, including hot dogs, deli ham, and turkey and bologna, in order to control *L. monocytogenes*. However, and well over a decade later, the FDA is still reviewing the petition.

Chemical Antimicrobials

The list of chemical interventions that have been developed to be applied to meat and poultry products or included as ingredients in product formulations is rather extensive and continues to grow with increasing demand. Traditional and commonly used antimicrobials applied to RTE meat and poultry products include: organic acids (lactic, acetic, and citric) and chemicals such as ozone, electrolyzed water, acidified calcium sulfate, potassium lactate, sodium diacetate (actually a mixture of acetic acid and sodium diacetate), sodium citrate, acetate, propionic acid, trisodium phosphate, and various salt compounds; naturally occurring spices and oils; and a variety of antioxidant compounds that exhibit antimicrobial properties. Most often these chemical interventions are used in combination or as a blend such as a blend of sodium or potassium lactate and sodium diacetate, which has been used extensively in product formulations such as sausages, hams, deli meats, and frankfurters in order to limit the growth of *Listeria* throughout product shelf life. The inclusion of lactate and diacetate as ingredients in a product formulation may prevent the outgrowth of the pathogen during extended refrigerated storage, and the addition of a surface treatment with an antimicrobial such as lauric arginate will provide an initial kill of the pathogen. However, not all of these antimicrobials are appropriate for all processed meat products. Processors using a chemical antimicrobial in their product must consider the impact these different antimicrobials have on the quality attributes (color, flavor, yield, etc.) of their products. The application method for the antimicrobial must also be taken into consideration in order to achieve the maximum lethality from the technology. Some chemical antimicrobials are used in product formulation, whereas others are applied as a spray or a dip to the surface of the product just before packaging or as a surface treatment sprayed into the package during packaging.

Clean Label Alternatives

Consumers are becoming more aware of product labels and are demanding products that are preservative free, have minimal processing, and are avoiding products containing ingredients that the average consumer does not recognize. Therefore, many food manufacturers are revisiting product formulations and cleaning up product labels by replacing ingredients that have a chemical-sounding name or any terms that implies that the product contains any artificial ingredients including preservatives. Any chemical-sounding name or any ingredient or process that does not sound natural and wholesome is generally not considered a clean ingredient. This presents a challenge to meat processors and product developers to use the latest available technology in order to ensure the safety of their products while maintaining a clean label at a reasonable cost. The newer, label-friendly antimicrobials formulated to meet these demands consist mainly of a blend of organic acid salts (primarily lactate) and sugars. The sugar source, which may be sucrose originating from cane or beet sugar or dextrose originating from corn, is fermented to organic acids, primarily lactic acid, by microorganisms commonly used in the food industry for the production of cheese or probiotics. The technology provides clean label solutions and may carry a simple ingredient statement including cultured (cane, beet, or corn) sugar and vinegar.

Probiotic Bacteria and Bacteriocins

Probiotic bacteria are bacteria, generally lactic acid bacteria, thought to be beneficial to the host. Bacteriocins are proteinaceous substances produced by one kind of bacteria to inhibit the growth of similar or closely related bacterial strain(s). The addition of bacteriocins, such as nisin and pediocin, and probiotic bacteria, such as lactic acid bacteria, has been evaluated as an alternative to chemical preservatives in order to inhibit the growth of *L. monocytogenes*. Although there are many natural antimicrobials, most do not have sufficient antimicrobial activity to be considered for commercial development or for inclusion in product formulations. Typical applications of bacteriocins for use in meat processes and products include the direct addition of purified bacteriocins to food products, the inoculation of a meat product with lactic acid bacteria that will produce bacteriocin in the product itself, such as a starter culture during fermentation, and the use of an ingredient in food processing that has been previously fermented with a bacteriocin-producing bacteria. The consideration and use of certain bacteriocins in commercial meat processing applications is in part due to the relative heat resistance of these substances as thermal processing is used extensively in meat processing. Both bacteriocins and probiotic bacteria are also evaluated on the basis of their scope of activity against a target organism such as *L. monocytogenes*, their regulatory acceptance, status as a natural ingredient, ease of

use, and cost. Antimicrobial bacteriocins and probiotic bacteria are among the several hurdle technologies and methods that have proven to be effective when used either separately or in combination with other technologies such as active packaging.

Bacteriophage

Bacteriophages, also known as phages, are viruses that infect bacteria. They are ubiquitous organisms and can be found in every living ecosystem including soil, water, and in the intestines of animals. Phages are highly specific for bacteria and therefore cannot infect eukaryotic cells such as those of humans/animals and plants. In addition, phages are very precise in their target such that one phage can only infect a subgroup of strains within the same bacterial species, without affecting strains of other bacterial species. Bacteriophages destroy their host cell by disrupting host cell's metabolic activity, leading to disruption of the cell membrane and eventual cell death. In 2006, the US FDA approved the use of a bacteriophage-based preparation, composed of six different bacteriophages specific against *L. monocytogenes*, as a food additive for use in RTE meat and poultry products. However, due to an unfavorable reception by consumers willing to have 'viruses' put onto their food, phage technology has yet to gain widespread acceptance or use.

Plant Extracts

Plant extracts have received a considerable amount of attention as they represent a natural alternative to many synthetic and chemical antimicrobials in use today. In addition to antimicrobial, specifically listericidal, properties, many extracts also have additional antioxidant properties that are attractive to consumers. Some of the extracts include those found in plums, prunes, grape seed, and in the essential oils of herbs and spices such as rosemary, basil, anise, and oregano. Although plant extracts have had some success when incorporated into packaging films, they are not in widespread use in the meat industry; however, they do offer an additional step as part of the company's multihurdle approach to maintaining product safety.

Active Packaging

A significant amount of research and development has been performed by the food industry, government, and academia in order to discover new and novel methods to control and/or eliminate microbial pathogens, specifically *L. monocytogenes*, from processed meat and poultry products. One of these novel technologies involves the incorporation of antimicrobials into packaging materials, also known as 'active packaging.' The concept is based on the slow release of the antimicrobial from the packaging onto the product to inhibit microorganisms on the surface of food during storage. For the technology, and the antimicrobial, to be effective, there must be substantial and complete contact between the packaging material and food product; therefore, the potential application is more appropriate for vacuum or skin-packaged processed meat products. Additionally, there must be a continual slow release of the antimicrobial throughout the shelf life of the product. Some of the antimicrobial compounds used in this 'active packaging' technology include organic acids, plant oils, and bacteriocins such as pediocin and nisin.

High-Pressure Processing

As the food industry strives to meet consumer demand for more natural and minimally processed RTE foods, the demand increases for innovative nonthermal intervention technologies. Additionally, food manufacturers want to maintain product quality attributes and extend the shelf life of their products while ensuring product safety. The application of heat to many products such as processed meat and poultry products not only reduces or eliminates bacteria but also often adversely affects many of the organoleptic characteristics of the food. Several alternative processing technologies are available to processors, including HPP, pulsed electric fields, radio frequency electric fields, ultraviolet light, and irradiation, which preserve the quality attributes of product while reducing levels of foodborne pathogens. Several of these technologies may be combined, or used in concert with minimal heat treatments, to achieve a greater reduction in levels of microorganisms. Although most of these technologies have undergone extensive research, they have not had widespread application to meat products and may be better suited for decontamination of surfaces or water used in processed meat processes. One nonthermal process that has gained widespread use, as irradiation of processed meats has not yet been approved in the USA, is HPP. Exposing RTE meat products, such as cold cuts and hams, to very high pressures such as 5500–9000 bar (~80 000–130 000 lb per square inch (psi)), for a few minutes or less, inactivates foodborne pathogens by interrupting their cellular function without the need for heat irradiation or chemicals. HPP will kill most vegetative microorganisms that grow in foods under normal storage conditions; however, it is not effective in killing microbial spores. The process also extends product shelf life by inactivating spoilage organisms and when appropriately used, HPP does not alter the texture, appearance, or flavor of foods. HPP is of particular interest for foods where thermal pasteurization is not an option due to flavor, excessive purge, texture, or color changes. Because products are processed in the final consumer package, the potential for recontamination is eliminated. When HPP first emerged in the 1990s, as a food pasteurization alternative to heat or irradiation, it was not as available to many processors as were other intervention methods such as chemical antimicrobials, due to the prohibitive costs of investing in the equipment and the lack of availability to the technology. However, as the process becomes more widely available through commercial HPP processors, it has also become more affordable for food processors. In addition, HPP has been a very promising technology for RTE meats as there are few barriers to approval by regulatory authorities, limited trade barriers, and no special labeling requirements. A major

challenge for implementation of HPP remains in keeping up with production throughput.

Validation

As with all validations, the objective of the process must be kept in mind during validation of an antimicrobial treatment. For example, is the postlethality treatment sufficient to eliminate the levels of *L. monocytogenes* contamination more likely to occur on the product? Another and equally important consideration for a company intending to use an antimicrobial ingredient or process is to determine the current regulatory approvals as written for their particular product for the country they are producing in or exporting to. In the USA, antimicrobials and approval for use in certain meat and poultry products and associated labeling requirements are listed in the USDA FSIS Directive 7120.1. These approvals vary from one product to another and a particular antimicrobial approved for application to beef bologna as a spray at a certain level (ppm) and/or for a specified amount of time may not be approved for use as a dip for the same product and may not be approved for any other processed meat products. These approvals are based on the data and documentation submitted by a company intending the use the product and/or by the manufacturer of the particular ingredient or process. Therefore, it is recommended that one of the first steps taken in the evaluation of an antimicrobial is a search of the current regulatory approvals related to that particular ingredient and/or process. During the validation and implementation of an antimicrobial intervention, ingredient, system, or process, all pertinent equipment and product characteristics should be considered. Thermal processes such as hot water or steam pasteurization will require equipment qualification and the development of a temperature profile by mapping the process in order to better understand the process and the impact of the product on the process and equipment performance. Chemical and biological antimicrobials may require a challenge study to determine their effectiveness in different products with varying product characteristics (i.e., pH, water activity, salt, meat block, etc.).

A combination of more than one intervention treatment may be used in a hurdle approach to microbial control where the synergistic effects of the combined treatments is more effective than either treatment used alone. Some of these interventions are applied directly to the product itself, some during packaging or to in-package product depending on the regulatory approvals, labeling requirements, and the overall desired effect on product and the target microorganism(s).

The primary objectives of any antimicrobial product or process is to maintain safety of the food supply and to determine the efficacy and suitability of the intervention process whether it be a thermal technology (i.e., postpasteurization or radiant heat), a nonthermal technology (i.e., ionizing irradiation or HPP), biological, chemical, or a combination of these. Processors must determine the best fit for any and all of these processes as each intervention has associated costs and may impact product quality. Additional considerations for systems that require equipment installation include space requirements, effluent output, and maintenance and upkeep of equipment. The result in using any or all of these interventions will likely outweigh the costs and inconvenience as most of these technologies result in an added improvement in product shelf life in addition to the larger goal of protecting human health and ensuring product safety.

Microbial Contamination of Fresh Meat

OA Aiyegoro, Agricultural Research Council, Pretoria, South Africa

This article is a revision of the previous edition article by K Koutsoumanis, JN Sofos, volume 2, pp 727–737, © 2004 Elsevier Ltd.

Glossary

Acid–adaptation responses The stress response that confers microorganisms with resistance to organic acid food preservatives.

Enteric pathogens Rod-shaped Gram-negative bacteria in intestines of humans and animals.

Enterobacteriaceae Family of rod-shaped Gram-negative bacteria, most of which occur normally or pathogenically in intestines of humans and other animals.

Immunoassay A biochemical test that measures the presence or concentration of a macromolecule in a solution through the use of an antibody or immunoglobulin.

Mesophiles Organisms that grow best in moderate temperature, neither too hot nor too cold, typically between 20 and 45 °C (68 and 113 °F).

Nucleic acid probe Nucleic acid that complements a specific RNA or DNA molecule or fragment; used for hybridization.

Polymerase chain reaction (PCR) A biochemical technology in molecular biology to amplify a single or a few copies of a piece of DNA.

Psychotrophes The cold-tolerant bacteria that have the ability to grow at low temperatures, but have optimal and maximal growth temperatures above 15 and 20 °C, respectively.

Psychrophiles The microorganisms that are capable of growth and reproduction in cold temperatures, ranging from −15 °C to +10 °C.

Total viable counts A quantitative idea about the presence of microorganisms such as bacteria, yeast, and mold in a sample.

Introduction

Meat commences as sterile muscle in a living animal. During transport, lairage, stunning, slaughter, and dressing, the now exposed muscle is showered by bacteria and other contaminants while it undergoes anaerobic glycolysis and becomes meat. The ever-changing surface of the meat presents a range of suitable environments for growth of various microorganisms.

Microorganisms on fresh meat may be pathogens, i.e., microorganisms causing food poisoning that are a high risk to human health. They include *Salmonella*, *Escherichia coli*, *Campylobacter jejuni-coli*, *Yersinia enterocolitica* (pork), *Listeria monocytogenes*, *Staphylococcus aureus*, *Clostridium perfringens*, *Clostridium botulinum*, *Bacillus cereus*, etc. Other microorganisms on fresh meat could be spoilage bacteria – these are microorganisms that cause off-odors and slime on meat surfaces; this group include Gram-negative rods (*Acinetobacter–Moraxella*, *Aeromonas*, *Alcaligenes*, *Flavobacterium*, *Pseudomonas*, and Enterobacteriaceae), Gram-positive rods (*Corynebacterium*, Lactic acid bacteria, *Brochothrix thermosphacta*, *Bacillus*), Gram-positive cocci (micrococci, staphylococci, fecal streptococci), yeasts, and molds.

Sources of Microbial Contaminants in Fresh Meat

Microbial contaminants are more common than any other form of meat contaminants as meat-producing animals naturally harbor them, either externally or internally (intestinal or respiratory tracts). Microbial status of fresh meat is affected by animal rearing, transportation, slaughtering, cutting, and packaging, besides hygiene and processing conditions of the slaughter plant. The natural surface flora of meat animals usually are not important as the contaminating microorganisms from their intestinal or respiratory tracts. However, hides, hooves, and hair contain not only large numbers of microorganisms from soil, manure, feed, and water but also important kinds of spoilage organisms. Meat animals may contain *Micrococci*, *Staphylococci*, and *Streptococci* on the skin or from the respiratory tract; these organisms may find their way onto the carcass (such as by an aerosol or by handling) and consequently contaminate the meat. The feces and fecal-contaminated products of animals can contain many enteric organisms including *Salmonella*; people working in meat-processing plants also can act as vector of many food-borne pathogenic bacteria. Findings suggest that processing procedures may generally be of far greater importance for determining the microbiological condition of dressed carcasses than is the condition of the hide of the animals. Plant design and operations as well as speed of slaughter and dressing may also be major factors in transfer of contamination from external animal and other surfaces to carcasses and cuts.

Slaughtering

As a rule, carcass meat is sterile immediately after slaughtering. However, the preslaughter environment can alter the rate of contamination in subtle ways. The animal origin and feed can affect the amount of excreta on the hides during transport and this can be exacerbated during lairage. If there is an excessively stressful preslaughter environment, the meat's ultimate pH can be adversely affected and this alters the way various microorganisms grow resulting in unacceptable odors and flavors

at relatively low bacterial numbers. This is particularly unacceptable in vacuum packaging. In the case of pork, the various scalding and dehairing and flaming procedures can result in variable numbers of bacteria on the surface. Poultry are defeathered and washed using various decontamination procedures so the exterior of whole birds may be affected. Bacterial contamination of the muscle from visceral bacteria does not usually occur through migration, but in exceptional cases, bacteria may end up in the muscle through contamination of intestinal contents. If good manufacturing practice (GMP) is applied during slaughtering, there is 1 bacterium/10–100 g of meat present.

Dressing

During dressing (removal of the hide, appendages, and viscera from animal carcass), contamination takes place via skin or hide, knives, hands, clothing, water, and equipment. If GMP is applied, the total number of bacteria for beef, mutton, and pork range between 10^2 and $10^6/cm^2$ and the total number of Enterobacteriaceae range between 10 and $10^3/cm^2$.

Chilling

Quick chilling at low temperatures with high air speed reduces the total viable count (TVC) on the surface of the carcass. Under less rigorous conditions, the TVC increases, but the number of mesophiles increase faster than the number of psychrophiles and psychotrophes, and because pathogens have a mesophilic character, the risk of food poisoning increases. GMP for chilling requires fast chilling to below 3 °C.

Cutting

Cutting and boning enlarge the relative surface that causes an increase in the TVC/g, depending on the initial contamination of the carcass, the conditions of hygiene, and the temperature/time in which those actions occur. Good results are achieved at 10 °C if efficiently cleaned and disinfected equipment is used.

Detection of Microbial Contaminants

Techniques explained by American Public Health Association (APHA) and International Commission on Microbiological Specification for enumeration and isolation of bacteria are widely acceptable although there are several other techniques available. Methods such as immunological, chemical, biochemical, biophysical, nucleic acid probe, polymerase chain reaction (PCR), and biosensor-based techniques have been developed to monitor the incidence of pathogenic bacteria in meat. However, problems associated with such methods include the following:

- Difficulties in the recovery of bacterial species from meat, as some coextractive materials come at the time of enrichment in selective broth medium.
- Excessive time taken to get samples that can significantly extend duration of the isolation and detection procedure.
- Inefficiencies in extraction of the target pathogens from the food matrix.
- Poor separation from elements of the competitive micro flora.

All of these can lead to subsequent problems in the accurate detection and/or differentiation of target organisms. Thus, coextractive materials can interfere with DNA hybridization test in PCR assay and immunoassay. Furthermore, these methods require approval by any governmental organization or other agencies such as Codex Alimentarius Commission (CAC), Association of Analytical Communities, APHA, International Organization for Standardization (ISO), etc. Traditional cultural and serological methods are used, though time-consuming and labor-intensive.

Traditional and standardized analysis of food for presence of bacteria relies on the enrichment and isolation of presumptive colonies on solid media, using approved diagnostic artificial media. The ISO has elaborated several standards for the detection of important pathogenical bacteria by a traditional method. For example, *Salmonella* (ISO 6579), *L. monocytogenes* (ISO 10560), thermo-tolerant *Campylobacter* (ISO 10272), *E. coli* O157 (ISO 16654), and *Staphylococcus* spp. (ISO 6888).

Indicator Tests for Pathogen Contamination in Meat

Meat can be contaminated with a variety of pathogens and spoilage bacteria and it would be difficult to monitor all of these organisms in a scientific manner. Indicator organisms are therefore used and are groups of bacteria that indicate the possible presence of organisms of concern, and may point to the origins of microbial contamination. Generally, it can be assumed that the numbers of a pathogen are less than the numbers of the corresponding indicator organism. Also, a reduction in the number of indicator organism will produce a similar reduction in the number of any pathogen associated with it.

Total Viable Counts

Most of the bacteria on raw meat originate from the skin and the intestine of the animals. Some of the contamination is of fecal origin but it is supplemented by the normal flora of the skin (staphylococci, micrococci, pseudomonads, yeasts, and molds) as well as a variety of organisms from soil and water. Only a small proportion of bacteria present is able to grow once the meat has been chilled and factors such as temperature, surface dryness, and gaseous atmosphere influence how quickly these bacteria can multiply.

Under moist and aerobic conditions, the bacterial population increases quickly and is probably dominated by pseudomonads. Off-odors and slime on the meat surface are evident when pseudomonads reach 100–500 million per cm^2. Imminent spoilage of the meat can be anticipated if a total bacterial count approaches these numbers. However, in vacuum-packed meat, the packaging brings about changes in the bacterial flora, and the storage life depends more on the nature

of the flora that develops during storage rather than on the total number of bacteria present after processing.

Generic *E. coli*

Escherichia coli forms part of the rumen or the lower intestinal tract contents, therefore, *E. coli* presence on fresh meat is considered to be a specific indicator of fecal contamination during the slaughtering and dressing processes.

The growth and survival characteristics of *E. coli* are broadly comparable to many pathogenical Enterobacteriaceae species such as *Salmonella* and pathogenical *E. coli*. Therefore, increases in *E. coli* during chilling, storage, and distribution suggest that the meat has been subjected to conditions that would also allow growth of other pathogens.

Coliforms

Part of the Enterobacteriaceae family are coliforms, which include *E. coli*, *Enterobacter*, *Klebsiella*, and *Citrobacter*. Many of them are capable of surviving below 5 °C; this attribute makes the use of coliforms as indicators of pathogen contamination in chilled meat rather suspect, resulting in erroneous conclusions regarding pathogens. *Escherichia coli* cannot grow below 7 °C, so a high coliform count does not imply growth of fecal pathogens. Processing or unsatisfactory postprocess contamination might cause an increase in the number of coliforms in meat, but the history of the product must be examined closely before the exact source of contamination can be ascertained.

Microbiological Criteria

Microbiological criteria may be used to define the acceptability of a process, product, or food batch. The criteria could be the absence, presence, or number of microorganisms, and/or the quantity of their toxins/metabolites in samples.

Microbiological criteria may be used either

- by an individual establishment, to verify that their process control systems are working as intended to prevent contamination; or
- to set national baselines to allow benchmarking against the overall performance of all meat processors and to satisfy market access issues.

The CAC of the United Nations World Health Organization has established internationally accepted guidelines for the development of microbiological criteria. The guidelines state that microbiological criteria should only be established if it is practical and necessary to do so. Codex states that the following factors are relevant for assessing need and practicality:

- Evidence of actual or potential hazards to health;
- Effect of further processing on the likely microbiological status of the food and intended use of the product;
- Likelihood and consequences of microbial contamination and/or growth during subsequent handling, storage, and use;
- The underlying health of the consumers concerned.

The American Meat Science Association convened a panel of leading microbiologists, statisticians, and other food safety experts from the USA, Canada, Australia, New Zealand, and UK to examine the role of microbiological testing in a beef food safety program. The panel was asked to document the science behind the sampling process and to present clear recommendations for the evaluation of sampling programs. The panel found that

- at no stage during a process will pathogen testing assure food safety;
- pathogens or other microorganisms at a low incidence cannot be used to assess process control;
- food-borne pathogens will not be detected consistently when they are not randomly distributed and/or occur at low incidence;
- testing for appropriate nonpathogenical organisms will allow validation and verification of process control systems designed to improve food safety;
- effective microbiological testing programs are based on sound food-safety objectives with definable microbiological performance criteria; and
- the main purpose of microbiological testing of foods is to validate and verify process control measures in the context of a properly implemented hazard analysis and critical control points system.

Processes to Reduce Microbial Contamination on Meat Carcasses and Cuts

- For the meat industry to implement interventions with the objective of improving the microbiological condition of carcasses at slaughter and consequently of resulting meat cuts, decontamination processes must be applied – these include animal washing and chemical dehairing, carcass knife-trimming, steam vacuuming and immersion, flooding, cascading, deluging, rinsing or spray-washing with water or chemical solutions, before and after evisceration (removal of viscera – internal organs, especially those in the abdominal cavity). The effectiveness of these treatments in reducing microbial contamination is affected by a number of factors including water pressure, temperature, chemicals used and their concentration, time of exposure (which depends on speed of slaughter and length of the application chamber), method of application, and time or stage of application during slaughter or carcass dressing. There are a number of concerns associated with the application of decontamination interventions.
- Depending on the spraying pressure used, application of spraying/rinsing treatments to carcasses may cause penetration of bacteria into the meat or their spreading and redistribution over the carcass. The problem may be solved by using decontamination interventions that may inactivate (hot water, steam, and chemical solutions) rather than remove contamination.
- The period of time before decontamination has an important effect on bacterial attachment; biofilm formation and potential protection of the microorganisms from

exposure to the decontamination treatment is another concern. Spray washing of carcasses before evisceration may owe its usefulness to the fact that it removes contamination very quickly after removal of the hide, while bacterial attachment is still minimal.

- The physiological stage of the bacterial cells or the development of resistance in microorganisms exposed to sublethal decontamination treatments (e.g., acids, hot water, or steam) may be of major concern.

The use of two, three, or more decontamination processes in sequence may yield synergistic or additive decontaminating effects. The higher the initial contamination level, the greater the decontamination effect of single or multiple sequential decontamination technologies. In multiple decontamination interventions, the sequence of processes is of great importance. In addition, increased water temperatures (50–55 °C) enhance the effect of acid solutions.

Carcass decontamination interventions are very useful because they may contribute to the production of carcasses with lower levels or inactive microbial contamination and to a reduction in the prevalence of enteric pathogens. However, further studies are required on possible additional consequences of decontamination treatments related to food safety. Studies have shown that exposure of pathogens to conditions similar to those occurring during decontamination may result in the development of acid–adaptation responses, increased resistance to the conditions of the gastrointestinal environment, and possibly increased pathogenesis. In addition, further investigation is required of the effect of decontamination treatments on the background microflora of meat that may act antagonistically to the growth of pathogenic bacteria during product storage.

Microbial Contamination of Processed Meat

OA Aiyegoro, Agricultural Research Council, Pretoria, South Africa

Glossary

Aerobic It means requiring air (oxygen).
Anaerobic It means without air (oxygen).
Bacilli Taxonomic class of Gram-positive, rod-shape bacteria; can be obligate aerobes or facultative.
Bacteriocins Proteinaceous toxins produced by bacteria to inhibit the growth of similar or closely related bacterial strain(s).
Biocidal Chemical agent, such as a pesticide, that is capable of destroying living organisms.
Cocci Any bacterium that has a spherical shape.
Gram-positive Bacteria that do not retain crystal violet dye in the Gram staining protocol.
Microbes A microscopic organism.
Pathogenic microorganisms Microorganisms that can cause disease in other organisms or in humans, animals, and plants.
Virulence factors Molecules expressed and secreted by pathogens (bacteria, viruses, fungi, and protozoa) that enable them to start an infection.

Introduction

Processed meat could be defined as any meat preserved by smoking, curing, or salting, or with the addition of chemical preservatives; examples include bacon, salami, sausages, hot dogs or processed deli, or luncheon meats. These meat products maintain at least one-half of their original meat integrity after processing (i.e., the original meat qualities have reduced to one-half when a meat is processed into meat products); meat products are the most popular and one of the most consumed and highly savored food products worldwide.

Safe food supply is a challenge worldwide due to the presence of spoilage and pathogenic microorganisms, which has bewitched food processing and supply industries. 'Microbial contamination of food accounts for approximately 2500 cases of illness and approximately US$200 million in monetary loss in the United States annually.' In spite of modern innovations in harvest hygiene and food production techniques, the safety of commercially processed meat products is a major area of concern.

The absence of centralized harvest facilities and the small volume of retail business (i.e., the retail venture is usually a small market), prohibitive capital costs on mechanized infrastructure, and recurring expenditures have been the hurdles for hygienic processing of meat.

Reduction of initial bacterial load in meat is of prime importance in an attempt to improve the shelf life of products. Shelf life of meat products depends on several factors – the most important of which is the microbiological quality. Several studies have indicated that consumption of meat and meat products has been associated with incidence of outbreaks of foodborne illnesses. Foodborne pathogens are the leading causes of illness and death in developing countries costing billions of dollars in medicare and social costs. Foodborne disease and microbial spoilage of food results from the failure or inability to control microorganisms at one or more stages of the food chain from raw material to consumption of the final product. The implications of situations that result in food poisoning outbreaks or food spoilage can be severe for food producers, retailers, consumers, and regulatory authorities.

Microbial growth during storage is one of the main factors affecting the quality of meat products leading to contamination and spoilage and, hence, economic loss. Microbiological criteria should take into account any organisms that are likely to be present in the meat product. The levels of tolerance applied at the time of manufacture should be such that, even after allowing for predictable growth of these organisms, products should remain safe and wholesome till the end of shelf life, provided they are stored under the appropriate conditions.

The safety of foods of animal origin for human consumption has become an essential component of public health debates. Thus, microbiological ecology of meat products will mainly depend on the environment, kind of meat and raw material, equipment, handling practices, processing, packaging, and storage temperature.

Traditionally, control of microorganisms in food has been demonstrated by microbiological testing of samples at various stages of production, including the final product. The potential for growth and/or toxin production of residual microbial population in finished products depends on the type of organisms present and their ability to grow to a level of concern under the storage conditions applied during the product shelf life.

Sources of Microbial Contaminants in Meat Products

Meat products can be contaminated with microorganisms from meat handlers who carry pathogenic microorganisms during the processes of manufacturing, packing, and marketing. One of the major risks of food contamination originates from the working practices of food handlers and disease-causing microorganisms present in or on the food handler's body that are subsequently transported from the food handler to the food during the handling process. Personal hygiene is very important in food processing because a major source of contamination leading to food poisoning caused by *Staphylococcus aureus* is human. Poor personal hygiene practices, such as negligence to wash hands after visiting the bathroom may result in

up to 10^7 CFU (colony-forming units) ml^{-1} pathogens under the fingernails of food handlers. Spice, which has an important role in meat products, can be contaminated with bacteria, molds, and yeasts. Microbial load of spice depends on its variety, processing method, granule size, and moisture content. Minced meat and spice mix have been identified as the primary contamination sources in sausage manufacturing. The most probable reason for minced meat having high microbial load is the poor hygienic quality of raw meat. Microbial quality of raw meat and nonmeat ingredients affects the quality of final products. The hygienic condition and level of sophistication of the harvesting and processing equipment are also contributory sources of contamination in processed meat products. Studies have revealed that contamination of meat with microbes decreased with increased sophistication of harvest facilities. Also, the incidence of various foodborne pathogens in processed meat may be different in different parts of carcasses from which the processed meat is obtained; for instance, studies have shown that thigh muscles were highly prone to contamination compared to the breast muscle, irrespective of the processing conditions.

Some Microbial Contaminants of Processed Meat

Many groups of microorganisms potentially contribute to meat spoilage under appropriate conditions. This makes the microbial ecology of spoiled meat products very complex, and thus the spoilage is very difficult to prevent. Many studies have determined the presence of foodborne pathogens in meat products, such as *Listeria monocytogenes*, *S. aureus*, *Escherichia coli*, *Clostridium perfringens*, and *Samonella* spp.

Listeria monocytogenes is a Gram-positive, nonspore forming, highly mobile, rod-type, facultative anaerobic bacterium. It can grow in a wide range of temperature conditions and pH range. The organism can tolerate salt and nitrite, and is widely spread in the environment. The Centers for Disease Control and Prevention reported that a multistate outbreak between 1998 and 1999, which caused 101 cases and 21 deaths, was linked to the contamination by *L. monocytogenes* in frankfurters and deli meats. In 2000, a multistate outbreak involving deli turkey meat resulted in 29 cases, 4 deaths, and 3 miscarriages or stillbirths. The recall of 26 million pounds of meat products in 2002 indicates the economic consequences of contamination with *L. monocytogenes*. The U.S. Department of Agriculture (USDA) has thus established a 'zero tolerance' policy for *L. monocytogenes* in meat products. Therefore, it is important to prevent contamination in meat products.

Staphylococcus aureus is one of the most common agents in bacterial food poisoning outbreaks; it is also a major causative pathogen of clinical or subclinical mastitis of dairy domestic ruminants. Poultry, meat and egg products as well as milk and milk products have been reported as common foods that may cause staphylococcal food poisoning. *Staphylococcus aureus* is one of the commonest etiological agents of bacterial diseases worldwide due to its ability to produce a broad range of exotoxins and other virulence factors. Among them, the staphylococcal enterotoxins produced by some *S. aureus* strains are the main cause of most widespread foodborne intoxications. Staphylococcal food poisoning, together with toxic shock syndrome toxin-1 are responsible for toxic shock syndrome and staphylococcal scarlet fever. Studies have shown that augmentation of the additives, onion garlic meal, pepper, and E vitamin can decrease the microbial agents in meat products.

Other contamination bacteria in processed meat products include *Salmonella*, *Bacillus*, *Clostridium*, *Escherichia*, *Campylobacter*, *Acinetobacter*, *Aeromonas*, *Enterococcus*, *Moraxella*, and *Psychrobacter*. Some of the pathogenic bacteria, such as *Salmonella*, can be found in fermented meat products because this organism can tolerate or adapt to a wide variety of environmental stresses during meat fermentation. Food poisoning outbreaks caused by the consumption of fermented meat products contaminated with *Salmonella*, such as *Salmonella typhimurium* DT 124 and *S. typhimurium* PT 193, in salami have been reported. Although these pathogenic bacteria can be destroyed during cooking by heat treatment, some consumers prefer to consume raw or medium-cooked products.

Intervention against Microbial Contaminants of Processed Meat

Most microbial vegetative cells and toxic products are sensitive to heat treatment and can easily be inactivated by cooking. Therefore, postcooking recontamination during packaging is the main concern. Postpackage decontamination methods such as in-package thermal pasteurization and irradiation, and formulating meat products with antimicrobial additives are common approaches to control microbial contaminants in processed meat. Therefore, it is to the manufacturer's advantage to take measures for reducing contamination in food.

Irradiation

Ionizing radiation is a process in which products are exposed to radiant energy. Ionizing radiation includes gamma rays, electron beams, and X-rays. E-beam irradiation was reported to be more effective than gamma-ray irradiation in decreasing *Bacillus cereus* and *E. coli* O157:H7, but not for *L. monocytogenes*. In cooked pork chops and hams inoculated with *L. monocytogenes*, low-dose (0.75–0.90 kGy) irradiation reduced *L. monocytogenes* by >2 log. Irradiation treatments were significantly more lethal under aerobic packaging than in either vacuum or modified atmosphere packaging conditions. One concern about using modified atmosphere packaging in irradiated meat or poultry is that pathogens may grow and/or produce toxins because of low competing organisms. This is of even greater concern if spoilage is suppressed and does not provide the usual warning signals. Temperature effects must be carefully considered because reduced irradiation temperatures result in fewer adverse changes in the sensorial properties of meat and poultry products. However, low temperature conditions require greater radiation doses to inactivate the foodborne pathogens. The irradiation dose rate is another factor because, at low dose rates, microbial enzymes may have more time to repair damage to cells,

resulting in higher resistance. Generalization of the effects of irradiation can be misleading because the effectiveness of irradiation is affected by irradiation conditions and product compositions.

Food Preservatives

Chemical antimicrobials: The salt of lactate (SL) is frequently used as an antimicrobial in meat products due to its beneficial properties to meat quality when applied at appropriate concentrations. The addition of lactate to food products with neutral pH offers good prospects for prolongation of shelf life. In general, Gram-positive bacteria were more sensitive toward lactate than Gram-negative bacteria under optimum growth conditions (pH 6.5, 20 °C). The combined application of lactate and diacetate resulting in a synergistic inhibitory effect on the growth of pathogenic organisms in meat products has been reported to be very effective. A chemically synthesized short-chain peptide composed of 6 leucine and 8 lysine residues was shown to be biocidal against several foodborne organisms, including *L. monocytogenes* suspended in phosphate buffer at concentrations 5–50 μg ml^{-1}. Peptide concentrations of 100 μg ml^{-1} inhibited aerobic and anaerobic microorganisms present in meat exudate. Sodium hypochlorite, quaternary ammonium compound, and peroxyacetic acid used as sanitizers in meat processing plants were effective in eliminating *L. monocytogenes*.

Lactobacilli, probiotic bacteria, and bacteriocins: Biopreservation with various strains of lactic acid bacteria is a suitable alternative to chemical preservatives. The antimicrobial activity of a bacteriocin-producing *Lactobacillus plantarum* MCS strain against *L. monocytogenes* was observed in naturally and artificially contaminated salami, all showing strong antimicrobial effects. Thus, the application of *Lactobacillus*, *Pediococcus*, or *enterococci* bacteria in starter cultures may provide an additional hurdle against pathogens in fermented meat products. Lactic acid bacteria can also be used to inhibit the growth of bacterial contaminants in nonfermented products. Addition of *Lactobacillus sakei* Lb 706 prevented the growth of *L. monocytogenes* pasteurized minced meat and comminuted cured raw pork during the first few days after production. The *L. sakei* strain applied to cooked products at a concentration of 10^5–10^6 CFU g^{-1} immediately before slicing and vacuum packaging inhibited the growth of a cocktail of 3 rifampicin-resistant mutant *L. monocytogenes* strains both at 8 °C and 4 °C. Bacteriocins are ribosomally synthesized polypeptides produced by bacteria with an ability to kill or inhibit the growth of similar bacterial strain(s). Nisin is the most commercially important bacteriocin due to its relatively long history of safe use. It is currently recognized as a safe food preservative in approximately 50 countries.

Plant extracts: Plant extracts, due to their antioxidant and antimicrobial activities, have a broad spectrum of antimicrobial activity against many genera of bacteria and fungi. It has been reported that eugenol (clove extract) and pimento extract significantly inhibit the growth of *Aeromonas hydrophila* and *L. monocytogenes* inoculated in cooked beef slices. The numbers of *E. coli* O157:H7, *L. monocytogenes*, and *S. typhimurium* in treated raw ground beef declined when 1% pine bark extract was used as an antimicrobial on the ground beef after 9 days of refrigerated storage. These results suggest that natural plant extracts have a potential to be used with other preservation methods to reduce pathogens in processed meat.

In-Package Thermal Pasteurization

Effects of surface pasteurization temperatures on the survival of *L. monocytogenes* in low-fat turkey bologna showed that all the *L. monocytogenes* cells were destroyed after exposure to an 85 °C water bath for 10 s (> 6-log reduction), but viable cells were detected at up to 10 min of heating at 61 °C (< 6-log reduction). The effectiveness of in-package pasteurization in inactivating pathogenic organisms depended upon package size and the roughness of the product surface. The strains of bacteria also influence the effectiveness of thermal pasteurization. Cells grown at 42.8 °C before heat treatment were more thermotolerant than those grown at 37 °C. Heating at slowly increasing temperatures (0.7 °C min^{-1}) enhanced the thermotolerance of *L. monocytogenes*, and starvation in phosphate-buffered saline pH 7 for 6 h at 30 °C increased the heat resistance of the organism in broth.

High-Pressure Processing

High-pressure processing (HPP) is a novel, nonthermal method of food processing where food is subjected to elevated pressures with or without addition of heat. HPP can inactivate microorganisms without significant changes in texture, color, or nutritional value of food. HPP is not only a powerful tool to control pathogenic organisms but also is effective on spores and viruses. The decontamination efficacy of HPP also depends on many other factors, such as level of pressure, treatment temperature, exposure time, pH, water activity, and food composition. Many studies have shown that the effectiveness of HPP was slightly reduced at room temperature compared with refrigerated temperature. Also, the presence of oil reduced the effectiveness of high pressure in killing *L. monocytogenes* and cell morphology also had an effect on HPP, with bacilli being more sensitive to pressurization than cocci. When HPP was combined with antimicrobials, like bacteriocins, death rate increased because of sublethal injuries to living cells.

Combination Therapy Technology

The concept of combination therapy technology is based on the application of combined preservative factors to achieve microbiological safety and stability of foods. The most important hurdles used in food preservation are temperature, water activity, acidity, redox potential, antimicrobials, and competitive microorganisms. A synergistic effect could be achieved if the hurdles hit at the same time at different targets that disturb the homeostasis of the microorganisms present in foods. For meat products, the most frequently applied hurdles include thermal processing, vacuum packaging, refrigerated storage, and nitrite. However, these hurdles seem insufficient for *L. monocytogenes* due to its ubiquitous nature, ability to grow at refrigerated temperature and anaerobic condition, and resistance to salt and nitrite.

Microbial Contamination Intervention and Processed Meat Quality

Although interventions are very effective in controlling foodborne pathogens in meat, it generates free radicals that can cause lipid peroxidation and other chemical changes, which influence the quality of processed meat. Irradiated meat products can develop a characteristic odor described as 'bloody sweet' or 'barbecued corn-like.' Sensory analysis indicated that sulfur odor increased as irradiation dose increased. In addition to sulfur compounds, irradiation dramatically increased other volatiles in the meat products. Irradiation can induce a variety of color changes depending on irradiation dose, animal species, muscle type, pH, and reducing potential of meat and packaging type. The color change induced by irradiation is associated with carbon monoxide production during irradiation, which is correlated with increased redness of irradiated meat. They characterized the pigment that causes pinkness in irradiated turkey meat as carbon monoxide-myoglobin (CO-Mb). Irradiation is also reported to cause the oxidation of amino acids by generating high yields of side-chain hydroperoxides that relates to the oxidation of proteins and lipids.

Injection of SL to cooked, vacuum-packaged beef top rounds resulted in higher cooking yields and darker, redder color with less gray surface area. Flavor notes associated with fresh beef were also enhanced by the addition of SL, and flavor deterioration during storage was minimized. In Chinese-style sausage, the addition of 3% SL resulted in better quality regarding physicochemical characteristics. Research reports have shown that SL added to fresh pork sausage did not affect the internal lean color but resulted in more rapid surface discoloration, and that 2% potassium lactate had no effect on quality and sensory properties of low-fat pork sausage or lean color during refrigerated aerobic storage. Adding 2% SL to turkey breast rolls resulted in lower color values, but increased hardness, springiness, cohesiveness, chewiness, and resilience of turkey breast rolls. Including 3.3% commercial SL in frankfurter formulation did not affect textural profile of sausage. Addition of potassium sorbate up to 0.1% or sodium benzoate up to 0.1% in product formulation had no effects on the texture of products. These results suggest that the effect of SL on the quality of products depends on SL level and product types. A high concentration of sodium diacetate (SDA) has a negative effect on flavor of ham products. However, at lower levels (0.1%), SDA does not influence the quality of meat products. The addition of potassium benzoate greatly increased the content of benzene in the volatiles of irradiated RTE turkey ham and breast rolls, suggesting that benzoate salt is not a good antimicrobial to be used in products for irradiation. HPP causes minimal changes in 'fresh' characteristics of foods because it can be conducted at ambient or refrigerated temperatures. However, there is no doubt that HPP causes quality changes of meat. Some of the changes such as color and lipid oxidation are detrimental, whereas other changes such as pressure tenderization and pressure-assisted gelation are beneficial.

Conclusion

Microbial contamination can occur and can be reduced at different stages of processing of meat. Experiments have confirmed that coliform bacteria, fecal coliform bacteria, *E. coli*, total *Enterococcus* spp. and aerobic plate count are the most important indicator organisms that are most commonly used to ensure food safety. In some instances, enumeration of yeast performed on samples taken during processing in small businesses to verify good manufacturing practices is also good. This verification through monitoring was found to be an attractive alternative to the examination of end products.

To ensure the microbiological quality of final products, raw meat and ingredients must be inspected before entering the processing plant. Certified suppliers must be selected. Strong criteria for hygienic quality of raw meat must be set for suppliers. After receiving raw meat and ingredients, they must be stored in appropriate conditions until use. Effective cleaning and sanitation programs must be performed in processing plants. Personnel should follow the standard hygienic procedures and health conditions of personnel must be monitored regularly, and finally, appropriate time and temperature settings for meat processing should be selected.

Glossary

Amplicon Target amplified deoxyribonucleic acid (DNA) sequence.
Amplification The process of making multiple copies of DNA.
Endonucleases Enzymes that cleave DNA at specific sequences.
Horizontal gene transfer The transfer of genes between microorganisms.
Indels Mutation where insertion or deletion of DNA bases occurs.
Melt curve The analysis of disassociation of DNA from double stranded to single stranded with the addition of heat.
Nucleotide substitutions A single base pair change in DNA between two populations.
Primer A small piece of DNA that acts as a starting point for DNA synthesis and extension.
Template The DNA from organisms to which primers bind in order that amplification can occur.
Thermal cycling The cycling of temperatures to allow DNA denaturation, primer annealing, and DNA extension.

Molecular Detection of Foodborne Pathogens

Traditional methods of detection of pathogenic bacteria on meat products constitute a challenge, as the bacteria are often present in low numbers, camouflaged by the food matrix and background microflora, and are frequently injured or stressed. Therefore, conventional culture methods include long preenrichment/enrichment steps, along with isolation, and are often followed by biochemical/serological/immunological confirmation. This multistep process is time and labor extensive, creating a high demand for development of rapid identification methods. Molecular detection plays a key role in decreasing the amount of time needed to obtain critical results by reducing enrichment time required due to corresponding increase in sensitivity. Importantly, the decision to accept or reject fresh meat products or to release ready-to-eat meat products can be made by screening enrichment for the presence or absence of virulence gene(s) carried by the pathogen of interest. Molecular methods provide increased sensitivity/specificity, higher throughput, minimal technician training, and less subjective test results. Development of novel molecular detection platforms helped to increase speed of detection; however, recent advances in full genome sequencing have really revolutionized molecular detection of pathogens in meat products by revealing target deoxyribonucleic acid (DNA) sequences unique to pathogens of interest.

Polymerase Chain Reaction-Based Detection

Conventional polymerase chain reaction-based detection methods

Conventional polymerase chain reaction (PCR) is a technique used to amplify millions of copies of a predetermined sequence of DNA by replicating the DNA replication process *in vitro*. The method uses short pieces of synthetic DNA (primers) that flank the DNA sequence of interest along with enzyme, cofactor, substrate, and buffers in order to amplify template DNA. To generate millions of copies of the targeted DNA, PCR relies on thermal cycling – cycles of repeated heating and cooling to allow double-stranded DNA to denature, primers to anneal to the template, and for enzymatic extension or 'replication' of the DNA to occur (Figure 1).

Agarose gel electrophoresis is most commonly used to resolve the DNA products. This process separates nucleic acids by an electrical current, which allows the movement of negatively charged particles through the agarose. Migration of DNA

 doi:10.1016/B978-0-12-384731-7.00066-0

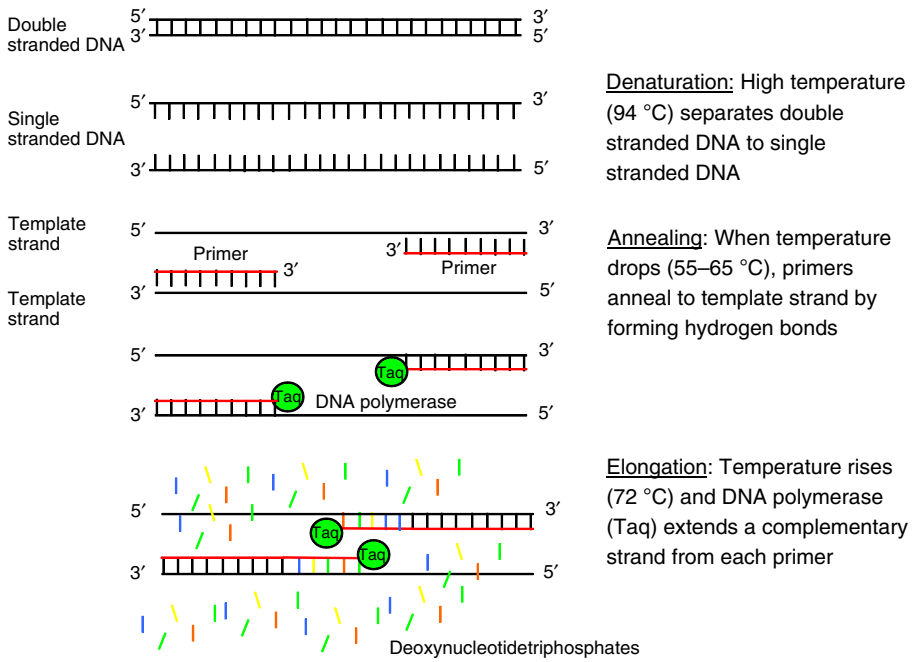

Figure 1 Polymerase chain reaction (PCR).

fragments through the agarose matrix is largely determined by their molecular mass, so that comparison of the distance of migration of a DNA fragment with that of size standards can verify that the amplified DNA fragment is of identical size as that of desired target amplicon. The DNA fragments can be visualized by preparing or staining the gel with fluorescent DNA intercalators, such as Ethidium Bromide or products such as SYBR® safe.

Multiplex polymerase chain reaction

Multiplex PCR is a variant of conventional PCR, permitting simultaneous amplification of more than one target of interest in a single PCR reaction by incorporating more than one pair of primers. Multiplex PCR is a rapid, convenient, and repeatable assay that may include analyses of mutations (e.g., nucleotide substitutions, indels, or horizontal gene transfer events) that have been accumulated in the genomes of different bacterial isolates. Typically, multiplex PCR is used for identification applications where simultaneous analysis of multiple markers is required. Conventional PCR may be used to simultaneously screen for the presence or absence of multiple pathogens (e.g., *Escherichia coli* O157:H7, non-O157 shiga toxin-producing *E. coli* (STEC) of regulatory significance, and *Salmonella*) from the same enrichment. Additionally, incorporation of multiple targets is a simple way to increase specificity. Multiplexing requires optimization of primer concentrations and annealing temperature to deter formation of primer dimers and to facilitate amplification of all target sequences. An internal amplification control should be included in conventional PCR assays for testing purposes to insure that the food matrix and enrichment media have not inhibited the PCR reaction. Although, universal primers that amplify 16 s rDNA (present in all bacteria) may seem like an obvious choice for an amplification control, the potential for the amplification control to outcompete targets in the presence of high levels of background microflora should be carefully considered.

Real-time polymerase chain reaction-based detection methods

Real-time PCR follows the same procedure as conventional PCR; however, the amplified DNA is quantified in real time as fluorescence accumulates after each amplification cycle, rather than an amplicon being determined at the end of the reaction as in conventional PCR. The amount of DNA is quantified either by the use of fluorescent dyes, such as SYBR® green, that intercalate with double-stranded DNA, or by using fluorescently labeled probes that hybridize the DNA fragment flanked by a set of PCR primers. The point at which the fluorescent signal is measured in order to calculate the initial template quantity can be either at the end of the reaction (endpoint semiquantitative PCR) or at the time when the amplification is still in progress (real-time quantitative PCR). For probe-based chemistries, eventually, enough accumulated fluorescence will be produced to drive the amplification signal above baseline. The intensity of fluorescence detected is proportional to the concentration of double-stranded DNA in the reaction and thus provides a measure of the quantity of newly synthesized product. If a standard curve is created from samples of known concentration, the initial number of target cells/DNA can be determined. Although SYBR® green-based assays are performed on real-time equipment, results cannot technically be obtained in real time and thus the assay should be referred to as endpoint semiquantitative PCR; this is because accumulation of SYBR® green is not quantified until the melt-curve analysis is run. A melt or dissociation curve is the gradual melting of the PCR products at the end of the PCR run. In short, it charts the change in fluorescence observed when double-stranded DNA with the intercalated dye dissociates or

'melts' into single-stranded DNA as the temperature of the reaction is raised, ultimately preventing results from being interpreted in real time as fluorescence accumulates.

Commercial systems that use real-time PCR-based chemistries are available, such as the DuPont Qualicon BAX® detection system, PALL GeneDisc® system, Applied Biosystems MicroSeq® detection kit, BIOFIRE R.A.P.I.D.® LT Food Security System, AES Chemunex ADIAFOOD PCR kits, Bio-Rad iQ-Check real-time PCR test kit, and the BIOTECON foodproof® kit, to name but a few. These systems are available for detection of meatborne pathogens such as *Campylobacter* (spp. *jejuni*, *coli*, and *lari*), *Listeria* (*monocytogenes* and spp.), *Salmonella* spp., and *E. coli* (*E. coli* O157:H7, the top six serogroups of non-O157 STEC, and Enterohemorrhagic *E. coli* (EHEC)). These systems consist of preparation on enriched samples, followed by automated amplification and detection utilizing fluorescent dyes, such as SYBR® green or fluorescently labeled probes (i.e., Scorpion probe or Taqman© probe) developed for targeted organisms.

Isothermal Detection

Novel discoveries in molecular biology of DNA synthesis *in vivo* revealed that DNA amplification can occur in isothermal conditions *in vitro*, negating the need for expensive thermocycling equipment and time required to perform two- or three-step cycling to amplify DNA. The use of DNA polymerase with high-strand displacement activity and other various accessory proteins allows replication at a constant temperature of 60–65 °C. Owing to the use of multiple primer sets to identify distinct regions on the target gene, there is also a direct increase in assay specificity.

The Neogen amplified nucleic single temperature reaction (ANSR)™ Isothermal Pathogen Detection System is a commercially available kit for *Salmonella* and *Listeria* spp testing that uses ANSR technology for *in vitro* DNA amplification. Nicks created in double-stranded DNA by specific endonucleases allows polymerization of target nucleic acid and thus amplification and detection of target sequences in real time using fluorescent molecular beacon probes. ANSR removes many of the limitations that antibody- and PCR-based technologies are associated with in terms of food matrix effects on detection. Additionally, results are available within as little as 10 min after a minimally enriched sample is loaded into the system.

The commercially available 3 M™ Isothermal Molecular Detection System© also utilizes isothermal DNA amplification but does so in combination with bioluminescence detection for detection of *E. coli* O157, *Salmonella* spp, and *L. monocytogenes* and other *Listeria* spp. Briefly, the assay works by producing pyrophosphate ions during targeted DNA amplification. These pyrophosphate ions and adenosine 5′ phosphosulfate are enzymatically converted into adenosine triphosphate (ATP) by ATP Sulfurylase. This ATP drives the luciferase-mediated conversion of luciferin to oxyluciferin, which generates visible light in amounts that are proportional to the amount of ATP. The light produced is subsequently quantified, indicating the presence of DNA from the target organism. This rapid system allows the simultaneous amplification and detection process to complete in 75 min postenrichment.

Ribonucleic Acid Detection

Roka Bioscience© pathogen detection assays uniquely target ribosomal ribonucleic acid (rRNA); however, the system is able to target mRNA or DNA as well. rRNA is an optimal target for molecular technology in meat- and foodborne pathogen detection applications mainly because targeting rRNA permits increased sensitivity due to the high cellular copy levels of rRNA versus low levels of DNA, ultimately reducing the time needed for an enrichment step. Currently, Roka Bioscience© has developed the Atlas™ System for both *Listeria* and *Salmonella*. A system for *E. coli* is estimated to be Association of Analytical Communities approved this year. Unlike other commercial kits, these assays combine the use of target capture, transcription-mediated amplification, and hybridization protection.

Target capture concentrates and purifies the nucleic acids before the amplification step, much like other immunomagnetic bead separation techniques. In short, oligonucleotides, which are bound to magnetic beads, capture the targeted nucleic acid. These magnetic beads, now containing bound target nucleic acids, are then drawn to the side of the tube using magnetism. Keeping the nucleic acids of interest bound and stable in the tube allows inhibitory particles to be washed away before amplification begins. Transcription-mediated amplification is an RNA transcription-mediated isothermal amplification system. Briefly, it uses two enzymes to drive the reaction: RNA polymerase and reverse transcriptase, enabling amplification of either DNA or RNA. Finally, the Atlas™ System also uses hybridization protection, where a specific oligonucleotide probe is used for final detection. The probe is labeled with an acridinium ester detector molecule that emits a chemiluminescent signal and hybridizes with target rRNA.

Microarray/Gene Chip

A microarray or gene chip is an assembly of DNA spots attached to a solid surface. DNA microarrays are often used to simultaneously measure the expression levels of large numbers of genes. Each DNA spot contains a specific DNA sequence (probes/oligos) that is a short section of a gene/DNA segment which is used to hyrbridize cDNA. cDNA is DNA that has been made from conversion of mRNA to DNA using reverse transcriptase. Probe–target hybridization is most often detected and quantified by chemiluminescence-, fluorophore-, or silver-labeled targets used to quantify target nucleic acid sequences.

VereFoodborne™ is a nucleic acid-based device that combines two molecular biological technologies: multiplex PCR and microarray hybridization. This allows the system to detect, differentiate, and identify multiple foodborne pathogens simultaneously in a single test. Pathogens that the system is able to simultaneously detect includes: *Vibrio* spp., *Staphylococcus aureus*, *Listeria* spp., *Bacillus* spp., *Clostridium perfringens*, *Campylobacter* spp., STECs (*E. coli* O157 and O104), *E. coli* spp., *Shigella* spp., *Salmonella* spp., *Cronobacter sakazakii*, and Norovirus genogroups I and II. The process of the

VereFoodborne™ chip includes DNA extraction directly from enrichment, culture, an isolated colony, or surface swab. PCR amplification is then carried out to amplify copies of target DNA that is unique to the specific foodborne pathogens of interest. This step is followed by hybridization of amplified product onto the microarray chip. After washing the chip, the array can then be analyzed. Analysis of the chip allows you to visualize what unique DNA segments from your unknown sample hybridized to the DNA spot on the chip.

Beacon's BrightSPOT™ is another system that uses microarray and DNA chip technology. It uniquely combines an extremely sensitive light sensor with very bright light-producing molecules from the deep oceans. As stated above in this section, most chip technologies that are based on light detection use chemiluminescence, such as firefly luciferase. This system utilizes *Gaussia* luciferase (originates from a deep-sea copepod) and produces a bright blue light approximately 10 000 times brighter than other luciferases. The chip is able to perform up to a hundred different diagnostic tests on a 10 µl biological sample. The unique design of the BrightSPOT™ System allows it to test samples without the need for time-consuming sample preparation or enrichment, giving you results in approximately 35 min.

DNA Subtyping of Foodborne Pathogens

Subtyping can be defined as the ability to characterize a group of isolates beyond the species or subspecies level. It has two broad categories: (1) phenotypic methods that differentiate isolates on the basis of enzymes, proteins, or toxins and other cellular metabolites that are expressed and (2) molecular methods that differentiate isolates on the basis of interrogation of nucleic acid sequences, which can be accomplished using a variety of approaches. PCR-, restriction band-, and DNA sequence-based methods are widely and routinely employed to molecularly detect or confirm the presence of a foodborne pathogen in a given sample and to further characterize isolates representing a pathogen beyond the species or subspecies level. Along with pathogen detection, the implementation of DNA-based subtyping methods has provided important insight into genetic diversity, evolution, and population structure of clinically important foodborne bacterial pathogens, including *Campylobacter*, STEC, *L. monocytogenes*, and *Salmonella*.

DNA sequence-based subtyping methods continue to be developed and have become increasingly more popular for improving the discriminatory power and epidemiological concordance to characterize bacterial foodborne pathogens beyond the species or subspecies level. Although macrorestriction band-based molecular methods continue to serve as the 'gold standard' for subtyping of foodborne pathogens, the enhanced availability of full genome sequence data in recent years has served as the impetus for the development of novel DNA sequence-based subtyping methods. Deciphering results of sequence data is much less subjective than interpreting patterns from band-based subtyping methods, and unlike band-based methods, results are easily transferable and comparable between laboratories.

Polymerase Chain Reaction-Based Subtyping

Molecular serotyping

The cell wall of pathogenic bacteria contains numerous components (e.g., proteins and lipopolysaccharides) and each of these different structures can be termed an antigen. The three types of antigens, which are of importance in prokaryotes, are the flagellar (H), somatic or polysaccharide (O), and capsular (K) antigens. Conventional serotyping, which is a phenotypic subtyping method, probes a pathogen's reaction with many different antisera to determine which antigens are present on the cell surface. Based on the combination of antigens that are detected, isolates can be further differentiated beyond the species level into serotypes.

Classifying a foodborne bacterial pathogen isolate into a serotype provides clinically relevant information and can facilitate surveillance of foodborne diseases and epidemiological investigations during an outbreak of foodborne disease. For example, serotyping is potentially useful for defining subtypes and clonal groups of *L. monocytogenes*. More than 95% of human listeriosis cases are caused by a few specific *L. monocytogenes* serotypes (i.e., 1/2a, 1/2b, 1/2c, and 4b), where serotype 4b is responsible for a majority of listeriosis epidemics. The development of a simple multiplex PCR-based serotyping method has provided one with a molecular assay for the identification and grouping of *L. monocytogenes* into four groups, each containing one of the most common human disease-associated serotypes (1/2a, 1/2b, 1/2c, and 4b). Molecular serotyping protocols have also been developed for *E. coli* and *Salmonella* that targets, genetically, the same antigens used in conventional serotyping. Serotyping is the basis of pathogenic *Salmonella* diagnostics. The flagellar, polysaccharide, and capsular antigens determine the strain's pathogenicity. The Luminex© xMAP® *Salmonella* Serotyping Assay is a Centers for Disease Control (CDC)-developed, molecular *Salmonella* serotyping assay that drastically improves the speed of determining serogroup, a very important tool in an epidemiological setting. The xMAP® assay is a suspension analysis system and consists of three separate tests (PCR, bead technology, and flow cytometry) that determine O and H antigens simultaneously. The assay tests for 7 O Groups and 35 H antigens and their results are based on combinations of O and H antigen PCR products. This novel molecular technology can differentiate the top 100 most commonly occurring human pathogen serotypes of *Salmonella enterica*.

DNA Macrorestriction Band-Based Subtyping

Pulsed field gel electrophoresis

Pulsed field gel electrophoresis (PFGE) is a band-based molecular subtyping method that does not include PCR but rather involves macrorestriction of total bacterial DNA (chromosomal and plasmid) using an infrequent cutting restriction enzyme. The large DNA fragments produced from restriction digest are susceptible to mechanical shearing; therefore, in order to prevent DNA breakage, whole bacterial cells are embedded into an agarose plug. Once whole cells are embedded, they are subjected to lysis detergents/enzymes and extensively washed to remove remaining cellular or chemical contaminants. The agarose plug containing the genomic DNA is

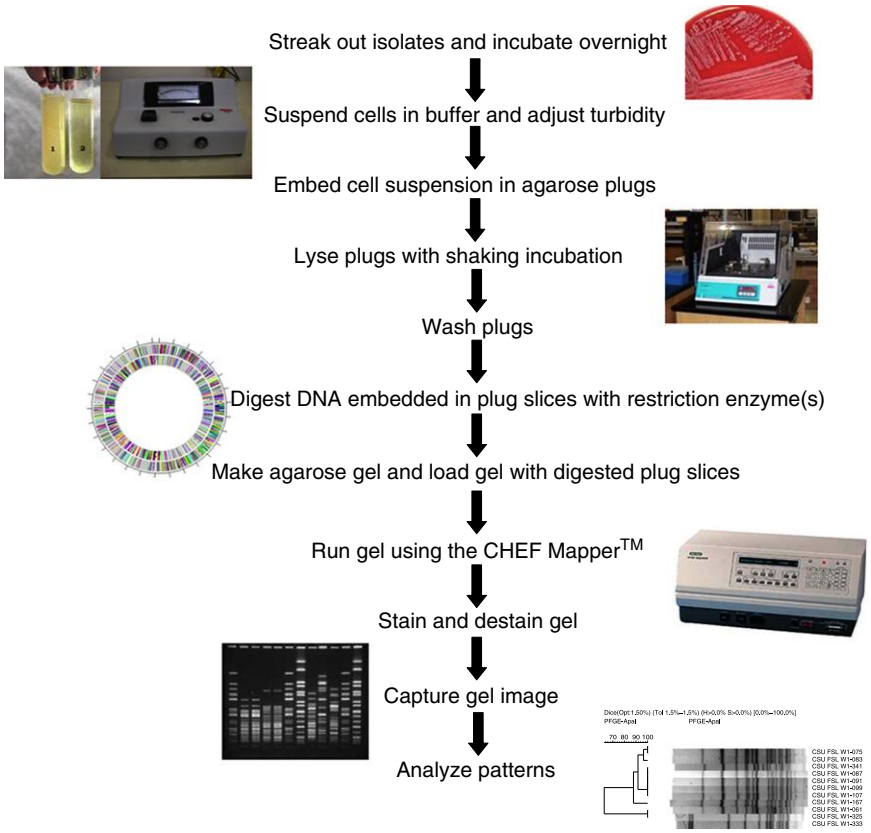

Figure 2 Pulsed field gel electrophoresis (PFGE).

then digested with a restriction enzyme known as a 'rare cutter.' Following digestion, a slice of the digested plug is loaded into an agarose gel as in PCR; however, it is then separated using a unique electrophoresis apparatus called the contour-clamped homogeneous electric field electrophoresis system. This system, unlike post-PCR gel electrophoresis, uses 24 electrodes evenly spaced in a hexagonal arrangement. This electrophoresis system produces uniform and homogeneous electric fields across the gel by constantly alternating current at 120° angles, moving the large DNA segments evenly through the gel and eliminating distorted bands at the bottom of the lanes (Figure 2).

PFGE is the current 'gold standard' subtyping method used to deposit molecular subtyping data into the PulseNet system. PulseNet is a national surveillance program, which was created by the CDC in collaboration with the Association of Public Health Laboratories (APHL), to provide scientists at public health laboratories with access to a searchable electronic database of PFGE patterns in order to facilitate real-time comparison of bacterial PFGE patterns isolated from cases of foodborne illness throughout the country. The CDC, along with state public health laboratories, PulseNet, US Food and Drug Administration, and the United States Department of Agriculture-Food Safety and Inspection Services employ PFGE to identify epidemiologically and genetically related isolates associated with clinical cases during outbreaks of foodborne illness. Since 1996, PulseNet has been imperative in detection, investigation, and control of numerous outbreaks caused by STEC O157:H7, *L. monocytogenes*, and *Salmonella*.

Ribotyping

Ribotyping is a molecular subtyping method that analyzes genetic components that code for rRNA (i.e., 5 S, 16 S, and 23 S rRNA). rRNA genes or rDNA are located throughout the chromosome, making ribotyping an effective approach to probe genetic diversity throughout the genome. rRNA genes are housekeeping genes that are needed for proteins synthesis and are thus pertinent for cell survival. As rRNA, along with other housekeeping genes, diversifies slowly, analysis of rRNA genes, therefore, provides a stable target for assigning molecular subtypes. Briefly, ribotyping is performed by lysing the bacterial cell and releasing total bacterial DNA. This is subsequently followed by digestion with a 'frequent cutter' restriction enzyme. The digested DNA is then electrophoresed to separate DNA fragments by size, and DNA fragments are then captured and immobilized on a nylon membrane. Once on the membrane, hybridization of the DNA with a chemically labeled rRNA operon probe occurs. After the DNA fragments and the rRNA operon probes hybridize, the membrane is washed and a chemiluminescent substrate is added to allow the bands containing rRNA to be visualized. Banding pattern data are then normalized against a molecular marker and similarity analysis is used to classify isolates into a ribotype on the basis of an existing database.

With the exception of cell lysis, ribotyping may be fully automated if performed using the Riboprinter® System (DuPont Qualicon), and thus requires minimal labor. The development of fully automated ribotyping systems improved the repeatability and reproducibility of interlaboratory

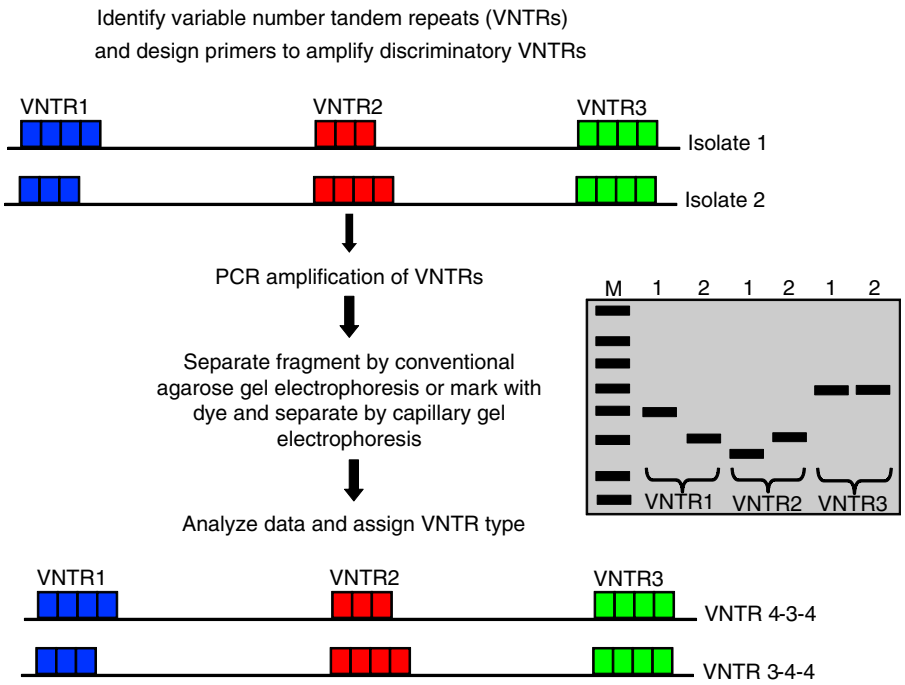

Figure 3 Multiple-locus variable-number tandem repeat analysis (MLVA).

ribotyping. The RiboPrinter® includes a database of bacterial ribotype patterns that includes more than 5700 patterns encompassing more than 180 genera and 1200 species. Ribotyping has most commonly been used to trace the spread of particular bacterial pathogens, especially *L. monocytogenes*, from farm to fork. Most importantly, it has been used for pathogen tracking during meat processing to help to identify harborage sites and routes of transmission.

DNA Sequence-Based Subtyping

Multilocus sequence typing

Multilocus sequence typing (MLST) is a nucleotide-based approach to subtyping bacterial foodborne pathogens. The MLST method is based on sequence variability within a set of five to seven genes or gene fragments, which typically focuses on housekeeping genes. In the MLST method, internal fragments ranging from approximately 400–600 bp in size (from particular genes such as virulence or housekeeping genes) are amplified and subsequently sequenced to determine the allelic and MLST types for each isolate. Once sequence data for all genes are ascertained, each gene is assigned a numerical allelic profile and is compared with other strains to determine genetic relatedness by nucleotide base changes rather than DNA fragment size.

Housekeeping genes, which are most commonly chosen genes to type, are not as subject to selective forces. Diversification occurs slowly within housekeeping genes by the accumulation of neutral variations and consequently highly conserving these genes within a species. If accumulation of genetic variation occurs rapidly (i.e., as in other genes, such as virulence genes), there is difficulty in distinguishing whether its descendants came from a common ancestor. Therefore, studying evolutionary questions using MLST data from housekeeping gene data provides more reliable information about the relationship between strains.

Multiple-locus variable-number tandem repeat analysis

Multiple-locus variable-number tandem repeat analysis (MLVA) methods are novel subtyping methods that have been designed by data gathered from genomic sequencing projects. The most recent analysis of multiple prokaryotic genomes revealed a high percentage of DNA that consists of multiple copies of repeat sequences, which are termed variable number of tandem repeats (VNTRs). The repeat regions can either be clustered in one specific area in the genome or be dispersed throughout the genome and are ideal for genomic events, such as DNA polymerase slippage and recombination. Recently, a number of studies have looked into the use of these VTNRs as a way to subtype bacterial strains. For very clonal organisms, such as *E. coli* O157, MLVA has been proven to be an appropriate way to address the minimal genetic diversity of such highly homogeneous species. The MLVA method uses these DNA elements repeated in tandem within bacterial chromosomes to base the observation that individual strains often carry the same elements with different copy numbers. Multiplex PCR primers are utilized to amplify regions of the genome that contain the VNTRs, and the repeat unit is subsequently assessed on agarose gels, or more frequently by separation of labeled amplicons using capillary electrophoresis. The resulting repeat size defines the repeat copy number; therefore, the allele type for each locus, ultimately designating an MLVA type (Figure 3).

Single-nucleotide polymorphism genotyping

With the increasing number of prokaryotic genomes that have been fully or partially sequenced, single-nucleotide polymorphism (SNP) genotyping is a recent development in

subtyping of bacterial pathogens. An SNP is a change in a single nucleotide (A, T, C, or G) in one sequence relative to another. As bacteria evolve, genetic divergence occurs through nucleotide substitutions, insertion, or deletion of genetic sequences, horizontal gene transfer, and recombination. The past decade has experienced an increased demand for high-throughput DNA analysis and SNP genotyping to detect genetic markers correlated with an important phenotype. SNPs can be detected using a multitude of methods and chemistries that enable allelic discrimination. The majority of SNP genotyping assays can be classified into one of four groups based on molecular mechanisms: (1) allele-specific hybridization, (2) primer extension, (3) oligonucleotide ligation, and (4) invasive cleavage.

Indicator Organisms in Meat

DW Schaffner, Rutgers University, New Brunswick, NJ, USA
S Smith-Simpson, Nestle Nutrition, Fremont, MI, USA

Glossary

Hazard analysis and critical control point (HACCP) A comprehensive system designed to manage and insure food safety.

Indicator organism An organism to be considered of optimal use in identifying potential hazards.

Most probable number (MPN) A microbiological sampling technique designed to convert a series of yes/no results from test tubes containing samples at different dilutions into a quantitative assessment of the number of organisms present.

National Shellfish Sanitation Program (NSSP) A program administered by the US Food and Drug Administration that works together with the US state government officials and the regulated industry to assure the safety of clams, oysters, and mussels.

Salmonella A foodborne pathogen. Indicator organisms are used to indicate the presence of pathogens like *Salmonella*.

Introduction

This article will provide a brief overview of the historical development of indicator organisms, reasons for using indicators, and the qualities of an acceptable indicator. The benefits and limitations of indicators to detect hazardous contamination of raw materials, assess the adequacy of processing treatments to reduce or eliminate dangerous pathogens, and evaluate the recontamination of meat products will be discussed. Finally, this article will conclude with a brief discussion of the use of indicator organisms within hazard analysis and critical control (HACCP) and regulatory systems.

Historical Perspective

To understand the current application of indicators in meat systems it is desirable to understand their earliest use in food safety. The concept of indicator organisms had its beginnings in the early history and development of shellfish sanitation. As early as 1603, oysters and other shellfish were being implicated as the vehicle for typhoid fever and other enteric diseases, but it was not until the late nineteenth century that many European scientists began routinely collecting bacteriological and epidemiological data to confirm the correlation. By 1879, it was widely accepted by European health officials that 'typhoid bacillus' (now known as *Salmonella typhi*) was present in raw sewage. If this sewage was dumped into shellfish beds, *Salmonella* could subsequently contaminate those oysters and thus cause typhoid fever in individuals consuming shellfish from those beds. Between 1904 and 1909, 124 of 855 typhoid cases in Birmingham, England implicated mussels as the source of infection. Bacterial examination of mussels in the Birmingham Markets over the course of a year found a correlation between the quantity of microorganisms and the purity of the mussel harvest sites. This, in turn, led to the development of a classification system that was based on (1) the total number of microorganisms, (2) the number of *Bacillus* spores, (3) the number of glucose-fermenting organisms, and (4) the number of *Streptococci* detected in mussels and harvest beds.

Concurrent to European activities, consumption of shellfish in the US was also high, interest in sanitation was low, and the number of typhoid fever outbreaks was rising steadily. A well-documented typhoid fever outbreak on a Connecticut college campus involving oysters led investigators to begin microbiological testing of shellfish in the US.

In the early 1900s, it was very difficult to compare results between laboratories as no standard microbiological methodologies had yet been developed. The American Public Health Association charged a committee to provide the industry with a system for scoring bacteriological results from the newly developed most probable number (MPN) technique on *Bacillus coli* (now *Escherichia coli*) in 1909; however, this committee was not prepared to give any sanitary significance to these MPN scores.

Investigations into controlling shellfish contamination continued periodically and the issue was finally given priority after outbreaks in Chicago, New York, and Washington, DC in 1924. One year later a committee appointed by the National Shellfish Sanitation Program (NSSP) recognized that *B. coli* was often being used as an indicator of pathogens from fecal origin, yet it was only 'roughly related to the presence of disease-causing germs.' The committee did agree, however, that the level of *B. coli* in fresh shellfish was a fair index of the cleanliness or contamination of the waters from which they originated. Subsequently, various guidelines based on the presence and levels of *B. coli* in water were developed and implemented at the state level.

The use of *B. coli* as an appropriate indicator of contamination was by no means unanimous. Total coliforms were judged by some to be the indicator of choice based on data collected on the fate of coliform bacteria within oysters. The New York State Conservation Department, for example, set acceptable limits using total coliform counts in clams. This standard was derived using an average ratio of pathogens to coliform density in drinking water supplies, the number of typhoid cases, and several other assumptions. The suitability of either standard is still an active topic of debate and the current NSSP guidelines allow a water quality standard based on either total or fecal coliform count for shellfish waters.

Objectives of Indicators

The main objective for any use of microbial indicator organisms is to assess the microbial quality of a food product. Indicators may also reveal flaws in process controls that could allow food to be contaminated or a pathogen to multiply to dangerous levels. A specific pathogen may not be present in the sample being tested, but the presence of indicator organisms is meant to suggest that pathogens have a reasonable likelihood of occurring in other samples of the same product. There are many types of organisms that may be used as indicators, and Figure 1 shows the relationships between such organisms.

Qualities of a Good Indicator Organism

For an organism to be considered of optimal use in identifying potential hazards it must fulfill many requirements. The source of the indicator organism should be known. If an organism is being used to indicate pathogens of fecal origin, it must be from a fecal source. Ideally, the indicator will always be present when the hazard is present.

The indicator organism should also behave in a physiologically similar manner to the pathogen of interest; inactivation and growth rates should be similar, as should their resistance to environmental conditions. If the indicator organism multiplies rapidly at the normal storage temperature of a meat product but the pathogen does not, indicator results will be skewed. Additionally, if the indicator organism is inactivated more quickly during processing than a pathogen, the utility of the indicator has been lowered. Ideally, a change in pathogen concentration should result in a concomitant increase or decrease in the corresponding indicator organism.

An indicator organism should be easy to culture and differentiate from any other microorganisms normally present in the meat product. There should be standard methods of detection for this organism and they should be simple, reliable, accurate, rapid, and widely accepted. If the tests are either more difficult or less accurate than those that test for the pathogen of concern, then little is gained. An optimal indicator organism will be present in the food at levels that can be correlated to the pathogen, yet will be absent from foods not contaminated with the hazard. Even though such a wish list is nice in principle, there is no single indicator organism capable of meeting all of these requirements. Although no single indicator has been shown to be a perfect surrogate, it has been suggested that if measurements are taken with sufficient frequency to detect changes in the distribution and level of these indicators, performance could be improved.

Common Uses of Indicator Organisms

Identification of Contaminated Raw Materials

The quality and safety of a finished meat product is highly dependent on the raw materials used. Indicator organisms are often used to assess quality and identify hazardous contamination of carcasses and raw meat products. Aerobic plate count (APC) can help to evaluate the impact of time–temperature history or slaughter sanitation conditions if these factors are unknown. If counts are very high or vary widely among samples from different lots or within the same lot,

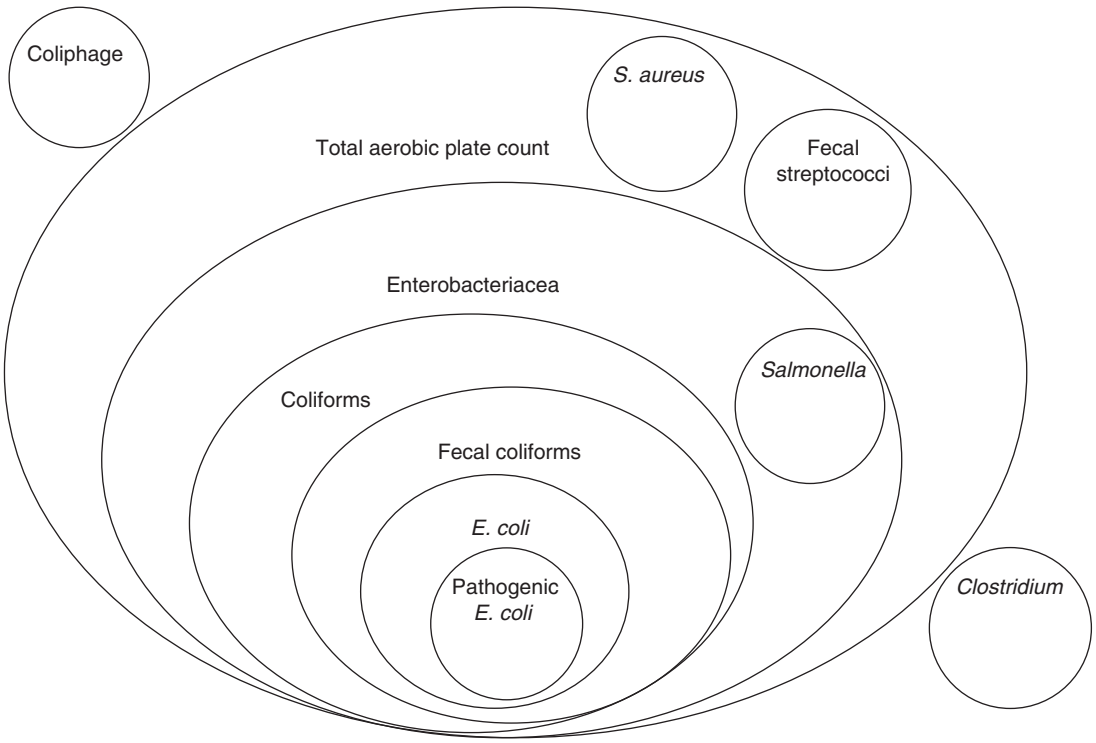

Figure 1 A Venn diagram showing the relationships between different groups of organisms used as indicator organisms.

inadequate microbiological control during processing or transport may be one explanation. Although APC has some utility, it is generally less accurate than other indictors in indicating the presence of pathogens in meats. Normal and spoilage microflora are typically included in the APC, and thus APC values are skewed when these counts are high.

Cross-contamination of meat with coliforms originating on hair, hooves, or hide during slaughter can be very common and has thus been responsible for their suggested use as an indicator of enteric pathogen contamination. Total coliforms include all aerobic and facultative anaerobic Gram-negative, nonspore-forming bacilli that have the ability to ferment lactose to acid and gas within 48 h at 35 °C. This group is classified according to biochemical reactions, not genetic relationships, and thus coliforms do not represent any specific taxonomic group. Organisms included in this group are *E. coli*, *Citrobacter freundii*, *Enterobacter aerogenes*, *Enterobacter cloacae*, and *Klebsiella pneumoniae*. Coliforms are relatively easy to detect yet classical methods are targeted at 'typical' organisms and sacrifice accuracy for speed. Coliforms inhabit both human and animal intestinal tracts and have been associated with both fecal and nonfecal matter. The overall levels of Enterobacteriaceae have been shown to be an accurate predictor of the absence of *Salmonella* in a beef carcass after slaughter, yet with many species of this organism found naturally in the environment, including meat processing plants, this indicator may not be as reliable as *E. coli*.

It is very difficult to avoid *E. coli* contamination of carcasses during slaughter due to the organism's close association with animals. *Escherichia coli* is considered the most prominent fecal coliform, and some believe it is the only indicator that should be used to suggest the presence of pathogens from fecal origin. A limitation to utilizing *E. coli* as an indicator of pathogens of fecal origin is the cost and complexity of *E. coli* testing compared with those of other methods. As with other indicators, the presence of *E. coli* does not guarantee that pathogens of fecal origin are present, nor does its absence ensure that contamination has been avoided. Additionally, seasonality effects should be considered when using *E. coli* as an indicator as significantly higher counts have been observed during summer months, impacting correlations to pathogenic targets. Although numerous studies have reported positive results measuring *E. coli* as an indicator of process controls, its use in isolation to measure cross-contamination events during slaughter is not advised.

A correlation between fecal streptococci and enteric pathogens in unprocessed, raw meats has also been suggested. The correlation has been shown to be much better than with meats that are heated, cured, frozen, or dried. Fecal streptococci (or Enterococci) are Gram-positive, catalase-negative cocci from selective media that grow on bile aesculin agar at 45 °C and are loosely referred to as fecal streptococci. These organisms are able to survive outside the intestines better than coliforms. Fecal streptococci include *Streptococcus faecalis*, *Streptococcus faecium*, *Streptococcus equinus*, *Streptococcus mitis*, *Streptococcus salivarius*, *Streptococcus avium*, and numerous *Enterococcus* spp. The correlation of fecal streptococci with enteric pathogens in meat products is still controversial. Fecal streptococci may be found in the intestinal tracts of humans and warm-blooded animals, on the hide, hair, hooves, and feathers of animals, and are also widespread in nature. Their universal presence may restrict their use as an indicator of pathogens of fecal origin. The presence of *Streptococcus bovis* and *S. equinus* indicates animal pollution possibly during slaughter, as neither is associated with humans.

Aeromonas has been investigated for use as an indicator of hygiene in a processing plant. Increasing numbers of *Aeromonas caviae* or *Aeromonas hydrophila* on processing equipment, such as dehairing machines, mesh gloves, and belts, could indicate inadequate sanitation. *Aeromonas* was also identified as a possible indicator for assessing carcass dressing procedures during swine slaughter.

The presence of spore-forming bacteria suggests the possible presence of *Clostridium perfringens*, *C. botulinum*, or *Bacillus cereus*, all of which have been associated with meat and meat-containing products. Spores present in raw meat have the ability to survive thermal processing and proliferate in finished meat products.

A high degree of correlation between fecal coliforms and F^{+}RNA coliphage counts has been seen while monitoring the microbiological quality of raw meat and poultry. Coliphages are viruses that infect *E. coli* bacteria. Because methodologies for concentrating and detecting coliphages are relatively simple and rapid, this new technology has shown promise as a future indicator of pathogens of fecal origin. Additional emerging technologies, including nucleic acids, biosensors, and nanotechnology, have been shown to provide rapid results with a low investment of resources by detecting multiple organisms or molecular markers concurrently.

Adequacy of Processes to Destroy Pathogens

APC is often used to test sanitation on a processing line during production. Ingredients may be sampled before or after addition to the product, or a complete product may be sampled before and after processing or during or after a period of delay. In addition, APC may be used to identify key steps involved in contamination during processing; APC will generally be low or at baseline levels before the processing step causing the problem, but will be significantly higher after contamination has occurred. Additionally, thermal processing will inactivate a high number of vegetative organisms present in raw materials, but some spore-forming pathogens are highly heat resistant and will probably survive most cooking operations. Most microorganisms found on meat are also very sensitive to drying and freezing and are thus less useful as indicator organisms for frozen or dried products. It may not be advisable to use APC as a microbial indicator in fermented meats because these products may have high APC from the starter cultures used in their manufacture. That being said, starter organism colonies do have a different appearance on agar plates, and thus experienced technicians may still be able to differentiate high counts due to contamination versus those due to the starter culture itself.

Another group utilized to indicate inadequate processing is the Enterobacterieae family. The Enterobacteriaceae have been classified as Gram-negative, glucose-fermenting, oxidase-negative, usually catalase-positive, and nitrate-reducing organisms. This includes not only many bacteria commonly associated with fecal

matter but also many nonfecal organisms. Common genera of this family include *Citrobacter*, *Enterobacter*, *Erwinia*, *Escherichia*, *Hafnia*, *Klebsiella*, *Proteus*, *Providencia*, *Salmonella*, *Serratia*, *Shigella*, and *Yersinia*. The detection of any member of the Enterobacteriaceae family present in a meat product has been used to imply the presence of enteric pathogens, but a direct correlation between Enterobacteriaceae presence and concentration and enteric pathogen presence and concentration is not assured. Enterobacterieae levels have been shown to be very similar to coliform concentrations, as there is a great deal of species overlap between these two groups. Enterobacterieae may also be used to evaluate hygiene and sanitation in processing plants, as they are readily inactivated by sanitizers and capable of colonizing a variety of niches when sanitation is inadequate. However, the presence or absence of high concentrations of these organisms cannot confirm the presence or absence of enteric pathogens.

Fecal coliforms, a subset of the total coliforms group, have the ability to multiply in hospitable environments, are destroyed by pasteurization and normal cooking, and are typically inactivated by freezing conditions, thus making them an indicator candidate for analysis of process controls. Fecal coliforms are defined as Gram-negative bacilli that ferment lactose within 48 h at 44.5–45.5 °C. Multiplication at higher temperatures often results in this group being referred to as 'thermo tolerant coliforms.' This group includes *E. coli*, *Enterobacter* spp., *K. pneumoniae*, and *C. freundii*. Testing for fecal coliforms arose from attempts to find rapid, dependable methods to detect *E. coli* without the need to isolate a pure culture. Fecal coliforms are generally specific to the intestinal environment of warm-blooded animals and thus high levels are found in fecal matter, but some organisms of nonfecal origin will occasionally test positive as fecal coliforms, and therefore care must always be taken in interpreting test results. Fecal coliforms are relatively easy and reliable to detect.

Escherichia coli have been shown to have similar rates of inactivation during thermal processing to enteric pathogens, including *Salmonella* spp., and thus have been suggested as indicators of process control. As new meat processing technologies (e.g., irradiation) are developed, care will need to be taken to insure that any difference in sensitivities is considered before determining the final suitability of *E. coli* as an indicator.

Fecal streptococci have been used as evaluators of frozen food plant sanitation due to their ability to survive freezing. They have also been used as indicators of adequate sanitation for their ability to resist inactivation by thermal processes, drying, detergents, and disinfectants. Yet use of organisms with increased resistance can lead to an indicator with undesirable stringency, as they outlast less durable pathogens, such as *Salmonella* and *Shigella*.

Identification of Recontamination of Processed Products

High numbers of coliforms may be representative of improper handling or storage of meat products, which allows for the multiplication of any coliforms present. High counts of coliforms on cooked meat products would indicate postprocessing contamination. High levels of Enterobacterieae can suggest postprocessing contamination or microbial proliferation due to inadequate storage conditions.

Staphylococcus aureus' association with human skin and oral–nasal cavities has prompted its use as an indication of inadequate employee sanitation and contamination due to handling. *Staphylococcus aureus* has also been suggested as an indicator to detect multiplication of bacteria during prolonged storage of processed meats without refrigeration.

Microbial Indicators and Hazard Analysis and Critical Control

HACCP plans are currently required in all meat and poultry plants within the US. The use of indicator organisms can offer assistance for establishing, monitoring, and verifying critical control points in HACCP operations. Indicators can best be used within an HACCP system to control processes that have the greatest influence on the level of microorganisms rather than to determine whether to accept or reject a given lot of product. When used for critical control point evaluation, a large number of samples can be progressively collected throughout a process. HACCP can use index organisms to assess the integrity of an evisceration procedure or thermal process by determining levels of indicator organisms before and after each process is completed. Indicator organisms can be used to establish upper limits for pathogen numbers, and thus actions should be implemented that strive to reduce indicator organism numbers to the lowest level possible. It is widely accepted that the regular monitoring of process controls in the meat industry must replace end-product testing.

Regulatory Issues

Current regulations require that meat and poultry processing plants test for generic *E. coli* within their HACCP plans to verify process controls. Testing for *Salmonella* spp. has been mandated to confirm that plants are controlling pathogens within meat plants. Slaughter plants are also required to sample carcasses for generic *E. coli* to verify the prevention and removal of fecal contamination from raw meat. Generic *E. coli* was chosen due to its suggested association with pathogens of fecal origin and the relative ease and low cost of enumeration. Although most global regulatory authorities do not require microbiological testing of raw meat products, for import into the US, processors must meet the United States Department of Agriculture regulations. Australia and New Zealand, which do require testing, were able to establish regulations for food quality and safety through government and industry collaboration.

Conclusions

None of the indicators mentioned above are obligate inhabitants of the intestinal tract of humans or warm-blooded animals. Environmental reservoirs for each have been identified. Many of the organisms mentioned here are commonly present in meat manufacturing facilities and may become part of the natural microflora. Because no one indicator can be

applicable for all pathogens or all situations, it has been suggested that several indicator organisms can be used for several different pathogens. Whatever decision is made regarding the use of indicator organisms in the meat processing plant, it should be made with the full knowledge of both the benefits and the limitations of the microbial indicators. No microbiological specification, no matter how perfect, should ever be used blindly or without common sense. Finally, a trained food microbiologist should be consulted when implementing or changing the use of microbial indicators in a food processing environment.

Glossary

CAMP A diagnostic test for *Listeria* based on production of factors that interact synergistically with *Staphylococcus aureus* β-lysin. It is named after researchers Christie, Atkins, and Munch–Petersen.
Enumeration Methods which determine the concentration of cells in a sample.
Pathogens Bacteria which produce toxins during growth on food that can cause foodborne illness if ingested.
Qualitative methods Methods of analysis which determine the presence or absence of the target organism in a sample.
Spoilage bacteria Bacteria which do not cause illness. Its metabolic activity during replication induces unacceptable sensory changes in a food.
Standard methods Defined as recognized methodologies that have been collaboratively studied and validated before acceptance.
Verotoxigenic *Escherichia coli* (VTEC) *Escherichia coli* which carry the genes for and produce the virulence factor verotoxin. The terms shiga toxin producing *E. coli* and enterohemorrhagic *E. coli* are synonymous. *Escherichia coli* O157:H7 is the most common serotype of VTEC in North America.

Introduction

Standard methods can be defined as recognized methodologies that have been collaboratively studied and validated before acceptance. In some instances they form the basis for official, regulatory control actions, whereas in others they may be used for quality control purposes. Some international agencies concerned with the development and assessment of microbiological sampling plans and methodologies for foods include the AOAC International (formerly known as the Association of Official Analytical Chemists), the International Commission on Microbiological Specifications for Food (ICMSF), the International Organization for Standardization (ISO), the Comité Européen du Normalization (CEN), and the Nordic Committee on Food Analysis (NMKL). Regulatory authorities may publish their own official methods (US Department of Agriculture Food Safety Inspection Service, *Microbiology Laboratory Guidebook*; US Food and Drug Administration, *Bacteriological Analytical Manual*; and Health Canada, *The Compendium of Analytical Methods*) or make use of methods published by international agencies; for example, ISO methods are required by the European Union for regulatory testing for pathogens on fresh meats.

Although standard methods for determining pathogens and indicator bacteria in meats are based on the same general principles, they are highly variable and are continually being modified to suit the needs of the agency and meat product in question. There are no standard methods for the recovery and enumeration of meat-borne spoilage bacteria. Thus, there are no truly international standard methods that are universally applied to characterize and enumerate bacteria contaminating meats.

In view of this, the objective of this chapter is to provide a concise reference of verified cultural and biochemical procedures that will enable the selection of reliable methods for the recovery, detection, and enumeration of the most potent meat spoilage bacteria and relevant human pathogens.

Types of Culture Media

Media can be formulated to be nutritionally complete (general purpose) or can be selective, differential, or elective. Nutritionally complete media would favor the unrestricted growth of most meat-borne genera and enable the recovery of the largest population of bacteria. Unfortunately, bacterial types cannot be distinguished on these media and additional cultural and biochemical tests must be undertaken to confirm the identity of selected colonies. The random selection and characterization of 30 colonies from countable plates gives a good estimate of bacterial composition.

Selective media contain restrictive antimicrobial substances that, in combination with incubation conditions, allow the growth of a specific group of microorganisms while suppressing others (Tables 2 and 4). Unfortunately, these selective agents can reduce the recovery of targeted strains (particularly sublethally injured cells), their selectivity is not absolute, and further characterization of the isolates may be warranted.

Differential media contain substrates or reagents that allow the differentiation of colonies on the plate. This can be due to a change in the appearance of the colonies themselves or to a change in the medium surrounding the colonies.

Media of value in improving the recovery of lactic acid bacteria (LAB), for example, from meats have been termed elective. These media satisfy the complex nutritional requirements of these bacteria, but they are not selective or differential.

Spoilage Bacteria

Characteristics

The biochemical and cultural characteristics of bacteria most commonly associated with meat spoilage, including the

characteristic spoilage defects, are depicted in Table 1. It is evident that a few simple tests can be utilized to differentiate the major spoilage flora; the most important of those include the Gram reaction, motility, oxygen requirements, catalase activity, oxidase activity, and glucose metabolism. Bacterial metabolism of arginine to produce alkaline by-products has also been suggested as a means to distinguish bacteria, but test results are highly variable and may not be a reliable tool.

Sample Preparation

Processing of meat samples is generally conducted by homogenization and dilution using 0.1% (w/v) peptone water. Diluted samples can be stored in this diluent for up to 2 h at room temperature or 6 h at 2 °C without appreciable change in bacterial numbers.

Common plating methods to recover and enumerate spoilage bacteria include pour plate, spread plate, spiral plate, and hydrophobic grid membrane filtration (HGMF). The pour plate method is usually performed by pipetting 1.0 ml of a sample dilution into a sterile Petri dish, followed by the addition of molten agar tempered to 45 °C and gentle mixing to distribute the cells. The spread plate technique utilizes Petri plates of solidified, predried agar media, which are inoculated by pipetting 0.1 ml of sample dilution onto the surface and then spreading using a sterile L-shaped glass or plastic rod to ensure an even distribution. Spiral plating is a semiautomated variation of spread plating in which a machine uses a stylus to deposit a volume of sample dilution on the surface of agar media. The sample dilution is deposited at a constant rate as the stylus moves from the center of the agar plate to the rim, resulting in a decreasing concentration of deposited sample; this permits a 2–3 log range of cell concentration to be enumerated on a single plate. The HGMF method usually involves the filtration of up to 10 ml of sample dilution through a 0.45 μm membrane filter (ISO-GRID, QA Life Sciences Inc., San Diego, CA, USA), after which the filter is placed on the surface of predried agar plates containing a suitable indicator dye. Treatment with enzymes and surfactants are often necessary to clarify meat suspensions before filtration. The HGMF method gives most probable number (MPN) results.

Sampling, diluting, and plating methods (pour and spread plate) that have a lower limit of sensitivity of 10–100 bacteria per unit volume, area, or weight are usually more than adequate for enumerating the prevailing flora in a spoiled meat product. If one is more concerned with the precise composition of the spoilage bacteria initially contaminating meats when numbers are expected to be low, it may be necessary to employ HGMF, which will facilitate detection of one bacterium per unit volume, area, or weight.

Media for Enumeration of Spoilage Bacteria

With knowledge of the type and history of the meat product and the spoilage symptoms, it is possible to select appropriate media to recover the targeted organism. Table 2 summarizes the performance of some of the more useful media for the recovery and enumeration of the dominant spoilage bacteria from meats.

An alternative to these direct plating procedures is HGMF methods. The ISO-GRID counting range is such that less sample dilutions are required and the lower limit of detection is less than that of conventional plating procedures. HGMF methods have been used to determine total psychrotrophs, *Pseudomonas* spp., *Brochothrix thermisphacta*, *Enterobacteriaceae*, and LAB from raw, chilled beef (Table 3) and counts were not different from those determined by conventional agar plating methods.

Aerobic and psychrotrophic plate count

An acceptable procedure for total plate counts is the spread plating of appropriate dilutions on plate count agar (PCA)

Table 2 Performance of selective media for enumerating meat spoilage bacteria

Media and incubation	*PCA aerobic 25 °C, 2 d*	*TSA aerobic 25 °C, 2 d*	*CFC aerobic 25 °C, 2 d*	*PI agar aerobic 25 °C, 2 d*	*STAA aerobic 25 °C, 3 d*	*VRBGA aerobic, 35 °C, 24 h*	*MRS anaerobic 25 °C, 2 d*	*Rogosa agar anaerobic 25 °C, 4 d*	*PIA aerobic 25 °C, 3 d*

[b] O indicates a light orange pigmentation of the colonies.

[c] B indicates blackening of the colony and surrounding medium.

Abbreviations: CFC, cephaloridine–fucidin–cetrimide agar; d, day; h, hour; MRS, deMan, Rogosa, and Sharpe agar; PCA, plate count agar; PI, Pseudomonas isolation agar; STAA, streptomycin-thallous acetate-actidione agar; TSA, tryptic soy agar; VRBGA, violet red bile glucose agar. All inoculations made from broth cultures by surface plating except that pour plate was used for VRBGA and PIA.

Table 3 Media for the recovery and enumeration of meat spoilage bacteria using HGMF

Bacteria	*Medium*[a]	*Appearance of colonies*
Total psychrotrophs	Plate count agar (PCA) + 0.25 g l^{-1} fast green (7 °C, 10 d)	Yellow/green
	PCA (7 °C, 10 d) + 0.1% triphenyltetrazolium chloride postincubation	Dark red
Pseudomonas spp.	Cephaloridine–fucidin–cetrimide agar + 0.25 g l^{-1} fast green (25 °C, 2 d)	Dark green/blue
Brochothrix thermosphacta	Streptomycin–inositol–neutral red agar (25 °C, 3 d)	Pink/red
Enterobacteriaceae	Violet red bile glucose agar (no overlay) 35 °C, 18–24 h, anaerobic)	Red
Lactic acid bacteria	Tryptone–phytone–yeast extract agar + 0.2 g l^{-1} erioglaucine (25 °C, 4 d, anaerobic)	Light green/pale blue

[a] The performance of these media was not different from that of traditional plate count methods using naturally contaminated or inoculated beef steaks. d, day; h, hour.

followed by incubation at 25 °C for 48 h. Tryptic soy agar (TSA) is a suitable alternative and produces counts of a similar magnitude.

Recommended methods for enumeration of total psychrotrophs are PCA with incubation at 5–7 °C for 7–10 days. If a total anaerobic plate count is required, PCA can be incubated in the absence of oxygen and in an environment containing 4–10% CO_2 (v/v). This can readily be achieved by utilizing anaerobic jars and commercially available disposable gas generators that remove oxygen and generate an atmosphere of 4–10% CO_2.

HGMF can be used for total counts by incorporating 0.25 g l^{-1} fast green in the PCA or TSA (Table 3). Colonies developing on this medium are yellow/green. A more tedious approach is to place the membrane filter on TSA and flood the plate with 1% triphenyltetrazolium chloride after incubation by introducing 2 ml of it under the filter to visualize and enumerate the red colonies.

Indicator bacteria

Both *Escherichia coli* and total Enterobacteriaceae counts have been proposed as indicators of hygiene and safety; they can be enumerated by direct plating procedures or using HGMF (Tables 2 and 3) and there are proposed standard methods (ISO and AOAC).

Pseudomonads

The most common meat spoilage pseudomonads are *Pseudomonas fragi* and *Pseudomonas fluorescens*. Cephaloridine–fucidin–cetrimide agar (CFC) is a selective medium routinely used to recover and enumerate spoilage pseudomonads from meats. The sample dilutions are spread plated and the medium is incubated aerobically at 25 °C for 2 days. Colonies developing on this medium are cream colored and are 2–5 mm in diameter. Although *Serratia liquefaciens* grows on CFC, it can be differentiated from the oxidase-positive pseudomonads using the oxidase reagent (1% w/v tetramethyl-*p*-phenylene-diamine hydrochloride). Also, CFC can be modified to differentiate pseudomonads from enterics by the addition of 1% (w/v) arginine and 0.002% (w/v) phenol red. The metabolism of arginine by the pseudomonads produces pink colonies.

HGMF methods can readily be applied by incorporating 0.25 g l^{-1} fast green into the CFC medium. Pseudomonad colonies are dull green/blue on the membrane filter (Table 3).

Brochothrix thermosphacta

The medium formulated for the selective enumeration of *Brochothrix thermosphacta*, streptomycin-thallous acetate-actidione agar (STAA), is highly selective and usually excludes all other members of the spoilage flora in meats, with the rare exception of some pseudomonads. Although *Xanthomonas campestris* grows on STAA, it would not be expected to contaminate meats.

Sample dilutions are spread on STAA and after aerobic incubation at 25 °C for 3 days, *B. thermosphacta* colonies are typically pale straw colored and approximately 1–2 mm in diameter.

To enable the use of HGMF for enumeration of *B. thermosphacta*, streptomycin–inositol–neutral red agar has been used. *B. thermosphacta* ferments inositol, giving rise to pink/red colonies on the membrane filter (Table 3).

Enterobacteriaceae

Members of the Enterobacteriaceae of importance to meat spoilage include *Hafnia alvei*, *Enterobacter agglomerans*, and *S. liquefaciens*. The traditional procedure for total Enterobacteriaceae counts for meats utilizes violet red bile glucose agar (VRBGA) and the pour plate technique. Solidified plates are then overlaid with approximately 5.0 ml VRBGA and incubated at 35 °C for 18–24 h. Purple/red colonies, 1–2 mm in diameter and surrounded by a reddish halo of precipitated bile, are presumptive enterics.

The short incubation time, the overlay, and the mesophilic incubation conditions enhance the selectivity of the procedure and limit the growth of other Gram-negative organisms (aeromonads and pseudomonads) that might give false positive results on this medium. The oxidase test can be used to assist in differentiating the oxidase-negative Enterobacteriaceae.

Total psychrotrophic Enterobacteriaceae are estimated following incubation of VRBGA at 4 °C for 10 days, but there is an increased risk of the proliferation of nonenterics under these conditions and some have suggested that enumeration of all visible colonies provides an estimate of the total Gram-negative counts.

The VRBGA medium can also be utilized with the HGMF method. After filtration of the diluted meat homogenate, the membrane filter is placed on a plate of VRBGA and incubated anaerobically in an atmosphere of CO_2 at 35 °C for 18–24 h. Enterobacteriaceae produce red colonies on the membrane filter.

Lactic acid bacteria

Members of the genera *Lactobacillus*, *Leuconostoc*, and *Carnobacterium* are the important spoilage LAB in meats.

The medium of choice for estimating LAB bacterial numbers in meats is the medium of deMan, Rogosa, and Sharpe (MRS). This medium contains acetate, which may restrict the growth of carnobacteria, but these bacteria can be selectively recovered from meats using cresol red–thallium acetate–inulin agar.

An acceptable method for recovering the largest population of LAB from meats is the anaerobic incubation of MRS agar at 25 °C for 4 days (spread plate) in an atmosphere containing CO_2. LAB colonies are small (1–2 mm) and characteristically white or cream colored. As evident from Table 2, most other members of the spoilage flora proliferate on this nonselective medium and a simple catalase test readily differentiates the catalase-negative LAB from other bacteria on the plates.

Rogosa agar and acetate agar have also been utilized to recover LAB from meats. These media have the selective pressure of both high acetate content and a lower pH (5.5), which favors the growth of meat-borne lactobacilli.

There is an HGMF procedure that utilizes tryptone–phytone–yeast extract agar containing 0.2 g l^{-1} erioglaucine. After anaerobic incubation in CO_2 at 25 °C for 4 days, presumptive LAB are light green to pale blue on the membrane filter.

Shewanella putrefaciens

This bacterium produces large amounts of hydrogen sulfide and can cause green discoloration of meat with a pH of 6.0 or greater. When this type of spoilage is evident, diluted samples are plated using peptone-iron agar (PIA) by the pour plate technique and the solidified medium is overlaid with approximately 5 ml of PIA. Incubation is done at 25 °C for 3 days. Colonies producing hydrogen sulfide are 1–2 mm in diameter and gray-black in color; in some instances the surrounding medium is blackened.

Because this medium is a nonselective, differential medium and other bacteria can produce hydrogen sulfide, it is necessary to select colonies for confirmation using cultural and biochemical criteria.

Meat-Borne Pathogens

In contrast to spoilage bacteria, pathogens are usually present in low numbers (i.e., less than one per gram or per 100 cm^2). Most pathogens associated with meat and meat products are mesophiles whose growth is restricted at refrigeration temperatures but are capable of surviving throughout the product's shelf life. Even with growth inhibited it is not possible to establish safe levels of exposure for some pathogens (e.g., verotoxin-producing *E. coli* and *Salmonella)* as the estimated infectious dose may be as low as 10 cells. Consequently, pathogen detection commonly uses qualitative methods, which include an enrichment step and determine the prevalence of the pathogen.

Although several pathogenic bacteria are found on meats, only six types are commonly associated with illness. *Salmonella* spp., pathogenic *E. coli*, and *Campylobacter jejuni/coli* are of most relevance to raw, chilled meats, whereas *Clostridium perfringens*, *Listeria monocytogenes*, and *Staphylococcus aureus* are of more importance to the safety of processed and ready-to-eat meats.

Pigs are an important reservoir for *Yersinia enterocolitica*. *Yersinia* can replicate on chilled meat at temperatures as low as −1 °C and is frequently recovered from pork-processing environments and pork tissues. Although outbreaks of meat-borne illness attributable to *Y. enterocolitica* are rare, some consideration is given to it, as it has the potential to emerge as an important pathogen.

Conventional procedures for determining both the prevalence and numbers of these bacteria are reviewed.

Bacterial Prevalence

Qualitative methods may be used to determine the prevalence of pathogens and have four stages: enrichment, screening, isolation, and confirmation (Table 5).

Enrichment

Enrichment is an initial culture step, with the aim of amplifying the concentration of the pathogen. The food sample is enriched by suspension in a liquid medium and incubation at a temperature permissive for growth. Enrichment simultaneously resolves a number of challenges in the bacteriological analysis of foods in that it converts solid samples to an aqueous suspension, raises the concentration of the target organism, and homogenizes distribution. This ensures that the success of screening and isolation is not dependent on the probability that aliquots of the sample suspension contain the target pathogen.

If pathogens have been exposed to environmental stress (heating, freezing, and pH) the cells may be injured and demonstrate an extended lag phase or be unable to replicate in the presence of selective agents or conditions. To improve the recovery of injured cells, enrichment may begin with a period of resuscitation, under relatively unrestrictive growth conditions (Table 5). Enrichment in nonselective media amplifies microflora indiscriminately, which may interfere with screening for the target or its isolation. To reduce nontarget microflora the enrichment can continue with increasing selectivity by the addition of selective agents or the transfer of an aliquot to a more selective media. In some protocols, to increase the probability of successful detection, the enrichment may be conducted in parallel in media with differing selective characteristics.

Screening

Following enrichment, analysis may proceed directly to isolation, or the enrichment broth may be screened for the presence of the pathogen. Screening tests commonly use serological methods or polymerase chain reaction (PCR) to determine the presence of molecules or gene sequences associated with the pathogen. The purpose for screening enrichment broths is not detection of the target organism, as the enrichment broth contains a mixed population of organisms and there is a potential for false positive results, which need to be eliminated by isolation and confirmation. Instead, the purpose of screening tests is to reduce the number of samples that need to proceed to isolation, by identifying which samples are negative for the pathogen. Screening tests for the major pathogens associated with meat are commonly available commercially in a kit format.

Isolation

The purpose of isolation is to establish a pure colony of the target pathogen, separating it from other microflora that can interfere with analysis or the interpretation of results. Isolation is conducted by plating an aliquot of the enrichment broth onto agar media. The agar media ideally have selective and differential characteristics which aid the analyst in identification of target colonies. As with enrichment, multiple media may be used for isolation to increase the probability of success. Isolation is completed by the establishment of pure subculture on nonselective media.

To reduce the amount of nontarget cells transferred to the agar media from the enrichment broth, immunomagnetic separation (IMS) may be used. In IMS, cells bearing a target surface antigen are bound to magnetic beads conjugated with an antibody to the anitgen. The magnetic beads are then recovered from the enrichment broth with a magnet and repeatedly washed to remove cells that are not bound to the antibody. The washed IMS beads are then plated onto agar media. IMS beads are commercially available for *Listeria* spp., *Salmonella* spp., and a variety of *E. coli* O types associated with verotoxin production (O157, O26, O45, O103, O111, O121, and O145).

Confirmation

Once multiple presumptive isolates of the pathogen have been subcultured, a series of tests are conducted to verify the identity of the pathogen on the basis of species and the presence of virulence or virulence-associated characteristics. Individual confirmatory tests may be biochemical, serological, or molecular tests for species and virulence-associated traits. As with screening tests, some confirmatory tests for major pathogens are available in kit format.

Enumeration

Direct plating

For some pathogenic bacteria, direct plating may be a suitable alternative to enrichment procedures and provides an estimate of numbers. Direct plating is applicable only if the numbers of the pathogen are high enough (>100 CFU g^{-1}).

If cells are injured, a resuscitation step may be required. This can be achieved by agar overlay or membrane filter plating. In agar overlay the sample diluent is spread plated onto a nonselective agar media, which is then incubated for a period sufficient for growth to occur, but before visible colonies form (4–6 h), the agar plate is then overlain with a layer of molten selective agar at 45 °C. The second agar layer is allowed to gel and then incubation is continued. Alternately, if samples are spread onto the surface of a membrane filter or the sample is filtered through membrane filters, the filters may be first incubated on nonselective media and then transferred to the surface of a selective agar medium for continued incubation.

Most probable number determination

The determination of the MPN of pathogens in a meat sample utilizes the advantages of both enrichment and enumeration and allows very low concentrations of cells to be enumerated. Known weights of sample are introduced into replicate tubes (commonly 3–10) containing enrichment broth and additional 10-fold dilutions of the sample and replicate tubes are prepared. For example, if 1 g of meat is introduced into the first set of five tubes, 0.1 g would be put in the second set of five tubes and 0.01 g in the third set of five tubes. Tubes are incubated and observed for growth or a particular metabolic characteristic and scored as positive or negative. The specificity of an MPN analysis can be increased

by plating broth from tubes onto an appropriate agar medium and confirming the identity of the resulting colonies. The concentration of cells in the original sample is estimated statistically with the assistance of MPN tables or computer applications, a variety of which are available from online resources.

Hydrophobic grid membrane filtration

As with direct plating onto membrane filters, HGMF can be used to both resuscitate and enumerate pathogens. Media have been designed to have the potential to detect and enumerate *Salmonella* spp., *S. aureus*, *Listeria* spp., and *E. coli* O157:H7 (Table 6).

Considerations for Specific Pathogens

Campylobacter spp.

In most meat samples, except possibly for raw poultry, numbers of *Campylobacter* spp. can be expected to be low. *Campylobacter* spp. are microaerophilic and capnophilic. They can lose viability under atmospheric oxygen concentrations and so must be cultured in an environment with 5% oxygen, 10% carbon dioxide, and 85% nitrogen. The optimum growth temperature for *Campylobacter* spp. is 42–43 °C. Enrichment and plating media are composed of a nutritious medium containing laked or lysed horse or sheep blood or charcoal with selective agents (Table 4). If cells of young colonies are observed microscopically, they will appear as small, thin, and curved rods with corkscrew motility. Latex agglutination tests and enzyme-linked fluorescent assays can be used to confirm the identity of *Campylobacter* spp.

Clostridium perfringens

Clostridium perfringens can frequently be encountered in raw and cooked meats. It must be present in high numbers to cause illness and in the event of a food-borne illness outbreak attributable to *C. perfringens*, direct plating is usually appropriate. Sulfite-cycloserine agar without egg yolk, prepared by the pour plate method, is the preferred isolation medium (Table 6) and *C. perfringens* metabolizes sodium metabisulfite and ferric ammonium sulfate to form black colonies. For examination of lecithinase activity, some isolation media include egg yolk.

Alternative plating media include horse blood agar with neomycin, but neomycin is likely to inhibit some strains.

If cells are expected to be stressed, *Bacillus cereus–C. perfringens* broth (BCP) containing catalase, hydrogen peroxide degraders, and fresh egg yolk is effective for cell recovery before plating. If an MPN analysis is needed, iron milk medium incubated for up to 18 h at 45 °C is recommended. *Clostridium perfringens* causes a 'stormy fermentation' from the production of acid from lactose and fractionation of the curd. Motility and the ability to reduce nitrate, to ferment lactose, and to liquefy gelatin are characteristics used to confirm *C. perfringens*.

Escherichia coli O157:H7 and Nonmotile O157 Strains

Escherichia coli O157:H7 and nonmotile O157 strains can be isolated with relative ease in the presence of other *E. coli*, as they normally do not ferment sorbitol and lack β-glucuronidase activity. A variety of differential agar media based on these traits are commercially available. Selectivity can be imparted to enrichment and isolation media by the use of the antimicrobials novobiocin, tellurite, and cefixime, to which *E. coli* O157 strains commonly display superior resistance.

Large sample sizes have become established for the detection of *E. coli* O157 in some beef products. The USDA-FSIS requires a sample size of 325 g (or 5 × 65 g) for ground beef or ground beef precursor material. The sample is enriched and then screened for potential *E. coli* O157 by PCR or lateral flow device (Table 5). Isolation is performed using IMS beads conjugated with anti-O157 antibodies and plating onto selective/differential agar. Confirmation of presumptive positive samples would include latex agglutination, hemolysis on blood agar plates, and biochemical, serological, and molecular confirmation, including expression of verotoxin and the O157 antigen.

Verotoxin-Producing *Escherichia coli*

Escherichia coli O157:H7 is one serotype of a group of *E. coli* pathogens known as verotoxin-producing *E. coli* (VTEC) or shiga toxin-producing *E. coli* (STEC). These other VTEC serotypes are increasingly recognized as an important cause of food-borne disease and standard methods for their detection have been established. Analysis for VTEC in the presence of other *E. coli* is challenging because, unlike *E. coli* O157, they have no shared physiological characteristics on which selective or differential culture media can be based.

Standard methods for a limited range O-serogroups, associated with higher public health risk (US, O26, O45, O103, O111, O121, O145; EU, O26, O103, O111, and O145), are published. These methods use enrichment and isolation media that are permissive for *E. coli* growth. Enrichment broths are screened by PCR for verotoxin (*stx*) and O-group genes; some protocols test for additional virulence factors, such as the intimin (*eae*). In an attempt to increase selectivity in isolation, IMS for target serogroups is used, but large numbers of colonies of diverse morphology must still be tested.

Other Pathogenic *Escherichia coli*

No cultural methods provide enrichment specific for pathogenic types of *E. coli*, nor are there any bacteriological media that allow their differentiation from nonpathogenic strains. Individual colonies are examined for virulence factors using molecular approaches. In meat samples, numbers of pathogenic strains are usually low and numerous colonies must be examined, with little chance of recovering a pathogenic strain. An example of a pre-enrichment and enrichment protocol is shown in Table 5. Typical colonies are selected for further characterization. If large numbers of *E. coli* are expected, surface plating may be appropriate (Table 6).

Table 4 Examples of selective and diagnostics agents used for the recovery and differentiation of pathogenic bacteria

Enrichment		*Plating*			*Appearance of colonies*
Medium	*Selective agents*	*Medium*	*Selective agents*	*Differential agents*	
Campylobacter spp.					
Bolton broth	Cefoperazone, vancomycin, trimethoprim, and cycloheximide	*Campylobacter* medium with charcoal	Cefoperazone and amphotericin B	NA[a]	NA[a]
Listeria spp.					
Listeria enrichment broth (UVM-1)	Acriflavin and nalidixic acid	Modified oxford agar	Colicin and moxalactam	Ferric ammonium citrate and aesculin	Hydrolysis of aesculin produces black halo around colonies. No change in color
Fraser broth	Acriflavin and nalidixic acid	Palcam agar	Polymyxin, ceftazidime, acriflavine, and lithium chloride	Mannitol, phenol red, ferric ammonium citrate, and aesculin	Hydrolysis of aesculin produces black halo around colonies. No change in color of medium and colorless colonies owing to lack of mannitol fermentation
Pathogenic *E. coli*					
Tryptone phosphate broth		Levine's eosin–methylene blue agar		Lactose, eosin Y, and methylene blue	Dark-centered colonies with or without a metallic sheen
		MacConkey agar	Bile salts	Lactose and neutral red	Fermentation of lactose results in formation of brick red colonies with or without a surrounding precipitate
Escherichia coli O157:H7/NM					
EHEC enrichment broth	Cefixime, cefsoludin, and vancomycin	Tellurite-cefixime sorbitol MacConkey agar	Bile salts and crystal violet	Sorbitol and neutral red	No change in color of the medium and colorless colonies owing to lack of sorbitol ferrmentation
Salmonella spp.					
Tetrathionate broth	Bile salts, brilliant green, and iodine	Bismuth sulfite agar	Brilliant green	Ferrous sulfite, bismuth sulfite indicator Lactose, sucrose, salicin, acid fuchsin, bromothymol blue, sodium thiosulfate, and ferric ammonium citrate	Brown, gray, or black colonies with or without a metallic sheen. Surrounding medium may be discolored
Rappaport–Vassiliadis medium	Magnesium chloride, sodium chloride, and malachite green	Hektoen enteric agar	Bile salts	Lactose, sucrose, salicin, acid fuchsin, bromothymol blue, sodium thiosulfate, and ferric ammonium citrate	Blue or blue green colonies with or without black centers. Colony may appear to be completely black
Yersinia spp.					
Irgasan–ticarcillin–chlorate broth	Ticarcillin, irgasan, potassium chlorate, and malachite green	Cefsulodin–irgasan–novobiocin agar	Cefsulodin, irgasan, novobiocin, crystal violet, and sodium deoxycholate	Mannitol and neutral red	Transparent colonies with deep red centers with entire or irregular edges

[a]Not applicable. Only *Campylobacter* will grow.

Abbreviation: EHEC, enterohaemorrhagic *E. coli*.

Table 5 Examples of pre-enrichment, enrichment, and plating procedures used for the recovery of meat-borne pathogens

Primary enrichment	*Secondary enrichment*	*Plating*	*Agency*[a]
Campylobacter spp.[b]			
Bolton broth a. Sample taken within 10 days of production, incubate for 4 h at 37 °C b. Sample taken 10 days or older from production, incubate at 30 °C for 3 h and at 37 °C for 2 h	Transfer primary enrichment broth to microaerobic atmosphere (42 °C for 24–48 h)	Abeyta–Hunt–Bark or modified Campylobacter blood-free agar (37–42 °C, 24–48 h)	USDA-FDA
Park and Sanders Enrichment Broth, incubated under microaerobic atmosphere (37 °C for 3–4 h)	Transfer primary enrichment broth to microaerobic atmosphere (42 °C for 24–48 h)	Campylobacter medium with charcoal and deoxycholate with cefoperazone, amphotericin, and Preston agar (37 °C, $\leq$72 h)	HC
None	Blood-Free Bolton enrichment broth incubated for 48 $\pm$ 2 h at 42 °C, under microaerobic atmosphere	Campy–Cefex agar (42 °C, 42–72 h) under microaerobic atmosphere	USDA-FSIS
Listeria spp.			
Buffered Listeria Enrichment Broth with sodium pyruvate, without selective agents (30 °C, 4 h)	Add selective agents to primary enrichment broth (30 °C, 20 and 44 h)	Oxford agar or Palcam agar or Modified Oxford agar (35 °C, 24–48 h) or lithium chloride-phenylethanol-moxalactam medium (LPM) fortified with esculin and Fe^{3+} (30 °C for 24–48 h)	USDA-FDA
Listeria Enrichment Broth (UVM-1 formulation) (30 °C, 48 h)	Inoculate Modified Fraser broth with primary enrichment broth after 24–48 h incubation (35 °C, 24–26 and 48 h)	Oxford agar and one of ALOA formulation agar, A.L. Agar, BBL CHROM agar Listeria, Chromogeneic Listeria Agar Plate, modified Oxford agar, PALCAM agar, RAPID'L.Mono (35 °C, 48), or LPM (30 °C, 48 h)	HC
UVM (Incubate at 30 °C, 23–26 h)	MOPS-BLEB (35 °C, 18–24 h)	Horse Blood Overlay Medium agar (35 °C, 18–26 h) and Modified Oxford agar (35 °C, 24–53 h)	USDA-FSIS
Pathogenic *E. coli* (non-O157)			
Brain-heart Infusion (35 °C, 3 h)	Transfer primary enrichment to double strength Tryptone-phosphate broth (44 °C, 20 h)	Levine's eosin–methylene blue and MacConkey agars (35 °C, 20 h)	USDA-FDA
Escherichia coli O157:H7 and O157:NM			
Modified Buffered Peptone water with pyruvate (37 °C, 5 h)	Add selective agents (Acriflavin–Cefsulodin–Vancomycin) to pre-enrichment (42 °C, 18–24 h)	TC-SMAC and Rainbow® Agar O157 or R&F® *E. coli* O157:H7 agar (37 °C, 18–24 h)	USDA-FDA
None	Modified Tryptone Soy broth (mTSB) with (42 °C, 15–24 h)	IMS with anti-O157 beads, acid treated or directly plated onto Rainbow agar with 5 mg l^{-1} novobiocin, 0.05 mg l^{-1} cefixime, and 0.15 mg l^{-1} potassium tellurite (35 °C, 20–24 h)	USDA-FSIS
mTSB with 20 mg l^{-1} novobiocin or for samples with high bacterial load Enterohemorrhagic *E. coli* Enrichment Broth (42 °C, 22–24 h)	Optional: Enterohemorrhagic *E. coli* Enrichment Broth (35 °C, 18–24 h)	IMS with anti-O157 beads, plated onto two agar media, either two group 1 or one group 1 and one group 2 Group 1: Modified Hemorrhagic Coli Agar with Tellurite and Cefsulodin (42 °C, 18–24 h) mHC Agar with CT supplement (35 °C, 18–24 h) BBL CHROMagar for *E. coli* O157 (BD) Group 2: Modified Sorbitol MacConkey agar with Tellurite, Cefixime, and Cefsulodin (42 °C, 18–24 h)	HC

(*Continued*)

Table 5 Continued

Primary enrichment	*Secondary enrichment*	*Plating*	*Agency*[a]
		CT-SMAC or CR-SMAC (35 °C, 18–24 h)	
VTEC serogroups O26, O45, O103, O111, O121, and O145			
None	mTSB with (42 °C, 15–24 h)	IMS beads acid treated or directly plated onto Rainbow agar with 5 mg l^{-1} novobiocin, 0.05 mg l^{-1} cefixime, and 0.15 mg l^{-1} potassium tellurite (35 °C, 20–24 h)	USDA-FSIS
Salmonella spp.			
Nutrient broth or buffered peptone water (35 ± 0.5 °C, 18–24 h)	Rappaport–Vassiliadis medium and tetrathionate brilliant green broth (42.5 °C, 24 ± 2 h)	Two of bismuth sulfite (BS) agar, brilliant green sulfa agars, or Brilliance Salmonella agar (35 °C, 24 h; BS can be incubated up to 48 h)	HC
Lactose broth (35 °C, 24 ± 2 h)	Rappaport–Vassiliadis medium (42 °C, 24 ± 2 h) and tetrathionate broth (43 °C if microbial load is high and at 35 °C if microbial load is low, 24 ± 2 h)	Bismuth sulfite, xylose lysine deoxycholate, and hektoen enteric agars (35 °C, 24 ± 2 h)	USDA-FDA
Buffered peptone water (35 °C, 20–24 h) or mTSB (42 °C, 15–24 h)	Rappaport–Vassiliadis R10 broth and TT broth (Hajna) (42 ± 0.5 °C, 22–24 h)	Double-modified lysine-iron agar (DMLIA), and brilliant green sulfa agars (35 °C, 18–24 h)	USDA-FSIS
Yersinia spp.[c]			
None	Irgasan–ticarcillin–cholate broth (25 °C, 2 and 3 day)	KOH treatment before plating or direct plating onto Cefsulodin–irgasan–novobiocin (CIN) agar (32 °C, 18 h)	USDA-FSIS
Tryptic soy broth (25 °C, 24 h)	Bile–oxalate–sorbose broth (25 °C, 3 and 5 day)	Salmonella-Shigella deoxycholate calcium agar (SSDC; 30 ± 1 °C, 24 h) and KOH treatment before plating or direct plating onto CIN agar (32 °C, 18 h)	USDA-FSIS
None	Phosphate buffered saline (4 °C, 14 day)	KOH treatment before plating or direct plating onto CIN agar (32 °C, 18 h)	USDA-FSIS

[a]USDA-FDA, United States Department of Agriculture, Food and Drug Administration; USDA-FSIS, United States Department of Agriculture, Food Safety Inspection Services; HC, Health Canada.
[b]Incubation conditions for *Campylobacter* spp. are microaerobic, established by flushing with a gas mixture (10% CO_2, 5% O_2, and 85% N_2) or using gas-generating kits.
[c]All three enrichment procedures are recommended followed by plating.

Listeria spp.

Listeriae are psychrotrophic and can grow under microaerobic conditions so that their numbers can increase during refrigerated storage of meats, both anoxically and aerobically packaged. *Listeria* spp. can be difficult to recover and two enrichment broths are usually used (Table 5). After enrichment, PCR screening test may be performed and enrichment media is streaked onto at least two selective media to ensure isolation of as many *Listeriae* as possible. Typical colonies are selected for biochemical and serological characterization. Recovery of injured cells is problematic with *Listeria* and the use of Listeria Repair Broth has been suggested. *Listeria* can be confirmed and differentiated using a kit such as the API Listeria kit, observation of hemolysis, and the CAMP test for β-lysin factor.

Salmonella spp.

Salmonella spp. are usually present in low numbers and form only a small part of the total microflora. Usually two enrichment broths and two plating media are recommended to allow recovery of most strains (Table 5). Enrichment broths may be screened by PCR for gene markers. Kits such as the AP1 20E (bio Merieux, Marcy-l'Etoile, France), MICRO-ID (bio Merieux), VITEK (bio Merieux), or Enterotube II (Becton Dickinson, Franklin Lanes, NJ) can be used to characterize putative salmonellae, but confirmation of *Salmonella* requires somatic (O) antigen and flagellar (H) antigen agglutination reaction using polyvalent and single grouping antisera.

Staphylococcus aureus

Staphylococcus aureus can be isolated from both raw and cooked meats; however, it is a poor competitor and its growth in raw meats is limited. It does grow well in cooked meats. Illness from *S. aureus* infection is the result of ingestion of a heat-resistant toxin, so that large numbers of *S. aureus* must have been present. Foods are usually examined for *S. aureus* using direct plating (Table 6) and there is almost universal acceptance that Baird–Parker agar is the most appropriate medium. It

Table 6 Examples of direct plating procedures for isolation of pathogens

Organism	*Filtration*	*Plating medium and incubation conditions*	*Additional steps*
Clostridium perfringens			
	Not used	Sulfite-cycloserine agar (pour plate, 35 °C, 24 h)	Count black colonies as presumptive *C. perfringens*
Escherichia coli			
	Membrane filter and surface plating	Nutrient agar (35–37 °C, 4 h), followed by tryptone-bile agar (44.5 °C, 20 h)	Soak filter in p-dimethylaminobenzaldehyde dissolved in 1 mol l^{-1} HCl and count pink (indole positive) colonies as *E. coli*
	Not used	Tryptone bile *X*-glucuronide agar (30 °C, 4 h followed by 44 °C, 18 h)	Count blue colonies as *E. coli*
	Hydrophobic grid membrane filter	Lactose–monensin–glucuronate agar (LMG, 35–37 °C, 24 ± 2 h), followed by buffered 4-methylumbelliferyl-β-D-glucuronide agar (BMA, 35–37 °C, 2 h)	Illuminate BMA agar plates with long-wavelength UV light and count blue-while fluorescent colonies as presumptive *E. coli*
Escherichia coli and *E. coli* O157:H7			
	Hydrophobic grid membrane filter	SD-39 agar (44.5 °C, 24 h)	Count green colonies as presumptive *E. coli*, pink as presumptive *E. coli* O157: H7
Staphylococcus aureus	Spread plating or hydrophobic grid membrane filter	Baird–Parker agar (35 °C, 48 ± 2 h)	Count black colonies[a] with a clear zone with or without a white precipitate in the medium as presumptive *S. aureus*
Listeria spp. and *Listeria monocytogenes*			
	Hydrophobic grid membrane filter	LM-137 agar with 50% egg yolk emulsion (35–37 °C, 22–24 h)	Count pink colonies as presumptive *Listeria* spp. and *Listeria monocytogenes.* Confirm *Listeria monocytogenes* using further testing

[a]When using HGMF, only the color of the colonies is considered.

contains both selective agents (lithium chloride, glycine, and potassium tellurite), which inhibit most other bacteria, and differential agents (egg yolk and potassium tellurite). Further biochemical tests include the coagulase test using human or rabbit blood plasma and identification using commercial systems such as API Staph or VITEK Gram-positive identification card.

Yersinia spp.

Yersinia spp. are able to grow at refrigeration temperatures and one approach to their isolation is cold enrichment (Table 5). Cultural methods for the isolation and identification of yersiniae require a great deal of effort and are thought to underestimate its presence. Molecular methods, either by deoxyribonucleic acid (DNA) colony hybridization or by nested PCR, have been shown to increase sensitivity significantly (25% using nested PCR). *Yersinia* spp. are resistant to alkaline treatment, so exposure to potassium hydroxide is used as an additional tool to separate *Yersinia* spp. from background flora. Identification of isolates as *Yersinia* spp. includes no utilization of citrate, only carbohydrate fermentation, no production of hydrogen sulfide, and evidence of urease activity.

Conclusion

In relation to meat-borne pathogens, standard methods are promulgated by regulatory agencies throughout the world. Such methods are necessary to support microbiological standards with legal status. In contrast, methods to recover, enumerate, and characterize meat-borne spoilage bacteria are considerably more variable and can best be described as 'recommended procedures' that have been widely practiced and are generally accepted. Harmonization of methodologies will be essential if it is required to compare meat-borne bacterial numbers reported by different laboratories.

MICROBIOLOGICAL SAFETY OF MEAT

Contents

Aeromonas spp.

RE Levin, University of Massachusetts, Amherst, MA, USA

This article is a revision of the previous edition article by JA Hudson, volume 2, pp 830–835, © 2004 Elsevier Ltd.

Glossary

Cytotoxin A chemical substance (usually a protein) having specific toxicity to certain organs or tissues.
Endotoxin Refers to a bacterial toxin retained by the cell and not released extracellularly. Usually synonymous with the lipopolysaccharide component of the outer cell membrane of Gram-negative bacteria.
Enterotoxin A bacterial toxin causing vomiting, diarrhea, or abdominal pain.
Gastroenteritis Infection of the intestine usually resulting in diarrhea.
Hemolysin A biologically active protein molecule capable of rupturing red blood cells.
ß-Hemolysis A zone of clearing surrounding a bacterial colony on a blood agar plate.
Hemolytic uremic syndrome Bacterial infection resulting in lysis of red blood cells and severe damage to the kidneys.
Hepatobilliary Refers to the liver, gall bladder, and bile ducts.
Meningitis Infection of the meningeal membrane surrounding the brain.
Septicemia Occurrence of bacteria in the blood.

Introduction

The genus designation *Aeromonas* was established for bacterial cells with a single polar flagellum producing gas from glucose to distinguish such isolates from members of the genus *Vibrio* that characteristically also produce a single polar flagellum but do not produce gas from glucose. Members of the genus *Aeromonas* are Gram-negative, facultatively anaerobic, catalase positive, cytochrome oxidase positive, and rod-shaped bacteria. The genus *Aeromonas* has undergone a number of taxonomic changes over the past two decades. It was originally allocated to the family *Vibrionaceae*; however, subsequent phylogenetic studies indicated that the genus *Aeromonas* is not closely related to vibrios. This resulted in the establishment of a new family, the *Aeromonadaceae* under which the genus *Aeromonas* is housed.

The aeromonads are composed of two major subgroups. The mesophilic group, typified by *Aeromonas hydrophila*, consists of motile isolates that grow well at 35–37 °C and are associated with a variety of human infections. The second group consists of psychrophilic strains allocated to the species *Aeromonas salmonicida* that cause diseases in fish, are nonmotile,

and have optimal growth temperatures of 22–25 °C. In the last edition (2005) of Bergy's Manual of Systematic Bacteriology, deoxyribonucleic acid (DNA)–DNA hybridization studies led to the expansion of the original 5 *Aeromonas* species to recognition of 17 hybridization groups (HGs) or genospecies and 14 phenospecies including the 6 human pathogenic species, *A. hydrophila*, *Aeromonas caviae*, *Aeromonas veronii*, biotype sobria, *A. veronii* biotype veronii, *Aeromonas schubertii*, and *Aeromonas jandaei*. The term 'phenospecies' was coined to refer to a single heterogeneous species containing multiple HG groups within it.

There are presently 24 species names in the genus *Aeromonas* in the published literature derived from recent descriptions of new species, some of which are considered synonymous with previously described species. A minimum of five well-characterized strains has been recommended for each valid species in addition to almost complete 16S ribosomal ribonucleic acid (rRNA) sequences, phenotypic properties, and molar G+C content of the genomic DNA. The phylogenetic depth of the 16S rRNA gene tree for the genus *Aeromonas* is considered notably shallow, with all species exhibiting interspecies sequence similarity values of approximately 98% or higher and in most cases >99%.

Habitats

Members of the genus *Aeromonas* are found in a wide variety of habitats including freshwater rivers, lakes and streams, and marine water estuaries, and have been isolated from soil, the intestines of healthy cattle and humans, meat and vegetable products, and are frequently present in dairy products.

Occurrence of *Aeromonas* in Raw Meat and Poultry

A 1993 study indicated that *Aeromonas* spp. were commonly isolated from ground beef and poultry. The dominant species in ground meat were *A. hydrophila* and *A. caviae*. In chicken, *A. sobria* was common. *Aeromonas hydrophila* was isolated from 75% of ground meat samples and from 62% of chicken samples.

A later study indicated that a relatively high percentage 16/23 (70%) of *Aeromonas* containing samples from poultry (5/6), red meat (9/14), and other meat products (2/3) was reported by Neyts *et al*. in 2000 in a Belgium study. *Aeromonas* counts from one sample were as high as 10^5 cells per gram.

In a more extensive study, in a total of 563 samples of various foodstuffs purchased, 287 were found to contain mesophilic *Aeromonas* spp. The most frequently contaminated samples were poultry (79.3%) and offal (84.3%). The researchers concluded that both raw and cooked foods are potential sources of *Aeromonas* species such as *A. hydrophila* and *A. sobria*. This conclusion implies postprocessing contamination of cooked ready-to-eat foods.

A more recent study indicated that among 80% of raw turkey meat samples, 43 (53.8%) were positive for the presence of motile *Aeromonas* species. *Aeromonas hydrophila* was the most prevalent *Aeromonas* species followed by *A. sobria* and *A. caviae*. A separate study resulted in *Aeromonas* species isolated from 53/92 (57.6%) raw poultry samples and 27/158 (17%) minced meat samples. *Aeromonas hydrophila* and *A. caviae* were the most frequently isolated *Aeromonas* species followed by *A. sobria*, *A. jandaei*, and *A. veronii* in that order of frequency. A somewhat earlier study involving cuts of raw beef, goat, and lamb found 53/60 (88%) of samples to be positive for *Aeromonas*. The most frequent species isolated was *A. sobria* (67.3%) and *A. hydrophila* (21.2%). Three additional species occurred in minor proportions, with all the *Aeromonas* isolates exhibiting β-hemolysis. Initial *Aeromonas* counts for a variety of refrigerated meats have been found to range from $<10^2$ to $>10^5$ CFU g^{-1} and that after 7 days, numbers can increase from 1 to 3 logs in most raw meat products.

Phenotypic Characteristics

All members of the genus *Aeromonas* have been found to exhibit a number of common phenotypic features, which are listed in Table 1 along with characteristics of 98–99% of all isolates. The production of extracellular DNase, elastase, hemoysin, and H_2S has been found to be variable.

Virulence Factors

Although pathogenicity of *Aeromonas* was earlier open to some question, mounting evidence in recent years involving aeromonads solely present in septicemic, meningitis, and other infections and the recognition of the production of various toxins by the implicated isolates have contributed to the recognition that aeromonads are primary as well as opportunistic pathogens.

Pathogenicity among *Aeromonas* spp. is associated with the ability to produce exotoxins (hemagglutinins and hemolysins), cytotoxins, endotoxins, enterotoxins, siderophores, invasins, adhesins (pili), S-layer (surface array protein layer), flagella, several hydrolytic enzymes, and to invade tissue cultured cells. The hemolysin (also known as aerolysin) is encoded by the *aero* gene and has been shown to have hemolytic, enterotoxic, and cytolytic activity. Aerolysin is a hydrophilic protein that binds to eukaryotic cells and forms pores in the membrane resulting in the destruction of membrane permeability and cell lysis. Among these various virulence factors presumably contributing to the pathogenicity of *Aeromonas*, β-hemolysis seems to be related to enterotoxigenicity. There is evidence that adherence to tissue culture cells and hemolysis are plasmid mediated.

Human and Veterinary Clinical Infections

The large majority of *Aeromonas* clinical isolates consist of *A. hydrophila*, *A. caviae*, and *A. veronii* biovar sobria (Table 2). The genus *Aeromonas* comprises species that exhibit opportunistic and primary human pathogenicity causing septicemia among the immunocompromised, wound infections in otherwise healthy individuals, and various other illnesses including peritonitis, meningitis, and infections of the eyes, joints, and bones, in addition to gastroenteritis. Aeromonads can cause invasive infections, especially in patients with hepatobiliary diseases, malignancy, and diabetes mellitus.

Table 1 Phenotypic characteristics common to all species of *Aeromonas*

Characteristic	*Phenotype*[a]	*Characteristic*	*Phenotype*[b]

The genus *Aeromonas*: Taxonomy, pathogenicity, and infection. Clinical Microbiology Reviews 32, 35–73.

Diarrhea due to *Aeromonas* presents with varied clinical symptoms. Watery and self-limited diarrhea is common. Patients with cholera-like diarrhea and rice water stools have been reported. However, some patients may develop fever, abdominal pain, and bloody diarrhea. Approximately 35% of patients exhibit fever and vomiting. It has been difficult to prove in a definitive manner that aeromonads are causative organisms of gastroenteritis. No single clonally related outbreak of diarrhea has ever been reported to be associated with an aeromonad. In addition, no suitable animal model exists to allow Koch's postulates to be fulfilled, by inducing similar diarrhetic symptoms in a laboratory animal. However, there are a small number of cases in the literature where *Aeromonas* is unquestionably the cause of gastroenteritis, with the diagnosis based not only on isolation of the organism from feces but also on an immune response. One recent study of travelers to Africa, Asia, and Latin America, found that 50% of the individuals returning with *Aeromonas*-associated diarrhea had symptoms lasting 14 days or longer. The vast majority (>80%) of cases of *Aeromonas* septicemia occur in severely immunocompromised individuals. Predisposing factors for systemic infection are hepatic necrosis (54%) and malignancy (21%).

On an annual basis there are large numbers of individuals who are stricken each year with acute gastroenteritis, resulting in only members of the genus *Aeromonas* being isolated from feces, and the absence of other pathogens. In 1995, a food poisoning outbreak occurred involving *A. hydrophila*. A group of 27 people consumed a typical Swedish 'landgång' containing shrimps with mayonnaise, liver paté, ham, sausage, and legume salad purchased from a food store. Twenty-two of the 27 individuals became ill within 20–34 h after consumption. Symptoms included severe acute diarrhea, abdominal pain, headache, fever,

and vomiting. Among the remaining five healthy persons who consumed the leftover food the next day, two became similarly ill. Symptoms lasted for several days. Bacteriological examination of the leftover food samples resulted in the isolation of *A. hydrophila* from the shrimp with mayonnaise, smoked sausage, liver paté, and boiled ham. The number of *A. hydrophila* per gram of these foods was 10^6–10^7 per gram of food sample. *Aeromonas hydrophila* was not isolated from the legume/mayonnaise salad samples.

Among 1485 patients with acute gastritis reporting to a hospital in India in 2002, a total of 67 patients yielded *Aeromonas* strains as the sole bacterial pathogen. *Aeromonas hydrophila* (64.2%) was the dominant isolate followed by *A. sobria* (28.4%) and *A. caviae* (7.4%). The sources of the *Aeromonas* isolates were not identified.

An outbreak of acute diarrhea due to *A. sobria* in Benghazi occurred during a 1-month period in 1977. Among 69 patients admitted with acute gastroenteritis, 28 were positive for *A. sobria*. The source of the infections was not determined, nor was molecular typing of the isolates undertaken to determine if a single monoclonal strain was responsible.

Soft-tissue infections following water-related injuries are frequently due to *Aeromonas*. A number of pneumonia cases have been reported due to near drowning, resulting from aspiration of freshwater into the lungs, with symptoms occurring in less than 24 h with a death rate of 63%. Snake bites have been reported to result in infections by aeromonads. Infections in burn patients by aeromonads are notably rare, with less than two-dozen cases reported to date. Some of these cases yielded *Aeromonas* isolates from infected burn tissues and others from primary septicemic infections. *Aeromonas* appears to be a major nosocomial pathogen in patients with hepatic cirrhosis, resulting in septicemia with a rapidly fatal outcome. *Aeromonas hydrophila* and *A. veronii* biotype sobria have been reported to be causative agents in spontaneous empyema (puss in the pleural cavity) among hepatic cirrhotic patients exhibiting pleurisy. At least six cases of hemolytic uremic syndrome due to *Aeromonas* have been reported involving *A. sobria*, *A. hydrophila*, and *A. veronii* biotype sobria involving a cytotoxin with homology to Shiga toxin 1. These three species account for approximately 85% of all clinical isolates of *Aeromonas*. *Aeromonas hydrophila* has been reported to be the cause of abortion in sheep and cattle, whereas *A. sobria* has been associated with abortions in buffaloes. There are more than 96 distinct serogroups of *Aeromonas* on the basis of unique somatic antigens and they are not species specific.

In an interesting study in 2012, poultry farmers were found to be a high-risk group for *Aeromonas* infections. The study was initiated from recognition that there is a high incidence of *Aeromonas* in poultry stool samples, carcasses, and processing plant wastewater. Among a total of 63 stool samples from asymptomatic poultry workers employed by 23 poultry farms in Brazil, 12 (18.5%) were positive for *Aeromonas*. In contrast, stool samples from a control group of 72 from an urban community were all negative for *Aeromonas*. Poultry stools allowed the identification of *Aeromonas* in only 6 of the 23 farms (26.1%). In four of these farms, 50–70% of the workers were contaminated. Although asymptomatic at the time of analysis, 78% of the *Aeromonas*-positive workers complained of frequent diarrhea during the previous 6 months. Interestingly, all of the workers (those testing positive and negative) reported frequent gastrointestinal tract disorders during the first month of employment in the poultry farms.

Quorum-sensing molecules have been detected in *A. hydrophila* and *A. salmonicida* that result in the activation of one or more genes at a critical cell density. Little is known regarding the role of quorum sensing among these species, which potentially may influence biofilm formation and control of virulence genes.

The association of aquatic environments and human infections is exemplified by the tsunami that struck Thailand in December 2004. One study indicated that among the 305 tsunami survivors with skin or soft-tissue infections, *Aeromonas* was the single most frequently isolated pathogen, accounting for more than 20% of the 641 isolates identified.

Controlling the Numbers of *Aeromonas* in Foods

Considering that the ultimate source of *Aeromonas* spp. associated with meat and poultry is the intestines of warm-blooded animals, one approach to reducing the numbers of Gram-negative, nonspore-forming pathogens, such as *Escherichia coli* O157:H7, *Salmonella*, *Shigella*, *Campylobacter*, and *Aeromonas*, is to scald the internal and external surface of carcasses with water at 176 °F (80 °C) and to guard against recontamination during further handling and processing. Giblets from poultry represent a subset of tissues to which this is not readily applicable. It is, therefore, essential that giblets be well cooked. A precautionary defense against the presence of Gram-negative pathogens, including *Aeromonas*, recommended by the World Health Organization, is to heat all meat to an internal temperature of at least 158 °F (70 °C).

An additional mechanism for the destruction of aeromonads is the application of gamma irradiation. In a recent study, chicken tissue was seeded with a mixture of *A. salmonicida*, *A. caviae*, *A. jandaei*, *A. hydrophila*, and *A. veronii*. The decimal reduction dose (D_{10}) value was found to be 0.089 ±0.003 kGy. This translates to the fact that a low dose of 1 kGy will destroy 10 log cycles of cells, which is far more than would be encountered on a raw meat product.

Cross-contamination from raw meat to raw vegetables should always to be avoided. This is most readily achieved in homes by vigorous washing of hands with hot water and soap or detergent after handling raw meat, and ideally applying a 70% alcohol-based handwash before handling raw vegetables. Some preservation methods, such as refrigeration, vacuum packaging, and modified atmosphere packaging appear ineffective in inhibiting the growth of *A. hydrophila*.

Antibiotic Sensitivity and Resistance

Aeromonas species have been reported to be largely resistant to penicillin, ampicillin, first-generation cephalosporins, carbenicillin, clindamycin, ticarcillin, and vancomycin. Susceptibility to chloramphenicol, trimethoprim-sulfamethoxazole, and fluoroquinolones has been consistently reported. A high level of *in-vitro* sensitivity to aztreonam, imipenem, and fluoroquinolones against *Aeromonas* species has been observed. Third-generation cephalosporins or fluoroquinolones,

especially ceftriaxone and cefotaxime are considered the agents of choice.

Isolation of Aeromonads

Aeromonads grow well at an alkaline pH range of up to pH 9.0, which is used in alkaline-peptone enrichments (pH 8.5–9.0) from stool, environmental, and food samples. Some of the mesophilic mobile aeromonads grow from 0 °C to 45 °C with an optimum growth temperature of 22–35 °C.

Ampicillin blood agar containing 20 mg ml^{-1} of ampicillin has been found to yield a higher recovery of *Aeromonas* directly from stool samples than Cefsulodin-Irgasan-Novobiocin (CIN) agar. It also has the advantage over CIN agar in that hemolytic colonies can be directly tested for cytochrome oxidase, which greatly reduces screening. It is to be noted that approximately 10% of all *Aeromonas* isolates are non-hemolytic. An alternative medium is *Aeromonas* agar (AA) which contains Irgasan, and uses D-xylose (which areomonads do not ferment) for differentiation. Pseudomonads which are indistinguishable from aeromonads on AA can be distinguished from aeromonads on the basis of their obligately aerobic metabolism using the Hugh-Leifson medium.

Commercial identification systems have proven to be unreliable for the identification of *Aeromonas* species, tending to erroneously identify most clinical *Aeromonas* isolates as *A. hydrophila*. It has been suggested that the cytochrome oxidase test be performed on all stool isolates to distinguish *Aeromonas* from enterobacteria.

Molecular Characterization of *Aeromonas* Isolates

A number of evolutionary markers have been applied to members of the genus *Aeromonas* for determining phylogenetic relationships among species. These include 16S rRNA, *gyrB* (B-subunit of DNA gyrase), *rpoD* (σ^{70}, RNA polymerase subunit), *rpoB* (β-subunit of DNA-dependent RNA polymerase), and *dnaJ* (heat shock protein 40 genes). Recent results indicate that there is less divergence in 16S rRNA gene sequences than there is within these four housekeeping genes, making them more valuable for species discrimination.

The use of the polymerase chain reaction (PCR) targeting the cytotoxin, enterotoxin, and hemolysin virulence genes present in mobile aeromonads from a variety of raw foods revealed 59%, 26%, and 33.3% of samples from fish, poultry, and shrimp to possess aeromonads carrying these genes. PCR assays of samples from hams and raw cured beef yielded 10.5% of *Aeromonas* isolates from both sources possess these virulence genes.

Fatty acid methyl ester analysis and amplified fragment length polymorphism have been used to identify *Aeromonas* isolates from foods to the DNA hybridization (HG) level.

The hemolysin and aerolysin genes have been used for genotyping *Aeromonas* isolates. A statistically significant correlation was found between cytotoxin levels (from Vero cell culture cytotoxicity assays) and the hemolysin genotype. Genotype 4 isolates (possessing both *ahh1* and *aerA* genes) expressed higher cytotoxin titers than isolates of other genotypes suggesting that genotype 4 isolates may have a greater clinical significance.

Polymerase Chain Reaction Detection of *Aeromonas*

Two fundamental approaches to the PCR detection of aeromonads have been utilized. One involves a pair of primers that amplify a conserved 16S rDNA sequence uniformly unique to the genus *Aeromonas*. The second involves a pair of primers unique and common to a specific species of *Aeromonas* such as the β-hemolysin or the cytolytic autolysin *aero* gene for the detection of *A. hydrophila*. Table 3 lists a number of PCR primers and the *Aeromonas* genes that have been targeted for amplification.

Distribution of *Aeromonas* Virulence Genes

The distribution of three toxin genes among 115 *Aeromonas* isolates from 1735 children with diarrhea has been studied. Alt is a heat-labile cytotonic enterotoxin; Ast is a heat-stable cytotonic enterotoxin; and Act is a cytotoxic enterotoxin. In addition, 27 aeromonads isolated from 830 control children, and 120 randomly selected aeromonads from different components of surface water in Bangladesh were also examined for the distribution of these three toxin genes. The number of isolates positive only for the presence of the *ast* gene was significantly higher for the environmental samples than for samples from diarrheal children. Isolates positive only for the presence of the *act* gene were not found in any of the three sources. Importantly, the number of isolates positive for both the *alt* and *ast* genes was significantly higher for diarrheal children than control children and the environment. Among the 11 *A. hydrophila* isolates from diarrheal children, none harbored the *alt* or *ast* genes individually, but 6 (54.6%) harbored both the genes. In contrast, none of the five isolates of *A. hydrophila* from diarrheal children harbored both the *alt* and *ast* genes whereas among the *A. hydrophila* isolates isolated from the environment, only two (11.1%) harbored both the *alt* and *ast* genes. The products of both the *alt* and *ast* genes may therefore synergistically act to induce severe diarrhea.

The presence of a type III secretion system (T3SS) has been reported for *A. hydrophila* and its contribution to virulence established. A cytotoxin-designated *Aex*T associated with a T3SS having ADP-ribosyltransferase activity has been described. The toxin was derived from a diarrheal isolate of *A. hydrophila*. A new *Aeromonas* T3SS effectors (*aexU*) has been described and characterized. The *aexU* gene was found in various isolates among 250 aeromonads from clinical and water sources.

Restriction Fragment Length Polymorphism Studies

The characterization of the PCR products from *Aeromonas* isolates from clinical, environmental, and food sources by PCR-restriction fragment length polymorphism (PCR-RFLP) using the endonuclease *Hpa*II and PCR-amplicon sequence analysis revealed three types of amplicons indicating that the virulence genes are classified into three main groups: (1)

aerolysins-hemolysins, (2) cytolytic enterotoxins, and (3) cytotonic enterotoxins.

RFLP has been applied to reference strains of all species of *Aeromonas* and 76 clinical isolates of diverse origin. PCR primers were used to amplify a 1502-pb sequence of the 16S rDNA of all *Aeromonas* species. The resulting amplicons were restricted with *Alu*I and *Mbo*I and the resulting DNA fragments (33–346-bp) resolved as banding patterns by agarose gel electrophoresis. The resulting banding patterns were used to identify isolates of *Aeromonas* at the species level. Most RFLP results were in agreement with biochemical identification.

Glossary

Chromogenic Media Culture media incorporating at least one chromogen, which is a substance that can be converted into a detectable pigment or dye. The ability to utilize the chromogen substrate is diagnostic of the target organism/s.
Dodecadepsipeptide Dodeca (*Gk*. 12) and depsipeptide is a peptide in which one or more of the amide (-CONHR-) bonds are replaced by ester (COOR) bonds. Cereulide is a twelve-chain depsipeptide.
Emetic syndrome Vomiting caused by a toxin that survives high temperatures and survives in cooked foods.
Enterotoxin Toxin results in a diarrheal illness – it is heat labile and the most common cause of *B. cereus* food poisoning.
Enzyme-linked immunosorbent assay (ELISA) An immunological assay technique making use of an enzyme bonded to a particular antibody or antigen.
Liquid chromatography–mass spectrometry (LC–MS) LC–MS is an analytical chemistry technique that combines the physical separation capabilities of liquid chromatography (HPLC) with the mass analysis capabilities of mass spectrometry.

Introduction

Bacillus cereus is ubiquitous in the environment and can be found in soil, dust, air, water, decaying matter, and plants. Consequently, raw foods of plant origin are the major source of *B. cereus*. Dried herbs, spices, and dehydrated foods have all been shown to contain *B. cereus*. The widespread distribution of this organism, ability of its spores to survive dried storage, and the thermal resistance of spores mean that processed foods can contain *B. cereus*. Thus, control measures to prevent growth of *B. cereus* in those foods are required, especially if cooking has eliminated the competing microflora.

Bacillus cereus is an aerobic endospore former next in importance to *Bacillus anthracis* as a pathogen of humans and other animals. *Bacillus cereus* was first associated with food poisonings in the 1950s, when outbreaks involving vanilla sauce were reported. It causes two forms of food poisoning: an emetic syndrome and a diarrheal illness. The emetic syndrome is caused by a toxin that survives high temperatures and exposure to trypsin, pepsin, and pH extremes. This syndrome is mostly associated with cooked rice and other cereal-based foods. For example, in an incident involving seven people, the heat stable toxin was indirectly ingested and caused illness via contaminated hands following the use of contaminated rice in a children's kindergarten craft activity. The diarrheal illness is caused by a heat-and acid-labile enterotoxin and is mostly associated with proteinaceous foods. Reported outbreaks of *B. cereus* food poisoning due to meat products have been of the latter type.

Although *B. cereus* can be isolated from raw meat, it is mostly the ingredients added to processed meat products such as sausages, or seasonings added to spiced meat dishes, that is the cause of *B. cereus* food poisoning involving meat products. When processed meats containing *B. cereus* are improperly stored after cooking, surviving endospores may germinate and grow to high numbers.

Characteristics of *Bacillus cereus*

Bacillus cereus is a Gram-positive or Gram-variable spore-forming rod (Figure 1). It grows best aerobically but grows slowly under anaerobic conditions. The rods, which are typically 1.0–1.2 μm in diameter and 3.0–5.0 μm in length, tend to grow in long chains. The optimum temperature for growth is between 28 and 35 °C, although the growth temperature range extends from 5 to 50 °C; it has been reported that some strains can grow even at 55 °C. It can grow over a pH range from 4.3 to approximately 9.3 and at salt concentrations up to 7.5% w/v. The minimum water activity (a_w) for vegetative growth is 0.912. The generation time is in the range 18–27 min, under optimum conditions.

Although vegetative cells of *B. cereus* are readily killed by heat, the spores are moderately heat resistant. Heat resistance varies with differences in food matrices. Heat resistance of spores is increased in high-fat and oily foods. For example, in soybean oil, the time for *B. cereus* numbers to be reduced by

Figure 1 Gram stain of *Bacillus cereus* cultured on sheep blood agar showing typical growth in chains and endospore formation.

 doi:10.1016/B978-0-12-384731-7.00042-8

90% (the *D* value) is 30 min at 121 °C. Other examples of heat resistance that have been recorded are D_{85} °C = 33.8–106 min in phosphate buffer and D_{95} °C = 1.5–36.2 min and 1.8–19.1 min in distilled water and milk, respectively. Heat resistance is also enhanced in foods of low water activity.

Spores of different strains vary considerably in heat resistance. Some have *D*-values at a given temperature up to 20 times greater than those of more sensitive strains. Spores are more resistant to dry heat than to moist heat and can remain dormant for long periods in dried foods stored at ambient temperatures.

Once it is formed, boiling, frying, roasting, and microwave heating will not destroy or biologically inactivate the extremely heat-stable emetic toxin. The toxin can survive 90 min at 126 °C and is not affected by extremes of pH (2–11). In contrast, the diarrheal toxins are inactivated at 56 °C in 5 min.

Isolation and Identification

Most procedures for isolation of *B. cereus* from meat involve direct plating onto a selective agar. The selective agars commonly used are polymyxin egg yolk mannitol bromothymol blue agar (PEMBA), mannitol egg yolk polymyxin (MYP) agar, and Kim and Goepfert agar. The antibiotic polymyxin B is added to the media as the preferred selective agent, because it inhibits growth of most of the Gram-negative bacteria that usually predominate in meat microflora.

Most media incorporate egg yolk for ready recognition of the *B. cereus* colonies. A turbid zone forms around a colony of *B. cereus* in the presence of egg yolk, owing to the organisms' secretion of an enzyme complex that includes lecithinase and phospholipase, which react with the egg yolk. However, some strains of *B. cereus* have lost the ability to form a turbid zone, probably because the genes for these enzymes are not expressed. Most media include mannitol and an indicator to allow discrimination between fermenters and nonfermenters of mannitol. *Bacillus cereus* does not ferment mannitol, but it hydrolyzes casein in order to change the pH of the medium to alkaline under and around the colony. On MYP agar, the agar changes to pink color, whereas on PEMBA, the color of the colonies is bluish. Chromogenic media are being used more frequently in food laboratories, and the media properties that allow selection of *B. cereus*, *Bacillus thuringiensis*, and *Bacillus weihenstephanensis* are improving. Each chromogenic medium has its own advantages and limitations. Some limitations seem to be resolved by incubation at 30 °C instead of 37 °C, as is recommended.

Bacillus cereus may occur in foods as vegetative cells, as sporulating sporangia or, as free spores. However, in organic liquid media such as milk, vegetative cells do not sporulate readily at refrigeration temperatures. The recovery of *B. cereus* from most foods does not usually require a resuscitation step, as most spores germinate readily. Therefore, isolation by spread plating on the media mentioned above is adequate. There are certain foods such as dried meat meals or protein powders that may have been subjected to heating and drying processes that leave *B. cereus* present as only dormant spores. In this case, it may be necessary to use a method that includes a resuscitation step, such as a three-tube most probable number (MPN) method using tryptic soy broth supplemented with polymyxin B. Positive growth in each tube is confirmed by streaking a loopful of the contents onto MYP agar plates. The MPN indicated by the pattern of positive tubes is a good estimate of the concentration of bacteria in the tested food.

Bacillus cereus and organisms closely related to it, including *B. anthracis*, *B. thuringiensis*, *B. mycoides*, and *B. weihenstephanensis* are included in the *B. cereus* complex. *Bacillus* sp. strain Ba813 carries a chromosomal marker, Ba813, that is otherwise found only in *B. anthracis*. *Bacillus thuringiensis* is an insect pathogen that has become very important in food microbiology. Its use as a commercial insecticide has increased its presence in food commodities where it can be mistakenly identified as *B. cereus*. Although there have been no outbreaks linked to *B. thuringiensis*, toxigenic strains of the organisms have been identified. *Bacillus thuringiensis* may then have some role in foodborne illness. *Bacillus mycoides*, (previously, *B. cereus* var. *mycoides*) is used as a promoter of plant growth. It has recently been separated into two species, *B. mycoides* and *B. pseudomycoides*. *Bacillus weihenstephanensis* now encompasses psychrotolerant strains of *B. cereus*. This new species grows at 7 °C but not at 43 °C and can be identified rapidly using rDNA or PCR targeted to a gene for the shock protein *cspA*. The taxonomic position of *B. weihenstephanensis* may still be in doubt, because strains intermediate between it and *B. cereus* exist and there are psychrotrophic strains of *B. cereus* that cannot be classified as *B. weihenstephanensis* as they do not carry the *cspA* gene. In at least one study, cytotoxicity and the growth temperature range *of B. cereus* strains were found to be independent. Some strains of *B. cereus* may be able to adapt to cold storage, and strains of *B. weihenstephanensis* have been shown to tolerate exposure to 47 °C after exposure to the nonlethal temperature of 38 °C. Exposure to other stresses such as high salt concentration, low pH, a high ethanol concentration, or low temperature also result in development of increased heat tolerance in *B. weihenstephanensis*. The hemolytic enterotoxin HBL seems to be widely distributed among strains of the *B. cereus* group. The enterotoxin is not associated with a particular species or a specific environment. In one study of 50 *B. weihenstephanensis* strains, 72% were not cytotoxic, although all strains had part of at least one of the *B. cereus* enterotoxins Hbl, Nhe, or CytK. *Bacillus weihenstephanensis* was found to produce the emetic toxin cereulide at temperatures as low as 8 °C.

It has been suggested that the *B. cereus* group may constitute a single species; difficulties remain with conventional laboratory differentiation of the current species. Evaluation of *Bacillus* growth characteristics on Anthrax Blood Agar and Cereus Ident Agar showed that some strains of *B. cereus*, *B. mycoides*, *B. thuringiensis*, and 30% of *B. weihenstephanensis* strains could be misidentified as *B. anthracis*. Indeed, the Australian Standard Method used in NATA-accredited laboratories for isolating *B. cereus* from foods draws attention to the fact that although *B. cereus* can be reported on the certificate of analysis, the methodology does not differentiate *B. cereus* and *B. thuringiensis*.

Identification of *B. cereus* isolates in most laboratories is based on a traditional morphological and biochemical classification scheme. If this approach is complemented with molecular techniques, classification of isolates can be more complicated. However, identification based on methods such

as gas chromatography–mass spectrometry, whole-cell fatty acid analysis, 16 s RNA gene sequencing, or other methods of genetic analysis is not commonly performed in food laboratories.

The best approach is to confirm that the isolate belongs to the *B. cereus* complex (Table 1) and then to differentiate *B. cereus* from the other species included in the complex (Table 2). When access to a fully equipped microbiology laboratory is limited, the miniaturized API 50 CHB kit (bioMérieux, Marcy-l'Étoile, France) can be used.

Characteristics of Foodborne/Meatborne Disease

The *B. cereus* emetic type of illness occurs 1–6 h after consuming contaminated food, whereas the diarrheal illness occurs 10–12 h after consumption. The symptoms of the emetic syndrome, which result from ingestion of preformed toxin in foods, are nausea and vomiting, occasionally followed by diarrhea. The illness can be confused with *Staphylococcus aureus* intoxication.

Diarrheal symptoms result from ingestion of vegetative cells or spores and their subsequent multiplication and toxin production within the intestinal tract. Although diarrheal toxins may be produced during exponential growth in foods, their sensitivity to low pH and proteolytic enzymes precludes survival of the toxin in the environment of the stomach. The symptoms of abdominal pain, watery diarrhea, and occasional nausea are indistinguishable from those arising from *Clostridium perfringens* infection.

Recovery is rapid for both syndromes, usually within 12–24 h. Very few fatalities have been reported. However, in a large outbreak associated with the consumption of vegetable puree that affected 44 elderly persons, 6 patients developed bloody diarrhea and 3 died of necrotic enteritis.

All people are believed to be susceptible to intoxication and infection, but the intensity of symptoms may vary between individuals. There are no known long-term effects of *B. cereus* intoxication or infection. Unusual forms of *B. cereus* illness, such as invasive infection in immunocompromised children following consumption of tea, have been reported. Also, toxigenic *B. cereus* complex organisms have been isolated from commercial ground roasted coffee, which suggests that coffee may be a vehicle for *B. cereus* food poisoning.

Generally, large numbers of *B. cereus* ($>10^5$ g^{-1} of food) are required to produce enough toxin to cause illness or infection. However, some strains may cause food poisoning at concentration as low as 10^3–10^4 bacteria per gram. Any food containing more than 10^4*B. cereus* per gram can be considered unsafe for consumption.

Most *B. cereus* food poisoning incidents result from eating cooked foods that have been cooled slowly and stored incorrectly. Outbreaks of emetic-type illness generally result from eating rice dishes or starchy foods such as potato and pasta. Outbreaks of diarrheal type illness result from eating a variety of foods, from vegetables and salads to meat and

Table 1 Confirmation of an isolate as a member of the *Bacillus cereus* complex

Characteristics	*Description*
Width of rod	1.0–1.2 μm, medium-length broad rods
Voges–Proskauer reaction	Positive
Catalase	Positive
Mannitol	Negative
Egg yolk turbidity factor	Positive (some strains could have delayed reaction)
Anaerobic growth	Positive
Spore[a]	Presence of oval spores stained green. Do not swell cell
Lipid granules[a]	Presence of lipid granules within cells, stained dark blue. Other parts of vegetative cells stained red

[a]Rapid confirmatory test includes staining with 5% malachite green for spores, with 0.3% Sudan black for presence of lipid granules, and with 0.5% safranin as a counterstain (Bennett and Belay, 2001).

casseroles, in which *B. cereus* organisms have grown to large numbers. Meat products that have been responsible for *B. cereus* diarrheal food poisoning outbreaks include sausages, meat loaf, barbecued chicken, forcemeat, tongue, beef stew, veal broth, and cooked turkey. In Hungary, there has been a clear association between the large number of *B. cereus* food poisoning cases and consumption of highly spiced meat dishes.

Bacillus thuringiensis has been isolated from an institutional food poisoning outbreak, which also involved Norwalk-like virus, but *B. mycoides* has not yet been linked to any outbreak, although some strains carry enterotoxin genes. Species of *Bacillus* that are not members of the *B. cereus* complex, namely *B. subtilus* and *B. licheniformis*, have been associated with foodborne illness. Cooked turkey, peppered steak, meat pasties, pies and rolls, meat curry, stuffed poultry meat, meat paté, and Greek meat dishes have been vehicles of *B. subtilis* food poisonings. Meat dishes incriminated in *B. licheniformis* food poisonings include meat and poultry pies and pasties, meat stews, curried meat and poultry, chicken with sauce, boiled sausages, meat paté, and cold cooked meats.

Mechanism of Pathogenicity

The toxins that induce the two syndromes are very different from one another. The emetic toxin is a 1.2-kDa dodecadepsipeptide and is preformed in the food. Also known as cereulide, this emetic toxin is believed to be enzymatically synthesized rather than being a gene product. Cereulide exhibits fungistatic action and so may give *B. cereus* a competitive advantage in food ecosystems. The toxin does not appear to be associated with sporulation. Nonspecific toxin activity assays, such as formation of vacuoles in Hep-2 or Vero cells in tissue culture, are used for detection of cereulide. When incubated with boar spermatozoa, cereulide disrupts the outer membrane of mitochondria, causing them to swell. The toxin does not cause fluid accumulation in rabbit and mouse ileal loops. It has been shown to stimulate the vagus afferent nerves by recognition of the 5-HT_3-receptor site. However, the mechanism of action of cereulide is still not defined.

The diarrheal syndrome is caused by two types of enterotoxin. These related toxins are the hemolytic BL enterotoxin (HBL) and the nonhemolytic enterotoxin (NHE). Both enterotoxins are composed of three proteins. The HBL enterotoxin can be detected by the *B. cereus* Enterotoxin Reverse Passive Latex Agglutination (BCET-RPLA) test kit from Oxoid (Unipath, Basingstoke, UK). The L2 component is the antigen detected by this kit. This protein is not the enterotoxigenic component; the B component is. These two components form a complex that produces the biological effect.

The NHE enterotoxin, which is also known as the *Bacillus* diarrheal enterotoxin or BDE, can be detected by the TECRA *Bacillus* Diarrheal Enterotoxin Visual Immunoassay (VIA) kit (Tecra Diagnostics, Roseville, Australia). The TECRA VIA kit detects the 40-kDa and 41-kDa nontoxic components of the NHE enterotoxin. A third type of toxin, enterotoxin T, has been cloned and sequenced. It has limited homology with the nucleotide sequence of the enterotoxin B component of the HBL toxin, but its biological significance remains to be determined.

Strains of *B. cereus* that produce emetic toxin may also produce one or both of the diarrheal enterotoxins. This explains the occasional manifestation of diarrhea in emetic intoxications. Because cereulide is very stable to heat, low pH, and proteolytic enzymes, preformed toxin in foods is unlikely to be inactivated during passage through the stomach. Cereulide is not antigenically active and no ELISA-style commercial test kit is available for easy detection of the emetic toxin. Only very specialized laboratories with tissue culture capability and specialized skills have been able to detect and quantify this toxin. However, recently it has been shown that emetic toxin can be accurately quantified by high performance liquid chromatography (HPLC)–mass spectrometry. LC–MS/MS techniques have now been developed to detect cereulide.

Epidemiology

The true burden of illness acquired from food is unknown, because episodes involving less commonly identified pathogens such as *B. cereus* are less likely to have their etiologies confirmed; these organisms are not always considered in clinical, epidemiological, and laboratory investigations of food-associated illness; and they commonly cause sporadic cases rather than major outbreaks. Illness associated with food products may also be underreported, because few of those affected seek medical attention owing to the mild nature and short duration of symptoms.

Food poisoning caused by *B. cereus* is recognized by symptoms such as vomiting, cramps, abdominal pain, and diarrhea. The order in which symptoms are experienced and the incubation period between consumption of suspected food and onset of symptoms are important for initial diagnosis of food poisoning. Other information that can assist with epidemiological investigations are details of recent food consumption before the episode, attack rates relating to types of food consumed, and isolation of *Bacillus* organisms from feces or vomit during the acute stage of the illness. Demonstration of enterotoxin in fecal samples further assists the diagnosis.

Bacillus cereus is not part of the normal gut flora. The presence of these organisms in feces could represent ingestion of vegetative cells or spores in normal food intake. In healthy individuals, counts are usually low or below the level of detection. However, after a bout of illness, up to 10^9 CFU g^{-1} can be found in feces. One or both types of enterotoxin can be demonstrated from fecal homogenates if both the Oxoid and TECRA kits are used for detection.

Typing of *B. cereus* isolated from food poisoning episodes can be useful in understanding the epidemiology of outbreaks. So far, serotyping of the flagellar (H) antigens has been used. It has been shown that the H1 flagellar type is more common (approximately 70%) in emetic than in diarrheal types of *Bacillus* food poisonings. In one outbreak, H26 was found to be the common type. However, overall the diarrheagenic types were too inconsistent for H typing to be of value. The H antisera are not commercially available and the typing scheme is used routinely only in the UK.

Plasmid profiling, phage typing, and biotyping based on biochemical reactions have also been used with differing degrees of success. Information published before 1984 showed

that certain serotypes of emetic toxin producers are incapable of hydrolyzing starch or fermenting glycogen, whereas diarrheagenic strains tend to ferment salicin. Recently, molecular fingerprinting methods based on randomly amplified polymorphic DNA (RAPD)-polymerase chain reaction (PCR) and multiplex RAPD–PCR have been found to be useful in typing isolates commonly involved in outbreaks.

Control and Preventive Measures

Although *B. cereus* is found in many foods, the ingestion of small numbers in ready-to-eat foods will not cause illness. The vegetative form is inactivated by most cooking procedures, but problems remain with the survival and subsequent outgrowth of spores during inadequate cooling and storage, particularly of moist protein-based foods and rice. For the occurrence of food poisoning, large numbers of enterotoxigenic *B. cereus* cells must be present in the food ($>10^5$ CFU g^{-1}); hence, it is important that control measures should be directed toward effective temperature management. Cooked foods should, therefore, be stored at >60 °C or cooled rapidly and stored under refrigeration (<5 °C). The Australia New Zealand Food Standards Code, Standard 3.2.2, for example, defines a two-step process of cooling foods: cool from 60 to 21 °C within 2 h, followed by cooling from 21 to 5 °C in a further 4-h time period. There is potential for *B. cereus* to be found in reheated foods if this cooling requirement is not followed, as reheating temperatures are usually not high enough to inactivate bacterial spores. The time taken for cooling and reheating thus provides an opportunity for bacteria to grow. Composite food products may be at a higher risk of *B. cereus* contamination due to the numerous ingredients that may carry spores. Spore-forming bacteria are problematic for the food industry as it is not always possible to apply enough heat during food processing to destroy spores without detrimental effect on desired qualities of the food. *Bacillus* species can represent up to 95% of the total bacteria in herbs and spices. A study of 45 isolates of *B. cereus* from spices found that all were capable of producing enterotoxins. Thus, the presence of *B. cereus* in spices could well result in food poisoning incidents when they are added to foods that are subjected to no or minimal heat treatment. Irradiation or fumigation of spices can be used to avoid such situations. Surveys of the distribution, prevalence, and concentration of *B. cereus* in a broad range of retail foods have been performed. In one such survey, *B. cereus* was not detected in chilled raw beef; however, chilled raw diced chicken had the highest prevalence and mean count of *B. cereus*, at 5.5% and 4.3 log cfu g^{-1}, respectively. In other surveys, *B. cereus* has been detected in poultry feed and in raw poultry meat. If *B. cereus* spores are present in raw foods, they will only pose a food safety risk if they survive the cooking process and the food is subsequently temperature abused for a sufficient time. Holding foods at refrigeration temperatures is the recommended means of controlling bacterial growth. However, it has been shown that psychrotolerant strains of *B. cereus* are able to grow in foods stored at 4–6 °C. A study of enterotoxigenic strains of *B. cereus* isolated from spices found that 50% and 87% were able to grow at 5 °C and 7 °C, respectively. Another study showed 53% *B. cereus* isolates from pasteurized milk were able to grow at 7 °C. These could compromise the safety of foods, even when they are stored at refrigeration temperatures. Cells of *B. cereus* can also be adapted to grow at low temperatures by prior storage at cold temperatures. Refrigeration temperatures less than 4 °C may be needed to avoid growth of *B. cereus* spores in pasteurized or cooked ready-to-eat foods.

Preservatives can be used to inhibit the growth of *B. cereus*. When preservatives are used in combination with reduced pH, increased salt concentrations, modified atmospheres, and/or heat treatment, the levels of preservatives can be reduced. Growth of *B. cereus* has been shown to be inhibited by 0.26% sorbic acid at pH 5.5 and by 0.39% potassium sorbate at pH 6.6. Nisin is commonly used to inhibit spore germination and growth in processed cheese, dairy desserts, canned foods, cured meats, and high-moisture baked products, such as crumpets and pikelets. Other antimicrobials that have an effect on *B. cereus* include benzoate, sorbate, ethylenediaminetetraacetic acid, and polyphosphates.

Most chemical sanitizers used routinely in the food industry will destroy vegetative *B. cereus* on food preparation surfaces. Sanitizers such as chlorine, iodophors, and peroxyacetic acid compounds are sporicidal. The commonly used quaternary ammonium compounds (QAC) are not sporicidal but will inhibit growth of both spores and vegetative cells. QAC are especially effective against Gram-positive bacteria. As with most chemicals, correct usage of sanitizers in the right concentrations and appropriate situations is important for their optimum effectiveness.

Spores are more resistant to radiation than vegetative cells are; however, *B. cereus* spores become sensitive to heating at 90 °C after irradiation at 4 kGy. It has been observed that *B. cereus* spores in vegetables and broth were more susceptible to gamma-irradiation than those in cereals. Gamma-irradiation of ready-to-eat foods with up to 10 kGy did not eliminate *B. cereus* spores, nor did such treatments damage their enterotoxin-coding genes.

Clostridium botulinum and Botulism

JW Austin, Tunney's Pasture, Ottawa, ON, Canada

This article is a revision of the previous edition article by JA Boerema, DM Broda, volume 2, pp 786–793, © 2004, Elsevier Ltd.

Botulism

Foodborne botulism is an intoxication resulting from consumption of foods in which *Clostridium botulinum* has grown and produced toxin. Depending on the amount of toxin ingested, the onset of botulism usually begins 18–36 h after ingesting toxin-containing food. As with other bacterial foodborne illnesses, the initial symptoms may include diarrhea and vomiting. Botulinum intoxication results in a descending symmetrical flaccid paralysis. Cranial nerves are affected initially, resulting in one or more of blurred and double vision, fixed and dilated pupils, ptosis (drooping eyelids), dysphonia (difficulty swallowing), dysphagia (difficulty speaking), and dry mouth. Paralysis may descend causing muscle weakness and paralysis affecting the diaphragm. Fatal cases are normally the result of respiratory failure. Botulism is frequently confused with other illnesses, especially in geographical areas where the disease has a low incidence. The symptoms of botulism are commonly confused with Guillain–Barré syndrome, stroke, and myasthenia gravis.

A diagnosis of botulism can be made by demonstration of botulinum neurotoxin in the patient's serum or the toxin and/or the organism in feces. As *C. botulinum* is not normally part of the human intestinal microflora, its isolation from feces or gastric contents, in association with classic symptoms of the disease, is diagnostic. Owing to improved medical care, such as the use of respiratory support systems and timely administration of antitoxin, the fatality rate due to botulism has fallen significantly in recent years.

In Europe, more than 2500 cases of foodborne botulism were reported in 1999–2000. Countries with a high reported incidence include Armenia, Azerbaijan, Belarus, Georgia, Poland, Russia, Turkey, and Uzbekistan. A smaller but significant number of cases are reported annually in France, Germany, Italy, China, and the USA. It should be noted that the true incidence of foodborne botulism is likely to be much higher, with underreporting being an issue. Foodborne botulism is not reportable in all countries and the efficiency with which potential outbreaks are investigated varies from country to country.

Being described first in 1976, infant botulism has become the most commonly reported form of botulism in the US, with approximately 80–100 cases occurring annually. Unlike foodborne botulism, infant botulism is caused by ingestion of spores, followed by colonization of the intestinal tract by *C. botulinum*, with *in situ* production of neurotoxin. A third form is wound botulism, wherein the organism infects tissue and produces toxin at a wound site. With no cases being reported in the UK before 2000, wound botulism has now become the most common form of botulism in the UK as a result of injection of illicit drugs. As only foodborne botulism relates to the microbiological safety of meat, further discussion will be limited to that type of illness.

Foodborne botulism is likely as old as food preservation. 'Sausage poisoning' was first seriously studied following an outbreak in Wildbad, Germany, in 1793, which resulted in 13 cases with 6 deaths. Although originally attributed to belladonna poisoning (caused by consumption of leaves or berries of the Nightshade plant), it was more widely accepted that the cause was consumption of a locally produced blood sausage 'Blunzen,' which was a pig stomach filled with blood and other ingredients, briefly boiled, and preserved by smoking. Following the Wildbad outbreak, the number of reported cases of sausage poisoning rapidly increased, prompting an 1829 study of the disease by the local health officer, Justinius Kerner, who described 230 cases of sausage poisoning over a period of 25 years. The illness became known as 'botulism' after '*botulus*,' the Latin word for sausage. Kerner's report was the first published complete description of the clinical symptoms of foodborne botulism.

An outbreak of botulism involving 34 cases caused by salted ham served at a gathering of amateur musicians in Ellezelles, Belgium, occurred in December 1895. The outbreak was investigated by Prof. E. Van Ermengem of the University of Ghent. Van Ermengem reported that portions of ham fed to mice, guinea pigs, and monkeys caused flaccid paralysis and death. Filtered extracts of ham had the same effects as macerated ham. Van Ermengem found an anaerobic sporulating bacillus, which was named *Bacillus botulinus*, in cultures of the ham as well as a culture of spleen from a deceased victim. Cultures and culture filtrates had the same effects as the macerated ham and ham filtrates, indicating involvement of a filterable toxin that was produced by the bacterium. In the investigation of this outbreak, Van Ermengem established that botulism was an intoxication, not an infection, and the toxin was produced by a spore-forming obligately anaerobic bacterium.

C. botulinum

Clostridium botulinum is the 'species' name assigned to an assemblage of anaerobic, spore-forming, rod-shaped bacteria, all of which produce botulinum neurotoxin that causes the severe neuroparalytic condition known as botulism. Morphologically, members of the *C. botulinum* assemblage are Gram-positive, anaerobic, motile rods, 4–6 μm by 0.9–1.2 μm in size with oval, subterminal spores (**Figure 1**).

Originally, all organisms known to produce botulinum neurotoxin were included in this species. There are seven types of *C. botulinum*, A through G, based on the serological specificity of the neurotoxin produced. Human botulism, including foodborne, wound, and infant botulism, is associated with

 doi:10.1016/B978-0-12-384731-7.00036-2

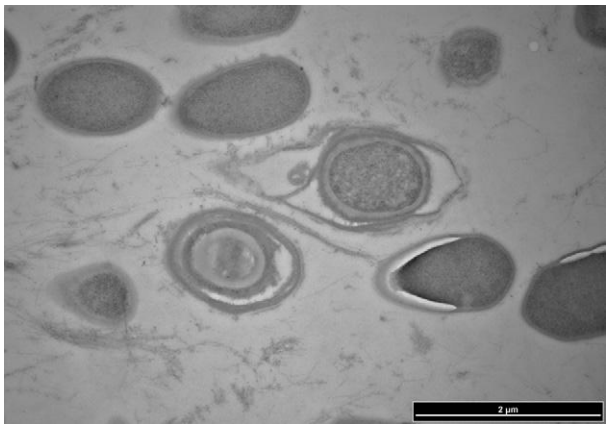

Figure 1 A transmission electron micrograph of a thin section through several vegetative cells and spores of *Clostridium botulinum*. Bar represents 2 µm.

types A, B, E, and F. Types C and D cause botulism in animals. To date, there is no direct evidence linking type G to the disease.

The species is also divided into four groups on the basis of physiological and genomic differences. Strains belonging to group I include all type A strains and proteolytic strains of types B and F. *Clostridium botulinum* Group II includes all type E strains and nonproteolytic strains of types B and F. *Clostridium botulinum* Group III includes all type C and D strains. *Clostridium botulinum* group IV, or *C. botulinum* type G, has been renamed *Clostridium argentinense*. A high degree of relatedness exists among strains within each group, but there is little relatedness between groups.

Group I strains are proteolytic and are typified by strains that produce neurotoxin type A. The optimal temperature for growth is 37 °C, with growth occurring between 10 °C and 48 °C. High levels of neurotoxin are typically produced in cultures. Spores of proteolytic strains are resistant to heat, with D_{100} °C values of approximately 25 min (the D value is the time required to inactivate 90% of the population at a given temperature). To inhibit growth, the pH must be less than 4.6, salt concentration more than 10%, or the water activity (a_w) less than 0.94.

Group II strains are nonproteolytic, have a lower optimum growth temperature (30 °C), and are psychrotolerant, that is to say, being capable of growth at temperatures as low as 3.0 °C. The spores have a much lower heat resistance than those of group I strains, with D_{100} °C values less than 0.1 min. Group II strains are inhibited at pH less than 5.0, salt concentrations more than 5%, or water activities (a_w) less than 0.97. The original strain isolated by van Ermengem in 1895 was probably nonproteolytic *C. botulinum* type B, and many type B cases in Europe are still due to strains of nonproteolytic *C. botulinum*. Recorded outbreaks of botulism involving nonproteolytic *C. botulinum* have most frequently been associated with meat, fish (e.g., salted, dried, vacuum, or smoked), and homemade foods prepared by the peoples of Alaska and northern Canada, such as aged beaver tail and paw, aged salmon roe and 'muktuk' (i.e., whale skin and fat).

Group III includes strains producing types C and D neurotoxins, which are not involved in human botulism but cause animal botulism. These strains are nonproteolytic, grow optimally at 40 °C, and do not grow at temperatures less than 15 °C. Group IV strains, which produce type G neurotoxin, grow optimally at 37 °C and have a minimal growth temperature of 10 °C.

These four groups, plus neurotoxin-producing strains of *Clostridium butyricum* type E and *Clostridium baratii* type F, make a total of six distinct genomic groups that produce botulinum neurotoxin. With a few exceptions, infant botulism is caused by proteolytic strains of *C. botulinum*. In the few exceptional cases, other clostridia (*C. baratii* producing type F toxin and *C. butyricum* producing type E toxin) have been implicated.

Isolation and Characterization of *C. botulinum*

The diagnosis of foodborne botulism is generally confirmed if, in addition to the clinical syndrome, botulinum toxin and/or viable *C. botulinum* are detected in a suspect food or a clinical specimen. Suitable specimens for toxin analysis are serum, feces, enema fluid, and stomach contents. The same specimens, except serum, are also suitable for the detection of *C. botulinum*. Botulinum toxin is detected by injecting serum or extracts from foods and clinical specimens into mice, and then observing them for characteristic symptoms including ruffled fur, labored breathing, and a pinched waist. These symptoms, combined with the absence of these symptoms in specimens neutralized with specific antisera, can be considered an earlier endpoint for the mouse assay negating the requirement for death as an endpoint.

The detection of *C. botulinum* involves anaerobic incubation of foods and clinical specimens in liquid media, and then subsequent toxin analysis. In major outbreaks or in the isolation of uncommon serotypes, the analyses are followed by the isolation of the incriminated microorganism. The customary procedure for isolation of *C. botulinum* from food is based on an enrichment procedure followed by detection and serotyping of toxin in culture supernatant fluid. Commonly used enrichment procedures include preliminary heat or ethanol treatments to destroy competing nonsporing bacteria, followed by anaerobic culture in media such as cooked meat medium or trypticase-peptone-glucose-yeast extract broth. Enrichment incubation is normally at temperatures between 26 °C and 35 °C for 5–10 days. A selective and differential agar medium containing antibiotics and egg yolk may be used for isolation of the organism from enrichment broth.

Botulinum Neurotoxin

The specificity of botulinum toxin for neurons makes it exquisitely toxic. The lethal dose of botulinum toxin for a 70 kg human is estimated to be approximately 0.09–0.15 µg intravenously or intramuscularly and 70 µg orally. Following ingestion, the toxin is absorbed through the gastric and upper intestinal mucosa from where it enters the bloodstream. Botulinum neurotoxin then gains access to the nervous system, where it blocks the release of the neurotransmitter acetylcholine,

preventing muscle contraction and thereby causing flaccid paralysis.

The active toxins are first synthesized as single polypeptides with low activity that require posttranslational proteolytic cleavage to form the active dichain molecule consisting of heavy and light chains joined together by a disulfide bridge. Strains of Group I *C. botulinum* are proteolytic and self-activate the toxin with endogenous proteases. However, Group II strains, all of which are considered nonproteolytic, need exogenous proteolytic enzymes or trypsin treatment to activate the toxin. The toxin is stable in acidic conditions (pH 3.5) but is easily inactivated in slightly alkaline conditions. The toxin is heat labile; consequently, normal cooking procedures should ensure a food's safety with respect to botulism. However, freezing does not destroy the toxin.

Incidence of *C. botulinum* in Meats

Spores of proteolytic and nonproteolytic *C. botulinum* are widespread in nature and are found in soils, aquatic sediments, and the gastrointestinal tracts of animals. Given the ubiquitous nature of *C. botulinum* spores, their presence in meats must be assumed and appropriate controls to prevent growth and toxin production must be applied. Information regarding the prevalence rates for *C. botulinum* on meat is not readily available, mainly because of the cost and difficulties of detecting *C. botulinum* in foods. However, the studies that have been done indicate that the incidence and levels of *C. botulinum* in meats are low, compared with fish and fishery products. Several studies indicate that the incidence of *C. botulinum* in meat samples is often less than 10%, with levels at approximately 1 spore per kg. The more frequent occurrence of botulism acquired from pork than from other meat products suggests more frequent contamination of pork than that of beef, lamb, and other meats. Toxin type B is typically implicated in cases of meat-borne botulism. Survey results reveal that nearly all toxin types identified from raw and semi-preserved meats were either A or B. The finding of low numbers of spores of *C. botulinum* in pig and cattle's feces indicates that clinically healthy animals occasionally carry *C. botulinum* spores. Thus, the contamination of carcasses with *C. botulinum* spores during carcass dressing seems likely.

Botulism Incidents Involving Meat Products

Home processing of meat is more common in continental Europe than in the UK or North America and an increased incidence of foodborne botulism, most frequently associated with meat products, has been observed in eastern European countries. Nonproteolytic type B strains are the etiological agents in most outbreaks of botulism in Germany, France, and Portugal that have been caused by home-prepared salted or cured hams. Homemade bottled pork meat is the main vehicle of botulism in Poland. Three incidents occurring in the UK and Ireland involved Polish nationals and were associated with the consumption of home-prepared meat products originating from Poland. Of 106 cases of botulism in Romania diagnosed during 2007–09, 86 (81.1%) were associated with the consumption of home-prepared pork products (ham, bacon, blood pudding, mosaic salami, raw sausages, and smoked-dried meat), whereas commercially canned products were involved in 20 cases (18.9%).

Most cases of botulism due to meat products in North America result from consumption of traditional northern foods by Inuit or Eskimos. Peccant foods include meat and fat from seal, whale, walrus, and beaver. Other than these northern foods, botulism from meat products is rare in Canada and the US. Commercial pate was the cause of two cases of botulism in Quebec in 1995, whereas commercial jarred pork caused a single case in Quebec in 2001. In July of 2007, an outbreak from commercially canned hotdog chili sauce caused 10 cases of botulism in Texas and Indiana. A 15-case botulism outbreak, also caused by chili, occurred in Texas in 2001. As both these cases involved chili, a food with several ingredients, it was not determined whether meat, or another ingredient, contributed the spores. Occasional single cases were reported in the US from home-prepared foods including stew and home-canned beef and peas; however, in these cases, it is also impossible to determine whether meat was the responsible ingredient.

Although home and artisanal production remain the principal causes of botulism outbreaks, the proportion of cases attributable to commercial products is increasing, especially in Europe, where recent outbreaks have been linked to widely distributed, commercially produced foods. Methods for preserving food products are changing, and fresh products that are vacuum-packed and refrigerated with extended shelf-lives, or products that are heat treated at temperatures and times too mild to inactivate *C. botulinum* spores, are increasing the risk of botulism from commercial foods.

Control of *C. botulinum* in Meats

Safe food production is based on either destroying spores of *C. botulinum* using a thermal process or inhibiting growth of the organism in foods, in combination with low storage temperatures and limited storage times. Incorporation of a combination of inhibitory factors such as reduced pH or water activity, added preservatives, and competing microflora provide multiple barriers and help processors to achieve a safe product. In addition to inhibition of growth of *C. botulinum*, the microbiological safety of foods also relies on good control and monitoring of processes throughout manufacture and distribution.

Refrigeration

The psychrotolerant nature of nonproteolytic strains of *C. botulinum* makes these strains of particular concern in refrigerated products. Psychrotrophic *C. botulinum* has the ability to survive mild heat treatment of minimally processed foods and may grow during cold storage. Growth of psychrotrophic *C. botulinum* occurs in response to extrinsic parameters such as storage at temperatures and redox potentials permissive for growth and parameters intrinsic to the food, such as pH and water activity.

Toxin formation by *C. botulinum* is both time and temperature dependent. At its lowest growth temperatures, it takes a *C. botulinum* strain many weeks to produce toxin. However, a slight rise in incubation temperature is accompanied by a rapid increase in growth rate of *C. botulinum* and a reduction in time to toxin detection. Storage of foods for several weeks at refrigeration temperatures is needed for toxigenesis by nonproteolytic strains. Thus, refrigerated products with a short shelf-life normally would not present significant risk. However, products with extended shelf-lives stored at refrigeration temperatures for extended periods may produce toxin by nonproteolytic strains of *C. botulinum*.

As strict temperature control of refrigerated products is often not maintained during their storage, distribution, display, and subsequent handling in domestic, food service, or institutional facilities, the likelihood of toxin production by nonproteolytic strains of *C. botulinum* in extended shelf-life products is increased. However, low-temperature storage cannot be reliably used as the sole means of controlling growth and toxin production by *C. botulinum*.

Consumer demands for ready-to-eat convenience foods, combined with an emphasis on little or no preservatives and less processing, have placed a new focus on *C. botulinum*. The lack of a heat treatment sufficient to destroy spores of *C. botulinum*, use of packaging that mostly or totally exclude oxygen, prolonged storage at chill temperatures, and the lack of heating before consumption combine to increase the risk of botulism from these foods. These products often do not use additional preservative systems such as reduced pH or water activity. In those foods where such treatment would adversely affect product quality, other controls, such as reduced water activity or acidification, should be considered. Subinhibitory levels of several factors can be combined to control growth of *C. botulinum* by application of what is known as the hurdle concept.

Thermal Processing

A great number of botulism outbreaks during the early twentieth century in Europe and North America were associated with the widening use of canning and bottling processes to extend shelf-life. This led to the development and enforcement of the 'botulinum cook' for commercial processing. The 'botulinum cook' was developed as a heat process for low acid foods (>pH 4.6) in order to destroy the spores of *C. botulinum*, and its widespread use led to substantial reductions in the number of botulism outbreaks. Spores are a dormant form of the organism that are resistant to high temperatures, high pressure, UV light, and desiccation. The 'botulinum cook' process is designed to reduce the population of the most resistant *C. botulinum* spores to 10^{-12} of their original numbers. The decimal reduction time (D value) is the time in minutes at a given temperature in order to produce a one log reduction in *C. botulinum* spore number. Much higher temperatures are required to inactivate spores of Group I strains, compared with those of Group II. Group I strains typically have D values in the range of 0.21 min at 121 °C, whereas Group II strains have D values of 2.4 min at 82.2 °C. Botulism in canned foods results from underprocessing or postprocess contamination. In the case of underprocessing, it is the heat-resistant proteolytic strains that are of concern with regard to product safety. *C. botulinum* is controlled in shelf-stable canned meats using thermal processing.

Redox Potential and Atmosphere

C. botulinum is a strict anaerobe. However, even within foods exposed to oxygen, the redox potential is often low enough to support the growth of this organism. Vacuum packaging and modified atmosphere packaging were developed for the extension of product shelf-life, but concerns have been raised about risks from these products with respect to botulism. In modified atmosphere packaging of certain meat products, the air in the headspace of the package is replaced by CO_2 and N_2, resulting in a low O_2 environment. There is concern about the safety of these products with respect to the potential for growth and toxin production by nonproteolytic *C. botulinum*. Vacuum or modified atmosphere packaging in atmospheres without O_2 restricts the growth of aerobic spoilage bacteria but not of clostridia or other anaerobic bacteria. There have been a number of reports describing low temperature spoilage of vacuum-packaged meats caused by psychrotolerant *Clostridium* spp. These incidents demonstrate that conditions within a chilled vacuum pack may select for the growth of psychrotolerant clostridia. Outbreaks of type E botulism in the 1960s were linked to vacuum-packed smoked fish. Studies have shown no difference in the rate of toxin production in high- and low-oxygen barrier films. However, it is of concern that the use of high-barrier oxygen film may increase the organoleptic acceptability of a toxic product. Inhibition of competing organisms may permit toxin production by *C. botulinum* in refrigerated modified atmosphere packaged foods without obvious sensory evidence of spoilage.

pH

C. botulinum will not grow in highly acidic foods that have a pH value less than 4.6. Consequently, acidification is widely used to control the growth of *C. botulinum* in food products. Cases of botulism have been linked to the consumption of high-acid foods in which the growth of yeasts or molds has raised the pH sufficiently to allow the growth of *C. botulinum*. In general, proteolytic strains of *C. botulinum* are more tolerant of acidic conditions than the nonproteolytic strains.

Water Activity

The generally accepted minimum a_w for growth of *C. botulinum* in foods, under otherwise optimal conditions, is 0.94 and 0.97 for proteolytic and nonproteolytic strains, respectively. The values 0.94 and 0.97 correspond to salt concentrations of approximately 10% and 5%, respectively. Today, high salt concentrations in foods are unacceptable to most consumers. Lower salt concentrations can, however, be effective when used in combination with other inhibitory factors such as pH and nitrite.

Preservatives

Nitrite

Sodium nitrite is a multifunctional food additive, responsible for the characteristic color and flavor associated with cured meats and at the same time providing protection against growth and toxin formation by *C. botulinum* in cured meats subjected to temperature abuse. The exact mechanism of botulinum inhibition by nitrite is not known. Its efficacy depends on interactions involving pH, salt, heat treatment, storage temperature and time, and the composition of the food matrix. It has been shown that nitrite interacts with nitrogenous compounds to form carcinogenic nitrosamines and intestinal bacteria mediate the formation of nitrosamines in the body. As a result, in recent years, consumer and regulatory pressure has mounted to reduce the levels of nitrite in processed meats. The maximum concentration of sodium nitrite ($NaNO_2$) in meat products typically is 150 mg kg^{-1}. *C. botulinum* in cured meat products is primarily controlled by refrigeration and the use of nitrite. The control measure to apply is the addition of a sufficient quantity of nitrite salt (defined by the sodium nitrite ($NaNO_2$) concentration).

Nisin

Bacteriocins, antimicrobial peptides that inhibit the growth of a broad spectrum of Gram-positive microorganisms, offer a natural alternative as biopreservatives for safeguarding minimally processed foods. Nisin is a peptide antibiotic produced by some strains of *Lactococcus lactis*. It has been used as a food preservative in many countries for more than 50 years and has been granted generally regarded as safe status. Nisin is not only active against closely related lactic strains but is also effective for inhibiting the growth of the foodborne pathogens *Listeria monocytogenes*, *Staphylococcus aureus*, and *C. botulinum* under certain conditions. Nisin sensitivity varies among *C. botulinum* strains. Growth conditions and food components also affect nisin's effectiveness. Factors decreasing nisin's ability to inhibit *C. botulinum* growth include a low-acid environment and high protein and phospholipid concentrations in foods.

Competing Microorganisms

In most foods, competing organisms, when present, often grow more rapidly than *C. botulinum*, as this microorganism is a poor competitor. The growth of organisms such as the lactic acid bacteria lowers the pH and, consequently, inhibits the growth of *C. botulinum*. Strains of lactic acid bacteria have been found to produce bacteriocins (low molecular weight proteins) that are inhibitory to *C. botulinum*. These strains hold promise for use in the food industry, where they may provide 'natural' protection against *C. botulinum* hazards.

Hurdle Technology

Although hurdles to growth of *C. botulinum* have been reviewed separately, they are typically used in combination. Thermal processing resulting in a 12 log reduction of *C. botulinum* spores, although acceptable for canned foods, would render many meat products inedible. Reliance on refrigerated storage alone results in the risk that a food may be temperature abused.

Perishable meat products rely on chilling, in combination with intrinsic factors, in order to control growth of *C. botulinum*. Products such as luncheon meats in hermetically sealed containers receive a mild heat treatment but remain shelf stable due to refrigerated storage, and nitrites and salt are added to inhibit growth of *C. botulinum*. Bacon and some fermented, undried sausages are preserved by chilling, in combination with nitrite, and reduced water activity and pH.

Shelf-stable meat products rely on intrinsic factors to prevent growth of *C. botulinum*. For example, Italian mortadella relies on a combination of a thermal process, reduced water activity, low pH, and the addition of nitrite and smoke. Other meat products rely more on a limited number of hurdles. For example, canned unsalted meat relies only on the thermal process, whereas Parma-type ham relies primarily on reduction of water activity with salt, with a lesser reliance on reduced pH.

This article is a revision of the previous edition article by DM Broda, JA Boerema, volume 2, pp 793–798, © 2004, Elsevier Ltd.

Glossary

Enterotoxin A toxin produced in the intestine.
Gastroenteritis The inflammation of stomach or intestine.
Plasmid A genetic element separate from the nucleus and which is not required for growth. The genes carried in plasmids provide antibiotic resistance or mediate toxin formation.
Polymerase chain reaction (PCR) A laboratory method of amplifying specific gene(s) that may be involved in virulence by certain bacteria.
Spore A dormant structure produced by bacteria which is usually resistant to physical agents such as heat.

Introduction

Clostridium perfringens is an opportunistic pathogen capable of causing a broad spectrum of human and veterinary disease conditions, including gas gangrene, meningitis, appendicitis, respiratory and urinary tract infections, septicemia, sudden infant death syndrome, and a variety of gastrointestinal disorders. The association of this microorganism with outbreaks of food poisoning has been known since the turn of the nineteenth century, but its etiological role as a causative agent of human foodborne disease was not established until the 1940s. Today, *C. perfringens* is recognized as a principal causative agent of two forms of foodborne disease: *C. perfringens* type A gastroenteritis and *C. perfringens* type C necrotic enteritis. The symptoms of the gastroenteritis are usually mild and rarely fatal; however, owing to its high incidence this condition is a substantial public health concern. The necrotic enteritis, also known as pigbel or darmbrand, is a severe disease with a mortality rate of up to 25%, but it is exceptionally rare in Western countries. Consequently, the emphasis in this article will be on *C. perfringens* type A gastroenteritis and its causative agent(s).

Characteristics of *C. Perfringens*

Clostridium perfringens is a Gram-positive, spore-forming, encapsulated microorganism.

Vegetative cells of *C. perfringens* are straight rods with blunt ends, occurring singly or in pairs. Spores are large and oval, distending the cell at either the central or subterminal position. Spores are rarely observed in foods and/or in laboratory cultures.

Clostridium perfringens is proteolytic and saccharolytic. The majority of *C. perfringens* strains reduce sulfite to sulfide, hydrolyze gelatin, reduce nitrate to nitrite, produce acid from lactose, are lecithinase-positive and ferment sucrose. In contrast to other sulfite-reducing anaerobes, *C. perfringens* is nonmotile.

Clostridium perfringens grows optimally at temperatures between 43 and 47 °C, and at these temperatures it has a generation time of less than 10 min. Typically, the growth range is from 15 to 50 °C. Vegetative cells of *C. perfringens* are sensitive to low temperatures, such as those employed for refrigerated storage of foods. Generally, *C. perfringens* cells are sensitive to heat and in laboratory media are easily destroyed by exposure to temperatures above 55 °C. However, the sensitivity of vegetative cells to heat is thought to be strain specific. Spores of *C. perfringens* are relatively cold resistant and can survive refrigeration or freezing at −18 °C. *C. perfringens* spores are renowned for their high resistance to heat, with D_{95} °C values (the time in minutes at 95 °C required for a 90% reduction in a population of viable spores) exceeding 200 min in meat-based media. Heat resistance of *C. perfringens* spores varies depending on both genetic and environmental factors. Reports indicate that strains implicated in *C. perfringens* type A gastroenteritis outbreaks may show D_{95} °C values 60 times higher than those obtained for nonoutbreak strains. This reflects the location of the *cpe* gene on the chromosome or on a plasmid (see section Molecular Methods).

Clostridium perfringens grows optimally at pH values between 6.0 and 7.0, and its growth is inhibited at pH values below 5 and above 8.3. The minimum water activity (a_w) that will permit growth of *C. perfringens* is between 0.93 and 0.97. The organism is relatively tolerant to oxygen but will not produce colonies on the surface of solid media exposed to air. Under carbon dioxide atmospheres, the growth of *C. perfringens* cells is somewhat inhibited but not completely prevented. Growth is completely inhibited by either 6–8% NaCl, 10 000 ppm $NaNO_3$, or 400 ppm $NaNO_2$. However, when these salts are used together, the inhibition of growth occurs with substantially lower concentration of each salt.

Clostridium perfringens produces a variety of toxins that are detrimental to humans and animals. Of the greatest significance to food-borne disease is *C. perfringens* enterotoxin (CPE), which belongs to a group of endotoxin that are produced inside the bacterial cell. CPE is a polypeptide of 319 amino acids and has a molecular weight of approximately 35 kDa. It is a unique protein that has only limited amino acid sequence homology with other bacterial proteins. CPE is sensitive to heat, and it is readily inactivated by 5 min exposure to a

temperature of 60 °C. In contrast to vegetative cells of *C. perfringens*, CPE retains its biological activity during refrigerated storage. Intracellular synthesis of CPE occurs throughout the various growth stages of the bacterium but increases exponentially (at least 1500-fold) during sporulation. CPE accumulates in the cytoplasm of the sporulating cell and is released only when *C. perfringens* cells lyse to free mature spores.

In addition to CPE, the organism produces at least 15 extracellular toxins or exotoxins, with novel *C. perfringens* toxins continuing to be discovered. Exotoxins are thought not to be responsible for the symptoms of gastroenteritis, but β1 and β2 toxins induce hemorrhagic necrosis of the intestinal mucosa, which is characteristic of food-borne necrotic enteritis. On the basis of mouse lethality tests and according to the various combinations of four major exotoxins (alpha, beta, epsilon, and iota), *C. perfringens* is divided into five toxinotypes, A–E. Each toxinotype causes distinct disease symptoms, with *C. perfringens* type A being associated with either gas gangrene or gastroenteritis symptoms, and *C. perfringens* type C being responsible for necrotic enteritis symptoms.

Clostridium perfringens toxinotypes correspond to a diverse range of genotypes. The full genome sequence of *C. perfringens* identified a total of 25 genes that contribute to the organism's virulence. Genotypes of the majority of strains include the *plc* gene that encodes alpha toxin and, at the same time, none, one or two genes encoding other type-specific exotoxins. Each genotype may or may not carry the *cpe* gene. *C. perfringens* exotoxin genes reside either on the chromosome or on large plasmids that occur singly or in low copy numbers. Similarly, the genome location of the gene encoding CPE may vary, with the *cpe* gene residing on the chromosome in *C. perfringens* strains associated with foodborne disease but positioned on a plasmid in strains associated with nonfoodborne gastrointestinal disorders (e.g., antibiotic-associated or sporadic gastroenteritis) or in strains of veterinary origin. When located chromosomally, the *cpe* gene can be found on mobile genetic elements, such as a lysogenized phage or a transposon.

Isolation and Identification

Quantitative recovery of viable *C. perfringens* cells from, and detection of CPE in, food and/or patient specimens are key steps for the diagnosis of *C. perfringens* gastroenteritis. In addition, molecular methods are increasingly being used for the detection of *C. perfringens* toxin genes and epidemiological typing of *C. perfringens* isolates.

Conventional Methods

The procedure for enumeration of *C. perfringens* in meat is based on initial recovery of microorganism on solid media for sulfite-reducing anaerobes, followed by confirmation of colonies as *C. perfringens* with further biochemical tests.

Tryptose sulfite cycloserine (TSC) agar is the medium presently recommended by both Association of Official Analytical Chemists (AOAC) International and the International Organization for Standardization (ISO) for use in quantitative recovery of *C. perfringens*. The initial selection is on TSC agar with or without egg yolk. Egg yolk has traditionally been added to media to enable detection of lecithinase activity previously thought to be characteristic of *C. perfringens*. However, it is now recognized that not all strains of *C. perfringens* are lecithinase-positive. Consequently, the lecithinase reaction is not required as a differential property of the TSC agar, and the egg yolk can be omitted. It should be noted, however, that adding lysozyme or egg yolk to the medium may enhance the recovery of thermally injured *C. perfringens* spores. TSC agar contains the antibiotic cycloserine, which suppresses the growth of facultative anaerobes. Ferric ammonium citrate incorporated into the medium reacts with the sulfide that is produced during sulfite reduction, forming a black iron sulfide precipitate. Black colonies that develop during incubation are reported as sulfite-reducing anaerobes. ISO recommends that TSC agar be inoculated using the pour plate method. Alternatively, the medium can be inoculated using the spread plate method and overlayed with a small volume of TSC agar. Incubation is at 37 °C under anaerobic conditions.

Owing to the sensitivity of *C. perfringens* to low temperatures, food samples to be tested for the presence of this microorganism must not be refrigerated or frozen before analysis. Instead, samples should be tested as soon as possible after collection. However, activation of the heat-resistant spores of *C. perfringens* is heat dependent and only approximately 4% of spores of food-poisoning strains will germinate without prior heat shock. Patient specimens should be heat treated before plating on TSC agar to maximize the recovery of spores.

Isolates recovered from TSC agar are subsequently screened with biochemical tests for motility, nitrate reduction, lactose fermentation, and gelatin hydrolysis. Isolates that are nonmotile, reduce nitrate, ferment lactose, and hydrolyze gelatin are identified as *C. perfringens*. Species-level identification of *C. perfringens* can be achieved using commercially available miniaturized test kits, for example, the RAPID ID 32A (bioMérieux, Marcy-l'Etoile, France) or BBL Crystal Anaerobe kits.

Detection of *C. Perfringens* Enterotoxin

The detection of CPE in the stools of patients with food poisoning enables a definitive diagnosis of *C. perfringens* gastroenteritis to be made. CPE can be routinely detected in stool specimens by enzyme-linked immunosorbent assay (ELISA) and reverse passive latex agglutination (RPLA) assay. These assays are capable of detecting as little as 2–4 ng g^{-1} CPE in fecal material, well below the levels of 1 μg g^{-1} that are expected to occur in stool specimens from *C. perfringens* gastroenteritis patients. Even higher levels of assay sensitivity for CPE detection can be achieved with Western immunoblotting.

Molecular Methods

A number of DNA-based methods exist for the detection and identification of *C. perfringens*. These methods include polymerase chain reaction (PCR) assays and gene probes for the specific detection of the *cpe* gene to establish the

isolates 'or foods' potential for toxigenicity. Multiplex PCR has been developed for simultaneous detection of several toxins, including exotoxins and CPE, and this assay can be used to replace conventional toxin typing. Recently, a duplex PCR assay was described for differentiation of *C. perfringens* type A isolates carrying chromosomal *cpe* genes from isolates carrying this gene on a plasmid. DNA-based methods also include real-time PCR and a PCR assay for the detection and/or identification of *C. perfringens* using 16S rDNA-based specific primers.

Plasmid profiling, phage typing, ribotyping, pulsed-field gel electrophoresis (PFGE), and amplification of fragment length polymorphism (AFLP) analysis have been used for tracing *C. perfringens* isolates from patients back to the outbreak food sources. While ribotyping, PFGE and AFLP each demonstrate significant discriminatory power for strain-specific differentiation of *C. perfringens* isolates, the genetic diversity of *C. perfringens* strains and necessary expertise may prove inhibitory for successful use of these methods in routine epidemiological investigations. As both CPE-producing and CPE-negative *C. perfringens* strains may possess indistinguishable fingerprints, it is recommended that before traceback studies, the potential for CPE production by outbreak isolates is established using a *cpe* gene detection assay.

Characteristics of *C. Perfringens* Foodborne Disease

In contrast to foodborne botulism, the symptoms of *C. perfringens* foodborne disease develop after ingestion of food containing viable *C. perfringens* cells rather than preformed toxins. *C. perfringens* type A gastroenteritis is usually characterized by profuse diarrhea and cramping in the lower abdomen. The onset of the disease usually begins 6–12 h after the ingestion of foods containing at least 4×10^9–6×10^9 *C. perfringens* vegetative cells (equivalent to 8–10 mg of CPE). Vomiting and fever are uncommon. The symptoms lessen after a further 24 h and usually resolve spontaneously. The mortality rates associated with *C. perfringens* type A gastroenteritis are low, but death may occur in immunocompromised patients, for example, the elderly. Gastroenteritis symptoms caused by *C. perfringens* type A and *Bacillus cereus* are virtually indistinguishable. *Clostridium perfringens* type C necrotic enteritis takes the form of severe gastroenteritis characterized by bloody diarrhea, cramps, nausea, vomiting, and necrotic inflammation of the small intestine. The disease has a high mortality rate of up to 25%.

Traditionally, a diagnosis of *C. perfringens* type A gastroenteritis was made on the basis of clinical signs and lesions as well as quantitative recovery of *C. perfringens* from patient specimens and food specimens. *Clostridium perfringens* was typically verified as a causative agent of the disease when (1) *C. perfringens* was present in implicated food at a level of 10^5 colony-forming units (CFU) g^{-1} or higher; (2) *C. perfringens* was present in patients' stool samples at level of 10^6 CFU g^{-1} or higher; and (3) serotyping indicated similarity of serotypes of *C. perfringens* strains isolated from food and stools of patients. However, the traditional diagnostic scheme has significant drawbacks, such as occasional carriage of *C. perfringens* in stools of asymptomatic individuals at levels approaching those present in clinical specimens, or untypeability with commercially available antisera of many outbreak strains owing to the antigenic heterogeneity of *C. perfringens*. Consequently, the criteria for diagnosis of *C. perfringens* type A gastroenteritis were expanded to include evidence for the presence of CPE in stool specimens of affected patients. More recently, it was proposed that diagnosis may also be helped by the detection of the *cpe* gene in food and fecal material, and by establishing the chromosomal location of this gene in outbreak strains.

Mechanism of Pathogenicity

The events leading to pathological changes within the gastrointestinal tract that later manifest themselves as symptoms of gastroenteritis are typically initiated with the ingestion of vegetative cells of *C. perfringens*. It is thought that the majority of these cells survive exposure to the acidic environment of the stomach and start to multiply rapidly once the alkaline environment of the small intestine is reached. Sporulation of *C. perfringens* occurs readily in the presence of human intestinal contents. CPE accumulates inside the cell during the sporulation and is subsequently released into the lumen.

In the small intestine, CPE interacts with several proteins of the epithelial cells. The toxin binds initially to a claudin protein receptor of the intestinal cell brush border and forms part of a small, and then large, protein complex that becomes associated with the cell membrane. On formation of the large complex, cell membrane permeability is affected, so that leakage of small molecules occurs and, subsequently, synthesis of DNA, RNA, and protein is inhibited. These changes result directly in the death of the affected epithelial cells.

CPE induces a number of morphological changes in the small intestine. The histopathological effects include formation of blebs; shortening, desquamation, and necrosis of the tips of the intestinal villi; and loss of the folded configuration of the brush border. It is thought that the histopathological damage is responsible for the disturbances to fluid and electrolyte transport in the intestinal loops that eventually manifest as acute diarrhea.

Epidemiology

Reservoirs of *C. Perfringens*

Clostridium perfringens is one of the most widely distributed pathogenic bacteria and can be found in soil, dust, water, and air of natural environments. *Clostridium perfringens* type A occurs in soil at levels of 10^3–10^4 CFU g^{-1}. Strains of *C. perfringens* known to cause gastroenteritis in humans are normal inhabitants of the intestinal tract of humans and animals, occurring in feces of healthy or asymptomatic individuals at levels of up to 10^5 CFU g^{-1}.

Food reservoirs of *C. perfringens* include raw beef, chicken and pork, fresh and vacuum-packed fish and shellfish, raw fruit and vegetables, soups, sauces and gravy mixes, cheese, and spices. It is thought that approximately 50% of consumer-ready items of raw meat and poultry contain *C. perfringens*. The organism may be found on the surface of beef, pork, and lamb carcasses and is also recognized as an intrinsic organism

present in the deep tissues or internal organs (spleen, liver, kidneys or lymph nodes) of slaughter animals.

Traditionally, the widespread presence of *C. perfringens* in the environment and foods was thought to explain the high prevalence of *C. perfringens* type A food poisoning. However, early surveys rarely identified the potential for toxigenicity of clostridial isolates. Retrospective screening of *C. perfringens* isolates showed that nearly half of the strains recovered during outbreaks did not carry the *cpe* gene and were thus genetically incapable of causing the disease. At present, it is estimated that less than 5% of the total population of culturable *C. perfringens* strains possess the *cpe* gene. Recently, none of the *C. perfringens* isolates that were obtained in a comprehensive survey of retail foods in the US was found to carry the *cpe* gene. Consequently, high incidence rates obtained for *C. perfringens* in foods and the environment may be of little relevance to food safety. At present, the reservoirs for *C. perfringens* strains that cause human gastroenteritis remain unknown. A novel proposal is that humans are a source of enterotoxigenic foodborne isolates.

Studies have indicated that despite the widespread presence of *C. perfringens* in domestic animals, only a small proportion of veterinary strains are CPE positive, carry the chromosomal *cpe* gene, or produce heat-resistant spores. Depending on the species, the incidence of *C. perfringens* strains capable of CPE production in domestic animals in the US ranges from 0% to 22%, with prevalence in steers/heifers reaching 1.0% and that in cows/bulls reaching 2.7%. Only a few of these CPE-positive strains have a chromosomally located *cpe* gene. Consequently, food animals have a lower potential for causing *C. perfringens* gastroenteritis than was initially thought.

Characteristics of Outbreaks

Outbreaks of *C. perfringens* type A gastroenteritis typically occur when meat or poultry containing *C. perfringens* spores are cooked in advance, left to cool slowly with inadequate refrigeration, and not reheated adequately before serving. The dishes are usually prepared in a manner that favors the development of anaerobic conditions, for example, as rolled roasts or in large vats. The outbreaks are large, with a median size of 25 or more cases, and frequently result from consumption of food cooked by commercial catering companies. Commercial meat processors are rarely implicated in outbreaks of *C. perfringens* type A gastroenteritis.

It is thought that, under the conditions just described, heat-resistant *C. perfringens* spores will survive and become activated during the cooking process. These spores will germinate, outgrow, and multiply rapidly after the temperature of the prepared dish falls below 50 °C and before it reaches ~15 °C. The resulting vegetative cells, now present in the dish at 10^6–10^7 cells per gram, will not be destroyed in the absence of adequate refrigeration and/or during inadequate reheating.

The usual vehicles for *C. perfringens* gastroenteritis outbreaks are meat and poultry dishes. Between 1973 and 1987, approximately 30% of *C. perfringens* outbreaks in the US were associated with consumption of beef, whereas chicken and turkey dishes accounted for approximately 15% of outbreaks. More recently, meat and poultry dishes were confirmed as vehicles in approximately one-third of all reported cases of foodborne *C. perfringens* gastroenteritis in the US.

Incidence of the Disease

Of the three spore-forming bacteria most commonly associated with foodborne disease, that is, *Bacillus cereus*, *Clostridium botulinum*, and *C. perfringens*, *C. perfringens* causes the most outbreaks and cases. *C. perfringens* gastroenteritis is the second most common cause of cases of bacterial foodborne disease in the US after *Salmonella*.

In Europe also, *C. perfringens* gastroenteritis is the second most common cause of foodborne disease after *Salmonella*. In 2000, 22% of deaths due to foodborne disease in England and Wales were caused by *C. perfringens*. In the UK, the fall in the numbers of cases and deaths due to *C. perfringens* gastroenteritis observed during the past decade is thought to be due to a decline in the consumption of red meats.

In many countries, *C. perfringens* type A gastroenteritis is not a notifiable disease. Because of lack of adequate reporting, the incidence of this disease and its economic impact are likely to be underestimated.

Control and Preventive Measures

A number of factors contribute to the ability of *C. perfringens* to cause outbreaks of foodborne disease. Of these factors, its widespread presence in foods and the environment, its formation of heat-resistant spores and its short generation times significantly influence the approach to control of this microorganism, and the disease it causes.

Because *C. perfringens* is prevalent in the farm environment, the organism is frequently detected in slaughter animals, on dressed carcasses and in abattoir environments. Traditionally, it was thought that during slaughter and dressing, carcasses inevitably became contaminated with *C. perfringens* spores because of their transfer to the carcass as opening cuts are made in the skin. Consequently, the possibility of raw meat being free from *C. perfringens* was thought to be unrealistic and its presence in meat was regarded as unavoidable. Now it is recognized that only a small proportion of *C. perfringens* strains from food animals and abattoir environments are capable of causing foodborne disease, control of carcass/cut contamination with *C. perfringens* spores may become feasible, by identification of farm and/or abattoir reservoirs of contamination with outbreak strains. Once these reservoirs are identified, specific control measures can be developed to reduce the initial contamination of raw meat and eliminate transfer of clostridial spores to processed meats. Similarly, following the identification of reservoirs of foodborne disease-causing *C. perfringens* strains, control measures could be directed at specific operations within the retail sector, commercial catering facilities, and/or food industries.

In the past, removal or inactivation of *C. perfringens* spores present on carcasses or cuts proved unsuccessful. Unless extreme measures are employed, various carcass decontamination treatments frequently result in only approximately 1 log reductions in the levels of *C. perfringens* spores. With the high

D_{95} °C values of some strains, the use of thermal treatments to destroy *C. perfringens* spores without impairing the desired organoleptic attributes and palatability of prepared foods is generally not possible.

Traditionally, the approach to control of *C. perfringens* type A gastroenteritis centered on inhibiting the multiplication of the organism in food. The most practical way of preventing *C. perfringens* gastroenteritis appears to be by preparing meat and poultry dishes shortly before they are served, and by adequate cooling, refrigeration, and reheating of cooked products. The USDA guidelines recommend that cooked meat dishes are cooled from an internal temperature of approximately 54 °C to approximately 27 °C within less than 1.5 h, and from approximately 27 °C to approximately 4 °C within less than 5 h in order to avoid multiplication of *C. perfringens*. Following cooling, food should be stored refrigerated, and should be reheated immediately before serving to reach an internal temperature of 70 °C or above.

Interestingly, regardless of initial contamination of the raw material, times and temperatures employed during cooking of food and cooling rates achieved for the cooked product, *C. perfringens* type A gastroenteritis could be avoided if food was reheated to 70 °C before serving. It seems that regardless of the other, various possibilities for control of *C. perfringens* during food manufacturing, education of food service workers remains paramount for effective prevention of *C. perfringens* foodborne disease.

Glossary

Alpha (α)-haemolysis Haemolytic activity that results in the formation of green zones around bacterial colonies on blood agar media.
Bacteriocin A protein toxin produced by some strains of bacteria which inhibits the growth of, or kills of similar or closely related bacterial strains.
Binary toxin Toxins consisting of two independent polypeptides which are produced by some *Clostridium* spp.
Cytotoxin A substance that has a toxic effect on certain cells.
Endocarditis An inflammation of the endocardium (the membrane that lines inside of the heart), particularly of the heart valves.
Enterotoxin A type of harmful protein produced by bacteria that is specific for the mucous membrane of the intestine and causes the vomiting and diarrhea associated with food poisoning.
Fimbriae A fringe like structure of certain bacteria that is thinner and shorter than a flagellum, and is associated with antigenic properties of the cell surface.
Natural casings Edible casing for sausages made from the submucosa layer of animal intestines which consists mainly of collagen.
Plasmid An extrachromosomal self-replicating structure of bacterial cells that carries genes for a variety of functions not essential for cell growth and that can be transferred to other cells by conjugation or transduction.
Polyarthritis An inflammation that involves more than one joint. The inflammation may migrate from one joint to another, or there may be simultaneous involvement of two or more joints.

Introduction

Emerging pathogens have been defined as organisms that cause illnesses that have appeared or been recognized only recently, or which are rapidly increasing or spreading. For foodborne pathogens, the term has been extended to include organisms long established as human pathogens but for which food has only recently been recognized as a vehicle for their transmission. Those definitions obviously encompass a wide and diverse range of organisms, including organisms that are well recognized as pathogens as well as organisms that have only recently been associated with human disease. Among the former group are a number of pathogens that can be acquired from meat such as verotoxigenic *Escherichia coli*, *Campylobacter jejuni*, and *Yersinia enterocolitica*. These are the subjects of individual articles in this Encyclopedia. Among the latter group are many organisms for which the modes and vehicles of their transmission have not been established. Clearly, proper consideration in a short article of all the possibly meatborne organisms to which the label 'emerging pathogen' has been attached would not be possible. Therefore, for the purposes of this article, emerging meatborne pathogens are defined as organisms that have been found on meat, have been recognized recently as causes, or are suspected of being causes of human illness that are increasing in incidence, and are known or suspected of being acquired from meat. Four species of bacteria that comply with this definition and about which concerns have been increasing are discussed as representative emerging meatborne pathogens.

Acrobacter butzleri

Arcobacter spp. are members of the family Campylobacteraceae, which includes the genera *Campylobacter* and *Sulfurospirillum*. *Campylobacter* spp. are generally nutritionally demanding microaerophilic organisms that do not grow at temperatures much below 30 °C, and colonize mucosal surfaces of the digestive or urogenital tracts of animals and birds. Many campylobacters are established or suspected pathogens of animals, birds, and/or humans. In contrast, *Sulfurospirillum* are free-living organisms, various species of which can reduce sulfur, arsenate, or tetrachloroethane. Arcobacters are superficially similar to campylobacters in that they are Gram-negative, curved or s-shaped organisms that are motile by means of polar flagella, and grow optimally under microaerobic conditions. As with *Campylobacter*, species of *Arcobacter* are difficult to distinguish by phenotypic characteristics because of limited and weak biochemical activities. However, arcobacters are tolerant of aerobic conditions; at least some species can grow anaerobically using nitrate or other electron acceptors for anaerobic respiration; and they grow at temperatures of 15 °C or less.

Five species of *Arcobacter* have been isolated from animals and birds. Three of those species, *Arcobacter butzleri*, *Arcobacter cryaerophilus*, and *Arcobacter skirrowii*, have been isolated from both healthy livestock and animals with disease conditions of the urinogenital and gastrointestinal tracts. The involvement in human illness of *A. skirrowii is* uncertain, possibly because of difficulty with its isolation from stool samples; but *A. butzleri* and *A. cryaerophilus* are associated with gastroenteritis in humans. Of the latter two organisms, *A. butzleri* is the species most often isolated from diarrheic stools. Diarrhea attributed to *A. butzleri* is reported to be more persistent and watery than diarrhea caused by *Campylobacter* spp. and, unlike with *Campylobacter* spp., stools are not bloody.

Arcobacter spp. have been isolated directly and, generally with greater frequency, by enrichment from feces of pigs, cattle, sheep, horses, and cloacal contents of poultry. Carriage of

 doi:10.1016/B978-0-12-384731-7.00047-7

Arcobacter is apparently frequent in pigs, but relatively uncommon in broiler chickens. Even so, the prevalence of *Arcobacter* spp. on chicken carcasses and portions is often high and generally greater than the prevalence on pork. *Arcobacter butzleri* is greatly predominant among arcobacters recovered from meats on retail sale, even though *A. cryaerophilus* may be recovered more frequently from animals or newly dressed carcasses. These various findings suggest that *A. butzleri* found on meat are mostly not fecal contaminants but instead originate largely from meat processing environments. Other findings that support this suggestion are that *A. butzleri* has been recovered from fresh and sea waters, shellfish, and meat processing environments; the organism can survive in cold waters for long times; and it has been shown to grow at 5 °C and form biofilms on surfaces when cultivated in a poultry meat exudate medium. Because its minimum temperature for growth has not been determined, it might be less than 5 °C. In addition, sequencing of the *A. butzleri* genome has shown that it contains a large number of genes associated with survival and growth under a broad range of environmental conditions, which is indicative of *A. butzleri* being a free-living organism.

The basis for *A. butzleri* pathogenicity is uncertain. Genes in *A. butzleri* that correspond with those for some putative virulence factors in *Ca. jejuni* have been identified; but those do not include genes coding for the *Campylobacter* cytolethal distending toxin. Whether or not *A. butzleri* produces toxins of any sort remains to be determined. Resistance to multiple antibiotics is apparently common among *A. butzleri* strains, with resistance genes being chromosomal rather than being borne on plasmids. Plasmids may not be of common occurrence in *A. butzleri*. Evidently, much remains to be learned about the role of *A. butzleri* in enteric illness.

Clostridium difficile

Clostridium difficile is a Gram-positive, strictly anaerobic, spore-forming bacterium that was originally isolated from the feces of newborn infants. It was found to be a usual component of the fecal flora of infants, and subsequently to be commonly present in neonates of a wide range of wild and domestic animals. The organism was not regarded as a pathogen until 1978, when it was identified as the cause of pseudomembranous colitis, i.e., inflammation of the gut wall, with the formation of pseudomembranes composed of fibrin, mucin, neutrophils, and cell debris. Since then, the incidence of *Cl. difficile* infection (CDI) has steadily increased in most developed countries to become the most common cause of nosocomial, i.e., hospital-acquired diarrhea. Consequently, *Cl. difficile* and CDI have been extensively studied in recent years.

Pathogenicity is associated with toxin production by some strains of the organism. A chromosomal pathogenicity locus encodes two toxins and factors that control transcription of the toxin genes. Both toxins were thought to be necessary for the development of CDI, with damage to epithelial cells by the enterotoxin TcdA being required for entry and inactivation of cells by the cytotoxin TcdB. However, TcdA-negative strains that cause CDI have been identified, and laboratory-created mutants that express only one or other of the toxins have been shown to cause disease in laboratory animals. In addition, *Cl. difficile* can produce a binary toxin, but what role it may have in CDI is not known.

CDI is associated with the treatment of patients with broad-spectrum antibiotics, which suppresses the normal gut microflora therby facilitating extensive colonization of the gut by *Cl. difficile*. The disease, with symptoms that range from mild diarrhea to often fatal pseudomembranous or fulminant colitis, occurs predominantly in patients aged over 65 years who receive antibiotic therapy during prolonged hospitalization. The increasingly frequent outbreaks of the disease in hospitals can be difficult to contain, because the highly resistant spores produced by the organism readily survive outside the host to be spread during normal hospital procedures.

Since the early years of the current century there has been a continuous rise in the incidence of CDI in North America and Europe. Recent estimates for CDI in the USA are approximately 500 000 cases per year with up to 20 000 fatalities. Although a large majority of cases still occur among elderly hospital patients that receive antibiotic therapy, CDI in individuals who have not been treated with antibiotics and have no association with hospitals is becoming increasingly common. Such community-associated CDI has been found to occur in groups, such as the young and pregnant women, for which the risk of CDI was thought to be low.

Food has obviously been considered as a possible source of the *Cl. difficile* responsible for community-associated CDI, with meat being a possible vehicle for the organism. *Clostridium difficile* was known to be the cause of sometimes fatal enteric disease in horses, but its occurrence in food animals has been investigated only in recent years. Findings are that large numbers, possibly majorities, of piglets and chickens in at least some herd or flocks are infected with *Cl. difficile*. Substantial fractions of calf populations also carry the organism. *Clostridium difficile* causes diarrhea in piglets, but the illness is rarely fatal. It apparently does not cause illness in chickens; and any role it may have in illness in calves remains unclear. Certainly, many young of all three species can carry *Cl. difficile* without any symptoms of illness. How infants and young animals are protected, more or less, from CDI has not been established. Healthy adults and mature animals can also carry *Cl. difficile*, but apparently at frequencies of only a few percent. Strains of *Cl. difficile* involved in human CDI have been isolated from food and companion animals.

Clostridium difficile has been recovered from beef, pork, chicken, and ready-to-eat meats offered for retail sale. The isolates recovered from meats have commonly been found to be toxigenic, and have included strains that could not be distinguished from strains recovered from CDI patients. The prevalence of *Cl. difficile* in various meats have mostly been reported to be between 1% and 10%. However, in some studies, no *Cl. difficile* was recovered from some meats, whereas in others high prevalence up to 40% were found.

Although spores of *Cl. difficile* are less resistant to inactivation by heating than spores of some other Clostridia, their numbers were reduced by little more than 1 log unit by heating to 71 °C for 30 min. Cooking of ground beef and other meats to 71 °C is generally considered sufficient to ensure the meat is free of enteric pathogens; yet spores of *Cl. difficile* have been recovered from ground beef at numbers approximately 3 log cfu g^{-1}. It therefore seems that the *Cl. difficile*

spores in meat might well survive cooking relatively often, with consumers being exposed to spores with corresponding frequency. The available information could, therefore, be taken as strongly suggesting that community-associated CDI might be acquired by consumption of meat contaminated with *Cl. difficile* spores. However, there is as yet no direct evidence for such an occurrence.

Mycobacterium avium subsp. *paratuberculosis*

Mycobacterium avium subsp. *paratuberculosis* (MAP) is the cause of Johne's disease in cattle, sheep, and other ruminants. Apparently, infection with MAP usually occurs when animals are young, by ingestion of the organism; but symptoms of diarrhea and chronic loss of weight generally appear only in animals that are 2 years or older, and many infected older animals might have no symptoms.

Infection with MAP is initiated by invasion of the ileum and associated lymph nodes. The infection can spread to much of the small intestine, and to the large intestine in some species. When the disease is advanced, MAP can be disseminated in organ and muscle tissues, and lymph nodes throughout the body. Dissemination may also occur episodically at early stages of infection. Both young and old animals infected with MAP shed the organism sporadically in feces. The MAP-infected gut wall is infiltrated by white blood cells, becomes granulomatous and thickened, and develops a characteristic, corrugated appearance. In advanced cases of the disease, mycobacteria in the tissues can be numerous and easily detected as acid-fast bacteria in tissue sections prepared for microscopy. However, infected tissues of characteristic appearance may contain very few acid-fast organisms.

In Crohn's disease, a chronic inflammatory disorder of the human gut, the appearance of the gut wall is similar to that seen in Johne's disease. Consequently, it has long been considered that MAP might be the cause of Crohn's disease; or at least be involved in the condition. However, this has proved difficult to confirm or disprove. MAP has been found to be present in gut tissues from patients with Crohn's disease, but not consistently and never in high numbers. Also, in some studies, MAP has been detected in the blood of patients with Crohn's disease; but in other studies it was apparently present in similar prevalence in blood of both Crohn's patients and healthy individuals, or it was not detected in blood from either group.

The uncertainty as to whether or not MAP is involved in human disease is in large part due to difficulties with establishing its presence unambiguously. Mycobacteria mostly grow only slowly, and MAP is the slowest growing of mycobacteria that can be cultivated on microbiological media. With a generation time of several days, incubation for a minimum of 6 weeks and usually much longer is necessary if colonies are to be obtained. As the organism is nutritionally demanding, media that will support its growth will allow the much more rapid growth of other microorganisms. Therefore, media for MAP are supplemented with antibiotics to which the organism is relatively resistant. Even so, overgrowth of MAP by other organisms is likely; so samples are usually subjected to a decontaminating treatment before they are used to inoculate MAP-selective media. Like all mycobacteria, MAP has a thick and waxy cell wall that renders the cells resistant to various, harsh, decontaminating treatments that are effective against other organisms. However, the extent to which MAP is affected by any decontaminating treatment is uncertain and very likely variable. Thus, reliable recovery of MAP when it is present in samples in small numbers cannot be expected.

Because of the difficulties with, and the effort required to recover MAP from samples, many studies have been conducted using indirect methods such as enzyme-linked immunosorbent assays for detection of MAP antibodies in blood or detection of MAP deoxyribose nucleic acid (DNA) sequences by polymerase chain reaction (PCR) tests. However, such tests can give both false-positive and false-negative results, and generally cannot establish the presence of viable MAP in samples.

The same problems arise with establishing the presence of viable MAP in foods. Thus, in the only two studies of MAP in meat on retail sale, no viable MAP were recovered; but in one no MAP DNA was detected in ground beef by PCR, whereas in the other MAP DNA corresponding to MAP at numbers up to 4 log cfu g^{-1} was detected in beef, pork, chicken, and fermented sausages by quantitative PCR. The far more numerous studies of MAP in milk and milk products have yielded similarly ambiguous results. Nonetheless, the presence of viable MAP in at least some raw meat products is likely. Animals with symptoms of Johne's disease are culled; and their meat is considered suitable for human consumption because MAP is currently not regarded as a human pathogen. Most meat from culled cattle is ground, so some ground beef must inevitably include MAP-infected muscle and lymphatic tissue from animals in which the organism was disseminated. In addition, all beef and lamb will be contaminated to some extent with fecal organism that can include MAP. Moreover, fresh natural casings are likely to be contaminated with MAP, and some may survive the preservation of casings with salt.

Whether or not MAP is involved in Crohn's disease or in other diseases, such as type I diabetes with which it has been linked, it is frequently suggested that the exposure of humans to MAP should be minimized, as a precautionary measure. In view of the widespread occurrence of the disease among farmed animals and the difficulties with identification of infected animals, exclusion of MAP-infected animals from milk and meat production is hardly a practicable proposition at present. Instead, reduction in the exposure of humans to MAP may well result from improving the control over contamination of meat with fecal organisms, and ongoing efforts in many countries to reduce the prevalence of MAP among farm animals.

Streptococcus suis

Streptococcus suis is a Gram-positive, facultatively anaerobic coccus that possesses cell wall antigens related to those of enterococci, such as *Enterococcus faecalis*, *Enterococcus faecium*, and *Enterococcus durans*, and other organisms that are members of Group D in the Lancefield classification of streptococci. However, it is not closely related genetically to the other member of this group. All strains of this species are α-hemolytic on sheep blood agar plates, but unlike enterococci

they are not able to grow in broth containing 6.5% NaCl. *Streptococcus suis* has been recovered from many species of mammals and birds. It is a usual component of the microflora of upper respiratory, urinogenital, and gastrointestinal tracts of healthy pigs. However, it is a cause of disease in pigs of all age groups, but with *S. suis* disease being most common among neonatal and young animals. Disease conditions caused by the organism include septicemia, meningitis, pneumonia, endocarditis, and polyarthritis. Infected animals can die suddenly, or may have various symptoms such as dyspnea (labored breathing), cyanosis, and/or wasting. The disease is endemic among pigs in most countries with sizable pig populations, and is the cause of substantial economic losses.

Thirty-five serotypes of *S. suis* have been identified based on capsular polysaccharide antigens. There is a wide variation in virulence within as well as between serotypes. Only some serotypes have been found to be responsible for infections in pigs, with serotype 2 being the most common. Knowledge concerning the virulence factors of *S. suis* serotype 2 is limited. There are ongoing problems with identification of virulence factors for the organism, although there is agreement that there are virulent and nonvirulent strains of *S. suis* serotype 2. Molecules that have been suggested to be associated with virulence include the capsule polysaccharide (CPS), which confers resistance to phagocytosis, muramidase-released protein (MRP), extracellular protein factor (EF), and suilysin. Despite the fact that CPS is the only proven critical virulence factor, nonvirulent encapsulated strains have been reported; and whereas MRP, EF, and suilysin protein are produced by the most virulent European strains, they are absent in most North American strains. Recently, other virulence factors, including adhesins, proteolytic enzymes, bacteriocins, and fimbriae have also been suggested.

The mechanisms of *S. suis* pathogenesis are not fully understood. Pigs may acquire infection via either vertical transmission, during farrowing, or horizontal transmission due to close contact with carrier or infected animals, their feces, and/or housing structures. There is no clear explanation of why *S. suis* successfully colonize some piglets and not others. Carrier animals typically harbor the bacteria in their tonsils and might never develop disease, whereas others will eventually develop bacteremia, septicemia, and meningitis. In these latter cases, *S. suis* must breach the mucosal epithelium in the upper respiratory tract to reach the bloodstream and invade various organs to cause inflammation.

In 1968, *S. suis* was first reported as the cause of human disease in Denmark. Since then, human cases have been found in many countries, but with few occurring in North America and Europe in comparison with the number of cases in South East Asia. As with pigs, *S. suis* disease in humans is caused mainly by serotype 2. Infections usually present as meningitis, but present as septicemia in approximately 20% of cases. Mortality is higher with the latter than with the former type of illness, but loss of hearing is a common sequel to meningitis.

Streptococcus suis can be transmitted to humans in close contact with sick or carrier pigs, such as pig farmers, abattoirs workers, meat processing workers, and veterinarians, via exposed cuts and abrasion in their skin. Consequently, most cases of human *S. suis* disease have occurred sporadically among such groups of people. However, in recent years there have been large outbreaks of human *S. suis* disease that were contemporaneous with extensive occurrence of disease caused by the organism among pigs in the outbreak regions. Patients in these outbreaks included people who had no contact with pigs or pig products other than the consumption of pork. It, therefore, appears that humans might be infected by contact with or consumption of contaminated pork.

Streptococcus suis serotype 2 can survive in water at 60 °C for 10 min. Consequently, cross contamination of carcasses with the organism might occur during carcass scalding as well as during dressing operations on carcass heads and throats. Survival of the organism on carcasses for up to 6 weeks has been reported. Pork may then commonly be contaminated with the organism; particularly when the meat is from carcasses dressed without being suspended in traditional Asian abattoirs, and when there is an outbreak of *S. suis* disease in local herds of pigs. Fortunately, *S. suis* is inactivated by most common disinfectants and cooking of meat to 70 °C. Thus, acquisition of the disease by consumption of pork should be readily contained if basic hygienic precautions are observed during handling of raw pork and the meat is cooked to a medium–well done condition, i.e., to at least 71 °C. However, hygienic handling of the meat during traditional marketing of pork in developing countries is not practicable. Therefore, further outbreaks of human *S. suis* disease in some East Asian countries are likely to occur.

Conclusion

The continuing emphasis on food safety in developed countries is likely to at least contain, and probably reduce infections with established human pathogens acquired from meat by consumers. Even so, the incidences of some infections may apparently increase, because of improved detection of some organisms, and/or increased reporting of the diseases they cause. Moreover, increasing production of meat in developed countries where the infrastructure needed for hygienic handling of meat is as yet limited might result in increased incidences of some diseases caused by meatborne pathogens. The broad definition of emerging pathogens would allow all organisms found to be involved in human disease with increasing frequency to be classified as such.

In addition, ongoing advances in medical and food microbiology are likely to result in the identification of disease conditions caused by meatborne microorganisms that currently are poorly characterized or are regarded as benign. Such organisms will, of course, be categorized as emerging pathogens. However, some meatborne organisms currently viewed as probably pathogenic for humans, such as MAP, might prove to be uninvolved in human disease. Others, such as *Cl. difficile*, might be carried by, but not be acquired from meat. Evidently, any organism characterized as being of those sorts cannot properly be referred to as emerging meatborne pathogens.

Hurdle Technology

SE Gragg, Kansas State University, Olathe, KS, USA
MM Brashears, Texas Tech University, Lubbock, TX, USA

Glossary

Extrinsic factors Factors associated with the environment external from the food product.
Homeostasis Maintenance of cellular equilibrium.
Intrinsic factors Inherent properties associated with a food product.
Redox potential The tendency of the food matrix to either donate (reduce) or accept (oxidize) electrons, which is most commonly influenced by the amount of oxygen in a food product.
Water activity The amount of water that is not bound by the food matrix and available for microorganisms to utilize for growth.

Introduction

Food preservation has been practiced for centuries, with salting generally recognized as the earliest form of preservation. Several intrinsic and extrinsic factors associated with foods serve to promote preservation, the most important of which include: water activity (a_w), temperature (low or high), preservatives (i.e., nitrite), acidity (pH), competitive microorganisms (i.e., lactic acid bacteria), and redox potential (Eh). These extrinsic and intrinsic factors are limited when applied singly. However, when combined with one another in a sequence or applied simultaneously, the activity of each is considerably enhanced. This effect is likened to a series of hurdles that become increasingly harder to overcome the more hurdles that are utilized. The result is synergistic food preservation referred to as a hurdle effect. To fully understand the effects of these hurdles on microbial populations, extensive research has focused on defining the critical limits for growth, survival, and death of the most significant microorganisms associated with the food supply. This information has provided a foundation for designing effective food preservation strategies. Thus, the term hurdle technology represents the intentional combination of hurdles, without necessarily listing them, at independently sublethal levels to preserve novel and traditional foods. Hurdles can be strategically combined such that it is possible for a food to become increasingly economical, have improved microbial safety and stability, as well as enhanced nutritional and sensory characteristics. The overall goal is for the hurdles to control the naturally occurring microbial population by either inhibiting growth or inactivating the microorganisms.

Aspects of Hurdle Technology

Creating a hostile environment for microorganisms is an important aspect of food preservation. Microbial death or growth is dependent on their response to the hostile conditions imposed on them by hurdle technology, which is implemented by altering intrinsic and extrinsic factors. To fully understand their response, an understanding of microbial homeostasis, stress reactions, and how the effects of multiple stressful conditions can lead to metabolic exhaustion is necessary.

Organisms require a certain amount of internal stability and uniformity for survival and growth. For example, the osmotic pressure of a living cell must be well maintained to achieve homeostasis. Thus, hurdles can be employed to disrupt the homeostasis of microbial cells, thereby restricting growth or causing cell death. Food preservation is accomplished when hurdles effectively disturb the homeostasis of microorganisms in a food either permanently or temporarily.

Maintaining homeostasis can rapidly deplete microbial cellular energy and lead to metabolic exhaustion. Hurdle technology subjects microorganisms to multiple hostile factors, some of which may result in sublethal injury to the cell. Thus, microorganisms will employ every possible repair mechanism to overcome the antagonistic environment and return to a state of cellular homeostasis. In doing so, they completely deplete their energy, which leads to an inability to maintain cellular functionality (i.e., metabolic exhaustion) and death. This process will eventually result in 'autosterilization' of hurdle technology foods. Therefore, the safety of such foods improves throughout storage, particularly when they are stored at ambient temperatures, as hurdles can have a lasting residual impact on the death of the cell.

The efficacy of food preservation hurdles can be limited by the various stress reactions induced by microorganisms. For example, stress shock proteins are synthesized by bacteria as they become more resistant, and in some cases more virulent, under stressful conditions (i.e., ethanol, heat, pH, a_w, and starvation). Fortunately, this does not result in a complete loss of hurdle efficacy, as microorganisms typically have more difficulty with turning on stress shock protein genes when a variety of stresses are experienced simultaneously. This requires energy consumption by the cell to synthesize multiple stress shock proteins concurrently. Bacteria are unable to meet this need and succumb to metabolic exhaustion.

For hurdle technology to be efficacious, a strategic combination of hurdles must be applied simultaneously with the intent of attacking various targets within the cell (i.e., cell membrane, pH, DNA, etc.), an approach known as multitarget preservation. By applying multitarget preservation, the

hurdles in a food begin to act synergistically with one another to disrupt homeostasis within microbial cells. As a cell is simultaneously exposed to hurdles aimed at multiple cellular targets, the cell is forced to initiate a variety of repair mechanisms, including stress shock protein synthesis. This overwhelms the cell, ultimately leading to metabolic exhaustion and cell death. Thus, applying different preservation hurdles in small amounts could be more effective than using large amounts of a single preservative, as multiple preservatives will target a variety of cellular components and act synergistically.

Hurdle Technology and Food Quality

Food preservation hurdles present within a food might influence stability and safety of a food, but may also affect the nutritive, sensory, economic, or technological properties of a product. Hurdles have the potential to either negatively or positively impact the overall quality of a food and a single hurdle may have a positive or negative impact depending on hurdle intensity. For example, water activity must be sufficiently low in fermented sausages to restrict pathogenic bacteria; however, the water activity cannot be so low that taste and texture are compromised. Some hurdles, like the addition of nitrite in the process of curing meat, provide antimicrobial activity while also creating the characteristic 'cured meat taste' and a color that is desirable. Thus, hurdle technology is also applicable to food quality, and motivation for implementing food preservation hurdles should not be driven solely by the microbial stability and safety of a food product. However, for maximal food safety and quality to be achieved, effective application of hurdle technology requires a specific understanding of the efficacy of each hurdle within a particular product and each hurdle must remain within their respective optimal range.

Application of Hurdle Technology in the Meat Industry

The conversion of live animals into raw meat and meat products allows for the introduction of spoilage and pathogenic microorganisms to be introduced onto the carcass via cross-contamination from animal hides, viscera, employees, equipment, and food-contact surfaces. Because meat processors in most countries of the world strive to produce products with low amounts of contamination, particularly pathogenic microorganisms, hurdle technology has been implemented extensively in the meat industry worldwide.

Fresh meat commonly has a water activity above 0.90 and is classified as a high-moisture food. Because many microorganisms are capable of survival or growth in this range, water activity at this level is not a sufficient preservative. Thus, other food preservation hurdles are necessary to control the microbial safety and stability of fresh meat products.

During animal harvest, hurdle technology is implemented as a simultaneous or sequential systems approach consisting of two or more chemical and/or physical procedures designed to decrease carcass contamination in an additive or synergistic fashion. Such processes commonly include hide cleaning before or after knocking, knife-trimming of visible contamination, a pre-evisceration carcass rinse (hot water or chemicals), steam-vacuuming, steam or hot water treatment, and organic acid rinses. Warm acid solutions and a combination of chemicals may also be applied to the carcass simultaneously to achieve synergism. These hurdles are strategically utilized throughout animal harvest to attain extensive reductions in the microbial population present on a carcass such that control of any remaining microorganisms can be more readily achieved by subsequent hurdles (i.e., refrigeration, freezing, and packaging). Some hurdles are also applied to chilled carcasses, subprimals and beef trim. Research has shown that implementation of multiple hurdles in a sequential fashion results in progressively reduced bacterial counts as carcasses advance through harvest and additional reductions can be achieved during fabrication.

Numerous nonthermal interventions may be combined with the sequential hurdle approach described above to enhance meat preservation. Extensive research has described the efficacy of refrigeration/freezing, irradiation, chemical preservatives, biopreservation/natural antimicrobials (i.e., nisin), physical intervention technologies (i.e., high hydrostatic pressure), and packaging (i.e., modified atmosphere packaging (MAP)) as additional fresh meat hurdles. For maximal effectiveness, these hurdles can be intelligently combined in a strategic sequence, and applied at their optimal intensity, in order to maximize antimicrobial capacity of the hurdle system without selecting for microbial stress adaptation or resistance.

The combination of natural antimicrobials with other nonthermal interventions has been investigated as a means to enhance antimicrobial capacity. Synergism is achieved when these nonthermal hurdles weaken bacterial cell membranes causing increased susceptibility to natural antimicrobial activity. For example, bacteriocins can be used as a hurdle before packaging of both raw and or cooked meat products as a means to prevent microbial growth. These antimicrobial peptides/proteins are manufactured by bacteria and do not have specific molecular sites that are targeted and the capability exists for some to rapidly destroy bacterial membranes. When applied in combination with other interventions such as chelating agents (i.e., ethylenediaminetetraacetic acid) or high hydrostatic pressure, bacteriocins have exhibited enhanced antimicrobial activity. For example, nisin, which is generally most effective against gram positive cells, has efficacy against gram negative microorganisms when used in conjunction with chelating agents and organic acids. When in the presence of organic acids and their conjugate salts, bacteriocins have increased solubility and a net charge that allows for diffusion of the bacteriocin through the bacterial cell membrane to exert their antimicrobial activity within the cell. Live lactic acid bacteria can also be added directly to whole muscle cuts or ground beef (trim or final product) to kill foodborne pathogens throughout the process. Certain strains of lactic acid bacteria have been identified that kill foodborne pathogens during refrigerated storage but do not grow during storage and, therefore, do not negatively impact the quality of the meat.

Combining hurdles with MAP or vacuum packaging have also been used to optimize antimicrobial activity.

Organic acids (i.e., lactic acid) have been utilized in conjunction with MAP (i.e., 80% $CO_2 + 20\%$ O_2) to control pathogenic microorganisms while MAP has also been combined with plant essential oils to decrease spoilage microbes and extend product shelf life. Irradiation can be an effective hurdle; however, it can also lead to the production of sulfur compounds associated with an off-odor of the product. For this reason, combining irradiation with vacuum packaging may be beneficial, as this environment can decrease oxidative activity thereby limiting the production of volatile compounds believed to be associated with off-odors. Combining irradiation with MAP has been effective at reducing microbial loads and extending the shelf life of meat and meat products.

A well-established product in the meat industry preserved by hurdle technology is shelf-stable sausages. Many hurdles are represented in this process, including additives (i.e., salt, nitrites/nitrates) and competitive microflora (i.e., lactic acid bacteria cultures) that lower the redox potential as well as the pH and decreased water activity from product drying. Some semidry sausages also undergo smoking, which adds an additional hurdle for microorganisms to overcome. Stability of a fermented meat product manufactured in this fashion is achieved when the pH ranges from 4.6 to 5.3 with a water activity of <0.95, whereas a pH of <4.5 or a water activity of <0.91 would be required if both hurdles were not in place. Furthermore, by implementing two mild hurdles with the same antimicrobial efficacy as one harsher hurdle, meat quality can also be considered.

Design of Effective Hurdle Technology for Meats

The design of many meat products is a multidisciplinary task that requires a team of experts to create a product that is both safe and stable and retains consumer acceptance properties. A microbiologist will assess the types and intensity of hurdles required, whereas a food technologist and meat scientist will identify the ingredients and/or processes necessary to institute these hurdles into the product. In doing so, the sensory, nutritive, technological, and legal restrictions must be accounted for, while also considering the marketing, economic, and engineering components of the product.

The use of computer-based predictive microbiology has shown promise for designing hurdle technology products. This approach allows for quantitative predictions of microbial activity (growth, survival, and death) in foods; however, models may be limited by the number of hurdles that can be evaluated simultaneously. Given the number of hurdles that could potentially be included in a meat product preserved by hurdle technology, it is not possible to include every model in the model. Thus, predictive microbiology essentially predicts the fate of microorganisms in a product using the most important hurdles. Because not all hurdles may be accounted for in a model, the predicted efficacy of the resultant safety and stability of the product will be on the conservative side. Although predictive microbiology does not replace the need for challenge testing and process validation, it does provide a useful tool for product design.

Conclusion

The use of hurdle technology in the meat industry is a simple concept but usually requires a strategic combination of hurdles, involving water activity (a_w), temperature (low or high), preservatives (i.e., nitrite), acidity (pH), competitive microorganisms (i.e., lactic acid bacteria), and redox potential (Eh). The various procedures commence during animal processing and progress throughout product packaging and storage and retail activities. Meat products preserved by hurdle technology result in improved shelf life and safety with little to no adverse effects on quality. Because quality is more readily maintained by implementing multiple hurdles at a lesser intensity than a single intervention, hurdle technology is a successful approach for producing mildly processed meat products that are both safe and desirable to consumers.

Listeria monocytogenes

RA Holley and RP Cordeiro, University of Manitoba, Winnipeg, MB, Canada

This article is a revision of the previous edition article by S Buncic, SM Avery, volume 2, pp 804–814, © 2004 Elsevier Ltd.

Glossary

Biofilm A thin layer of microorganisms adhering to the surface of a structure by means of the material that they secrete.

Haptens A small molecule that can elicit an immune response only when attached to a large carrier such as a protein.

Chemotaxonomy The identification and classification of organisms by comparative analysis of their biochemical composition.

Lineage A group composed of species, taxa, or individuals related by descent from a common ancestor.

Phylogenetic Study of evolutionary relatedness among various groups of organisms.

Introduction

Listeria monocytogenes is a foodborne pathogen that causes a group of human illnesses collectively called listeriosis. Human listeriosis is mostly acquired by ingestion of ready-to-eat (RTE) foods contaminated with *L. monocytogenes*. Consumption of such foods and concerns about listeriosis have increased greatly during the past 30 years in developed countries. Factors contributing to concerns about listeriosis include the increased proportion of immune-compromised persons at risk for listeriosis; increased use of refrigeration to extend perishable food shelf life; increased consumer demand for RTE, refrigerated, or frozen foods; improved diagnostic methods; and enhanced public health surveillance. Foodborne listeriosis in less developed nations with less developed food supply systems is less frequent. *Listeria monocytogenes* was confirmed as a foodborne pathogen after the occurrence in the mid-1980s of large common-source outbreaks associated with various foods, including meats. Although there has been a large worldwide research effort into different aspects of foodborne *L. monocytogenes* infections during the past 25 years, many aspects remain unclear.

General Characteristics of *Listeria*

Taxonomy

Since the first description of *L. monocytogenes* in 1926, when it was called *Bacterium monocytogenes*, the pathogen has been reclassified repeatedly. Numerous studies over the past 30 years, based on numerical taxonomy, chemotaxonomy, and ribosomal ribonucleic acid (rRNA) sequencing, show that among the other prokaryotes, *Listeria* is most closely related to *Brochothrix*. *Listeria* belongs to the *Clostridium* subbranch together with *Staphylococcus*, *Streptococcus*, *Lactobacillus*, and *Brochothrix*, and is characterized in this phylogenetic position by a low average guanine–cytosine content of 38%. Presently, on the basis of deoxyribonucleic acid (DNA) homology, 16S rRNA sequencing homology, chemotaxonomy, and multilocus enzyme electrophoresis (MEE) analysis, the genus *Listeria* comprises six species: *L. monocytogenes*, *Listeria ivanovii*, *Listeria innocua*, *Listeria welshimeri*, *Listeria seeligeri*, and *Listeria grayi*. Recently, phylogenetic analyses have identified and described novel species of avirulent *Listeria* named *Listeria rocourtiae* sp. and *Listeria marthii*, which were isolated from precut lettuce and the natural environment, respectively. Among all the *Listeria* species cited, only *L. monocytogenes* and *L. ivanovii* are pathogenic. *Listeria monocytogenes* infects both man and animals, whereas infection by *L. ivanovii* is more frequent among animals than among humans.

Morphology, Culture, and Metabolism

Listeriae are Gram-positive, short rods (diameter 0.5 μm, length 0.5–2 μm) with rounded or sometimes coccoidal ends (Figure 1). They do not form spores or capsules. *Listeria* are motile with peritrichous flagella at 20–25 °C, but are not motile, or less noticeably motile at 37 °C. All listeriae show characteristic tumbling motility when viewed microscopically in hanging-drop fresh broth cultures and, owing to their microaerophilic nature, grow in 'umbrella' forms approximately 0.5-cm below the surface of stabbed semisolid media.

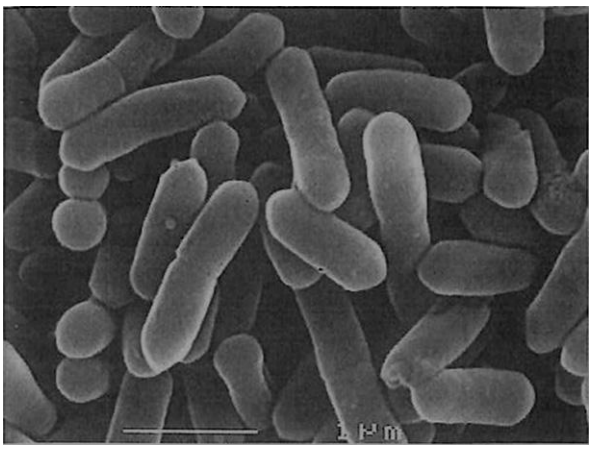

Figure 1 Photomicrograph of *Listeria monocytogenes*; bar = 1 μm. Courtesy of JA Vazquez-Boland. Copyright © JA Vazquez-Boland.

 doi:10.1016/B978-0-12-384731-7.00039-8

Listeriae are fastidious, and grow on common bacteriological media. After overnight incubation, the colonies are smooth, bluish-gray, translucent, and 0.2–0.8 mm in diameter, but after prolonged incubation can be much larger. Rough colonies are sometimes observed. Colonies on a clear medium, which when viewed under a microscope with obliquely transmitted light, typically appear sparkling blue-green, a characteristic useful for distinguishing them from colonies of other microorganisms.

Listeria utilize glucose, forming lactate, acetate, and acetoin under aerobic conditions, but acetoin is not produced anaerobically. They are oxidase-negative and catalase-positive; hydrolyze aesculin but not urea, gelatin, or casein; and are methyl red- and Voges–Proskauer-positive. *Listeria* are facultatively anaerobic but prefer microaerophilic atmospheres when growing aerobically. *Listeria* require cystine, leucine, isoleucine, arginine, valine, cysteine, riboflavin, biotin, thiamin, and thioctic acid for growth. *Listeria* are able to grow at temperature, pH, and water activity (a_w) ranging from 0 to 45 °C, 5.6 to 9.6, and 0.90 to >0.97, respectively.

Isolation and Identification

Conventional Methods

Foods can simultaneously contain relatively low numbers of *L. monocytogenes* and large numbers of background microorganisms, which can make isolation of the pathogen difficult. Previously, a cold-enrichment procedure was attempted, with incubation of the enrichment broth at 4 °C for weeks or months to increase the numbers of listeriae before their isolation on solid media. Subsequently, modern *Listeria*-selective enrichment broths and solid media, which require shorter incubation times and contain selective agents to inhibit background microorganisms, were developed (**Table 1**). However, selective agents may not allow growth of all *Listeria* strains, and can inhibit injured *Listeria* cells that are often present in foods. This is problematic, especially for methods involving direct plating on selective agars without prior enrichment, as their effectiveness is determined by the fitness and levels of both *Listeria* and the background microorganisms.

Although a nonselective enrichment (buffered peptone water or a universal broth) can be used to recover injured listeriae before subculturing in a selective enrichment, there is a risk of listeriae being overgrown by competing organisms in the process. As an alternative, the thin agar layer (TAL) method has been used for recovering injured *L. monocytogenes* from foods. The TAL method requires the preparation of plates of a selective agar overlaid with a nonselective agar shortly before the plates are incubated. During the first hours of incubation, injured cells recover and start to grow on the nonselective agar. After diffusion of agents from the selective agar into the upper layer, colonies typical of those on the selective agar are formed whereas other microorganisms are inhibited. A list of official methods for the isolation of *L. monocytogenes* from food and the environment are presented in **Figure 2**. For the identification of *Listeria* species, tests including hemolysis and acid production from D-xylose, L-rhamnose, α-methyl-D-mannoside, and mannitol are recommended. Additional identification tests include a number of commercially available, multicomponent, miniaturized biochemical assays, as well as some DNA- or polymerase chain reaction-based methods.

Serotyping is a quick, traditional method for subspecies characterization of *L. monocytogenes* isolates, based on the detection of specific somatic (O) and flagellar (H) antigens. Currently, 13 serotypes are distinguished: 1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4b, 4c, 4d, 5, 6a, and 6b. Three serotypes, 1/2a, 1/2b, and 4b, have been implicated in more than 90% of all human *L. monocytogenes* infections. Serotypes 1/2a and 1/2b are more commonly isolated from foods, but serotype 4b more frequently causes foodborne outbreaks of listeriosis. Molecular subtyping methods show that *L. monocytogenes* can be separated into three genetic groups. Serotypes 1/2b, 3b, 4b, 4d, and 4e form lineage I; serotypes 1/2a, 3a, 1/2c, and 3c form lineage II; and serotypes 4a, 4b, and 4c form lineage III. Lineage III strains appear frequently among isolates from animals with listeriosis. The distribution of serotypes is different in different geographic regions. The main causes of human listeriosis in the US are strains of lineage I serotype 4b, whereas lineage II serotype 1/2a strains cause the majority of human listeriosis in Europe and Canada. Lineage II strains were responsible for a large outbreak of listeriosis associated with RTE meat products in 2008 in Canada, and acid curd

Table 1 Examples of selective agents and related media for the isolation of *Listeria monocytogenes*

Selective agents	*Role*	*Broths with selective agents (numbered)*	*Agars with selective agents (numbered)*
1. Lithium chloride/ phenylethanol	Promotes *Listeria*, slowing growth of Gram-negatives	Fraser[a] (1+2+3)	Modified Oxford agar[a] – MOX (1+5)
2. Nalidixic acid	Inhibits Gram-negatives	UVM (2+3)	PALCAM agar[a] (1+3+4+5/6)
3. Acriflavin/trypaflavin	Inhibits Gram-positive cocci	FDA enrichment[a] (2+3)	ALPAMY agar (1+3)
4. Polymyxin B	Inhibits Gram-negatives and streptococci	L-PALCAMY (1+3+4+5/6)	RAPAMY agar (1+2+3)
5. Moxalactam	Broad spectrum: inhibits many Gram-positives and Gram-negatives	IDF enrichment[a] (2+3+6)	Modified McBride agar[a] (1)
6. Ceftazidime/ cycloheximide	Broad-spectrum antibiotic	LRB selective (2+3+6)	AC agar (3+6)

Practical relevance of methodologies for detecting and tracing of *Listeria monocytogenes* in ready-to-eat foods and manufacture environments – A review. Food Science and Technology 44, 351–362.

cheese contaminated with a serotype 1/2a strain caused outbreaks in Austria and Germany in 2009/2010.

Phage typing is another traditional method that is inexpensive, and easy to conduct. It can be more discriminatory than serotyping, but up to 50% of strains are not phage typeable.

Rapid Detection Methods

Conventional methods for the detection of *L. monocytogenes* are relatively slow, and unsatisfactory for purposes such as end product testing or various epidemiological investigations, for which results should ideally be obtained rapidly. Relatively rapid molecular methods have therefore been developed.

Nucleic acid amplification-based detection methods frequently target virulence genes of *L. monocytogenes*, particularly *hly*A (the gene producing *Listeria* listeriolysin O; LLO). These methods variously use the ligase chain reaction (LCR), PCR, or nucleic acid sequence-based amplification (NASBA). LCR methods use DNA targets such as the 16S rRNA gene as a template, and their particular strength is high specificity. PCR methods use thermostable DNA polymerase and flanking oligonucleotide primers to amplify targeted nucleic acid sequences, which include those of *hly*A, the genes for invasion-associated protein (*iap*), phospholipase B (*plc*B), or the delayed-type hypersensitivity factor. PCR methods are highly sensitive. NASBA amplifies nucleic acid targets with a series of enzymes including RNA polymerase and reverse transcriptase, and the templates used include 16S rRNA and *hly*A mRNA. Generally, nucleic acid amplification-based detection methods are rapid, but they can produce both false negative results due to inhibition of enzymatic reactions and false positives due to detection of nonviable cells or extracellular DNA.

Antibody-based methods detect *Listeria* antigens using enzyme-linked immunosorbent assay formats, where cells are either directly absorbed or immune-captured onto wells of microtiter plates and are then detected using antibodies carrying haptens or reporter enzymes. Alternatively, antibody-based assays can employ flow cytometry for the detection of immune-captured cells in solutions; or with immunomagnetic separation techniques, antibodies conjugated to magnetic beads can be used to capture and concentrate cells before plating onto *Listeria*-selective media.

Further improvements of current rapid methods will require the reduction or elimination of time-consuming enrichment steps, and the specific detection of only pathogenic *L. monocytogenes* rather than *L. monocytogenes* in general, or all *Listeria* spp.

Subtyping methods are important tools for confirming the identities of microorganisms associated with foodborne outbreaks, identification of new and emerging bacterial pathogens, tracking organisms as they colonize surfaces in food processing plants, and contribute to understanding the

genetics, epidemiology and ecology of foodborne pathogens such as *Listeria*. More modern, molecular subtyping methods include pulsed-field gel electrophoresis (PFGE), chromosomal DNA restriction endonuclease analysis (REA), MEE, restriction fragment length polymorphism (RFLP; ribotyping), random amplification of polymorphic DNA (RAPD), and arbitrarily primed PCR (AP-PCR). PFGE analysis of DNA macrorestriction patterns is presently considered the best subtyping method for *L. monocytogenes*, as it can distinguish closely related strains indistinguishable by other methods. Nevertheless, it is relatively slow (2–3 days) and expensive in terms of both reagents and equipment required. REA is universally applicable for *L. monocytogenes* and is easy and cost effective, but its limitations include the production of very complex and difficult to compare profiles. MEE, which distinguishes strains on the basis of the electrophoretic mobility of their enzymes, is a powerful tool in taxonomic studies of *L. monocytogenes*, but is moderately discriminatory in epidemiological investigations and is rather laborious. RFLP, which analyses polymorphisms associated with ribosomal operons, is widely used and can be conducted using a commercially available, automated system. As its discriminatory power for *L. monocytogenes* is not very high, it should be used in combination with other typing methods such as PFGE or PCR. RAPD and AP-PCR methods are both based on PCR. They are relatively simple and have good discriminatory power for *L. monocytogenes*, but results obtained with these methods are not very consistent. Other, promising subtyping methods that are yet to be fully developed include DNA sequence-based techniques.

Listeriosis

Listeriosis in Meat Animals

Listeriae are ubiquitous in animal environments. Listeriosis in meat animals is not notifiable in most countries; so it is difficult to compare the prevalences among countries. In all animal species, a proportion of clinically healthy animals can shed the pathogen in their feces, and *L. monocytogenes* can also be shed in milk from animals with or without symptoms of mastitis. The most common forms of animal listeriosis are encephalitis ('circling' disease), placentitis with abortion, and septicemia. Infection can occur via the gut from contaminated feeds, with poor-quality, i.e. insufficiently acidic, silage frequently being a vehicle for the pathogen. Infection through lesions in the mouth, nostrils, or conjunctiva can also occur. Factors contributing to infection include poor animal husbandry, stress, losing or cutting teeth, sudden changes in diet, concurrent disease, introduction of new animals to herds, and overcrowding.

In adult sheep and goats, meningoencephalitis is the most common form of the disease, with death often occurring in 2 or 3 days. Septicemia occurs primarily in neonates and lambs. Sheep seemingly have a relatively high natural resistance to *L. monocytogenes* because often only one-tenth of animals in an exposed flock exhibit clinical symptoms.

In cattle, listeriosis encephalitis is probably the most common form, but diseased cattle survive longer than diseased sheep. In pigs, listeriosis primarily manifests itself as septicemia, whereas encephalitis and abortion are rare. Diseased piglets usually die, but adult pigs generally survive. Listeriosis in horses is not common and is usually associated with feeding silage, or housing or grazing horses with cattle or sheep.

In domestic and wild birds, the proportion of healthy *L. monocytogenes* carriers is generally higher than the proportion in meat animals, probably owing to pecking of contaminated materials including soil. In contrast, clinical listeriosis is much less frequent in poultry than in meat animals. The most common form of listeriosis in poultry is septicemia, with few overt symptoms and death within 5–10 days. Encephalitis in poultry is rare but nearly always fatal.

Listeriosis in Humans

Listeria monocytogenes can be excreted in the feces by 1% to >50% of healthy people. Factors that tend to increase carriage of the organism include laboratory work with *L. monocytogenes*, household contacts with listeriosis patients, and working in cheese factories.

The incubation period for listeriosis is highly variable and can range from 1 day to more than 3 months. The reasons for this variability are not known, but they may include variations in the dose ingested or in the responsiveness of the host's immune system. Maternal listeriosis occurs during pregnancy, most commonly during the last 3 months and more frequently among women with multiple pregnancies. The infected mother can be asymptomatic or have relatively mild nonspecific (flu-like) symptoms, but the infection can be transmitted via the placenta to the fetus and may cause abortion or stillbirth. Neonatal listeriosis can occur as early- or late-onset disease, which is often fatal. The early-onset form is due to intrauterine infection of the infant with the development of listeriosis, usually presenting as sepsis or meningitis, either at birth or within a few days of birth. The late-onset form of the disease occurs between 1 week and several weeks after the birth of usually healthy infants and often presents as meningitis. The infection may have been acquired during the intrauterine phase, during passage through birth canal, or from other neonates in the hospital.

In other than expectant mothers, listeriosis occurs primarily in 'at risk' individuals who are immunocompromised owing to acquired immunodeficiency syndrome, immunosuppressive therapy or old age, or who have malignant diseases, diabetes, or hepatic conditions. The most common clinical symptoms are meningitis/meningoencephalitis, with mortality rates between 20% and >50% and sepsis. Other forms of disease caused by *L. monocytogenes* include endocarditis, cutaneous infections in farmers and veterinarians associated with handling infected animals, and variously localized infections.

Some reports indicate that noninvasive listerial infections can occur in healthy adults, primarily after ingestion of high numbers of the pathogen in food, with an incubation time of 24 h and febrile gastroenteritis symptoms, including vomiting and diarrhea. This condition is usually self-resolving but sometimes progresses to bacteremia.

The drug of choice for the treatment of listeriosis is a β-lactam antibiotic (e.g., penicillin) alone, or in the case of immunocompromised patients in combination with an aminoglycoside (e.g., gentamicin). As a second choice, especially

for patients allergic to β-lactams, trimethoprim and sulfonamide (e.g., sulfamethoxazole) are used in combination. The treatment may last as long as 6 weeks in immunocompromised patients, owing to the risk of relapse from *L. monocytogenes* surviving within the host cells. Although *L. monocytogenes* strains from food and food processing environments as well as human isolates are susceptible to the antibiotics commonly used for the treatment of listeriosis, some strains are resistant to one or more of the antibiotics nalidixic acid, oxacillin, clindamycin, tetracycline, and oxytetracycline. Usually, the antibiotic resistance of *Listeria* spp. is due to the acquisition of mobile genetic elements. Therefore, the potential for acquisition of resistance by *Listeria* spp. to a broader range of antibiotics is possible, with consequent difficulties for management of invasive infections.

Mechanism of Pathogenicity

The pathogenesis of listerial infection is still poorly understood. Although small numbers of *L. monocytogenes* may often be ingested with foods, the prevalence of listeriosis is low. The infective dose is variable, as is the incubation period. These variations are caused by interrelationships between the three main factors that determine the course of an infection. These are the number of *Listeria* cells ingested, the pathogenicity/virulence of the strain involved, and the immunological status of the host.

Virulence heterogeneity among *L. monocytogenes* isolates has been commonly observed. It is of interest that most isolates from foods belong to serogroup 1/2, but more than 50% of listeriosis cases worldwide are caused by serotype 4b. It might be that serotype 4b is particularly well adapted to host tissues. Further, some species-related tropisms exist among strains of *L. monocytogenes*. For example, some ribotypes of *L. monocytogenes* serotype 4b associated with human foodborne outbreaks are only infrequent causes of ruminant listeriosis.

Colonization of the Host

Ingested *L. monocytogenes* cells apparently invade the host tissue via the M cells that overlay Peyer's patches in the intestine; but the mechanism by which they enter these cells is still unclear. Subsequently, the pathogen is carried in the blood and lymph to the mesenteric lymph nodes, the liver, and the spleen. Resident macrophages in the liver and spleen rapidly clear the pathogen from the blood with most of the invading cells being captured and killed by liver Kupffer cells. However, surviving *L. monocytogenes* multiply within the hepatocytes and spread directly between them. Hepatocytes respond by releasing neutrophil chemoattractants, initiating apoptosis, and producing a local immune response. After mononuclear cells and lymphocytes from the blood become involved, characteristic granulomas are formed. Several days after infection, *L. monocytogenes* starts to disappear gradually from the organs as a result of a complex immune reaction involving macrophage activation and the action of cytotoxic T lymphocytes that finally destroy *Listeria*-infected cells. In the immune host previously exposed to the pathogen from foods or the environment, this chain of events results in rapid elimination of the pathogen from the liver. In immunocompromised hosts, the immune response in the liver is inadequate and, consequently, *L. monocytogenes* can proliferate, recontaminate the blood, and subsequently infect a range of tissues, but with significant tropism for the pregnant uterus and central nervous system.

Intracellular Cycle of Infection

Listeria monocytogenes can be internalized within various types of eukaryotic cells. The process starts with the pathogen's adhesion to the cell surface, on which it recognizes a number of receptors. It then is gradually engulfed by the host cell and becomes internalized within a phagocytic vacuole.

Listeria monocytogenes can remain viable in the vacuole because it prevents phagosome maturation to the phagolysosomal stage. Subsequently, it disrupts the phagosome membrane by a hemolysin-mediated process and enters the cytoplasm. In the cytoplasm, the bacteria start to multiply and become surrounded by actin filaments, which later form an actin tail at one end of each bacterial cell. The actin tails allow the bacterial cells to move in the cytoplasm until some of them reach the host cell membrane. When a bacterium presses against the cell membrane, a protrusion with the bacterium at the tip is formed. The protrusion penetrates a neighboring tissue cell. The bacterium and the protruded membrane become engulfed in a secondary phagosome so that the bacterium is surrounded with a double membrane. Dissolution of these membranes frees the pathogen to begin a new intracellular cycle.

Virulence Factors

Numerous genes and virulence factors contribute to the pathogenicity of *Listeria*. Virulence factors involved in infection are hemolysin (LLO); two phospholipase C enzymes, PC-PLC, and PI-PLC; internalins A (InIA), B (InIB), and C (InLC); and the protein ActA. Although InIA interacts with E-cadherin to mediate *L. monocytogenes* entry into epithelial cells, InIB facilitates its entry into a much broader range of cell types including hepatocytes, fibroblasts, and epithelioid cells. InLC may promote invasion of neighboring host cells. The vacuole formed around *L. monocytogenes* when it invades a cell is lysed by LLO and the two phospholipase C enzymes. LLO not only mediates lysis of the primary phagosome formed during uptake of the bacterium, but it is also required for escape from the double membrane vacuole that is formed during cell-to-cell spread of *L. monocytogenes*. The pores or membrane lesions caused by LLO probably facilitate access of the phospholipases to their substrates, leading to total dissolution of the phagosome. The intracellular mobility and cell-to-cell spread of *L. monocytogenes* require another surface protein, ActA, which is cotranscribed with PC-PLC. ActA mediates the formation of the polarized actin tail that propels the bacterium within the cytoplasm.

The adaptive, stress-mediated response of *L. monocytogenes* following exposure to sublethal hot, acidic, cold, or starvation conditions can increase its resistance to subsequent stressful conditions. Such stress hardening, particularly that caused by the acid condition that can be encountered in some foods and in the stomach, may also affect pathogenicity. Antioxidants such as catalase and superoxide dismutase play

a key role in the pathogen's defense against the oxygen-dependent microbiocidal mechanisms of the host.

Epidemiology of Meatborne Listeriosis

Contamination of Meat Processing Environments and Meats

Listeria monocytogenes is ubiquitous in the environment (see Figure 3), and is commonly present in food plants, including red meat and poultry abattoirs, and meat processing facilities. The organism can colonize equipment, walls, floor surfaces, and drains, as it adheres to and can form biofilms on stainless steel, glass, rubber, and polypropylene surfaces. The widespread presence of *L. monocytogenes* on raw materials and in processing environments leads to relatively frequent contamination of meat products with the organism. However, the strains found in meat products are a limited group of the strains present in animals, raw materials, or food manufacturing environments.

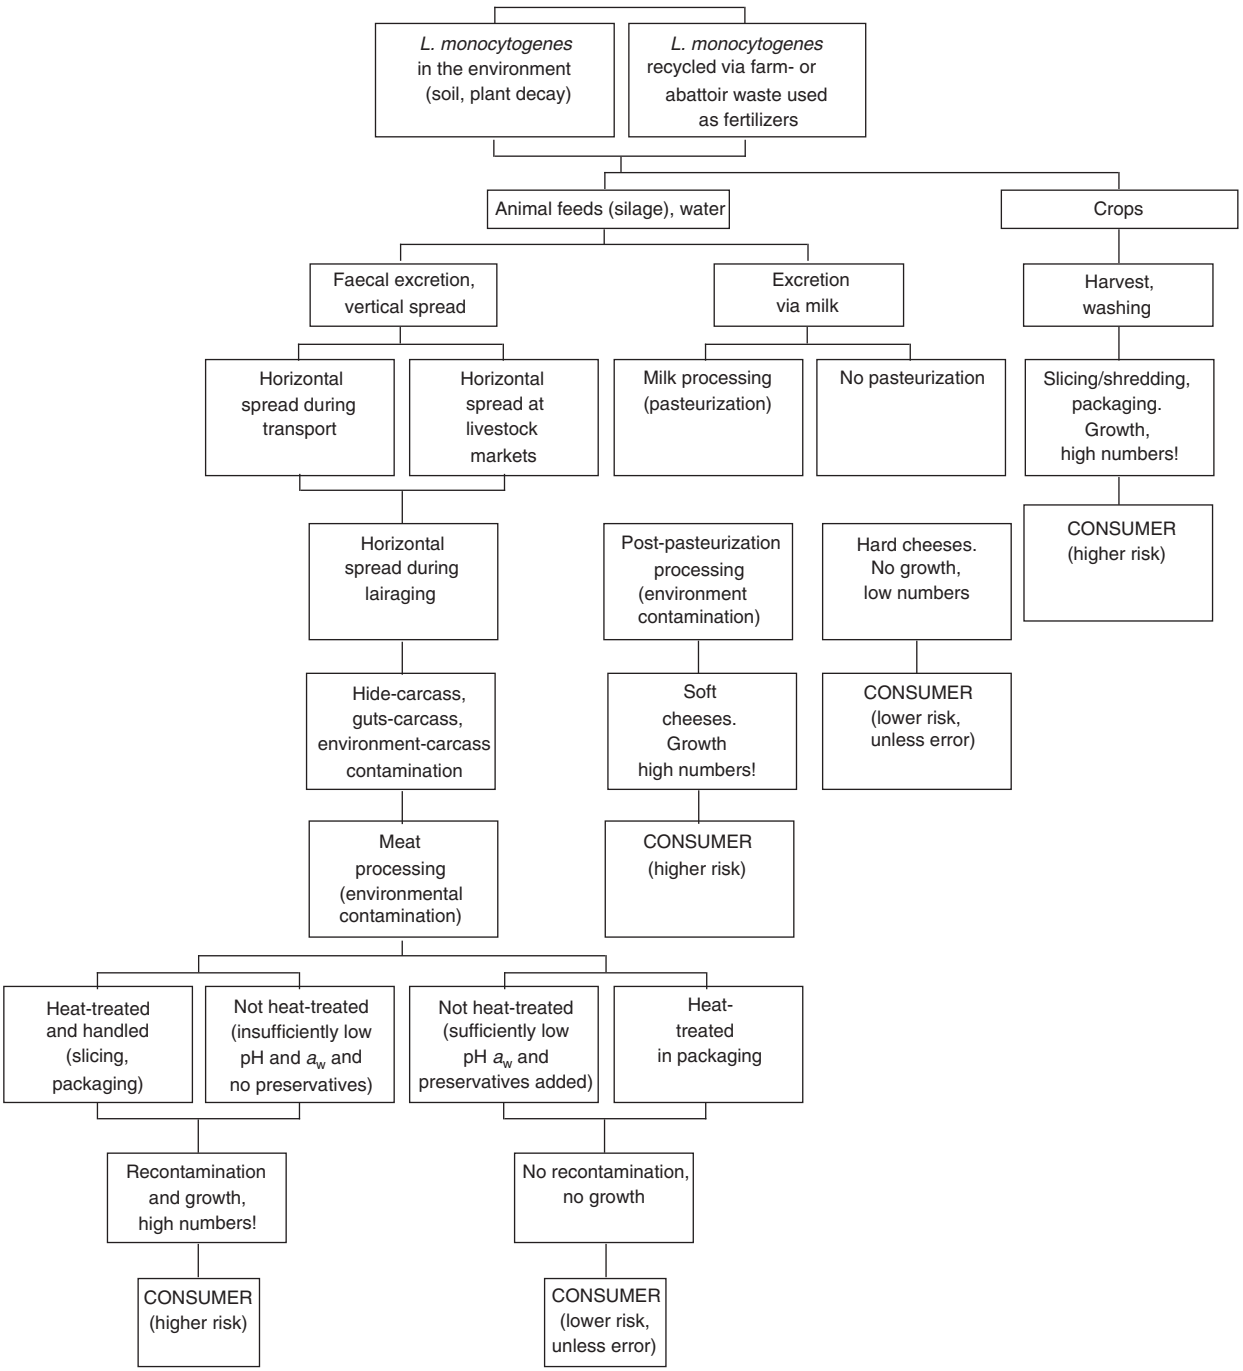

Figure 3 General epidemiology of foodborne listeriosis.

Incidence, Growth, and Survival on Meats

Reported prevalences of *L. monocytogenes* in meats (Table 2) vary greatly owing to differences in isolation methods, sizes of samples, product type, place and time of sampling, sanitation practices, production volume, season of the year, and temperature. Although *L. monocytogenes* is frequently located on product surfaces, it has occasionally been found within muscle tissue, indicating possible contamination of animal tissues before or during slaughter.

Listeria monocytogenes grows well on many foods, including meat, poultry and fish, but growth is dependent on temperature, pH, a_w, and the atmosphere around the food. The lower limits of temperature, pH, and a_w for growth of *L. monocytogenes* appear to be –0.4 °C, 4.4, and 0.90, respectively. The organism can grow in 10% NaCl. In foods, the temperatures, pH values, a_w values, and NaCl concentrations at which growth occurs are usually more restricted and are affected by food type, oxygen availability, and *Listeria* strain variability. Reported rates of growth of *L. monocytogenes* on meats are inconsistent, because of differences in the conditions used in studies; and because results obtained with different strains grown under the same condition can vary substantially.

Heat treatment is the most effective means of eliminating *L. monocytogenes* from meats. *Listeria monocytogenes* appears to be more heat resistant than other nonspore-forming foodborne pathogens, so cooking recommendations designed for rendering meat safe with respect to *Salmonella* might not be sufficient to eliminate *Listeria*. Table 3 illustrates the heat resistance of *L. monocytogenes* in meat substrates.

Listeriosis Associated with Meats

The incidence of listeriosis in human populations varies among countries. In the European Union (EU), the number of confirmed listeriosis cases in humans increased by 19.1% from 2008 to 2009. On the basis of the reported fatality rates and the total numbers of confirmed cases, it was estimated that in 2009 there were approximately 270 human deaths due to listeriosis in the EU. In the US, although *L. monocytogenes* is not among the five pathogens that cause most domestically acquired foodborne illnesses or hospitalizations, the number of deaths caused by this pathogen is relatively high. Although there were only 125 cases of foodborne listeriosis reported from 1996 to 2010, the case–fatality ratio of 12.8 was the highest among those pathogens that cause the most foodborne illnesses. In Canada, *Listeria* cause similar low rates of illness, but in 2008 a listeriosis outbreak caused by consumption of contaminated RTE meats claimed 23 lives.

Vehicles of infection in outbreaks of foodborne listeriosis have included dairy and various meat products (Table 4). Generally, it is accepted that *L. monocytogenes* levels at the time of consumption of < 100 cfu g^{-1} of food represent a very low risk for all populations. This limit relates not to dose but to a concentration, and is not based on a formal dose–response formula. Although this level might not be exceeded at the time of production of a RTE food, it might be exceeded after growth in the food. Risk management strategies are focused on those foods in which *L. monocytogenes* can multiply and are consumed without cooking.

Control and Preventive Measures

In some countries, such as the US, the total absence of *L. monocytogenes* from all RTE foods is required. In others, such

Table 5 Grouping of ready-to-eat (RTE) foods relative to control potential for *Listeria monocytogenes*

Categories	*Food related*	*Sampling*	*Analysis*	*Action level for* L. monocytogenes
1. RTE foods in which growth of *L. monocytogenes* can occur throughout the stated shelf life, for example, durable life date shown as a 'best before' date on the package	Deli meats, soft cheeses, hot dogs, and pâté	5 sample units (min 100 g or ml each), which are representative of the lot and the production conditions, taken aseptically at random from each lot	5×25 g analytical units are either analyzed separately or composited	Detected in 125 g
2. (a) RTE foods in which a limited potential for growth of *L. monocytogenes* to levels not greater than 100 cfu g^{-1} can occur throughout the stated shelf life (e.g., durable life date shown as a 'best before' date on the package)	Refrigerated gravlax/ cold-smoked rainbow trout and salmon, fresh-cut produce, etc.	5 sample units (min 100 g or ml each), which are representative of the lot and the production conditions, taken aseptically at random from each lot	5×10 g analytical units	>100 cfu g^{-1}
(b) RTE foods in which growth of *L. monocytogenes* cannot occur (i.e., <0.5 log cfu g^{-1} increase (validation may be needed)) throughout the stated shelf life, for example, durable life date shown as a 'best before' date on the package	Ice cream, hard cheese, dry salami, dried-salted fish, and varieties of prosciutto ham	5 sample units (min 100 g or ml each), which are representative of the lot and the production conditions, taken aseptically at random from each lot	5×10 g analytical units	>100 cfu g^{-1}

Source: Data from Health Canada, 2011. Policy on *Listeria monocytogenes* in ready-to-eat foods. Bureau of Microbial Hazards Food Directorate Health Products and Food Branch. Identification Number: FD-FSNP 0071. Available at: http://www.hc-sc.gc.ca/fn-an/legislation/pol/policy_listeria_monocytogenes_2011-eng.php (accessed 06.11.13).

as Canada, this is regarded as unattainable. Instead, foods are classified with respect to risks from *L. monocytogenes* according to the lethality of the process used, controls in place to prevent recontamination, and the potential for growth of *L. monocytogenes* during food storage. The categories currently used in Canada are presented in **Table 5**, but groupings are somewhat different in other countries. Packaged, long shelf life foods that are not cooked in the final package generally pose the highest risks with respect to foodborne listeriosis.

The control of *L. monocytogenes* in RTE meat and poultry products is extremely important given the ubiquitous presence of *Listeria* in the environment, its tolerance to unfavorable environmental conditions such as low pH and high NaCl levels, its ability to survive on equipment, its potential to contaminate products after processing, and its ability to multiply at cold temperatures. Commonly, thermal processing eliminates *L. monocytogenes* from products, but recontamination from food contact surfaces and aerosols generated during cleaning represent constant challenges.

To control *L. monocytogenes* on RTE meat and poultry products, the US Department of Agriculture requires adoption of one of the three processing alternatives: (1) the use of a postlethality treatment that reduces or eliminates *L. monocytogenes* and an antimicrobial agent or process that supresses or limits *L. monocytogenes* growth throughout product shelf life; (2) the use of either a postlethality treatment or an antimicrobial agent or process that achieves the same result; or (3) reliance upon a suitable sanitation program to control *L. monocytogenes*. End-product sampling requirements for *L. monocytogenes* increase with the risk inherent in the processing alternative chosen, the product type, and production volumes/unit time.

As freezing causes injury in surviving *L. monocytogenes* cells, it is not surprising that when combined with another antimicrobial hurdle, cells in thawed RTE meats grow relatively slowly at 4 °C. It is worth noting that the organic acids naturally present in products like pepperoni were more antilisterial during product temperature abuse (12 °C and 25 °C) than at 4 °C.

Regardless of whether foodborne illness from *L. monocytogenes* is caused by fresh produce (celery and melons) or packaged cured meats, processing plants are critical points where control can be achieved and must be applied. With processed meats, cooking (69–71 °C) eliminates the organism, but its survival and growth on downstream processing equipment, as well as on food contact surfaces used for any of these types of product must be constantly addressed to prevent cross-contamination arising as a result of biofilm development.

Pathogenic *Escherichia coli*

N Fegan and KS Gobius, CSIRO Animal, Food and Health Sciences, Werribee, VIC, Australia
GA Dykes, Monash University, Bandar Sunway, Malaysia

Glossary

Bacteremia The presence of bacteria in the blood.
Bacteriophage Any virus that can infect bacteria.
Epithelium A tissue that lines surfaces and cavities in the body.
Fimbriae A thin surface appendage produced by many bacteria.
Pathogenicity island A horizontally transferred group of genes that confer virulence to a bacterium.
Plasmid A deoxyribonucleic acid molecule that is not part of the chromosome and can replicate independently of it.

Introduction

Most *Escherichia coli* live as harmless commensals in the intestines of warm-blooded animals, but certain types can cause disease in their hosts; these latter organisms are referred to as pathogenic *E. coli* (PEC). The diseases that might be caused by PEC are varied and depend on the site of infection.

Extraintestinal PEC (ExPEC) cause diseases outside the gastrointestinal tract, the most common of which are urinary tract infections resulting from infection with uropathogenic *E. coli*. ExPEC have also been associated with sepsis, meningitis, pneumonia, and wound infections. The sources of ExPEC are believed to be the intestines of humans, although evidence is emerging that animals might be a source of at least some ExPEC.

Of greater current concern with respect to food are *E. coli* that cause diseases of the gastrointestinal tract. Gastroenteritis can be caused by a variety of different types of PEC. The major types are described in Table 1. Symptoms range from diarrhea, which can be either acute or chronic, to more severe complications that can result in death. These pathogenic types are grouped on the basis of the diseases they cause and on specific virulence factors, which are involved in the disease process. Those factors that are known to be important in gastrointestinal diseases tend to be associated with attachment of the organisms to the intestines and, in some cases, the production of toxins.

Enteroinvasive *E. coli* are closely related to *Shigella* spp. They cause a disease similar to shigellosis, with invasion of the intestinal epithelium and inflammation of the intestines. The genes that confer invasiveness are carried on a plasmid referred to as pInv. Enterotoxigenic *E. coli* (ETEC) are the major cause of traveler's diarrhea. Infection is initiated through attachment to and subsequent colonization of the intestines. Attachment involves the production of fimbriae called colonization factors. Once the intestines have been colonized, ETEC produce heat-stable (ST) and heat-labile toxins, which cause a watery diarrhea that might be mild, short lived, and self-limiting or severe and possibly fatal, as in patients with cholera.

Enteroaggregative *E. coli* (EAEC) have been associated with persistent diarrhea (i.e., lasting more than 14 days) in infants in developing countries, but EAEC can also cause acute diarrhea in adults and infants and are the second greatest cause of traveler's diarrhea. This group of *E. coli* is diverse with respect to virulence factors but generally display aggregative adherence (AA), i.e., the cells attach to the gut wall and form layers with one another in a stacked-brick appearance. Most EAEC produce AA fimbriae, which are involved in AA and can also be important in attachment to the host tissues. EAEC can also

Table 1 The diseases and major virulence factors of pathogenic *Escherichia coli* associated with intestinal illnesses

Type	*Time to illness*	*Disease*	*Major virulence factors*	
			Attachment	*Toxins*
Enteroinvasive *E. coli*	8–24 h	Watery diarrhea and dysentery with blood and mucus	Invasion-related plasmid (pInv)	
Enterotoxigenic *E. coli* (ETEC)	8–44 h	Watery diarrhea and traveler's diarrhea	Colonization factors	Heat labile and heat stable
Enteroaggregative *E. coli* (EAEC)	8–48 h	Watery diarrhea, acute and persistent diarrhea, and the second greatest cause of traveler's diarrhea after ETEC	Aggregative adherence fimbriae	EAEC heat-stable enterotoxin
Enteropathogenic *E. coli*	12–36 h	Watery diarrhea with mucus and infant diarrhea	Locus of enterocyte effacement (LEE) and bundle-forming pilus	
Enterohemorrhagic *E. coli* and Shiga toxin-producing *E. coli*	3–4 days	Diarrhea, bloody diarrhea, hemolytic uremic syndrome, and death	LEE and others	Shiga toxins (Stx1 and Stx2)

produce the enteroaggregative ST toxin, which is similar to ST found in ETEC, and can possess genes for a variety of other possible virulence factors.

Enteropathogenic *E. coli* (EPEC) are a leading cause of diarrhea in infants in developing countries. EPEC cause attaching and effacing (A/E) lesions in the intestines as a result of the intimate attachment that occurs between the bacteria and the host cells. The cell components required for this intimate attachment are encoded by genes located on a pathogenicity island termed the locus of enterocyte effacement (LEE). Most EPEC can also produce fimbriae called bundle-forming pili, which are responsible for bacterium–bacterium attachment and can be involved in the initial attachment of EPEC to intestinal cells.

Enterohemorrhagic *E. coli* (EHEC) can cause bloody diarrhea (hemorrhagic colitis) or more severe disease, such as hemolytic uremic syndrome (HUS) that can lead to death. EHEC are a subset of the broader group of Shiga toxin-producing *E. coli* (STEC) that can produce Shiga toxins (Stx). EHEC is the term given to STEC that have caused clinical disease, although STEC is often used more broadly when referring to EHEC. The term verotoxin-producing *E. coli* is an earlier synonym of STEC that is still sometimes used in the literature and refers to the toxicity of these strains against Vero monkey kidney cells *in vitro*. In addition to Stx, most EHEC also carry LEE or other adherence factors that assist in colonization of the host's intestines. EHEC of serotype O157:H7 have been responsible for large foodborne outbreaks, many of which have been linked to the consumption of meat and meat products. For this reason, in 1994, *E. coli* O157:H7 was declared an adulterant of ground beef by the Food Safety and Inspection Service (FSIS) of the United States Department of Agriculture (USDA). The term STEC has been used to refer to this group of strains in its broader sense throughout most of this article as opposed to the more specific EHEC.

Other *E. coli* that are able to cause diarrhea include diffusely adherent *E. coli*, cell-detaching *E. coli*, and cytotoxic necrotizing *E. coli*, but little is known about the significance and impact of these *E. coli* as human pathogens or their relationships with animals used for meat production. Many of the virulence factors of PEC are mobile and can move between strains of *E. coli* to produce new pathogenic types. Thus, the *E. coli* O104:H4 outbreak in Germany and other parts of Europe during 2011, which affected more than 4000 people, with more than 900 cases of HUS and at least 50 deaths, was caused by a strain of serotype O104:H4 that was essentially an EAEC which had acquired Stx and multiple antibiotic resistances. New combinations of virulence factors in *E. coli* are most likely to lead to new pathogenic types arising in the future.

All gastrointestinal PEC can be spread from human to human, either directly or through food and water that has been contaminated by humans. In addition to human sources, STEC have animal reservoirs and can be transmitted to humans through consumption of foods made from contaminated meat or by direct contact with contaminated animals. Ruminants, particularly cattle, are the major reservoir of STEC, and milk and meat have been implicated in outbreaks. For this reason the focus of the remainder of this article is on STEC as they are the most significant PEC associated with meat.

Clinical Significance

Human infection with STEC can cause a spectrum of diseases ranging from asymptomatic carriage to death. Worldwide, *E. coli* O157:H7 is the most common cause of HUS. However, in several outbreaks, the *E. coli* O157:H7 outbreak strain was isolated from stools of asymptomatic persons as well. The normal signs of *E. coli* O157:H7 gastroenteritis include abdominal pain, nonbloody diarrhea followed by bloody diarrhea after 1–4 days, absence of fever, and five or more bowel movements per day. HUS develops 5–13 days after initial diarrhea in 10–15% of patients, most commonly children who are less than 5 years of age. HUS is characterized by an acute onset of kidney damage. Additional severe extrarenal complications, including neurological impairment, increased pancreatic enzymes, edema, necrosis of the colon wall, and myocardial and central nervous system damage, can result from HUS and often lead to death. STEC infections generally do not result in bacteremia, indicating that the systemic complications of HUS are attributable to circulating Stx. The cell surface receptor glycosphingolipid globotriaosylceramide (Gb3) is present on cells in the human kidney. Stx binds to Gb3 and is internalized by endocytosis, resulting in protein synthesis inhibition through disruption of the 28S ribosomal subunit.

Molecular Aspects of Pathogenicity

Production of Stx is essential for the pathogenesis of bloody diarrhea and HUS caused by both *E. coli* O157:H7 and non-O157 STEC. Two main Stx types are encoded by bacteriophages integrated into the chromosomes of STEC/EHEC strains. Stx1 is closely related to the Stx of *Shigella dysenteriae*, but Stx2 shows only 55–60% deoxyribonucleic acid (DNA) and amino acid similarity to Stx1. Although a variety of genetic subtypes of stx_1 and stx_2 genes have been described, expression of the stx_2 gene is most strongly associated with significant clinical manifestation of bloody diarrhea and HUS. In addition to Stx production, all *E. coli* O157:H7 and most non-O157 STEC (e.g., serotypes O26, O45, O103, O111, O121, and O145) also encode the LEE pathogenicity island. However, HUS is also caused by some LEE-negative serotypes (e.g., O91, O104, and O113), indicating that LEE is not essential for HUS causation and that additional virulence factors might contribute to the severe illnesses caused by these serotypes.

There are phylogenetic and geographic variations among *E. coli* O157:H7 strains in the potential for disease causation and the severity of the illness they cause. Three lineages of *E. coli* O157:H7, LI, LII, and LI/II, have been identified. Although all lineages are found in the bovine O157 reservoir, LI and LI/II are overrepresented among human O157:H7 isolates. LI predominates in North America and Japan, whereas LI/II is most prevalent in the Netherlands. Stx bacteriophage association with the different lineages are also frequently observed: LI isolates carry stx_1 and stx_2 bacteriophages; LII isolates carry stx_{2c} bacteriophage; and LI/II isolates carry stx_2 alone or stx_2 and stx_{2c} bacteriophages. Eight virulence clades were identified among North American human isolates and these clades were correlated with historical *E. coli* O157:H7 outbreaks occurring

in the United States. Infections caused by clades 1, 2, and 3 (also typed as LI) isolates from 1982 and 1993 hamburger outbreaks were less severe than clade 8 (also typed as LI/II) isolates from the 2006 spinach and lettuce outbreaks.

Ecology

STEC shed in animal feces can remain viable in the environment for up to several months. Animal manure and wastes that carry STEC can enter water sources. Contaminated water used for irrigation contaminates fresh produce. Swimming in or drinking contaminated water can lead to human illness, as can direct contact with animals on farms or at petting zoos.

Most of what is known about the ecology of STEC comes from the study of *E. coli* O157:H7. Much less is known about STEC of other serotypes. The major reservoir of *E. coli* O157:H7 are ruminant animals, particularly cattle. *Escherichia coli* O157:H7 has also been isolated from sheep, deer, and goats. Nonruminant animals, such as pigs, horses, rabbits, birds, and flies, have also been found to carry *E. coli* O157:H7 on occasion. *Escherichia coli* O157:H7 does not cause disease in cattle. It is found in the intestines of healthy animals and, if so, is shed in feces, which commonly contaminate animal hides. The organism is also found in the mouths of animals. The prevalence of *E. coli* O157:H7 in herds of cattle can vary over time. In the Northern Hemisphere, the highest prevalence is observed in the warmer summer months. Not all animals within a herd may shed *E. coli* O157:H7 at the same time, and those animals which do, mostly shed only very low numbers. Occasionally, an animal may shed high numbers ($>$ 10 000 cfu g^{-1}) of *E. coli* O157:H7. These animals, which have been termed super shedders, are thought to pose the greatest risk for meat contamination during slaughter and processing. The reasons why some animals on occasion shed high numbers of *E. coli* O157:H7 are unknown. Various means of preventing shedding of *E. coli* O157:H7 have been proposed with a view to reducing contamination of meat and meat products. However, no method has as yet been shown to have consistent and substantial effects in practice.

STEC generally are commonly found in ruminant and other animals. STEC other than *E. coli* O157:H7 can account for more than half of STEC illnesses in humans. Non-O157 STEC are transmitted to humans in the same manners as are *E. coli* O157:H7.

Presence and Survival on Meat

Most published data on STEC in meat and meat products are for the prevalence of *E. coli* O157:H7. The prevalence of *E. coli* O157:H7 on carcasses and on retail product is generally less than 0.3%. However, some studies have reported prevalence on carcasses and retail product $>$30% and $>$3%, respectively.

To cause foodborne disease, STEC need to survive and possibly grow on meat products. There is very little evidence to suggest that PEC on meat products behave much differently from *E. coli* generally. On raw chilled or frozen meats, *E. coli* O157:H7 and other STEC can survive for extended periods but do not grow. Although some decrease in numbers of the pathogen might occur during storage under refrigeration, this is not usually sufficient to eliminate them. Their presence on refrigerated products is of concern because of their relatively low infectious doses and because cross-contamination of other food products may occur. STEC is eliminated in properly cooked products. The survival and growth of STEC in processed meats is dependent on factors such as the pH, water activity, and the presence of preservatives in the products. Control of these qualities in some products, such as certain types of salami, is critical for preventing the growth of these pathogens. Although it has been suggested that *E. coli* O157:H7 are more resistant to acidic conditions than other *E. coli*, the available evidence indicates that this is not the case. Control of PEC growth can generally be achieved by the same measures that control the growth of generic *E. coli* (see Section 'Control' below).

Detection

There are many challenges associated with the detection and isolation of PEC in meat and meat products. These include low prevalence, low numbers if present, and the presence of other bacteria, including non-PEC in meat and meat products. Sampling plans and test methods have been progressively developed to counter these challenges. An example of this is the microbiological testing program for *E. coli* O157:H7 in beef developed by the USDA FSIS. This was introduced in 1994 when US legislation categorized *E. coli* O157:H7 as an adulterant of ground beef. There have been several changes made since then to improve the sensitivity of the methods, for example, adoption of improved detection methods and increasing the amount of meat tested from 25 to 375 g. The general approach for detection of PEC in meat involves enrichment, screening to determine whether the target *E. coli* is present, and then isolation and confirmative identification of the pathogen. Enrichment is used to increase the numbers of PEC; however, this also increases the numbers of other bacteria. Selective agents, such as antimicrobials or other chemicals, may be added to inhibit competing bacteria. After enrichment, samples may be screened, using molecular methods (such as polymerase chain reaction) or immunological methods (such as enzyme immunoassays), for the presence of virulence factors, such as Stx and the *E. coli* attaching and effacing gene (*eae*) component of LEE, and specific serotypes, such as O157, O26, and O111.

If a molecular screening test is positive, the specific *E. coli* of interest must be isolated and confirmed. Within a single sample, the target serotype and individual virulence factors might each reside in a different *E. coli*. For example, a sample might test positive for Stx (or *stx*), *eae*, or LEE and serotype O111 on screening, implying that non-O157 STEC of serotype O111 is present in the sample. However, the *stx* gene might be carried in a nonpathogenic STEC, the *eae* gene in a different *E. coli*, and the O111 strain might be in yet another *E. coli*. In this case, the sample is negative for non-O157 STEC of serotype O111. The isolation of PEC from enriched samples can be difficult because of the presence of large numbers of other bacteria. Immunocapture can assist isolation of specific serotypes of *E. coli* through concentration of the target

organisms. For this, antibodies specific to a serotype are coated on magnetic beads or other particles. These antibodies bind cells of the target serotype by forming antibody–bacteria complexes. The coated particles can then be removed from the sample. In the case of magnetic particles, a magnet is used to remove the particles. This process is termed immunomagnetic separation. The antibody–bacteria complexes may then be tested further for the presence of the target serotype using selective and differential plating media or molecular detection methods.

Differentiating target *E. coli* from other *E. coli* on selective and differential media presents challenges as most *E. coli* share common phenotypic properties. A range of selective and differential media have been tested for the isolation of *E. coli* O157:H7 and non-O157 STEC. Most *E. coli* O157:H7 are phenotypically different from other *E. coli* in that they are unable to ferment sorbitol. Consequently, most *E. coli* O157:H7 produce colorless colonies on Sorbitol MacConkey Agar (SMAC), whereas other *E. coli* produce pink colonies. Cefixime and tellurite are commonly added to SMAC to improve its selectivity by inhibiting the growth of competing bacteria. *Escherichia coli* O157:H7 are also unable to produce the enzyme glucuronidase, a trait that differentiates them from most other *E. coli*. Such variations in biochemical abilities of different *E. coli* strains have been exploited to produce a range of chromogenic media for detection of different strains of *E. coli*. These media contain substrates that change color when cleaved by enzymes produced by bacteria. Unlike *E. coli* O157:H7, the non-O157 STEC are not easily differentiated from other *E. coli* on the basis of phenotypic differences. Once suspect colonies have been obtained, confirmation is necessary to ensure that the organism is an *E. coli* that carries the specific virulence factors and belongs to the serotype of interest. A range of biochemical, molecular, or immunologically methods can be used for confirmation.

There are many commercial test kits (including molecular and immunological) for detection of *E. coli* O157:H7. Methods for the non-O157 STEC are becoming commercially available in response to six of the non-O157 STEC serotypes being declared adulterants of ground beef by the USDA FSIS. Ongoing research into the pathogenic mechanisms of *E. coli* can identify more specific targets and lead to improvements of detection and isolation methods in the future.

Control

Numerous methods have been developed and applied in an attempt to control PEC on meat in general and beef in particular. These methods are applied at points in the production and supply chain from on the farm through primary processing to preservation of retail products. Some of the methods used and found to be effective not only control PEC but also affect generic *E. coli* and other bacteria as well. General approaches to hygiene and preservation fall into this category. More specific approaches to the control of PEC in meat have tended to focus on the control of *E. coli* O157:H7.

Results obtained with on-farm methods for the control of *E. coli* O157:H7 generally have been inconclusive, with many being found effective under some conditions but not under others. Given the diversity of agricultural practices associated with the production of meat, this is not surprising. Manipulation of diet has been one approach with, for example, high-fiber/low-energy and low-fiber/high-energy diets reportedly resulting in different prevalence and shedding rates of *E. coli* O157:H7 in various meat animal species. In particular, it has been postulated that the ratios of volatile fatty acids in and the pH of the rumen, which change with different diets, contribute to this effect. The gastrointestinal tracts of ruminants are, however, very complex and many factors might influence their functioning. Thus, no clear recommendations on the best diet to use to reduce *E. coli* O157:H7 carriage and shedding can be made. Vaccines represent another type of intervention that has been investigated for the control of *E. coli* O157:H7 in cattle. Although showing some promise, none of the vaccines developed so far can eliminate or consistently reduce carriage of this pathogen. Other methods that have been investigated to control *E. coli* O157:H7 on farm have been the supplementation of the feed or water of livestock with probiotics (live microbes with beneficial effects), bacteriophages (viruses that infect and kill specific bacteria), and chemicals, such as sodium chlorate. Although these methods have proved effective in trials, their practical value has generally been shown to be not as great as initially thought. On-farm interventions have included attempts to control PEC in the farm environment in order to restrict cross-contamination and reinfection of animals. Increased sanitation of equipment, such as water troughs, is an example of this form of control. Although such interventions are commendable and may reduce spread of a range of bacteria, they are unlikely to greatly reduce the risks posed by these bacteria.

A very wide range of methods have been applied for control of PEC (particularly *E. coli* O157:H7) during primary processing and in retail ready products. Many of these are general antimicrobial techniques that have either been tested on, or refined for effect on, PEC. Interventions that have been applied include steam pasteurization and treatment of carcasses, cuts trimmings, and other forms of meat with ionizing radiation, ozone, ultraviolet light, and chemical antimicrobials, such as chlorine and organic acids. Many of the methods have been shown to be effective in reducing both prevalence and numbers of, in particular, *E. coli* O157:H7 on carcasses and in retail products. None of the techniques have been shown to be completely effective for eliminating this pathogen under all conditions. In addition, many of the methods used have drawbacks associated with them, including the presence of potential harmful residues or a reduction in the quality of the meat product to which they have been applied. In most cases, a series or combination of rigorously tested and approved (by regulation) treatments used in combination have been shown to reduce the risks associated with these pathogens but not eliminate them.

The control of PEC throughout the food system is an area of active and ongoing research. Progress has been made in controlling PEC, particularly *E. coli* O157:H7, but the recent emergence of new serotypes and strains of concern to public health has complicated this endeavor. The search for effective means of controlling an ever-increasing array of pathogenic strains of *E. coli* will, undoubtedly, continue.

Glossary

Astrogliosis An abnormal increase in the number of astrocytes, which are large, star-shaped cells in tissues of the nervous system, due to the destruction of nearby neurons.

Lymphoreticular system The tissues of the lymphoid and reticuloendothelial systems are regarded together as one system. It comprises primary lymphoid organs (bone marrow, bursal tissue, and the thymus), which are responsible for the production of lymphocytes, and the secondary lymphoid organs (lymph nodes, spleen, and gut-associated lymphoid tissue such as the tonsils and Peyer's patches), which function to provide an environment where lymphocytes can react to antigens from the tissue fluid, blood, and mucosal surfaces. The main functions of the lymphoreticular system are the removal of dying cells and the production of immune cells.

Neuropil A network of interwoven dendrites and axons and neuroglial cells in the gray matter of the central nervous system.

Introduction

Prion proteins are naturally occurring cell surface-anchored glycoprotein cellular proteins (PrP^Cs) that are found in fish, amphibians, birds, and mammals including humans. The biochemical function of PrP^C is not clear, but PrP^Cs are known to protect cells from oxidative damage, control circadian rhythms and sleep, and to be associated with the formation of memories. When PrPs are present with an abnormal conformation they can be infectious and recruit other PrP^Cs to change shape to the disease-forming isoform PrP^D. PrP^Ds are unique infectious agents that cause fatal neurogenerative diseases in humans and animals. In contrast to bacteria, viruses, and parasites, PrP^Ds do not contain nucleic acid, they are extremely difficult to destroy, and disease takes years to develop. Stanley Prusiner received the Nobel prize in 1995 for isolating proteinaceous infectious particles, which he termed 'prions,' and recognizing that prions are able to proliferate in the absence of nucleic acid. PrP^D is very resistant to degradative enzymes and cannot be broken down by the nerve cells. Nerve cells that incorporate PrP^D are eventually cleaved into fragments to leave cell-free holes in the brain. The cell fragments aggregate and precipitate to form plaques in the brain tissue, which eventually results in death. The spongiform damage, which is characteristic of prion-infected brain tissue, gave rise to the formal name 'transmissible spongiform encephalopathy (TSE)' for the disease condition caused by prions. TSEs include scrapie in sheep and goats, bovine spongiform encephalopathy (BSE) in cattle, chronic wasting disease (CWD) in elk and deer, transmissible mink encephalopathy in mink, and feline spongiform encephalopathy in cats. Human TSEs include Creutzfeldt–Jakob disease (CJD), fatal familial insomnia (FFI), Gerstmann–Sträussler–Scheinker syndrome (GSSS), and kuru. BSE is the only animal TSE known to be transmissible to humans.

An epidemic outbreak of BSE, also known as mad cow disease, occurred in the 1980s in the UK. The outbreak was apparently due to the practice of supplementing cattle feed with rendered animal byproducts that included bovine tissues carrying BSE prions. The outbreak had a devastating economic impact on the beef industry worldwide when concerns were raised about the microbiological safety of meat derived from animals infected with BSE as a result of a reported increase in new variant CJD (vCJD) in humans. This suggested that dietary exposure to BSE prions might in time give rise to a major epidemic of vCJD. Before 1986, TSEs were not regarded as agents of foodborne disease in humans and little was known about the mechanism of prion diseases. Since then, much research effort has been invested in the detection, origin, distribution, pathogenicity, transmission, control, and eradication of, and assessment of risks from, animal and human TSEs.

Biochemical and Biophysical Properties

The amino acid sequence of PrP^D is identical to that of PrP^C. The conversion of PrP^C to PrP^D involves a change in the secondary structure of a part of the protein, from α-helix to β-sheet. Thus, human PrP^C contains 42% α-helix and 30% β-sheet, whereas PrP^D contains 30% α-helix and 43% β-sheet. The β-sheet conformation is more hydrophobic than the α-helix conformation, which leads to aggregation of PrP^D and the formation of amyloid plaques. It is unclear if host-encoded cofactors are involved in the conversion of PrP^C to PrP^D. The mechanism of conversion between PrP^C and PrP^D and the three-dimensional conformation of PrP^D have not yet been resolved.

PrP^C is totally degraded by proteinase K and is soluble in detergents, whereas PrP^D is only partially degraded by the proteinase and is insoluble in detergents. PrP^D is extremely resistant to inactivation by chemical or physical methods. Total inactivation of materials contaminated with PrP^D can be achieved by incineration, autoclaving at 134 °C for 4.5 h, exposure to 1 M NaOH in combination with autoclaving, or exposure to 2% sodium hypochlorite, which is very corrosive. Materials treated with formaldehyde are more difficult to disinfect as formaldehyde cross-links and further stabilizes the

 doi:10.1016/B978-0-12-384731-7.00044-1

protein. PrP^D infectivity can be reduced by exposure to protein denaturing compounds, such as phenolics, guanidium thiocyanate, urea, and acidic 5% sodium dodecyl sulfate, or high doses of proteases, such as trypsin or proteinase K. BSE prions from cattle appear the most resistant to inactivation.

New techniques such as protein misfolding cyclic amplification, a concept similar to polymerase chain reaction (PCR) for amplification of nucleic acids, have been successful in detecting minute quantities of PrP^D from a wide range of species and matrices and could be a promising tool for screening tissues and blood of asymptomatic animals and humans.

Pathogenesis of Transmissible Spongiform Encephalopathies

Animal TSEs are transmitted primarily by the oral route. The minimum infectious dose is estimated at approximately 6 PrP^D monomers. Initially, PrP^D crosses the mucous membranes and is detected in the tonsils, Peyer's patches, and other gut-associated lymphoid tissue. PrP^D can be detected in the lymphoid tissue as early as 6 weeks and 3 months after exposure in CWD and scrapie, respectively. Replication of PrP^D can occur over months or years in the lymphoreticular system; however, with BSE and some scrapie cases, replication of PrP^D apparently does not involve the lymphoreticular system. The pathway and mechanism involved in the movement of PrP^D from the lymphatic tissues to the central nervous system (CNS) is not well understood. After a prolonged period of replication, PrP^D accumulates in the brain tissue, causing fatal neurodegenerative changes. TSEs are characterized by the accumulation of PrP^D in neurons and glial cells, with consequent vacuolation or spongiform changes in the neuropil and neuronal bodies in the gray matter of the CNS. In addition, some changes that may or may not be observed include neuronal death, astrogliosis, and the formation of amyloid plaques. As the amino acid sequence of a PrP^D is identical to that of the PrP^C that is encoded by the host, it is not recognized as a foreign protein by the immune system and an inflammatory response against PrP^D is not initiated.

Interspecies transmission of prion diseases is restricted by differences in the amino acid sequences of PrP^C from different species. However, PrP^D from a different species can infect and adapt to a new host. As the disease progresses, the concentration of host PrP^D increases which results in a more effective and efficient infection and transmission of disease. When the amino acid sequence of the acquired PrP^D prion closely matches that of the host PrP^C, there is a relatively high probability of the host developing the disease. When there is a lack of homology between the infectious prion and the host PrP^C, the probability of infection is reduced or the incubation period of the disease increases.

Animal Transmissible Spongiform Encephalopathiess

Bovine Spongiform Encephalopathy

The first case of BSE was diagnosed as a scrapie-like spongiform encephalopathy, in the UK in 1986, on examination of the brain tissue of an animal with neurological symptoms. Subsequent analysis indicated that BSE was present in cattle in the UK in 1985. Approximately 190 000 cases of BSE in farmed cattle have been reported worldwide to date, with more than 180 000 cases being in the UK. The outbreak peaked in 1992 in the UK, with 37 280 reported cases. Other affected countries include most European countries, Israel, Japan, Canada, and the USA. In 2011, there were 7 confirmed cases of BSE within the UK and 22 confirmed cases of BSE elsewhere.

Based on epidemiological evidence, the outbreak of BSE has been attributed to cattle feed which contained meat and bone meal (MBM) that was contaminated with BSE prions. Although the origin of BSE is unknown, it is widely suspected that the source of BSE prions was a cow that acquired BSE by a spontaneous conversion of PrP^C to PrP^D. The infected carcass was rendered into MBM and the PrP^D-contaminated MBM was served to cattle. The UK implemented a ban on feeding ruminant-derived MBM to ruminants in 1988. Owing to concerns about cross-contamination of ruminant feeds with nonruminant feeds that might contain ruminant proteins, the ban was extended in 1994 to the feeding of any mammalian proteins to ruminants; and further extended in 1996 to a complete ban on feeding mammalian MBM to any farmed livestock, including horses and fish. Cases of BSE occurred mainly in Europe because cattle producers in North America typically use plant-based dietary supplements rather than MBM.

A cow infected with BSE can spread PrP^D to her offspring, but embryos used in embryo transfers do not appear to carry or transmit BSE to the host or offspring. BSE does not appear to be transmitted directly from animal to animal and cattle do not appear to have a genetic disposition for infection with BSE prions. Young cattle are more susceptible than older cattle to infection with BSE prions, with cattle 0.5–1.5 years old being the most susceptible. The incubation period for naturally occurring BSE in cattle ranges from 2 to 8 years and the mean incubation period is estimated to be 4.5–5.5 years.

The pathway and mechanisms involved in the movement of PrP^D from the gut to the CNS are not well understood. Studies with mice have demonstrated that infectious BSE PrP^D accumulate in the Peyer's patches of the gut-associated lymphoid tissue. In cattle, there is little PrP^D replication in the lymphoid tissue, and PrP^Ds are thought to infect the CNS via the nerve endings in the intestinal tract. In cattle with clinical signs of BSE, infectious BSE particles are found in the brain, spinal cord, and dorsal root ganglia but not in peripheral nerves, lymphatic tissues, the gastrointestinal tract, reproductive and other organs, muscle, blood, or milk. BSE is difficult to detect as the incubation period is long, symptoms are apparent only toward the end of the incubation period, and cattle are often slaughtered before the onset of disease. Clinical symptoms include apprehension, nervousness, increased sensitivity to sensory stimuli such as light and noise, reluctance to be milked, aggression toward humans and animals, abnormal posture, lack of muscle control, difficulty in rising from a lying position, decreased milk production, and weight loss despite a normal appetite. The symptoms may persist for 2 weeks to 6 months before the animal dies, if it is not destroyed. There is no treatment or vaccine available for BSE.

Definitive diagnosis and confirmation can currently only be obtained postmortem by microscopic examination, immunohistochemistry, western blotting, and animal bioassays of the brain tissue. The classic diagnosis of BSE is the observation of characteristic sponge-like changes in sections of brain tissue, followed by confirmatory testing using immunohistochemistry and western blotting. Atypical strains of BSE have recently been identified by western blotting. These atypical strains have been distinguished as H-type and L-type based on relative higher (H) and lower (L) molecular mass banding patterns of the unglycosylated isoform of PrP^D in comparison with the classic BSE (C-type) associated with the original UK outbreak. The discovery of the L- and H- types, mainly in animals that were 8 years or older, has raised concerns about the existence of sporadic or spontaneous BSE. The L-type has been detected in cattle in Belgium, Italy, Canada, and Japan, whereas the H-type has been detected in cattle in France, Germany, the UK, Sweden, Canada, and the USA. Transmission studies in cattle and mice have shown that both H- and L-type BSE have biological characteristics that are different from those of the classical BSE agent. Sampling procedures may play an important role in recognizing and discriminating atypical strains from the classical strains of BSE, as discrimination by immunohistochemistry of atypical forms of BSE was apparently more reliable when tissue samples were obtained from the cerebellum instead of the medulla or brainstem. There is, as yet, a lack of knowledge about the zoonotic potential of atypical cases of BSE. However, experiments with transgenic mice that carry the human prion gene suggest that the L-type of BSE is capable of causing disease in humans.

In addition to the ban on feeding MBM, extensive surveillance programs, and rapid response, prevention, and control measures for BSE have been put in place. These include targeted enhanced testing programs for high-risk animals; surveillance of incidents of clinical neurological disease; strict control measures on the importation of cattle; routine screening tests at slaughter; removal during carcass dressing of specified risk material (SRM) such as the brain, spinal cord, thymus, and spleen for animals older than 6 months, and in addition the vertebral column with dorsal root ganglia for animals older than 30 months (OTM); exclusion of SRM from animal feeds; transparent communications in the event of BSE; livestock identification and traceability; and appropriate disposal of affected cattle. Animals that are OTM are excluded from the food chain if they are sourced from regions where there is risk of cattle developing or harboring BSE; and if not excluded from human consumption they are slaughtered in a facility that is approved for slaughter of OTM cattle. Meat from OTM cattle slaughtered anywhere in the European Union (EU) may only be released for consumption after brain tissue from each carcass has been tested and found negative for BSE.

BSE is a reportable disease. When it is detected, the entire herd and all contacts and offspring are destroyed. Worldwide, control of BSE has resulted in the destruction of more than 4.4 million animals. Outbreaks of BSE can have a devastating impact on the livestock sector and the overall economy of a country, as in the UK. The overall costs of even small outbreaks can be in billion dollars. Thus, the costs associated with an outbreak of BSE in Canada, with 17 confirmed cases since 2003, were estimated at US$6–US$8 billion as a result of loss of international markets for live animals and meat products, contraction of domestic markets, and loss of 75 000 jobs. In addition, increased rates of suicide, depression, and divorce were observed in cattle-rearing rural regions of Canada.

BSE is reported to have naturally infected goats as a result of their ingesting feed containing contaminated MBM, but there are no known cases of naturally acquired BSE in sheep or pigs. Even so, there is concern that endemic scrapie could mask BSE in sheep populations. When goat and sheep were experimentally infected with BSE, the neuropathological changes in the brain tissue were similar to BSE but distinct from scrapie. Furthermore, with increasingly sensitive diagnostic methods, PrP^D has been detected in the livers of sheep that were naturally infected with scrapie or experimentally infected with BSE. This raises concerns about potential risks to human health from BSE in sheep because sheep accumulate infective PrP^D in the blood during the preclinical and clinical stages of the disease. Precautionary measures to reduce the risk of BSE-infected sheep meat from entering the food chain are in place in the EU. SRM for sheep include the skull, brain, eyes, tonsils, and spinal cord of animals over 12 months old, and the spleen and ileum of all sheep, but not offal such as liver.

When pigs were infected with BSE by the parenteral route, the neuropathological changes in the brain tissue were similar to BSE but the distribution of lesions in pigs was different from that in cattle. Domestic cats and large members of the cat family and exotic ruminants in zoos in the UK developed feline spongiform encephalopathy and ungulate spongiform encephalopathy, respectively, during the epidemic outbreak of BSE, presumably from the consumption of BSE-infected meat or MBM. When deer were infected by intracerebral inoculation with BSE, the neuropathological changes and clinical signs were similar to CWD.

Scrapie

Scrapie was first described in the eighteenth century as a fatal infectious disease affecting flocks of sheep and goats in Europe. Scrapie has long been known to be widespread in Europe, Asia, and America, but it was thought to be absent from Australia and New Zealand. The spread of the disease to America has been attributed to the importation of infected animals. In 1978, Iceland's attempt to eradicate scrapie by destroying all indigenous sheep and goat flocks and importing scrapie-free animals from New Zealand several years later was unsuccessful. The appearance of classic scrapie in some of the imported flocks suggested that scrapie is persistent for a long period of time in pastures and could be difficult to eradicate. Scrapie is a reportable disease. To remain competitive and maintain market access, scrapie control programs are in place or being developed in many countries to reduce the incidence of scrapie and, possibly, eradicate it.

Scrapie is transmitted through the placenta of infected females to their offspring or, at birth, to other exposed animals in the flock. Males can contract scrapie but they do not transmit the disease to other animals. Scrapie is transmitted between sheep and goats under natural conditions. The susceptibility of sheep to scrapie is associated with a polymorphism of the *PrP* gene at codons 135, 154, and 171 where an increased susceptibility is observed when alleles are

homozygous for valine at codon 136 and glutamate at codon 171. Suffolk sheep, a common breed in North America, are homozygous for glutamate at codon 171 and susceptible to scrapie. The Suffolk genotype likely has been transmitted to other breeds. Selective breeding programs for scrapie-resistant genotypes containing dominant negative polymorphisms, such as arginine at codon 171 of the *PrP* gene, are being implemented as part of control strategies.

Clinical signs are observed in animals between 2 and 5 years of age. Once clinical signs are apparent, animals typically die within 2 months. The clinical condition progresses more rapidly in goats than in sheep but the symptoms are similar. Symptoms vary between cases of scrapie but typically include severe weight loss, poor appetite, itchiness, wool loss, depression, and neurological signs such as uncoordinated muscle movements and inability to keep up the head. PrP^D accumulates in the tonsils, lymph nodes, spleen, and gut-associated lymphoid tissue as well as in the placenta and peripheral nervous system. The peripheral distribution of PrP^D is dependent on the strain of scrapie and genotype of the host. The neuropathological lesions in the brain tissue are similar as those reported for BSE, but scrapie can be differentiated from BSE by western blotting. The molecular weight of the unglycosylated band for scrapie is higher than that of BSE. Furthermore, scrapie reacts with the $MAbP4^b$ antibody against a specific N-terminal sequence of the PrP protein, whereas BSE does not.

There is no epidemiological evidence to suggest that classical scrapie causes disease in humans. However, concerns are being raised about the potential risk to humans and animals from atypical strains of scrapie in sheep and goat that have been detected in a number of countries, including New Zealand and Australia, as a result of active disease surveillance. These atypical strains have been found in sheep of a PrP genotype that confers a high resistance to classical scrapie. In addition, atypical scrapie does not seem to be transmitted between animals in a herd. The neuropathological lesions observed for atypical scrapie differ from those seen with classical scrapie and BSE. The atypical scrapie strains isolated from different countries appear to represent a uniform type of scrapie prion. Atypical scrapie can be transmitted orally, and infectivity but not PrP^D can be detected in gut tissues after 12 months. Current surveillance methods may be inadequate for reliable detection of atypical scrapie. More knowledge on the origin, pathogenesis, transmission, and zoonotic potential of atypical scrapie are required before the risk it may pose to human health can be properly assessed.

Chronic Wasting Disease

CWD is a TSE that affects members of the Cervidae family. CWD has been detected in white-tailed deer, black-tailed deer, mule deer, moose, and elk in 14 states of the USA and 2 provinces in Canada, in both free-ranging and captive herds, and also in captive elk in Korea. CWD was first described in 1967 and recognized as a TSE in 1978. The origin of CWD is unknown. CWD in North America is concentrated in certain regions that are separated by large distances.

Prp^D is present in high levels in tonsils and Peyer's patches of infected cervids. The presence of CWD in free-ranging animals presents a significant obstacle to control the disease because it is impossible to eliminate infectious CWD prions from grazing areas and soil that are deposited in saliva, fecal material, and decomposing carcasses. Horizontal transmission of CWD is highly efficient. Thus, the prevalence of CWD is 30% among free-ranging deer populations and up to 100% in captive herds. Vertical transmission of CWD has not been investigated. The highly contagious nature and geographical spread of CWD has raised concerns about the potential transmission of CWD to livestock, because cattle graze on land that is frequented by infected cervids. When cattle were challenged with CWD by oral or contact exposure, infectivity was not detected. When cattle were challenged with CWD by intracerebral inoculation, 38% of cattle developed prion infection but spongiform encephalopathy was not observed. In contrast, when cattle were challenged with scrapie by intracerebral inoculation, 100% of cattle developed neurological disease and plaque deposits were observed in the brain tissue.

In addition to concerns about CWD spreading to livestock, concerns have been raised about the possible zoonotic transmission of CWD to humans through the ingestion of game meat. Infectious prions and Prp^D seeding activity have been detected in skeletal muscle of infected cervids. The ability of CWD prions to infect human is uncertain but, based on *in vitro* and transgenic mice studies, the risk is considered to be very low or nonexistent. As much remains to be discovered about the transmission barrier, infectivity, and disease progression of CWD, it is advised that no parts of animals infected with CWD should be used for animal or human food.

CWD prions appear to disseminate via the lymphatic system and Peyer's patches before entering the CNS. Clinical signs are nonspecific and difficult to detect, or may be absent altogether. Clinical signs include depression and separation from other animals, difficulty swallowing, excess salivation, excessive thirst and urination, lack of coordination, lowered head position, pneumonia, and weight loss. CWD is a reportable disease which can only be confidently diagnosed post-mortem by testing of brain tissue or tonsils. The neuropathological lesions in the brain tissue are similar as those reported for BSE in cattle and scrapie in sheep.

Human Transmissible Spongiform Encephalopathies

Kuru

Kuru is an acquired prion disease in humans. It was transmitted among the Fore people of Papua New Guinea at epidemic levels during the 1950s and 1960s as a result of ritual cannibalism that included the consumption of infectious brain tissue of deceased people. Once the practice of cannibalism was discouraged, the disease progressively declined and has now mostly disappeared. Kuru was the first human prion disease that was experimentally transmitted to animals.

Gerstmann–Sträussler–Scheinker Syndrome

GSSS is an extremely rare inherited prion disease. It is found in only a few families around the world. The onset of the disease usually occurs between the ages of 35 and 55 years. The

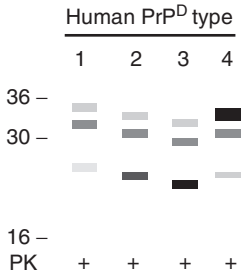

Figure 1 Differential mobility of proteinase K digestion products for di-, mono-, and unglycosylated PrP^D for sporadic CJD (1), iatrogenic CJD (2), kuru (3), and vCJD (4) by western blot. Adapted from Wadsworth, J.D.F., Collinge, J., 2012. Molecular basis of prion diseases. In: Brady, S., Siegel, G., Albers, R.W., Price, D. (Eds.). Basic Neurochemistry: Principles of Molecular, Cellular and Medical Neurobiology. New York, NY: Academic Press, pp. 872–885.

disease is characterized by a lack of muscle coordination followed by a prolonged period of dementia. Symptoms usually last from 2 to 10 years and result in death.

Fatal Familial Insomnia

FFI is an inherited prion disease caused by a missense mutation at the polymorphic codon 178 of the *PrP* gene. FFI typically appears in middle to late adulthood, although onset in people under 30 years old has been reported. FFI is characterized by disturbances of the wake and sleep cycle, autonomic dysfunction, and dementia (Figure 1).

Creutzfeldt–Jakob Disease

CJD is a rare prion disease that can be either sporadic or inherited. Approximately 85% of cases of CJD are sporadic with a prevalence of approximately 1–3 cases/million people/year and an estimated lifetime risk of 1:50 000. Sporadic CJD occurs in people between 55 and 65 years of age with a rapid increase in dementia that leads to death within 6 months of onset. The cause of sporadic CJD is unknown but it is speculated that PrP^C may spontaneously convert to PrP^D. In addition, approximately 300 accidental outbreaks of iatrogenic CJD have been linked to neurosurgical procedures, such as dura matter grafts and corneal transplants, treatment with human growth hormone harvested from the pituitary glands of human cadavers, and using contaminated instruments or equipment. Susceptibility to sporadic CJD has been linked to homozygous alleles encoding either methionine or valine at the polymorphic codon 129 of the *PrP* gene. Inherited CJD has been linked to missense or nonsense mutation in the *PrP* gene.

Between 1995 and 1996, a number of atypical cases of CJD were reported in a much younger than the usual age group, with distinct neuropathology and biochemical properties that were different from those of sporadic CJD but similar to those of BSE. The disease was recognized as vCJD in 1996 and linked to exposure to infectious BSE prions. Whereas the infectivity of sporadic CJD is confined to the CNS, infectivity of vCJD is detected in peripheral lymphoid organs as well, which raised concerns about iatrogenic transmission of vCJD through routine surgical procedures. Furthermore, transmission of vCJD through blood transfusions from infected donors has been reported. Between 1996 and 2011, 175 cases of vCJD in the UK and 49 cases in other countries have been confirmed. Since 2000, the number of cases in the UK has steadily declined. The total impact of the BSE outbreak on vCJD cases is not known as knowledge of the incubation time and susceptibility factors for vCJD are lacking. Incubation periods for acquired TSEs in humans may be longer than 50 years. To date, almost all patients with vCJD were homozygous for methionine at codon 129 of the *PrP* gene. The prevalence of the allele in the northern European population is 38%.

Glossary

Enzyme-linked immunosorbent assay (ELISA) method A detection method in which antigens or antibodies are fixed in wells. Antigen–antibody complexes are formed after addition of a sample containing the corresponding antibody or antigen. Complexes are labeled with enzymes and visualized by an enzymatic color reaction.

Hazard analysis critical control point (HACCP) systems A scientific approach to establishing plant- or process-specific control systems in the food industry.

Host-adapted The adaptation of a microorganism to a specific host species. Therefore, the microorganism is found mostly in the host species and only infrequent in other species.

Lipopolysaccharides (LPS) An antigenic part of the outer cell membrane of Gram-negative bacteria.

Macrophage A cell that is specialized for engulfing foreign material and microorganisms that gain access to the body. Macrophages break down the foreign substances and present them to the immune system.

Muscle fluid The fluid obtained from thawed meat (also called meat juice).

Salmonellosis A general term for clinical disease caused by *Salmonella*, but frequently restricted to clinical infections from nontyphoid *Salmonella* serovars.

Sequelae The secondary clinical conditions following a primary disease.

Subclinical infection An infection without recognizable clinical symptoms.

Zoonoses The diseases that can be transmitted between animals and humans.

Introduction

Salmonella is a pathogen, the main reservoir of which is the gastrointestinal tract of warm-blooded animals. Among numerous serovars of *Salmonella enterica* subsp. *enterica* (*S.*), serovar Typhi and the serovars Paratyphi A and B infect only humans and are not spread from animals. The remaining (nontyphoid) *Salmonella* serovars originate from the animal reservoir. Through fecal contamination of meat during slaughter, meat animals are among the most important sources of human salmonellosis.

The effort to reduce human salmonellosis is challenged by a widespread, mostly subclinical occurrence of *Salmonella* in a variety of meat animals together with an ability of *Salmonella* to adapt to and survive changing environmental conditions.

Since the early 1990s, many new detection and typing methods, surveillance programs, and control methods for *Salmonella* in the farm-to-fork continuum have become available and have been implemented in an increasing number of countries worldwide. The growing awareness of a global food market has led to international initiatives toward global control of *Salmonella*.

Characteristics of *Salmonella*

The genus *Salmonella* belongs to the family *Enterobacteriaceae*. *Salmonella* are Gram-negative, facultatively anaerobic, motile rods that are catalase positive and cytochrome oxidase negative, produce gas from glucose, and are able to reduce nitrate. *Salmonella* and *Escherichia coli* are closely related and are believed to share a common ancestor. During evolution *E. coli* has acquired the ability to utilize lactose through being closely associated with mammals, whereas *Salmonella* is unable to utilize lactose and is more associated with reptiles and birds. The acquisition of pathogenicity islands, of which SPI-1 and SPI-2 are the most prominent, conferred virulence on *Salmonella*.

The genus *Salmonella* is comprised of two species: *Salmonella enterica* and *Salmonella bongori*. *Salmonella enterica* is composed of more than 2500 serovars, but *Salmonella bongori* has only 22 serovars. *Salmonella enterica* is divided into 6 subspecies. Subsp. I (*enterica*) is comprised of approximately 1500 serovars and is particularly associated with infections in warm-blooded animals (Table 1).

Seroagglutination of outer membrane O-antigens (LPS) and flagella H-antigens define the serovar according to the Kaufmann–White scheme. For example the antigenic structure O:1,4,5,12 and H1/H2 b:1,2 defines *Salmonella enterica* subsp. *enterica* serovar Typhimurium (in short *Salmonella* Typhimurium or *S.* Typhimurium).

A few serovars are termed host specific or host adapted. *Salmonella* Typhi, *S.* Paratyphi A, *S.* Paratyphi C and *S.* Sendai infect only humans. *Salmonella* Choleraesuis is associated with pigs and *S.* Dublin is adapted to cattle but both serovars can cause serious infections in humans. *Salmonella* Gallinarum and *S.* Pullorum are specific for poultry. The factors that determine host specificity have not been clarified. In general, the remaining serovars of subspecies 1 are zoonotic and have a wider host range. The two most prominent serovars in human disease are *S.* Typhimurium, which in particular has a broad host spectrum, and *S.* Enteritidis, which can infect many hosts but has a predilection for poultry.

In general *Salmonella* grow between 5 °C and 46 °C with growth being optimal at temperatures between 35 °C and 37 °C. Physical conditions such as temperature, salinity, pH, and water

activity will affect the growth rate. *Salmonella* can grow between pH 4.5 and pH 9.0 with optimal growth at pH 6.5 to 7.5. *Salmonella* do not grow at water activities below 0.93. Although the generation time for *Salmonella* is rather long at low temperatures, significant growth in fresh meat can occur at temperatures above 5 °C, which may pose a consumer risk. Although the background flora in meat can be numerous and interactions with the meat flora can reduce the growth rate of *Salmonella*, they will not stop *Salmonella* growing. A range of *Salmonella* serovars have been shown to survive freezing for months without any substantial reductions in numbers.

Isolation and Identification of *Salmonella*

Conventional Culture Detection

Several media have been developed for culture and isolation of *Salmonella* from food. Owing to low numbers of *Salmonella* in meat, direct plating of samples on selective agars lacks sensitivity. *Salmonella* detection in foods requires three culturing steps:

1. Preenrichment, to allow recovery and growth of injured and uninjured cells. Typical preenrichment media are buffered peptone water (BPW) and lactose broth (LB).
2. Selective enrichment in a broth medium that suppresses growth of most bacteria but supports growth of *Salmonella*. Typical media are Rappaport–Vassiliadis broth (RV), selenite cystine broth (SC), or tetrathionate broth (TB). From the RV medium a modified semisolid agar has been developed (MSRV), which allows detection due to swarming of motile *Salmonella*.
3. Plating on indicative media. The indicative media take advantage of biochemical features such as the ability to grow in the presence of bile salts and fermentation of sucrose or xylose, but not lactose. Examples are brilliant green agar (BGA); bismuth sulfite agar (BSA), and xylose lysine deoxycholate agar (XLD).

Suspect colonies are subcultured on nonselective media that allow seroagglutination and verification of the serovar. International standardization committees such as the International Standards Organization (ISO), the American Association of Analytical Chemists (AOAC), the International Dairy Federation (IDF), and the Nordic Committee on Food Analysis (NMKL) provide procedures for *Salmonella* detection to support international harmonization.

Rapid Detection Methods

As culture detection of *Salmonella* requires 3–5 days to provide a positive result, rapid detection methods have been developed. They are typically DNA based, e.g., polymerase chain reaction (PCR), or immunological- (antibody) based methods, e.g., enzyme-linked immunosorbent assay (ELISA). Although termed rapid, preenrichment is often necessary to obtain the required numbers of *Salmonella*, 10^4–10^5 cells ml^{-1}, needed for detection. These methods have reduced detection times to between 12 h and 24 h, which enable release of meat for shipment direct from cooling facilities at the slaughterhouse.

Immunological methods are developed based on interactions between *Salmonella* antigens and specific antibodies raised against *Salmonella*. The format can vary. The linking of an enzyme to the antibodies allows antigen–antibody complexes to be detected by conversion of a substrate of the enzyme with development of a visible color, light, or fluorescence when *Salmonella* is present.

For DNA-based methods, PCR methods are predominant. The principle of PCR is an enzymatic-driven multiplication of a *Salmonella*-specific portion of the *Salmonella* genome. The reaction is exponential and can produce a positive result in less than 2 h. However, the reaction takes place in a very small volume and a preenrichment step is usually needed to obtain sufficient cells from which the required amount of DNA (or RNA when relevant) can be extracted. With the recent development of real-time PCR, a robust and sensitive DNA-based method of detection has been made available.

Typing Methods for Epidemiology and Outbreak Investigation

Phage typing

Phage typing of *Salmonella* is based on the ability of specific bacterial viruses, i.e., bacteriophages, to destroy *Salmonella*. In phage typing, a number of bacteriophages are spotted onto agar plates with a confluent culture of the isolate to be typed. If a phage is able to infect and destroy the isolate, a spot cleared of cells appears. The pattern of spots determines the phage type. A phage typing scheme has been developed for a range of *Salmonella* serovars, and it has been part of the classical characterization for *S.* Enteritidis and *S.* Typhimurium for half a century (Figure 1).

Pulsed-field gel electrophoresis (PFGE)

In these methods, the bacterial chromosome is cut into large fragments by restriction enzymes and the fragments are separated by electrophoresis in a pulsing electric field. Bacteria showing the same bands on the gel are considered to be the same. PFGE has been widely used and has long been the standard method for investigation of *Salmonella* outbreaks (Figure 1). Other novel technologies are now replacing PFGE. These include multilocus sequence typing, multiple loci variable number of tandem repeats analysis and full genome sequencing.

Multilocus sequence typing (MLST)

MLST is based on sequencing of internal fragments of seven housekeeping genes. Different base sequences (alleles) can occur in each of the seven genes. Sequences for all seven genes are stored in an international database. To obtain a MLST type, the seven gene sequences determined for an isolate are forwarded to the database and a sequence type is returned. If sequences for two isolates are identical they will be classified as the same MLST type. MLST is becoming increasingly prominent in *Salmonella* epidemiological and outbreak investigation.

Multiple loci variable number of tandem repeats analysis (MLVA)

MLVA typing is based on the occurrence of short, repetitive base sequences in the DNA of the chromosome. The numbers of sequences vary, and strains with an identical number of sequences are considered identical. Each of five regions of the chromosome is analyzed for the number of repetitive sequences. The method has become important for typing of *Salmonella* (Figure 1).

Detection of Antibodies to *Salmonella* by Enzyme Immunoassay

Since the mid-1990s detection of specific antibodies to *Salmonella* LPS in blood samples, muscle fluid, milk, or egg yolk from food animals has been possible. Despite the inherent delay in antibody response (1–2 weeks after infection), an association between seropositivity and shedding of *Salmonella* has been documented. Serology is a convenient, inexpensive and sensitive method for monitoring and classification of *Salmonella* infection in groups of animals, but it is less suitable for testing individual animals. ELISA test kits are commercially available. Serological assays tailored to targeted *Salmonella* serovars are parts of *Salmonella* surveillance programs and are used for research worldwide.

Characteristics of Salmonellosis

Salmonellosis in Meat Animals

Most *Salmonella* infections in meat animals are subclinical; but infections with the host-adapted *Salmonella* serovars can

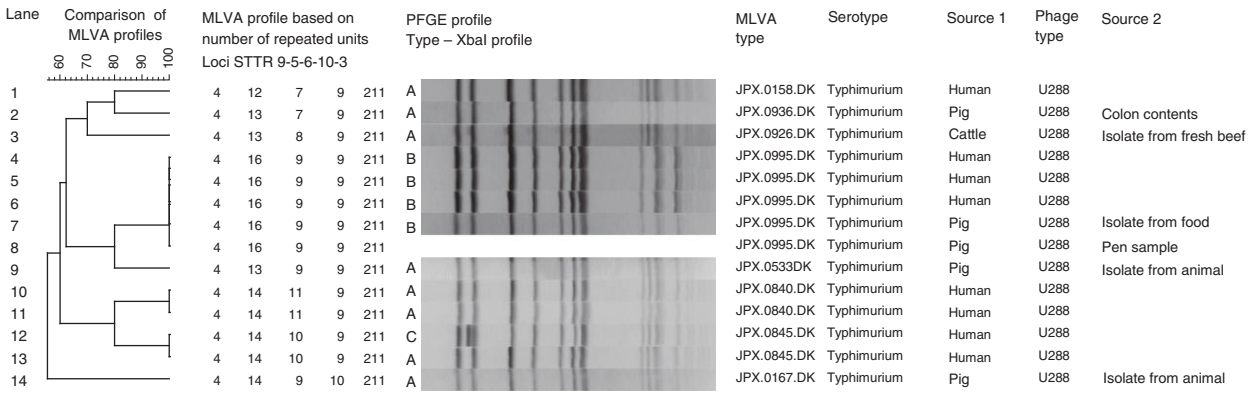

Figure 1 Subtyping methods applied to a selection of five *S.* Typhimurium isolates from an investigation of a human outbreak of *S.* Typhimurium phage type U288 in Denmark, Norway, and Sweden in 2008[a] (lane 4–8). All had identical MLVA type (JPX.0995.DK), and four were PFGE-typed and had identical PFGE types (type B). Lane 4–6: Three human outbreak isolates from Danish cases. Lane 7: Food isolate from Danish raw pork sausage meant for heat treatment. Lane 8: Isolate from a pen fecal sample from a Danish sow herd. The two food and animal isolates of MLVA JPX.0995.DK were epidemiologically related to a specific pig slaughterhouse and cutting plant identified as the site of contamination. Isolates in lane 1–3 and 9–14 are added for comparison and were not related to the outbreak. Source 1: Animal species or human origin. Source 2: Sample type of nonhuman isolates. [a]Bruun, T., Sørensen, G., Forshell, L.P., *et al.*, 2009. An outbreak of *Salmonella* Typhimurium infections in Denmark, Norway and Sweden, 2008. Eurosurveillance 14, 1–6.

cause severe, acute, clinical diseases. Outbreaks of such diseases can have high mortality rates and cause heavy economic losses. Symptoms are mainly related to septicemia (fever, weakness, loss of appetite), but enteritis is also common, and pneumonia, reproductive failure, and abortion may occur.

Non host-adapted serovars of *Salmonella* are considered potentially capable of infecting most meat animals, but certain serovars are more commonly isolated from certain meat animal species (e.g., *S.* Enteritidis in poultry, *S.* Derby in pigs) (Table 2). Infection of meat animals with the non host-adapted serovars may occasionally cause herd outbreaks of mainly gastrointestinal infections (diarrhea, fever, and dehydration) in young animals. Compared to infections with host-adapted serovars, infections with non host-adapted serovars generally have a lower mortality.

Table 2 Annual incidence of notified human salmonellosis (confirmed cases) in European Union (EU) Member States, 2010, and detection of *Salmonella* in broilers, turkeys, and slaughter pigs in baseline studies conducted in EU Member States between 2005 and 2007. Salmonellosis in Humans

Nontyphoid salmonellosis in humans is one of the most common gastrointestinal bacterial zoonoses worldwide. Salmonellosis peaks in warm seasons and the annual incidences per 100 000 population varies between regions and countries (e.g., Australia, 2009, 43.6; Canada, 2009, 18.0; European Union (EU), 2010, 21.5 (Table 2); New Zealand, 2010, 26.2; USA, 2010, 17.6). The incidence is probably underestimated by a factor of between 5 and 20, and comparisons between countries are confused by different sensitivities of the surveillance systems.

All *Salmonella* are considered potentially pathogenic to humans, but worldwide the serovars *S.* Enteritidis and *S.* Typhimurium are predominant in human disease (Table 1). The infective dose for healthy adult persons is believed to be approximately 100 000 cells, but it can be as low as 10 cells depending on the susceptibility of the person, the food vehicle, and the strain of *Salmonella*.

Typically, onset of symptoms is 12–72 h after exposure, and the duration of the illness is 4–5 days, often followed by a period of fatigue. Symptoms are mainly gastrointestinal, often accompanied by fever, headache, and muscle or joint pains. The infection is usually self-limiting and clinically indistinguishable from other common bacterial gastrointestinal infections. Sequelae are observed in 1 to 2% of the patients, and the mortality rate with many serovars is a few percent. In contrast, human infections with the host-adapted serovars (e.g., *S.* Dublin and *S.* Choleraesuis) often leading to septicemia, require antibiotic treatment, and show mortalities of 20–30%.

Food vehicles, commonly associated with sporadic and outbreak-related salmonellosis, are table eggs, and fresh pork, beef, and poultry meats. Increasing attention is being paid to nonanimal foods (fruit, vegetables, fresh herbs, sprouts) as vehicles for *Salmonella*. Various models have been developed to relate human cases to *Salmonella* reservoirs.

Mechanisms of Pathogenicity

Six serovars carry virulence (*spv*) genes on virulence plasmids. These include the host specific/adapted zoonotic serovars, and *S.* Typhimurium and *S.* Enteritidis.

Infection Cycle

Salmonella has both an animal and an extra-animal phase. *Salmonella* can survive in humid environments (soil, slurry) for months and in dry matter for years. Once ingested, *Salmonella* has to survive passage through the stomach. Although the stomach is perceived as presenting a harsh acidic environment, recent studies suggest that a pH gradient allows substantial fractions of ingested *Salmonella* to pass to the duodenum alive. On entering the small intestine the pH increases and the bacteria face intestinal proteases, bile salts, the gut microbiota, and the release of inhibitory antimicrobial peptides. Furthermore, *Salmonella* has to pass the mucus layer and overcome secreted antibodies (mainly IgA) before invasion of the intestinal epithelium provides the organisms with a relative safe intracellular compartment. Multiplication in the epithelial lining leads to shedding of *Salmonella* in feces.

Virulence Mechanism

Salmonella controls its own invasion of enterocytes and M-cells associated with intestinal lymphoid tissue. The uptake in M-cells occurs in close connection with macrophages, which process and exposes *Salmonella* antigens directly to the immune system. *Salmonella* is transported in macrophages to the lymph nodes. From there *Salmonella* enters the lymphatic system and the blood stream, from which it is taken up by macrophages in liver and spleen. If *Salmonella* growth exceeds its uptake by macrophages, generalized infection results. *Salmonella* can also be taken up directly from the intestinal lumen by dendritic cells (DC). Loosening of tight junctions enables DCs in the submucosa to protrude through the intercellular space and take up *Salmonella* directly from the lumen.

Epidemiology

Reservoirs

The primary reservoir for nontyphoid *Salmonella* is the gastrointestinal tract of animals and humans. Fecal counts of 10^6 cfu g^{-1} and 10^{12} cfu g^{-1} are common in the first week of subclinical and clinical infections, respectively. Asymptomatic, intermittent shedding may continue for months. *Salmonella* may also be isolated from intestinal lymph nodes, the oral cavity, and tonsils of infected animals and from blood culture of septicemic individuals.

Birds and wild animals, including rodents, particularly in the environments of infected farms and near dumps with human waste, may harbor *Salmonella*. Manure, slurry, or human sludge used as fertilizer and irrigation water of poor hygienic quality can contaminate crops used for animal feed or human consumption.

Transmission to Meat Animals

In populations of farmed animals in which *Salmonella* is prevalent, exposure of meat animals to *Salmonella* occurs mainly through direct or indirect fecal–oral transmission from animals brought in from outside the herd, or from other animals in the herd as a result of insufficient cleaning, drying, and disinfection of pens. In poultry production there is an additional vertical transmission from hens to chickens from internal contamination of eggs (often by *S.* Enteritidis). The serovars *S.* Typhimurium, *S.* Infantis, *S.* Derby, *S.* Dublin, and *S.* Enteritidis are examples of serovars that are mainly isolated from and transmitted by animals. Introduction of *Salmonella* into herds and maintenance of *Salmonella* infection within herds may also occur via infected wild birds or rodents and contaminated equipment or personnel. When *Salmonella* is not prevalent in farmed animals, the importance of transmission of *Salmonella* from contaminated animal feed or feed ingredients increases.

Salmonella in Animal Feed

In animal feed, *Salmonella* is found mainly as a contaminant of oil seeds (soy and canola) and in feed of animal origin, but the prevalence in commercial heat-treated feed often is below 1% of samples. The most common serovars in meat animals are rarely contaminants of feed whereas other serovars, often referred to as 'exotic' or 'feed-borne' serovars (e.g., *S.* Livingstone, *S.* Mbandaka, *S.* Putten, *S.* Rissen, and *S.* Senftenberg), are rare in meat animals and humans but common in feed.

Because sampling of the huge amounts of feed used for meat animals is necessarily limited, monitoring of *Salmonella* in feed by culture methods is inadequate for control of *Salmonella*. In many countries end product monitoring is supplemented with process control based on processors' own check programs and hazard analysis critical control point (HACCP), and in several countries heat treatment or acidification of commercial feed is part of *Salmonella* control programs.

Salmonella in Meat Animals

Monitoring of *Salmonella* in meat animals may be conducted in herds or at slaughter, by detection of *Salmonella* in fecal material, dust, or internal organs, or by detection of antibodies against *Salmonella* in blood samples, egg yolk, muscle fluid, or milk.

Poultry

Salmonella is commonly isolated from broiler chickens worldwide, although large differences between countries exist. In a baseline study in 23 EU Member States during 2005–06, *Salmonella* was detected in 23.7% of the flocks (Table 2). More than 50% of the isolates were *S.* Enteritidis or *S.* Infantis. Targeted mandatory surveillance programs for *S.* Enteritidis and *S.* Typhimurium in the EU have led to reduced flock prevalence, determined in routine monitoring to be 4.1% in 2010 (0.4% target serovars). *Salmonella* is also commonly isolated from other poultry. An EU baseline study in 2006–2007 found *Salmonella* in 30.7% of turkey flocks (Table 2). Common serovars in turkeys are *S.* Hadar, *S.* Heidelberg, and *S.* Saintpaul. Commercial flocks of geese and ducks frequently harbor a wide variety of *Salmonella* serovars.

Pigs

With the exception of some, mainly North European countries, *Salmonella* is widespread in pig populations. In an EU baseline study in 2006–2007, 13.9% of intestinal lymph nodes from slaughter pigs were positive for *Salmonella*, with *S.* Typhimurium and *S.* Derby being the predominant serovars (Table 2). Prevalence of *Salmonella* in slaughter pigs is as high as 40%, as measured by various sampling techniques, have been reported. An EU baseline study found boars and sows culture positive in approximately 30% of breeder and production units. An increasing number of countries worldwide have implemented surveillance programs for *Salmonella* in pigs. The Danish integrated program, which covers the entire production continuum, is among the most comprehensive of these. The pig herds are classified on the basis of serology and microbiology, enabling risk-based prevention and control actions to be taken in herds and at slaughter.

Cattle

The occurrence of *Salmonella* in cattle is often low (0–1%) but variable, with reports of 5–10% of animals shedding *Salmonella* being rare. *S.* Dublin and *S.* Typhimurium are the predominant serovars in cattle. Owing to the severe illnesses from *S.* Dublin infection in humans and cattle, this serovar deserves special attention as a target for control efforts. *Salmonella* in cattle is mainly detected as a result of animals showing clinical symptoms. Comprehensive monitoring programs in the primary stages of production are rare. In Denmark, a *S.* Dublin eradication program was initiated in 2007. It is based on routine serological monitoring of milk or blood samples from all cattle herds in the country. The program has significantly reduced the prevalence of seropositive dairy and other herds.

Salmonella at Slaughter

Salmonella in poultry slaughterhouses

In many countries, decontamination of carcasses is part of normal slaughter procedures for broilers, for which there is a lack of effective slaughter hygiene measures. Decontamination has only recently been accepted in the EU. *Salmonella* carcass prevalence varies considerably between countries. In a US study, approximately 10% of carcasses were positive for *Salmonella*. In the EU a declining trend has been observed for *Salmonella* in broiler carcasses, parallel to the declining prevalence of *Salmonella*-positive broiler flocks, after targets for reduction of *S.* Enteritidis and *S.* Typhimurium in broiler flocks were set.

Salmonella *in pig slaughterhouses*

Salmonella is widespread in slaughter pigs in many countries. During transport and lairage *Salmonella* will be exchanged between pigs, which will add to the *Salmonella* load on the slaughter line. Recent epidemiological studies suggest that direct contamination between carcasses is not the main driver of carcass contamination but rather the many stages of processing at abattoirs, in particular the operations of carcass polishing and splitting. There are large variations between the extents of *Salmonella* contamination of carcasses at different plants, and many factors are likely to contribute to this. Between 1% and 8% of dressed carcasses have been reported to be *Salmonella* positive.

Salmonella *in cattle slaughterhouses*

S. Typhimurium and *S.* Dublin are often isolated from cattle. In an American study during 1998–2000, *Salmonella* was isolated from 70% of cattle hides, 13.3% of fecal samples, and 6.7% of carcasses, and most frequently during August to October. Seasonality in *Salmonella* prevalence has been reported from Europe also.

Salmonella in Cutting Plants

Meat can be cross-contaminated during fabrication of cuts, and too high temperatures may allow growth of *Salmonella* on meat and meat plant equipment. HACCP-based own control

systems in cutting plants should enable the industry to maintain product hygiene. Dutch data suggests that if *Salmonella* contamination is high on meat delivered for cutting, only little control over contamination of product with *Salmonella* can be expected from the plants' own HACCP-based control systems.

Salmonella at Retail

The microbiological status of retailed meat is largely determined by the hygienic adequacy of handling practices and temperature control during distribution. At retail, the mincing process in particular adds to cross contamination and possibly allows growth of *Salmonella*. Minced beef and pork both present risks to consumers from *Salmonella*. In Ireland in 2007, a *Salmonella* prevalence of 5% has been reported as compared to 1.8% in Denmark in 2006, whereas a prevalence up to 50% was estimated for minced meats in The Netherlands (1998). The prevalence of *Salmonella* in meat cuttings from Danish butcher shops was 8.1% compared to a prevalence in meat cuttings from supermarkets of 2.6%.

Control and Preventive Measures

Control and Preventive Measures on Farms

The purpose of control strategies for *Salmonella* in meat animal farming is to reduce or eliminate *Salmonella* in animals that are presented for slaughter. The need for preharvest control depends on subsequent post harvest control. Focus of preharvest control varies with the animal species, but the basic principles of preharvest control are common for all. These are:

- Prevent introduction into the herd
- Prevent transmission within the herd
- Reduce prevalence and shedding in infected populations.

Table 3 Main risk factors and recommendations for reduction of subclinical *Salmonella* in slaughter pig herds

	Risk	*Protective factors/Recommendations*
Purchase of animals	Purchase of infected pigs[a]	Purchase from noninfected supplier herd
	High number of supplier herds[b]	
Management	Continuous production	Strict batch production (all-in/all-out)[b,c]
	Mixing of pigs	One-way flow of pigs – no mixing[d]
	Slurry flooding	Keep low levels in slurry pits[c]
Hygiene	Insufficient cleaning of pens	Thorough cleaning and desiccation and proper choice and use of disinfectant[c]
	Transmission from tools/boots	Separate tools and boots for each unit[c]
	Transmission from rodents/herd environment	Rodent control and other biosecurity[b,c]
Feed and feeding	Dry feed[d,e,f]	Wet feed – preferably fermented to pH < 4.5
		Alternatively acidification of feed (0.5–1% formic- or lactic acid[g] or whey[b])
	Finely grinded feed corn[h]	Coarser grinding of feed corn
	Commercial pelleted feed[b,d,f,h]	Home-mixed meal feed
		Alternatively 25% of corn fed as nonheat treated, coarsely grinded[i]
	Low % of barley in feed corn[j]	> 25% barley of feed corn
Herd size	Increasing herd size[a,d,e] but less *Salmonella* in the largest herds[d]	Practical and financial potential to implement the reduction means above

Control in poultry farms

In poultry production the very efficient vertical dissemination of *Salmonella* through the breeding system demands a top–down eradication control strategy. Successful elimination of *Salmonella* from broiler flocks has taken place in many countries. Good farming practices, with strict batch production and biosecurity in confined production systems, and heat treatment of commercial poultry feed have been important elements. Thus, the flock prevalence in Danish broiler flocks was reduced from approximately 70% in 1990 to few percent since 2001. Reductions of *Salmonella* in other types of poultry have been achieved with similar procedures.

Control in pig farms

Eradication of *Salmonella* from pig farms has taken place in only a few North European countries with an a priori low prevalence, but monitoring and reduction of *Salmonella* in pig populations in which it is endemic have become more common. Risk factors for high prevalence of *Salmonella* in pig herds are well known, and it has proven possible to reduce high infection levels to moderate or low levels by purchase of noninfected pigs, strict all-in/all-out production, improved hygiene, and biosecurity. The use of certain feed and feeding practices can cause microbiological and chemical changes that reduce proliferation of *Salmonella* in the gastrointestinal tract (Table 3).

Control in cattle farms

In the last decade, evidence-based interventions to control *S.* Dublin in cattle herds have been developed. Introduction of *Salmonella* from purchased animals must be avoided, and introduction from equipment and herd environments may be prevented by strict hygiene and biosecurity measures. In infected herds, the risk of triggering an outbreak of salmonellosis can be reduced by good hygiene in calving and calf units. Infection from cow to calf through contact after calving should be avoided by supplementing calves with colostrum from a colostrum bank, and a one-way flow of animals in the farm should be established.

Vaccination against *Salmonella* is mainly used with poultry and may under some circumstances and for some serovars reduce *Salmonella* in the flocks. Serological vaccine reactions in routine monitoring assays should be taken into account when vaccination is considered.

Antibiotics should never be used to control subclinical infections with *Salmonella* due to the risk of development of antimicrobial-resistant *Salmonella*.

Control and Preventive Measures Postharvest

Salmonella cannot be dealt with through classical meat inspection practices as production animals mostly are asymptomatic carriers. In many countries physical (e.g., steam) and chemical (e.g., lactic acid or chlorine) decontamination of carcasses is used to reduce pathogen levels. Laboratory and in-line investigations of decontamination effects show that hot water and steam on average reduce *Salmonella* levels by 100- to 1000-fold, whereas the effect of chemical decontamination often is within the range of 10- to 30-fold. The use of two or more decontamination methods is common and can further improve efficacy. In Denmark, serological classification of herds has been used to direct 1% of all pig carcasses to hot-water decontamination. Plant control systems are often in place with routine monitoring of slaughter hygiene. This can also be required in relation to export to countries such as the USA. In the USA, *Salmonella* performance standards at different levels in the meat chain have been mandated, and in the EU process hygiene criteria have been instituted.

Staphylococcus aureus

JA Hudson, Food Safety Programme, ESR, Christchurch, New Zealand

This article is a revision of the previous edition article by JA Hudson, volume 2, pp 820–825, © 2004, Elsevier Ltd.

Glossary

a_w (water activity) The available water in a given substrate. Values range from 0 to 1, where 1 is a_w of pure distilled water.

D-value The decimal reduction time, or the duration of an antibacterial process (such as heat or irradiation) at a given intensity which results in a 90% reduction in the bacterial population.

Fail-safe Used in predictive microbiology to represent a situation where a model predicts growth but none occurs. The model has failed but in a safe manner.

Humectant An additive that binds water and controls water activity.

Microflora The naturally occurring microorganisms in a given environment.

Introduction

The first link between *Staphylococcus aureus* and food poisoning was made following an outbreak associated with eating cheese, and the first recognized meat-related outbreak, involving a fatality, was reported in 1894. The organism has subsequently been incriminated in incidents involving a wide range of food vehicles including meat, poultry, dairy, cream-filled bakery, and egg products as well as salads and canned mushrooms.

Staphylococcal food poisoning is an intoxication caused by the consumption of one of a variety of enterotoxins. A number of species of *Staphylococcus* are able to produce these toxins but only one species, *S. aureus*, is commonly associated with foodborne disease. It is regarded as an organism that competes poorly with the natural microflora of raw meats but is able to grow at low water activity (a_w) values. These two characteristics are reflected in the types of meat products normally associated with staphylococcal foodborne disease: i.e., foods that have been cooked and hence have no competitors present; and low a_w foods, often with high salt concentrations, which are conducive for the growth of *S. aureus*.

The toxin produced is heat stable and can survive commercial canning. *Staphylococcus aureus* may, therefore, be absent from a food, yet the food can still contain the toxin and cause disease. Good food handling practices (e.g., good personal hygiene, prevention of cross-contamination and temperature control) are the most effective way of preventing staphylococcal intoxications.

Characteristics of the Organism and its Toxin

The Organism

Staphylococcus aureus is a Gram-positive, catalase-positive coccus, 0.5–1.5 μm in diameter, which forms clusters of cells appearing as characteristic 'bunches of grapes' when viewed microscopically. In laboratory media it has an optimum temperature for growth of 37 °C with a range of 7–48 °C. However, when growing in food these limits may be reduced. For example, limited growth of *S. aureus* occurred on vacuum-packed ham and turkey, but not on chicken stored at 10 °C. The optimum pH for growth is 7.0–7.5 with a range of 4.2–9.3. The lower pH value at which growth occurs is raised when organic acids such as acetic and lactic acids are used as the acidulant, and no growth occurs at room temperature in vacuum-packaged fermented meat products of pH ≤ 5.3. Growth is optimal under aerobic conditions but the organism can also grow anaerobically. Of note is the organism's ability to grow at low a_w values. Growth can occur at a_w values as low as 0.86 (equivalent to 20% NaCl) depending on the humectant used (e.g., NaCl, sucrose, etc.), and the organism grows well in the presence of 7–10% NaCl.

Staphylococcus aureus is moderately heat resistant for a nonspore-forming foodborne pathogen, with a mean *D*-value (i.e., time for a 90% reduction) of approximately 5–7 min at 60 °C. However, in salty foods its thermal resistance is much greater. For example, the mean *D*-value at 60 °C increased from 6 to 25 min when the NaCl content of meat macerate was increased from 0% (w/v) to 8.4%. Microwave heating to 65 °C results in reductions of numbers of the order of 1.7–2.5 $\log_{10}$ cfu ml^{-1} or g^{-1} in a variety of foods. *D*-values for irradiation are in the range of 0.3–0.6 kGy depending on the atmosphere, temperature and nature of the food substrate in which the organism is irradiated. However, *D*-values as high as 0.86 kGy have been reported.

For a nonspore-forming organism, *S. aureus* is very resistant to adverse conditions and it can survive long periods of desiccation. For example, the organism can survive for more than 1000 days on a dry plastic surface. Survival during frozen storage is good at temperatures ≤10 °C, although there can be some loss of viability during freezing.

Staphylococcus aureus is frequently found in meat products, but usually at low concentrations. Some examples are given in Tables 1 and 2. Data are presented for detection of the organism and toxin by conventional methods, but reported prevalence rates are higher when molecular methods such as the polymerase chain reaction (PCR) are used.

An emerging concern with *S. aureus* is the acquisition of methicillin resistance and the roles that food production and

consumption may have in infections of people with methicillin-resistant *S. aureus* (MRSA). Testing of Canadian feedlot cattle just before slaughter failed to detect MRSA; but MRSA has been detected in other food animals such as pigs, and in a variety of retail meat products. Examples are given in Table 3. Widespread or emerging resistance to other antibiotics is also a cause for concern.

Staphylococcal Enterotoxins

The organism causes disease through the production of 1 of a group of at least 20 structurally similar protein toxins. Only five subclasses of these toxins are commonly involved in human disease, i.e., staphylococcal enterotoxins (SE) types A, B, C, D, and E, with type C toxins being further divided into types C_1, C_2, and C_3. Human disease usually involves SE-A. Toxin production occurs under more restrictive conditions

Table 3 Examples of data for the prevalence of methicillin-resistant *S. aureus* (MRSA) in meat

Country	*Samples (number tested)*	*Number +ve for MRSA/Number tested*	*Percentage positive*
The Netherlands[a]	Beef	42/395	10.6

than those that allow growth. It occurs between 10 and 45 °C and at pH 4.8–9.0, and is optimal at temperatures between 35 and 40 °C and pH values between 5.3 and 7.0. Toxin production is greater under aerobic than under anaerobic conditions, and occurs at a_w values ≥0.90. The toxin is very resistant to heat. For example, the *D*-value for SE-B is 100 min at 149 °C and an a_w of 0.99, and 225 min when the a_w is 0.90. The toxin is also resistant to the proteolytic enzymes that occur in the gastrointestinal tract, dehydration, gamma irradiation, and extremes of pH.

Because the toxin is heat stable, it is possible for a food to be free of viable organisms yet still be the cause of SE poisoning. This may occur if the required population was reached, enterotoxin was produced, and the cells were then inactivated by a process such as cooking.

Ingestion of less than 1.0 μg of toxin can result in illness, but this level is reached only when the population of *S. aureus* exceeds 10^5 g^{-1}. Concentrations as high as 1.5×10^{10} cfu g^{-1} have been reported in outbreak-related foods and ingested levels of 1–5 μg of toxin are normally associated with outbreaks, although children have become sick at a dose of 17 ng.

Not all isolates of *S. aureus* produce toxin. For example, one study of coagulase-positive food isolates found that only 30.5% were unequivocally enterotoxin positive.

Isolation and Identification

Enumeration and Detection

Because relatively high numbers of the organism are required to cause illness, in most cases an estimate of the concentration of the organism in a sample is needed rather than a sensitive detection method.

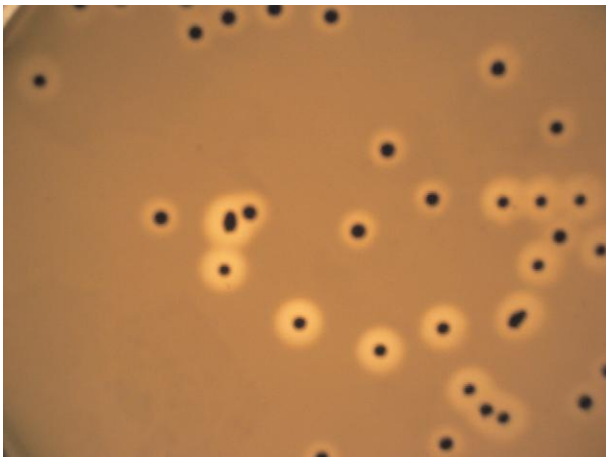

Figure 1 Typical colonies of *S. aureus* growing on BP agar.

There is a good overall agreement with regard to the methods that are appropriate for *S. aureus* (see ISO 6888-1 and ISO 6888-2). Baird-Parker (BP) agar is used as a plating medium in the ISO and many other methods. Typical colonies on BP agar appear 2–3 mm in diameter, black and shiny, surrounded by a white edge and a clear zone (Figure 1). Other media such as Rabbit Plasma Fibrinogen Agar (RPFA) are available. In this case, the medium identifies coagulase- and thermonuclease-positive colonies. With these media, the sample is prepared and dilutions either spread onto them (BP) or added to pour plates (RPFA),

the plates are incubated and suspect colonies counted and confirmed. A Most Probable Number method using enrichments of sample dilutions in Giolitti and Cantoni broth followed by plating to BP agar is recommended by the American Public Health Association (APHA). A number of other proprietary media are available in conventional agar and film formats.

For detection of *S. aureus* in foods in which cells may be injured, for example, in processed foods, the APHA recommend a short enrichment in a nonselective medium followed by a period of incubation with NaCl present as a selective agent. Isolates are then obtained on BP agar.

Several PCR methods that allow detection of *S. aureus* have now been published and commercial systems based on PCR are also available. Because the methods target different genes, they vary in their suitability for various tasks. General methods target genes such as *nuc* which encodes thermostable nuclease production. Others more specifically target toxin or antibiotic resistance genes. PCR methods are available as real-time applications for the detection of the organism in foods, and such techniques offer the possibility of quantifying rather than just detecting the presence of *S. aureus*.

Identification

Staphylococci are usually distinguished from other Gram-positive facultatively anaerobic cocci by the presence of catalase in *Staphylococcus*. Distinction between *S. aureus* and the micrococci is more difficult but can be achieved using the tests shown in Table 4. *Staphylococcus aureus* is characteristically positive for the following tests; thermostable nuclease, coagulase, clumping factor, yellow pigment, acetoin production, and hemolysis. The presence in *S. aureus* of clumping factor can be used to distinguish it from other coagulase-positive *Staphylococcus* species.

Not all *S. aureus* isolates are capable of producing toxin and it may be necessary to demonstrate the toxin-forming capability of food isolates. Because *S. aureus* may have grown, produced toxin, and then have been inactivated by cooking, a ready-to-eat food containing low numbers of the organism may not be safe. Toxin testing is therefore necessary in outbreak investigations where there is potential for enterotoxin to have been produced in the food before a bactericidal treatment.

Rapid test kits for the detection, identification, and confirmation of *S. aureus* are readily available from diagnostics manufacturers. In addition, kits are available for the detection of the SE. While being too numerous to detail, a list of approved test kits, along with their status in terms of recognition is maintained by AOAC International.

Table 4 Biochemical tests that discriminate between *S. aureus* and Micrococci

Test	S. aureus	*Micrococci*
Lysostaphin resistance	S	R
Coagulase production	+	−
Lysozyme resistance	R	R/S
Thermostable nuclease production	+	−
Anaerobic glucose fermentation	+	−
Anaerobic mannitol fermentation	+	−
Modified oxidase	−	+
Erythromycin resistance (0.4 μg ml^{-1})	R	S

Abbreviations: R, resistant; S, sensitive.

Typing

Numerous methods have been developed for the typing of *S. aureus*. Some of the methods that have been applied to meat products or outbreak investigations are briefly mentioned here.

Isolates may be assigned to different biotypes/ecovars according to staphylokinase, *β*-hemolysin, coagulase, and crystal violet agar growth tests. These ecovars are largely host-specific being grouped into human, poultry-like, bovine, ovine, and nonhost-specific ecovars. Molecular typing produces data that also tend to reflect a clonal association of *S. aureus* types and animal hosts. A few tests may therefore be useful in identifying the animal origin of *S. aureus* isolates, although a significant proportion of isolates may be of unspecified origin.

Phage typing is useful for the differentiation of isolates, and most enterotoxin-producing isolates have been shown to belong to a restricted range of phage types. However, the level of expertise required to use the methodology is likely to preclude small or routine testing laboratories from using it. Coagulase typing has also been used.

Pulsed field gel electrophoresis (PFGE) is a highly discriminatory molecular typing technique that has been successfully used to type *S. aureus* isolates. The primary restriction enzyme used was *Sma*I, with *Ksp*I being used subsequently to further evaluate indistinguishable isolates. *Sma*I digests produced profiles with 10–20 fragments in the 20–700 kb range. Clusters produced by PFGE correspond to those produced by biotyping, but not phage typing. PFGE has been shown to be more discriminatory than amplified fragment length polymorphism analysis. Staphylococcal protein A (*spa*) typing and multilocus sequence typing are other techniques that have been applied.

Characteristics of Foodborne Illness

Symptoms are caused by the production of a toxin which is thought to act by causing a signal to be sent from intestinal tract receptors to the medullary emetic center of the brain. The precise area in the abdomen that is stimulated has not been identified.

Symptoms normally occur 0.5–6 h (usually 2–4 h) after ingestion of the toxin and are most often nausea, frequent vomiting, and abdominal cramps for up to 48 h. Diarrhea is less common but can occur in a significant proportion of cases, and always occurs in conjunction with vomiting. In severe cases, headaches, fever, and collapse may occur. Recovery is usually swift, occurring over a few hours to 1 day, and generally no treatment is required. Death is not a common consequence of staphylococcal intoxication, but has been reported in the young and elderly. The organism may also be associated with autoimmune disorders. Estimates from the USA for illness associated with this organism are a hospitalization rate of 6.4% and a case fatality rate of $<0.1\%$.

Outbreaks of illness are often caused by contamination of foods by food handlers with uncovered infected wounds. It may also be transferred to food from the nose, where it is a commensal in 30% of the population, or other moist parts of the body, for example, mucous membranes and the skin. Enterotoxin production seems to be linked with isolates of human origin, further strengthening the link between food handling and food poisoning. An exception is the ovine biotype, isolates of which also frequently produce enterotoxin. PFGE has been used to type isolates from a meat processing plant and the results support the view that *S. aureus* on beef carcasses originate primarily from the hands of workers engaged in carcass dressing.

The organism is generally regarded as a poor competitor with other foodborne microorganisms. It, therefore, generally does not grow and cause problems in raw meats. Because of its tolerance to low water activity, its growth is favored in foods that are salted or dried, such as cured and fermented meats. It may also grow in foods such as cooked meats in which a competing flora has been reduced during processing.

Epidemiology

Staphylococcal intoxication contributes substantially to the burden of illness acquired from contaminated food. In 2008, in the EU, there were 291 outbreaks suspected as being attributable to staphylococcal intoxication, accounting for 5.5% of the total number of outbreaks of foodborne disease/intoxication. Of these outbreaks, 27.8% were verified. Two patients died. It is generally thought that, as symptoms are often self-limiting, only 10% of people with staphylococcal intoxication seek medical treatment.

Typical outbreaks occur through postcooking contamination by food handlers, with subsequent temperature abuse of the food that allows growth of and toxin production by *S. aureus*. For example, in an American outbreak where ham was the implicated vehicle, contamination probably occurred when an infected food handler removed casings from the hams which were subsequently stored at temperatures above 10 °C for more than 15 h.

Control and Preventative Measures

An important preventative measure centers around the training and personal hygiene of staff who handle food. Staff should cover wounds with sticking plasters and gloves where appropriate, and refrain from touching their noses, hair, or other parts of their body while working with food. If such events occur, then hands should be washed immediately.

Because the organism will grow well on foods with a background microflora reduced by cooking, it is essential to avoid cross-contamination of cooked foods by bacteria from raw foods in which staphylococci are likely to be present. Holding foods at a temperature less than 7 °C will ensure that the organism cannot grow and produce toxin.

Product formulations can be manipulated to prevent the growth of the organism by using multiple 'hurdles.' For example, pH and a_w may be used in combination at levels which alone would not prevent growth of the organism. Preservatives such as potassium sorbate and potassium nitrite may also be used to inhibit growth of the organism, especially when used in combination with another controlling factor. As an example, the inactivation rate in the presence of 2.5% potassium sorbate increases with increasing concentrations of CO_2 in packed atmospheres. Less is understood about the use of preservatives to prevent toxin formation specifically. Naturally occurring compounds, such as plant essential oils, are now also being considered as hurdles.

Predictive models, which model the growth rate of the organism given various input parameters such as pH and temperature, have been reported to overpredict growth. Therefore, they are generally, but not always, fail-safe. Other models predict the growth/no growth boundary in particular meat products. These may be useful tools for evaluating shelf stability.

In general, proper cleaning and sanitizing are effective in removing the organisms from manufacturing plants because the organism is sensitive to sanitizers used in the food industry.

Thermotolerant *Campylobacter*

AM Donnison and CM Ross, AgResearch Ltd., Hamilton, New Zealand

This article is a revision of the previous edition article by AM Donnison, CM Ross, volume 2, pp 798–804, © 2004, Elsevier Ltd.

Introduction

Campylobacters are a major cause of foodborne gastrointestinal disease, especially in the developed world, with foods of animal origin and fecally contaminated waters being the most common sources of infection. For humans, infection usually causes self-limiting diarrhea (campylobacteriosis) but occasionally more serious extraintestinal disease develops. The majority of reported campylobacteriosis is caused by thermotolerant species, principally *Campylobacter jejuni*, followed by *Campylobacter coli* and, to a much lesser extent, *Campylobacter lari*. Thermotolerant Campylobacters occur over a wide geographic range and have been isolated from the intestines of many warm-blooded animals. Although large numbers of *Campylobacter* are shed in feces, the bacteria are susceptible to environmental stresses and the health risk is usually associated with consumption of undercooked food or untreated drinking water. As thermotolerant *Campylobacter* spp. do not multiply at temperatures of less than 30 °C; appropriate temperature control and good food hygiene practices, including preventing cross-contamination, are important barriers to infection.

Characteristics of Thermotolerant *Campylobacter*

Thermotolerant *Campylobacter* belongs to the family *Campylobacteraceae* (from the Greek word for curved rod). Cells are slender, spirally curved rods typically 0.2–0.5 μm wide and 0.5–5 μm long with up to four 'windings.' After exposure to unfavorable conditions cells may round up to a coccoid shape. A typical curved *Campylobacter* cell is shown in Figure 1.

Members of the genus *Campylobacter* are Gram-negative motile bacteria that typically have a single flagellum, at one or both ends of the cell that drives their characteristic corkscrew darting motion. They are oxidase positive and have a respiratory type of metabolism. Energy is derived from either amino acids or tricarboxylic acid cycle intermediates but carbohydrates are not used. Although oxygen is required for respiration, thermotolerant *Campylobacter* are fastidious microaerophiles and do not grow, or grow poorly in air and do not grow under anaerobic conditions. Optimal growth occurs in microaerobic atmospheres usually comprising 5% oxygen, 10% carbon dioxide, and 85% nitrogen. In addition to the thermotolerant species that have an optimal growth temperature of 42 °C, other species with temperature optima in the 30–37 °C range have been linked to human illness.

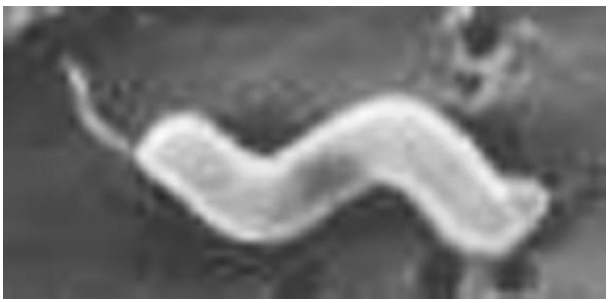

Figure 1 Scanning electron microscope image of *C. jejuni* showing characteristic spiral shape (typical dimensions 0.5 x 2.0 μm).

Campylobacter cells are fragile and sensitive to a wide range of stress factors including UV light, hydrogen peroxide, superoxide anions, low pH (<pH 5.0), drying (except under refrigeration), salt (>2%), and temperatures between 10 °C and 30 °C or above 55 °C.

Isolation and Identification

Traditional Methods

Standard protocols for the isolation of thermotolerant *Campylobacter* spp. from food, water, and feces by laboratory culture have been published by the International Standards Organization and the US Food and Drug Administration. These protocols are based on research results obtained over many years.

Skirrow was the first worker to demonstrate the link between contaminated food and campylobacteriosis, by plating fecal and food samples directly to a *Campylobacter*-specific agar. Plates were incubated in a microaerophilic atmosphere at 42 °C for at least 48 h. Although there have been modifications to Skirrows's agar recipe, direct plating is still widely used for the analysis of highly contaminated samples in both clinical laboratories and laboratories analyzing samples from the poultry industry.

The small size and motile nature of campylobacters are exploited in the passive filtration technique. A sterile cellulose acetate filter with either a 0.45 or 0.65 μm pore size is placed on an agar plate and several drops (approximately 100 μl) of test sample suspension carefully applied. The plate is left upright at either room temperature or 37 °C, in an ambient atmosphere, for approximately 45 min. The filter is then removed and the plates inverted and incubated in a microaerophilic atmosphere at 42 °C for 48 h. Nonselective blood agar plates are used for isolation of campylobacters sensitive to selective agents but selective agars are usually favored for fecal samples.

In contrast, isolation from food and water is more difficult because samples usually contain small numbers of cells that

 doi:10.1016/B978-0-12-384731-7.00038-6

have been injured by exposure to various stresses. Analytical techniques for these types of samples include procedures that concentrate the bacteria into a suitably sized volume for inoculation and that maximize the recovery of sublethally damaged cells. The essential components of *Campylobacter* media are peptone growth substrates, oxygen quenching agents that include lysed horse blood, and antibiotics to suppress competing microorganisms. Inoculated liquid media can be incubated in air if containers are filled to the top.

Homogenates of solid foods are produced by gentle mixing to avoid excessive oxygenation, whereas liquid samples require concentration by centrifugation (milk) or filtration (water). Aliquots of homogenate, centrifuge pellet, or filters are inoculated into liquid *Campylobacter* enrichment medium that is then incubated at a reduced temperature for a time to enhance the recovery of injured cells. The most widely used resuscitation procedure is incubation for 4 h at 37 °C before enrichment for a further 44 h at 42 °C. However, extending the resuscitation period to 12–24 h at 37 °C followed by incubation for 24 h at 42 °C is used for water samples with low levels of contamination. Following incubation, enrichments are subcultured onto *Campylobacter* selective agar that has the same basic components as the liquid media, to obtain isolates that can subsequently be identified to a species/subspecies level.

The most widely used selective agars contain charcoal instead of blood. Charcoal and blood are both effective oxygen quenching agents but agar that contains charcoal has a longer shelf life. Inoculated plates are placed in a gas-tight vessel that is filled with an appropriate microaerophilic atmosphere and incubated at 42 °C for at least 24 h. *Campylobacter* colonies can vary in morphology, mostly depending on the degree of hydration of the plates. On moist plates colonies are grayish in color and spreading whereas on drier plates colonies are often small (1–2 mm diameter) and discrete.

Modern risk management protocols designed to ensure production of safe food and drinking water are based on quantitative data. Therefore, laboratories are required to enumerate thermotolerant *Campylobacter* in test samples. For fecal samples from infected individuals direct plating of known amounts of sample can be used, although the spreading nature of colonies can make counting difficult. However, the more reliable multitube most-probable-number (MPN) method is used for food and water samples

Species identification

The identities of presumptive *Campylobacter* colonies on selective agars need to be confirmed. A series of basic biochemical tests to do this includes: Gram stain, oxidase reaction, and microscopic examination of a wet mount for cell morphology and motility. The characteristic features confirmative for *Campylobacter* are Gram negative, oxidase positive, 'seagull-'shaped cells, and a rapid corkscrew motion.

Species identification is carried out on selected isolates that have been grown in pure culture. A range of biochemical tests is required to differentiate species of thermotolerant *Campylobacter* with the most basic including microaerophilic growth at 25 °C and 42 °C, hippurate hydrolysis, the presence of catalase, resistance to 30 μg ml^{-1} nalidixic acid, and resistance to 30 μg ml^{-1} cephalothin (reactions for the most common species are shown in Table 1). A large number of carefully standardized biochemical tests are required to accurately identify isolates to the species level.

Table 1 Typical biochemical reactions of three commonly isolated species of thermotolerant *Campylobacter* (+, positive; –, negative; S, sensitive; R, resistant)

Characteristics	Campylobacter jejuni	Campylobacter coli	Campylobacter lari
Growth at 25 °C	–	–	–
Growth at 42 °C	+	+	+
Nalidixic acid	S	S	R
Cephalothin	R	R	R
Catalase	+	+	+
Hippurate hydrolysis	+	–	–

Subspecies identification by serotyping

For epidemiological tracing of an infectious source, pathogens need to be identified to a level below that of species. For thermotolerant campylobacters this has traditionally been done by serotyping using heat-stable antibodies (Penner serotyping) or heat-labile antibodies (Lior serotyping). These methods have enabled tracing the source of outbreaks of infection but they are increasingly being replaced by molecular typing methods.

Molecular Methods

Specialist laboratories are adopting molecular techniques to identify the presence of specific species of *Campylobacter*, or to actually enumerate them, directly in samples. These methods are based on amplifying specific target gene sequences by the polymerase chain reaction (PCR) using primers that are specific for target species of thermotolerant *Campylobacter*. Enumeration is done either by adapting the identification to an MPN-type format or increasingly by the use of 'real-time' PCR.

Subspecies identification by pulsed-field gel electrophoresis

Molecular techniques for identification at a subspecies level allow rapid source tracing of the large numbers of isolates associated with sporadic cases of campylobacteriosis. A widely used method in clinical laboratories is pulsed-field gel electrophoresis (PFGE) in which large fragments of DNA are generated by a chosen restriction enzyme (e.g., *Sma*I) and separated by a specialized (pulsed field) electrophoretic technique. Classification is achieved by using computer programs to compare the DNA restriction fragment patterns of an isolate to those of reference markers. Some laboratories use more than one restriction enzyme for a more precise classification.

Multilocus sequence typing analysis of Campylobacter jejuni *populations*

Recently the diversity and relationships within populations of specific *Campylobacter*, most commonly *C. jejuni*, have

been defined by the technique of multilocus sequence typing (MLST). In this technique, variations and similarities within the fragments of several (typically seven) key genes required for metabolic function are identified by sequencing. The clonal complexes defined by computer analysis have been found very useful for tracing sources of infection through the food chain. MLST typing has demonstrated the close relationship between populations causing human disease and those commonly found on poultry. International sharing of information is facilitated by a publicly accessible database hosted by the Department of Zoology at Oxford University, UK. (pubmlst.org/*Campylobacter*).

Characteristics of Campylobacteriosis

Thermotolerant campylobacters are highly infectious and the infective dose for *C. jejuni* can be as low as 500 cells. Unlike with many enteric pathogens, there is usually limited spread of these *Campylobacter* within families and the main reservoirs of infection are animals. Although humans can be infected directly from animals, most disease is associated with consumption of contaminated food or water. In developed countries the routes of infection, in approximate order of frequency are undercooked chicken, red meat, raw milk, fecally contaminated water, bird-pecked bottled milk, cross-contaminated ready-to-eat foods, and puppies and kittens.

Symptoms appear between 1 and 7 days after infection. Thermotolerant *Campylobacter* infection can lead to a variety of disease scenarios. The onset is often abrupt, with cramping abdominal pains followed by diarrhea. The diarrhea may mimic that of either, or sometimes both, cholera (*Vibrio*), with copious amounts of water excreted in response to toxin production by the bacteria, or bacillary dysentery (*Shigella*) with mucus and blood present in the stool. Although nausea is a frequent symptom only a small proportion of patients actually vomit. A particular feature of *Campylobacter enteritis* is abdominal pain, which can mimic acute appendicitis. Some patients suffer a nonspecific influenza-like phase with one or more symptoms of fever, headache, and nausea. These patients may develop a more severe illness than those whose illness starts with diarrhea. Death due to *C. enteritis* itself is rare and is usually confined to elderly patients or those already suffering from another serious illness. However, a number of more serious conditions occasionally follow infection. These include the paralytic Guillian–Barré syndrome, an autoimmune disease that affects the peripheral nervous system, and reactive arthritis or Reiter's syndrome, which cause inflammation of the joints.

Patients who are not treated with antibiotics continue to excrete *Campylobacter* in their feces for several weeks after they have clinically recovered. Antibody studies have identified very high infection rates in young children in both developed and developing countries. Most adults in the Netherlands, rural and urban, tested positive for *Campylobacter* antibodies in spite of an antibody half-life of only approximately 2 years. It may be that many people are exposed to multiple infections and that some of these cause no or only very mild gastrointestinal disease. Although disease can occur in animals, in many cases infected animals that shed thermotolerant *Campylobacter* in large numbers are free from any symptoms.

Mechanism of Pathogenicity

Whether or not disease follows infection by thermotolerant *Campylobacter* depends on the susceptibility of the person and the relative virulence of the infecting strain. The rapid corkscrew motion of campylobacters facilitates penetration of the thick viscous mucus barrier of intestinal cells and this is followed by attachment to the enterocyte cells of the small intestine. Adhesion to cells involves surface components including flagella and lipopolysaccharides, outer membrane protein antigens, and carbohydrate moieties.

Once colonization has been established *Campylobacter* multiply rapidly and may produce a range of toxins, the most common of which are enterotoxins and cytotoxins. Enterotoxins cause watery, cholera-like diarrhea that is the most frequently occurring symptom of campylobacteriosis in developing countries. In developed countries the most commonly observed symptom is due to cytotoxins that cause microlesions of enterocytes leading to bloody diarrhea. During invasion, the host immune system is activated with various classes of immunoglobulins produced. One class, IgA, can cross the intestinal wall and immobilize *Campylobacter* cells resulting in short-term immunity whereas other immunoglobulins can act on bacteria entering the bloodstream, preventing bacteremia.

Recently, an alternative model of pathogenicity has been developed to account for cases with which correlation between human disease and the production of functional toxins is lacking. This 'immunopathogenic' model proposes that penetration and disruption of the intestinal mucosa by *Campylobacter* activates an immune response that can lead to a release of cytokines that are in fact responsible for the symptoms of diarrhea. If this is the case then most strains of *Campylobacter* have potential to cause disease and the outcome of infection will depend on the specific immune response of the infected individual.

Epidemiology

Thermotolerant campylobacters are constituents of the commensal intestinal microflora of birds, cattle, sheep, goats, and pigs and they seldom cause disease in these hosts. *C. jejuni* is particularly associated with birds and is also commonly isolated from the feces of farmed animals and pets.

Many developed countries have reported increasing rates of campylobacteriosis from the latter years of the twentieth century up to the early years of the twenty-first century. The reasons for this could include both improved detection and isolation techniques and increasing consumption of poultry and 'fast-foods.' Campylobacteriosis is a foodborne disease rather than food poisoning. The commonest causes of infection are considered to be insufficient cooking of meat, especially poultry, and cross-contamination from raw meats to ready-to-eat food. Although campylobacteriosis remains a major reported infectious disease recent data demonstrate an encouraging decline in rate. For example, New Zealand rates (per 10^6 population) declined from 384 cases in 2006 to 168 in 2008. This reduction has been linked to measures introduced by the poultry industry from 2007. However, ever since

Table 2 Reported occurrence of thermotolerant campylobacters on retail meats in seven countries

Country	*Food type*	*Sample number*	*% positive*	*Reference*
UK	Beef			Little *et al.*, 2008

	Pork	55	0	
	Poultry	155	45.6	

2008 the New Zealand rate remains higher than that in many other developed countries such as Australia (108), England and Wales (92), EU (45), and USA (13).

Campylobacter is sensitive to dehydration, especially at room temperature and does not usually survive cooking or pasteurization. However, viable campylobacters were recovered from artificially contaminated beef roasts that had reached an internal temperature of 50–53 °C. Although generally considered sensitive to freezing, viable cells have been recovered from the surface of both poultry and beef after several weeks of frozen storage. Equally disturbing is the survival of *C. jejuni* on vacuum or carbon dioxide packaged beef stored at −1.5 °C for 41 days.

Unlike other foodborne pathogens such as *Salmonella*, *Campylobacter* do not have specific environmental survival mechanisms. The survival of campylobacters is related to the large numbers of cells that are released in the feces of carrier animals. A consequence of this is that most cases of campylobacteriosis are sporadic. Seasonal peaks are also common, particularly in rural areas. There is a relationship between peaks in the numbers of *Campylobacter* shed by dairy cows in spring and autumn and the seasonal peaks of human infection that occur in rural areas. Where large outbreaks of infection occur the origin has been traced to a common source such as highly contaminated water, milk, or poultry.

Thermotolerant *Campylobacter* has been recovered from retail meats in a number of countries throughout the developed world as shown by the data in Table 2. Although the reported numbers are always higher for poultry, especially chicken, direct DNA techniques have demonstrated that other meats can also be sources of infection. Risk assessment modeling suggests that control and preventative measures need to be applied at all stages from production to consumption.

Control and Preventative Measures

Control of the transmission of thermotolerant *Campylobacter* requires the implementation of food safety management

systems from production to consumption. The Codex Alimentarius Commission (i.e., the body responsible for developing international food standards and codes of practice and guidelines on behalf of the Food and Agriculture Organization of the United Nations and the World Health Organization) has endorsed the use of food safety management systems such as Hazard Analysis and Critical Control Points (HACCP) to control the spread of foodborne campylobacteriosis. Within the production system quality assurance programs include good agricultural practices (GAP) and good manufacturing practices (GMP), and involve the understanding, analysis, and control of food production practices. These management systems need to be supported by control measures in animal rearing facilities.

Control Strategies on Farms

As thermotolerant campylobacters are components of the normal commensal intestinal microflora of healthy animals they are not considered an animal health/welfare issue that impacts on production. However, at least for poultry and pigs, efforts are increasingly being made to reduce the level of *Campylobacter* on a whole flock/herd basis. Animal housing presents a significant risk factor for the introduction and spread of campylobacters and needs careful management. In addition, transport of animals and their assembly for slaughter are stressful and can increase shedding leading to environmental contamination and cross-infection.

Although animal housing is a risk factor, most poultry production is based on all-in all-out intensive production that can be rigorously controlled. In contrast, the grazing of open grassland by sheep and cattle or free-range rearing of poultry and pigs are more challenging environments for elimination of *Campylobacter* from farms.

Control in Poultry Houses

Poultry have a well-described association with campylobacteriosis and good hygiene and biosecurity measures are essential to protect poultry from acquiring *Campylobacter*. Contamination of flocks has been identified as the major source of infection in poultry. Chickens can become campylobacter-positive after transfer to growing houses, which suggests an environmental source of the organism. To control infection, thorough routine cleaning and disinfection of the houses is needed, especially between flocks. Drinking water should be of high quality; and adequate biosecurity measures such as the exclusion of wild birds, flies, rodents and pets (dogs and cats) and wearing dedicated in-house shoes and clothing is essential. Interventions that show promise for inhibiting *Campylobacter* include adding a bacteriocin (a toxin produced by another species of bacteria) to drinking water a few days before slaughter, oral administration of bacteriophage (specific for *C. jejuni*) or feeding the supplement caprylic acid.

Control in Meat Processing Plants

Campylobacter that enter processing plants on the skin, hide, or feathers or in feces of carrier animals have the potential to be spread within the plant. For poultry, in particular, prevention of gross carcass contamination by feces is a high priority because processing techniques include scalding, plucking, and eviscerating and can include cooling carcasses in tanks, all of which will inevitably lead to cross-contamination of carcasses. Cross-contamination is less likely during processing of carcasses that are dressed on an individual basis such as cattle, sheep, and pigs, although pig carcasses can be cross-contaminated during mechanical dehairing. For all processing, good butchering skills together with good personnel hygiene and sanitation of equipment and moving surfaces are essential to reduce the likelihood of contamination to a minimum. Although good hygiene is important it has been shown that some strains of *Campylobacter* can survive routine cleaning and decontamination procedures. It has also been shown that *Campylobacter* can establish in biofilms in, for example, water distribution systems, and potentially survive disinfection. The USA Department of Agriculture has approved chemical disinfection of carcasses by application of various antimicrobial solutions. However, chemical disinfection is not permitted in Europe (under European Union rules). Pasteurization of beef carcasses with hot water or steam, and spraying carcasses with 5% lactic acid are now common and effective decontaminating treatments used in North American beef packing plants. However, there is little specific information on the effects of these treatments on campylobacters.

Freezing is a control technique used in some countries. A reduction in campylobacteriosis in Iceland has been associated with freezing carcasses and a number of Scandinavian countries now require carcasses from flocks that test positive for *Campylobacter* to be frozen for several weeks. Crust freezing, in which carcasses are exposed to a stream of air at −30 °C, shows promise in pathogen reduction although the costs are even higher than for carcass freezing.

Control during Food Distribution

It is not possible to guarantee that raw meats will be pathogen free when they leave a processing plant, so distribution chains need be designed and operated to prevent cross-contamination or multiplication of bacteria. Cross-contamination can occur as a result of pack leakage. To minimize this, raw animal products should to be packaged in approved packaging films. The use of 'leak-free' packaging for raw chicken is considered to have made a major contribution to the recent reduction in campylobacteriosis in New Zealand. To avoid cross-contamination, ready-to-eat foods should be transported and stored in separate containers or compartments to those used for raw foods. Good temperature control is required throughout the distribution chain to maintain an acceptable microbiological condition for meat that reaches retail outlets.

Butcher shops and retail outlets

Most countries have laws aimed at ensuring that food offered to consumers is safe to eat. Usually, such legislation requires that food business employees are suitably trained and that food safety management systems, based on scientific principles, such as the HACCP system are implemented. *Campylobacter* may be present on a variety of foods, especially

raw poultry and other raw meats. Given its low infectious dose, care in handling such foods is needed to minimize the risk to consumers. However, growth of *Campylobacter* would not be expected. Handling practices must prevent both recontamination and cross-contamination. Essential components of the HACCP system include suitable premises and equipment, high-quality potable water, very high standards of employee hygiene, and constant attention to hygienic food handling practices.

Restaurants and fast food outlets

Where cooked foods are offered for sale the same type of HACCP system as is employed in butcheries is required. In restaurants, a variety of different types of foods are brought together with a consequent high potential for cross-contamination. To address this, cooking procedures should be sufficient to destroy any *Campylobacter* present. After cooking, subsequent handling practices must ensure that there is no possibility of recontamination.

Control in the Home

Preparation of food in the home kitchen has been identified as an important factor affecting the prevalence of foodborne disease. Householders need to handle meats with the same attention to hygiene and cooking practices as are required by restaurants. Meats need to be kept under refrigeration and stored and prepared in such as way as to avoid cross-contamination. Cooking procedures need to be sufficient to destroy any residual bacteria, especially when prepared foods are reheated. During meal preparation care is needed to avoid contamination, by ensuring that hands are thoroughly washed after handling raw meats and by keeping knives, chopping boards, cooking and serving utensils clean. Ideally, different sets of equipment should be used for raw and ready-to-eat products. To protect people from avoidable diseases such as campylobacteriosis and to constantly reinforce the need for care, public information to promote effective hygiene in the kitchen needs to be easily accessible and readily understood.

Viruses

TH Jones, Agriculture and Agri-Food Canada, Lacombe, AB, Canada

Glossary

Gnotobiotic Animals that are born under aseptic conditions and raised in a sterile environment to permit investigations of the effects of exposing animals to microorganisms under controlled conditions.
Seroprevalence The frequency of individuals in a population that has antibodies to a specific pathogenic microorganism in their blood serum.
Vertical transmission Infectious diseases that are naturally transmitted from mother to infant during the period immediately before and after birth. Transmission routes include crossing the placenta, breast milk, or through direct contact during or after birth.
Viremia The presence of viruses in the bloodstream.
Zoonotic transmission Infectious diseases that are naturally transmitted between vertebrate animals and humans. Transmission occurs at the human–animal interface through direct or indirect human exposure to animals, their products and/or their environments.

Introduction

Until recently, the contribution of viruses to foodborne disease associated with the consumption of meat has largely been overlooked and underappreciated. However, enteric viruses are responsible for the majority of foodborne disease outbreaks worldwide and are often suspected when the causative agent is unknown or cannot be identified. Enteric viruses have a very high acid resistance, which allows them to survive the low pH of stomach acid. Unlike bacteria, viruses require a living host cell for multiplication and therefore viruses are unable to multiply in food. The infectious dose of enteric viruses, however, can be extremely low. Thus 10 or less infectious particles may be sufficient to cause disease. Enteric viruses are excreted in high numbers ($>10^{10}$ infectious particles per g of feces) by infected humans and animals. Furthermore, enteric viruses are extremely stable at low and freezing temperatures and are generally more resistant to environmental stresses than bacteria. As a result, current strategies to reduce bacterial pathogens in food may not be fully effective against viruses. Although the inability of viruses to multiply in foods is favorable from a food safety perspective, the low number of virus particles present in foods presents a challenge for their detection. Most enteric viruses cannot be cultivated and their detection is therefore restricted to molecular techniques, which have their own limitations as both infectious and noninfectious particles will be amplified if primer sets are sufficiently robust to detect and amplify the targeted genetic sequence.

The number of documented foodborne virus outbreaks is increasing due to advances in molecular detection and characterization methods and sample processing methods, as well as a rise in the consumption of raw and minimally processed foods, the globalization of trade between countries with widely different standards of hygiene and sanitation, and increasing vulnerable populations of elderly and immunocompromised individuals in some countries. The majority of foodborne illnesses are caused by viruses of human origin such as norovirus (NoV), hepatitis A virus (HAV), rotavirus (RV), and astrovirus, and are associated with the consumption of ready-to-eat foods, vegetables, fruits, and shellfish that are contaminated by infected food handlers, contaminated water, or by cross contamination of food. However, there are increasing concerns over the zoonotic transmission of NoV and RV through undercooked meat products due to an increasing evidence of the existence of animal strains of NoV and RV that are closely related to human strains; whereas the zoonotic transmission of hepatitis E virus has been demonstrated.

Hepatitis E Virus

Virus Characteristics

Hepatitis E virus (HEV) is the only member of the genus *Hepevirus* of the newly proposed *Hepeviridae* family. HEV is a small, nonenveloped virus with a diameter of 27–34 nm and positive sense 7.2-kb ribonucleic acid (RNA) genome. The genome contains a short 5′noncoding region, three open reading frames (ORF1, ORF2, and ORF3), a 3′ noncoding region, and a poly(A) tail. ORF1 encodes a polyprotein that is presumed to cleave into nonstructural proteins involved in viral replication that include a methyltransferase, RNA-dependent RNA polymerase, and helicase. ORF2 encodes the major capsid protein that is the target for vaccine development, whereas ORF3 encodes a small phosphoprotein that is thought to be a viral regulatory protein involved in intracellular signal transduction and the assembly of new virus particles.

HEV is classified into five genotypes: genotype 1 contains human epidemic strains circulating in Asia and Africa; genotype 2 contains human strains circulating in Mexico and Africa; genotype 3 strains are distributed worldwide and have been isolated from humans in sporadic cases of acute hepatitis E as well as from pigs in North America, Europe, and Japan; genotype 4 contains strains circulating in humans and pigs in Asia; and genotype 5 contains strains of avian HEV, isolated from chickens in North America, which are genetically very different from mammalian HEV. Although extensive sequence variation exists among the five genotypes, all belong to a single

serotype. Antibodies against HEV have been detected in pigs, cattle, chickens, sheep, goats, deer, wild boar, mongooses, dogs, cats, primates, and rats. Recent progress in the cultivation of HEV in a cell culture system may advance the understanding of HEV pathogenesis and permit research on virus stability and inactivation.

Disease

The incubation period of HEV is relatively long, 2–10 weeks, which is problematic when attempting to identify the source of infection. The disease is usually self-limiting, lasting for 1–4 weeks, and generally does not result in chronic hepatitis. Typical symptoms include jaundice, hepatomegaly (i.e., swollen liver), malaise, abdominal pain, anorexia, vomiting, fever, viremia, and dark urine. The primary site of HEV replication has not been identified but the intestinal tract is a likely candidate. After HEV finds its way to and infects the liver, HEV enters the bloodstream, accumulates to high concentrations in bile, and is subsequently excreted in feces. The immune response, initiated after 2–3 weeks of infection, is primarily responsible for the liver damage. The mortality rate in the general population is between 0.5% and 4% but increases dramatically to as high as 42% for pregnant women. Women in the third trimester of pregnancy are particularly at risk, possibly due to changes in hormone levels. Mortality may be up to 75% for patients with underlying chronic liver disease. Person-to-person transmission of HEV among family members of patients that have contracted HEV is rare, with rates estimated to be approximately 0.7–8.0%. Vertical transmission of HEV from a pregnant mother to her infant has been documented.

A treatment for HEV does not exist but the first vaccine against HEV, HEV 239, was approved by China in 2012 and may soon be commercially available for protection against HEV. The persistence of anti-HEV IgG antibodies is thought to provide long-term immunity to HEV. HEV is identified and diagnosed by the detection of IgM and IgG antibodies against recombinant HEV antigens or by reverse transcriptase (RT)-polymerase chain reaction (PCR) and nucleic acid sequence analysis for detection and genotyping HEV RNA in serum or feces.

Zoonotic Transmission

HEV genotypes 1, 2, and 4 are associated with epidemic and sporadic cases of acute viral hepatitis in humans in the regions of Asia, Africa, and Central America where the virus is endemic. Most of these outbreaks are associated with fecal contamination of drinking water. According to World Health Organization estimations there are approximatelyt 14 million symptomatic cases, more than 300 000 deaths and 5200 stillbirths annually associated with HEV. As sanitation and access to good quality water improve and vaccines become commercially available, such outbreaks will likely be reduced dramatically.

HEV genotype 3 is associated with sporadic cases of locally acquired HEV in industrialized countries where epidemics are not reported. The number of sporadic cases appears to be increasing in Europe, due to either an increase in surveillance or real increases in the disease. Although some cases of HEV are travel related the proportion of nontravel-related cases is increasing, especially in older men, and may be traced to zoonotic origins. Immunocompromised individuals, such as transplant patients, appear to be particularly vulnerable to chronic infection with HEV genotype 3. HEV is endemic in Japan, Australia, USA, and Europe, and seroprevalence as high as 36% has been reported. HEV is now widely accepted as a zoonotic disease that is carried by domestic pigs, wild boars, and deer. Infection in pigs generally occurs between the age of 2 and 3 months and HEV is shed in the feces for approximately 3–7 weeks. The majority of pigs over 6 months of age do not shed HEV in their feces but the seroprevalence of HEV in commercial pigs can be as high as 80%.

Swine veterinarians and persons handling swine have a higher frequency of IgG antibodies to HEV than the general population. Similar strains of HEV appear to circulate within the animal and human population. Swine HEV readily cross-reacts with an antibody to the capsid of human HEV. Furthermore, the genetic sequences of swine HEV closely resemble those of human strains, human HEV can infect swine, and swine HEV can infect nonhuman primates.

The consumption of undercooked or raw meat from animals that are reservoirs for HEV is a major risk factor. In Japan, four cases of HEV were directly linked to the consumption of raw deer meat, with the identical strain of HEV being isolated from the infected patients and the meat. Furthermore, several cases of HEV have been linked epidemiologically to eating undercooked pork liver or wild boar meat. Figatellu, a pig liver sausage that is traditionally consumed raw in France, has also been implicated as a source of HEV infection. In surveillance studies, HEV RNA was detected in 2%, 7%, and 11% of pig livers sold at the retail level in Japan, the Netherlands, and the US, respectively. Furthermore, infectious HEV has been recovered from liver in the US. The infectious dose required to cause disease is not known but it is thought to be high as the seroprevalence in human and swine populations is quite high, whereas the number of reported cases of HEV is very low.

Survival of Hepatitis E Virus in Food

There is little information on the stability of HEV in food. Heating a fecal suspension of HEV diluted to a final concentration of $<5\%$ in phosphate buffer solution (PBS) for 60 min at 56 or 60 °C was not sufficient to inactivate all the virus particles. HAV is more heat stable than HEV; after 1 h at 66 °C infectious HAV particles were not detected, suggesting that HEV would be inactivated under those conditions. The inactivation of HEV in PBS is likely greater than inactivation in meat tissue held at the same temperature for the same time as viruses will be protected by proteins in the liver and muscle matrix. The United States Department of Agriculture recently reduced the recommended temperature to be achieved during cooking of pork from 71 to 63 °C. This is of concern with respect to inactivation of HEV as the virus may be exposed to such temperatures for only a very short period of time. HEV was

unable to infect susceptible pigs when naturally contaminated liver was cooked to an internal temperature of 71 °C by stir-frying for 5 min or when liver was boiled in water for 5 min. However, when the infected liver was incubated at 56 °C for 1 h, a temperature representative of the minimum temperature attained by medium-rare meat, 80% of pigs became infected. These limited data suggest that pork must be thoroughly cooked to control the risk of foodborne transmission of HEV, particularly to the most vulnerable and susceptible segments of the population.

Caliciviruses

Virus Characteristics

Caliciviruses are nonenveloped viruses with a diameter of 27–40 nm and positive sense RNA genome ranging in size from 6.4 to 8.5 kb. The family *Caliciviridae* contains five recognized genera to date. These are the established genera *Norovirus*, *Sapovirus*, *Vesivirus*, *Lagovirus*; and a new genus *Nebovirus* that contains the bovine strains Newbury agent 1 and Nebraska and a number of unclassified caliciviruses, including rhesus enteric calicivirus (Tulane virus), St. Valérien-like viruses in swine, and chicken caliciviruses. Caliciviruses cause a variety of diseases and have a broad host range. NoVs and sapoviruses (SaVs) are linked to the majority of outbreaks of food or waterborne, acute, nonbacterial gastroenteritis in humans worldwide and the close genetic relationship between human and animal strains has raised concerns about their zoonotic potential (Figure 1).

On the basis of the complete sequence of the capsid gene, NoVs are classified into five genogroups (GI–GV). Human NoV strains are located in GI, GII, and GIV, whereas porcine NoV strains are also found in GII. NoVs in GIII infect cattle and sheep, whereas GV infect mice. The genogroups are subdivided further with 8 genotypes for GI, 19 genotypes for GII, 3 genotypes for GIII, and 1 each for GIV and GV to date. The porcine GII NoVs belong to 3 genotypes that are distinct from human GII genotypes. SaVs too are classified into 5 genogroups. Human SaV strains are located in GI, GII, GIV, and GV, whereas porcine SaV strains are located in GIII. It is expected that a number of porcine strains that do not fit in GIII will be classified into new genogroups GVI and GVII as more genotypes are discovered.

The genome organization of NoV differs from SaV; the genome of NoVs contains three ORFs, whereas the genome of SaVs contains two ORFs. For NoVs, ORF1 encodes six nonstructural proteins required for viral replication, ORF2 encodes the major capsid protein VP1, and ORF 3 encodes a minor capsid protein VP2. VP1 folds into a shell domain and a protruding (P) domain, which is further subdivided into a P1 and P2 domain. The P2 domain is the hypervariable region of the capsid and contains both the immune and cellular receptor sites. For SaVs, ORF1 encodes the nonstructural proteins and VP1, whereas ORF2 encodes the minor capsid protein VP2. The RNA genome is replicated by the RNA-dependent RNA polymerase, which has no proofreading activity and causes a high error rate in transcription. This makes the caliciviruses highly flexible and diverse.

Disease

NoV is the leading cause of acute gastroenteritis from contaminated food or water. Approximately 25% of illnesses of human NoV in the US are attributed to food; however, the majority of outbreaks are associated with person-to-person transmission, particularly in populations with close contact, such as those of nursing homes, educational institutions, day cares, cruise ships; and in populations after natural disasters when personal hygiene and sanitation may be compromised. Outbreaks occur most frequently during the winter months. NoV is transmitted not only via the fecal–oral route but also via aerosols generated from vomit and contaminated surfaces. The number of outbreaks globally has increased dramatically since 2002, possibly due to changes in the predominant circulating strain. NoVs shed in the stool at levels $>10^8$ genome copies per g, and may persist for 3–4 weeks after clinical symptoms have disappeared from a resident population. NoV is extremely persistent in the environment and resistant to disinfectants; and the infectious dose is extremely low. The incubation time is short, from 12 to 72 h with a median of 33–36 h, and the symptoms typically last for 1–3 days. Symptoms include projectile vomiting, watery nonbloody diarrhea, abdominal cramps, and nausea. Low grade fever, headache, and muscle aches may also occur. Although the disease is described as self-limiting in the healthy population, the young, elderly, and immunocompromised individuals are particularly vulnerable to complications such as dehydration and possibly death. Owing to the short incubation time and rapid spread of secondary infections, it may be difficult to trace the outbreak back to its original source. Prior infection with NoV does not provide long-term immunity and the high antigenic variability of NoV makes it difficult to develop an effective vaccine. The most effective control is through proper handwashing and isolation of infected individuals. Most outbreaks in humans are caused by NoV GII genotype 4 (GII.4) and it appears that new GII.4 subtypes replace prevalent subtypes every 2–3 years. Sporadic cases of NoV are most often associated with diverse strains belonging to GII, with a smaller contribution from strains belonging to GI.

Human SaV infections, which mainly affect children under 5 years of age, do not occur as frequently as NoV infections and do not follow a seasonal pattern. The symptoms include diarrhea, fever, and vomiting, but projectile vomiting does not occur. SaV are excreted for approximately 2 weeks. NoV and SaV infections are thought to involve the small intestine, but little is known about the mechanisms of the disease as a cell culture system does not exist for these caliciviruses. NoV and SaV are detected by RT-PCR. Real time RT-PCR is increasingly being used for the detection of NoV as it is faster and more sensitive than conventional RT-PCR. Multiple primer and probe sets are required for NoV and SaV detection as, due to their genetic diversity, it is currently not possible to detect all known NoVs or SaVs with a single assay.

Zoonotic Transmission

The status of NoV and SaV as zoonotic agents is uncertain. Porcine NoV GII are closely related to human NoV GII. Porcine NoVs have been detected in Asia, Europe, and North

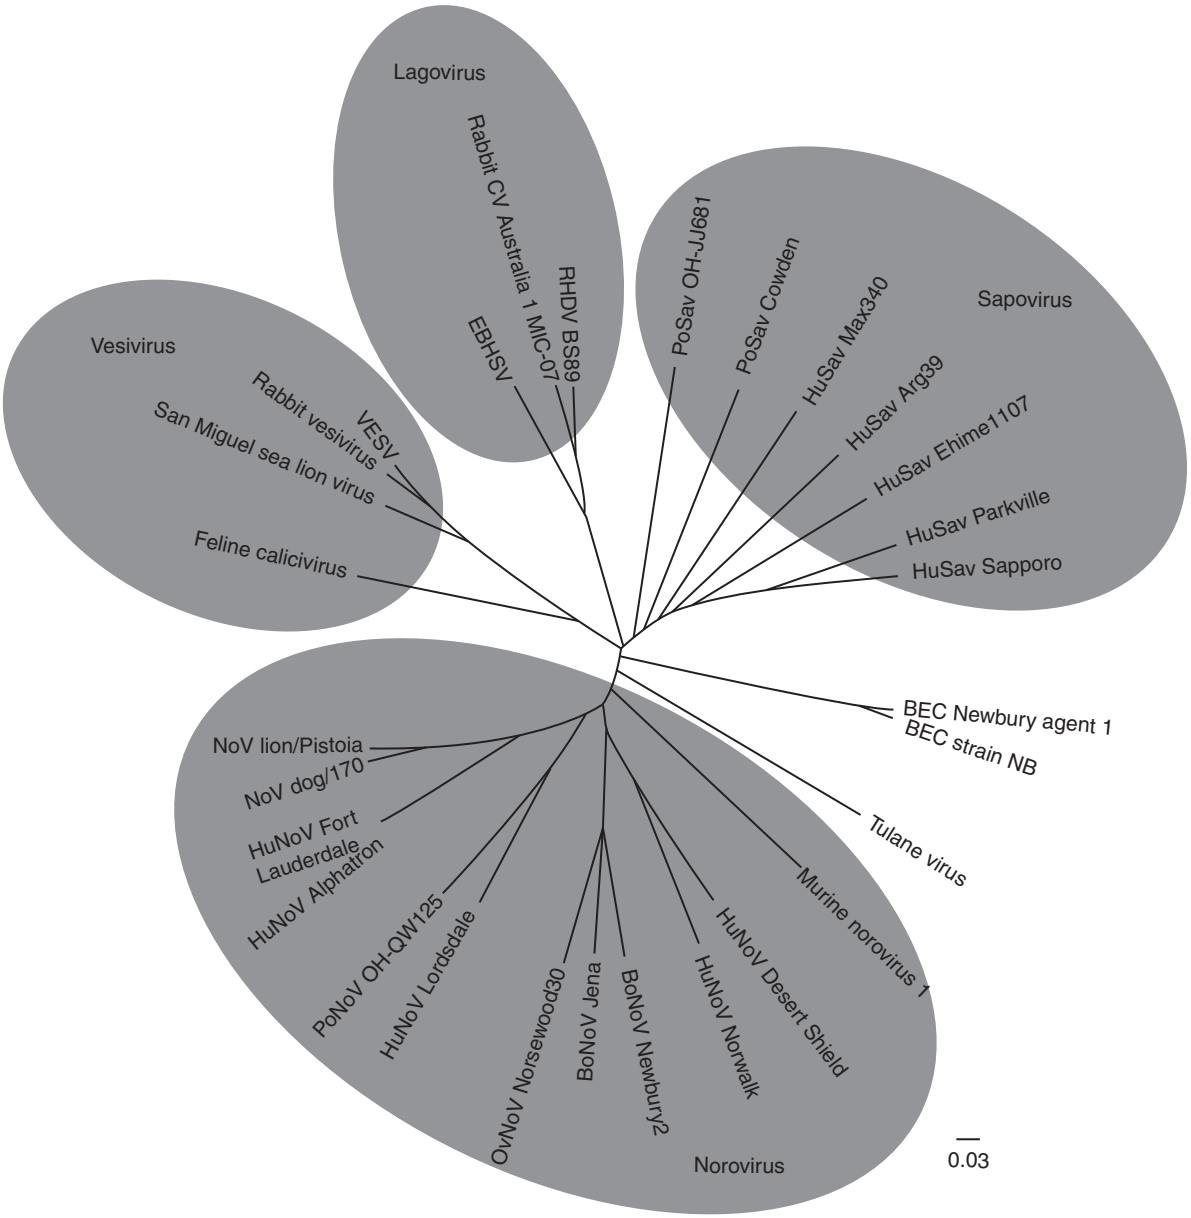

Figure 1 Classification of caliciviruses based on the nucleotide sequences of the complete capsid protein. Reproduced with permission from Greening, G.E., Wolf, S., 2010. Calicivirus environmental contamination. In: Hansman, G.S., Jiang, X.J., Green, K.Y. (Eds.), Caliciviruses: Molecular and Cellular Virology. Norfolk, UK: Caister Academic Press, pp. 25–44.

America and cause mild or asymptomatic infections in pigs. When gnotobiotic pigs were infected with human NoV GII.4, 74% of pigs developed mild diarrhea and 59% became seropositive. Furthermore, antibodies against human NoV GI and GII have been detected in swine. These findings suggest that swine could be a reservoir for human NoV. In addition, NoV GII.4-like RNA was detected in swine and bovine manure as well as in raw pork at the retail level. It is unknown if the source of the GII.4-like strain on the retail meat was of animal or food handler origin. Porcine SaV have been detected worldwide and cause mild or asymptomatic infections in young and adult pigs. The concerns about the zoonotic potential of SaV are lower than for NoV as the limited number of porcine SaV that have been identified to date are genetically different from human SaV.

Bovine GIII NoV infections can cause diarrhea or are asymptomatic in calves and cattle. A closely related NoV GIII was recently detected in fecal material from asymptomatic sheep. Although animal NoVs have not been detected in human stool samples, veterinarians have a higher frequency of IgG antibodies to NoV than the general population, which suggest that bovine NoV may infect humans. The ability of human NoV to infect cattle has not been demonstrated.

Concerns about the zoonotic potential of animal caliciviruses revolve around coinfection and interspecies

transmission. If either animals or humans are coinfected with both human and animal strains, then a potential recombinant animal/human NoV could emerge with an increased host range or increased virulence. Recombination occurs regularly in NoV and SaV, mainly within genogroups but intergenogroup recombinations have been reported. Furthermore, if animal caliciviruses adapt sufficiently to acquire the ability to infect humans, there will be major health implications. As NoV is found in the intestinal tract, NoV could be a likely contaminant on the surfaces of carcasses and meat as a result of fecal contamination during carcass processing. Considering that NoV GII.4-like RNA has been detected in swine, cattle, and retail meat, more surveillance and research is clearly required to address the concerns about the zoonotic potential of animal caliciviruses and to develop effective control or preventative measures.

Survival of Caliciviruses in Food

Human NoV cannot be grown in cell culture, therefore survival studies are typically carried out with cultivable surrogates. The results of such studies need to be interpreted with caution as murine NoV and feline calicivirus do not appear to be good models for human NoV in heat inactivation studies. Data suggest that time/temperature conditions recommended for pasteurization, such as 72 °C/15 s for milk or 70 °C/2 min for other foods are insufficient to inactivate GII.4 NoVs and consequently the risk of transmission of NoVs when such recommendations are used may be underestimated. On the basis of temperature inactivation profiles obtained with surrogate viruses, it was suggested that pasteurizing treatments of 63 °C/30 min or 70 °C/2 min were more effective than the high-temperature short-time pasteurization treatment of 72 °C/15 s. Murine NoV is more heat labile than human NoV but more heat resistant than *Escherichia coli*. Murine NoV and *E. coli* were reduced by 1.9 and 3.9 log units, respectively, after 30 s at 65 °C in raspberry puree. As caliciviruses are potentially present on meat surfaces, cooking recommendations adequate for inactivating caliciviruses should be identified and the potential risk of foodborne transmission of human caliciviruses by ground meat products should be assessed.

Rotavirus

Virus Characteristics

RVs belong to the genus *Rotavirus* and are a member of the *Reoviridae* family. RVs are nonenveloped viruses with a diameter of 60–80 nm. They contain a 16–27 kb double-stranded RNA (dsRNA) genome that comprises 11 segments surrounded by three protein layers. Each segment of RNA encodes a single structural or nonstructural protein, whereas two segments encode for two proteins. RVs are classified into seven serogroups (A–G) based on the viral capsid protein VP6 located in the middle protein layer. In addition, RVs are subdivided into 23 glycosylase or G-genotypes and a minimum of 32 protease sensitive or P-genotypes, which are based on the outer capsid proteins VP7 and VP4, respectively. VP7 and VP4 are encoded by separate gene segments. Serogroups A–C cause diarrhea in humans, whereas all serogroups (A–G) cause diarrhea in animal species. Group A RV (GARV) is associated with a wide range of mammals and birds; group B RV(GBRV) is primarily associated with pigs, cattle, sheep, and rats; group C RV (GCRV) with pigs, cattle, and dogs; groups D, F, and G mainly infect poultry, whereas group E has been associated with swine.

Disease

GARV has been linked to 90% of RV illness, which is an acute gastroenteritis occurring mostly in young children less than 5 years old. Clinical symptoms typically appear 1–2 days after infection and include vomiting, abdominal pain, and watery diarrhea caused by RV enterotoxin that put infants and children at risk of dehydration, and viremia that last for 3–8 days. RV infections are generally self-limiting but estimates suggest that GARV are responsible for more than 500 000 deaths annually in developing countries. The strain prevalence usually changes on a yearly basis. Strains that are prevalent in 1 year may be undetected in the subsequent year. Vaccines have recently become commercially available and appear to be highly effective in controlling RV disease. GBRV infects mainly adults and GCRV infects people of all ages. Approximately 100% of children are seropositive for GAVR by the age of 5 years, whereas approximately 60% of the population is seropositive for GCRV by the age of 60 years. GCRV is considered an emerging pathogen. RVs are typically shed in the feces for 5–7 days but shedding may last for several months in immunocompromised patients. The infectious dose is low, with 10–100 particles being sufficient to cause disease. Estimates suggest that 1% of RV cases are foodborne, whereas the majority are spread by person-to-person contact.

Zoonotic Transmission

GARV has been recognized as the major cause of diarrhea in calves and piglets and results in large economic losses for producers arising from treatment, reduced weight gain, and the death of animals. Animal strains are typically distinct from human strains but there is increasing evidence that GARV is being transmitted from animals to humans. Non-GARV infections are more predominant in animals than in humans. GCRV infections are widespread in swine and also occur in cattle. There are concerns about the zoonotic potential of GCRV due to an increase in seroprevalence of antibodies to GCRV in rural human populations. Unusual animal-like GCRVs are being detected in humans but direct transmission from animal to humans has not been reported. RVs are genetically diverse and are continually evolving into new genotypes, serotypes, and viral species as a result of point mutations, genetic reassortments, genomic rearrangements, or intragenic recombination. When animals or humans are coinfected with animal and human strains, RVs could potentially reassort into a novel strain during replication if one strand of the dsRNA genome was acquired from human RV and the other from animal RV.

Survival of Rotavirus in Food

RV is very stable in the environment and can survive for months at 4 °C and at freezing temperatures. Although limited data are available, RV is apparently more heat labile than other enteric viruses. A suspension of RV was rapidly inactivated at 60 °C or higher and *D* values of 8 and 5.8 min were reported for heating at 50 and 55 °C, respectively. As RV is associated with viremia as well as with the intestinal tract, meat must be thoroughly cooked to control the risk of foodborne transmission.

Yeasts and Molds

DYC Fung, Kansas State University, Manhattan, KS, USA

This article is reproduced from the previous edition, volume 2, pp 835–846,
© 2004, Elsevier Ltd.

Introduction

Yeasts and molds are important microorganisms related to human welfare and food resources. They contribute greatly to the food industry in areas such as wine making, single cell protein production, brewing, baking, vitamin production, etc. However, under special conditions they can act as potential spoilage organisms in food, especially in processed, preserved, and refrigerated food. The enumeration and identification of yeasts and molds from foods are of great importance in understanding the true value of these organisms in various food systems. Although yeasts and molds are normally not a major concern to most producers and processors of meats, under conditions such as drying, curing, freezing, and the use of preservative agents, yeasts and molds can compete effectively with bacteria and become the dominant microflora. A knowledge of how certain yeasts and molds colonize meat products and of the their effects on the meat products is essential in order to prevent economic losses during spoilage or to maximize desirable fermentation of certain cured meat products by yeasts and molds. Occasionally, some pathogenic yeasts and molds may occur in meat and meat products and can pose food safety issues in these products.

Yeasts and molds are ubiquitous microbes in our environment and play an important role in the entire cycle of processes that influence the balance of energy of all living and nonliving matter. Along with other microbes, they can be very beneficial to humans through their roles in the various geochemical cycles such as the phosphorus cycle, the carbon and oxygen cycles, the nitrogen cycle, and the sulfur cycle. Without their influence, the earth would not be habitable by humans. They are also important in various fermented foods such as wine, cheese, beer, vinegar, bread and soybean products, and in the production of industrially important acids, solvents, antibiotics, steroids, and enzymes. They can even be eaten as foods such as mushrooms, yeasts, and single-cell protein. On the other hand, they can spoil our food supplies and cause devastating diseases in animals and humans that, if unchecked, could actually destroy the human race.

Yeasts and molds belong to the eukaryotes since they have defined nuclear membranes surrounding the nucleic acids, as opposed to bacteria, which belong to the prokaryotes and do not have defined nuclear membranes. In the ranking of biological systems, yeasts and molds belong to the Division Eumycetes in the Phylum Thallophyta. Collectively, yeasts, molds, and mushrooms are termed fungi.

Yeasts are single-celled fungi. The cells are usually oval in shape and divide by budding in the asexual cycles or by formation of ascospores in the sexual cycles. Molds are multicellular, complex organisms that produce sexual and asexual spores. They grow by germination of sexual or asexual spores and elongation of the thallus (a complete cell) into hyphae, which may be septated or nonseptated. The intertwined hyphae will form a complex called mycelium, which appears as fuzzy and cottony growth in the environment and on meats, foods, clothing, walls, paper, and other materials.

Both yeasts and molds have sexual and asexual cycles. There are four types of asexual spores. Sporangiospores are enclosed in the sporangium. Conidiospores are released with microconidia and macroconidia. Chlamydospores are thalli that form a thick wall and become asexual spores. Arthrospores are formed by fragmentation of a septated mycelium. There are also four types of sexual spores. Oospores are formed by mating of a smaller 'male' thallus with a larger 'female' thallus. After exchange of genetic materials, sexual spores are formed. Zygospores are formed by the mating of two homogamous thalli. After exchange of genetic materials, sexual spores are formed. Ascospores are formed when two sexual spores mate and then, after exchange of genetic materials, the sexual spores are formed in a sac (ascus). Basidiospores are formed after exchange of genetic materials; sexual spores are formed at the basidium of very complex structures found in mushroom development.

A synopsis of the four classes of fungi is as follows:

- Phycomycetes: Sexual spores are free zygotes. Asexual sporangiospores are enclosed in the sporangium, which is developed from the sporangiophore. Mycelia are nonseptate (coenocytic). Important genera include *Mucor* (Figure 1), *Rhizopus* (Figure 2), and *Absidia*.
- Ascomycetes: Sexual spores in asci. Asexual spores are formed at the end of the conidiophore and are released. These structures are very distinctive for different genera of molds. Filamentous cells belong to the mold group and nonfilamentous cells are true yeasts. Important molds in this class include *Aspergillus* (Figure 3), *Penicillium* (Figure 4), *Fusarium* (Figure 5), *Alternaria* (Figure 6), *Botrytis* (Figure 7), *Cladosporium* (Figure 8), *Geotrichum* (Figure 9), and *Stemphylium* (Figure 10). Important yeasts in this class include *Saccharomyces cerevisiae, Candida albicans, Schizosaccharomyces, Hansenula*, and *Kloeckera*.
- Basidiomycetes: Sexual spores on basidium. Asexual spores are very rare. Mycelium is septated. Mushrooms and toadstools belong to this class.
- Deuteromycetes (Fungi imperfecti): These are the 'imperfect fungi' since only sexual or asexual cycles, but not both cycles, are observed. This is a catchall group. When both sexual and asexual cycles are observed, the organisms become assigned to one of the other three classes, usually into the *Ascomycetes* class. More detailed description of yeasts and molds related to food science and meat science can be found in *Modern Food Microbiology* by JM Jay (see Further Reading).

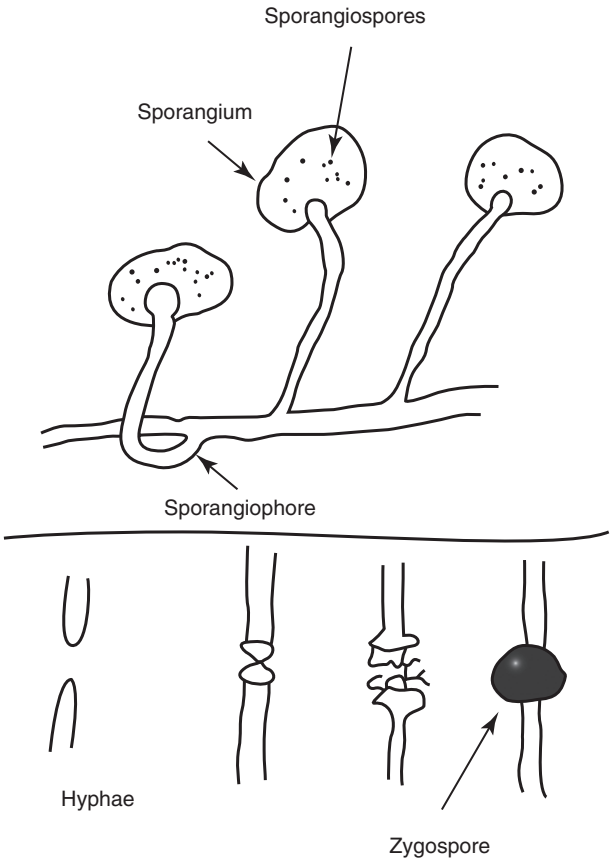

Figure 1 *Mucor* is very widespread and appears as a messy gray mass.

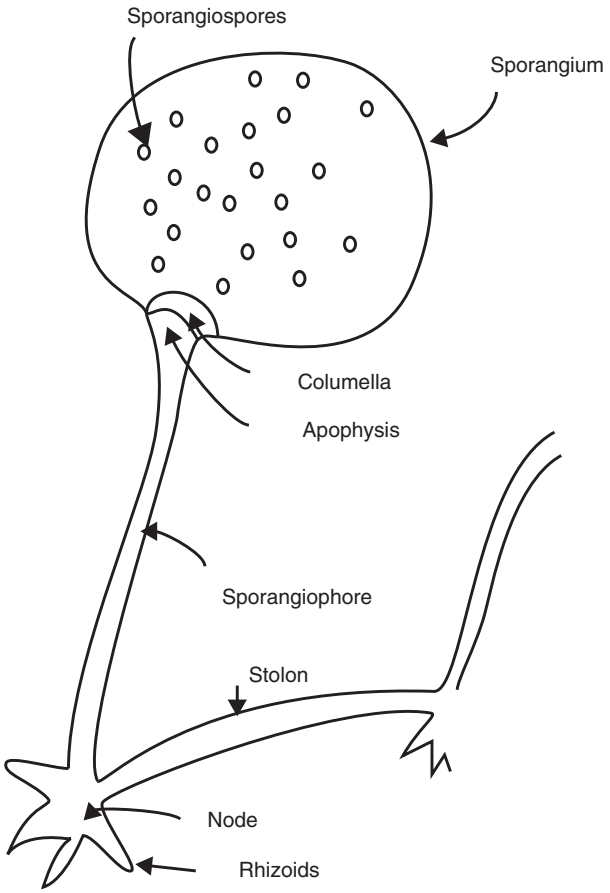

Figure 2 *Rhizopus nigricans*. This mold is very widespread and grows on fruits, preserves, and bread (the classic 'bread mold'). Sporangia are black.

Identification and Enumeration of Yeasts and Molds in Foods

Yeasts and molds are relatively large microbes and can be observed at 400 times magnification under the compound microscope. They can be tentatively identified to the genus level by experienced mycologists according to the type of hyphae, the shape, the size of sexual and asexual spores, and the morphology of various fruiting bodies of the organisms. Some special structures of yeasts and molds are described in the previous section. For further identification of the organisms, a variety of morphological and physiological tests must be made.

For identification of yeasts, some of the following criteria can be used:

1. Cultural characteristics on or in a variety of liquid and agar media such as glucose–yeast extract–peptone water, surface assimilation media, malt agar plus 2% calcium carbonate, morphology agar, etc.
2. Vegetative reproduction characteristics such as formation of asexual endospores, chlamydospores, germ tubes, and ballistospores.
3. Sexual characteristics such as formation of ascospores and observation of the life cycle.
4. Physiological characteristics such as fermentation or assimilation of carbohydrates and other carbon compounds, breakdown of arbutin, assimilation of nitrate and nitrite, acid production from glucose, starch formation, breakdown of fat, etc.

Recently, however, commercial 'rapid systems' have been developed that allow the identification of a large number of yeast isolates using convenient multichamber units containing various essential growth media and reagents. After growth and application of reagents, the data collected can be matched with known databases, manually or electronically, to ascertain the identity of the isolates. The Uni-Yeast-Tel (Flow Lab Inc., McLean, VA), Analytab (API-bioMerieux, Hazelwood, MO), and Minitek (Becton Dickinson, Sparks, MD) systems are some of the useful diagnostic kits for rapid yeast identification. The most ambitious automated system is the Vitek system (bioMerieux, Hazelwood, MO), which utilizes a plastic card with 30 tiny wells containing reagents for growth and biochemical reactions of a pure culture isolate of interest. There are 26 tests for each isolate. After the pure culture is injected into the plastic card, the card is incubated at 30 °C for 24 h and the results and interpretation of the identity of isolates are then produced automatically by the instrument. Vitek can also identify many types of pathogenic and nonpathogenic bacteria of especial importance in medical microbiology.

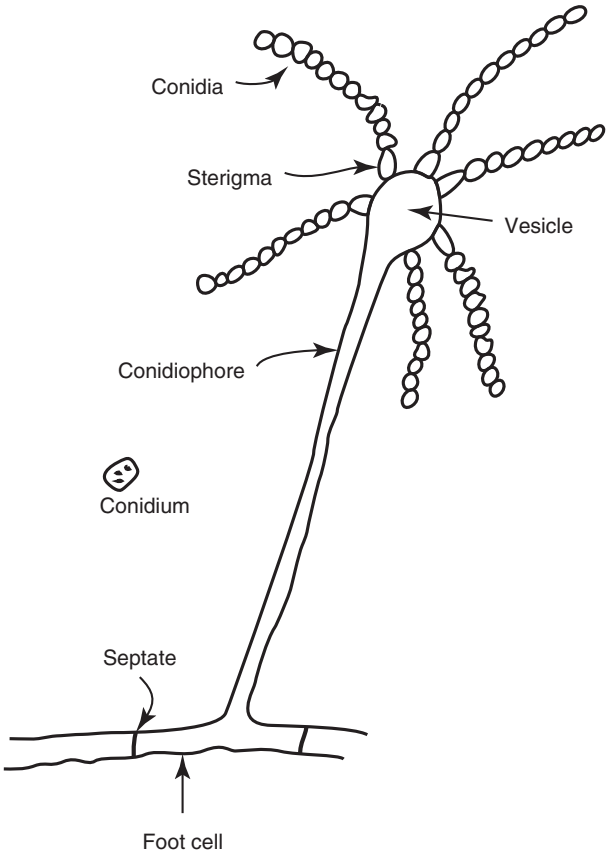

Figure 3 *Aspergillus*. The mold is yellow, green, or black; it grows on many foods. Some species produce aflatoxins.

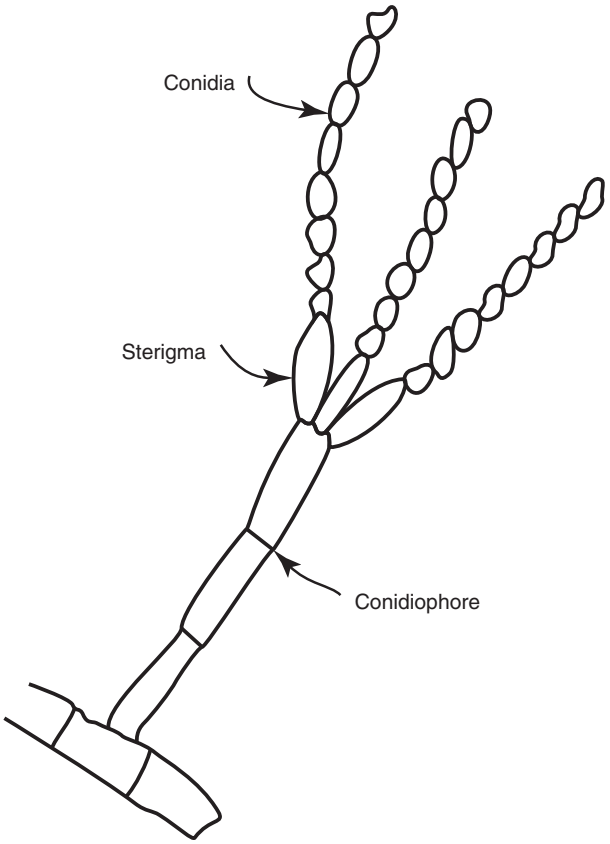

Figure 4 *Penicillium* (=‘a brush’). The mold is blue or blue-green.

For identification of molds, the following criteria can be used:

1. Septate or nonseptate hyphae.
2. Presence or absence of rhizoids (roots).
3. Presence or absence of fruiting bodies and arrangements of asexual and sexual spores.
4. Arrangement of conidia (microconidia and macroconidia).
5. Color and morphology of various molds in specialized agar, etc.

It takes an experienced mycologist to recognize a fungus to the genus by the above tests. To obtain species-level identification, a variety of physiological, immunological, and genetic tests may have to be made. At present there is no ‘rapid method’ for mold identification. The techniques of polymerase chain reaction (PCR) and enzyme-linked immunosorbent assay (ELISA) are being investigated by various research groups for rapid identification of molds.

Enumeration of yeasts and molds in liquid or food can be made by observation under the microscope using a specialized slide with grids, such as the Petroff–Hauser counting chamber (for individual yeast cells) or the Howard mold-counting chamber (for observation of mold filaments). After obtaining the average number of yeast cells in a few grids (usually 10), the number can be multiplied by a microscope factor (usually 6–7 log) to obtain the number of yeast cells per milliliter or per gram of liquid or solid. Similarly, mold filaments can be counted and converted to mold filaments per milliliter or per gram of food.

For enumeration of viable (living) yeast and mold cells, the best way is first to make a 1:10 dilution of the food and homogenize the mixture thoroughly; serially dilute (1:10) the sample in sterile buffer solution and place a known volume of the diluted sample (e.g., 1 ml) into a Petri dish; then pour a warm selective agar such as Yeast and Mold Agar (YM Agar, DIFCO, Detroit, MI) at pH 3.5 into the Petri dish. After incubation at 21 °C for 3 days, typical yeast and mold colonies, if present, can be counted and reported as yeast or mold count per milliliter or per gram. Yeast colonies on the agar are usually white, smooth and round. For molds, a variety of morphologies can occur with different colors, shapes and sizes. Prolonged incubation will give erroneous results as the spores of the first mold colony can be discharged and land on another part of the agar plate, greatly increasing the number of mold counts.

There is no accepted safe standard for yeasts and molds in liquid or solid food. Suggested appropriate ranges for bacterial, yeast, and mold counts for consideration of acceptance or rejection of food items, and in air, are given in Table 1.

Of course, these numbers do not indicate the presence of pathogens. Any pathogen such as *Escherichia coli* O157:H7, *Salmonella*, *Listeria monocytogenes*, etc. will not be acceptable. There is no yeast and mold standard that would render the food totally unacceptable at low numbers.

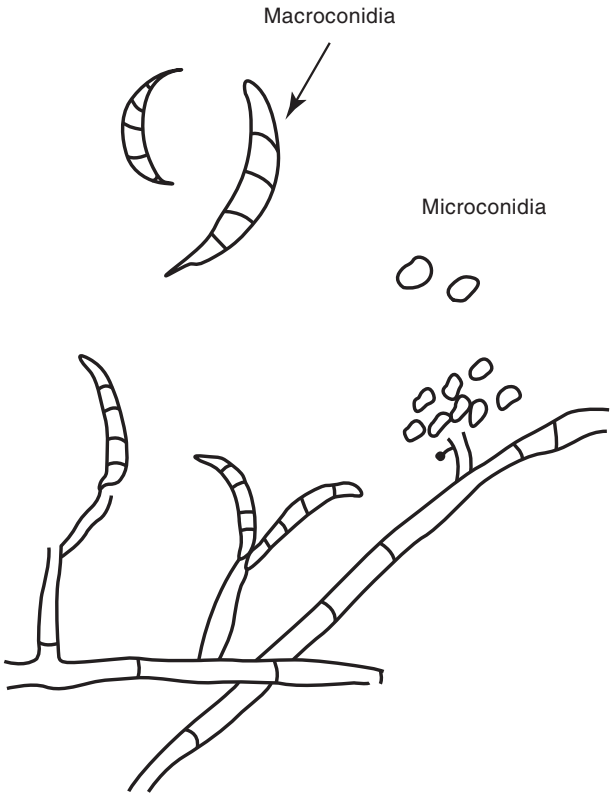

Figure 5 *Fusarium*. Grows on fruits (bananas) and vegetables; causes neck rot; has boat-shaped macroconidia.

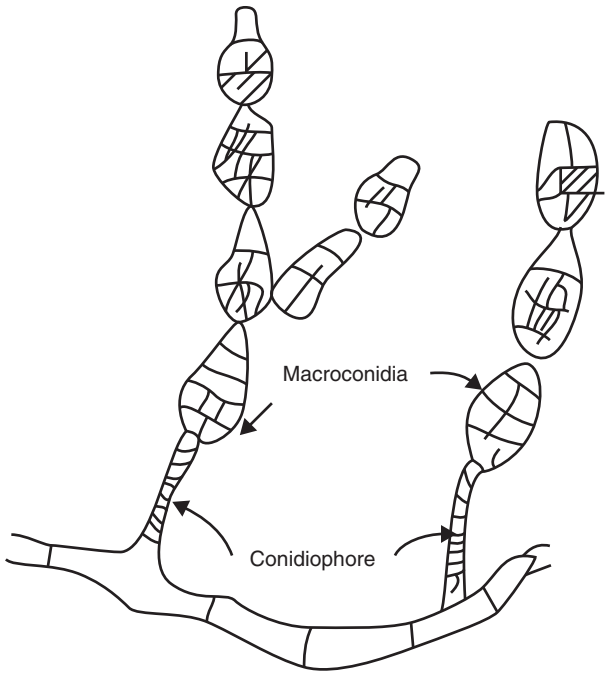

Figure 6 *Alternaria*. The appearance is dark yellow, green, or black. The mold damages plants.

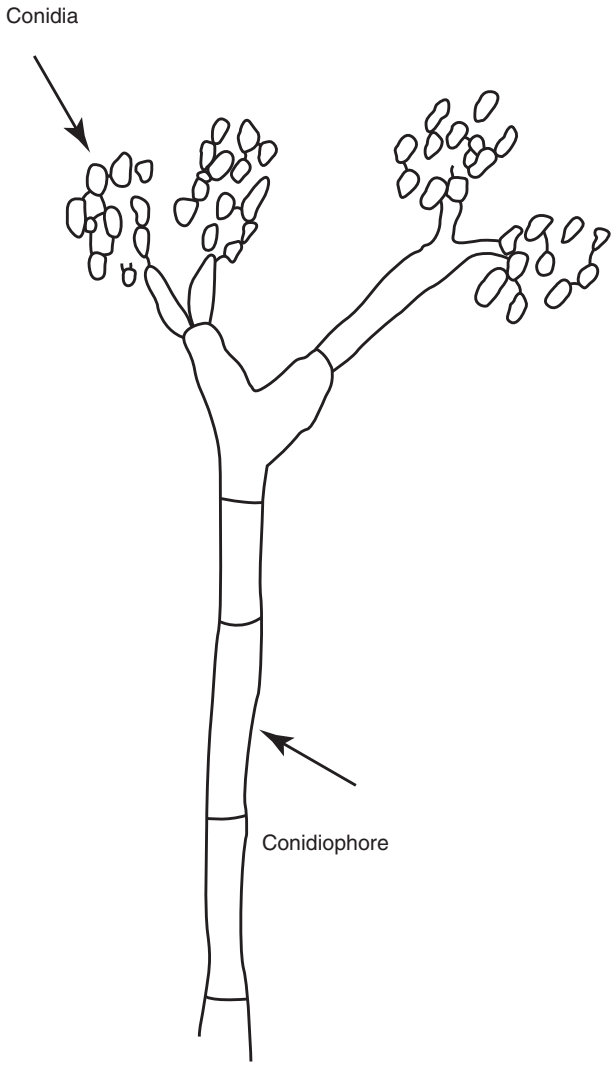

Figure 7 *Botrytis*. The appearance is gray. The mold spoils various foods.

Importance and Occurrence of Yeasts in Meats

According to NJW Kreger-van Rij there are 60 genera and 500 species of yeast. Foodborne yeasts account for approximately 43 genera and 220 species. This is because various foods provide extremely wide ecological environments for yeasts.

JM Jay has indicated that common yeasts found in fresh and refrigerated meats include *Candida*, *Cryptococcus*, *Debaromyces*, *Hansenula*, *Pichia*, *Phodotorula*, *Saccharomyces*, *Torulopsis*, and *Trichosporon*. The following are examples of the presence and activities of yeasts in various meat systems.

HK Dalton and colleagues isolated and identified 383 yeasts in a comparative study of yeast flora in British fresh sausage and minced (ground) beef. The majority yeast genera were *Candida*, *Cryptococcus*, *Debaryomyces*, *Pichia*, *Rhodotorula*, and *Torulopsis*. *Debaryomyces hansenii* was the most commonly isolated yeast from most samples, followed by *Candida zeylanoides*, and *Pichia membranaefaciens*. The sulfide in sausages did not appear to affect the numbers and kinds of yeasts present.

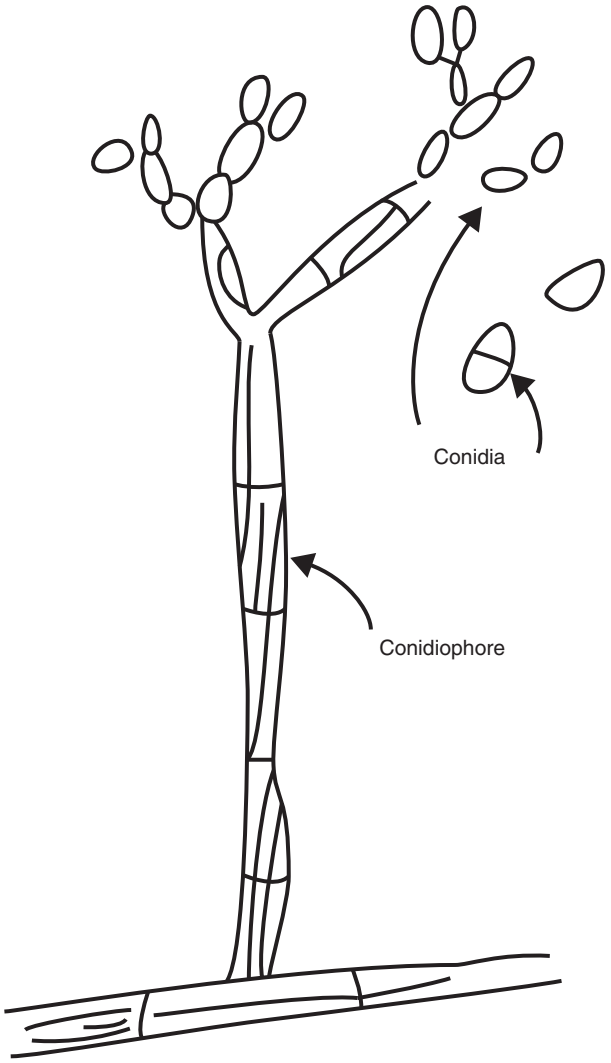

Figure 8 *Cladosporium*. The appearance is of dark conidiophores and green mold. Causes 'black spot' on beef.

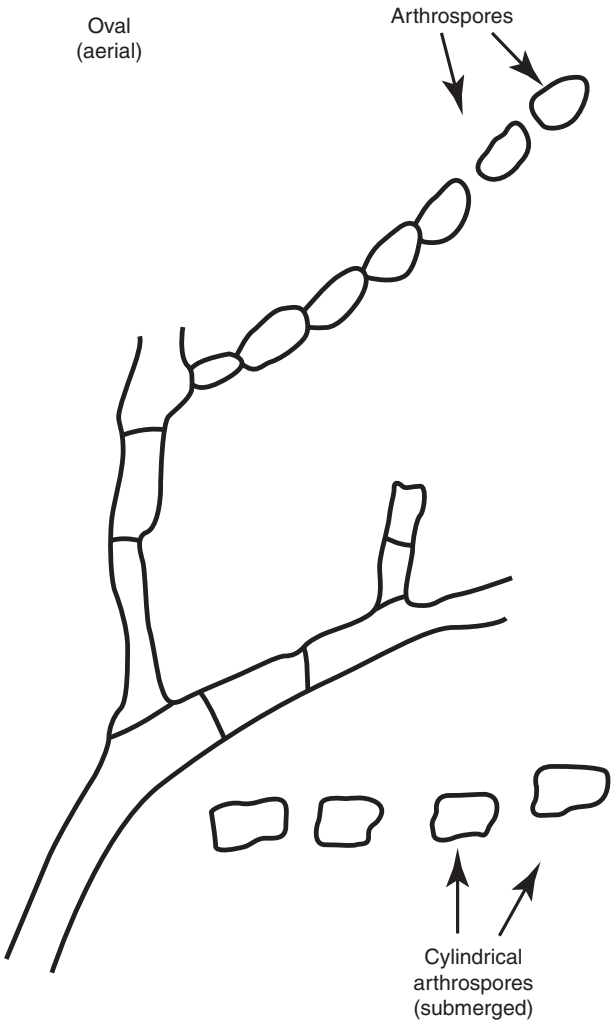

Figure 9 *Geotrichum*. Forms arthrospores. This 'dairy mold' imparts flavor and aroma to cheeses.

E Monte and colleagues studied the fungal profiles of Spanish country-cured hams. From 160 surface samples of 40 hams, yeast counts were between 4 log and 5.4 log CFU per gram (CFU = colony forming unit) and filamentous fungi counts were from 2.7 log to 4.4 log CFU per gram. *Debaryomyces marama* isolated from these samples could grow at 16% NaCl. Various filamentous fungi, such as *Eurotium repens, Pencillium expansum, Pencillium cyclopium, Pencillium viridicatum, Pencillium brevicompactum,* and *Pencillium simpliciissimum* were identified. G Comi and colleagues researched total yeast counts on 150 samples of fresh and refrigerated meat obtained from various locations in Italy. They found that most fresh samples had a yeast count of 0–100 CFU per gram, with 80% in the range of 0–3 log CFU per gram; 60% of the samples stored under refrigeration for 7 days had counts of 5–6 log CFU per gram; and after 14 days 60% had 6–7 log CFU per gram. To study the growth of yeast during refrigerated storage (2 °C; 80% relative humidity), 40 meat samples were classified into five groups, depending on initial count level, and stored for 18 days, with yeast count determined every 3 days. The results for the composition of the yeast flora on fresh and refrigerated meat samples revealed that *Torulopsis* spp. were predominant (35% of total) on fresh meat, followed by *Trichosporon* (25%). After 7 days of refrigerated storage, *Trichosporon* spp. predominated (45%), followed by *Candida* spp. (20%). *Debaryomyces hansenii, Endomycopsis platypodes,* and *Lipomyces starkeyi* were present on fresh samples but absent from refrigerated samples. *Rhodotorula* spp. and *Cryptococcus* spp. increased on refrigerated samples.

DY Hsieh and JM Jay characterized and identified 194 yeasts isolated from 28 samples of fresh and 4 samples of spoiled minced beef. Seventy-nine strains were from five genera, with the genus *Candida* accounting for 82% of the strains and 61% of the identified species. Other genera found were *Rhodotorula, Torulopsis, Trichosporon,* and *Cryptococcus. Candida lipolytica* was the most frequently isolated species in their study, and *Ca. zeylanoides* was more indigenous to minced beef than any of the other 21 species identified.

E Johannsen and colleagues examined the yeast flora present in minced beef before and after irradiation. No reduction

in the number of yeasts was observed after the meat was irradiated at a dose of 2.5 kGy. A definite increase in the number of psychrotrophic yeasts was observed in irradiated meat after 14 days of storage at 4 °C. The recovered yeast flora comprised representatives of the following species: *Candida famata*, *Cryptococcus albidus*, *Cryptococcus infirmominiatus*, *Cryptococcus laurentii*, *Trichosporon cutaneum*, *Trichosporon pullulans*, *Rhodotorula minuta*, and *Rhodotorula rubra*.

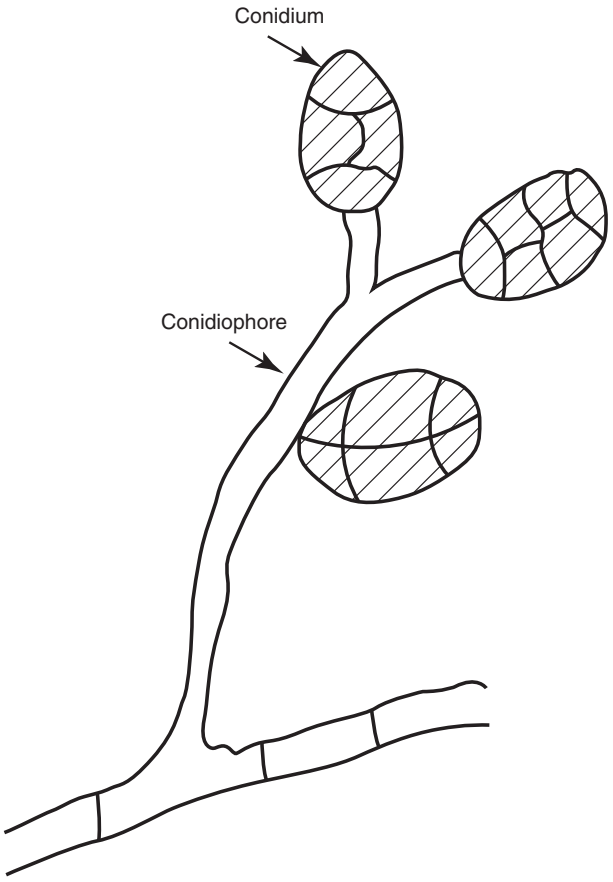

Figure 10 *Stemphylium*. Causes gray leaf spot.

PD Lowry and CO Gill studied the yeast flora on frozen lamb stored at −5 °C. Lamb loins wrapped in gas-permeable plastic film and stored at −5 °C developed a yeast flora with a maximum number of approximately 6 log CFU per cm^2) after 20 weeks. Yeasts were identified as *Cr. laurentii*, *Cr. infirmominiatus*, *T. pullulans*, and *Ca. zeylanoides*. No microbial growth was detected on lamb loins stored at −10 °C for 40 weeks.

CCS Lin and DYC Fung isolated and identified yeasts from various foods. *Ca. lipolytica*, *Ca. zeylanoides*, and *R. rubra* were isolated from beef; *Coleophora azyma*, *Ca. famata*, and *Ca. lipolytica* from ham; *Ca. famata* and *Ca. lipolytica* from hot dogs; *Ca. famata*, *Ca. lipolytica*, and *R. rubra* from turkey ham.

Studies have also been carried out on the effect of yeasts on the sensory properties and quality of meat products. G Comi and colleagues determined the lipolytic enzyme and esterase activity of yeasts from raw ham on various substrates. The highest lipolytic activity was shown by *Torulopsis* spp., *T. cutaneum*, and an unidentified *Trichosporon* species. For most species, the lipolytic activity of the yeasts was generally less than that of the bacterial genera *Lactobacillus* and *Micrococcus*. The results revealed that yeasts did not present a major problem in relation to lipolysis in raw ham. However, in another report by G Comi and colleagues, two endopeptidases from *Torulopsis* spp. isolated from raw ham were observed. The enzyme activity was related to the concentration of NaCl.

RJ Winger and PD Lowry made a sensory evaluation of lamb after growth of yeast at −5 °C. *Cryptococcus laurentii* was inoculated at various densities onto lamb loins, which were then frozen and stored at −5 °C for 10 weeks. During storage, yeast numbers increased by 2 log cycles. No foreign flavors associated with the high yeast numbers could be discriminated by a trained taste panel.

In a study by M Kobatake and H Kurata, proteolytic and lipolytic yeast species were widely distributed among the genera *Candida*, *Cryptococcus*, *Debaryomyces*, *Leucosporidium*, *Rhodotorula*, and *Trichosporon*. All yeasts tests were isolated from chilled household foods and raw seafood.

Table 1 Ranges of fungal/bacterial counts and their significance for acceptance/rejection/remedial action

Count[a]	*Significance/indication/action*
In foods (CFU per g, per ml, or per cm^2)	
$0–10^2$	Low count: no problem
$10^3–10^4$	Intermediate count: no problem but slight concern
$10^5–10^6$	Definite concern: corrective action to be taken
10^7	Index of spoilage
10^8	Odor will develop
10^9	Slime will form
10^{10}	Absolutely unacceptable
In air (CFU per m^3)	
$0–10^2$	Low count: no problem
$10^2–3 \times 10^2$	Intermediate count: no problem but concern
$>3 \times 10^2$	Definite concern: corrective action to be taken

[a]CFU = colony forming unit.

Note: The scales were developed by the author at Kansas State University.

SU Nwahakwu and TVI Akpata studied the utilization of carbohydrate and protein by *Ca. famata* during spoilage of snail meat. The results indicated that *Ca. famata* was a potential spoilage organism for snail meat. The shelf life of snail meat at room temperature could be increased by eliminating *Ca. famata*.

These are, of course, only some examples of the occurrence of yeasts in meat. Suffice to say that yeasts can spoil meat under unfavorable conditions and, since they can grow both aerobically and anaerobically, control of the contamination of meat with yeasts should be considered a priority in food safety and preservation.

Importance and Occurrence of Molds in Meats

There are literally hundreds and thousands of species of mold on record. JM Jay has indicated that common molds found in fresh and refrigerated meats include *Alternaria*, *Aspergillus*, *Cladosporium*, *Fusarium*, *Geotrichum*, *Monascus*, *Monilia*, *Mucor*, *Neurospora*, *Penicillium*, *Rhizopus*, *Sporitrichum*, and *Thamnidium*. The following are examples of the presence and activities of molds in various meat systems.

The ubiquity of molds in the preparation, handling and storage environments of fresh meats is such that their presence in these products should be expected. However, molds are rarely involved in spoilage of fresh meats, except under special circumstances, such as storage at a low temperatures or use of preservatives. It has been established that molds can grow at pH values between 2 and 11, at water activities (a_w) between 0.62 and 0.995, at temperatures between $-1\,^{\circ}C$ and around 60 °C, and over a wide range of nutrient limitations. Some mold chlamydospores, conidia, and vegetative cells are known to retain viability more than 22 years, while spores may retain viability for more than 30 years. However, molds are not as versatile as bacteria in their capacity to grow over wide ranges of oxidation–reduction potentials. Most foodborne mold isolates require aerobic conditions or positive Eh values, unlike many bacteria, which can proliferate under negative Eh conditions. Under natural conditions that permit the growth of a variety of bacteria and molds, bacteria invariably outgrow the molds, and no fungal growth is observed on fresh and processed meats. In fact the mycology of most meats has not received much attention until recently, owing to the capacity of these foods to support rapid bacterial growth. Nevertheless, when meat-preservation processes such as aging, curing, drying, or freezing are employed, molds can compete effectively with bacteria and become the dominant microflora. Researchers have noted the presence of molds on fresh meat since the 1920s. FT Brooks, CG Hansford, and MA Wright studied the condition of beef quarters known as 'black spot,' 'whiskers,' and 'white spot' and showed them to be caused by molds such as *Cladosporium*, *Sporotrichum*, and *Thamnidium*. The growth of these molds on the surface of beef occurs due to a lack of sufficient moisture to permit bacterial growth. Fat decomposition, 'green patches,' off-odor, and stickiness are other spoilage manifestations of moldy meat. For minced beef and pork, mold counts range from 70 to 480 000 CFU per gram. Counts for fresh and frozen fish range from 600 to 270 000 CFU per gram. Determinations for chicken meat range from 100 to 97 000 CFU per gram or CFU per cm^2, while sausage samples were found generally to contain lower numbers.

According to RA Hart, a total of 20 genera of mold have been reported on cured, fresh, processed, or stored meats. The most frequently recorded species belong to the genera *Aspergillus* and *Penicillium*. This may be a reflection of their generally higher incidence in meat environments. It may also be a reflection of the greater ease of their identification, of their ability to grow at low a_w, or of some other property that these two groups to adapt to meats with greater ease than other molds. **Tables 2** and **3** give incidences of fungi in different muscle foods and different muscle foods from which fungi have been isolated as reported by RA Hart.

Mold growth is favored over bacterial growth in country-cured hams and some dry sausage products. Thirteen genera of mold were isolated and identified by JC Ayres in 1967 in a mycological study of cured hams and sausage. The genera *Aspergillus* and *Penicillium* were isolated from both products more frequently than any others; *Cladosporium* and *Alternaria* were isolated from 14 samples of ham. *Aspergillus* spp. generally grow better in the low-a_w country-cured hams, while *Penicillium* predominates in higher-a_w fermented sausages.

Cold or frozen storage often tends to reduce the a_w of meat, thus simultaneously selecting for psychrotrophic and xerotolerant molds. None of these cold-storage molds are known to be pathogenic or mycotoxigenic. A dark discoloration known as 'black spot' is one of the most economically important forms of psychrotrophic mold spoilage. Beef, mutton, pork, veal, lamb, and rabbit are prone to this type of spoilage. Strains that can produce 'black spot' include *Cladosporium cladosporioides*, *Cladosporium berbarum*, *Penicillium hirsutum*, and *Aureobasidium pullulans*. *Cladosporium*, in addition to producing deep-seated black spots, is also proteolytic. 'White spot,' another type of meat spoilage, is caused by *Chryosporium pannorum* and occasionally by *Acremonium*, *Thamnidium*, *Mucor*, and *Rhizopus* cause the cottony gray–black growth found in beef stored in cold rooms, called 'whiskers.'

One of the 'whisker' molds, *Thamnidium elegans*, grows rapidly enough to compete successfully with psychrotrophic bacteria at or near 0 °C. Growth of whisker molds on meat is sometimes considered desirable, as some believe that the flavor and tenderness of beef is enhanced during the growth of these molds.

One of the major problems concerning molds in foods is the production of mycotoxins by several genera of molds. *Aspergillus flavus* and *Aspergillus parasiticus* can produce aflatoxins B_1, B_2, G_1, and G_2, which are carcinogenic to animals. B_1 can be converted to M_1 through dairy cows in milk. Aflatoxins are most likely to be found in stressed crops grown in arid climates such as in the southeastern United States. The toxic effects of aflatoxins on animals can have devastating consequences for human and animal health. Other mycotoxins include trichothecene, zearalenone, ochratoxins, sterigmatocystin, patulin, and *Alternaria* metabolites. Ochratoxin A can be produced by *Aspergillus ochraceus* and several strains of *Penicillium* in grain that is insufficiently dried at harvest and is transferred to pigs and poultry eating moldy grains. In Denmark, all pig carcasses with light or enlarged kidneys are analyzed for ochratoxin A and condemned if the content is above a threshold level.

Beneficial Aspects of Yeasts and Molds in Meat Systems

The benefits from yeasts and molds in fermented food around the world are enormous. *Saccharomyces cerevisiae* is probably the most economically important industrial yeast in the world, being the microorganism responsible for alcoholic fermentation of beer and wine and indirectly contributing to the distilled liquor industry. It is also used in bread making. The mold *Aspergillus oryzae* is as important in Oriental food fermentation as *Ca. cerevisiae* is in Western food fermentation. This mold is responsible for the huge soybean-based fermented food industry in the Orient. Many molds are responsible for fermentation of dairy products and legume products. However, yeasts and molds are not heavily involved in fermented meat products. Yeast has very little beneficial functions in fermented meat products. Molds are known to contribute to the quality of some dry European-type sausages and Italian salami. JC Ayres described nine species of penicillia and seven aspergilli on fermented sausages and attributed beneficial effects to these molds in the preservation of the sausages. JC Ayres also considered mold growth beneficial in dry-cured ham products in the southern United States. More recently, it was found that up to 96% of the mold in fermented sausages in northern Italy were penicillia and 4% are aspergilli. The initial flora of the sausage was made up of 95% yeasts, but after 2 weeks of fermentation the proportions of yeast and mold were equal. After 4–8 weeks, molds constituted more than 95% of the fungal flora. In other studies, *Penicillium camemberti* and *Penicillium nalgiovense* have been added to raw dry sausages to prevent the growth of mycotoxigenic molds.

Spoilage and Food Safety Issues of Yeasts and Molds

Yeasts and molds are very important in spoilage of all types of meat by the production of various enzymes that degrade protein and lipid structures and by the production of undesirable colors and unsightly visible mold colonies on meat surfaces and on the casings of sausages. Although these growths may not be harmful to health, the very presence of yeast and mold growth is reason for discarding these products, causing economic losses. Yeasts and molds can contaminate meat and meat products through human and animal contact, contact with equipment, water, or ingredients and even as a result of air contamination.

The real threat from molds in meat safety is the production of mycotoxins by some molds. The most important mycotoxins are the aflatoxins (B_1, B_2, G_1, and G_2) produced by *A. flavus* and *A. parasiticus* and the ochratoxins produced by *A. ochraceus* and several strains of *Penicillium*. These mycotoxins are usually produced in grains and plant products and seldom in meat products. Research performed in the author's laboratory has indicated that inoculated *A. flavus* and *A. parasiticus* cultures can produce detectable amounts of aflatoxins in experimental salami. However, due to the presence of antioxidants, such as combinations of butylated hydroxyanisole, butylated hydroxytoluene, tertiary butyl hydroxyquinone, and propyl gallate the amount of aflatoxin production is greatly suppressed.

Conclusions

Yeasts and molds are important microorganisms in meat and meat products, mainly as spoilage organisms and seldom as food-poisoning agents. In certain conditions they can be beneficial in meat fermentation. It is important to monitor the presence of yeasts and molds regularly in the food processing

Table 3 Fungi isolated from different muscle foods

Fungal species/strain	*Food source*
Alternaria spp.	Bacon, beef, country-cured hams, untreated poultry
Aspergillus clavatus	Meats
Aspergillus flavus	Country-cured hams, Italian-type salami, Spanish dry-cured hams
Aspergillus fumigatus	Meats, Spanish dry-cured hams
Aspergillus glaucus	Country-cured hams, meats, katsuobushi (fermented fish)
Aspergillus gracilis	Country-cured hams
Aspergillus niger	Chilled beef carcass, country-cured hams, fermented sausage, meats, moldy hams, salami
Aspergillus ochraceus	Moldy hams, salami
Aspergillus repens	Country-cured hams, moldy hams, salami
Aspergillus ruber	Country-cured hams, fermented sausages
Aspergillus tamarii	Moldy hams, salami
Aspergillus versicolor	Country-cured hams
Aspergillus wentii	Fermented sausage, moldy hams, salami
Aspergillus spp.	Bacon, country-cured hams, dry European sausage, fish protein concentrate, moldy hams, poultry meat, refrigerated beef, salami, smoked fish
Aureobasidium pullulans	'Black spot' of beef
Botrytis spp.	Bacon
Chrysosporium pannorum	Frozen lamb
Cladosporium herbarum	'Black spot' of beef
Cladosporium cladosporioides	'Black spot' of beef, frozen lamb
Cladosporium spp.	Chlortetracycline-treated poultry, country-cured hams, refrigerated beef
Fusarium spp.	Bacon, meats
Geotrichum candidum	Poultry

Yersinia enterocolitica

J Mills, AgResearch Ltd., Hamilton, New Zealand

Glossary

Apoptosis The biochemical events leading to cell changes and programmed cell death in a multicellular organism.
Cytotoxicity The ability to cause damage to cells.
Epidemiology The study of the prevalence of disease in populations.
Fermentation An anaerobic oxidation–reduction reaction where an organic substrate acts as the final electron acceptor instead of oxygen.
Heterogeneous Consisting of more than one form.
Pathogen An organism capable of inflicting damage.
Phenotype The observable characteristics of an organism as determined by genetic and environmental influences.
Psychrotroph An organism capable of growth at low temperatures but having an optimum growth temperature of $>15\,^{\circ}C$.
Virulence The potential ability of an organism to cause disease; determines pathogenicity.

Introduction

Yersinia enterocolitica is a particularly versatile foodborne pathogen, adept at survival in many habitats, both within and external to host animals. Pathogenic *Y. enterocolitica* organisms are significant causes of human disease in many parts of the developed world. Infections are most usually associated with pig meats, but all types of meats have been shown to harbor the bacterium.

The genus *Yersinia* belongs to the family Enterobacteriaceae and 11 species are currently recognized. A further six species have been proposed for inclusion into the genus. Three species are considered pathogenic to humans: *Y. enterocolitica*, which is primarily associated with food- and waterborne illness; *Yersinia pseudotuberculosis*, which is associated with enteropathogenic zoonotic infections; and *Yersinia pestis*, the cause of bubonic plague. A further seven of the remaining species (previously characterized as '*Yersinia enterocolitica*-like organisms'), although not considered pathogenic, share habitats with these organisms and so must be differentiated from them by testing laboratories.

Yersinia enterocolitica is differentiated by negative citrate and mucate tests, the ability to ferment sucrose, and an inability to ferment rhamnose, raffinose, and melibiose at 25 °C. *Yersinia enterocolitica* is motile and indole-positive below 30 °C, but not at 35 °C. The Voges–Proskauer reaction is positive at 22–28 °C, but negative at 37 °C for the majority of strains, which can be a problem when proprietary biochemical test kits are used for identification.

Even with the classification of separate species within the *Y. enterocolitica*-like group, *Y. enterocolitica sensu stricto* remains highly heterogeneous, and has been divided into subgroups on the basis of biochemical activity (biotypes, five currently recognized) and lipopolysaccharide O antigens (serotypes, at least 75 currently recognized). A connection between particular biotypes and serotypes is well documented, as is the correlation between these characteristics and the potential to cause human infection. Thus, biotype and serotype determination (expressed as bioserotype) provides one means of determining whether a strain is potentially pathogenic or of environmental origin. An association between serotypes and geographical niches has also been established, although with

Characteristics of the Organism

Yersiniae are Gram-negative, nonspore-forming, straight rods or coccobacilli, 0.5–0.8 μm in diameter and 1–3.5 μm in length (Figure 1). Variations in size or shape (i.e., pleomorphism) may occur, depending on culture medium and temperature. These bacteria are facultatively anaerobic organisms, catalase-positive, oxidase-negative, and ferment glucose with little or no gas, while lactose is not fermented. Phenotypic criteria are frequently influenced by temperature, optimum activity generally being between 25 and 29 °C, which create difficulty for identification by traditional biochemical tests.

Yersinia enterocolitica sensu stricto is one of the eight species currently designated within the '*Yersinia enterocolitica* group' of this genus. The biochemical differentiation between these species is shown in Table 1. The group is highly heterogeneous and some strains of different species overlap in their biochemical reactions, antigen expression, and ecological niches.

time, this has become less valid, possibly owing to international trade in food products:

- Biotype 1A strains were previously considered to be not virulent; however, recent studies suggest that some are capable of causing human disease.
- Biotype 1B is considered to be highly pathogenic, and includes several pathogenic serotypes predominantly isolated from North America, of which O:8 is the most common.
- Biotypes 2 and 3 are classified as moderately pathogenic and contain pathogenic serotypes O:5,27 and O:9, the latter being most often isolated in northern Europe.
- Biotype 4 is classified as moderately pathogenic and is associated with serotype O:3; it has worldwide distribution.
- Biotype 5 strains appear largely restricted to animals, notably rodents and ruminants, although some human infections have been reported in Europe.

Biochemical differentiation of the biotypes of *Y. enterocolitica*, is outlined in **Table 2**.

Two subspecies have been identified from deoxyribonucleic acid (DNA)–DNA hybridization and examination of 16 S gene sequences. *Yersinia enterocolitica* subsp. *enterocolitica*, consisting of the highly pathogenic bioserotype 1B strains, and *Y. enterocolitica* subsp. *palearctica*, consisting of the

remaining biotypes 1A, 2, 3, 4, and 5, which are of varying pathogenicity.

For subtyping serotypes of *Y. enterocolitica* for epidemiological purposes, pulsed-field gel electrophoresis (PFGE), ribotyping (DNA restriction fragment polymorphism of ribosomal ribonucleic acid (rRNA)), and random amplification of polymorphic DNA (RAPD)-based fingerprinting have been used with some success. Schemes for phage typing have been developed but are restricted to a small number of reference laboratories.

Clinical Presentation

Infections with *Y. enterocolitica* present the clinician with a wide range of symptoms and outcomes. Yersiniosis, the disease caused by *Y. enterocolitica*, primarily affects the lymphatic system, particularly the glands associated with the gastrointestinal tract. The most common initial symptom of infection is a self-limiting diarrhea, but more serious symptoms are not uncommon, particularly in Scandinavia. The incubation period is usually between 24 h and 36 h, although postingestion intervals of up to 11 days have been reported.

In most cases, symptoms occur in children less than 5 years of age, typically diarrhea, usually accompanied by fever and abdominal pain (i.e., enteritis), which normally lasts for a few days, but sometimes up to 3 weeks. In rare cases, acute enteritis symptoms may be followed by more serious illness. In older children and adolescents, acute disease symptoms are similar to those of appendicitis.

Septicemia is a rare complication, usually associated with high-virulence type 1B strains, most often affecting immunocompromised people. If *Y. enterocolitica* become disseminated into the bloodstream, the consequences are serious and can include abscesses of the spleen, liver, or lungs.

Although most cases of disease are self-limiting and without long-term complications, 2–3% of infections with *Y. enterocolitica* are associated with a variety of conditions that follow the acute phase. Reactive arthritis is the most commonly encountered, typically following the onset of acute disease by 7–14 days. The joints most commonly affected are fingers, wrist, elbow, knee, ankle, and toes. The arthritis migrates, affecting one joint after another, in around 85% of affected patients.

The majority of gastrointestinal infections attributed to *Y. enterocolitica* are self-limiting so that antimicrobials are not usually prescribed. However, treatment is necessary in cases of severe enteritis, particularly in immunocompromised people and for patients with septicemia or other invasive infections. Antibiotic susceptibility varies among subgroups, but the organism is usually susceptible to aminoglycosides, cotrimoxazole, tetracycline, third-generation cephalosporins, and fluoroquinolones.

Mechanism of Pathogenicity

Only a proportion of *Y. enterocolitica* strains are capable of causing human disease. These pathogenic strains are ingested with contaminated food or water. They are able to pass through the stomach (which has low pH, <3) undamaged because they produce the enzyme urease, which releases ammonia, neutralizing the pH in the immediate vicinity of the bacterial cell. On reaching the small intestine, bacterial cells first bind to epithelial cells, then penetrate the intestinal mucosa via M (microfold) cells, colonizing the Peyer's patches, where they multiply. From the Peyer's patches, they infect the lymphatic system, frequently involving adjacent regions of the intestine and mesenteric lymph nodes and, in rare cases, the liver, spleen, and bloodstream. A capacity to resist nonspecific host defense mechanisms is shared with other members of the genus including *Y. pestis* and *Y. pseudotuberculosis*.

Pathogenic strains can be divided into a group of lower pathogenicity that is nonlethal to mice and comprises organisms from biotypes 2 to 4, and a highly pathogenic group of biogroup 1B strains that are lethal to mice. Strains of the low-pathogenicity group possess multiple virulence factors, some chromosomally mediated and some derived from a 70–75 kbp plasmid, pYV. Both plasmid- and chromosome-associated virulence factors are required for full expression of virulence. Strains of the high-pathogenicity group possess a further chromosomal locus, designated the high-pathogenicity island (HPI), which is shared by certain other species of Enterobacteriaceae. Nonpathogenic strains lack the pYV plasmid and chromosomally mediated virulence proteins.

The following are the major virulence mechanisms currently identified in *Y. enterocolitica*:

- Cell adhesion. Adhesion to host cells is the function of two proteins: YadA, encoded by the virulence pYV plasmid, which mediates bacterial autoagglutination and attachment to host cells; and the chromosomally encoded MyfA, which synthesizes a fibrillar structure.
- Cell invasion. Cell invasion is induced by the bacterial outer membrane protein, invasin, encoded by the chromosomal *inv* gene. A second bacterial chromosomal gene, *ail*, encodes an outer membrane protein, unrelated to invasin, which appears to have a secondary role, possibly contributing to persistence within the Peyer's patches.
- Toxin production. The bacterial chromosome encodes a heat-stable enterotoxin *Yst*, that causes diarrhea. The plasmid encodes a number of factors, collectively known as *Yops*., which are postulated to form a pore to enable passage through the eukaryotic cell membrane. The lipopolysaccharide cell wall has also been shown to influence virulence, possibly by increasing cell hydrophilicity, or in association with *ail* and *YadA*.
- HPI. Free iron is essential for bacterial growth; however, in the human host, it is actively bound by transferrin and lactoferrin, or incorporated into heme groups, and is thus present in only very low amounts. The chromosomal HPI associated with biotype 1B strains encodes synthesis, regulation, and transport of a high-affinity iron chelator (known as a siderophore), yersiniabactin, which enhances iron uptake by the cell. Other strains are, however, capable of making use of siderophores from other sources, hence the association between deferroxamine treatment and systemic infections. Biotype 1B strains possess a further pathogenicity island (Ysa-PI) that is associated with colonization of gastrointestinal tissues during the initial phases of infection.

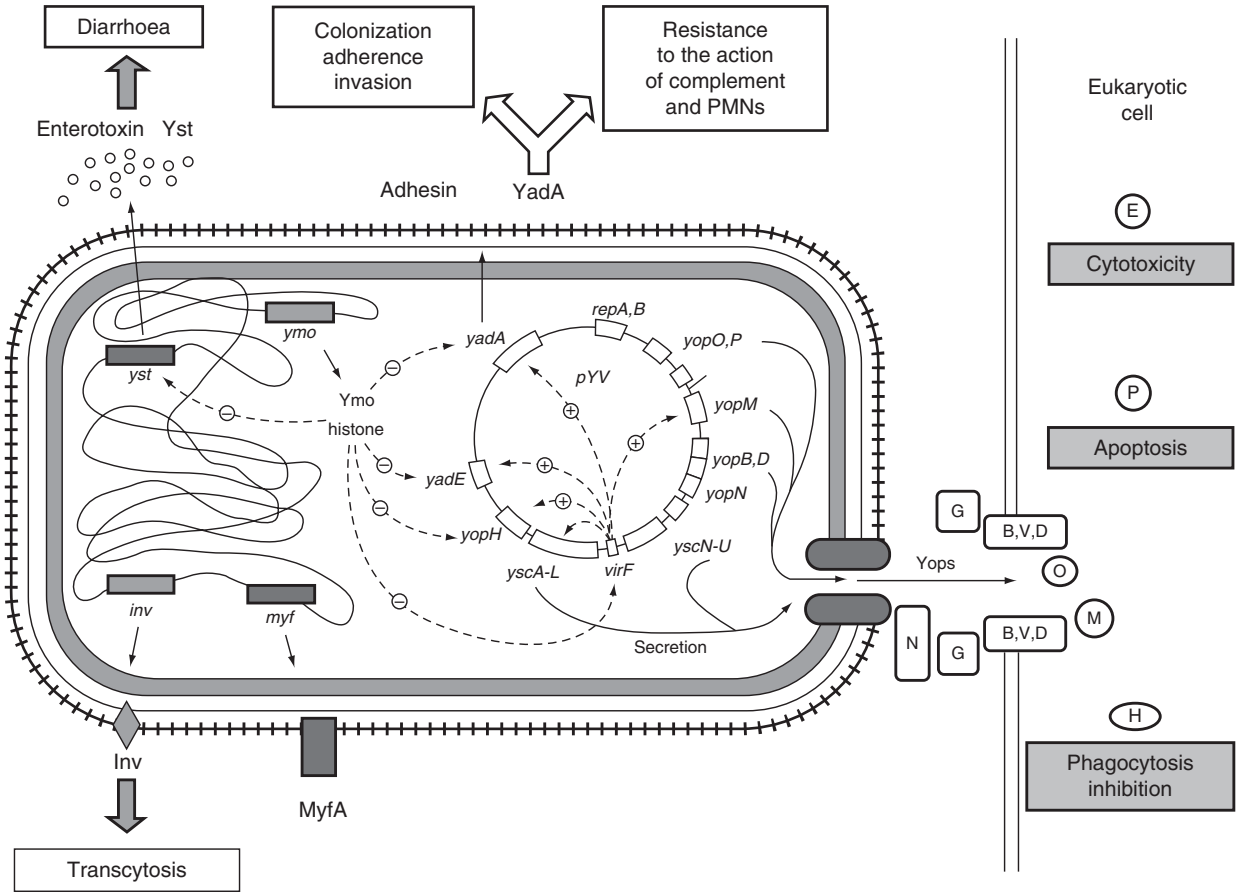

Figure 2 Simplified overview of the virulence factors of *Yersinia enterocolitica*. (PMN, polymorphonuclear cells). Reproduced from Sory, M., Cornelis, G., 2000. Virulence determinants of the bacterial pathogen *Yersinia enterocolitica*: mode of action and global regulation. In: Cary, J., Linz, J., Bhatnager, D. (Eds.), Microbial Foodborne Diseases – Mechanisms of Pathogenesis and Toxin Synthesis. Lancaster, PA: Technomic, pp. 131–155, with permission from CRC Press.

Environmental factors (temperature, pH, ionic strength) regulate optimal expression of these factors. To give examples, *Yersinia* outer-membrane proteins (*Yops*) and the adhesin YadA, are induced at 37 °C, whereas urease production is induced at 25 °C. A number of regulatory genes, such as plasmid *VirF* and chromosomal *ymo*, are involved in mediating this expression.

The interaction between these factors and the consequences for infection are graphically portrayed in Figure 2.

Isolation and Identification

Established methods for detection of *Y. enterocolitica* continue to rely on traditional enrichment and selective plating protocols. Owing to the heterogeneous nature of *Y. enterocolitica*, no individual enrichment scheme will be effective for isolating all serotypes or biotypes. Consequently, multiple enrichment and plating approaches are utilized. Nevertheless, conventional culture procedures are likely to significantly underestimate the presence of *Y. enterocolitica*. Factors that may influence this include background microbiota present on the meat/product being tested and the proliferation of this microbiota during sample enrichment, resulting in suppression of *Yersinia* spp. present in the sample. Certain culture conditions may also result in an inability to determine the pathogenicity of an isolate due to loss of the plasmids coding for virulence factors. Quantitative analysis is normally not performed from meat or meat environments, although modification of existing methods using multiple-tube techniques is feasible.

A number of molecular-based methods have been published in the scientific literature for the detection of *Y. enterocolitica* in foods. To date, however, only one has been formally gazetted as a reference method. Nordisk Metodikkomité for Næringsmidler method 163 has two options: one for detecting potentially pathogenic strains based on the *ail* gene (method A), and the other for detecting fully virulent bacteria based on *yadA* (method B). Method A is validated for detection of serotypes O:3, O:9, O:8, and O5,27. Method B is considered suitable for detecting all pathogenic variants.

Isolation and identification of an organism from meat as *Y. enterocolitica* is incomplete without determination of virulence expression. Although the plasmid essential for full virulence expression is stable at 25–28 °C, the physiological traits are only expressed at 37 °C, at which temperature the

plasmid becomes unstable *in vitro*. In consequence, detection is hampered by protocols employing 35 °C or 37 °C incubation temperatures for isolation, as is normal in clinical laboratories.

Sample Preparation

Initial suspensions of 1:5 weight to volume for meat samples, or a method to achieve a 1:2 ratio of surface area to volume for swabbed surfaces, are made in an appropriate diluent such as 0.01 mol l^{-1} phosphate-buffered saline (pH 7.6).

Enrichment

Various approaches have been adopted for enrichment of *Y. enterocolitica*. Advantage is taken of the psychrotrophic nature of yersiniae to outgrow mesophilic organisms at low temperatures. The concern with all cold enrichment protocols is the compromise, which must be made, between achieving maximum recovery and having a timely result available for appropriate action to be taken when a product is found to be contaminated. Other methods have, therefore, been developed incorporating antimicrobials (e.g., irgasan, ticarcillin) into more nutritious culture media. Finally, some protocols utilize the resistance of the organism to high pH.

Typical cold enrichment methods utilize nonselective media including phosphate-buffered saline (PBS), PBS plus 1% sorbitol, or tryptic soy broth. Incubation time depends on temperature; at 4 °C, incubation for 14–21 days is normally recommended, but this can be shortened to 3 days by increasing the temperature to 10 °C. Cold enrichment has also been applied with peptone sorbitol bile broth (American Public Health Association (APHA)/Food and Drug Administration (FDA)).

Selective antimicrobial enrichment broths include bile oxalate sorbose broth (BOS), irgasan ticarcillin cholate broth (ITC), and modified Rappaport medium (MRM). BOS is best-suited for recovery of serotype O:8, whereas the latter two media are more suited to isolation of serotype O:3 and O:9 strains. The enrichment broths are inoculated either direct from sample homogenates or from cold-enriched cultures at ratios of 1 volume inoculum to 100 volumes broth, with incubation typically being at 22–25 °C for 3 days (with BOS being further incubated for another 2 days and then subcultured again).

Treatment of cold enrichment cultures with alkali (1–9 parts 0.25% KOH in 0.5% aqueous NaCl, for 3–4 s) has been shown to significantly reduce background microbiota before plating. This procedure has also been applied to BOS cultures, but is not appropriate for ITC/MRM.

Isolation

Although yersiniae can be isolated on general enteric plating media (e.g., MacConkey agar), specific media have been developed for isolation of *Y. enterocolitica*. These include cefsulodin irgasan novobiocin agar (CIN) and Salmonella–Shigella agar modified by addition of desoxycholate and calcium (SSDC) agar. CIN and SSDC plates are routinely incubated at 30–32 °C for 24 h. On CIN agar, characteristic *Y. enterocolitica* colonies are small (≤1 mm), smooth, with red center, and translucent rim. On SSDC, they are also small (≤1 mm), but gray colored, with an indistinct rim.

Identification

A convenient initial screen involves the inoculation of Kliger iron agar (KIA) and urea agar slants, and incubating them at 25–28 °C for 24–48 h. Isolates that produce an alkaline slope and acid butt with little or no gas production in KIA, and are urease positive require further investigation.

Definitive identification of *Y. enterocolitica* to the biotype level requires a test for motility and battery of biochemical tests (see Tables 1 and 2 for reactions). These should all be performed at 25–30 °C. Commercially available identification systems may be utilized, but these should also be incubated at 25–30 °C; and the results should be evaluated critically, as the majority of the test systems available do not include all of the species in their databases, nor do they contain the tests necessary to discriminate between all of the species within the '*Y. enterocolitica*-like' group.

Serotyping is not called for in routine testing protocols; however, if it is required for epidemiological purposes, antisera are commercially available (Denka Senken antisera are available through Oxoid, Basingstoke, UK. Antisera can now also be sourced from SSI, Copenhagen, Denmark).

Tests of Pathogenicity

The most commonly used test for pathogenicity is that of Congo red/crystal violet binding, and calcium dependency, which is performed on Congo red magnesium oxalate agar (CR-MOX). A suspension that will give discrete colonies is spread-inoculated onto CR-MOX and incubated at 37 °C for 24 h. Pathogenic organisms produce tiny red colonies, indicative of Congo red binding and calcium dependency. Crystal violet binding is indicated by flooding this plate with 85 μg ml^{-1} aqueous crystal violet and decanting off the dye after 2 min. Pathogenic isolates display small, intensely purple colonies.

Other phenotypic indicators of pathogenicity include autoagglutination at 37 °C and negative esculin, pyrazinamidase, and salicin reactions. Polymerase chain reaction techniques have been devised for detection of virulence genes, but these are currently utilized only by reference and research groups.

Epidemiology

The *Y. enterocolitica* group is found worldwide and is distributed widely in the environment, owing in no small part to the organisms' ability to remain metabolically active at extremes of temperature, nutrients, and pH.

Yersinia enterocolitica has been isolated from lakes, streams, well water, soil and vegetables, animal sources including humans, pigs, dogs, cats, ruminants – particularly deer and goats, rodents, and monkeys, and invertebrates such as crabs, snails, and molluscs.

By far the most commonly identified source of pathogenic strains has been pigs. There is a particular association with pig tonsils, though studies have found offal meats, notably tongue, heart, liver, and kidney, together with minced pork, to carry significant levels of *Y. enterocolitica* contamination. *Yersinia enterocolitica* O:3 isolates from healthy pigs and human infections were found to be indistinguishable in Australian studies using a number of molecular fingerprinting techniques. It has been postulated that cross-contamination from pork occurs directly or indirectly by contact with equipment and foodhandlers or through the air in meat processing facilities, retail shops, and kitchens. As a psychrotolerant organism, *Y. enterocolitica* can multiply at all stages along the cold chain from meat producer to home refrigerator.

Household pets are possible intermediate hosts, particularly for transmission to small children. Direct human-to-human transmission may also occur via the fecal–oral route and via asymptomatic carriers.

Meat products associated with *Y. enterocolitica* contamination include pork, game meats, beef, lamb, and poultry. An association has also been found with washing of food in untreated water. Outbreaks of *Y. enterocolitica* infection have been associated with well water, streams, milk, pork, cheese, chocolate milk, chitterlings (pork intestines), and raw vegetables. It should be noted, however, that many of the studies outside of swine have failed to establish the pathogenicity of isolates.

Control Measures

The temperature range for growth of *Y. enterocolitica* is very wide; in optimal conditions growth has been recorded between −1.3 °C and 42 °C. The organism will also grow at pH values between 4.2 and 9.6 and at salt concentrations up to 5% NaCl. There is thus a high potential for growth on chilled, vacuum-packed meats and meat products. However, several studies have shown that pathogenic strains will multiply poorly in the presence of competing organisms such as *Hafnia alvei* and avirulent *Yersinia* spp. Yersiniae survive freezing and remain viable for long periods in frozen food and after thawing. The organism is also relatively resistant to chlorine, particularly in aquatic environments containing predatory protozoa.

Potassium sorbate (in mildly acidic conditions) is an effective inhibitor of *Y. enterocolitica* in preserved foods. Also some inhibition at 5 °C has been observed with use of 150 ppm sodium nitrite.

Yersinia enterocolitica is susceptible to heat, being destroyed by pasteurization at 71.8 °C for 18 s or 1–3 min at 60 °C.

Because pigs are implicated as a major source of infections (particularly with bioserotype 4, O:3, which is the type most commonly isolated worldwide from human infection), interest has centered on means of reducing this contamination. *Yersinia enterocolitica* is unlikely to be detected by traditional post-mortem inspection. Indeed, traditional inspection processes, such as submaxillary lymph node excision to detect tuberculosis, may result in transfer of *Y. enterocolitica* to other tissues. Control measures remain the subject of debate, but removal of the head, or at least the tongue and pharynx, as early as possible in the dressing process and certainly before evisceration, has been recommended, with these tissues being removed to a separate location for inspection away from the carcass. Stringent application of other good manufacturing practices, such as bung sealing and careful cleaning of the environment during slaughter and dressing, will further minimize the risk.

In retail environments, and kitchens, it is important to separate raw pork from ready-to-eat foods. Normal techniques for food and personal hygiene will also reduce the risk of infection. The eating of raw pork, which is customary in some countries, is to be discouraged.

MICROORGANISMS AND RESISTANCE TO ANTIBIOTICS, THE UBIQUITY OF

Contents

Antibiotic Resistance by Microorganisms

PJ Fedorka-Cray, Russell Research Center, Athens, GA, USA

Glossary

Acquired resistance Resistance that is obtained as a result of exposure to the antibiotic being administered. It typically happens through spontaneous mutation, transformation (uptake of naked DNA), transduction (DNA transferred via bacteriophages), or conjugation (cell-to-cell contact).

Commensal bacteria Bacteria that are part of the normal flora that exist within the host without causing disease or gaining any real benefit from the host.

Intrinsic resistance Resistance that is inherently part of the bacterium through structural or functional properties of the bacterium itself. The bacterium has never been susceptible to an antibiotic to which it is intrinsically resistant.

Nontarget bacteria Bacteria in the host that are exposed to the antibiotic used in treatment of the target pathogen. These bacteria may develop resistance to the antibiotic as a consequence of residing in the host when the antibiotic was administered to treat a target pathogen.

Target pathogen The bacterium or disease complex for which the antibiotic was developed and marketed for treatment.

Zoonotic bacteria Bacteria that can be transferred between animals and man and vice versa.

Introduction

Antibiotics in Human and Veterinary Medicine

Antibiotic use in food-animal production can illicit great debate among scientists regarding the merit and contribution to increased public health costs and disease. Regardless of the discussion, the fact is that antibiotics are used, and are necessary, in both human and veterinary medicine, including food-animal production. Guidelines have been established in both the medical and veterinary professions, which underscore the need to educate patients and producers on the proper use of antibiotics. Consumers are also more aware and involved in the antibiotic dialog. They have increased their demand for meats produced without the use of antibiotics, which is noticeable in the increased share of space given to antibiotic-free meat in the marketplace.

Antibiotics were first developed for use in human medicine; related applications or compounds were developed later for use in veterinary medicine. As an example, tetracycline was first used in human medicine. Currently, oxytetracycline and chlortetracycline are most often used in veterinary medicine while doxycycline and minocycline are most often used in human medicine. Ceftriaxone, a third generation cephalosporin, was developed for use in human medicine; later, ceftiofur, also a third generation cephalosporin, was developed for use in veterinary medicine.

The vast majority of antibiotic compounds used today originated from the soil or fungi. As resistance developed to the original antibiotic, the 'next generation' antibiotic was often developed by manipulating the chemical structure of the initial compound. Subsequent generations were developed the same way. However, as resistance developed to the newest generation of antibiotics within a given class of antibiotics, resistance was usually also conferred to all lower generations of antibiotics within the same class. This can make an entire class of antibiotics ineffective against certain bacterial populations or bacterial strains.

Antibiotics and Use

Antibiotics can be developed for either narrow- or broad-spectrum activity against a particular microorganism or a wide range of microorganisms. Regardless of their activity, antibiotics are labeled and marketed for a specific use. This can be

 doi:10.1016/B978-0-12-384731-7.00205-1

for a specific disease related to a single bacterium, multiple bacteria, a disease complex (i.e., bovine respiratory disease (BRD) in veterinary medicine), or some other use. Treatment of BRD can include the recommendation to use third generation cephalosporins, fluoroquinolones, florfenicol (a relative of chloramphenicol) or tilmicosin, a macrolide antibiotic. These are intended to treat bacterial pneumonias caused by *Pasteurella* species or *Haemophilus somnus*.

Fortunately, these bacteria do not cause disease in humans and are not transferred in meat. However, use of any antibiotic will confer resistance to nontarget bacteria as well as target bacteria throughout the host. This happens in human medicine as well; for example, when children are given an antibiotic for ear infections or adults are treated for sinus or respiratory infections. As treatment continues, and in concert with the host immune system, target bacteria are killed and eliminated from the host; the illness suppresses and the animal or human is cured and feels better. However, it is possible that as treatment continues resistance develops in the target bacteria and an unintended consequence develops as a resistant nontarget population of bacteria also develops. This nontarget resistant bacterial population can persist within the host and/or be shed into the environment. Also, the resistant genes in these bacteria can also be transferred to other nonresistant bacteria conferring resistance. One population of nontarget bacteria are commensal bacteria that are discussed below in the Section Commensal Bacteria.

Target versus Zoonotic Pathogens

As described above in the Section Antibiotics and Use, antibiotics in veterinary medicine are commonly used to treat specific bacterial diseases in animals that do not transfer to humans. One exception is *Salmonella*. More than 2500 serotypes of *Salmonella* have been named excluding antigenic formulas. Of these, some are known to be host-adapted, such as Dublin for cattle and Choleraesuis for swine. These host-adapted serotypes can cause serious disease within their respective host and antibiotic treatments are often used when disease arises. The other serotype that is not host-adapted but does cause serious illness among most food animals is *Salmonella* Typhimurium. Mostly, zoonotic pathogens typically do not cause disease in animals and behave in a commensal-like relationship; they persist within the host without causing overt disease. However, when animals are treated with antibiotics for other diseases meant for a specific target pathogen, zoonotic bacteria are also exposed to the antibiotic and can become resistant.

Antibiotic Treatment in Humans

As described in other articles, foodborne disease results in a large number of cases of human illness on a global, national, and local level costing hundreds of millions of dollars annually. However, gastroenteritis is typically self-limiting and resolves in 5–7 days, thus the use of antibiotics is contraindicated. However, antibiotic treatment might be warranted in the young, the elderly, the immunocompromised or when septicemia occurs. Antibiotics are always contraindicated for use in infection with Shiga-toxin-producing *Escherichia coli* (STEC).

Antimicrobial resistance is a global problem. Multiple-antimicrobial-resistance compounds the problem because treatment options can become severely limited. This has occurred in human medicine as observed with extensively drug-resistant tuberculosis. Once heralded as 'miracle drugs,' limited access to antibiotics could drastically impact the global population that is expected to reach approximately 10 billion people by 2050. Further, our food supply must grow to meet the protein demands of this population, doubling by 2050. Because no additional land mass will be available, as with current intensive food-animal production practices, future food animal production will also require the use of antibiotics, particularly for the prevention and treatment of disease. Therefore, the development of resistant bacteria in human and veterinary medicine is inevitable. Our ability to manage and control these antimicrobial resistant populations is critical.

Zoonotic Bacteria

Salmonella

Zoonotic bacteria can be transferred between animals and humans and are most often associated with meat. The most common zoonotic bacteria are *Salmonella* and *Campylobacter*. As described in other articles, these bacteria are ubiquitous in nature and have been recovered from nearly all vertebrate animals. As a result of their wide ecological exposure and association with food animals and humans, bacteria [including zoonotic bacteria] are exposed to natural and man-made antibiotics. Because many antibiotics originated from the soil, and as hospital waste water, industrial runoff, pasture runoff, animal manure, and waste treatment plants can contribute some level of active metabolite, the complexity associated with sorting out exposure levels and understanding (even in part) the diverse interaction within the ecosystem between bacteria, man, animal, and environment is critical.

Antimicrobial resistance in *Salmonella* has been studied widely. However, there are several critically important things to remember when interpreting antimicrobial resistance in *Salmonella*: (1) While one can obtain a 10 000-ft view by analyzing resistance using total '*Salmonella*' for any one antibiotic, it is paramount to assess resistance at the serotype level. This is critically important as the acquisition of resistance (acquired resistance) does not occur equally between serotypes. Some serotypes are resistant to many classes of antibiotics and many antibiotics within a class. They can also acquire resistance from mobile genetic elements (in particular plasmids and transposons), which appear to have carried resistance attributes for a very long period of time, perhaps before some antibiotics were used. *Salmonella* Typhimurium and its association with the Inc A/C plasmid and multiple-drug resistance is a good example of this. (2) The predominant serotypes vary among animal sources and they can vary among years. As a result, an analysis must be done within each food animal source. For instance, although the top two serotypes recovered from humans and animal sources may remain fairly consistent, changes within the top ten serotypes recovered

from year to year are often observed. (3) Within a particular serotype, genetic diversity is observed, which indicates that there can be heterogeneity among isolates within a serotype. This is particularly critical when one begins describing a 'serotype.' For instance, analysis of PulseNet or USDA VetNet or most molecular data associated with many different isolates within a particular serotype will identify differences in antimicrobial resistance attributes and/or molecular or virulence attributes and/or temporal, demographic, or source data that clearly indicate a difference between the isolates. Therefore, one cannot simply talk about 'all *Salmonella* Typhimurium or *Salmonella* Kentucky, or *Salmonella* Derby, etc.' as they may in fact, not have the same genotypic and phenotypic characteristics or respond the same to antimicrobial treatments or intervention and control measures.

Fluoroquinolones (ciprofloxacin) and extended-spectrum cephalosporins, particularly the third generation cephalosporin (ceftriaxone), are important in human medicine for treating complicated zoonotic infections. In the US, a fluoroquinolone is licensed for treating respiratory infections in swine and cattle and ceftiofur, a third generation cephalosporin, is licensed for use in food animal production. Recently, ciprofloxacin resistance has emerged in some *Salmonella* serotypes. Resistance to the cephalosporins has also begun to rise among certain serotypes in humans and food animals. In addition, extended-spectrum beta-lacatamases have also been detected in increasing frequency globally. Beta-lactamases are unique enzymes produced by some bacteria making them resistant to antimicrobials such as penicillins and carbapenems; carbapenem antibiotics may be a last line of treatment for some diseases.

In developing countries where antibiotics can be purchased over the counter for use in both human and veterinary medicine, or in countries where antibiotic use practices are not tightly monitored, resistance to the fluoroquinolone and cephalosporin classes of antibiotics can be quite high. The World Health Organization and other global bodies are working to develop programs to mitigate antimicrobial resistance in these instances and have taken steps to publish lists of critically important antimicrobials.

Multiple-drug resistance, most often defined as resistance to three or more classes of antibiotics, is also dependent on serotype. A most interesting factor is the emergence of large plasmids carrying multiple resistance genes that appear to easily move between and within *Salmonella* serotypes. A classic example is the emergence of definitive type (DT) 104 Typhimurium in England in the late 1990s. DT104 carries penta-resistance to five antimicrobials: Ampicillin, Chloramphenicol, Streptomycin, Sulfamethoxazole, and Tetracycline (ACSSuT). It was most often associated with carriage in cattle although it was also isolated from cats, horses, foxes, and other animals. Disease was noted in both humans and animals, rose to epidemic status, eventually resolved, and the strain, while recovered in low numbers from animals, humans and meats, ceased to cause significant disease. Although DT104 has been transmitted globally, in the US, the UK epidemic strain was never isolated although other strains of DT104 were recovered from food animals (primarily cattle and swine including retail meat) and were particularly predominant in the Pacific Northwest. In the US, *Salmonella* Newport and Dublin also acquired ACSSuT resistance through acquisition of a large plasmid emerging predominantly in isolates recovered from cattle and ground beef.

It is interesting to observe that for countries with *Salmonella*-monitoring/surveillance systems, antimicrobial resistance among *Salmonella* isolates originating from humans can often exhibit no resistance to all antimicrobials tested. When resistance does occur to one antibiotic it is most often to tetracycline. Multiple-drug resistance to three antibiotics is most often to tetracycline, streptomycin, and the sulfa antibiotics. These three antibiotics were the first developed more than 50 years ago and have been in use longer than the other classes of antibiotics. It is quite interesting to observe that it is unusual to encounter 100% resistance to these three antibiotics either alone or in combination in a population of bacteria unless they were acquired from a specific source and the antibiotic use practice was known.

Campylobacter

Antimicrobial resistance in *Campylobacter* has been studied primarily in *Campylobacter jejuni* and *Campylobacter coli*. *Campylobacter jejuni* is most often associated with disease in humans. Although *C. jejuni* can be recovered from all food animal species, it is most prevalent and disease is most often associated with consumption of poultry, both chicken and turkey. Antimicrobial resistance has been observed predominantly to tetracycline, the fluoroquinolones, and the macrolide antimicrobials. In the mid-2000s, the fluoroquinolones were withdrawn from use in the US poultry industry. Since then, resistance to ciprofloxacin in *C. jejuni* recovered from humans, US retail chicken breasts and chicken carcasses postslaughter has not changed significantly. Interestingly, resistance to erythromycin, the antimicrobial of choice when treatment is indicated, remained less than 2% for the same time period in humans. Recently, resistance to gentamicin has emerged in *C. jejuni*.

Campylobacter coli is less often associated with disease in humans and is the predominant species recovered from swine. Antimicrobial resistance is most often observed to tetracycline, the fluoroquinolones, the lincosamides, and the macrolides. However, in the US, resistance has also emerged to the aminoglycoside, gentamicin as mentioned above for *C. jejuni*. Historically, antimicrobial resistance has always been higher in *C. coli* when compared to *C. jejuni*. The reason for this phenomenon is unknown.

Aquaculture

Food animals have specifically implied beef cattle, dairy cattle, swine, chickens, and turkeys, whereas *Salmonella* and *Campylobacter*, as well as other zoonotic bacteria, have been implicated in seafood outbreaks globally. Although antibiotics for use in the industry are limited, resistance has been reported to tetracycline.

Commensal Bacteria

Commensal bacteria are part of the normal flora that exists within the host without causing disease or gaining any real

benefit from the host. Interestingly, with the exception of those serotypes of *Salmonella* that cause disease in some animals, *Salmonella* can have a commensal-like relationship in food animals as can *Campylobacter* species. Because animals show no overt sign of disease, it is difficult to determine if an animal is carrying a zoonotic pathogen, regardless if it is resistant or not, into the processing plant before the derived meat enters the retail market.

However, that is only part of the story of commensal bacteria. *Escherichia coli* and *Enterococcus* species are often referred to as commensal bacteria and they are often included in antimicrobial resistance monitoring systems. Their inclusion is predicated on evidence that they serve as reservoirs of resistance genes, which can be passed to both nonpathogenic and pathogenic bacteria including the foodborne zoonotic pathogens *Salmonella* and *Campylobacter*.

Escherichia coli are Gram-negative bacteria and often respond in the same manner to selective antimicrobial pressures as do *Salmonella*. As such, it is not unusual for it to be interchanged with *Salmonella* as the sentinel organism in antimicrobial monitoring systems. *Enterococcus* species are Gram-positive bacteria; they also respond well to selective antimicrobial pressures and provide antimicrobial resistance information for Gram-positive bacteria being studied. Both are ubiquitous in humans, animals, and the ecosystem and they are easy to isolate. No one 'serotype' or strain of *E. coli* is selected for study; these are referred to as 'generic' *E. coli*. For *Enterococcus*, however, the species of choice are *Enterococcus faecium* and *Enterococcus faecalis*, which are important in human illness.

The same antibiotics are monitored for *E. coli* as for *Salmonella*. For *E. faecium*, of particular interest is resistance to the human antibiotic quinupristin/dalfopristin since a comparable antibiotic, virginiamycin, was licensed for use in veterinary medicine as a feed additive to promote growth. For both *E. faecium* and *E. faecalis*, resistance to the human antibiotic vancomycin is also important as the comparable veterinary antibiotic, avoparcin, was also available for use (avoparcin was never used in the US). Depending upon the socioeconomic status of the country, resistance to both antibiotics can vary. In the European Union, use of antimicrobial growth promoters was banned approximately 15 years ago, including avoparcin and virginiamycin. Since then, low levels of resistance to quinupristin/dalfopristin continue to persist in some countries. Virginiamycin is still used in the US.

Other Bacteria Associated with Food Animals

Methicillin-Resistant *Staphylococcus aureus*

Although methicillin-resistant *Staphylococcus aureus* (MRSA) has been associated with both healthcare (healthcare-associated; HA-MRSA) and the community (community-acquired; CA-MRSA), there is much debate over the association with meat and meat products. One strain, CC398, is called livestock-associated MRSA (LA-MRSA) and appears to be different from previous strains recovered from humans. It has been recovered from swine, cattle, and poultry and its association with meat and meat products is also under study. However, once in the animal population, amplification occurs through production practices in which large numbers of animals are comingled thus making it nearly impossible to stop the spread of bacteria among animals (especially on the skin). This almost assures colonization and exposure for the farmer/owner or production worker once contact with the animal(s) occurs.

Clostridium difficile

Clostridium difficile has been recovered from neonatal swine and calves as well as mature swine and dairy cattle. While it has been suggested that community-acquired *C. difficile* associated disease (CA-CDAD) can be facilitated by contact with ill animals or consumption of contaminated meat, additional studies are needed to confirm this. Antimicrobial resistance among *C. difficile* has been evaluated and resistance has been observed to the lincosamides, macrolides, penicillins, and fluoroquinolones in particular. As observed for other bacteria, the species of food animal plays a role in resistance as isolates recovered from one animal source can be more or less resistant to some antibiotics than isolates recovered from another animal source. This would not be unexpected as antibiotic use is specific for production of a particular food animal.

Other Factors to Consider

Travel

Travel appears to play a major role in the acquisition of resistant bacteria from meat, food, and food stuffs. Developed countries tend to report lower levels of resistance among bacteria collected within their respective countries. However, for people who travel and return with a foodborne resistant infection, the resistant isolate is often attributed to the country of travel, which may not control the use of antibiotics in the same manner as the country of origin. Therefore, it is important to consider the type of food eaten and hand washing hygiene when traveling to minimize the risk of acquiring a resistant foodborne pathogen.

Proper Handling, Storage, and Cooking

Proper handling and storage are critical components to the control of foodborne infections regardless of the presence or absence of resistant bacteria. The importance of safe storage, not mixing raw and cooked products, separate processing areas in the kitchen for vegetables and meats, proper cleaning and sanitizing of surface areas and utensils, hand washing, and (most importantly) utilizing proper cooking temperatures cannot be over emphasized. The presence of resistant bacteria makes this even more critical.

Conclusions and Summary

Antimicrobial resistance is of global concern. It takes a minimum of 10 years from discovery of a potential new antibiotic through testing to market. Unfortunately, there are very few new antibiotics in development for the foreseeable future.

Therefore, as bacterial resistance to multiple antibiotics use increases, treatment options in both veterinary and human medicine become more limited, which impacts animal health, the wholesomeness of food, and human health. Further studies are needed to develop mitigation and control measures to arrest the current progression of antimicrobial resistance. Surveillance and monitoring efforts should be expanded to cover more countries, more bacteria, and provide timely global reporting. Finally, scientists should be encouraged to find newer, novel antibiotics and be less dependent upon the need to manipulate the chemical structure of existing antimicrobials. Today, scientists have developed fifth-generation cephalosporins. Bacteria have one purpose survival. If we keep exposing them only to chemical structural changes and nothing new or novel, they will continue to develop resistance mechanisms faster, shortening the useful availability of the antibiotic even further.

Potential Environmental and Wildlife Sources of Microorganisms in Meat

JT LeJeune, Ohio State University, Wooster, OH, USA
DL Pearl, University of Guelph, Guelph, ON, Canada

Glossary

Antibiotic resistance The characteristic or ability of a microorganism to be unaffected by a particular class of chemotherapeutic agents.

Antimicrobial residue Trace amounts of chemicals (antibiotics) detectable in tissues or food products.

Zoonosis Diseases of animals transmissible to humans.

Introduction

There is growing concern that commensal bacterial flora and zoonotic pathogens which colonize food-producing animals are sources of antimicrobial-resistant organisms that not only contaminate the food supply but also serve as reservoirs of antimicrobial resistance genes that can be horizontally transferred to human pathogens. Theoretical and empirical evidence support the value of reducing the prevalence of zoonotic pathogens in live animals to improve food safety and human health. One proven method for the control of production-limiting diseases of food animals is through the application of biosecurity measures on the farm. Specifically, wildlife is known to contribute significantly to the epidemiology of many economically important infections of domestic animals, such as foot and mouth disease, influenza, and bacterial diseases of animals with zoonotic potential, such as brucellosis and tuberculosis. More recently, with the advent and application of modern molecular typing methods, the importance of wildlife–livestock interactions, as it relates specifically to food safety, has gained increased recognition and attention.

The species of animals raised, the production practices, and the location of the farming (or hunting) operation can all influence the likelihood of transmission of antimicrobial-resistant organisms between food animals and wildlife. For example, it is easier to restrict wildlife access in a confined indoor facility than it is to control interactions in an extensive outdoor production system. Likewise, types of wildlife and other domestic animals present in a particular geographic area may dictate the likelihood of contact. Notwithstanding, most animal rearing locations have at least some opportunities for contact with birds, rodents, or larger mammalian species, such as deer or feral pigs, or domestic animals such as dogs or cats. Transmission of microorganisms between wildlife and livestock and poultry should be considered bidirectional and may have significant implications for wildlife health and ecology, especially as it relates to organisms that cause morbidity and mortality in wildlife populations, or be of importance in the consumption of wild game. In addition, there are also viral (e.g., rabies and Nipah virus) and parasitic infections (e.g., *Toxoplasma gondii*) transmissible from wildlife to food animals that can render derived meat products unsafe. However, in this article, the authors consider only the available evidence to support transmission of antimicrobial-resistant organisms from environmental sources and aquatic, terrestrial, and avian animals.

Similarly, nonpathogenic bacteria carrying genetic determinants for resistance (e.g., integrons) can result in horizontal transfer of these determinants to pathogenic bacteria through a variety of means, including transduction, conjugation, and transformation.

Role of Wildlife

The role that wildlife play in the transmission of antimicrobial-resistant organisms to food animals depends on their capacity to become infected, maintain the infection, and infect subsequent hosts. In this regard wildlife may be classified as outlined (Table 1).

Environmental Exposure to Antimicrobial-Resistant Organisms

The composition and diversity of the intestinal microbial flora of animals is largely determined by their environmental exposures. Even as early as during the birthing process (or hatching), the inevitable presence of bacteria in the environment provide an abundant source of antimicrobial-resistant organisms, some of which may eventually colonize the host and persist long term. Other organisms may only be passed transiently through the digestive tract or contaminate the hide, skin, or feathers.

Many of the antibiotics in use today were originally derived from soil organisms. Typically, a gram of soil may harbor between 10^6 and 10^9 bacteria, the majority of which have not yet been cultured. It is, therefore, not surprising that antimicrobial resistance among soil bacteria is common. Even if these bacteria do not colonize animals or humans, soil bacteria serve as an enormous reservoir of antimicrobial resistance genes. Horizontal gene transfer occurs readily among several genera of bacteria of piscine, aquatic, avian, environmental, and mammalian origin. Metagenomic analyses of soil organisms and human pathogens further support the hypothesis that horizontal gene transfer is the origin of a large proportion of antimicrobial resistance genes present in human clinical pathogens.

In addition to endogenous antimicrobial-resistant organisms present in soil and aquatic sediments, anthropogenic actions may further contribute to, and select for, antimicrobial-resistant organisms in the environment. First, there

Table 1 Roles wildlife may play in the transmission dynamics of antimicrobial-resistant bacteria

Host type	*Definition*	*Comment*
Unsusceptible	Animals that may be exposed but do not become infected or colonized	Although these animals may be present or even predominant at the livestock–wildlife interface, they do not contribute to pathogen transmission
Maintenance	Animals in which the organism persists in the absence of transmission from other hosts	Wildlife may be a maintenance host for some bacterial organisms and not for others, depending on the fitness of the organism and its ability to persist in a novel environment. In contrast, other bacteria may be multihost organisms if they are adapted to several species
Mechanical vector	Transmission not related to infection, but simply external contamination	For example, conveyance of organisms on the feet, hooves, or paws
Spillover	A nonmaintenance host that is susceptible to infection following interspecies transmission	Wherein exposure is frequent, infection is persistent, or prevalence is high, a spillover host may have the appearance of being a maintenance host
Amplifier	A spillover host in which the organism replicates successfully	Increases the environmental load of the organism, favoring transmission
Dead end	A spillover host that is not capable of intra- or interspecies transmission	These animals do not contribute to the continued transmission of the organism, but in the case of food safety, they may be contaminated with the organism if harvested and consumed as food
Spillback	A term reserved for the infection of a maintenance host from a spillover host	

may be direct environmental contamination with antimicrobial-resistant organisms originating from human or animal wastes. Solid waste disposal and wastewater treatment sites may receive large numbers of bacteria, including resistant organisms. Runoff from these locations can contaminate waterways used for agricultural purposes, thus providing a conduit for colonization of livestock or the contamination of livestock feedstuffs. Moreover, these activities also attract wildlife and serve as a source from which wild animals and birds may become infected with antimicrobial-resistant organisms. The cycle is self-perpetuating as, in some ecosystems, wildlife is the primary cause of microbial impairment of watersheds.

In addition to the antimicrobial-resistant organisms present in animal manures that are used for fertilization of crops and occasionally aquaculture ponds, manure may contain unabsorbed antibiotics and bioactive metabolites that exert pressure for the selection of antimicrobial-resistant organisms in the environment, thereby increasing their fraction available to colonize animals in the environment.

Of particular relevance is the use of antibiotics in aquaculture. Similar to production systems for terrestrial animals, antibiotics are used in the production of finfish and crustaceans to treat and control bacterial infections. Information about the exact amount of antibiotics that are used around the world in aquaculture is scant. In some countries, antimicrobial use in aquaculture is highly controlled, but in other regions of the world, where regulations and oversight are lax, antibiotics are used liberally. The extent to which antibiotics end up in the environment depends on the production system (recirculating systems, indoor/outdoor systems, sea pens, etc.) and is still poorly defined. However, it is estimated that approximately 75% of the drugs used in aquaculture end up in the environment. As a result, the presence of antimicrobial-resistant organisms is higher in sediments collected near sea pens than that found in sediments farther away. Antimicrobial-resistant organisms can persist in the environment for extended periods, even in the absence of continued application of antimicrobial selection pressure.

Antimicrobial-resistant bacteria, including methicillin-resistant *Staphylococcus aureus* and methicillin-sensitive *Staphylococcus aureus*, have been isolated from wild and captive marine mammals. In these cases, molecular subtyping indicated that the organisms recovered were indistinguishable from epidemic clones in the human population, indicating that the marine mammals were more likely spillover hosts from human maintenance hosts. Multiple-antimicrobial-resistant organisms were commonly isolated from stranded pinnipeds in northern California and predatory marine fishes (sharks and redfish). Collectively, antimicrobial-resistant organisms in water and fish pose a food safety and public health risk. At the same time they serve as sentinels for environmental contamination.

In summary, the high prevalence of antimicrobial-resistant organisms in the environment where food animals are raised provides ample opportunity for exposure to pathogens and commensal organisms that may colonize poultry and livestock. Contamination of feedstuffs, water, and natural animal behaviors, such as feeding (grazing, foraging, and pecking), grooming and preening, and nesting, can transfer environmental organisms from the environment to the animals and their digestive tracts. There is mounting evidence that preharvest strategies to reduce the carriage of foodborne pathogens by animals will have significant impacts on the contamination of meat with these organisms. Likewise, control of contamination of the environment with antimicrobial residues and hygienic practices that reduce the contact animals have with antimicrobial-resistant pathogens may provide strategies to reduce the probability that meats derived from animals raised in these conditions are likely to become

contaminated with antimicrobial-resistant organisms at the time of harvest.

Transmission of Antimicrobial-Resistant Organisms from Terrestrial Animals

Among emerging human pathogens, 20% are resistant to one or more antimicrobials, and this number has significantly been increasing with time. Indeed, a large number of bacteria are zoonotic – shared between domestic animals or wildlife and humans. For example, it is estimated that 70% of all emerging pathogens of humans originate from wildlife sources. The routes through which bacteria are transferred from wildlife sources and humans are complex and are not fully elucidated. Direct contact with wildlife or the wildlife environment is but one infrequent mechanism that humans may become exposed to wildlife microflora. In contrast, poultry and livestock, depending on the management system, have many opportunities to interact with wildlife and share a common environment with wildlife. Wildlife is attracted to available feed supplies, water, and shelter provided at animal production facilities. Furthermore, expansion of livestock production into areas previously used for wildlife habitat provides many opportunities for the indirect transmission of bacterial flora to humans from the environment and wildlife through various food-producing animal intermediates.

Increasingly, researchers are recognizing the threat terrestrial wild animals pose to food safety. A variety of foodborne pathogens, both antimicrobial sensitive and resistant, including *Salmonella*, *Escherichia coli* O157:H7, and *Campylobacter*, have been isolated from wildlife. The complex ecosystems involving these enteric pathogens and antimicrobial-resistant organisms are now suspected to involve more than humans and food animals, that is, they also include wildlife as potential reservoirs and agents for dispersal. Although antimicrobial-resistant bacterial intestinal microflora can be isolated even from populations of wild animals with limited exposure to domestic animals or human activity, it is recognized that the major source of these pathogens are humans or agricultural animals themselves. Nevertheless, because of their mobility, wildlife can disperse these pathogens among farms and contaminate water, animal feed, and crops intended for human and farm animal consumption, making wildlife a concern for on-farm biosecurity and public health.

The frequency and types of antimicrobial-resistant bacteria exchanged between terrestrial wildlife and livestock are governed by the species of animals raised, level of confinement, extent of farm biosecurity, and the types of wildlife in the proximity. Although some bacterial pathogens of domestic animals are restricted to certain closely related animal species, nearly 70% of organisms can infect multiple animal hosts. In addition, wildlife may also serve as mechanical vectors for the transmission of antimicrobial-resistant bacteria. In such cases, the organism need not infect or colonize the wild animal, but rather it may simply contaminate the skin, fur, or feathers and be transferred from one location to the other as the animal moves bacteria between farms or regions.

The exact mechanisms on how wildlife acquires antimicrobial-resistant flora and the extent to which they transmit these organisms to food animals are unknown. Clearly, like production animals, wildlife may become colonized with organisms present in their environment. Animals in proximity to human activities have been found to share resistant organisms with domestic animals and humans. Although wildlife sharing a common environment with livestock or humans is sufficient to result in shared pools of antimicrobial-resistant bacteria or genes, it is not a prerequisite for colonization. Some animals without contact with agricultural animals or other human activities carry intestinal flora with reduced susceptibility to a number of antibiotics. This indicates that there are various points for entry and factors for selection and maintenance of novel antimicrobial resistance organisms or genes that are independent of livestock and poultry.

It is assumed that the transmission of organism between wildlife and livestock occurs via direct contact, contact by domestic animals of fomites or environments previously contaminated by wildlife, or through the contamination of feed or water supplies. Specific behavioral interactions define transmission outcomes. A classical example is the case for tuberculosis transmission between badgers and possums and cattle. During the advanced stages of disease, these wildlife species express atypical behaviors, including the loss of fear of other animals. Cattle and deer are able to approach these animals and, due to such proximity, large numbers of organism can be transmitted via direct contact or aerosol. Another way that bacteria may be transmitted, for example, between wild bison and domestic cattle is at the time of calving. Finally, carnivores may become infected from maintenance host from scavenging fetal membranes or mortalities.

In recent years, there has been increasing encroachment of wildlife habitats for food animal production. Reciprocally, animal production facilities often attract wildlife. Additively, these factors have augmented the potential for livestock–wildlife interactions. Probably the most common route of interspecies transmission of antimicrobial-resistant organism is through sharing a common environment, including feed, feed bunks, and water sources. Wild animals that often frequent livestock production facilities and from which antibiotic-resistant organism have been isolated include grazing ungulates, raccoons, wild pigs, rabbits, and other rodents. However, the directionality of the transmission in these cases cannot be deduced from simple cross-sectional studies.

Transmission of Antimicrobial-Resistant Organisms from Avian Species

The literature on the carriage of foodborne pathogens by wild birds is rich with descriptive studies on *Salmonella enterica* and antimicrobial-resistant bacteria, including indicator species such as *E. coli*. A great deal of this focus reflects the public health impact associated with *Salmonella* and antimicrobial-resistant infections as well as the likelihood of detecting these organisms in wild avian species.

Bacteria resistant or carrying genes for resistance to drugs of primary importance to human health, including fluoroquinolones, vancomycin, and third-generation cephalosporins, have been isolated from wild birds along with isolates showing multidrug resistance.

Salmonella enterica and antimicrobial-resistant bacteria have been isolated from a diverse array of species across several orders of wild birds from around the world, including passerines, gulls, cormorants, pelicans, waterfowl, cranes, pigeons and doves, raptors, galliformes, psittacines, and even penguins. A number of large national reviews of avian wildlife mortality events have also demonstrated the diversity of birds that may potentially carry *Salmonella*. Interestingly, the diversity of serotypes obtained from apparently healthy birds appears to be far richer than those documented from birds that have mainly died of salmonellosis and often reflect the proximity to human or agricultural environments where these birds forage. In addition, the diversity and prevalence of serotypes of *Salmonella* and antimicrobial-resistant bacteria may be much greater from bacteria isolated from the feet and feathers of birds than from their feces or gastrointestinal tracts, suggesting that 'mechanical vectoring' may also be a concern for interspecies transmission.

It is important to recognize that although the diversity of birds that could potentially carry *Salmonella* or antimicrobial-resistant organism is quite high, the prevalence of carriage may vary with bird species and geographical region depending on the behavior of the bird species and the availability of human and agricultural sources of these bacteria. For instance, researchers mist netted and collected fecal samples from more than 500 barn swallows (*Hirundo rustica*) but failed to find any samples that tested positive for *Salmonella* despite sampling across multiple regions and periods in Sweden. Interestingly, however, even in remote areas such as Antarctica and the Arctic, *Salmonella* serovars and antimicrobial-resistant bacteria commonly found in humans and domestic animals have been isolated from wild birds, suggesting the possibility of a complex recycling process involving humans, marine wildlife, and marine sources of food and feed ingredients. In a study on antimicrobial resistance, it has been found that there is a high prevalence of antimicrobial-resistant genes and integrons in *E. coli* isolates from black-headed gulls (*Larus ridibundus*) located in three nesting colonies near industrial cities (1 colony) and areas of intense agriculture (2 colonies) in the Czech Republic; the researchers noted that the most frequent phenotypes of antibiotic resistance were consistent with the consumption of antimicrobial drugs in human and veterinary medicine in the Czech Republic.

Investigators conducting a study on multidrug resistance in wild birds in Germany, involving one rural and one urban sampling area, suggested that birds of prey, waterfowl, and passerines represent a notable source of multidrug-resistant *E. coli* and that the patterns were similar to those isolated from domestic animal. Interestingly, on-farm studies focused on different species often suggest conflicting views on the significance of wild birds as a potential reservoir for antimicrobial-resistant organisms. For instance, in a study of house sparrows (*Passer domesticus*) on two Czech dairy farms, there was no evidence to suggest that the birds were infected with resistant *E. coli* isolates with the same phenotypes as those found in cattle from the same farms despite close contact between the animals. In contrast, in another study of red-billed choughs (*Pyrrhocorax pyrrhocorax*) in Spain, strong evidence was found that these birds carried multidrug-resistant strains of bacteria that resembled the waste, including pig slurry and sewage sludge, which was used as fertilizer on the fields where these birds forage for soil invertebrates. Consequently, predictions concerning the role of birds in spread of *Salmonella* and antimicrobial-resistant organism in agricultural systems need to be species specific and recognize complex ecological processes.

Antimicrobial-resistant organisms have been obtained from both ill and healthy birds using microbiological analysis of fecal, cloacal, and entire gastrointestinal tracts and entire carcasses. In addition to the source of animals and material used among studies, microbiological methods, sample sizes, and the number of sites used in determining prevalence estimates are quite variable. Consequently, a great deal of caution should be used in making comparisons among species and orders of birds, across regions, countries, and continents.

Research Needs

The literature concerning the transmission of antimicrobial-resistant bacteria has been dominated by descriptive studies that focus on whether these bacteria are carried by wildlife or the subtypes of these organisms, based on molecular techniques or antibiogram profiles, match those found in agricultural animals. From these studies, it is clear that these organisms are shared between wildlife and agricultural animals but is less clear in many situations, for example, whether wildlife are having a significant impact on the carriage of these organisms in the farm environment. Epidemiological studies focusing on the agricultural and wildlife ecosystem of populations of farms are required to address a number of issues, including the relation between the degree of contact with wildlife species and the probability of agricultural animals carrying these resistant organisms or having their feed, water source, or environment contaminated with antimicrobial-resistant organisms. These types of studies are needed to establish that wildlife is having a quantifiable role in spreading these bacteria to agricultural animals and not merely acting as sentinels for organisms that are being shed by agricultural species. Furthermore, randomized control trials, cohort studies, and case-crossover studies examining the impact of wildlife control measures on the prevalence of antimicrobial-resistant organisms are needed to further establish the causal role of wildlife in spreading these organisms to agricultural species and in identifying the most effective control measures. In terms of development of quantitative risk assessment and infectious disease transmission models, a number of inputs remain largely unknown, especially regarding the movement of populations of wildlife among farms, the probability of wildlife acting as biological or mechanical vectors for these pathogens, quantitative measures of the amount of bacteria transmitted by wildlife carriers, and basic information concerning the survival of these organisms within wildlife and their survival in the farm environment. Consequently, integrative research activities between wildlife biologists, veterinarians, epidemiologists, microbiologists, and experts in risk assessment and mathematical modeling are required to understand and quantify the risk posed by various wildlife species and to develop intervention strategies in order to prevent the transmission, distribution, and/or multiplication of these antimicrobial-resistant organisms in agricultural animal species and

subsequent food animal products. However, it is important to remember that the nature of these processes may be very different depending on the species of bacteria, species of wildlife, agricultural species and production system, and the temporal and spatial scale at which these questions are being addressed.

MINCED MEATS

KO Honikel[†]

This article is a revision of the previous edition article by KO Honikel, volume 2, pp 854–856, © 2004, Elsevier Ltd.

Glossary

Colloidal systems Colloids are substances which are dispersed in small particles (10^{-5}–10^{-7} cm in diameter) in gaseous, liquid, or solid compounds. In meat science they are important: as a gas in fluids which are foams, as fluids in gas which are mists or sprays, as solids (meat proteins and as solid fat particles) in aqueous solutions they are suspensions, or fluids (oil or molten fat) and in aqueous solutions are emulsions. Meat batters in a bowl chopper are often called emulsions but their correct physical definition is a suspension.

Swelling of meat proteins Fibrillar proteins of meat attract each other because of their positive and negative charges of amino acid side chains. Salt (NaCl), dissolving immediately in the aqueous environment of water in meat, added to minced meat lets the ions move in between the protein chains, in this way reducing their attraction and permits the swelling of the protein structure by the influx of water.

Introduction

Meat mincing is a process in which meat cuts with mainly intact cellular structures are reduced in particle size, usually with the help of a meat mincer or sometimes even a bowl chopper. Flaking machines can also be employed, producing small but discrete muscle pieces. In former times mincing was done by hand with knives cutting the meat into small pieces. Later, rocking knives (end of nineteenth, first quarter of the twentieth century) were mounted on top of a rotating bowl being the prototype of a modern bowl chopper. With all the mechanical equipments only a part of the cellular structures are disintegrated.

In contrast to an intensive comminution in a bowl chopper or in emulsion mills, in which very sharp knives cut many thousand times per minute through myofibrillar and connective tissue proteins of the batter, the degree of reduction of particle size and cellular destruction in minced meat is limited. In a meat mincer, the precut pieces of meat (1–4 cm cubes or strips) are fed onto a rotating spiral shaft (screw auger) or a pump-type system that presses the meat through a static end plate with holes of 1.5–10 mm diameter and against a rotating knife. The knife rotates at the speed of the spiral shaft. The degree of cutting of myofibrillar and filamental structures is rather limited. A mincer is able to grind semifrozen (−5 °C and higher) or unfrozen meat. The temperature should not exceed +2 °C at the end of the mincing process mainly for the reason of preventing microbial growth.

Thus, mincing involves a crude disruption of cellular structures of muscle and fat cells together with a mechanical disruption of the well-ordered fibrillar structures of myofibres and connective tissue sheets. Cellular and subcellular membranes are only partially disrupted; connective tissue sheets are cut into smaller pieces, but pieces of tendon are still recognizable; and the myofibrillar structures (myofibers and fibrils, usually in the state of rigor mortis) are broken down only into smaller pieces. By legal requirements in many countries, no additives are permitted in minced meat sold as such in raw state, but the addition of up to 1% salt is permitted. More than 1% salt, the fibrillar structure of the muscle would alter recognizably.

These steps are required for processing of meat into hamburger products, restructured meat, or they are applied as the first step for manufacturing meat products.

Flaking machines slice small pieces of meat with a rotating or a falling knife but without the perforated plate that is used in mincing. Usually, the meat is semifrozen so that its stiffness permits a clear cut through the meat.

The consequences for the structure of the meat are similar to those of mincing, but to a lesser degree, except that connective tissues (tendons) are more thoroughly cut than they are by mincing. Mincing and flaking simulate the manual use of a knife.

Further comminution to a more or less homogenous batter is done by mills or bowl choppers. Milling and chopping are applied for processed meat products like sausages. They form colloidal systems of dissolved, swollen, and undissolved meat proteins and fat particles in an aqueous dispersion, a general expression of a colloidal system consisting of solid particles in another solid, fluid, or gaseous material. In both cases, fast-rotating sharp knives cut through the meat. In contrast to mincing or flaking mills, choppers permit the direct addition of such ingredients as salt, additives, extenders, etc. Homogenous batters in which fibrillar structures and fat globules of fat cells are disrupted into very tiny parts (<100 μm) usually for sausage manufacturing, are obtained as the end product.

[†]Deceased.

 doi:10.1016/B978-0-12-384731-7.00240-3

Often these meat batters at ambient temperatures and below are called meat emulsions. Emulsions in its physical definition are colloidal systems of a dispersed fluid phase in a continuous fluid matrix, for example oil in water. This does not fully apply to a meat batter in a bowl chopper. In a meat batter water is the continuous fluid matrix with more than 50%, often exceeding 60%, in which a part of the meat proteins because of the addition of salt (2% and more, lower concentrations with additives like phosphates) are dissolved and solid particles of proteins (10–20%) and fat particles (up to 35%) are dispersed. Such a colloidal system is called a suspension. A part of the protein surfaces of the dissolved proteins have changed their three-dimensional structures and they have become partially more lipophilic. They try to form a protein 'net or skin' around the fat particles. The modified protein structures entrap the fat particles already during the chopping process. On heating the dissolved and undissolved (dispersed) protein molecules and particles form a three-dimensional network in which fat droplets and water are entrapped, bound, or immobilized. A complicated colloidal system is formed which cannot be called an emulsion in any state. As a consequence of the entrapped fat particles the meat batter becomes a heat stable three-dimensional network of which little or no water and fat cookout occurs (see **Table 1** E and F as batter-like structures in comparison to A through D as structures of minced meat).

In conclusion, mincing even the addition of water does not develop colloidal systems (see in **Table 1,** steps A and B).

Advantages of Mincing

Meat in the full state of rigor mortis – between 5 and 40 h postmortem, depending on species, preslaughter and slaughter stress, chilling, etc. – is tough because of the permanent cross-links of actin and myosin between filaments and the still intact longitudinal and transverse fibrillar structure of myofibres themselves. The various connective tissue sheets (endomysium, perimysium and epimysium) increase toughness, which increases with the age of the animal as a result of the increasing degree and maturity of cross-linking between the collagen molecules in the connective tissue.

Table 1 Water-holding (binding) capacity of beef (pH 5.5; 2% fat) after different processing steps, ending all with heating up to 75 °C; the mixtures were mixed for 1–2 min in a bowl by hand except for E and F, where a bowl chopper was employed

Status of processing	*Water (ml)/product (kg)*	*Cookout (%)*
Intact meat (100 g)	745	27
(A) Minced meat (3 mm plate)	745	22.5
(B) A+75 ml water	828	47.5
(C) A+2% salt	735	0.25
(D) C+75 ml water	822	9.1
(E) D+50% minced pork backfat	640	2.3
(F) E+0.2% diphosphate	640	0.5

Note: Owing to the low fat content of the beef in A to D no fat cookout occurred. In E a minor fat cookout of $<0.5\%$ was observed.

Mincing mechanically disrupts these protein structures and enhances the sensory tenderness. The disruption of cellular membranes allows a rapid distribution throughout the meat particles of subsequently added salt (usually in a mince or a Hamburger patty approximately 1%) or other additives for sausage manufacturing. The effect of higher salt contents in coarsely ground (minced) sausage products like salami-type sausages is that salt enhances the solubility of myofibrillar proteins as the salt is immediately available at the intracellular myofibrils, which are additionally fragmented into smaller pieces. The highly ordered and fixed postrigor fibrillar structures thus no longer exist to the same extent (see also **Table 1**).

The rapid action of salt in minced meat is also advantageous in prerigor (hot boned) meat. In the prerigor state, owing to the presence of higher concentrations of adenosine triphosphate (ATP), actin and myosin in the myofibrils are separated (there are no permanent cross-links). The addition of salt (1.5–4.5% NaCl) leads to a disintegration of the myofibres through swelling and dissolution of myofibrillar proteins. Rigor mortis with its actin-myosin cross-linking can no longer occur, and the meat remains structurally in a prerigor state despite the subsequent ATP depletion and pH fall. This prerigor salted meat has excellent water-holding capacity as swelling by salt does not necessarily promote an intensive disruption of the above-mentioned rigor structures. When 'emulsion-type' sausages are made with this prerigor salted meat, there is no need for additives such as phosphates or citrates, to enhance water binding. The salt contents can remain at a minimal level of approximately 1.6–1.8%. No jelly or fat cookout will be observed.

The effects of mincing and further processing are described together in **Table 1**. Mincing itself (A) enhances the water-binding capacity (WBC) slightly. It results in a lower cookout. Addition of 75 ml water to 100 g of meat (B) does not improve or change the WBC of the meat proteins. Proportionally more cookout is observed. However, the addition of 2% salt to meat (C) enhances the WBC and 75 ml water and 2% salt (D) exhibits a much higher WBC than (B). The use of diphosphate (F) enhances the WBC further. It will also be enhanced by further comminution and the addition of fat (E).

Mincing of meat permits mixing with other foods, allowing the extension of meats. Starch and other polycarbohydrates, nonmeat proteins, water, etc. are possible extenders. Use of extenders enhances the range of meat-containing products, from hamburgers to meat loaves and meat balls, in which meat may be a minor component.

Grinding/mincing also permits the formation of uniformly shaped restructured meats in moulds. Enhanced tenderness and a uniformly distributed flavor are easily achieved.

The nutritional quality of minced meats can also be enhanced by the addition of vitamins (e.g., antioxidative vitamins C and E) and changes in the fatty acid composition by the addition of mono- or polyunsaturated fatty acids are possible.

Disadvantages of Mincing

Mincing has two main disadvantages.

Oxidative Changes

Mincing permits the addition of substances that may enhance the microbial and sensory (rancidity) shelf-life, although mincing per se is counterproductive in terms of shelf-life as meat surfaces are tremendously increased. Oxygen and microorganisms can be distributed throughout the mince. In contrast, a solid meat cut is more or less sterile in its interior and also oxygen penetrates only a few millimeters deep.

The cellular membrane, essentially a lipid bilayer, contains in its phospholipids a considerable number of unsaturated fatty acids. Despite their tendency to oxidize easily, the unsaturated fatty acids are protected in intact muscle of a living being by the ordered bilayers and antioxidants such as vitamin E (tocopherols) between the phospholipids. Oxygen which is transported via the blood stream to the cell surface will penetrate through the bilayer into the intracellular space. The double bonds of the fatty acids will be the target of the oxygen on its way to the intracellular space. The tocopherols, however, are protecting the double bonds of these fatty acids from the oxygen radicals which in turn become oxidized. In a living organism, however, the oxidized antioxidant molecules are replaced but in postmortem tissues such a replacement cannot take place over long durations as the formation of reduced compounds need energy (anabolic pathways), which is exhausted with the onset of rigor mortis. Because grinding, usually carried out postrigor, disrupts the ordered cellular structures, irreversible oxidation can occur. In sensory terms, the oxidation of unsaturated fatty acids and the following formation of carbonyls (e.g., nonenal) lead sooner or later to rancidity. Rancidity does not occur over a period of a few hours, but even frozen or chilled storage in oxygen-permeable packages over time leads to slow but ongoing oxidation. These oxidative changes via oxygen radical formation or peroxides are a self-promoting process. It is a chain reaction which continuously enhances the concentration of rancid compounds. For this reason, the storage potential of frozen minced meat is rather limited. The fatter the minced meat is, the shorter its shelf-life, even if it is chilled or frozen.

Some countries permit the addition of antioxidants to minced meat, such as ascorbate/ascorbic acid (E 300–304), isoascorbates (E 315–316), tocopherols (E 306–309), or metal ions sequestering organic acids and their salt like citric acid/citrates and phosphates or chemical antioxidants like gallates, BHT, BHA (E- numbers 310 and 320 and 321) to minced meat to retard oxidation. Another possibility to reduce oxidation of minced meat is the immediate packaging of the mince after preparation into packaging with carbon dioxide and/or nitrogen. But in these packages the meat loses its attractive red color. In modified atmosphere packages (MAP), the color of the meat is highly dependent on the amount of oxygen. Initially, the bright oxymyoglobin layer is deep in the muscle, but after a time metmyoglobin layer can involve surface layers that become brown. With higher oxygen levels this is less likely but oxidized products can occur.

Microbial Spoilage

Meat itself in its composition is not only a well-balanced food for human beings, but also a good feeding medium for many microorganisms. In an intact muscle piece, microorganisms are usually on the surface only; the interior is more or less sterile. On mincing when the surface area is greatly increased, the microorganisms present on the meat surface are distributed throughout the mince. Immediate chilling from 0 to +2 °C retards or inhibits their further growth, but a common means of preventing microbial growth is to heat the mince immediately or within 24 h.

The use of antibacterial additives (no nitrite permitted) or salt also retards the microbial spoilage. However, in many countries minced meat must be sold without additives. In some countries, however, as mentioned above for retarding rancidity, the regulations permit a limited number of additives like sorbates/sorbic acid, borates, or benzoic acid.

MODELING IN MEAT SCIENCE

Contents

Meat Quality

SJ Lovatt, AgResearch Ltd., Hamilton, New Zealand
CE Devine, The New Zealand Institute for Plant and Food Research, Hamilton, New Zealand

Glossary

Causal model A qualitative or quantitative model that hypothesizes the relationships between two or more phenomena in a way that affirms the behaviour of at least one phenomenon to be directly caused by one or more other phenomena.

Component model A model that seeks to describe the behaviour of a single component within a system, typically by describing the relationships between several phenomena.

Statistical model A qualitative or quantitative model that hypothesizes the relationships between two or more phenomena in a way that affirms the behaviour of at least one phenomenon to be correlated with one or more other phenomena, but not necessarily implying that there is a direct causal relationship between them.

Introduction

To understand or design a meat processing operation, there is a wide range of potential processing options available. An incomplete list of the processing regimen characteristics that might affect meat quality attributes important to consumers would include:

- the muscles involved,
- the age, genetics, gender, and physical condition of the animal,
- the extent to which the animal was stressed, or not, before slaughter,
- the method of slaughter,
- the electrical treatments applied,
- the size and shape of the piece of meat,
- the way the meat is hung or otherwise supported,
- the temperature profile of the meat over time,
- the method of packaging,
- the method of storage,
- physical treatments during cooling and storage, including moisture loss and exposure to oxygen and other gases, and
- the method of preparation and cooking.

With such a large number of different characteristics to consider, it was difficult for managers and designers of meat processing operations to understand intuitively how combinations of these characteristics might affect meat quality attributes. This difficulty has been addressed by the development of mathematical models to predict meat quality as functions of the process and animal characteristics. These models have the further advantage that they have allowed managers and designers to make quantitative predictions of outcomes that previously required the expert judgment of a highly experienced meat scientist. It should be noted, however, that all models are simplifications of the real world, and this simplification is achieved by excluding those aspects of the world that are unimportant to the situation being studied. The decision as to which aspects are unimportant inevitably requires some judgment and experience in the field, and so it is desirable that a model user should have some knowledge of meat science before developing or applying the models described later in this article.

There are two broad approaches to modeling any problem. One approach is to develop a conceptual framework that shows some presumed causal links between the various phenomena involved in the system of interest, to express each link in the form of a model, and to find parameters for each model. This approach requires an understanding (or at least a hypothesis) of the causal relationships among the phenomena and detailed quantitative research to evaluate the parameters

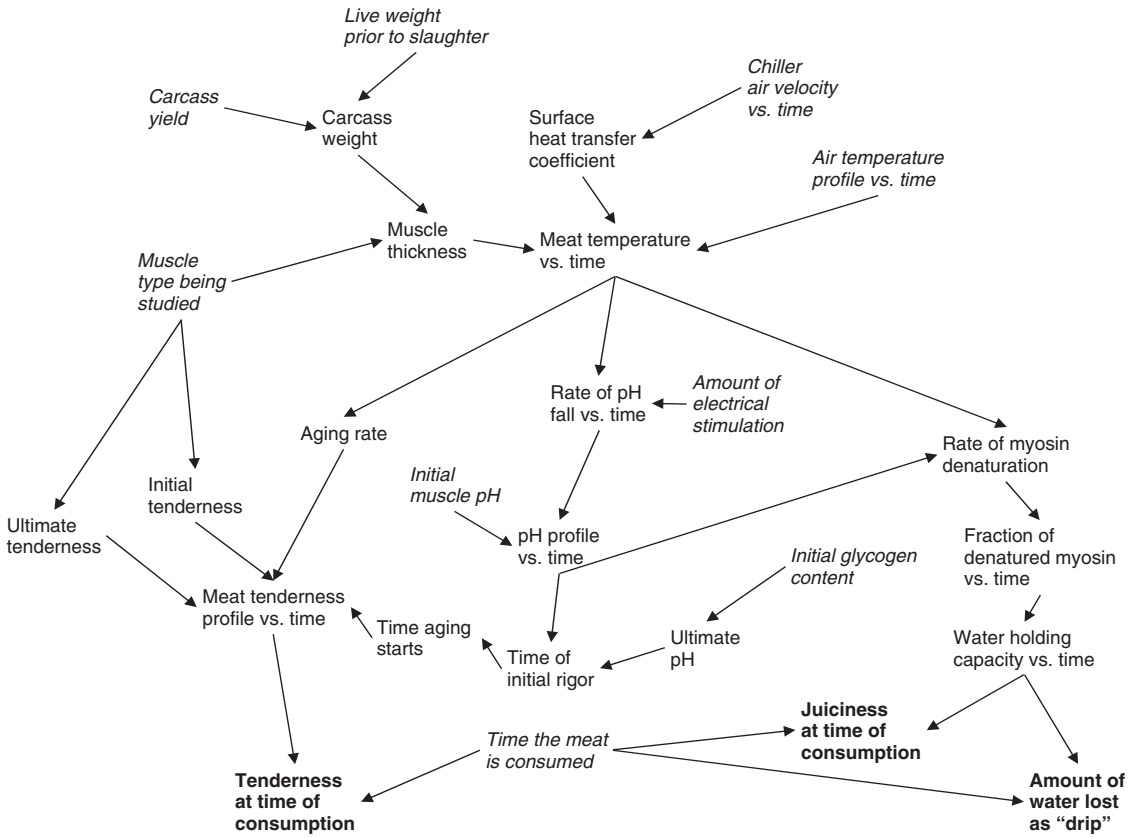

Figure 1 One of the many conceptual frameworks that could be used to understand the interactions among phenomena that affect a few measures of meat quality. Each arrow should be interpreted as saying that the phenomenon at the tail of the arrow appears to directly affect the phenomenon at the head of the arrow. Inputs that would have to be specified by any user of the model are shown in italics; outputs that would be predicted by the model are shown in bold. 'Time' is the amount of time since slaughter.

of those modeled relationships. Another approach is to use statistical techniques to relate system inputs and output phenomena, without hypothesizing specific causal relationships among them. This second approach requires a considerable amount of data for the inputs and outputs, with all relevant combinations of the input variables having to be included in the dataset if the resulting model is to be robust.

First, a causal model framework is considered that could be used to provide a qualitative description of the relationships among many phenomena that are relevant to meat quality. Second, component models of individual phenomena are considered that are relevant to meat quality. Third, a successful statistical model is examined that makes quantitative predictions of output variables from input variables.

An Example Causal Model Framework

The type of framework that is used, and the levels of phenomena and time scale on which it should operate will always depend on the purpose of the framework, that is, the behavior that it intends to illustrate or explain, or the outcomes that it intends to predict. In the area of meat quality, these behaviors and predictions could range from the submicroscopic scale of enzyme reactions to the macroscopic level of meat tenderness and drip loss.

An example model framework that attempts to illustrate the relationships among some of the macroscopic phenomena involved in the rigor and aging process is shown in Figure 1. Some points can be noted:

1. Although some values are indicated as inputs to this model, the selection of inputs depends on the selection of the model boundary. Thus, one could note that the live weight of an animal depends on its breed, gender, age, feeding regimen, and many other factors. This model is chosen to study the rigor and aging processes and not the process of animal growth; hence the live weight of the animal is considered immediately before slaughter.
2. The authors of this framework have decided that they are interested in predicting the tenderness of the selected muscle, its juiciness, and the total amount of water lost as drip, but have chosen not to examine the specific mechanism through which drip occurs, to predict the meat color, surface dryness or any of a number of other values that could have been of interest.
3. Within the model framework itself, the authors have chosen to simplify the relationships. The framework shown in Figure 1 does not include the effect on tenderness of low-temperature shortening (often called cold shortening) or

high-temperature shortening (often called heat or hot shortening, which also involves inhibition of tenderizing enzymes), or the effect of muscle type or fat content on juiciness. These simplifications may limit the applicability of the model, but they also reduce its complexity, and therefore make it easier to understand for the situations where it is applicable.

4. Where possible, the relationships have been limited to those where a cause can be tied directly to an effect by an understanding of the physics, biochemistry or sensory science behind the process being modeled. As an example, this model framework suggests that juiciness does not depend directly on the fraction of denatured myosin, but on water holding capacity.
5. The precise definitions of the variables within the model are important because they can often be measured in different ways. For example, drip might be measured in terms of the volume of liquid that is exuded by meat contained in a plastic bag. The amount of drip over time can also be measured by centrifuging a meat sample. The same phenomenon will be measured differently by the two techniques, though one would expect the two measures to be correlated.
6. Any model or model framework is a theory. While a good model will provide a very useful guide to the behavior of the system that it is designed to represent, any model is always an approximation to that system. Sometimes – especially in a rapidly developing field – a model is no more than a representation of a best guess as to how the phenomena in the system are related. One of the uses of the model, in this latter case, is to predict behavior that one should expect to see in the real system. By comparing the model's prediction with the behavior of the real system, one can discover how well the model embodies one's understanding of that system.

A model framework such as that shown in Figure 1 can allow one to draw conclusions about the system behavior without the need to make quantitative predictions. For example, one may ask if it might be expected that meat from larger animals of a species would be more tender than meat from smaller animals. This model framework suggests that it might be more tender, because the muscles on a larger animal will be thicker, hence they will cool more slowly, hence they will have more time to age, and will consequently have dropped closer to their ultimate tenderness by the time they are consumed than would the muscles from a smaller animal. In this way, a conceptual framework can be of considerable value by itself. To make quantitative predictions of the system outputs, however, a conceptual framework must be made more concrete by defining the relationships among the phenomena that it contains – usually through the use of mathematical equations.

Component Models of Meat Quality Attributes

Historically, the results of studies in meat science have been reported in graphical or tabular form, relating one or more manipulated variables to one or more response variables. Increasingly, however, these results are being formulated as mathematical equations that describe hypothesized relationships between causes and effects. The use of mathematical equations instead of tables or graphs can allow both a more concise description of the relationship and easy interpolation between the discrete conditions that were actually studied.

Examples of Algebraic, Differential Equation, and Computer Models

Where the relationships between phenomena apply at instants of time, they can be described using algebraic equations. For example, in 1977, Jeacocke measured the rate of pH change over time for beef muscles at various temperatures. He plotted his measured results in a graph that showed points between 0 and 35 °C, but this relationship could be expressed quite easily as a mathematical model if one fitted a convenient form of equation to the data. It turns out that eqn [1] fits Jeacocke's data very well:

$$r = 0.0837 - 0.0425T + 0.000225T^2 \qquad [1]$$

where r is the rate of pH fall in units per hour and T is the temperature in °C, and the model is applicable for temperatures between 0 and 35 °C. The data measured by Jeacocke and the fitted curve are shown in Figure 2.

Where the relationships between phenomena are rates of change, it is usually most effective to express them in the form of differential equations. To continue the example of Jeacocke's pH change measurements, a model to predict pH (as opposed to the rate of change of pH) could be expressed as shown in eqn [2].

$$dpH/dt = -0.0837 + 0.0425T - 0.000225T^2 \qquad [2]$$

While the transformation of a set of data points on a graph into eqn [2] is quite straightforward, this simple form of model construction can provide considerable predictive power. If one knew the initial pH, and knew (or could calculate) how the muscle temperature changed over time, one

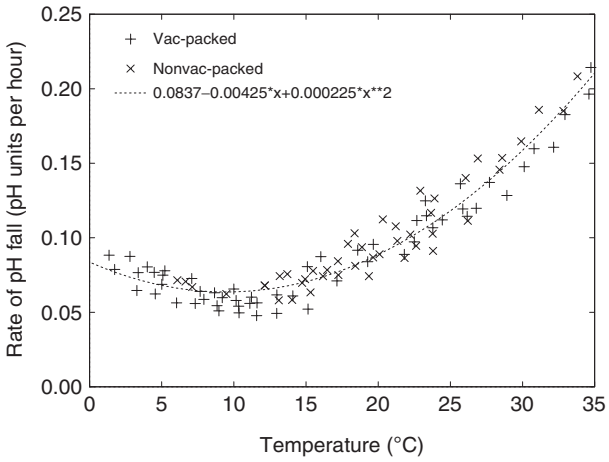

Figure 2 Measured rate of pH fall vs. temperature, with a fitted model curve, replotted from data collected by Jeacocke, R.E., 1977. The temperature dependence of anaerobic glycolysis in beef muscle held in a linear temperature gradient. Journal of the Science of Food and Agriculture 28, 551–556, with the curve added.

could solve this differential equation numerically to calculate a predicted pH at each point in time for that muscle. This would be impossible to achieve based only on the data points that were originally reported.

As discussed earlier, there are approximations and theories involved in any modeling process. In this case, by constructing the model shown in eqn [2], the authors have assumed that temperature is the only factor that affects the rate of pH fall and that, for example, the rate of pH fall is independent of the current pH of the meat. In fact, because any piece of meat has an ultimate level below which its pH will not drop, it is clear that eqn [2] will be incorrect once the pH drops below that level. A crude (but perhaps sufficiently accurate) way to deal with this problem might be to describe the pH profile by choosing between eqns [3] and [4], based on the current pH level.

$$\text{if pH} > \text{ultimate pH: } d\,pH/d\,t = -0.0837 + 0.0425T - 0.000225T^2 \quad [3]$$

$$\text{if pH} \leq \text{ultimate pH: } d\,pH/d\,t = 0 \quad [4]$$

This sort of choice can be made easily if the model is implemented in a computer program and, since that also makes it easy to solve the differential equations using numerical methods, computer programs have become the usual preferred method of implementing and evaluating most types of meat quality models.

A Model to Describe Formation of Pale, Soft, and Exudative Meat

One of the first models of meat quality phenomena was developed by Offer in 1991. Offer reported that "[although] the importance of pH and temperature conditions to the severity of the pale, soft and exudative (PSE) state has been much discussed, insufficient emphasis is often given to the importance of the time for which the carcass experiences these adverse conditions." Offer therefore used the dependence of the rate of denaturation of myosin *in vitro* on pH and temperature to predict the time-course of myosin denaturation in the prerigor period. To keep the focus of the model on protein denaturation, Offer used a linear rate of pH fall (rather than using a temperature-dependent model such as eqn [2]) and an exponential rate of temperature fall to specify the pH and temperature of the muscle at any given time during the rigor process. The exponential rate of temperature fall was modified by assuming that the heat produced by postmortem glycolysis was liberated at a constant rate.

Offer hypothesized that the denaturation of myosin was ultimately responsible for enhanced drip loss in the PSE condition, and that the rate of denaturation could be described using an Arrhenius equation. By reasoning from the combination of several earlier published results, Offer was able to estimate that the rate constant (k_d, in s^{-1}) approximately obeyed eqn [5].

$$k_d = 2.13 \times 10^{34} \exp(-43000/(R\,T)) \times 10^{-1.3pH} \quad [5]$$

where R is the gas constant and T is the temperature, in Kelvin. It was assumed that the rate of myosin denaturation would fall to zero when the muscle entered the rigor state because the myosin overlapped by actin filaments would bind to actin.

The model was then solved for a wide range of cooling rates and rates of pH fall. This allowed Offer to plot graphs to show the effects of time, pH fall rate, and cooling rate on the rate constant of the Arrhenius equation. Then the effects of these variables on the fraction of myosin denatured could be shown. The benefits of this modeling approach were summarized by Offer as follows:

> *The calculations described… help to rationalize several key aspects of processing practice and to explain certain previously puzzling phenomena connected with PSE. Seemingly unrelated features of processing to achieve optimal meat quality have been brought together under a reasonably simple and predictive model. This could be used to predict the amount of drip associated with various treatments of the carcass, thereby defining the critical conditions that have to be fulfilled if the severity of PSE is to be ameliorated.*

Additional Factors to Consider

As well as helping to explain relationships among observed data, modeling can also identify areas that need further research. For example, myosin, modified by pH and temperature prerigor, is not the only protein that changes during processing. During aging and tenderization postrigor, cytoskeletal proteins degrade and release free water (the rate depends on temperature, but the extent is relatively independent of temperature) that can contribute to drip, and this water needs to be included in the model.

Electrical stimulation not only accelerates rigor mortis and helps avoid cold shortening, but recent studies show that, in addition, stimulation improves the tenderness of tropical breeds so that they become more similar in tenderness to British and continental breeds and that both, in turn, are more tender after stimulation than unstimulated British breeds. There are opportunities to explore these sorts of relationships through cause–effect modeling or to quantify them through the sort of statistical modeling framework described in the following section.

An Example Statistical Modeling Framework

Where the relationships among phenomena to be modeled are indirect, or where each individual phenomenon cannot be separated out from the others, a statistical modeling approach might be most appropriate. This was the case for the Meat Standards Australia (MSA) beef grading system.

The MSA model sought to predict a meat quality (MQ) score using a variety of techniques, but mainly through a regression approach. In general terms, the model was as follows:

$$MQ\ \text{score} = (\text{formula } \textit{involving animal variables and treatment variables}) + (\textit{consumer variation}) \quad [6]$$

The researchers used data from 39 muscles or groups of beef muscles, each of which was cooked using up to five different methods (some or all of grill, roast, stir-fry, thin slice, slow cook). They collected the values of 140 variables for each of over 32 000 samples, including input data such as breed,

age, and feed regimen, processing inputs such as carcass suspension and electrical stimulation characteristics, marbling, fat depth and pH, position of the sample within muscle and days aged, and the cooking method. Output data included tenderness (*tn*), juiciness (*ju*), like flavor (*fl*), and overall liking (*ov*) scores evaluated by panels of 10 consumers per sample. The MQ score was constructed from the four sensory scores as follows:

$$MQ = 0.4\ tn + 0.1\ ju\ + 0.2\ fl + 0.3\ ov, \quad [7]$$

During the analysis, the researchers removed from the model variables that failed to predict eating quality either individually or in combination, and variables that were positively correlated with other variables that remained in the model.

The researchers found many relationships of interest in the model. For example, they found a negative correlation between eating quality and the percentage *Bos indicus* content in the animal. They also found a negative correlation between eating quality and ossification score. Both of these relationships were expected based on prior research.

A particularly interesting result apparent from the model was the effect of the method of carcass suspension and the eating qualities of different muscles. For example, the MQ scores of M. longissimus dorsi lumborum, M. biceps femoris, and M. semimembranosus were improved by suspension from the obturator foramen, while MQ scores of the M. psoas major and M. spinalis dorsi were made worse by this suspension method, when compared to suspension from the Achilles tendon.

Although considerable research has been done on the effect of aging on tenderness, much of that research has been carried out on a very limited range of different muscles. In contrast, the many different muscles used to develop the MSA model enabled the researchers to examine the relative effect of aging on tenderness for a range of muscles and for a variety of suspension methods.

When applied to the MSA dataset, the model was found to predict a consumer-evaluated grade (not satisfactory, three-, four-, or five-star) with an accuracy of between 50 and 70% and, if there was an error, the error was of the order of one grade. This allowed the model to be used as a grading tool, to provide feedback reporting to suppliers, and to be integrated with traceability and management systems. The MSA model for predicting eating quality is presently used to grade 2 million beef carcasses per year in Australia.

The Future of Meat Quality Modeling

The meat quality models developed to date have provided many benefits, in helping to predict meat quality attributes for the purposes of process design, in aiding understanding of the mechanisms that underlie those attributes, and in predicting consumer grades of meat with various characteristics. In the case of the MSA model for grading beef carcasses, which is used by the meat industry in Australia, the grading has resulted in increased returns to producers, processors, and retailers. These benefits will only be more important in the future as the understanding on which models are based and the need for quantitative predictions of product characteristics both increase over time.

Glossary

Combase A Combined dataBase for predictive microbiology

FSO Food Safety Objective, that is, the maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP).

GHP Good Hygienic Practice, refers to all practices which ensure that food is safe and suitable for consumption. GHP can be implemented at all stages of the food chain.

HACCP Hazard Analysis and Critical Control Points, is a systematic approach to food safety. Process steps, at which a food borne hazard would reach an unacceptable level, are identified and control measures/procedures for corrective actions implemented. In many countries, the compliance with HACCP principles is mandatory for businesses dealing with food of animal origin.

Model, deterministic A deterministic model will always produce the same output from a given starting condition or initial state.

Model, stochastic A stochastic process is a collection of random variables used to represent the evolution of some random value, or system, over time.

Monte Carlo simulation Monte Carlo methods are a class of computational algorithms that rely on repeated random sampling to compute their results.

Introduction

Contamination of food by pathogenic or spoilage bacteria is an important economic and public health issue worldwide. To estimate the risks of bacterial contamination of meat, it is necessary to know the bacterial responses (growth, survival, decay) in food matrices, and under food processing and storage conditions. Modeling of these microbial responses is based on the principle that growth or decay of microbial populations, even in the most complex organic commodities, is largely dependent on a few environmental factors only, such as temperature, pH, or availability of water, and growing bacterial cultures in adequately adjusted nutrient broths can be an appropriate *in vitro* simulation. Although, this is a more economical approach than testing artificially inoculated food, only a limited number of environmental conditions can be tested. When mathematical terms are employed to describe changes in microbial numbers as a response to the chosen factors, the responses can be interpolated. This allows the shelf life of food to be estimated and the microbial safety of novel product formulations to be assessed, and can be an integral part of safety assurance concepts.

The Need for Control of Microbial Activity in Meat and Meat Products

Both safety and shelf life of meat and meat products are strongly related to the presence and activity of microorganisms on, or in, these foods. Understanding of the dynamics of microbial populations in foods will allow the minimization of economic losses owing to food spoilage, but it is also a prerequisite to ensure equivalency in food safety in international trade. Changes in primary production (e.g., free-range animals), the preference for minimally processed foods with fewer preservatives (e.g., nitrite, sodium chloride), and different culinary preparation will influence the survival or growth of foodborne pathogens. Not only the exposure of consumers, but also the age distribution and immune status of the population may change, resulting in increased susceptibility.

Preventive Measures and Intervention Strategies

Three strategies are commonly used to improve and ensure the microbiological safety of meat and meat products:

1. Hygiene, i.e., prevention of microbial contamination, which increases shelf-life, but will not guarantee that a product is 100% free from pathogenic bacteria.
2. Antimicrobial treatment as a part of the production process (e.g., sterilization of cans, high-pressure processing) or as an 'additional treatment' (e.g., organic acids, irradiation). Such additional treatments are not allowed in all countries or for all food commodities.
3. Reduction of bacterial growth through control of the microbial environment (i.e., properties of the food and the conditions during processing and storage). These measures usually aim at generating suboptimal growth conditions.

Measures under (2) and (3) can be developed on a trial-and-error basis ('empirical'), which is rather expensive, inflexible (even minor changes in the process require a reassessment), and would ultimately mean that the assessment of safety would be based on testing the final product; however, even a large sample size cannot guarantee 100% safety.

The more scientific and economic approach is process-oriented, and in conformity with HACCP and risk assessment. Monitoring and control of the production process means control of the environmental conditions, and thus control of the growth and survival of contaminant microorganisms. This

 doi:10.1016/B978-0-12-384731-7.00070-2

is based on two assumptions: first, that growth or survival is understood to be a consistent response of bacteria to environmental conditions, and second, that the relatively complex food environment can be reduced to a small number of factors, for example, temperature, available water, and pH. The benefits of this approach not only include the knowledge of why specified conditions are safe, but also allow compensation for changes in one factor by readjusting others. It should hence be possible to predict safe conditions, and facilitate the development of new products.

Understanding of Microbial Dynamics in Muscle Foods

Description of Microbial Growth

Multiplication of microorganisms will occur only after a certain adaptation (lag) phase. This is followed by accelerated and then exponential growth (exponential phase, or log phase). When the nutrients are limited, a plateau – where multiplication and decay are in equilibrium – is observed (stationary phase), which is followed by a decrease in microbial cell numbers (see Figure 1). An important dynamic variable to define such a growth curve is the (instantaneous) specific growth rate $\mu(t)$, which is defined as the (instantaneous) change of population per unit time divided by the number of microorganisms at that time. When the population size is expressed as the natural logarithm (ln) of the number of cells and this is plotted against time, the specific rate represents the (instantaneous) slope of the growth curve. The most important parameters of these sigmoid growth curves are the maximum specific growth rate, the initial and final population size, and the lag period, which is commonly defined as the time when the tangent to the inflexion of the growth curve (the slope of which is the maximum specific growth rate, μ_{max}) intercepts the level of initial population size.

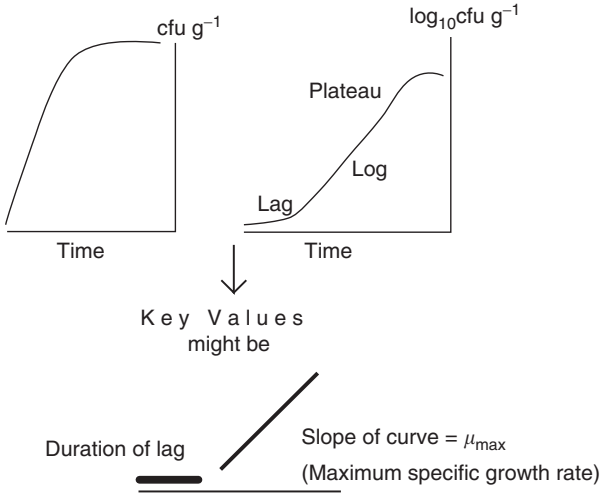

Figure 1 The microbial growth curve and derived key values. The upper-left diagram shows a typical 'growth curve', for example, generated from bacterial cultures grown in nutrient broth, where microbial numbers are plotted against time. Plotting the (natural) logarithms of the bacterial numbers against time will typically result in a sigmoid curve (see the upper-right diagram), which is composed of three distinct phases: a phase with practically no increase in bacterial numbers ('lag'), followed by a nearly linear increase ('log'), and then reduced multiplication ('plateau'). A tangent to the slope of the curve will represent the maximum multiplication rate. While the 'lag' represents the adaptation phase of the microbes to their 'new' environment, a plateau is only observed when the supply of nutrients is limited or microbial interactions reduce growth rate.

Microorganisms multiply by doubling, and, for a single cell, the time elapsed from birth to division is termed the 'generation time.' Although, this can be assessed by advanced image analysis systems, it is more common to specify the time a microbial population needs to double its numbers ('doubling time'). Whereas, the generation time has a frequency distribution in the microbial population, the doubling time is a single parameter meant as some sort of average value of the generation times of the single cells. This mean value is generally smaller than the arithmetical mean of the individual generation times, unless the cells divide synchronously.

Definition of Factors Controlling Microbial Growth

Factors influencing microbial growth in foods can be grouped as intrinsic (pH, water activity, structure), extrinsic (temperature, gaseous atmosphere), process-related (temperature regime, sterilization, chilling, high pressure), and implicit (properties of the bacteria of concern, microbial interactions).

Three approaches can be distinguished in studying the relative contributions of these factors to the production of safe and shelf-stable food products: first, the definition of growth boundaries; second, the qualitative description of time-intensity profiles of external factors constituting 'hurdles' for microbial growth; and finally, a quantitative approach, which results in mathematical models.

Growth boundaries

The range of temperature, pH, and water activity allowing growth is well known for a number of bacteria, and has been used for bacterial classification. Even with a very limited number of growth/no-growth observations, it is possible to set up tables like Table 1. This allows a quick assessment of risk/no-risk areas. Instead of a growth/no-growth criterion, decrease or increase limits in microbial numbers can be specified. For example, from these data it can be estimated that, at a temperature of 2 °C, a carbon dioxide content of 20% will

Table 1 Observations of growth/no-growth of a *Pseudomonas fragi* mixed culture (grown in Brain Heart infusion at pH 5.5, at various temperatures and with varying CO_2 content in the atmosphere). Own data

	100% CO_2	*50% CO_2*	*20% CO_2*	*Air*
20 °C	Ns	+(4.1)	+(2)	+(1.6)
10 °C	Ng	+(17.44)	+(6.1)	Ns
4 °C	Ng	+(45)	Ns	+(2)
2 °C	Ng	Ng	+(31)	+(6)

Ng, time to doubling >50 h; +, growth observed; doubling time in hours is given in brackets; Ns, condition not studied.

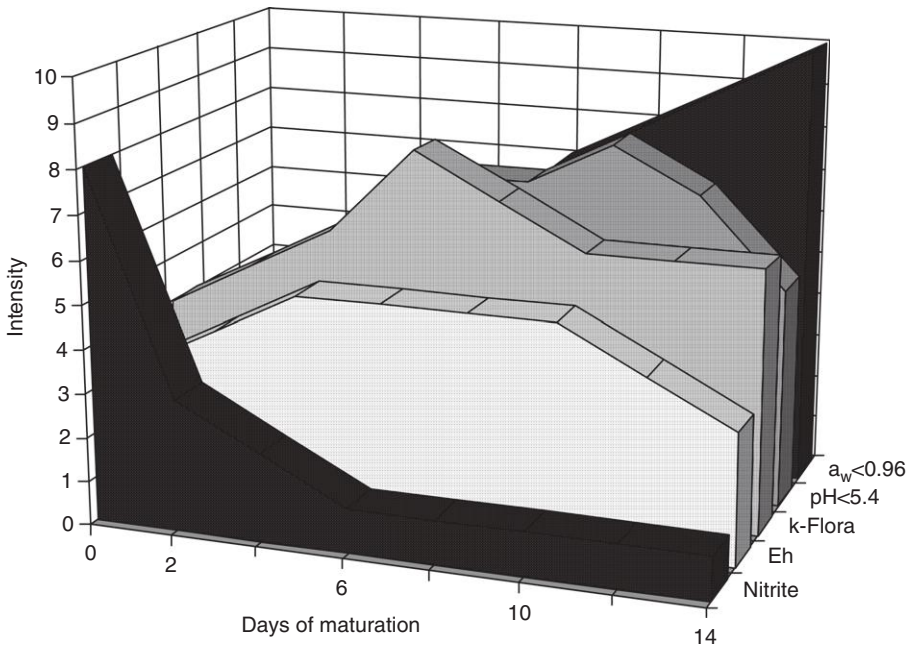

Figure 2 A time profile of the intensity of 'hurdles' during maturation of fermented sausage (a_w ... water activity; k-Flora ... , 'starter cultures'; Eh ... redox potential; Nitrite ... sodium nitrite added). This is a classical, but more qualitative, description of environmental factors influencing microbial growth. It clearly shows that there is a need for 'mathematical modeling' of microbial growth under varying, or fluctuating, conditions. Furthermore, the diagram raises the question as to whether these 'combined processes' are additive only or synergistic.

effectively retard *Pseudomonas* growth, allowing a mere doubling of numbers in 31 h.

Qualitative description

The intensity of the abovementioned intrinsic, extrinsic, etc. factors influences bacterial growth. Hence, it is possible to use a single factor for microbial control, with a lethal effect on microorganisms, as is the case for heat treatment in fully retorted canned food. However, such treatment may markedly affect the sensory and sometimes nutritional properties of foods and is not applicable to all types of meat products. A combination of two or more less intense control factors can function as one single 'effector'; fermentation and ripening of salami-type sausages is an often-cited example (Figure 2). Here a number of control factors or 'combined processes' with different time-intensity profiles interact, so that throughout the maturation period bacterial growth is controlled. This situation is more complex than the classical, original 'hurdle' concept.

Quantitative approach

Mathematical models are commonly classified as either empirical or mechanistic. The empirical, 'black box,' or descriptive approach aims to reproduce exactly particular data, while a mechanistic approach aims to identify the common structures behind various sets of observations. Thus, the term mathematical model is often explained not as a fixed (set of) formulae, but rather as an idea of how things might function. In the case of microbial growth, this is 'a set of basic hypotheses on microbial behavior.' In practice, a mixture of both approaches is used. Descriptive components are inflexible, as they represent a simple statistical representation of particular results and lack the ability to elucidate the underlying mechanisms. They must therefore be distinguished from 'real' models.

For some commodities, a few empirical data and quite simple mathematics will allow prediction of microbial activity. A classical example is thermal processing in the canning industry, which relies on mathematics for estimating the elimination of (spores of) the most infamous anaerobic organism, *Clostridium botulinum*. This is a typical empirical (statistical) approach. Notably, the decimal reduction time describes only one part of the microbial elimination curve; in practice a 'shoulder' is often observed before microbial cell numbers decrease in a log-linear way (Figure 3).

Another simple and straightforward example is a method for calculating the shelf-life of pasteurized milk (this concept can easily be applied to heat-treated meat products). The following assumptions are made: (1) a mere five spoilage bacteria are present in 1 l of milk ($=0.005\ ml^{-1}$ or $-2.3\ \log_{10}$ units ml^{-1}); (2) the standard deviation of microbial numbers is $s=0.4$ log cycles (per milliliter); (3) spoilage is observed at 7.5 $\log_{10}$ *Pseudomonas* sp. per milliliter of milk; (4) storage temperature is 4 °C; and finally (5) the doubling time for *Pseudomonas* sp. at this temperature is approximately 5.5 h. From these data, the difference between initial and final (spoilage) level is calculated to be 9.8 $(=7.5-(-2.3))$ $\log_{10}$ cycles. To reach a multiplication to the 9.8 $\log_{10}$ level, 32.5 doublings (i.e., $10^{9.8}\sim2^{32.5}$) of the initial five microorganisms are necessary. Consequently, the time to spoilage is 7.5 days ($32.5\times5.5=178.75$ h~7.5 days). Assuming there is a normal distribution, 95% of the initial contaminating flora are distributed in the range from 5 ± 2 times the standard deviation s,

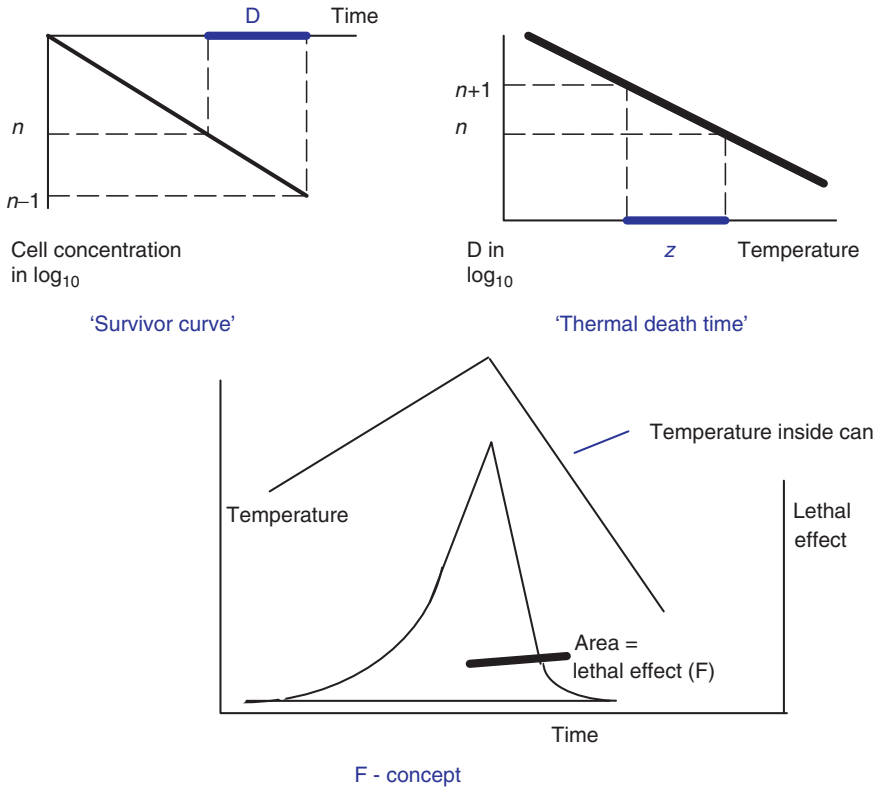

Figure 3 Model-building in thermally processed canned foods. Mathematical treatment of microbial processes became an issue in food canning technology around 1920. For practical purposes, a number of key values were derived: Decimal reduction time ('D'): In bacterial cultures exposed to 'lethal' temperatures at constant level, the reduction of the logarithm of viable cells per time will be nearly constant. The increase in temperature to effect a tenfold reduction in viable bacterial counts is termed 'z' value. However, these key values are not sufficient to estimate the total bactericidal effect during sterilization of cans, as the temperature inside the can varies with time (temperature rise – holding time – cooling). The lethal effect (F) is a sort of weighed time-temperature integral. This is a purely empirical, but effective, approach and implies some simplifications (e.g., during treatment with lethal temperatures, 'survivor curves' display an initial 'shoulder'). For pasteurization, similar mathematical treatment can be employed.

i.e., a range from 0 to approximately 31.5 microorganisms per liter ($= -1.5$ $\log_{10}$ units ml^{-1}) milk. As shelf life prediction should be set to this worst-case scenario, the difference between starting conditions and spoilage level is 9 ($=-7.5 - (-1.5)$] $\log_{10}$ units, which corresponds to approximately 30 doublings. For 30 doublings, 164 h, i.e., 6.8 days, are needed to reach spoilage levels.

Similar calculations for the spoilage of fish have been presented. It has been shown that the rate of growth (R) of spoilage bacteria at a given temperature t as compared to 0 °C can be expressed as $R=(1-0.1t)^2$. This simple equation represents a quantitative description of the well-known fact that a decrease in temperature rapidly reduces spoilage rate.

It should be noted that all the three examples mentioned above focus on one extrinsic or process factor. However, the problems faced by the meat industry are usually far more complex.

Variation of key factors

Given that there are tools available to describe microbial growth and key factors have been defined, it is feasible to create sets of data describing the different microbial response when a few well-defined key factors are varied.

Typically, a defined concentration of bacteria is inoculated in a series of adjusted nutrient broths, and during incubation at defined temperatures and atmospheric composition, concentrations of viable cells are determined by various methods. To these growth curve data, sigmoidal curves are fitted. This can be performed conveniently using computer software, and will result in a number of mathematical functions ('primary models'). The next step is to describe how the fitted parameters of each curve are affected by the various controlling factors. For this purpose, each curve is represented by a few parameters, most notably the maximum specific growth rate. This key value is plotted against the conditions under study, such as pH, sodium chloride content, and temperature, resulting in a response surface ('secondary model', see **Figure 4**). Often, polynomial functions of second order (i.e., quadratic) have been applied successfully.

From these functions, predictions of microbial behavior can be made and subsequently compared with independently acquired data, for example, those available from the literature. If this validation step is successful, one may consider applying the model to real situations. Ideally, the predictions from the simple model are accurate, i.e., they match observations from complex real food matrices. However, a systematic inaccurate overprediction often tends to give 'safe-side' results, which is

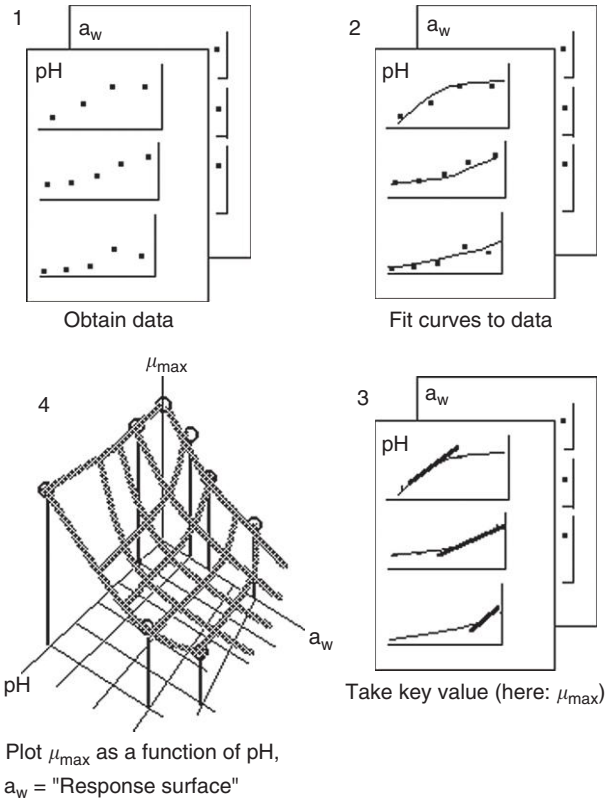

Figure 4 From growth curves to 'response surfaces.' Bacterial cultures are grown in parallel in a number of nutrient broths adjusted to different environmental conditions (pH, water activity, incubation temperature, atmosphere, etc.), and the bacterial numbers are plotted against time, with each data set representing the bacterial response to an individual environmental situation. To these data sets, a mathematical function is fitted (software packs are available for this purpose), from which key values can be derived (see also **Figure 1**). These key values can be plotted against the experimental conditions varied in the nutrient media (in this case, pH, and water activity). To these individual data points, a mathematical function can be fitted resulting in a 'response surface.' Thus, within the range of experimental conditions studied, it is possible to interpolate, for example, the μ_{max}, and to 'predict' microbial behavior for specific conditions that originally were not studied. Such response surfaces can be generated even from a very limited number of microbial experiments.

entirely acceptable, especially where pathogenic bacteria are concerned, for instance, growth rate in solid foods being lower than predicted by a model derived from experiments in nutrient broth, which is usually the case.

This analysis implies that first those variables need to be defined by which the food and microorganism under study can be described (e.g., temperature, pH, water activity, etc.). When these fall within the range of the model, it should be possible to predict situations where a risk of microbial activity may occur. Obviously, a great number of potential combinations of different growth conditions prevail under industrial circumstances. However, the availability of a model now enables us to focus attention on a significantly reduced number of conditions, i.e., those most likely to occur in practice. Only these have to be investigated via challenge tests. This approach reduces analytical effort considerably.

In addition to the logarithmic (exponential) phase of microbial growth, the relationship between lag time and fluctuations of environmental conditions, such as changes in temperature, may be of importance, as microorganisms react to these with an adaptation phase, during which metabolic or structural changes take place and multiplication is suspended. Changes in meat production and processing environment are mostly temperature changes. The mathematical description of the inactivation of microorganisms as a response to environmental conditions has been an issue in the canning industry for more than 80 years.

Limitations and Challenges

Mechanistic models are, by nature, a scientifically based, simplified, but versatile description of how, in our case, bacteria respond to various environmental conditions or changes thereof. Small discrepancies between observed and predicted results are inevitable; these discrepancies are termed 'errors.' Each step of model generation will contribute to these 'errors.'

The mathematical procedures will introduce numerical procedure errors. Simplifications of and assumptions about microbial behavior (for instance, assuming a homogeneous bacterial population and disregarding the natural biological variance) lead to homogeneity errors. For instance, different strains of the same bacterial species may respond quite differently to environmental conditions (intraspecies variability). In part, this can be explained by a different 'history' of the isolates, which will consequently influence the adaptation phase, but differences in the maximum specific growth rate have also been reported, for example, for *Listeria* and *Yersinia*. This is usually compensated when a mix of several strains is used for growth rate determination. The behavior of small numbers of cells is an issue when survival of low-infective dose pathogens (e.g., *Escherichia coli* O157:H7) has to be evaluated. When it comes to describing the behavior at an individual cell level, 'quantal microbiology' has been created, analogous to quantum mechanics in physics. By the same token, the mathematical concepts can be extended to a molecular biology level, i.e., modeling the expression of genes as a response to environmental factors.

Modeling on the basis of a few environmental key factors only necessarily implies incompleteness, and therefore results in completeness errors. The key factors have to be chosen in an appropriate way. Thus, when water activity is under study, the results depend not only on the final water activity, but also on the type of humectant (sodium chloride or carbohydrates).

Mathematical modeling of microbial growth and inactivation is still 'work in progress.' In particular, modeling of the food chain requires that fluctuating environmental conditions (e.g., temperature) and stochastic elements, as distributions of initial cell numbers, temperatures, etc. are considered. Monte Carlo simulations have been used for this purpose. For practical assessment of shelf life, time–temperature integrators have proven useful. Another issue is

that low cell concentrations and growth/survival near to the growth boundaries have not been sufficiently studied for all relevant bacteria.

Mathematical models as outlined above has become an indispensable tool in qualitative as well as quantitative microbial risk assessment, and the development of food safety objectives. Knowledge on extent and probability of changes in microbial numbers in the food chain is also an essential part of risk-ranking software.

Databases and User-Friendly Predictive Software Packages

Currently, a number of predictive software packages are available not only for use by food scientists, but also industry and food safety authorities. These include, but are not limited to, the 'Seafood Spoilage Predictor' of the Danish Institute for Fisheries Research (http://dtuaqua.dk), the Pathogen Modeling Program of the US Department of Agriculture (USDA) (http://www.ars.usda.gov/Services/docs.htmdocid=6786), the Growth Predictor and Perfringens Predictor of the Institute of Food Research (IFR) (UK) (http://www.ifr.ac.uk/Safety/GrowthPredictor/), Sym'Previus of the French ADRIA Developement company, France (http://www.symprevius.net/), and, finally, ComBase (http://www.combase.cc/). The latter software originated as a combination of the Pathogen Modeling Program of the USDA and the Food Micro Model from the UK. The Combase package (freely accesible on the internet or delivered as a stand-alone version) consists of a database containing >50 000 growth curves with detailed description of bacteria and experimental conditions; the database is regularly updated. Data sets can be filtered and retrieved by a built-in browser and growth curves can be fitted to selected data sets; in addition, growth prediction tools and tutorials are available.

Glossary

Half-cooling time The time taken for the temperature of an object to drop from its initial temperature to a temperature half way between its initial and its ultimate temperature, which will be the temperature of its surrounding environment.

Introduction

Many factors affect the quality and safety of a meat product, but perhaps the most important single factor is a meat product's temperature profile over time, because of its direct and indirect effects on many of the other factors. Reducing the product's temperature, through refrigeration, has an important impact on the rates of microbial growth, enzymatic action, pH fall, and aging, among other factors, making the ability to predict and control meat temperature critical to the success of any high-quality meat processing operation.

The prediction of temperature change (for instance), whether in an existing process or in a new process to be designed, is one purpose of modeling. Another, perhaps more important, purpose of modeling is to aid the scientist or technologist in understanding the complex physical and biochemical processes that take place during meat processing, storage, and transport. Either of these purposes would be sufficient in its own right for modeling to become a key technique in the development of modern meat science.

The process of developing any model of a refrigeration process will commence with the fundamental principles of refrigeration described elsewhere in this encyclopedia. From there, the development path to a practical and useful model will depend on:

- the purpose for which the model is to be used, and hence, the outputs that are required;
- the accuracy of prediction required for those outputs;
- the scope of the model, in terms of time (the periods of the process that are of interest) and space (the distance away from the meat product that the model should include) – both of which have a substantial influence on the amount of effort required to develop the model; and
- the data available for model input, and to validate the model's accuracy.

There are many components in a refrigeration system and models have been developed for every component (see Further Reading), but this article focuses on models of the meat products, grouped by the boundaries of each model component in both space and time.

Model Boundaries

Three possible sets of model boundaries are shown in Figure 1. The individual component models, for example, the meat product or refrigerant evaporator models, have the tightest boundaries. The next set of boundaries group the models that estimate the thermal load on the refrigeration system (i.e., the heat that the refrigeration system must remove from the refrigerated space per unit of time) into a group of 'application models' and those that describe the refrigeration system itself into a group of 'refrigeration plant models.' The largest boundary in Figure 1 encompasses the application and refrigeration plant models to form an overall 'meat refrigeration facility model.' These three spatial sets of boundaries may be perceived as natural ways to divide the problem, but they are far from being the only ways. For some purposes, it may be necessary to model only a small part of the meat product (e.g., the loin of a lamb carcass), and thus the entire model would lie inside the 'cooling meat product' component shown in Figure 1. For other purposes, it may be necessary to model many processing plants together (e.g., to predict the total meat production or energy consumption of the entire industry), in which case even the outer boundary shown in Figure 1 would only be a small part of the whole model.

Figure 2 shows some ways in which models could be categorized along the time dimension. Depending on the purpose of the model, one could choose to examine the process with a greater or lesser granularity in time, as shown in the Figure 2. The granularity of a model in the time dimension is determined by the interval between model outputs.

In some cases, a very fine resolution is required, so that one can examine changes that occur over periods of seconds or minutes, such as moisture loss through evaporation or moisture uptake during spray-chilling. In other cases it may be important to model longer time intervals, such as chilled storage and transport, with a longer model output interval to predict (for instance) the slow aging of meat during transport, or the growth of anaerobic microorganisms.

The effort required to construct and validate a model and the amount of input data required to execute the model increase in rough proportion to the number of individual model components and the total number of model output intervals to be observed. This means that it is important to restrict the model scope in both space and time so that the effort required of the model developer and user is acceptable and realistic compared to the benefits to be gained from the model.

Much of a model's value results from the fact that the model is much simpler to understand than the real object or process that it represents. In a successful model, this simplification results from model developer's choices to exclude those parts of

 doi:10.1016/B978-0-12-384731-7.00071-4

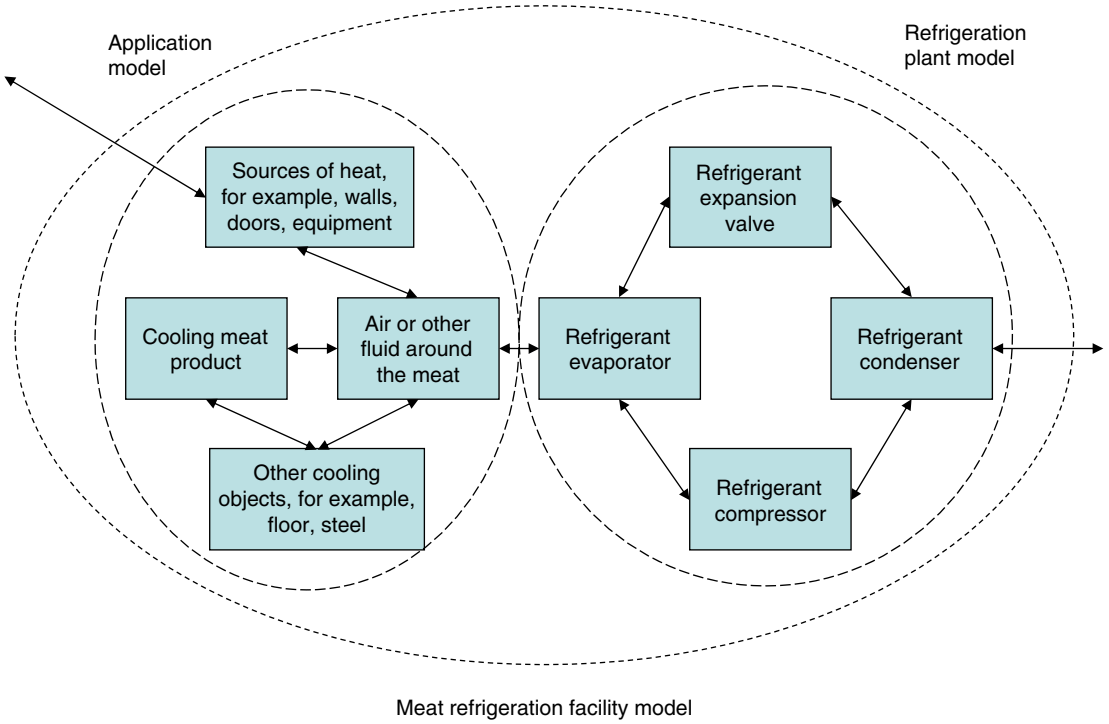

Figure 1 Conceptual division of a meat refrigeration model into an application model and a refrigeration plant model, and then into component models. Only one example of each component type is shown, though in most cases there would usually be many components of each type.

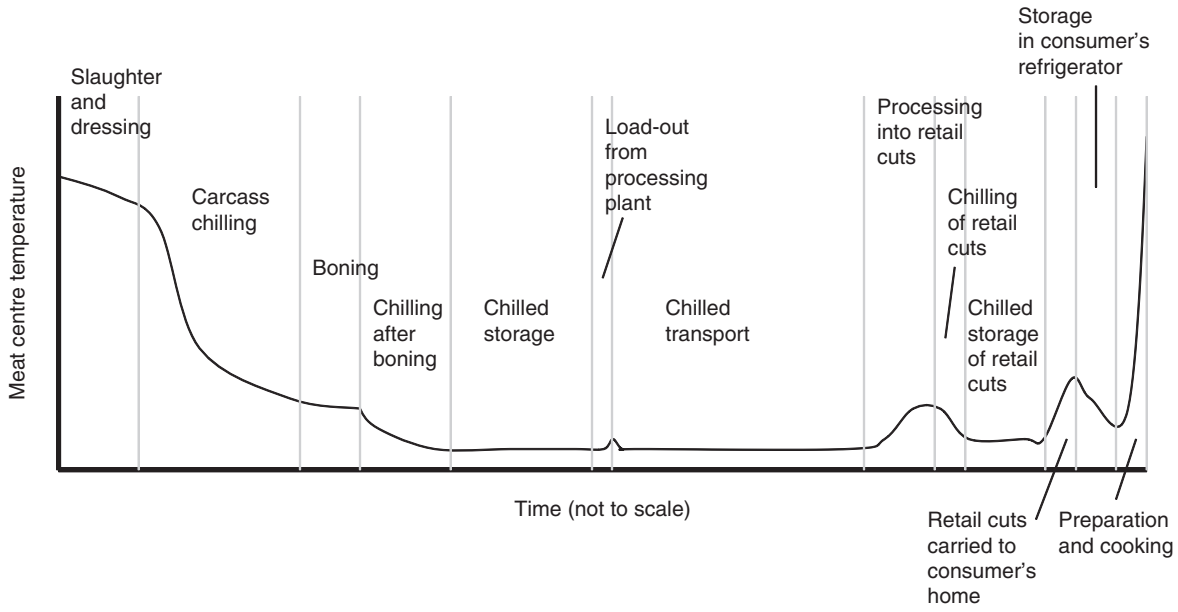

Figure 2 Conceptual division of a meat refrigeration model into components along the time dimension for a chilled meat process.

the real world that have little effect on the outputs of interest, or to include some parts only as averages or approximations.

For these reasons, scientists and engineers have developed many different models of meat refrigeration and its related processes, designed to gain insight into different aspects of the process, or to predict different outputs with more or less accuracy and, hence, effort required. Some of these models, or classes of models, are described in this article. Others can be found in the Further Reading section.

Meat Product Chilling and Freezing Times

Perhaps the simplest useful model of meat product chilling and freezing is the 'lumped-parameter' model, based on

Newton's law of cooling, which can be written as shown in eqn [1].

$$\frac{dT}{dt} = \frac{hA}{VC}(T_a - T) \quad [1]$$

where T, is the temperature of the meat product, °C; t, is time, s; h, is the heat transfer coefficient between the meat product and its surroundings, W m^{-2}K; A, is the surface area of the meat product, m^2; V, is the volume of the meat product, m^3; C, is the specific heat capacity of the meat product, J m^{-3}K; and T_a, is the temperature of the meat product's surroundings, °C.

This model has the advantage of a straightforward analytical solution for T in terms of t, if the other parameters are constant with time and temperature. If the other parameters change over time, this equation can be solved numerically. However, the model predicts only a single temperature for the meat product at any given time because it assumes that the temperature throughout the product is uniform. The validity of this assumption can be assessed by the value of the Biot modulus, Bi, shown in eqn [2].

$$\text{Bi} = \frac{h(V/A)}{k} \quad [2]$$

where k, is the thermal conductivity of the unfrozen meat product, W mK^{-1}.

A low value of Bi indicates that the relative resistance to heat transfer within the cooling object is low (and the rate of cooling is therefore controlled by the rate of convective heat transfer at the surface), whereas a high Bi value indicates that the relative resistance within the object is high (and the rate of cooling is therefore controlled by the rate of conduction through the object). If Bi is less than 0.1, it is often assumed that the lumped-parameter model is adequate; however, for larger values of Bi, a more sophisticated model is required to obtain reasonable accuracy.

The rate at which a meat product cools when conduction within the meat is important is defined by the Fourier equation, a partial differential equation describing the conservation of energy. For some cases, this equation can be solved analytically to predict how the temperature varies at any location in a cooling object; however, the analytical solutions only apply to objects with simple shapes, for example, an infinitely wide and long slab, an infinitely long cylinder, a sphere, or an infinitely long rod-like shape. Further, with a few exceptions, an analytical solution of the Fourier equation cannot be obtained in cases where the thermal conductivity and heat capacity of the object change significantly with temperature, as is the case for any meat product during freezing and for most cases where the conditions external to the cooling object change over time.

Although the Fourier equation is difficult to solve analytically for complex geometries and changing properties and conditions, there are several alternative modeling approaches that have simplified the problem by increasing the spatial and time resolution of the model. In terms of spatial resolution, if the object is not considered as a whole, but as many thin slices, elements, or volumes, each with a relatively simple shape, then this can make it possible to solve the Fourier equation for each of the slices, elements, or volumes (see Figure 3). Similarly, in terms of time resolution, the whole process can be divided into small intervals and each interval can be considered individually. In that case, it might be assumed that the temperature (and hence the temperature-dependent thermal properties) in each part of the object will not change significantly during an interval, or it might change according to a simple (e.g., linear) relationship with time, again making it possible to solve the Fourier equation for each time interval.

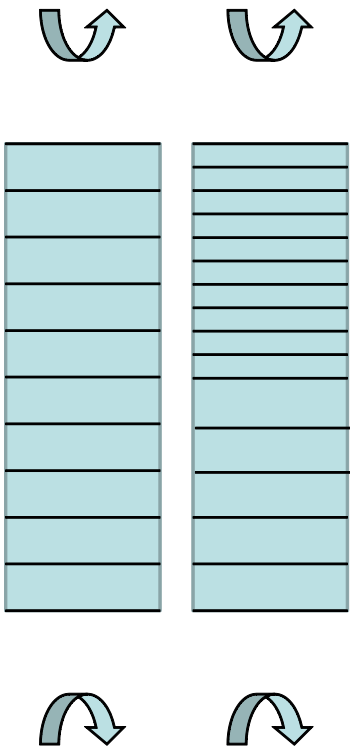

Figure 3 Two different ways of dividing a model of a slab-shaped meat product into slices so that Fourier's equation can be solved for each slice, with convective cooling at the top and bottom. The diagram on the left shows the model divided into equal-width slices, whereas the diagram on the right has thinner slices at the top to increase the accuracy of the computation at that end.

This type of reasoning has led to the development of many alternative models that can be applied to cooling meat products, of which the most popular have been the finite difference and finite element methods. If moisture diffusion is being considered as well as heat transfer, it may be necessary to use separate grids for heat and moisture transfer. Where modeling extends to the flow of fluid around the meat product, it may also be necessary to use computational fluid dynamics to evaluate fluid flow directions and velocities. These methods must generally be implemented in the form of computer software, and it is recommended that persons wishing to use them purchase or hire the use of specialist packages unless they have considerable time and effort to dedicate to the implementation. Even given the right computer software, the amount of data required to define complex meat product shapes for input to finite element software can be considerable and the amount of time required to collect the data can be substantial, especially if the modeling is to be carried out in all three spatial

dimensions. However, developments in the collection of three-dimensional shape data have made this task considerably easier.

In many cases, some simplification of the meat product shape is an acceptable compromise and this has led to the development of meat product cooling models that deal (approximately) with the whole meat product at once. These models can sometimes be solved analytically if the thermal properties and conditions do not change with temperature or time during the process. Alternatively, they can be evaluated with changing thermal properties and conditions by expressing them as ordinary differential equations (ODEs) and then dividing the process into short time intervals to solve the equations numerically. In either case, it is often satisfactory to use a single shape factor that adjusts the predicted chilling or freezing time upwards or downwards with respect to the freezing time of a reference shape with the same thermal properties as the meat product. One commonly used shape factor is the equivalent heat transfer dimensionality, E, developed by Cleland and Earle, which is dependent on both the shape and the Biot number. The Biot number dependence of E is complex but eqn [3] is a satisfactory definition at $\mathrm{Bi}=0$:

$$E=\frac{SX}{V},\quad \text{at}\quad \mathrm{Bi}=0 \qquad [3]$$

where X, is the radius, or half-thickness of the object, m.

The value of E varies between 1 and 3, with $E=1$ for an infinitely wide and long slab, $E=2$ for an infinitely long cylinder, and $E=3$ for a sphere at all values of Bi. For beef sides, a typical E value is approximately 1.3, for lamb legs $E\approx 2.1$, and for boxes of various shapes E might range from 1.2 to 1.5.

For chilling time, a popular model is that of Cleland and Earle, which can be expressed as shown in eqns [4] or [5].

$$\mathrm{Fo}_{1/2}=\frac{\mathrm{Fo}_{1/2,\mathrm{slab}}}{E},\ \text{for flat-sided objects (e.g., boxes)} \qquad [4]$$

$$\mathrm{Fo}_{1/2}=\frac{3\mathrm{Fo}_{1/2,\mathrm{sphere}}}{E},\ \text{for oval-shaped objects (e.g., carcasses)} \qquad [5]$$

where $\mathrm{Fo}_{1/2}$, is the half-cooling Fourier number (dimensionless time) for an irregularly shaped object, or a slab or sphere as indicated by the subscript.

The Fourier number is defined by eqn [6].

$$\mathrm{Fo}=\frac{kt}{CX^2} \qquad [6]$$

Because the rate of temperature change for an object exposed to constant external conditions follows an exponential function over time (after an initial time lag if the temperature of interest is that at the center of the object rather than the surface or mass average), the shape of that exponential can be defined by the time required for the temperature to fall half of the way from its initial value to its final value. This time is known as the half-cooling time, and the Fourier number calculated for the half-cooling time is known as the half-cooling Fourier number. The half-cooling Fourier number for a slab or sphere depends only on the Biot number. Values of $\mathrm{Fo}_{1/2}$ for a range of Biot numbers were tabulated by Cleland and Earle, or $\mathrm{Fo}_{1/2}$ could be calculated from the analytical solutions to the one-dimensional Fourier equation reported by Carslaw and Jaeger (see Further Reading). The fraction unaccomplished temperature change at the end of the chilling process, Y_{final}, is defined by eqn [7]:

$$Y_{\mathrm{final}}=\frac{T_{\mathrm{final}}-T_{\mathrm{a}}}{T_{\mathrm{initial}}-T_{\mathrm{a}}} \qquad [7]$$

where T_{initial} and T_{final}, are the initial and final product temperatures, °C.

The number of half-cooling times, $N_{1/2}$, required to chill the product to its final temperature can be calculated from eqn [8], unless the defined final temperature is at the center of the product, when the initial lag must be added:

$$N_{1/2}=\frac{-\ln(Y_{\mathrm{final}})}{\ln(2)} \qquad [8]$$

Equation [9] can then be used to calculate the total chilling time:

$$t_{\mathrm{c}}=N_{1/2}t_{1/2} \qquad [9]$$

where t_{c}, is the chilling time, s.

For freezing time, the model of Pham is both relatively accurate and convenient to use. Pham's model enhanced the converging freezing model described by Plank in 1941 (see Figure 4) by correcting Plank's assumption of a sharp freezing front and including the sensible heat content (i.e., the heat content removed as the product temperature is reduced) both above and below the freezing temperature, as well as the latent heat that is removed during ice crystal formation. Pham's model can be expressed as shown in eqn [5]

$$t_{\mathrm{f}}=\frac{1}{E}\left(\frac{\Delta H_1}{\Delta T_1}+\frac{\Delta H_2}{\Delta T_2}\right)\left(\frac{X}{h}+\frac{X^2}{2k_f}\right) \qquad [10]$$

where t_{f}, is the freezing time, s; ΔT_1, ΔT_2, are the temperature driving forces during chilling (1) and freezing (2), °C; ΔH_1, ΔH_2, are the enthalpy changes during chilling (1) and freezing (2), J m^{-3}; and k_{f}, is the thermal conductivity of the frozen meat product, W mK^{-1}.

The temperature driving forces and enthalpy changes were calculated based on the mean freezing temperature, T_{fm}, as shown in eqns [11–15].

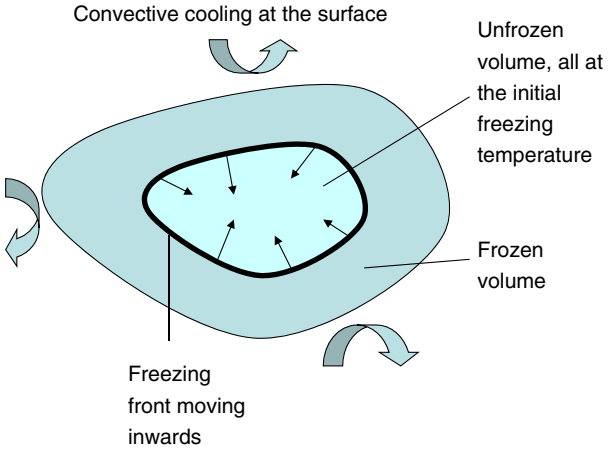

Figure 4 Plank's conceptual model of the freezing process, on which many freezing models are based.

$$T_{fm} = 1.8\ ^{\circ}C + 0.263T_c + 0.105T_a \quad [11]$$

$$\Delta T_1 = (T_{initial} + T_{fm})/2 - T_a \quad [12]$$

$$\Delta T_2 = T_{fm} - T_a \quad [13]$$

$$\Delta H_1 = C_u(T_{initial} - T_{fm}) \quad [14]$$

$$\Delta H_2 = L + C_s(T_{fm} - T_c) \quad [15]$$

where T_c, is the final center temperature, °C; C_u and C_s, are the specific heat capacities of the unfrozen and frozen product, J m^{-3}K; and L, is the latent heat capacity of the product, J m^{-3}.

These simplified methods for chilling and freezing time calculation can be expected to be accurate within ±10% of the chilling or freezing time, respectively, with 90% confidence.

Meat Product Chilling and Freezing Heat Loads

Models to predict chilling and freezing times produce a single value as an output – the time required to chill or freeze. When modeling the cooling of a meat product to predict the heat load that a product will place on the refrigeration system over time, however, these single values are not sufficient. In principle, the heat load of a chilling or freezing product can be derived from eqn [16].

$$\dot{Q} = hA(T_{surf} - T_a) \quad [16]$$

where $\dot{Q}$, is the heat load (or heat flux), W; and T_{surf}, is the surface temperature of the product at any given moment in time, °C.

Because T_{surf} varies during the course of the process, so does $\dot{Q}$, and models that predict the surface temperature of the product (such as the finite difference and finite element models described above, which predict temperatures throughout the product at each output interval) can therefore be used with eqn [16] to predict the heat flux. When another type of model has been used to calculate the cooling time, the mean heat load for a chilling process, $\dot{Q}_{mean}$, can be calculated from eqn [17].

$$\dot{Q}_{mean} = \frac{\Delta H_{process}}{t_c} \quad [17]$$

where $\Delta H_{process}$, is the amount of heat released as the product cools from $T_{initial}$ to T_{final}, J.

The variation in heat load during chilling can be modeled approximately by using the half-cooling time calculated by the method of Cleland and Earle, because one can calculate the mean heat load during the jth half-cooling period, Q_j, using eqn [18].

$$\dot{Q}_j = \frac{\Delta H_{total}}{2^j t_{1/2}} \quad [18]$$

where ΔH_{total}, is the total amount of heat that would be released if the product were cooled from $T_{initial}$ to T_a, J.

The differential equation model for the chilling heat load described by Lovatt *et al.* as shown in eqn [19] can be solved to provide a smooth curve of heat load versus time and allow for time-variable chilling conditions.

$$\frac{dH}{dt} = \frac{E}{3}\frac{V\beta_1^2 k}{X^2}(T_a - T_{ma}) \quad [19]$$

where H, is the specific enthalpy of the product, J m^{-3}; and β_1, is the first root of the equation $\beta \cot \beta + (\mathrm{Bi} - 1) = 0$. This bases the equation on the average product temperature instead of the surface temperature used in eqn [16]; T_{ma}, is the average temperature of the meat product, defined by $T_{ma} = \frac{H - H_f}{C} + T_f$ where H_f, is the specific enthalpy of the product at its initial freezing temperature, J m^{-3}; T_f, is the initial freezing temperature of the product, °C.

A similar model can be used to predict the heat load during the freezing process, using a modification of the converging freezing front concept developed by Plank. This model is shown in eqns [20] and [21]. Although the freezing time depends only on the time required for the slowest cooling point to freeze, the freezing heat load depends strongly on the overall shape of the meat product. As a result, this heat load model requires an additional shape factor, N, to define the way in which the volume of the frozen region, V, changes with the position of the freezing front, x_f.

$$\frac{dx_f}{dt} = \frac{T_a - T_{ma}}{L x_f^{E-1}\left[\frac{1}{hX^{E-1}} - \frac{\left(x_f^{2-E} - X^{2-E}\right)}{k_f(2-E)}\right]} \quad [20]$$

$$\frac{dV}{dx_f} = N\left(\frac{x_f}{X}\right)^{N-1}\frac{V}{X} \quad [21]$$

$$\frac{dH}{dt} = L\frac{dx_f}{dt}\frac{dV}{dx_f} \quad [22]$$

where L is the latent heat of freezing, defined by $L = H_f - C_f(T_f - T_{base})$ if freezing is assumed to start when T_{ma} is approximately equal to T_f, J m^{-3}; T_{ma} is the average product temperature, calculated from a suitable function that relates that average temperature to its enthalpy, °C; C_f, is the heat capacity of the frozen product, J m^{-3}K; and T_{base}, is the temperature at which H is defined to be zero, °C.

When chilling and freezing are described by separate ODEs, any freezing process that starts with the product being warmer than its initial freezing temperature is modeled initially as a chilling process (e.g., using eqn [19]), and then as a freezing process (e.g., using eqns [20–22]) once the surface actually starts to freeze. Criteria to determine when it is best to make the transition from the chilling model to the freezing model have been suggested in the literature, but they will not be discussed further here (see the Further Reading section).

Because they conceptually divide the meat product into small pieces, and model the behavior of each piece during each time interval, numerical models based on the finite difference or finite element methods (for instance) can predict heat loads and temperature profiles through the product with almost all combinations of external conditions that one

could envisage. In contrast, the ODE models described in eqns [19–22] assume that the temperature profile through a chilling product conforms to a consistent shape, or that the frozen volume of a freezing product can be defined by a single parameter – the position of the freezing front. As a result, one can easily define circumstances where the ODE models described here will predict heat loads poorly – for example, if the air temperature varied so much that it rose above the average product temperature, and thus the product started to warm up during part of the process. This highlights the importance of choosing a model that is simple enough to understand and evaluate, but not so simple that it fails to represent an important aspect of the process. Fortunately, the circumstances in which ODE models are unsatisfactory rarely occur in practical meat processing operations, with the result that ODE models are often used to design new industrial refrigeration systems and to evaluate the performance of existing systems.

MUSCLE FIBER TYPES AND MEAT QUALITY

T Astruc, INRA de Clermont-Ferrand-Theix, Saint Genès Champanelle, France

This article is a revision of the previous edition article by RG Taylor, volume 2, pp 876–882, © 2004 Elsevier Ltd.

Glossary

Adenosine triphosphatase (ATPase) Enzyme that catalyzes the hydrolysis of ATP to ADP, releasing energy that is used in the cell.
Muscle fiber Elongated muscle cells.
Myofibril Slender striated strand within skeletal muscle fibers, composed of bundles of myofilaments. Myofibrils occur in groups of branching threads running parallel to the cellular long axis of the fiber.
Myosin The commonest protein in muscle cells, forming thick filaments. Myosins are composed of one or two heavy chains and usually four light chains. Myosin and the protein actin form the contractile units (sarcomeres) of skeletal muscle. In the sarcomere, actin and myosin filaments slide past each other to cause the shortening of a muscle fiber.
Myosin heavy chain isoforms (MyHC isoforms) Heavy chains of myosin molecules with differences in several amino acid compositions.

Introduction

Skeletal muscle is essentially composed of muscle cells colloquially called 'muscle fibers' due to their elongated shape. Their diameter ranges from 10 to 100 μm, yet they can measure from a few mm to several cm in length. These muscle fibers are ensheathed in connective tissue (endomysium) and packed into fascicle groups of several dozen cells ensheathed in another layer of connective tissue (perimysium) to form fiber bundles.

Muscle fibers account for up to 90% of muscle volume. Muscle fibers share similar shape and appearance, but they are actually very different. Adult mammal muscle has four types of muscle fibers, called type I, type IIA, type IIX, and type IIB, which vary in terms of muscle metabolism and contractile speed. Muscles generally comprise various proportions of each muscle fiber type depending on the muscle's function.

Postmortem changes and the changes occurring during transformation processes also vary according to muscle fiber type composition, impacting meat, and meat product quality.

Muscle Fiber – General Structure and Composition

Muscle fibers contain alternating light and dark bands that give skeletal muscle its striated appearance. The muscle fiber is an elongated, spindle-shaped cylindrical filament measuring 10–100 μm in diameter but up to several centimeters long. Each fiber contains an outer shell packed with nuclei and is coated with a plasma membrane called the sarcolemma.

The sarcoplasm (muscle cell cytoplasm) houses the cellular organelles (Golgi apparatus, mitochondria, lysosomes, ribosomes, etc.) and the sarcoplasmic reticulum. It contains a medley of soluble proteins including glycolytic enzymes and the myoglobin that carries oxygen to the mitochondria and gives the cells a reddish pigmentation. It also hosts glycogen granules, which are the muscle cell's main energy store. The sarcoplasm also contains myofibrils measuring just 1–2 μm in diameter and which are arranged into bundles that fill almost all the intracellular volume (Figure 1).

These myofibrils are built from an assemblage of thin and thick myofilaments. The thin myofilaments are essentially composed of actin, troponin, and tropomyosin proteins.

The thick myofilaments are mainly composed of a complex of myosin molecules built of:

- four myosin light chains (MyLC; 20 000 g mol^{-1}) and
- two myosin heavy chains (MyHC; 230 000 g mol^{-1}), where the myosin heads host the adenosine triphosphatase (ATPase) activity that catalyzes the breakdown of ATP into adenosine diphosphate, thus releasing the chemical energy needed for muscle contraction.

Four different isoforms of MyHC have so far been identified, namely I, IIa, IIb, and IIx. These four isoforms are used to characterize not only the four main pure muscle fiber types – I, IIA, IIX, and IIB – but also hybrid fiber types containing several myosin isoforms, such as type I–IIA, type IIA–IIX, or type IIX–IIB fibers. These hybrid fibers are fibers whose properties are in the process of changing from a pure type into another type, driven by a change in age, physical activity levels, or exposure to prolonged stress. The type modification always follows the order I→I–IIA→IIA→IIA–IIX→IIX→IIX–IIB→IIB and back in reverse.

(a) ATPase activity has been demonstrated by histoenzymology after section preincubation at pH 4.45. Fiber I: black, fiber IIA: white, and fiber IIB and IIX: gray. (b, c, d) Double labeling of laminin (orange) and MyHC: green by immunohistofluorescence. (b) BAD5 antibody labeling MyHC I myosin isoform (fibers I). (c) BF35 antibody labeling MyHC I + MyHCIIa myosin isoforms (fiber I + fiber IIA). (d) SC71 antibody labeling MyHC IIa (intense) and MyHC IIx (fibers IIA and IIX). (e) Image recombined accurately identifying each fiber type. The immunohistofluorescence is heavier to implement, but unlike the histoenzymology method, it allows to discriminate the IIX fibers from the IIB fibers and hybrid fibers containing mainly two isoforms.

Muscle Fibers – Characteristics

The four main muscle fiber types found in adult mammal skeletal muscle present different sets of characteristics, as listed below.

- Type I: Slow twitch, red, oxidative metabolism. These fibers are specialized for endurance activities such as maintaining posture. The neurons fire at low frequency, the fibers contract relatively slowly, and myosin ATPase activity is low. The fibers are dense with lipids, mitochondria, and myoglobin. Type I are the smallest-sized fibers.
- Type IIA: Fast twitch, intermediate metabolism. These fibers have high myosin ATPase activity, can use both oxidative and glycolytic metabolism, and are dense with mitochondria and myoglobin. They are solicited for rapid-movement activity but are less fatigue resistant than type I.
- Type IIB and IIX: Fast twitch, white, glycolytic metabolism. These fibers are dominantly force generating, are mobilized for activities such as sprinting or weightlifting that

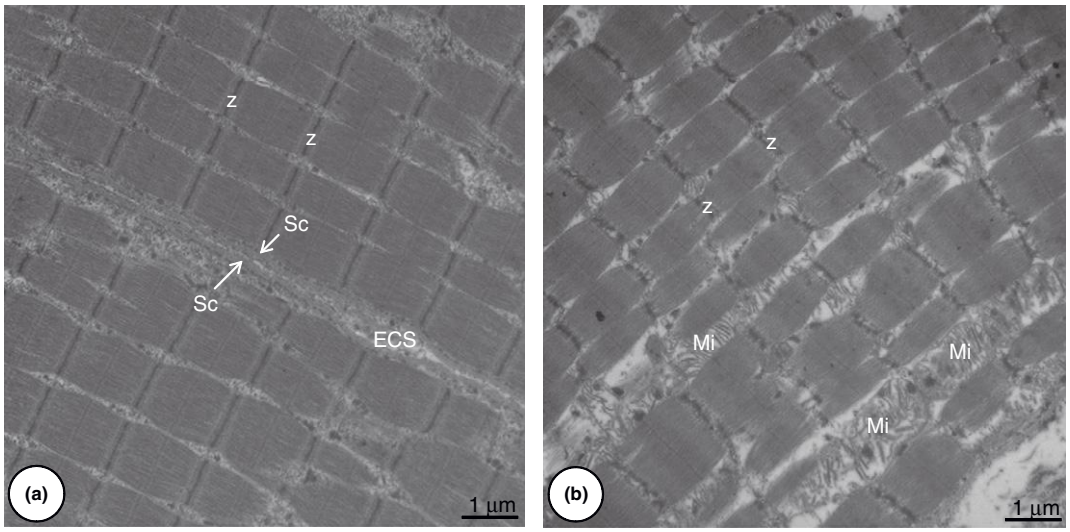

Figure 2 Ultrastructure of different bovine muscle fiber type: Z line (Z), Sarcolemma (Sc), Extracellular space (ECS), Mitochondria (Mi). (a) Two fast glycolytic fibers, probably IIX, as IIB are rare in cattle, recognizable by their extremely low density of mitochondria. (b) Oxydative fiber, I or IIA recognizable by its numerous mitochondria and its thicker Z lines than in IIX fibers.

predominantly rely on glucose as fuel, and they are innervated by high-frequency neurons. They have high myosin ATPase activity and are poor in myoglobin and mitochondria. Type-IIB fibers are the largest-sized fibers.

Contractile speed and proportion of glycolytic metabolism thus increase in the order I→IIA→IIX→IIB.

Muscle Fibers – Methods of Identifying Fiber Type

Various methods have been put forward for identifying fiber type, some relying on histological characterization, others on biochemical characterization.

Histochemistry

These methods are able to histologically characterize each individual fiber, making it possible to assess the in-tissue distribution of each fiber type. The proportions of each type are obtained by calculation. The use of computer algorithms allows semiautomated analysis of digital images, and this step is now faster and less arduous than before (Figure 2). Three main histological approaches are implemented to characterize the fibers based on their contraction speed, metabolic characteristics, or, using antigen/antibody reaction, to precisely identify the different myosin isoforms.

The first and most common method is based on the sensitivity differentials of actomyosin ATPase under different pH conditions (Table 1 and Figure 2).

The second method uses histochemical reactions for enzymes of aerobic oxidative metabolism reflecting mitochondrial content. It is often succinyl dehydrogenase activity that is highlighted, which distinguishes the glycolytic metabolism fibers from oxidative metabolism fibers.

Table 1 Histoenzymology staining properties of different fiber types

Stain	*Type I*	*Type IIA*	*Type IIB and IIX*
Adenosine triphosphatase (ATPase) pH 9.4	+	+++	+++
ATPase pH 4.6	+++	–	++
ATPase pH 4.3	+++	++	+
Nicotinamide adenine dinucleotide dehydrogenase	+++	++	+
Succinic dehydrogenase	+++	++	+

The third method is based on identifying the mysosin isoforms by immunohistochemistry using specific monoclonal antibodies. This highly accurate method is better for identifying hybrid fibers which contain multiple isoforms of myosin (Figure 2).

Biochemistry

MyHC isoforms have slightly different molecular weights, which means that they can be separated by electrophoresis. The density of each band is proportional to the quantity of the corresponding MyHC isoform. This technique, based on analysis of a muscle extract, is less arduous than histological methods and offers the added advantage of giving a global quantification of the proportion of each isoform.

The fact that monoclonal antibody specific to each isoform are now available has also opened up the possibility of using enzyme-linked immunosorbent assay to determine their respective proportions.

Finally, given that the different fiber types also vary in terms of metabolism, it is equally possible to evaluate their

respective proportions by assaying enzymes that reflect oxidative or glycolytic metabolism. This type of routine analysis is able to characterize type of muscle metabolism on a large number of samples, but the approach offers far less granularity than histology or electrophoresis, and it is unable to differentiate contractile type, which means it cannot differentiate the relative proportions of type-I and type-IIA fibers, both of which use oxidative metabolism.

Biochemical methods can fall down against histological methods because they cannot identify the distribution of each cell type and are unable to characterize hybrid fiber types.

The different histological techniques available are not strictly cross-compatible. The sharpest method available today uses immunohistochemistry to identify different MyHC isoforms. Coupling with histoenzymology techniques is time consuming but affords a more robust identification of cell types.

Muscle Fiber Types – Factors of Variation

The proportion of each fiber type in the muscle varies according to the muscle's function. Muscles that need to resist fatigue, like postural muscles, are generally dense in type-I and -IIA fibers. In contrast, muscles that need to be ready to deliver short bursts of intense work will mainly contain type-IIX and/or -IIB fibers. As stated earlier, fiber type can change from one type to another during the animal's lifetime.

Indeed, the characteristics of muscle fibers are shaped by muscle position and function, as well as species, breed, sex, age, physical exercise, environmental temperature, and even intake of growth hormones.

Genetic Factors

For any given muscle, fiber-type composition varies measurably between different species. Pigs, chicken, and turkey have pale muscles rich in glycolytic fibers (IIX and IIB) and less dense in oxidative fibers (I and IIA). The reverse pattern is found in cattle, sheep, horses, or ducks, which have red (therefore, myoglobin rich) and strongly oxidative muscle containing a majority of type-I and -IIA fibers (Table 2).

Fiber type composition is also shown to vary within the same species. Such variations are often the result of genetic selection efforts designed to increase carcass yield. This type of genetic selection policy tends to lead to an increase in the proportion of type-IIX and/or -IIB muscle fibers, which generally have a larger cross section. Wild boar, for example, has far redder oxidative muscling than the domestic pig. Furthermore, the domestic pig is sedentarized, whereas a wild boar will typically roam long distances on a daily basis, which promotes a more oxidative muscle metabolism (see Section Physical Activity).

Table 2 Percentage of fiber types in longissimus muscles of meat animals

Species	*Type I*	*Type IIA*	*Type IIB and/or IIX*
Cattle	22	33	45
Sheep	10	46	44
Pig	11	12	77
Rabbit	3	10	87

Physical Activity

Regular physical activity will progressively shift metabolic–contractile fiber properties to an oxidative muscle metabolism. Muscle from pigs experimentally subjected to several weeks of endurance training showed increased proportions of type-IIA and -I muscle fibers. To lesser extent, animals raised under free-range conditions generally present redder and more oxidative muscle than more sedentary animals raised indoors. Type-IIB and -IIX fibers give way to type-IIA and -I fibers, in a shift that always occurs in the order IIB→IIX→IIA→I via the transitional hybrid forms.

Age

The proportional composition of each fiber type changes with age of the meat animal. In cattle, it has been shown that rate of type I fibers increases with animal age, both in young cattle and older animals (cows and bulls), whereas rate of type IIB fibers decreases in young cattle and remains stable in older animals. This age-related increase in the proportion of type-I fibers is visibly transposable to other species.

Temperature

Animals adapt to temperature variations by adjusting their muscle metabolism and consequently by modifying the proportion of each main muscle cell type. Raising large white pigs in a cold environment will tend to increase the proportion of type-I fibers in their posture muscles.

Nutrition

As a general rule, feed and diet have little effect on muscle fiber type composition. However, extreme cases of diet restriction can trigger an increase in the quantity of type-I fibers in certain strongly oxidative postural muscles.

Influence of Fiber Type on Meat Quality Properties

Sensory and Technological Qualities

Tenderness

Tenderness is one of the decisive meat quality criteria. Fiber type has a paradoxical effect on meat tenderness. Calpain/calpastatin ratio is higher in fast-twitch glycolytic muscle (type IIX and IIB) than in redder slow-twitch muscle (type I). Furthermore, white muscle, dense in type-IIB and -IIX fibers, is more vulnerable to postmortem proteolysis than red, predominantly type-I muscle. Paradoxically, the increase in proportion of type-I fibers actually improves the tenderness of beef. It has been shown that muscle composed of fibers with a larger cross-sectional area yields tougher meat than muscle composed of lower diameter fibers. However, type-IIX and -IIB fibers are significantly bigger than type-I fibers. Taken together, these observations suggest that the mechanical

strength of type-IIX and -IIB muscle fibers could ultimately be due to their larger cross section. Meat tenderness is also tied to the connective tissue component. White muscles are designed to deliver ballistic-type power. The layering framework of connective tissue and probably extracellular matrix–muscle fiber interaction are adapted to these constraints, which could partly explain the higher mechanical strength of white muscle.

In certain cases, meat chilled too quickly will contract and lose much of its tenderness. This phenomenon, called cold shortening, only occurs in red meat that is dense in type-I fibers, i.e., mainly beef or sheepmeat. However, in contrast with type-IIB fibers, the Ca^{++} ion pump tasked with maintaining proper Ca^{++} homeostasis gets inhibited by cold stimulus in type-I fibers. Then, the muscles exposed to cold temperature soon after bleeding contract, yielding tough meat. The meat industry is well aware of the effects of cold shortening, and chilling process are generally adapted accordingly.

Flavor

Meat flavor stems largely from its lipid content. Oxidative muscle fibers packed with cellular organelles such as mitochondria are widely recognized as having higher phospholipid content than that by type-IIX and -IIB muscle fibers. Type-I fibers also contain intracellular lipid reserves in the form of lipid droplets that are only rarely observed in type-IIX and -IIB fibers. However, there are muscle lipid reserves stored in adipocytes that are usually found in the perimysium of all muscles, regardless of fiber type composition. Finally, the range of different results obtained to date is too wide to converge on a clear and specific relationship linking fiber type to total lipid content.

Given the range of compositional differences in phospholipids, glycogens, soluble proteins and so on, it is more likely that flavor is partly dependent on fiber type composition. Further targeted studies are needed in order to investigate the effect of fiber type on meat flavor.

Color and water-binding capacity (juiciness and product yield)

Meat color is dependent on the meat's myoglobin content. Myoglobin is the oxygen-binding protein that gives muscle cells a reddish pigmentation. Oxidative type-I and -IIA muscle fibers contain high amounts of myoglobin, and the higher the muscle's type-I and -IIA fiber content, the redder the meat. Heterogeneity in-muscle fiber type composition is sometimes the root cause of visible aspect defects. Two-shade coloring is a ham defect characterized by excessively darker red coloring in certain muscles tied to a higher proportion of myoglobin-rich type-I and -IIA fibers. Although without any obvious impact on flavor, patchy coloring prompts consumers to reject sliced cooked ham.

Myoglobin content is not the only factor of variation in meat color. Conditions of slaughter and slaughter technology affect the kinetics of postmortem muscle metabolism, with knock-on effects on rate and amplitude of pH drop in the meat.

In response to preslaughter stress, the added energy required from muscle cells is provided by a surge in muscle cell metabolism that is further accelerated by electrical stunning (pigs and poultry). This accelerated metabolism continues after exsanguination. When the bloodstream stops, metabolites like lactate and protons accumulate in the muscle cells, and this buildup leads to acidification of the meat muscle.

The glycogen degradation associated with this pH drop can be exceptionally quick in type-IIX and -IIB muscle fibers, especially in pork, and also, although to a lesser extent, in poultry.

A low pH combined with the fact that muscle temperature is still high causes partial denaturation of the meat proteins, which consequently lose some of their water-binding capacity. The meat end product will consequently be excessively pale, soft, and exudative meat, which loses a lot of juice during cooking and will ultimately turn out dry once cooked. This rapid change in postmortem metabolism, therefore, affects not only color but also juiciness and water-binding capacity as a whole. The proportion of intramuscular water lost through evaporation when the carcasses are chilled, then through exudation from the butchered meat cuts, and again during cooking, can vary substantially and measurably affect yield after cooking. Pig and turkey, unlike sheep and cattle, have the kind of highly glycolytic type-IIX and -IIB muscle that makes them particularly vulnerable to this phenomenon.

Salting – cooking

The agrifood industry has broadly adapted to consumer requirements by commercializing processed meat products. Although, beef and sheepmeat is still widely sold fresh, a large share of pork and turkey meat is industrially processed into ready-to-eat cold meats. Salting is an essential step in the cold meats chain. Not only does salting keep bacterial growth in check, it also reduces cooking losses and starts to breakdown the product structure, thereby improving end product juiciness, texture, and cooking yield.

Adding salt increases the ionic strength of the matrix, leading to partial denaturation of myofibrillar proteins. That said, a number of studies led on minced meat, myofibrillar protein extracts, and myosin converge to indicate that fast-twitch glycolytic muscle fibers (type IIX and type IIB) are more sensitive to the increased salt content than slow-twitch fibers (type I). However, Fourier transform infrared spectroscopy (FTIR) microspectroscopy studies have recently made it possible to characterize protein denaturation *in situ*, revealing changes in the secondary structure of myofibrillar proteins that were only weakly dependent on cell type.

Cooking, like salting, causes muscle protein denaturation, and myofibrillar protein extracts from glycolytic fibers are denatured earlier than myofibrillar protein extracts from type-I and -IIA fibers. As was the case with the denaturation tied to an increase in ionic strength, thermal denaturation as tracked by *in situ* FTIR microspectroscopy is practically independent of fiber type.

These findings suggest that myofibrillar protein denaturation is dependent on fiber type in meat that has been mechanically broken down, whereas the molecular interactions that are able to continue in the resulting meat pieces iron out the cell type-related differences in time course changes.

In the future, these characteristics could be capitalized in order to optimize meat salting processes and thereby reduce

NaCl content in meat products without losing out on sensory quality or technological properties. In today's industry chain, pork is by far the meat that goes through the most presale processing. Transposing these processing-induced transformations to meat from other species could enable significantly better value gains for certain muscles. Beef and sheepmeat is generally red muscle dominated by type-I and -IIA fibers. Process flows would need to be readapted in order to gain full process control over the sensory qualities and technological properties of any new product.

Nutritional Quality

Nutritional quality criteria on meat have traditionally revolved around lipid content and composition and essential amino acid profile in raw meat. Over the past few years, researchers have turned to look at the effects of meat structure and technological processes on the bioavailability of high nutritional value muscle proteins. The potential impacts of metabolic and contractile muscle type on nutritional qualities need to be investigated. Indeed, given the compositional differences between muscle fiber types, the nutritional qualities of meat can be expected to vary according to their proportions in the source muscle. Iron is an essential micronutrient, and heme iron, which is found mainly in type-I and -IIA fibers, is one of the nutrients that are easiest for the human body to assimilate. Vitamin B_3 is found in higher concentrations in muscle that has a higher proportion of glycolytic (type IIX and type IIB) fibers, whereas vitamin B_{12} is abundant in oxidative muscle (dense with type-I and -IIA fibers).

Carnosine is a bioactive dipeptide of β-alanine and histidine found in animal sources, where it is highly concentrated in muscle, especially glycolytic muscle (type-IIX and -IIB fibers). Its biological function is probably to buffer the intracellular pH variations induced by metabolic activity in glycolytic muscle. Carnosine has proven antioxidative properties and helps to protect against protein glycation and cross-linking. It may also play a vital preventive role against Alzheimer's disease.

The carnosine found in meat appears relatively unaffected by transformation processes. Although it is partially degraded in the small bowl, approximately one-fifth of all carnosine intakes is absorbed and released into the blood, where it can potentially be taken up into human body tissue.

Glutathione, which is also found in meat, is another bioactive peptide with antioxidant powers. However, no single specifically designed study to date has been able to establish a solid link between glutathione concentration and metabolic–contractile muscle class.

Food Safety Properties

There have been few attempts to evaluate the impact of muscle fiber type composition on the food safety properties of meat.

The microbiological properties of meat have been extensively documented but without finding evidence of fiber type composition-related variation in bacterial colonization. However, each muscle fiber type varies in composition and oxidative muscle generally has a higher ultimate pH than glycolytic muscle, and both these factors are known to modulate bacterial growth. Studies are underway to determine bacterial tropism toward the different fiber types.

Food safety properties are not driven by microorganism growth alone. For instance, it has been shown that certain cooking processes generate compounds that are potentially toxic for the end consumer, including heterocyclic aromatic amines, which are carcinogens that form at temperatures in the range 170–250 °C, typically reached when searing and panfrying. The production of these compounds varies according to muscle but is visibly independent of metabolic type and contractile class. This variability is thought to be tied to water transfer kinetics that differs according to muscle and depends on the muscle's structural organization.

Finally, various studies have shown that excessive consumption of red meat is associated with a moderate increase in the risk of colorectal cancer. Eating white meat (mainly poultry) is not associated with risk of cancer. These observations point out an effect of fiber type on cancer risk, as red meat contains high proportions of oxidative type-I and -IIA fibers. Recent research investigating the issue has singled out heme iron as the culprit, because it is thought to be a tumor promoter and is found in much higher concentrations in type-I and -IIA fibers than in type-IIX and -IIB fibers. However, protective nutrients like calcium or chlorophyll inhibit the heme's promoter effect. It would thus appear that simply getting calcium from dairy products significantly curbs the adverse effects of eating red meat. Other antioxidant nutrients from vegetables are equally more likely to possess similar protective properties to calcium and chlorophyll. Studies are underway to explore these issues further.

Conclusion

Muscle is composed of different types of fibers, all characterized in terms of contractile speed (fast or slow twitch), energy metabolism, and compositional profile of myosin isoforms. The in-muscle proportion of each fiber is essentially dependent on species, breed, and muscle function, but these proportions can change during the animal's life. Muscle fiber content and morphology vary according to metabolic type and contractile class and are responsible for variation in the sensory, technological, nutritional, and food safety properties of the meat.

Although genetic selection makes it possible to impel small-scale variations in the proportions of muscle fiber types, controlling muscle fiber composition and/or fiber type variability is not a conceivable option. Advanced characterization of the raw material combined with optimizations to its transformation processes should enable the food industry to gain greater process control over the quality properties of consumer end products. Nevertheless, further research is needed in order to gain deeper insight into the links between muscle fiber type and meat quality variability and the underlying molecular mechanisms involved.

NUTRIENT CLAIMS ON PACKAGING

KB Harris, Texas A&M University, College Station, TX, USA

This article is a revision of the previous edition article by E Desmond, DJ Troy, volume 2, pp 903–910, © 2004, Elsevier Ltd.

Introduction

Food packages are one of the primary tools used to provide consumers with information about the nutrient content of the product. Throughout the past few decades, food packages have also been used to provide health-related claims or information to assist consumers with their purchasing decisions. Labels on the product package and point-of-purchase information, can influence consumers' purchasing patterns and overall knowledge of the foods they are buying. Labeling information can include the actual nutrient content, as well as information on the structure–function or specific health claims related to the food. The nutrient content is based on product analyses or databases containing nutritional data; however, many consumers do not completely understand how to use this information to make decisions, so they rely more on the labeling statements dealing with the structure–function of the food, such as 'low fat,' 'lean,' 'no trans fat,' or on specific health claim statements, such as 'a low-fat diet reduces risk of heart disease.'

The nutrient content data are typically designed to present information in a standard format that allows consumers to easily make comparisons among foods at the point of purchase to enable food choices that meet certain consumer expectations and contribute to food choices that prevent or manage chronic disease. For example, a nutrient label might include information on serving size, kilocalories per serving, and fat from serving. Nutritional claims are typically general statements that allow consumers to make informed dietary choices based on recognized health recommendations and scientific criteria.

Over the past few years, there has been a growing trend in fitness programs across the United States, and individuals seem to have an increased desire to improve overall health through exercise and diet. The food industry has responded to this trend with 'healthier options' to allow consumers to make better choices. Other consumers have health-related conditions, such as diabetes and cardiovascular diseases, that often contribute to their food selections.

In the United States, the contribution of red meat products to the incidence of cardiovascular disease, obesity, and certain types of cancer is often criticized, and nutritional guidance encourages consumption in moderation. Unfortunately, the positive nutrient aspects of meat's role in the diet are often overlooked. However, from a global perspective, it is important to understand the contribution of red meat to key micronutrients and protein intake, especially for individuals with limited food supplies and in developing countries. According to the Food and Agricultural Organization (FAO), it is estimated that more than 2 billion people in the world are deficient in key vitamins and minerals, particularly vitamin A, iodine, iron, and zinc, and that meat and meat products contain important levels of protein and some micronutrients that are essential for growth and development. So this article will explore some of the perceived concerns, as well as the positive attributes of red meat in the diet.

Concern Over Fat

Overall, meat remains an important component of the Western diet and is a major component in total food expenditures in most European countries. It has been reported that the Americas, Australia, and Europe consume more meat per capita than other parts of the world, while Africa, the Middle East, South and Southeast Asia consumes the least. These differences are attributed to multiple factors such as overall economic development, cultural and religious preferences, and supply. Regardless of the location, health factors due to changing work and lifestyles, environmental and welfare concerns, and the

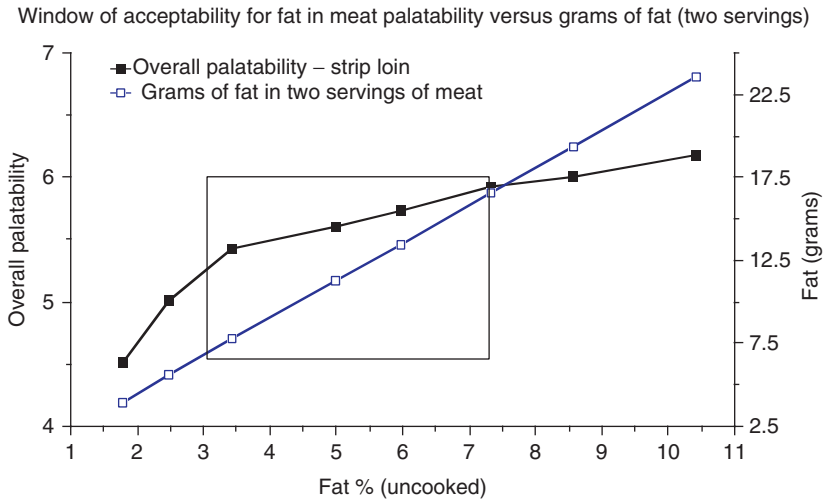

Figure 1 Reproduced from Savell, J.W., Cross, H.R., 1988. The Role of Fat in the Palatability of Beef, Pork and Lamb. Washington, DC: National Academy of Sciences.

availability of wider food choices have continued to influence eating habits and needs. These trends reflect the many factors influencing our modern food, nutrition, and health concerns. Diseases of the cardiovascular system account for half or more of the deaths in countries where death from infectious diseases can be prevented and treated.

The 2010 Dietary Guidelines Advisory Committee Report (USDA, 2010) advised healthy Americans to limit their intake of saturated fatty acids (SFA) to less than 10% of total energy intake and cholesterol to less than 300 mg per day. This and previous health-related nutritional recommendations have been automatically interpreted to mean they should change their diet to eliminate beef and other red meat. For example, in 2009, the International Food Information Council Foundation reported that 63% of consumers in the United States were trying to decrease the amount of animal fat in their diets. However, scientific data do not always support these nutritional recommendations.

A detailed review of 54 studies related to red meat consumption and coronary heart disease concluded that when fresh, lean red meat is low in saturated fat, and if consumed in a diet low in SFA, is associated with reductions in low-density lipoprotein (LDL)-cholesterol in both healthy and hypercholesterolemia subjects. Lean red meat provides key nutrients relative to the energy it provides that contribute to the fight against chronic diet-related noncommunicable diseases.

Changes in merchandising methods and livestock production practices have been credited with removing unwanted fat and improving the nutritional composition of beef, pork, and lamb, respectively. The role of fat on the characteristics of meat products is both diverse and complex. Fat itself is a mixture of a diverse group of substances consisting of triacylglycerols, phospholipids, sterols, and sterol esters. Fats' influence on meat product quality is profound. Fat level influences texture, flavor, binding properties, and color. Low-fat meat products often lack flavor, juiciness, and acceptable texture. The important parameters that influence consumer choices of purchase must be taken into consideration before a new meat product with a healthy image is marketed. A meat product perceived as being more 'healthy' must be similar in most other quality attributes to its 'less healthy' alternative. It is this challenge that is at the core of the technological problems associated with developing real healthy alternatives. This article examines the effects of fat reduction on the sensory and physicochemical properties of meat products, the use of fat replacers in meat products, and the legal aspects of fat reduction regarding labeling issues. The nutritional enhancement of meat products using functional ingredients is also discussed.

Role of Fat in Meat Products

Successful fat reduction in meat products requires a substantial knowledge of the functions of fat and functional food ingredients in meat products. The functional and sensory properties of fat as they relate to specific types of meat products are complex and somewhat product dependent. It is not a simple matter of using less fat in formulations because fat has significant effects on the physiochemical and sensory properties of the finished product. Humans have an inbuilt recognition for fat, which often plays a role in food acceptance. This has been ascribed to an innate human preference for a fat-associated volatile aroma, flavor, or textural feature. The 'Window of Acceptability' explains the relationship between fat and taste, and it demonstrates that consumers want a minimum of 3% fat for taste, but no more than 7.3% fat for diet health reasons (Figure 1).

Fat has a profound effect on the rheological and textural properties of meat products. It affects appearance, mouthfeel, texture, juiciness, flavor, and storage stability. It is not surprising, therefore, that fat removal adversely affects texture and results in a tough, rubbery, and dry product. As the fat content of processed meats is gradually reduced while the water content is increased, the product's water-binding capacity will replace its fat-binding capacity as the critical issue in production, thereby affecting the product's texture. In ground meat products, such as beef patties, fat imparts a soft texture, which is in contrast to the harder texture of the fibrous muscle proteins. Low-fat beef

patties are firmer, denser, and less cohesive during initial biting. In finely comminuted products, such as frankfurters, fat is present in the form of small oil droplets or particles surrounded by a protein film. When the fat level is reduced in these products, the products' structure is disrupted and the meat juices or added water are less effectively immobilized.

Fat is a major determinant of the sensory characteristics of products and it plays a key role in the flavor of meat products. Fat is a precursor to a large number of flavor compounds such as aldehydes, ketones, lactones, volatile fatty acids, and secondary alcohols. In addition, fat modifies the perception of existing or added flavor compounds by influencing the balance, intensity, and release of flavors, and by affecting their distribution and migration.

Prior to ingestion, binding of flavor compounds to ingredients within the food matrix occurs. During chewing, volatile aroma and flavor components are released. The amount of flavor released depends on the retention of flavor components in the food matrix and on the food type. In reduced fat foods, altered flavor–ingredient interactions result in different flavor release behavior and flavor tends to be intense but transient.

Fat also provides meat products with many functional properties during processing that will change when the fat level is changed. Fat is responsible for heat distribution during cooking, diluting protein content, and delaying protein extraction by physically separating muscle proteins, therefore allowing more tolerance in mixing procedures. For meat products to be viable on a commercial basis, it is necessary for water and fat losses that occur during processing to be kept to a minimum. Therefore, particular attention needs to be given to the water-holding capacity (WHC), cooking losses, and binding ability of meat systems produced by low-fat formulations. When fat is reduced in meat systems, either more lean meat (i.e., protein) is added or more water is added. In the former case, fat reduction combined with increased protein will increase the WHC. Alternatively, fat reduction by addition of water and no extra lean meat will result in a lower WHC. Because the WHC of a meat system derives from the protein component, any 'dilution' of this component will reduce its WHC.

Cooking losses not only affect the economics of producing processed meats, but can also result in compositional changes that can affect the palatability of finished products. Weight loss during cooking is due to the losses of both water (and water-soluble components) and lipids. The extent of loss depends on a number of factors including the extent of heating (i.e., time and temperature), shape and size of sample, composition, pH, physical properties of the fat, and cooking method.

Strategies for Fat Reduction

The main strategies for fat reduction in processed meat products generally follow two basic approaches: physical methods, such as the trimming of fat or using leaner materials, and the use of functional additives together with water. However, the addition of water alone adversely affects the quality of many low-fat meat products. Therefore, the most popular fat-reduction strategy today is the binding of added water with a protein or carbohydrate-based fat replacer.

Methods of reducing fat in meat products have been comprehensively reviewed; some reviews are listed in the 'Further Reading' section at the end of this article. It was not until the late 1980s and early 1990s that the development of ingredients specifically for fat replacement of all categories of food increased. The fact that there are so many ingredients now available for use in fat replacement means that this has been one of the strongest growth areas in the field of ingredient development for some time.

Many terms are used to describe ingredients that can be used for fat reduction, and these terms are often used interchangeably. Some authors give different descriptions for each. 'Fat replacer' is a blanket term used to describe any ingredient utilized in fat reduction. 'Fat mimetics' are defined as a partial replacement for fat by mimicking or imitating a particular function, but not all of the functions of fat in food. 'Fat substitutes' are ingredients whose physical and thermal properties resemble fat but have fewer calories than fat or have no calories. Most of the ingredients used in the reduction of fat can be classified under three headings: nonmeat proteins (soy, milk, wheat, blood, surimi, etc.); carbohydrates (hydrocolloids, gums, starches, fibers, and cellulose derivatives); and other products (functional blends, oils, and synthetic products). A list of some functional ingredients available and their suppliers is given in Table 1.

Nutritional Composition

For the most part, the United States has been leading the way in the commercialization of 'low-fat or lite' meat products, and the United States Department of Agriculture (USDA) nutritional database has a large number of 'lite' products from well-known US companies. For example, 'Fat-free' wieners have a 98% reduction in fat, are 76% lower in calories, and 46% lower in cholesterol; whereas 'light' wieners are 51%, 41%, and 13% lower in fat, calories, and cholesterol, respectively. In general, the 'normal' fat products have lower moisture contents than their low-fat or lite counterparts. It must also be noted that research using microscopy has shown that fat loss from meat products depends on two factors. The first is the instability of the fat itself (i.e., the fat droplet size and distribution, and the protective properties of the surrounding fat droplet membrane against coalescence). The other factor is the ability of fat to translocate from the inner to the outer parts of the product. The latter factor is enhanced when the probability of fat droplets to coalesce is increased, as in the case of high-fat coarse, comminuted meat products (e.g., hamburgers). In some cases, the solubilization of collagen can allow melted fat to diffuse along channels. Consequently, it is not surprising to find that the percent cooking loss increased as the fat level on the ground beef products increased from 5% to 25%.

Fat is more easily lost during cooking from high-fat burgers (30%) than low-fat burgers (10%) and researchers have found that the relationship between fat content of the beef burgers and fat loss is quadratic. This loss occurs due to expansion of fat droplets as they melt and the formation of pools and

Table 1 Some ingredients used in the fat reduction of meat products

Ingredient	*Product name*	*Manufacturer*
Soy protein	Supro	Dupont Protein Technologies (St. Louis, MO, USA)
Whey protein	Carbelac	Carbery Milk Products (Carbery, County Cork, Ireland)
	WPC30	Dairygold (Michelstown, County Cork, Ireland)
Blood protein	Plasma powder	Harimex (Loenen, The Netherlands)
Carrageenan	Gelcarin	FMC Biopolymer (Philadelphia, PA, USA)
	Genugel	Copenhagen Pectin (Lille Skensved, Denmark)
Starches		
Tapioca	Tapiocaline	Tipiak Ltd (Saint-Herblain, France)
	Instant N-oil	National Starch & Chemical (Bridgewater, NJ, USA)
	Instant Textra	National Starch & Chemical (Bridgewater, NJ, USA)
Waxy maize	Firm-tex	National Starch & Chemical (Bridgewater, NJ, USA)
Dietary fibers		
Potato	Potex	Lyckeby Stärkelsen (Kristianstad, Sweden)
Wheat	Vitacel	J. Rettenmaier & Söhne GmbH (Rosenberg, Germany)
Citrus	Herbacel	Herbafood Ingredients (Havel, Germany)
Oat	Advanced oat fiber	Food Ingredients International (Northants, UK)
Pea	Swelite	Consucra (Fontenay, Belgium)

Note: This table only shows a small number of ingredients used for fat reduction. There are various types of the above ingredients with numerous suppliers and manufacturers. The mention of an ingredient name or manufacturer does not constitute an endorsement by the author.

channels. The dense protein matrix of low-fat ground beef prevents fat migration by reducing the probability of fat droplets coalescing and expanding. When added water is used to replace fat, thereby increasing the amount of free water, cooking loss increases as fat decreases.

Nutritional Enhancement of Meat Products

In addition to health demands, consumers also want high-quality, convenient, and safe meat products. To satisfy their needs, food scientists are developing methods to enhance meat and meat products nutritionally. This is carried out in two ways: first, through the manipulation of the fatty acid profile of meat by altering the fatty composition of beef, for example, conjugated linoleic acid (CLA) and the n-3 fatty acid contents; second, functional ingredients, for example, dietary fibers, plant sterol esters, phytochemicals, vitamins/minerals, and proteins, can be added to existing meat products to fortify and improve their nutritive value.

CLA refers to a mixture of positional and geometric isomers of linoleic acid (18:2n-6) in which the double bonds are conjugated instead of existing in the typical methylene-interrupted configuration. CLA has been found to exhibit powerful anticarcinogenic effects at relatively low dietary levels. In addition, it has been shown to be antiatherogenic; to have antidiabetic properties; to enhance immune response; and to have beneficial effects on growth, health and body fat levels. Because there are potential health benefits from CLA consumption, there is considerable research effort directed to increasing the CLA content of ruminant-derived food. Research from Teagasc, Dublin, among others, has shown that an increase in the proportion of grass in the diet resulted in a linear increase in the CLA concentration, while a grass silage and concentrated diet resulted in a lower CLA concentration. CLA concentrations in Irish and Australian beef can be two or three times higher than those in US beef. This finding presumably reflects the greater consumption of polyunsaturated fatty acids (PUFA)-rich pasture throughout the year by cattle in these countries.

The fatty acid composition of beef can also be manipulated by including fatty acids in the diet of animals. Inclusion of bruised whole linseed, a rich-source of linolenic acid, resulted in 100% increase in the concentration of linolenic acid in muscle, while feed treated with a combination of linseed oil and fish oil increased the n-3 PUFA concentrations. Further research is in progress to improve the transfer of dietary PUFA to muscle as well as developing meat products, such as patties, which will contain higher amounts of n-3 fatty acids and CLA. Meat and fat for these products are being sourced from cattle raised on supplemented grass diets.

Although the meat industry has been slow to follow the functional trend and incorporate functional ingredients into products, some manufacturers have developed products in which they advertise the functional nature of the additives (Table 2). A meat company in Germany has developed a pork sausage and a turkey sausage with added calcium for the children's market. The company has also developed turkey salami with a probiotic culture, an additive normally seen in dairy products. Research carried out in the UK showed that the fortification of meat products with vitamins and minerals is technologically feasible. No adverse effect on color, texture, or flavor was found with any of the additives tested and, in most cases, there was no significant loss of added vitamins as a result of processing, storage, or cooking.

Dietary fiber from a number of vegetable and fruit sources, such as oat, wheat, soy, pea, potato, and citrus, have been added to the formulations of several meat products such as

Table 2 Examples of fortified and nutritionally enhanced meat products currently available

Product	*Company*	*Functional ingredient*
Sliced meats	Reinert (Germany)	Extra calcium
Sliced meats	Salumifico Fratelli Veroni (Italy)	n-3
Cured meat	Comprofio (Portugal)	Natural fiber
Sliced meats	Pouttu (Finland)	Plant sterols
Frankfurters	Atria Oyj (Finland)	Stanol ester
Chicken meatballs	Atria Oyj (Finland)	Stanol ester
Coated chicken	Glenhaven (Ireland)	Added vitamins
Coated chicken	Grampian (UK)	Added vitamins
Salami snack	R. Wilke (Germany)	Guarana, taurine, and ginseng

patties and sausages. In many instances, these fibers not only have beneficial physiological effects because they are more resistant to digestion in the human intestine, but they also have important technological properties that can offset the effect of fat reduction. Research at The National Food Centre has shown that the incorporation of pea and potato fiber in both reduced fat and normal fat beef patties reduced cooking losses and had no detrimental effect on flavor and texture. Preliminary studies have also shown that oat fiber delayed the release of flavor volatiles. Soy ingredients, in addition to being high-quality protein, have been identified as having beneficial health effects. A number of epidemiological studies have suggested that consumption of soybeans and soy foods is associated with lowered risks of several cancers and cardiovascular disease and improved bone health. Lycopene is the carotenoid in tomatoes that gives them the characteristic red color. This phytochemical antioxidant has been associated with reduced risks of cancer and coronary heart diseases. Lycopene has been used in the production of beef patties and has had significant antioxidative effects and considerably extended the shelf life of the products.

The invention of plant sterol ester led to the first commercial application of Benecol® margarine, in Finland in 1995. People have participated in nearly 40 published clinical trials that show the efficacy of plant stanol ester in lowering serum, total, and LDL-cholesterol concentration. These studies have shown that the use of 2–3 g of esterified stanol per day significantly reduces LDL-cholesterol levels by approximately 10–20%. Recent studies have shown that when stanol ester was added to low-fat meat products, LDL-cholesterol was lowered by approximately 14%. Since 1999, Benecol® foods enriched with stanol ester have been introduced in the United States and many European countries. To date, most of the products have been dairy based. However, chicken meatballs and frankfurters containing the stanol ester have recently been introduced to the Finnish market. Similarly, another Finnish company has introduced Multibene cold cuts, featuring a unique combination of cholesterol-lowering plant sterols, low-sodium PanSalt™, and beneficial minerals. The products will be among the first to be approved under the EU Novelty Food Act. According to the manufacturers of these 'healthier' meat products, the addition of the plant sterols has no detrimental effect on the flavor or texture of the products.

Labeling of Meat Products with Nutrient Claims

Regardless of type of meat product, it is important that information about foods and their nutritional value appearing on the label and used for their presentation, marketing, and advertising should be clear, accurate, and meaningful. The EU Regulation 1169/2011 on the provision of food information to consumers changes existing legislation on food labeling, and it requires mandatory nutrition information on process foods, as well as mandatory origin labeling for unprocessed meat from pigs, sheep, goats, and poultry. At an international level, Codex Alimentarius and FAO have developed guidelines (Table 3) for the most commonly used nutrition claims (such as 'low,' 'light,' etc.).

In the United States, The Nutrition Labeling and Education Act (1990) imposed new mandates for labeling of many food products and restricted how various nutrition claims may be made. In 1994, the Dietary Supplement Health and Education Act added even more complexity to the nutritional labeling program. The Food Safety and Inspection Service of the USDA regulates labeling of meat and poultry products. Nutritional labeling and nutrient claims requirements are codified in The Code of Federal Regulations in Sections 317.300–317.400 for red meat products and Sections 381.400–381.500 for poultry products. Most nutrient content claims are of two distinct types of statements: (1) implied nutrient claims, which are statements suggesting that a particular nutrient is absent or present at a certain level and (2) expressed nutrient claims, which is any direct statement about the level or range of nutrient in a food.

The US Food and Drug Administration (USFDA) and the US Department of Agriculture Food Safety and Inspection Service define 'lean' as a serving of meat, poultry, seafood, or game meat that contains fewer than 10 g of fat, fewer than 4 g of saturated fat, and fewer than 95 mg of cholesterol per 100 g. The USFDA's definition of 'extra lean' is a serving of meat, poultry, seafood, or game meat containing fewer than 5 g of fat, fewer than 2 g of saturated fat, and fewer than 95 mg of cholesterol per 100 g.

Additionally, simple, explicit statements that do not imply anything regarding low or high level or how the product compares to similar foods are allowed without any disclaimers. Statements indicating that a product is '___ free' or

Table 3 Table of conditions for nutrient contents

Component	*Claim*	*Conditions*
		Not more than
Energy	Low	40 kcal (170 kJ) per 100 g (solids) or 20 kcal (80 kJ) per 100 ml (liquids)
	Free	4 kcal per 100 ml (liquids)
Fat	Low	3 g per 100 g (solids) or 1.5 g per 100 ml (liquids)
	Free	0.5 g per 100 g (solids) or 100 ml (liquids)
Saturated Fat	Low[a]	1.5 g per 100 g (solids), 0.75 g per 100 ml (liquids), and 10% of energy
	Free	0.1 g per 100 g (solids) or 0.1 g per 100 ml (liquids)
Cholesterol	Low[b]	0.02 g per 100 g (solids) or 0.01 g per 100 ml (liquids)
	Free	0.005 g per 100 g (solids), 0.005 g per 100 ml (solids), and, for both claims, less than: 1.5 g saturated fat per 100 g (solids), 0.75 g saturated fat per 100 ml (liquids), and 10% of energy of saturated fat
Sugars	Free	0.5 g per 100 g (solids) or 0.5 g per 100 ml (liquids)
Sodium	Low	0.12 g per 100 g
	Very Low	0.04 g per 100 g
	Free	0.005 g per 100 g
		Not less than
Protein	Source	10% of NRV per 100 g (solids), 5% of NRV per 100 ml (liquids), or 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or 10% of NRV per serving
	High	2 times the values for 'source'
Vitamins and minerals	Source	15% of NRV per 100 g (solids), 7.5% of NRV per 100 ml (liquids), or 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or 15% of NRV per serving
	High	2 times the value for 'source'

[a]In the case of the claim 'low in saturated fat,' trans fatty acids should be taken into account where applicable. This provision consequentially applies to foods claimed to be 'low in cholesterol' and 'cholesterol free.'

[b]In the case of the claim 'low in saturated fat,' trans fatty acids should be taken into account where applicable. This provision consequentially applies to foods claimed to be 'low in cholesterol' and 'cholesterol free.'

Abbreviation: NRV, nutrient reference value.

'low' in a nutrient must comply with specific regulations for making a claim. Additional requirements apply to '_____ fat-free' claims. The rules for nutrition labeling and nutrient claims are extensive and complex, particularly in the United States, and care should be taken in designing labels for 'low-fat' or 'lite' products.

Summary

Many different factors influence consumer demand for meat products and, currently, health is a primary factor. Therefore, it is important that the industry produces great-tasting low-fat meat products that consumers enjoy as part of an ongoing healthier diet and lifestyle. This article provided an overview of health concerns related to meat consumers, strategies for reducing fat content in processed meat products, and key points related to nutritional labeling of meat.

NUTRITION OF MEAT ANIMALS

Contents

Pigs

CT Whittemore, University of Edinburgh, Edinburgh, UK

Introduction

Pigs accumulate lean and fatty tissues through the retention of protein, lipid, water, and ash in the process of growth. The nutrition of pigs grown for meat is, therefore, a matter of satisfying the provision of the nutrient requirements for growth. Pigs may be weaned at a weight (and an age) depending on the farm system, but usually at more than 6 kg and less than 16 kg live body weight (3–8 weeks of age). They can be harvested at any age, but usually at live weights of more than 60 kg and less than 160 kg, depending on particular market requirements.

With respect to the production of lean meat, the growth of pigs is best considered in relation to the whole-body protein mass (Pt). The chemical components of the whole live body of growing meat pigs can be expressed as a function of Pt using the allometric form $a \times Pt^b$, where a and b are parameters that show biological variations:

$$\text{water} = 3.62 \times Pt^{0.938} \quad [1]$$

$$\text{ash} = 0.265 \times Pt^{0.928} \quad [2]$$

$$\text{lipid} = 0.50 \times Pt^{1.30} \quad [3]$$

According to these equations, pigs approaching 60 kg live weight with 10 kg of Pt will have 31 kg water, 2.2 kg ash, and 10 kg lipid. As the Pt increases with growth to maturity, there is a decrease in the content of water and ash relative to protein. The major part of the body water is held in association with protein in muscle. The water content of fatty tissue ranges from 10% to 20%, the higher values being found in younger and less fat animals. The major minerals are retained at rates (grams of mineral per kilogram Pt) of approximately: calcium, 90; phosphorus, 60; potassium, 15; sodium, 10; and magnesium, 2.5. Pigs also contain a small amount of liver and muscle glycogen, glucose, and microminerals.

For lipid, the exponent in eqn [3] will range from 1.1 to 1.4, showing fatness to increase with growth to maturity. The lower value is associated with lean pig types and controlled feeding regimens, and the higher with fatter pig types and *ad libitum* access to feed. Lipid accumulation with increasing pig mass is shown in Figure 1, which relates to an exponent of 1.3. The ratio of lipid to protein in tissue gains achieved in any particular circumstance is dependent on the quantity and quality of the dietary nutrient provisions; that is, the intake of energy and the balance of energy to protein in relation to need.

There is a significant gut content (kilogram per kilogram live weight) of approximately 0.06 that is related, among other things, to the level of feeding, feed digestibility (fiber content or water-holding capacity), and specific ingredient inclusions.

Retention of Protein and Lipid in Pigs

As pigs grow, they change in weight, size, and shape. For adequately fed pigs, a general relationship between weight (W, kg) and pig age (t, days) can be expressed as:.

$$W = A - \exp\{-\exp[-B(t - t_0)]\} \quad [4]$$

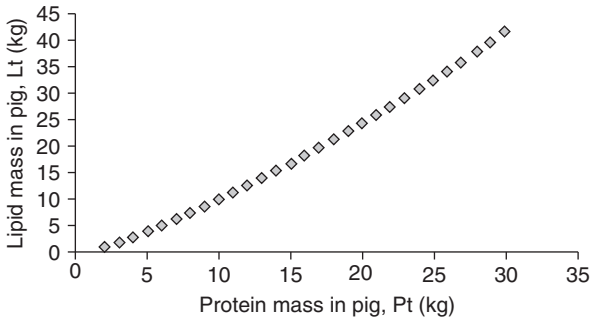

Figure 1 Lipid mass (Lt) in relation to Pt of pigs grown for meat.

The expression 'exp' denotes e^x (??). In the equation, A is the asymptote of W (mature weight) and B is a growth coefficient. The curve of weight against time is sigmoid (growth rate accelerating in early life and decelerating later), and t_0 is the point of inflection measured in terms of pig age and occurring at 1e (0.37) of the age at maturity. Meat pigs are usually harvested at less than 0.5 of their mature size. In the case of contemporary meat pigs, maturity may be attained at live weights of 200–300 kg. Typically, at the point of inflection, a maximum growth rate slightly in excess of 1 kg daily is achieved by healthy modern genotypes at approximately 100 kg live weight and 160 days of age.

It appears that the change in size may follow the same trajectory as weight, whereas shape may not. Width across the ham may increase more slowly than length and other breadth measurements. The area of the longissimus dorsi muscle increases at a lower rate than that of the whole carcass, the exponent of the allometric equation relating the two being approximately 0.73 for normal pig types, but greater for more muscular breeds.

To provide for nutrient requirements, an expectation for the daily rate of protein retention (PR, kilogram per day) is needed. This may be expressed as a function of pig live weight (W), or more dependably as a function of pig Pt:

$$\mathrm{PR}\ (\mathrm{kg\ day^{-1}}) = \mathrm{Pt} \times B \ln\left(\frac{\mathrm{Pt_{max}}}{\mathrm{Pt}}\right) \quad [5]$$

where, $\mathrm{Pt_{max}}$ is the asymptote (A) for Pt.

The peak value for the rate of growth, occurring at the point of inflection is ($A \times B/e$). Parameter values of 0.0110 for B and 30 kg for $\mathrm{Pt_{max}}$ may be used to describe the slower-growing pig types, and of 0.0125 and 50 kg to describe the faster growing types. Intermediate values are a reasonable expectation for high-quality commercial types, and these are used in Figure 2. In the figure, at approximately 30 kg live weight (Pt ~ 5 kg), potential rates for PR are approximately 0.1 kg daily, rising to a maximum of 0.16 kg or more between 60 and 110 kg live weight (Pt ~ 10–18 kg). The curve is quite flat topped, so some authorities are content to consider PR to be effectively constant for most of the 20–120 kg growth phase. Following the peak, the rate of PR declines (at a slower rate than it increased) to zero at attainment of mature weight.

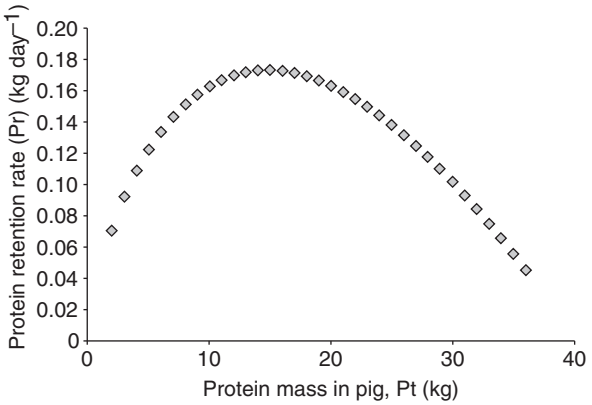

Figure 2 Daily rate of PR in relation to Pt of pigs grown for meat.

Obtaining numerical values for Pt and B from empirical data is more useful in defining growth expectations for Pt than for the lipid mass (Lt), as the latter is substantially more prone to environmental variation. However, expectations would be for the value of A in the case of lipid to be 2–3 times that of protein.

There appears to be a (minimum) level of fatness that pigs are genetically disposed to attain. To achieve this, they may forgo the use of dietary energy to fuel PR, the latter otherwise being the priority. This level can be represented as the minimum ratio of lipid to protein, $(\mathrm{Lt{:}Pt})_{\mathrm{min}}$, in the body. At fatnesses above this, pigs will catabolize body lipid to yield required energy should the dietary supply be limiting. The $(\mathrm{Lt{:}Pt})_{\mathrm{min}}$ is related to breed type and to sex (in the order male < female < castrate). Values of $(\mathrm{Lt{:}Pt})_{\mathrm{min}}$ appear to range between 0.5 and 1.5. The level of fatness above $(\mathrm{Lt{:}Pt})_{\mathrm{min}}$ actually attained will depend on the quantity and quality of the nutrient supply. Appetite limits will restrain daily lipid retention (Lr) to fatness levels at or near the minimum during the first quartile of growth to maturity. By the end of the second quartile, pigs given *ad libitum* access to food will have fattened to levels substantially beyond that normally required for optimum carcass lean (an Lt:Pt ratio of approximately, or less than 1:1; this seems like a high proportion of fat).

Growth promoters, such as hormones and beta-agonists, may increase PR and decrease Lr. This would influence the leanness of the carcass, the efficiency of growth, and the balance of protein to energy needed in the diet. However, presently available fast-growing and lean pig genotypes, together with modern production practice, indicate little need for the modification of pig growth by exogenous means.

Response to Nutrient Supply

Pigs respond linearly to reach a plateau when the nutrient supply is increased, according to the general rule of first limiting resource. Response in PR to increasing daily protein supply is limited by provision of essential amino acids, provision of energy, the production environment (particularly health), and ultimately the expectation for PR as described earlier. Given the absence of limitation by shortfalls in other resources, response to increasing energy supply is linear for both PR and LR (supporting $(\mathrm{Lt{:}Pt})_{\mathrm{min}}$) until the maximum expected daily protein retention ($\mathrm{PR_{max}}$) is attained. At this point, PR is maintained at the maximum daily rate (the plateau); further ingestion of energy goes to the retention of lipid and the animal fattens.

As $\mathrm{PR_{max}}$ varies not only according to pig type and production environment but also according to live weight (and Pt), it follows that the break point of the linear/plateau response alters as pigs grow. Changing live weight also brings a change in the balance of energy required for basic body functioning (maintenance) and energy required for protein and lipid retention. Thus, ideal nutrient allowances and balances are in a state of continuous and progressive change.

The overall efficiency with which feed is used for growth is approximately 2 kg of cereal-based balanced feed for 1 kg of body weight in young growing pigs, and approximately 3:1 in older pigs. This is because older pigs, being heavier, have a

higher maintenance requirement, and, eating more, are also more likely to be fattening.

Nutrition of pigs concerns both the quality and the quantity of the diet provided. The first addresses the balance of nutrients, whereas the second addresses the level of feed supply. In the first quartile of growth to maturity, PR_{max} is rarely attained, owing to appetite limitation. Pigs are, therefore, fed *ad libitum*, and indeed nutrient intake is encouraged by provision of nutrient-dense diets and the use of palatable food ingredients. If it is desired that fattening be prevented or constrained, the quantity of feed provided in subsequent quartiles may be appropriately restricted by imposition of a rationing regimen. Selection of the feeding level determines lean growth performance in the earlier phases of growth and carcass fatness in the later stages.

Control of feeding level is the most effective and most frequently used means of controlling both the rate and the composition of pig growth. Appetite encouragement will increase growth rate and the efficiency of conversion of ingested food into body tissues, provided that the growth increase is in terms of muscle and not fat growth. The water content of muscle (~70%) is much greater than that of fatty tissue (~15%). Pigs with a propensity to retain unwanted fatty tissue not only have carcasses of lower value but they also produce them less efficiently. Thus, reducing feeding level worsens the feed conversion efficiency of lean-growing pigs by slowing down growth, but improves the feed conversion efficiency of fat-growing pigs.

Feed Intake

Because the nutrients supplied daily to pigs are the products of diet nutrient density and level of intake, it is evident that formulation of the diet in terms of nutrient densities is contingent on knowledge of the amount of the diet that will be eaten. It may be supposed that, in the absence of any restraint, pigs will eat the amount of feed that will provide for requirements to maintain body functions (maintenance), and achieve PR_{max} and LR_{max}. One restraint is the capacity of the intestinal tract, which is related to the size of pigs. The utilization of the available capacity will further depend on the fiber content of the diet, the water-holding capacity of ingredients, and diet digestibility. Not only do feed ingredients interact with gut capacity, but also the prediction of food intake is further obfuscated by environmental effects, especially those of temperature, housing, and disease.

Empirical measurement of food intake (FI; kilogram per day) by pigs may be described as:

$$FI = a \times [1 - \exp(-b \times W)] \quad [6]$$

where, W is the live weight (kilogram) of the pig, and the coefficient a is indicative of the likely food intake limit. Expected values for a and the parameter b would normally be approximately 3.2 and 0.019, respectively (Figure 3). Food intake increases with the live weight of the pig, but at a diminishing rate. Both coefficient and exponent will vary according to pig type and production environment. In early life, feed intake is particularly influenced by the pig's health, whereas later it is influenced by the density of stocking and the method of feed provision.

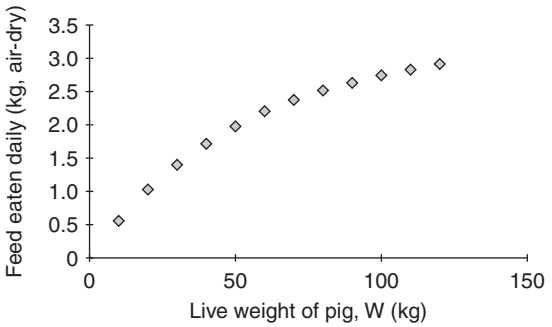

Figure 3 A food intake curve for pigs grown for meat.

Influence of Nutrition on the Eating Quality of Pig Meat

By far, the most important influence is through the direct effect of feed supply level on the absolute quantity of fat that is present in the carcass.

Eating quality comprises tenderness, juiciness, and flavor, usually assessed using a trained taste panel. Apart from influences through levels of fatness, nutrition of the pig affects these characteristics in only a limited way. Tenderness is the most important of the three and its level is raised after fast growth in the finishing stage, compared with slow or interrupted growth – at equal carcass leanness, faster growing pigs have more tender meat than those grown more slowly, but this effect is small.

In general, higher tenderness and juiciness are found in meat from fatter carcasses, the concentration of fat within the muscle (intramuscular or marbling fat) being the important determinant. The concentration of marbling fat is increased when diets with a high ratio of energy to essential amino acids are fed. In several studies, marbling fat has been increased by 30% or more using this strategy to the benefit of juiciness and tenderness in cooked pork.

The restriction of feed intake, the use of diets of low nutrient density, or the use of low-appetite pig types will improve carcass muscle percentage, and this characteristic is often taken as a substantive definition for the eating quality of meat from pigs. Increasing the feeding level (intake of energy) will, in contrast, directly enhance the fatness of the carcass. The attitude for or against fat depends on social custom, the market demand for lard as a commodity, human dietary requirements for energy, and dietary fashion. Approximately two-thirds of carcass fat is in the form of subcutaneous fat, which can readily be removed postmortem to varying degrees as required. Intramuscular fat (and, to a lesser extent, intermuscular fat) is associated with enhanced flavor, tenderness, and ease of cooking of meat.

The ratio of polyunsaturated fatty acids (PUFA) to saturated fatty acids in pig meat is generally favorable in relation to perceptions of human benefit in the Western diet. PUFA can be further enhanced by provision of unsaturates in the diet. The propensity for dietary fatty acids to be transferred unaltered to

carcass fat also facilitates the natural supplementation of pig meat with particular PUFA considered to be of benefit in the human diet. One approach is to include fish oil in the diet, a source of the key omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Another is to include linseed (flaxseed), a source of α-linolenic acid, which, once deposited in tissues, leads to the formation of EPA and DHA in the pig itself. High levels of PUFA (adversely) soften carcass fat because of their low melting point. Another potential problem is oxidation of PUFA during processing and storage of meat, leading to discoloration and off-flavors in cooked pork. These can be avoided by raising dietary levels of vitamin E, a powerful antioxidant. There has been a general increase in dietary vitamin E levels in recent years.

Apart from the effects of feeding level on carcass fatness (which is substantial), the influence of nutrition on the eating quality of pig meat is not particularly great. Of greater importance than nutrition are pig type, pre- and postslaughter treatment, and method of cooking. There may, however, be particular negative and positive dietary ingredient effects on meat flavors. This phenomenon, although appreciated by consumers of products from animals that range widely and have an eclectic choice of feed sources, is as yet largely unexamined by objective science.

In some countries, entire male pigs are reared for pig meat production, whereas in others the males are castrated at birth to reduce concentrations of skatole and androstenone, which cause off-odors and flavors after cooking. Feeding sources of fiber that are digested in the hind gut, such as chicory and the pulp of beet after sugar extraction, can reduce levels of skatole in carcass fat because the change in fermentation pattern causes less skatole to be absorbed from the gut. This appears to be associated with the nonstarch polysaccharides mitigating the effects of tryptophan degradation by gut bacteria. The concentration of skatole is closely linked to off-odor production, so this dietary change may remove the problem of boar taint. However, androstenone is not affected by dietary fiber, so its negative effects on taste may still remain.

Dietary Energy in Pig Feeds

The gross energy of the diet before ingestion (GE, measured in MJ) is of little value as a descriptor because some fractions contain energy that is unavailable to pigs due to their indigestibility. The digestible energy (DE) is that which is not voided in the feces. Energy digestibility is adversely affected by fiber content and positively affected by fat.

The DE content (MJ per kilogram DM) of a diet may be predicted from its chemical constituents. The following relation (eqn [7]) may be postulated from knowledge of the GE values of carbohydrate, oil, and protein, given that the energy of starch and oil is highly digestible and that of fiber is largely indigestible (each of the components is expressed in gram per kilogram).

$$\text{DE(MJ per kg DM)} = 0.016\ \text{Starch} + 0.035\ \text{Oil} + 0.019\ \text{Protein} + 0.001\ \text{Fiber} \quad [7]$$

This postulate is confirmed by empirical regression of chemical composition against DE determined in live pigs:

$$\text{DE (MJ per kg DM)} = 17.5 - 0.015\ \text{NDF} + 0.016\ \text{Oil} + 0.008\ \text{CP} - 0.033\ \text{Ash} \quad [8]$$

where, NDF is neutral detergent fiber and CP is crude protein. The constant of 17.5 reflects the starch contribution, whereas calculation of the contribution (MJ kg^{-1}) from dietary NDF ($17.5-[0.015 \times 1000]=2.5$) is low and that from dietary oil is large ($17.5+16.0=33.5$).

Because some of the DE is lost in the urine and in gases from the tract, and is, therefore, not available for metabolism, the term metabolizable energy (ME) may be used. The ME/DE ratio in pig diets is variable according to the rate of deamination, but is usually approximately 0.96.

Of the DE, the starch, lipid, and protein fractions are largely digested in the small intestine, yielding useful substrates for metabolism. Some dietary energy, particularly from the fibrous nonstarch polysaccharides, disappears in the large intestine as volatile fatty acids, and these are used less efficiently. Owing to the differing costs of metabolism of the different dietary components, DE may overvalue the energy contribution of proteins and nonstarch polysaccharides, and undervalue that of fats and starches. Further, older pigs use fiber more effectively than younger ones. These considerations suggest that foods would be more accurately valued according to their net energy (NE) yield. True NE is a combined function of the energy value of the feed and the use to which energy is put by the animal; that is, the body functions of maintenance, PR, and LR. Usually, for a growing pig diet, NE is approximately 0.71 of DE.

The laboratories of Institut National de la Recherche Agronomique in France have suggested eqn [9], where NE is MJ(kg DM)$^{-1}$ and the nutrient composition is in g kg^{-1}.

$$\text{NE} = 0.0113(\text{Digestible CP}) + 0.0350(\text{Oil}) + 0.0144(\text{Starch}) + 0.0121(\text{Digestible residue}) \quad [9]$$

The same laboratories have published tables of nutritive values of feeds containing, among other things, values for NE (see Further Reading).

Dietary Amino Acids in Pig Feeds

Of the amino acids that make up dietary protein, some 11 cannot be synthesized by pigs and are deemed 'essential': lysine, methionine + cysteine, threonine, tryptophan, isoleucine, leucine, histidine, phenylalanine + tyrosine, and valine. Lysine is often the first limiting resource in diets based on cereals, and it is common to express requirement in terms of lysine, with the other amino acids stated in terms of a ratio to lysine = 1, to give the appropriate balance. The balance of interest is that needed by pigs for the functions of maintenance, tissue turnover, and PR (Table 1). Of the total dietary provision, the amino acids not in balance will be deaminated and excreted. This is a natural consequence of pigs converting lower quality

Table 1 Balance of essential amino acids (in relation to lysine = 1.00) for growing pigs

Lysine	1.00
Methionine	0.30
Methionine + cysteine	0.59
Threonine	0.65
Tryptophan	0.19
Isoleucine	0.58
Leucine	1.00
Histidine	0.34
Phenylalanine	0.57
Phenylalanine + tyrosine	1.00
Valine	0.70

pig-food proteins into higher quality human-food proteins in the form of pig meat.

Most of the amino acids are digested anterior to the terminal ileum, from where they are absorbed. There is substantial endogenous secretion of amino acids into the small intestine. Some of these are not fully reabsorbed before the terminal ileum and are lost. Nitrogen compounds passing into the large intestine may appear to have been digested but are of no value to the pig.

There is a basal level of endogenous amino acid loss that will occur regardless of level of feeding or of feed-ingredient type, and this level is considered as a cost that should be attributed to the pig rather than to the feed. The other fraction of the endogenous losses is considered to be feed-related. When these losses are apportioned, the requirement for amino acids is expressed as 'standardized ileal digestible amino acids,' which is approximately 5% points higher than the empirically determined overall ileal digestibility. Consequently, the statement of pigs' requirements must be enhanced to cover the pig-related, unavoidable endogenous losses.

Diet Ingredients

The feeds that omnivorous and monogastric pigs may eat are diverse. Most diets are founded on carbohydrates from 'starchy' crops – maize corn, barley, wheat, rye, oats, sorghum, cassava, and rice. Also, widely employed in pig diets are the by-products of the use of these crops for the manufacture of human food, especially from the bread, bakery, brewing, and starch-based industries, and possibly also from new-technology energy-generating processes. Although feeds containing higher levels of nonstarch polysaccharide tend to be used for ruminant rather than monogastric diets, pigs do not abhor these. Roots are no longer frequently grown specifically for consumption by pigs, but by-products of potato and sugar beet processing are valuable.

Energy may also be supplied from vegetable and animal fats, such as soybean oil, oil-seed rape (canola) oil, and tallow. Approximately half of the amino acid requirement may be found in the 'starchy' food ingredients, the rest is provided in the form of protein supplements. In the middle and later stages of growth, these are usually of vegetable origin – soybean, oil-seed rape, sunflower, lupin, field peas, and beans. Oil extracted from the first three of these is a valued, volume, human-food commodity, and the extraction results in a by-product with a high concentration of protein.

In the earlier stages of growth, young pigs benefit from the inclusion in the diet of animal protein, such as fish meal, skimmed milk, meat and bone meal, and blood products. These are more expensive but are higher in concentration of essential amino acids and more readily digested. Nutritional values for some diet ingredients are given in Table 2.

Mineral and Vitamin Requirements of pigs

There are common and wide differences between estimates of pigs' requirement for minerals and vitamins determined on the basis of depletion experiments and the (higher) dietary inclusion levels found to be efficacious in practice. Furthermore, there are wide differences in efficacy depending on production circumstance. Table 3 gives guidelines for the diet content of macrominerals, and for the dietary additions of microminerals and vitamins. The provision of minerals and vitamins to pigs is not an exact science.

Water Requirement of Pigs

All growing pigs, including those given food that is mixed with water or is itself in liquid form, should have access to potable water. A separate watering point is needed for every 8–12 pigs. The variation in daily water consumption is large and depends on the health and welfare status of the pigs, the environment, and the feed type. It is suggested that under normal conditions, pigs will drink 4–6 times the weight of food that is eaten.

Energy Requirement of Pigs

The requirement for energy is the sum of the costs of maintenance, activity, PR, and LR. Energy is also expended in response to cold and disease, but thermoneutrality and reasonable health are assumed here.

Estimation of the DE requirement of growing pigs must include the metabolic costs of retention of new body tissues that are lost as heat:

$$\mathrm{DE}(\mathrm{MJ\ day^{-1}}) = [(0.444W^{0.75} \times 1.10) + (23.6\mathrm{Pr}/0.44) + (39.3\mathrm{Lr}/0.74)]/0.96 \quad [10]$$

The first term in eqn [10] estimates maintenance requirement, which is amplified by 10% to allow for activity. The second term states the energy content of the retained protein to be 23.6 MJ kg^{-1}, and estimates the efficiency of use of energy for PR to be 0.44. The third term states the energy content of the retained lipid to be 39.3 MJ kg^{-1}, and estimates the efficiency of use of energy for LR to be 0.74. These terms are expressed in ME, which is approximately 0.96 of DE.

Table 2 Guide to the composition of some diet ingredients (g kg^{-1} (air dry))

	DM (g kg^{-1})	*NE (MJ kg^{-1})*	*DE (MJ kg^{-1})*	*CP (g kg^{-1})*	*Standardized ileal digestible amino acids (g kg^{-1})*[a]

Table 3 Range of dietary additions of minerals and vitamins commonly found in compounded feed offered to growing pigs

	Weaned pigs of up to 15 kg live weight	*Growing pigs of 15–50 kg live weight*	*Growing pigs of 50–150 kg live weight*
Macrominerals (per kg final feed)			
Calcium (g)	7.5–9.2	6.0–8.2	5.5–7.2
Phosphorus (g)	6.5–7.0	5.0–6.4	5.0–6.0
Digestible phosphorus (g)	3.0–3.4	2.4–2.7	2.0–2.3
Sodium (g)	1.5–2.5	1.5–2.0	1.4–2.2
Microminerals (added to each kg final feed)			
Zinc (mg)	100–200	100–200	60–150
Manganese (mg)	30–50	30–50	25–45
Iron (mg)	80–175	80–150	65–112
Cobalt (mg)	0.2–0.5	0.2–0.5	0.2–0.5
Iodine (mg)	0.2–1.0	0.2–1.0	0.2–1.0
Selenium (mg)	0.2–0.3	0.15–0.3	0.15–0.3
Copper (mg)	6–20	6–15	6–15
Vitamins (added to each kg final feed)			
Retinol (mg)[a]	1.5–4.8	1.2–3.6	1.2–2.7
Cholecalciferol (mg)[b]	0.02–0.05	0.02–0.05	0.015–0.037
DL-α-Tocopherol acetate (mg)[c]	40–100	35–60	20–60
Menaphthone (mg)	2–5	2–4	1–2
Thiamin (mg)	1.5–3	1–2	1–2
Riboflavin (mg)	4–10	4–6	2–4
Nicotinic acid (mg)	20–40	15–25	10–25
Pantothenic acid (mg)	8–20	10–15	8–15
Pyridoxine (mg)	2.5–5	1–3	1–3
Cyanocobalamin (mg)	0.03–0.05	0.02–0.03	0.015–0.022
Biotin (mg)	0.125–0.20	0–0.15	0–0.05
Folic acid (mg)	0.5–1.5	0–1.0	0–1.0
Choline (mg)	200–500	100–300	0–200

[a]1 mg retinol is 3333 IU vitamin A.

[b]1 mg cholecalciferol is 40 000 IU vitamin D3.

[c]1 mg DL-α-Tocopherol acetate is 1 IU vitamin E.

Note: Essential fatty acids. The dietary requirement for essential fatty acids for all classes of pigs will be likely met from a dietary inclusion level of 5–50 g linoleic acid per kilogram.

Table 4 Energy and lysine requirements of growing pigs expressed as concentration of nutrient per kilogram air-dry diet. Feed intake was as presented in **Figure 3**

Live weight (kg)	*Net energy (MJ NE per kg diet)*	*Digestible energy (MJ DE per kg diet)*	*Standardized ileal digestible lysine (g kg^{-1} diet)*	*Total lysine (g kg^{-1} diet)*
10–30	10.4	14.7	9.7	11.5
30–60	9.3	13.6	8.1	9.6
60–90	9.0	13.2	7.1	8.4
90–120	8.9	13.0	6.2	7.3

Source: Reproduced from Whittemore, C.T., Hazzledine, M.J., Close, W.H., 2003. Nutrient Requirement Standards for Pigs. Penicuik: British Society of Animal Science.

Estimation of the NE requirement of growing pigs is by summation of the energy required for basal metabolism (maintenance of body functions when no feed is being consumed), and the energy value of PR (23.6 MJ kg^{-1}) and LR (39.3 MJ kg^{-1}). To the basal allowance of 0.750 MJ kg$^{-1}W^{0.60}$, a further 10% may be added to cover energy expended in activity. It is important that the estimation for maintenance used is that derived in accordance with the determination of the NE value of feeds. Energy requirements determined in this way are given in **Table 4**.

A statement of the requirement for lysine, when combined with **Table 1**, sets the requirement for all the essential amino acids. The requirement for lysine is estimated as that needed for maintenance, PR, and basal endogenous losses. Lysine requirements are given in **Table 4**. The lysine in protein used for maintenance is estimated as 0.058 kg lysine per kilogram protein. The lysine in PR is estimated as 0.070 kg kg^{-1}. Ileal digested lysine, even when supplied in limiting amounts, is used with less than 100% efficiency because of amino acid cycling in the body of pigs. The maximum efficiency appears to be 0.82, and lower values are often experienced. The requirement for amino acids is higher in the presence of disease; these estimates assume reasonable health. In **Table 4**, where the maintenance requirement is estimated as 0.9 g protein per kilogram $W^{0.79}$, and the basal endogenous losses are estimated at approximately 5%, the standardized ileal digestible lysine requirement (kilogram per day) is given as:

$$[((0.0009 \times W^{0.75} \times 0.058) + (\mathrm{Pr} \times 0.07))/0.82] \times 1.05 \quad [11]$$

Protein Requirement of Pigs

Protein is comprised of essential and nonessential amino acids. Minimum provision of the combination of the two may be estimated as 2.5 times the total of the essential amino acids, or 15.25 times the requirement for lysine. This minimum will usually be exceeded as the economic purpose of pigs is to convert feeds of lower quality into those of higher quality, and this will not be best served by the provision of perfectly balanced diets. The availability of industrially manufactured free amino acids, and the imperative to minimize (or to utilize effectively) releases of nitrogen into the environment does, however, raise awareness of the need for optimization of dietary provision of nitrogenous compounds. There is particular interest in the possibility of developing diets of significantly lower total protein (crude protein, or $N \times 6.25$) content, but adequately providing for the requirement of essential amino acids. Presently, this implies supplementation with manufactured amino acids. However, the possibility arises that specific pig genotypes might respond satisfactorily to dietary levels of protein (and amino acids) below those norms suggested presently here. Conventional wisdom suggests that such reductions in protein: energy ratios will cause a concomitant increase in carcass fatness; but that wisdom depends on the assumption that all pig genotypes will, inevitably, convert excess energy consumption into body fat; whereas this might not always be the case. Besides, there is a view that many pigs are already too lean for optimization of eating quality, and that some additional lipid, particularly within the muscle mass, might be beneficial.

Conclusion

The nutrition of growing pigs is a matter of process control. Energy supply, essential amino acid supply, and diet ingredient inclusion are all subject to management choice. By manipulation of the quantity and quality of the feed presented to pigs, the rate of meat production and the composition of that meat may be closely controlled. Such control is seminal to both the profitability of pig farming and consumer acceptability of the product.

This article is a revision of the previous edition article by V Ravindran, volume 2, pp 925–933, © 2004, Elsevier Ltd.

Introduction

Internationally, poultry meat production has consistently increased over the years and it is expected that this trend will continue. The major factor that has contributed to the consistent growth in world production of poultry meat is the genetic progress in poultry strains for meat production. In meat chickens, the age of male birds to reach the market weight of 2 kg has steadily decreased from 63 days in 1976 to 28–30 days in 2010 and the efficiency of converting feed into meat continues to improve. Rates of genetic change for growth and feed efficiency have also changed the physiology of the birds. Consequently, nutrient requirements and nutritional management have been changing to satisfy the genetic potential of the new strains. Poultry is unique among domestic animals in that any change in nutrition is reflected in bird performance in almost a real-time manner. This phenomenon has been successfully exploited by the commercial poultry meat industry to improve growth and carcass yield of birds.

Poultry is an omnivore, which can be classified nutritionally as having a simple digestive system with nonfunctional caeca. The digestive tract of poultry has more organs, but is shorter than in other domestic animals. In fast-growing meat chickens, the time taken for the feed to pass from mouth to cloaca (and to digest and absorb the nutrients) is less than 3 h. To compensate for the relatively short digestive tract and digesta transit time, poultry needs to be offered concentrated, easily digestible form of feeds that contain not only adequate concentrations, but also a good balance of nutrients.

The term 'poultry' encompasses a range of domesticated species including chickens, turkeys, ducks, geese, game birds (such as quails, pheasants, and partridges), and ratites (emus and ostriches). A discussion of the nutrition of all these species is beyond the scope of this article so the focus will be on meat chickens, which constitute more than 90% of the poultry meat market. However, in general, principles of nutritional management of meat chickens are applicable to other poultry species grown for meat. The overall aim of poultry feed formulations is to lower costs and maximize economic efficiency. In the past, there had been a tendency to overformulate diets when doubts existed on the availability of critical nutrients (especially amino acids and phosphorus) or if the nutrient requirement was uncertain. This practice is no longer acceptable because this is not only wasteful, but also excess nutrients are excreted in the manure and are ultimately a source of pollution. Future directions in poultry nutrition will be driven not only by the need to maximize biological and economic performance of birds, but also by societal issues (environment, antibiotic growth promoters, welfare, traceability, and the use of genetically modified ingredients).

Nutrient Requirements

For maximum growth and good health, the intensively reared poultry needs a balanced array of nutrients from its diet. In the main, poultry needs a steady supply of energy, protein, essential amino acids, essential fatty acids, minerals, vitamins, and, more importantly, water. Birds obtain the energy and the required nutrients following the digestion of natural feedstuffs, though trace minerals, vitamins, and some essential amino acids (lysine, methionine, threonine, and tryptophan) are offered as synthetic supplements.

Energy

In the real sense, energy is not a nutrient but the property of energy-yielding nutrients, primarily carbohydrates and fats, and also protein. These nutrients, when oxidized during metabolism, release adenosine triphosphate that serves as a precursor for the synthesis of chemical body components forming the muscle tissues. The energy value of a feedstuff for poultry is usually expressed as apparent metabolizable energy (AME) or true metabolizable energy (TME). The TME values are widely used in feed formulation in North America and some parts of Europe, whereas the AME concept is popular in the other parts of the world. The AME is defined as the gross energy of the feed consumed minus the gross energy contained in the excreta. In TME calculations, energy losses from endogenous sources are accounted for and it is defined as the gross energy of the feed consumed minus the gross energy of the undigested feed in the excreta.

It has been long known that the birds eat to satisfy their energy needs, provided that the diet is adequate in all other essential nutrients. The energy concentration in the diet is therefore a major determinant of feed intake in poultry. With changes in dietary energy concentration, the feed intake will change and specifications for other nutrients must be altered to maintain the required intake of nutrients. For this reason, the dietary energy concentration is often used as the starting point in the formulation of practical diets for poultry.

To sustain the faster growth rate, modern meat chicken strains are typically fed high-energy diets. Historically, the industry has used nutrient requirements recommended in the publication by National research Council (NRC). Recommended minimum nutrient concentrations for meat chickens at different ages are presented in Table 1. These recommendations, however, should only be considered as guidelines

Table 1 Nutrient requirements of meat chickens as percentages or units per kilogram of diet (90% dry matter)

Nutrient	*Unit*	*1–21 days*	*22–42 days*	*43–56 days*

and as the basis for setting dietary nutrient concentrations in practical diets. The most recent publication on poultry was in 1994 and is now 20-years-old, which is a long period given the genetic advances that have been made in both broilers and layers over this period. Currently, the recommendations suggested by commercial breeding companies provide guidelines that more closely match the requirements of modern bird strains than those recommended by NRC (1994).

The dietary energy concentrations employed in a given situation are largely dictated by the availability and cost of energy-rich feedstuffs. Because of the high cost of cereals, particularly of maize, the use of low-energy diets (as low as

2850 Kcal kg^{-1} or 11.9 MJ kg^{-1}) for broiler feeding is a common practice in many countries.

Protein and Amino Acids

The function of dietary protein is to supply amino acids for muscle growth and maintenance. The synthesis of muscle protein requires the supply of 20 amino acids, all of which are physiologically essential. Ten of these cannot be synthesized at all or rapidly enough to meet the metabolic requirements and are therefore designated as essential elements of the diet. The balance can be synthesized from other amino acids and referred to as nonessential elements of the diet. The essential amino acids for poultry are: lysine, methionine, threonine, tryptophan, isoleucine, leucine, histidine, valine, phenylalanine, and arginine. In addition, glycine is considered by some to be essential for young birds. Cysteine and tyrosine are considered as semi-essential amino acids because they can be synthesized from methionine and phenylalanine, respectively. Lysine, methionine, and threonine are the most limiting amino acids in practical poultry diets.

Poultry does not have a requirement for protein *per se*. However, to synthesize nonessential amino acids, an adequate dietary supply of nitrogen from protein is essential. This ensures that the essential amino acids are not degraded to supply the nitrogen for the synthesis of nonessential amino acids. Satisfying the recommended requirements for both protein and essential amino acids will therefore ensure that all amino acids are provided to meet the physiological needs.

Amino acid requirements of meat birds are influenced by an array of factors, including genotype, sex, physiological status, environment, and health status. However, most changes in these amino acid requirements do not necessarily lead to changes in the relative proportion of all of the different amino acids and the required changes in amino acids can be expressed in relation to a balanced protein or 'ideal protein' for the meat chicken. In the ideal protein concept, lysine is used as the reference amino acid and requirements for the other essential amino acids set as a percentage (or ratio) of the lysine requirement (Table 2). The advantage of this system is that once the lysine requirements under a variety of conditions are determined, the needs of all other essential amino acids can be calculated. This approach has now become an accepted practice in the industry to set the amino acid specifications in feed formulations.

A recent development has been the wider use of digestible amino acid concentrations, rather than total amino acid concentrations, in feed formulations. The use of digestible amino acid content is particularly relevant in regions where diets are formulated using poorly digestible ingredients such as canola meal, cottonseed meal, sunflower meal, meat meal, and feather meal. In the USA, where the highly digestible maize and soybean meal contribute more than 95% of the protein requirement, the use of digestible amino acid system is less relevant. Formulating diets based on digestible amino acids makes it possible to increase the range and inclusion levels of alternative ingredients in poultry diets. In effect, this approach improves the precision of formulation, reduces the need for safety margin, may lower feed cost, ensures more predictable bird performance, and reduces nitrogen excretion into the environment.

Table 2 Ideal amino acid ratios of meat chickens at three growth periods

Amino acid	*1–21 days*	*22–42 days*	*43–56 days*
Lysine[a]	100	100	100
Arginine	105	108	108
Histidine	35	35	35
Isoleucine	67	69	69
Leucine	109	109	109
Methionine+cysteine	72	72	72
Phenylalanine+tyrosine	105	105	105
Threonine	67	68.5	68.5
Tryptophan	16	17	17
Valine	77	80	80

[a]Recommended digestible lysine requirements for meat chickens during 1–21 days, 22–42 days, and 43–56 days are 1.070%, 0.865%, and 0.745%, respectively.

Fats and Fatty Acids

Because of the greater energy density of fat compared with carbohydrates and protein, fats are usually included in poultry diets to achieve dietary energy concentrations. In most practical diets, fat is added in the range of 3% to no more than 5%. Other benefits of using fats include better dust control in feed mills and poultry houses and improved palatability of diets. Poultry does not have a requirement for fats as a source of energy, but requirement for linoleic acid (18:2, n-6) has been demonstrated. Linoleic acid is the only essential fatty acid needed by poultry, but its deficiency has rarely been observed in birds fed practical diets.

Minerals

Minerals are needed for the formation of skeletal system, for general health, as components of general metabolic activity, and for the maintenance of acid–base balance in the body. Calcium and phosphorus are the most abundant mineral elements in the body and are classified as macrominerals along with sodium, potassium, chloride, sulfur, and magnesium. Macrominerals are elements required in the diet at concentrations of more than 100 mg kg^{-1}.

Calcium and phosphorus are necessary for the formation and maintenance of the skeletal structures. In general, 60–80% of total phosphorus present in plant-derived ingredients is in the form of phytate phosphorus. Under normal dietary conditions, phytate phosphorus is poorly utilized by poultry due to insufficient quantities of endogenous phytase. It is generally assumed that approximately one-third of the phosphorus in plant feedstuffs is nonphytate and is biologically available to poultry. For this reason, phosphorus requirement for poultry is expressed as nonphytate phosphorus, rather than total phosphorus. A ratio of 2:1 must be maintained between calcium and nonphytate phosphorus in poultry diets to optimize the absorption of these two minerals.

Dietary proportions of sodium, potassium, and chloride largely determine the acid–base balance in the body so that the

physiological pH is maintained. If a shift occurs toward acid or base conditions, metabolic processes are altered to maintain the pH with the likely result of depressed performance. The dietary electrolyte balance is described by the simple formula ($Na^+ + K^+ - Cl^-$) and expressed as mEq kg^{-1} diet. Prevention of electrolyte imbalance needs careful consideration. Under most conditions, a balance of approximately 250 mEq kg^{-1} diet appears satisfactory for optimum growth. It must be emphasized that overall balance between these three minerals as well as their individual concentrations is important. To be effective, their dietary concentrations must each be within respective acceptable ranges, not deficient and not excessive. Birds exposed to heat stress consume increased amounts of water and are better able to withstand heat when the water contains electrolytes. The replacement of part of the sodium chloride in the diet formulation with sodium bicarbonate has proven useful under these conditions.

Trace minerals, such as copper, iodine, iron, manganese, selenium, zinc, and cobalt, function as components of larger molecules and as cofactors of enzymes in various metabolic reactions. These elements are required only in very small concentrations in the diet (Table 1). Practical poultry diets should be supplemented with major and trace minerals because typical cereal-only based diets are deficient in these minerals. Organic forms of trace minerals are generally considered to have a higher biological availability compared to inorganic forms.

Vitamins

Vitamins are generally classified as fat-soluble (vitamins A, D, E, and K) and water-soluble (vitamin B-complex and vitamin C). All vitamins, except for vitamin C, must be provided in the diet. Vitamin C is not generally classified as a dietary essential because it can be synthesized by the bird. However, under adverse circumstances, such as heat stress, dietary supplementation of vitamin C may be beneficial. The metabolic roles of the vitamins are more complex than those of other nutrients. Vitamins are not simple body-building units or energy sources but are mediators of, or participants of, all biochemical pathways in the body.

Water

Water is the most important nutrient in poultry nutrition. Supply of clean water is essential at all times and deprivation even for a short period can irreversibly depress growth rates. Both feed intake and growth rate are highly correlated with water intake. Precise requirements for water are difficult to state and are influenced by a number of factors including ambient conditions, age, and physiological status of birds. Under most conditions, water intake is assumed to be twice the amount of feed intake.

Ingredients Used in Poultry Feed Formulations

Feed represents the major cost of poultry production, constituting up to 60% of the total cost. Of the total feed cost, approximately 95% is used for meeting the energy and protein requirements, approximately 3–4% for the major mineral, trace mineral, and vitamin requirements, and 1–2% for various feed additives. Poultry diets are formulated using a mixture of several ingredients, including cereal grains, cereal by-products, fats, plant protein sources, animal by-products, vitamin and mineral supplements, synthetic amino acids, and feed additives. These are invariably assembled on a least-cost basis using ingredient prices together with their nutrient contents. A classification and examples of ingredients used in poultry diets are given in Table 3.

Energy sources constitute the largest component of poultry diets, followed by plant protein sources and animal protein sources. Plant protein sources are included to supply the major portion of dietary protein (or nitrogen) requirements. Plant protein sources, with the exception of soybean meal, are generally imbalanced with regard to essential amino acids. Unless supplemented with animal protein sources or crystalline amino acids, diets based on plant-derived ingredients will not meet the requirements for certain essential amino acids.

Feed Additives Used in Poultry Feed Formulations

In addition to the ingredients discussed above, poultry formulations contain an array of substances known as 'feed additives.' These are nonnutritive substances usually added in amounts of less than 0.05% to maintain health status, uniformity, and production efficiency in intensive production systems. These additives have now become vital components in practical diets. A list of commonly used feed additives is presented in Table 4.

Special mention needs to be made of the ban in the European Union and different degrees of voluntary withdrawal in other parts of the world on the use of in-feed antibiotics in animal feeds. Antibiotics have been used in poultry diets for more than 60 years as growth promotant and as a prophylactic measure against necrotic enteritis, a fatal bacterial disease caused by *Clostridium perfringens*, in meat chickens. The withdrawal of these preventive measures has serious implications for the poultry industry, including disease outbreaks. At present, there is increasing focus on alternatives to sustain good gut flora and gut health, and potential alternatives include enzymes, probiotics, prebiotics, essential oils, botanicals, and organic acids (Table 4). During the past 10 years, these products have been widely tested and the evaluation will continue in the future. Most of these alternatives have been shown to 'mimic' the working effects of in-feed antibiotics on gut flora, but none of the current generation of alternatives, on their own, are capable of fully replacing the in-feed antibiotics.

Feeding Programs

Broilers are usually fed on an *ad libitum* basis to ensure fast growth to market age. However, in recent years, intermittent feeding programs are becoming popular, especially during the first 2–3 weeks of life, as a means of lowering mortality levels caused by metabolic diseases, such as sudden death syndrome

Table 3 Classification and examples of ingredients used in poultry feed formulations

1. Energy sources
   a. Cereals: maize, wheat, barley, sorghum, rice, triticale, and millets
   b. Cereal by-products: milling by-products from rice and wheat, maize gluten meal
   c. Root and tuber meals: cassava root meal and sweet potato tuber meal
   d. Fruit and fruit by-products: banana meal and date by-products
   e. Fats and oils: tallow and vegetable oils
   e. Miscellaneous: cane molasses
2. Plant protein sources
   a. Oilseed meals: soya bean meal, canola meal, cottonseed meal, sunflower meal, safflower meal, coconut meal, palm kernel meal, groundnut meal, and sesame meal
   b. Grain legumes: field peas and lupins
   c. Green leaf meals: alfalfa leaf meal, sweet potato vine meal, and cassava leaf meal
   d. Miscellaneous: dried brewers' spent grain and dried distillers grain
3. Animal protein sources
   a. Fish products: fish meal
   b. Animal by-products: meat meal, blood meal and poutry by-product meal
   c. Milk by-products: skim milk powder
4. Mineral supplements
   a. Calcium supplements: limestone and shell grit
   b. Calcium and phosphorus supplements: dicalcium phosphate, monocalcium phosphate, defluorinated phosphate, and bone meal
   c. Trace minerals: trace mineral premixes
   d. Sodium sources: salt and sodium bicarbonate
5. Others
   a. Vitamin supplements: vitamin premixes
   b. Nonnutritive feed additives (see **Table 4**)

Table 4 Feed additives commonly used in poultry feed formulations

Additive	*Examples*	*Reasons for use*
Enzymes	Xylanases, β-glucanases, and phytase	To overcome the antinutritional effects of arabinoxylans (in wheat and triticale), β-glucans (in barley), or phytate (in all plant feedstuffs) and to improve the overall nutrient availability and feed value.
In-feed antibiotics[a]	Avilamycin,virginiamycin, zinc bacitracin, avoparcin, tylosin, and spiramycin	To control gram positive, harmful bacterial species in the gut and to improve production efficiency; as a prophylactic measure against necrotic enteritis
Coccidiostats	Monensin, salinomycin, and narasin	To prevent and control the clinical symptoms of coccidiosis
Pigmentants	Xanthophyll (natural and synthetic)	To improve the skin color and appearance of carcasses
Antioxidants	Butylated hydroxy toluene (BHT), butylated hydroxy anisole (BHA), and ethoxyquin	To prevent autooxidation of fats and oils in the diets
Antifungals		To control mold growth in feed; to bind and mitigate the negative effects of fungal toxins
Antibiotic replacers[b]		
1. Direct-fed microbials	Probiotics	Provision of beneficial species such as *Lactobacilli* and *Streptococci*
2. Prebiotics	Fructo oligosaccharides and mannan oligosaccharides	Binding of harmful bacteria
3. Organic acids	Propionic acid and diformate	Lowering of gut pH and prevention of the growth of harmful bacteria
4. Botanicals	Herbs, spices, plant extracts, and essential oils	Prevention of the growth of harmful bacteria
5. Antimicrobial proteins/peptides	Lysozyme, lactacin F, lactoferrin, and α-lactalbumin	Prevention of the growth of harmful bacteria

[a]The use of avoparcin, zinc bacitracin, spiramycin, virginiamycin, and tylosin phosphate as animal feed additives was banned in 1998 in the European Union.
[b]Envisaging a total ban on in-feed antibiotic use, a multitude of compounds (individually and in combination) is being currently tested.

and a disease ascites, which are associated with fast-growing meat chicken strains.

Broiler diets are offered either as crumbles or pellets. Broiler starter diets are usually offered as crumbles, whereas grower and finisher diets are given as pellets. Compared to mash-type diets, crumbles and pellets reduce bulk density, improve feed intake, reduce feed wastage, and enhance the feed efficiency. This, in particular, has more effect on the growth rate of meat chickens fed low-energy diets where volumetric density has an adverse effect on feed intake.

Continuous genetic improvement has resulted in meat chickens that grow faster every year on less feed. Despite the dynamic nature of the industry, nutrient requirement recommendations have remained somewhat static. Current nutrient recommendations (Table 1) list the nutrient requirements only for three time periods, namely, 0–3 weeks, 3–6 weeks, and 6–8 weeks. In practice, however, the grow-out periods can range from 4 to 10 weeks of age, depending on local market needs. Recognizing that changes in nutrient needs are more dynamic than these general recommendations, phase-feeding systems are widely used by the commercial industry to maximize performance and increase profit margins. Dietary protein and amino acid specifications are usually decreased in a progression of feeds from start to finish in a manner that satisfies the requirements and economics. Typical feeding programs over a 5–7 week production cycle now include four to five feeds such as prestarter, starter, grower, and finisher; or prestarter, starter, grower, finisher, and withdrawal. Withdrawal diets are usually fed during the last 5 days of growth and involve the removal of pharmaceutical additives and the reduction of protein/amino acids. In recent years, this has been extended to the reduction of vitamin and trace minerals, and also to energy.

'Sex separate' growing is practised in some situations where the uniformity of the final product is important and where uniformity has been hard to attain. This practice requires specific formulations for male and female broilers and can lower feed costs because considerable evidence indicates that females require 1–2% less protein and amino acids than the males. Males and females have similar nutrient requirements during the first 2 weeks of life, after which the females, due to their slower growth rate, tend to respond differently to dietary amino acid levels. Sex separate feeding also allows the marketing of male birds at an earlier age than females.

A recent development has been the feeding of whole grains (wheat or barley) along with a balanced concentrate feed. The benefits of whole grain feeding include reduced feed processing costs and improved flock health. These benefits appear to arise from a combination of two physiological actions: physical benefits of gizzard development and increased proventriculus secretions, and better matching of daily requirements through self-selection by the bird. The usual method of whole grain feeding has been to blend 10–25% of the grain on top of the feed in the delivery trucks or at the poultry house.

Feeding for Leaner Carcass Production

A major reason for the popularity of chicken meat has been the consumer perception of a healthy product. In chickens and turkeys, the white meat from the breast is very lean. This image of low-fat meat has contributed much to enhancing the consumption of poultry at the expense of red meats. Nevertheless, there are opportunities to further improve the image of chicken meat and to lower fat levels in the whole carcass through nutritional manipulations.

Defining the most desirable amount of fat in meat chickens is complex. Fat deposition is an integral part of broiler growth and its extent and distribution in the carcass is an important aspect of meat quality. Although the skin fat is essential for acceptable eating qualities, visceral and abdominal fats are considered as waste materials. Excessive fat deposition is not only energetically expensive, but also lowers saleable carcass yield and increases cooking losses.

Restriction of Energy Intake

It is well established that when birds are fed energy in excess of metabolic needs, fat deposition increases largely in the area of abdomen and viscera. Several nutritional approaches are possible to restrict energy intake and these include feed restriction and narrower energy to protein ratios.

Novel Nutritional Approaches

A number of novel and potentially useful approaches have also been attempted in recent years. These include the use of β-agonists, conjugated linoleic acid (CLA), organic chromium, and polyunsaturated fatty acids (PUFA).

β-agonists

β-agonists have been studied as repartitioning agents in livestock species for nearly two decades. Although the exact mechanism of the action of β-agonists is unclear, a cascade of events is believed to occur following binding of the compound to the β_2-receptor, leading to tissue responses and partitioning of energy away from fat synthesis and into protein accretion. The interest in the use of β-agonists declined during early 1990s following an outbreak of food poisoning after eating livers from cattle treated with the β-agonist, clenbuterol. However, there is renewed interest in the use of β-agonists since the recent approval of ractopamine for use in pig diets by the Federal Drug Administration (FDA). The available data indicate that avian species do respond to β-agonists. In addition to performance responses, large decreases have been reported in the abdominal fat and carcass fat, with females generally responding more than the males.

Conjugated linoleic acid

CLA is a mixture of positional and geometrical isomers of linoleic acid (18:2); the predominant isomer being rumenic acid, a *cis*-9 *trans*-11 isomer. Ruminant meat products contain relatively high concentrations of CLA (0.5–1.5% of total fatty acids), whereas meats from simple-stomached animals are poor sources (0.1–0.2% of total fatty acids). CLA has been shown to regulate energy metabolism and repartition energy in a range of animals so that body fat is significantly reduced while lean body mass is increased. Studies in chickens have reported up to 35% decrease in abdominal fat with the dietary inclusion of 1% CLA.

Chromium supplementation

The beneficial effect of chromium in human health is well documented for its role as an integral component of the glucose tolerance factor, which potentiates the action of insulin. Insulin regulates energy production, muscle protein accretion, fat metabolism, and cholesterol utilization. Plant

feed ingredients commonly used in diet formulations contain low levels of chromium and additions of this mineral may therefore become a common micronutrient for animals in the future. Supplementation of broiler diets with 300–400 μg kg^{-1} organic chromium has been shown to markedly lower the carcass fat content and abdominal fat pad weight.

Concentration and source of dietary fats

Vegetable oils and animal fats are commonly used to achieve necessary levels of metabolizable energy in poultry diets. The type and concentration of fat used can contribute to excess fat deposition in fast-growing broiler chickens that are fed *ad libitum*. Of interest are the fats that contain high levels of PUFA. High dietary concentration of PUFA is known to inhibit lipogenesis and lower fat deposition in broilers. It is well documented that feeding diets containing sunflower oil (rich in PUFA of omega-6 series) and flax oil or fish oil (rich in PUFA of omega-3 series) lower abdominal fat pad mass in broilers compared to fats containing tallow (rich in saturated fatty acids).

Nutrition and Carcass Quality

Carcass quality in poultry may be considered in relation to two components. On the positive side, quality relates to physical appearance, including meat color, skin color, and finish, and the absence of off-flavors. On the negative side, presence of blemishes, in the skin and muscles, can downgrade the quality.

Skin Color

Skin color still influences the consumer attitudes toward fresh poultry. Pronounced regional differences in consumer preferences have been shown for fresh whole carcasses based solely on skin color, ranging from white to pale yellow to deeply pigmented. The deposition of pigments in the skin is determined by the dietary concentrations of the carotenoids, and can be easily manipulated by inclusion of ingredients with pigments (such as maize, maize gluten meal, and green leaf meals) or by the addition of synthetic xanthophyll sources.

Meat Color

Color of raw poultry meat is critical for consumer selection. Colors that differ from the expected pale tan to pink raw meat or from the tan to gray cooked meat will result in consumer rejection. Poultry meat color may be influenced by preslaughter and processing conditions, and nutritional factors have no effect on the color.

Carcass Finish/Downgrading

A good finish relates to acceptable physical appearance with no skin tearing or lesions. With the recent trend toward processing and the focus on special carcass parts rather than the whole carcass, the relative importance of carcass finish has declined during the past decade. Nutrition, provided that the feed has been properly supplemented with vitamins and minerals, is not usually associated with the physical downgrading of carcass.

Oily bird syndrome, a condition observed only in warmer climates, is associated with oily or greasy skin and increased skin tears. Because of the oily nature of the carcass, dietary concentration and source of fat have come under close scrutiny. Although there does not appear to be any simple relationship with fat concentrations, there is some evidence that the problem is more frequent in birds fed diets containing saturated fats such as tallow. A major quality problem encountered in turkeys, and more recently in meat chickens grown to heavy weights, is the incidence of pale, soft, exudative meat, but nutrition is not a factor in the development of this problem.

Skin strength is highly correlated with its collagen content and skin with less collagen is more prone to tearing. Zinc, copper, and vitamin C all play a role in collagen synthesis and, provided that processing conditions are not responsible, increased dietary additions of these may be useful in lowering skin tearing.

Maintenance of litter quality, in terms of moisture levels, is a critical component in producing meat birds of good carcass quality. Wet litter will not only lead to accumulation of ammonia and increase incidence of disease conditions, but also cause breast and hip lesions and lower the carcass quality. Several nutritional factors can increase the moisture content of the excreta, resulting in wet litter. Dietary electrolyte imbalance is a major cause of wet droppings. Electrolyte minerals, sodium, potassium, and chloride show independent effects for increasing water intake of poultry, when concentrations are increased above requirements. Dietary concentrations above 0.25% sodium, 1.15% potassium in young broilers (and 0.80% in older broilers), and/or 0.30% chloride increase water intake and wet litter problems. Feeding of diets based on cereals that contain significant amounts of nonstarch polysaccharides, such as wheat, barley, triticale, and rye, can also cause wet litter problems. But this can easily be mitigated by the use of appropriate feed enzyme supplementation.

Off-Flavors

The fatty acid composition of carcass lipid is the major determinant of the flavor and shelf-life stability of fresh and cooked meats. Large changes can be made to the diet without any effect on meat flavor, but the use of some ingredients is known to cause fish taints or rancid odors. These include fish meal, oils containing high levels of PUFA such as fish oil and flaxseed oil, and restaurant greases. The formation of off-flavors, however, can be largely suppressed by the provision of antioxidants, both natural and synthetic, in the diets.

Glossary

Adenosine triphosphate (ATP) The most common energy-carrying molecule used in cellular energy metabolism.
Conjugated linoleic acid (CLA) A long-chain fatty acid with anticancer properties.
FAMACHA A method of identifying parasitized sheep and goats by visually evaluating the color of their mucous membranes for anemia.
Squamous cells Flat, tightly packed cells which form a single layer of epithelium.
Volatile fatty acids (VFAs) Short-chain fatty acids which are the primary product of ruminal carbohydrate fermentation and they are the primary source of energy within the ruminant animal.

Introduction

Ruminants are mammals of the suborder Ruminantia and include animals in the families of Giraffidae, Cervidae, Antilocapridae, Ovidae, Bovidae, and Camelidae that chew their cud; respective examples are giraffes, deer, antelope, sheep, cattle, and camels. Although meat from most of these animals is consumed, only a few have been specifically domesticated for meat production. The principal and recurring cost of ruminant production is feed costs, and it is therefore economically important to understand the anatomical differences relative to other livestock; the manner in which the feed consumed is digested and the nutritional requirements of meat-producing ruminants. Thus, the nutritional management of various classes of the domesticated species is studied and documented scientifically.

Anatomical Distinction

Nutritional requirements of ruminants are different from those of nonruminants because animals in this suborder have a modified alimentary tract. Ruminant animals have four distinct chambers posterior to the esophagus and anterior to the small intestine. These chambers are the reticulum, rumen, omasum, and abomasum (Figure 1), with the first three being the 'forestomachs'; in the fourth chamber, or abomasum, acid secretion and peptic digestion occur, as in nonruminants. Following the abomasum is the small intestine and colon. In adult ruminants, these four chambers can occupy 75% of the abdominal cavity, with the rumen being the largest. The reticulum is the most cranial of the chambers and dorsally is continuous with the rumen. There are two, heavy muscular folds (sulcus ruminoreticularis and esophageal groove) extending from the cardia at the top of the reticulum to the omasum, which can contract to restrict the flow of partially digested feed or digesta into the rumen. The rumen itself is subdivided or saculated by muscular pillars. The contents of the rumen exit via the reticulo-omasal orifice into the omasum, a spherical chamber containing many muscular laminae with water- and nutrient-absorptive capabilities. Digesta exit the chamber into the abomasum via the omaso-abomasal orifice.

The interior of the forestomachs is covered with stratified squamous epithelium, which is organized into different structures in each of the three chambers (Figures 2–4). Unlike other stratified epithelium, that of the reticulum, rumen and omasum are vascularized, and the products of fermentation (volatile fatty acids (VFAs) and ammonia) are absorbed across the ruminal epithelium.

The rumen is proportionately smaller at birth than in adult animals and increases in size as it becomes progressively colonized by microflora. It is capable of fermenting feed within 4 weeks after birth and reaches adult proportions by 100 days after birth. The weight of ruminal contents in adult sheep and cattle varies with the type of feed provided, ranging between 4 and 6 kg in sheep and between 30 and 60 kg in cattle, and contains 10–15% dry matter (DM). The rumen harbors many different species of anaerobic bacteria, protozoa, and fungi (Table 1), which are involved in the proteolysis of proteins, hydrolysis and biohydrogenation of fats, and fermentation of carbohydrates in feed. These feed-digestive processes are aided

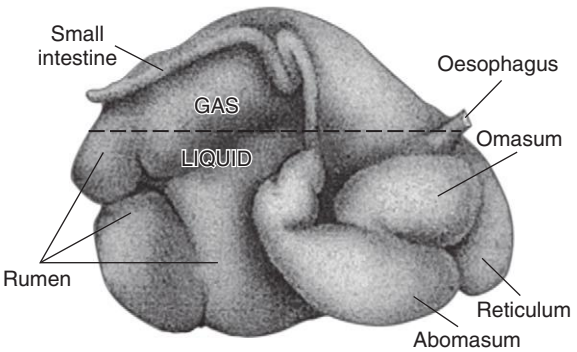

Figure 1 The chambers of the ruminant stomach (viewed from the right side). Reproduced from Bowen, R.A., 1997. Digestive Anatomy in Ruminants. Fort Collins: Colorado State University.

Figure 4 In the omasum, the epithelium is organized into broad longitudinal folds, which appear like leaves. Reproduced from Bowen, R.A., 1997. Digestive Anatomy in Ruminants. Fort Collins: Colorado State University.

Figure 3 In the rumen, the epithelium forms numerous papillae that vary in shape and size, depending on the feed provided to the animal. Reproduced from Bowen, R.A., 1997. Digestive Anatomy in Ruminants. Fort Collins: Colorado State University.

by the rhythmic contractions of the muscular pillars in the rumen wall, which mixes the digesta. These muscular pillars participate in the rumination of feed and eructation of gases produced during fermentation of feed components.

Rumination, or chewing the cud, is the process by which the animal is able to regurgitate part of the consumed feed, remasticate it, and swallow the digesta. This process aids in rupturing the cell walls of the feed and reinoculating the digesta with fresh microflora, facilitating the continuation of fermentation. Accumulation of gases produced during fermentation of feed can cause distension of the rumen; these gases are eliminated by the process of eructation or belching, a reflex event occurring once or twice a minute. The eructed gases contain methane and carbon dioxide and are of concern for the environment and for animal production, because they contribute to global warming and represent waste of feed energy. The estimated annual contribution of carbon dioxide and methane to the environment is 2741×10^6 and 82×10^6 metric tonnes, respectively, from domestic and wild ruminants.

Feed Digestion in Ruminants

The proteolysis of feed proteins results in the release of amino acids. These amino acids can either be incorporated into microbial protein or deaminated. The ammonia released is absorbed across the rumen epithelium and converted to urea in the liver, and the carbon skeletons of the amino acids are fermented. The urea produced in the liver is either excreted in urine or incorporated into saliva to be secreted into the mouth, mixed with the feed, and used for synthesis of microbial protein (Figure 5). Similarly, the ruminal microbes can utilize nonprotein nitrogen in feed for the synthesis of microbial protein. The rumen is a continuous culture system and the outflow from the rumen contains undegraded feed and products of fermentation, such as microbial biomass and water-soluble vitamins.

Fat in ruminant diets is very small in comparison to diets of nonruminants and rarely exceeds 6% of total diet DM. Feed

Table 1 Relative number and mass of microbial organisms in the rumen

Group	*Number per ml*	*Net mass (mg per 100 ml)*	*Percentage of total microbial mass*
Small bacteria	1×10^{10}	1600	60–90
Selenomonads	1×10^{8}	300	
Oscillospira flagellates	1×10^{6}	25	
Ciliated protozoa			10–40
Entodinia	3×10^{5}	300	
Dasytricha+Diplodinia	3×10^{4}	300	
Isotricha+Epidinia	1×10^{4}	1100	
Fungi	1×10^{4}	–	5–10

fats, which are galactolipids, are dismembered into their component galactose and triacylglycerols. The triacylglycerols, which are esters of fatty acids and glycerol, are hydrolyzed to their component fatty acids and glycerol. The alcohol and galactose are fermented to VFAs. The fatty acids are neutralized in the rumen by calcium salts forming insoluble particles that adhere to feed and microbes. Unsaturated oils in the diet can alter the microbial composition in the rumen by decreasing the protozoal population and the intimately associated methanogenic bacteria, altering the composition of the VFAs produced. The unsaturated fatty acids are extensively biohydrogenated to saturated fatty acids, usually to stearic acid, and in the process trap small, nonsignificant amounts of hydrogen, a byproduct of fermentation. During the process of biohydrogenation, some fatty acids can be converted into *trans* and conjugated fatty acids. When the double bonds in a fatty acid occur without being separated by a methylene group band ($-CH_2-$), conjugated fatty acids are formed (Figure 6). Conjugated linoleic acid (CLA) has demonstrated anticarcinogenic properties in many animal models. Thus, there is interest in producing products from ruminants that have elevated levels of CLA in the hope of preventing the onset of tumors in a wide section of the human population. Some of the unsaturated fatty acids in feed can also be deposited without being biohydrogenated when animals are supplied with high levels of oil in the diet as high-oil corn or flaxseed. Under these feeding conditions, the unsaturated fatty acids deposited in the meat can lead to formation of oxidative products, which can impart off-flavors to the meat.

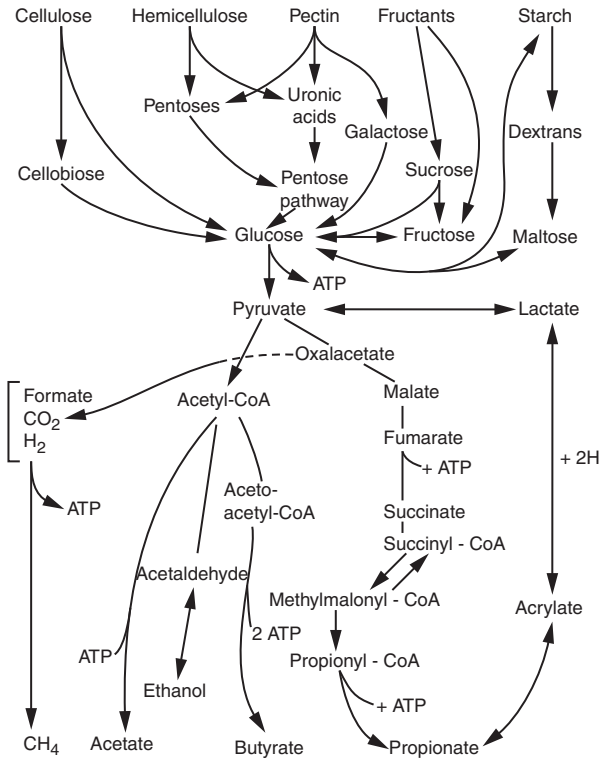

Figure 7 Pathways of carbohydrate metabolism in the rumen. Reproduced from Van Soest (1994). © Cornell University Press.

All carbohydrates in the feed and the carbon skeletons released from amino acids and lipids are fermented in the rumen to produce VFAs, namely, acetate, propionate, and butyrate, and the gases methane, hydrogen, and carbon dioxide (Figure 7). Some intermediary compounds of fermentation, such as lactate and succinate, can accumulate under certain feeding conditions. The rumen microbes produce VFAs, carbon dioxide, and methane to derive energy as adenosine triphosphate (ATP) for their life activities and growth. The fermentation of 1 mol of hexose (containing 2812 kJ of energy) completely to acetate, propionate, or butyrate will provide the animal 1758, 3072, or 2193 kJ, respectively. The amount of ATP generated and the yield of microbial biomass per mole of ATP are related to the outflow rate from the rumen (Table 2). When mixed feeds are fermented to varying proportions of fermentation products, the amount of bacterial protein nitrogen formed is approximately 27 or 36 g kg^{-1} of feed that is truly or apparently digested. The ATP available to the microbes for growth varies with the proportion of each of the VFAs produced. The proportions of each of the main VFAs and their production rate vary with the diet and the relative resistance of the feed components to fermentation.

Carbohydrates are the main repository of photosynthetic energy in plants, and in feeds constitute 50–80% of the DM of forages and cereals. Feeds contain cellular and cell wall carbohydrates. The cellular carbohydrates are generally storage carbohydrates, such as starches and compounds in intermediary metabolism as soluble disaccharides (two hexose units), hexoses, and pentoses and are very rapidly fermented in the rumen to VFAs. The starches are glucose units linked by α1–4 and α1–6 glycosidic bonds into straight and branching chains, respectively. These α1–4 and α1–6 glycosidic bonds of starch and the β1–4 glycosidic bond of lactose can be hydrolyzed by mammalian amylases and disaccharidases if these carbohydrates are not fermented in the rumen by the microbes. The amylases elaborated by the mouth and the pancreas hydrolyze starch and the disaccharidases in the brush border membrane in the small intestine hydrolyze the disaccharides to their component hexoses in preparation for absorption.

Table 2 Effect of dilution rate on fermentation products in a continuous fermenter with mixed rumen population and using glucose as an energy source

Product	*Dilution (turnover) rate (h)*		
	0.02	*0.06*	*0.12*
Acetate[a]	1.18	1.11	1.13
Propionate[a]	0.16	0.22	0.26
Butyrate[a]	0.23	0.18	0.15
Methane[a]	1.67	1.34	1.04
ATP[a]	5.59	5.19	5.03

The cell wall polysaccharides are composed of pectin, cellulose, and hemicellulose and provide structural support to the plant. They are more resistant to microbial degradation than are the cellular carbohydrates. Cellulose is comprised of β1–4-linked glucose chains, which are hydrolyzable by microbial cellulases but not by mammalian enzymes. Furthermore, the cellulose chains can twist around each other to enhance the resistance to hydrolysis. Resistance to degradation can be further increased with advancing maturity of the plant by the deposition of hemicellulose, which consists of polymers of arabinose, xylose, mannose, galactose, and glucuronic acids linked by either α or β bonds. Although pure hemicellulose is soluble, the hemicellulose in plants is intermolecularly and covalently associated with cellulose and lignin (phenolic compounds). This covalent bonding increases with plant maturity and renders the hemicellulose resistant to mammalian and microbial enzymes. Thus, fermentative degradability of cell wall carbohydrates in total is decreased with advancing plant maturity.

The fermentation of feed is unavoidable in ruminants. The advantage is that ruminants can consume and derive energy from cellulosic, fibrous feeds, and utilize nonprotein nitrogen to produce microbial biomass. Rumination is an added advantage for digestion of poor-quality roughage. Because the fermentation chamber precedes the main site of digestion, the fermentation products, which are microbial protein and water-soluble B vitamins, receive the most efficient use, unlike lower-tract fermentation in horses where the fermentation chamber is distal to the main site of digestion. Microbial proteins, being

a combination of bacterial and protozoal proteins, can be composed of a better balance of amino acids than some feed proteins and may meet the amino acid requirements of the host animal better than some feed proteins. In such situations, the synthesis of microbial protein is advantageous to the animal; but when higher-quality proteins, such as casein or soybean protein are extensively degraded, then pregastric fermentation is a disadvantage.

Extensive pregastric fermentation of dietary proteins, starches, and soluble carbohydrates is partially offset for the host animal by the opportunity to digest the fermented products, microbial protein, and B vitamins. Some loss of dietary energy must be expected because eructated gases are natural products of fermentation. Furthermore, only 50–70% of the microbial nitrogen is available protein, whereas the remainder is bound in cell wall structures and nucleic acids. Proteins, especially most soluble proteins, are extensively deaminated during fermentation and, although there is an opportunity to recapture this nitrogen as urea recycled via the saliva, the production of urea is energetically expensive to the animal and loss of urea in urine is inevitable. Thus, some valuable amino acids in high-quality proteins may be better used if they are not fermented because feed nutrients can be wasted during fermentation, reducing the efficiency of production.

The efficiency of production is largely related to the type of feed provided to the animals. Although feed-to-gain ratios in ruminants can be as low as 6.0, that cannot rival those in nonruminants such as swine (2.5). It is the ability of the ruminant to utilize fiber that places the domesticated ruminant in its unique position in the world economy. Owing to this ability, production of meat from ruminants can eliminate competition for the same foods between humans and livestock and yet provide humans in many developing nations with excellent quality protein. In developed nations, it is an opportunity to utilize the vast photosynthetic energy captured as forage because, even though ruminants can consume concentrate feeds, they have a requirement for fibrous feeds for maintenance of the functionality of the rumen.

Classes of Meat-Producing Ruminants

All animals can be harvested as meat, but there is a need to maintain a part of the herds to produce progeny that can be used for meat production. In developed countries, specific breeds of cattle, sheep, and goats have been developed for the purpose of producing high-quality beef, lamb, and goat meat and this is the focus here. In developing countries, livestock agriculture tends to be less intensive and the quality of product is not an important consideration. Animals have multiple uses and the ability to harvest meat is an additional opportunity. The discussion relating to nutritional requirements of different classes of meat-producing ruminants pertains to practices employed in developed countries.

Sheep and Goat Production

Sheep and goats are similar and many aspects are discussed elsewhere. Goats are raised extensively, for meat, milk, and fiber production, in nearly every country of the world. Although breeds differ greatly in productivity (milk, meat, and fiber production) and in their ability to adapt to terrain, climate, feed availability, and feed quality, the small size of goats relative to that of cattle often makes goats more cost-effective and adaptable for protein production than cattle, especially where high-quality feed resources are limited. Another unique aspect of goats is that, relative to cattle, they are highly selective browsers, and seek out leaves of woody shrubs and trees as a primary feed source. This makes goats ideal for areas where woody plants are abundant relative to grasses. In addition, goats can be used as a complementary species in conjunction with sheep, cattle, or horses, which primarily choose to graze grasses. When grazing pressure is managed properly, especially using a multispecies, complementary grazing program, goats can effectively control the spread of invasive woody plants in pasture or range environments.

Early age at puberty and frequent twinning make rapid establishment of a goat herd possible. Because of a five-month gestation period and early maturity, offspring can be ready for market one year after breeding. Goat meat is preferred to beef by members of many ethnic and religious backgrounds, and US consumption of goat meat has increased greater than 10-fold since 1989.

Productivity of goats, such as that of cattle, is highly dependent on availability of nutrients. Supplementation of poor-quality forage (mature grasses or cereal straws) with higher-quality feeds containing greater percentages of protein and energy (legumes, some tree leaves, and oilseed meals) will increase digestibility and consumption of the poor-quality forage and improve productivity. After the protein needs of both the animal and the rumen microbes have been met, supplementation of the diet with additional energy, in the form of cereal grains, grain byproducts, citrus pulp, fruits, or tubers, can increase productivity.

Management and control of internal parasites is the primary health concern in goat production, and the parasite species of primary interest differs widely depending on geographical region. Internal parasites primarily reside on pasture but complete their life cycle within the goat. Larvae are consumed by grazing goats; larvae mature into adults within the host; adult nematodes lay eggs in the digestive tract (either the abomasum or the small intestine) of the host; the eggs are passed in the feces and hatch into infective larvae on pasture. High animal density in confined pasture areas contribute to increased parasite exposure and increased parasite burdens in infected animals. Heavy parasite burden, particularly when animals are infected with *Haemonchus contortus*, causes anemia in goats, which can be diagnosed by observing differential color of mucous membranes around the eye, the gums, and inside the vulva. Edema or swelling below the jaw is also an indication of a heavy parasite load. A FAMACHA eye color chart, using a 5-point color scale applied to the inside of the lower eyelid, can be used to estimate the level of parasitism (**Table 3**). The level of redness is inversely proportional to the level of anemia and, hence, the level of parasitism (**Figures 8** and **9**).

Although internal parasites can be controlled using anthelmintics, cograzing of goats in conjunction with cattle permits each host species to safely consume the larvae of parasites specific to the other species, resulting in fewer

infective larvae consumed by the target host species. In addition, grazing forages high in condensed tannins, such as sericea lespedeza, birdsfoot trefoil, sainfoin, lotus, and sulla, as well as leaves from some shrubs, trees, and cassava forage, may reduce parasite infection. The condensed tannins suppress egg-hatching and larvae viability of nematodes. Overgrazing pastures contributes to the consumption of infective larvae as animals graze closer to the ground. To reduce level and prevalence of internal parasitism, grazing should be discontinued as forage height is reduced below 10 cm.

Table 3 Association between color of inside of lower eyelid and level of anemia

FAMACHA Scale	*Color*	*Anemia level*
1	Red	Nonanemic
2	Reddish-pink	Nonanemic
3	Pink	Mild anemia
4	Pinkish-white	Anemic
5	White	Severe anemia

Scrapie is a transmissible spongiform encephalopathy (TSE), which affects the central nervous system in goats and sheep, and is characterized by extensive scraping of the hide and, ultimately, death. Although rarely found in goats, scrapie is nearly 100% fatal and most often transmitted vertically from doe to kid early after birth, primarily through contact with placenta and birthing fluids. Quarantine and slaughter of infected animals is essential to eradication of scrapie from the herd.

Great caution must be taken whenever importing goats developed in regions with disparate climatic normalcy. Imported goats may have little or no resistance to local parasites and diseases. In addition, whereas goat breeds indigenous to equatorial and tropical regions are tolerant to high temperature and humidity, goats developed for high productivity under temperate climatic conditions will likely suffer greatly and have poor productivity and reproductive performance under tropical or heat-stress conditions.

Male goats are subject to development of crystals, termed urinary calculi, which obstruct the flow of urine from the bladder. Urinary calculi are rare in grazing goats and are primarily a risk in goats fed a grain-based diet. The risk can be dramatically reduced by (1) maintaining a 2:1 ratio of calcium-to-phosphorus and (2) including an ingredient, such as ammonium chloride or ammonium sulfate at 0.6% of the diet on a DM basis, to acidify the urine. Additional preventative measures include providing continuous, free-choice, access to salt and fresh, clean water. Intact male goats grow faster and have leaner carcasses compared to male castrates. However, with adequate nutrition, both male and female kids can reach reproductive maturity at 6 months of age. So to prevent early, unplanned, breeding, bucks should either be separated from does after weaning, or should be castrated if they cannot be separated after 4 months of age. There is anecdotal evidence

Figure 9 (left) Normal, healthy color of membranes of upper and lower gums and (right) anemic color of membranes of upper and lower gums. Photo courtesy of Dr. B. Faris.

that castration before 60 days of age may further exacerbate the risk of urinary calculi, so it is not recommended that goats intended for confined feeding be castrated before 60 days of age.

Beef Production

Beef production is on the rise worldwide and world annual per capita beef consumption is expected to rise from 5.6 kg in 1994 to 9.7 kg of retail beef by the year 2019. There is immense disparity in per capita beef and veal consumption among the nations, ranging from 1.5 kg in India to 70.2 kg in Argentina, with the United States being third at 45.3 kg in 2010. Trade in beef is expected to expand in the world as consumption in population-dense countries such as China increases, pressuring beef producers to improve efficiency. A part of this efficiency is achieved through improved nutritional management of beef cattle.

Traditionally in North America, calves are born in spring (February to May) and dam and calf are turned out into pasture, where they grow over the summer months. Bull calves other than those designated to be kept for reproduction are castrated. In the event that natural insemination is practised, the bulls are also put on pasture. Cows not with calf at the end of summer are culled, often fattened and processed. In late September or October, the calves are expected to be less dependent on the dam's milk for nourishment because they should have a fully functioning rumen and can be weaned without significant consequences. Calves weighing approximately 250 kg are separated into heifers and steers, and grazed or backgrounded in feedlots on growing diets until they are approximately 350 kg. At this weight, the cattle are adjusted to diets containing ever-increasing levels of concentrate (cereal grain) to produce animals weighing 525–600 kg and ready for processing by the age of 15–20 months.

Although extensive focus is placed on cattle in feedlots, there is substantial literature on balancing forage production in pastures to effectively manage maintenance of pasture for future years and to obtain the best feed for the cattle in the current year. The carrying capacity of pasture represents the number of animal units (dam and calf, a steer or heifer) that can be supported on a pasture for a month and is affected by many factors (Table 4).

The majority of the cattle to be harvested are placed in feedlots for fattening before processing. To achieve efficient growth performance, cattle in most North American feedlots are implanted with pelleted androgenic or estrogenic steroidal hormones in the ear, or heifers are fed melengestrol acetate (MGA; specifically for heifers to suppress ovarian follicle stimulation), and provided with beta adrenergic agonists, ionophores, and antibiotics. Beta agonists approved for use in feedlot cattle include ractopamine hydrochloride and zilpaterol hydrochloride. Beta agonists increase the amount of lean muscle deposited on a beef carcass by upregulating gene transcription resulting in increased protein production and reduced protein degradation in the muscle cell. The ionophores licensed for use in growing and fattening cattle are monensin, lasalocid, laidomycin propionate, and salinomycin. The ionophores control the microbial fermentation in the rumen and shift the VFAs produced in the rumen toward more (49–76%) of the higher energy-yielding propionate, with corresponding reductions in acetate or butyrate for significant diets. This shift in the rumen metabolism translates to a 5–8% increase in feed conversion efficiency due to decreased feed intake (4–10%) with small increases in weight gain. The implants appear to increase weight gain in animals by influencing the use of energy and amino acids absorbed from the alimentary tract toward protein accretion. Antibiotics such as tylosin are provided to fattening cattle when they are fed in excess of 80% grain on DM basis. Under such conditions, the fermentation in the rumen is brisk, with high rates of VFA production, and the ruminal pH is reduced (<5). This situation leads to erosion of the rumen papillae and can aid the passage of pathogenic bacteria, which can lodge in the liver and cause abscesses. Provision of low doses of tylosin in fattening cattle diets can decrease or eliminate the abscesses. The use of implants and nontherapeutic, feed-grade antibiotics is banned in the European Union because it is suspected that there is transfer of the steroidal compounds in meat to humans and because of development of antibiotic-resistant pathogens.

Because the beef industry is of immense economic importance, the romance of cattle ranching has given way to practical considerations of meeting cattle needs. At slow rates of gain, an animal takes longer to arrive at target weight, so that more nutrients and energy are expended in maintaining an animal than if rates of gain are high. To achieve the required efficiency, the nutritional requirements of cattle are continuously being assessed and published periodically by the National Research Council of the Agriculture Research Service, United States Department of Agriculture. Similar publications are available in the United Kingdom, the European Union, and Australia that outline the requirements of beef cattle for their particular circumstances. These publications include discussion of the factors (Table 5) that affect nutritional requirements of beef cows and bulls through various stages of life and those of heifers and steers maintained exclusively for the production of beef.

The rate of production in feedlot-fed cattle is related largely to the frame size and the amount of feed they can consume. Cattle have a requirement for fiber and cannot be provided complete concentrated diets without negative consequences, which can limit the amount of feed they can consume. This limitation is especially observed when young weaned calves are brought into the feedlot. In these calves, the rumen capacity is limited and they cannot consume high levels of concentrate because the microbes in the rumen are not adapted to high levels of grain. It is preferable not to feed high levels of grain quickly to young calves, as this will make them gain fat rapidly and animals will be ready for slaughter at lower final

Table 4 Factors affecting carrying capacity of a pasture

- Cultivated or native – forage production
- Fertilization
- The species mix and percentage of each forage
- Climate – temperature, precipitation, and hours of daylight
- Type of terrain
- Distance to water source
- Type of animal unit – cow and calf or steer

Table 5 Factors affecting energy and nutrient requirements

- Intended use of the animal
- Sex of animal
- Age of animal
- Frame size of animal
- Surface area of the animal (area affected by the weather)
- Physiological state of animal (young, pregnant, lactating, etc.)
- Previous nutritional state (animals with poor nutritional status gain at faster rates when adequate nutrients are fed as they are compensating for previous status)
- Expected rate of production, and whether animals are being grazed or feedlot-fed (for grazed cattle, the terrain they have to traverse to obtain food will affect their requirement)
- Type of diet provided – high-forage or high-grain
- Relative digestibility of the feed
- Intake potential of the animal
- Anabolic implants or growth promotants
- Ambient temperatures (animals placed outside the zone of thermoneutrality on either side will be affected)

weights with lower yields of edible meat. Therefore, lower-energy diets with adequate protein are provided for the animals to grow in frame size until they weigh approximately 350–400 kg. Once this is achieved, animals must be adapted to higher-grain diets in 5% grain increments per week until they receive 85–95% grain on DM basis to capture the residual growth and deposit the appropriate amount of external and internal fat in readiness for processing. Byproducts from the grain processing industries (for production of grain-based ethanol and extraction of starch for food-grade, corn-based sweeteners) are often substituted for 5–60% of the grain portion of the finishing diet. The ingredients most commonly used as supplements in cattle growing or fattening diets include distillers' grains (either wet or dried, mostly from corn, but also from sorghum, wheat, and barley), corn gluten feed, and wet or dried citrus pulp. Although these byproduct ingredients are high in neutral detergent fiber, the fiber is nonstructural in function and is highly fermentable. Although these byproducts are often relatively high in crude protein, their abundance in cattle-producing areas, their energy content, and their competitive price result in their inclusion as an energy source rather than strictly as a protein supplement. The overall digestibility of such high-grain diets does not exceed 76% and, if economical, lower-grain diets can be used successfully.

Beef cattle can benefit from higher-quality protein, such as soybean protein, that is protected from degradation in the rumen when they are younger and there is an opportunity for the animal to absorb the amino acids to support the growth acceleration that is possible in these animals. But at the 400 kg weight, the rumen is large enough that the microbial protein produced will meet the reduced demand adequately. The concern is to meet the requirements of the rumen microflora, which is approximately 12% crude protein. Although rumen microflora can propagate with a nonprotein source of nitrogen such as urea, their growth rates are improved when true protein is provided in the diet.

The production of sheep and goats is less extensive in North America, than in the United Kingdom, Australia, and New Zealand. However, sheep and goat production is less intensive than beef production and is based on grazing cultivated or native pasture. As in the case of beef production, the specific nutritional requirements of sheep and goats have been studied and publications detailing their requirements are available.

Veal Production

Veal is usually produced from culled dairy bull calves and is a minor part of the industry. Traditionally, veal is pale, lean beef from very young animals. After the calves have received colostrum, they are separated from the cow and maintained on a liquid diet of whole milk or milk replacer until they are approximately 154 kg or 3 months of age. These calves are susceptible to digestive disorders and therefore have to be limit-fed cautiously until they are approximately 4-weeks old, after which they can be provided whole milk or milk replacer ad libitum. At ad libitum intake, calves can consume 1–1.6 kg of DM per day or 1.5% of body weight without any detrimental effects. Feed conversion efficiencies ranging between 1.3 and 1.5 kg of milk DM per kilogram gain have been observed. Such high feed efficiencies are possible because whole milk or equivalent quality milk replacer is fed to the calves, because the calves are maintained on fluid feed and the development of the rumen is discouraged, and because the provision of fluid diets up to slaughter maintains the esophageal groove functionality and, as a result, fluid milk passes directly from the reticulum to the omasum. Since the components of the diet are not subjected to fermentation in the rumen, the calves reap the benefit of the high quality of the milk proteins and other components at a time when they have a high growth potential.

Veal is produced with high-quality feed that could otherwise be used for human consumption. Although milk proteins can be substituted by vegetable proteins, such as soy protein in milk replacers, calves can develop allergic reactions to the proteins, which thus require extensive processing to render them safe for use in milk replacers. The incorporation of adequate amounts of vitamins and minerals into milk replacers is essential to produce superior-quality veal. Often, insufficient iron is provided in the diet in order to maintain the pale color; however, this can affect the calves' growth rate and the elimination of supplementary iron is a practice that is not recommended by many national animal welfare councils.

General Aspects of Feeding Ruminants

Cattle, sheep, and goats need supplemental fat-soluble vitamins A, D, E, and K, which pass to the lower alimentary tract for absorption. Ruminants also require various elements, and especially cobalt to facilitate the synthesis of B_{12} for the host animal. The requirements of all the mineral elements for each class of cattle along with the signs of deficiency and toxicity for each mineral element are also detailed in numerous livestock management publications.

The capture of energy in the feed can vary substantially, depending on the extent of processing applied to feed. Hay is

Table 6 Equation for water requirement of cattle

Water intake (liters per day) = −019.76+[0.4202×Maximum temperature °F]+[0.1329×DM intake (kg/d)]−[6.5966×precipitation (cm per day)] −[1.1739×dietary salt (% DM)]

Source: Equation from National Research Council, 1996. Nutrient Requirements of Beef Cattle, seventh revised ed. Washington, DC: National Academy Press.

better used than silage, but if climate at a location is such that hay or pasture is not available year round, then feed must be harvested and stored for later use. Forage can be harvested for hay, if weather permits, or as silage. Cereal crops can be grown and harvested for grain or forage, such as barley or corn silage. Many grains need to be processed to crack the exterior hull to facilitate attachment and degradation by ruminal microbes. However, overprocessing of the grain can lead to very high fermentation rates that cause overproduction of VFA, leading to acidity in the rumen and in the blood. If fermentation rates are very high, the rate of gas production is enhanced to such extents that the animal is unable to eructate the gas and bloat will follow. Bloat can lead to pressure increases and distension of the rumen, which can block the air passage, causing asphyxiation without warning. Similarly, bloat can occur when ruminants are fed hay from or are pastured on certain immature succulent legumes such as clovers or lucerne (alfalfa). Therefore, if animals are grazing legume pastures they must be watched. Pastures must contain an adequate percentage of grasses to reduce the occurrence of bloat-related hazards; alternatively, 'bloat guard' additive can be provided to the animals.

Above all, animals require water, and the requirement relates to the ambient temperature, to exercise, to animal size, to feeds provided to the animals, and the amount consumed. The requirement for water is less if the pasture is immature, as in early spring, but as the pasture matures the DM content increases and so does the need for water. Similarly, water need increases with the grain content of the diet. The water requirement for feedlot cattle can be calculated (Table 6) and can double between 4 and 32 °C for any class of animal. Just as the DM intake influences water requirement, the water availability affects DM intake. To achieve profitable production efficiencies, it is necessary to pay close attention to provision of adequate clean water along with other nutrients.

O

ON-LINE MEASUREMENT OF MEAT COMPOSITION

R Clarke, Milmeq Ltd., Penrose, Auckland, New Zealand

This article is a revision of the previous edition article by R Clarke, volume 2, pp 935–941, © 2004, Elsevier Ltd.

Glossary

At-line Refers to a measurement device that is installed beside a processing line, but requires a product to be either partially diverted or sampled in order to take a measurement due to the measurement device requiring more time to take a measurement than the process throughput permits.

Chemical lean 1 minus the fat content, as measured by chemical analysis, commonly expressed as a percentage (e.g., 80CL = 80% lean by chemical composition).

Hyperspectral imaging Hyperspectral imaging is the technique by which spectral cameras collect information as a set of 'images.' Each image represents a range of the electromagnetic spectrum and is also known as a spectral band. These 'images' are then combined and form a three-dimensional data set for processing and analysis.

In-line Refers to a measurement device that is installed as part of a processing line, operating at the same throughput and measuring product in a continuous manner without the need for product sampling, diversion or intervention.

Spiral CT CT scanner whereby the object being imaged moves linearly through the CT aperture as the object is scanned, creating a spiral scanning path through the object.

Introduction

Meat in its fundamental form is generally modeled by way of a three-compartmental model comprising fat, water, and protein. Of these three, fat content is generally the most commonly measured attribute. For example, boneless beef (termed manufacturing meat) is commonly traded on the basis of chemical lean (CL). CL is equivalent to 1 minus the fat content and is commonly expressed as a percentage (e.g., manufacturing meat with 20% fat content is referred to as 80CL). A number of techniques exist for measuring the various qualities and compositional attributes of meat. This article outlines some of the near- and on-line techniques for measuring the compositional nature of meat within a meat-processing environment. Consideration of the methods to evaluate a technique against reference methods is also discussed.

Performance of In-Line Methods

Official reference methods for determining meat composition in terms of fat, water, and protein (herein referred to as base tests) are the accepted benchmark against which in-line or near-line measurement technologies are assessed. The performance of the base test is critical because any uncertainty in the base test will contribute to, and fundamentally limit, the performance of the new technology.

The performance of a base test is usually expressed as repeatability, reproducibility, and bias. Repeatability is the standard deviation of repeated measures by the same laboratory, reproducibility is the standard deviation of repeated measures by different laboratories, and bias is the consistently high or low values produced by a method relative to known values. These figures are expressed from a perspective of the performance of the base test to the known or actual value of the sample. However, when comparing different on-line methods for measurement, it is important to express the performance of the measurement technique in terms of its ongoing predictive ability to produce a measure relative to the accepted value for the sample.

From a production perspective, the two most important indicators of performance of any near-line or on-line measurement technique is its *accuracy* and its *repeatability*. These terms are often confused and rarely explained. Manufacturers

 doi:10.1016/B978-0-12-384731-7.00072-6

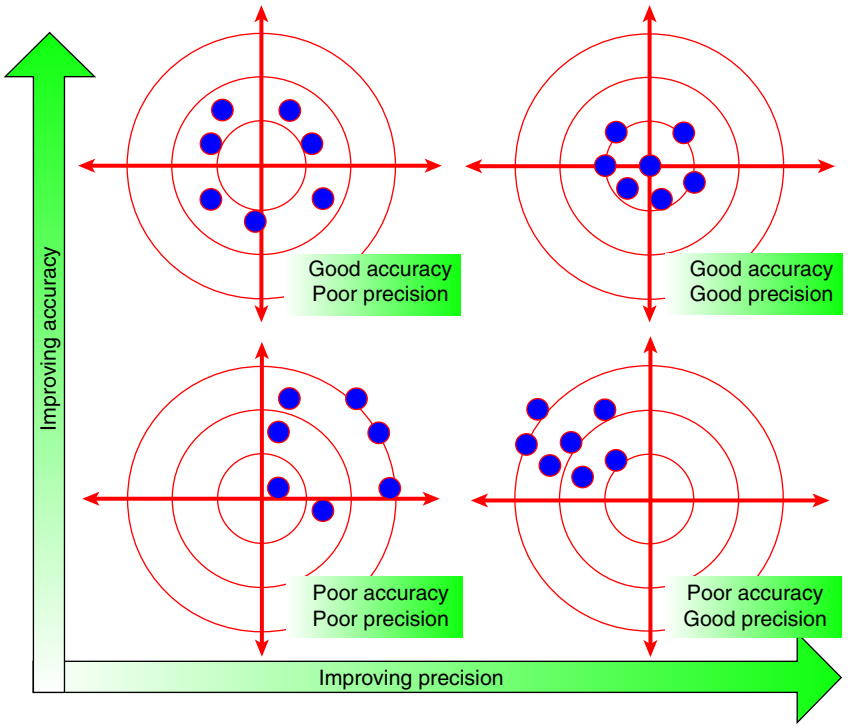

Figure 1 Example of accuracy and precision.

often quote performance figures that present a measurement device in the most favorable light. This often leads to disappointment with the actual performance.

Accuracy refers to how close an average measurement is to the accepted value of the sample. People discussing the accuracy of a measurement device should state which base test has been used to quantify the accuracy of that device. Otherwise, the concept has little meaning.

An easy way to understand the concept of device accuracy is to think of its measurements as being shots at a target, as in Figure 1. The center of the bull's-eye represents the best estimate of the actual value as determined by the base test.

Good accuracy is achieved when the average of many measurements (i.e., the center of the grouping of shots) lies close to the center of the bull's-eye, as in the top two targets.

Precision refers to the *repeatability of many measurements on the same sample*. Accuracy includes the effects of precision, because variations in individual measurements due to poor precision will generally reduce the individual *accuracy* of each measurement compared to the base test, even though the average of many test results may be close to the bull's-eye.

A measurement device with high precision will produce virtually identical measurements of the same sample (right two targets in Figure 1). However, if that device has poor accuracy, all these measurements may be 'off target' (bottom right target in Figure 1).

A measurement device can have excellent precision but poor accuracy and vice versa. The ideal measurement device will have both good accuracy and good precision, as in the top right target in Figure 1.

The figure for accuracy will always be greater than the figure for precision and is the performance figure that is most often quoted when comparing techniques and technologies. Where possible, performance figures of the measurement techniques discussed here are accuracy figures, expressed as the standard deviation of the error in prediction of the measurement technique as compared to the actual value as determined by way of the accepted base test.

Precision and accuracy are reported using a variety of units. Although Pearson's correlation coefficient (R^2) is often cited as a measure of accuracy, it indicates only the strength of the correlation between two variables after performing some form of fitting. Similarly, the root mean squared error (RMSE) indicates the degree of closeness of a fit. More useful measures of accuracy include metrics such as the standard error of prediction (SEP) or standard error of estimate (SEE), generated using data from independent validation trials.

Optical Systems

Optical Sorters

Humans, with their inherent ability to discriminate on the basis of color, shape, and size, are able to discriminate quite accurately between similar cuts of meat on the basis of (visible) fat content. Because humans primarily use their sense of sight for inspection tasks, it is not surprising that significant effort has gone into utilizing technology that mimics this sense to automate inspection tasks. There are numerous companies that manufacture and market optical-based natural product inspection systems for a variety of applications. Key Technology Inc. (Walla Walla, WA, USA, www.keyww.com) is one of the leading manufacturers and suppliers of product inspection,

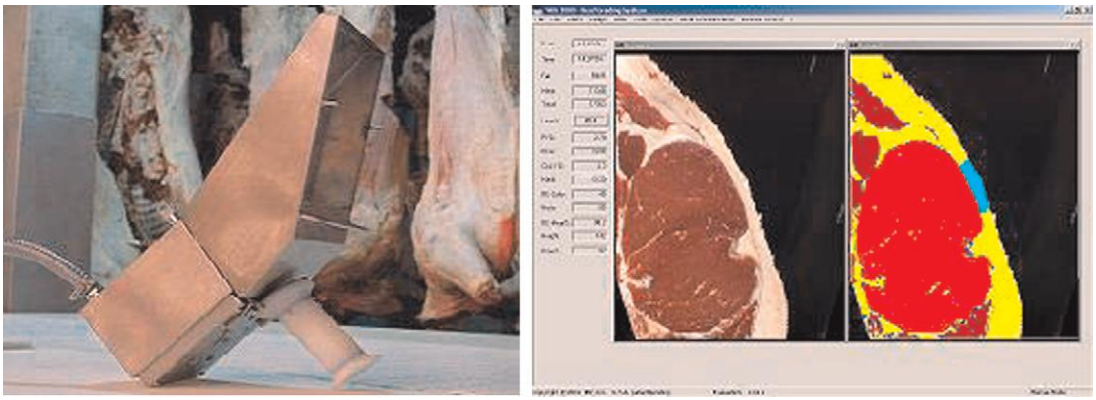

Figure 2 e+v's VBG beef camera and output screen. Reproduced with permission from e+v (http://www.eplusv.com/start_E.htm).

sorting, and control systems, for a wide range of food products, including meat and meat products. Their Prism@2 sorter, for example, uses controlled illumination and a variety of camera configurations to detect and discriminate between acceptable and unacceptable (including contaminants) product at high throughput rates. The use of monochrome, color, and visible/infrared (Vis/IR) cameras further enables vision technology to be optimized for a wide range of natural product inspection applications. Complex product transportation and conveyor mechanisms enable full 360 degree inspection of the surface of the product.

This technology has been proposed for the measurement of CL in diced (or finely portioned) meat products by using color cameras to discriminate between meat and fat, then using this difference to estimate the CL of a diced meat stream-based on the relative amounts of visible meat and fat. Although a correlation between the visible level of fat and the overall CL of a meat product stream does exist, this correlation depends on, and is proportional to, the individual portion shape and size within the product stream and the author is not aware of any published trials or operational systems currently in operation. Although potentially suited to continuous flow of diced meat product, they are not particularly well suited to inspection of discrete portions such as meat boxes, because the visible fat-to-lean ratio will be highly dependent on species, cut, orientation, shape, and even seasonal variations.

Video Image Analysis

Video Image Analysis (VIA) systems use electronic camera technology, along with computer-based digital image analysis techniques, to extract key features from one or more images of carcasses and derive estimates of various carcass attributes including carcass yield and composition. Because VIA only images the visible surface of the carcass, a variety of approaches are used to infer internal attributes such as fat depth and muscle size and dimension. Color is commonly used to infer fat depth from carcass images, whereas multiple VIA images taken from different viewpoints (including views of the inner surface in situations where the carcass is split along the backbone before imaging) are used to assist in estimating meat yield and distribution. Some systems also use a series of lines

Figure 3 e+v's VSS 2000 lamb VIA system. Reproduced with permission from e+v (http://www.eplusv.com/start_E.htm).

of light to extract additional three-dimensional information about the outer shape of the carcass. In applications where the carcass or side is cut at right angles to the spinal column (e.g., beef sides quartered in the chiller), VIA can be used to obtain direct measures of fat cover, eye muscle size, and dimension to infer composition and yield (Figure 2).

VIA systems such as ViaScan (Cedar Creek Company, Brisbane, Australia) and VSS 2000 (e+v Technology GbH, Oranienburg, Germany) are commercially deployed in Europe, North America, and Australasia, primarily for beef and lamb carcass assessment as well as for pork and poultry (Figure 3). However, because they only measure surface topography, they are not as accurate as measurement technologies that are able to perform tomographical measurements of internal structure.

Ultrasound

Ultrasonic scanners use ultrasound to determine the boundaries between meat and fat using ultrasound signals that are reflected off these boundaries. These are noninvasive but require the ultrasound transducers to be in contact with the surface of the carcass or live animal to ensure reliable ultrasonic coupling. Ultrasound is primarily used as a technique for inferring fat

Figure 4 Carometec AutoFOM. Reproduced with permission from Carometec (http://www.carometec.com).

depth and (occasionally) key muscle dimensions as a means of estimating carcass composition and yield. Although the majority of these are hand-held probes, Carometec (Carometec A/S, Herlev, Denmark) sell an automated ultrasound carcass assessment system that estimates total lean meat percentage, predicting the yield to an RMSE of 2% (Figure 4).

Because these scanners require direct contact with the surface to prevent air pockets blocking the signal, they are largely deployed in pork assessment where the skin is left intact on the carcass. With beef and lamb, the pelt-removal process results in air gaps within the surface fat due to bubbles or tears, resulting in very poor ultrasonic signal transmission. As a result, ultrasonic scanners have proved commercially unreliable when applied to assessing beef and lamb carcasses post hide or pelt removal.

Near Infrared Spectroscopy

Other chapters within this publication cover near infrared spectroscopy (NIR) as a noninvasive technology capable of inferring a variety of meat-related attributes on carcasses, cuts, and end products (Listed in See also section). NIR refers to the range within the electromagnetic spectrum with wavelengths from approximately 760–2500 nm, slightly longer than visible light (approximately 400–760 nm). In combination with midinfrared (approximately 2500–30 000 nm), NIR is often referred to as vibrational spectroscopy, because the spectra measured is the result of intermolecule vibrations due primarily to the covalent bonds within molecules. The sample is illuminated with a broad-band visible/NIR illuminant (usually extending down into the visible range) and the resulting (reflected/transmitted/transflected) NIR light detected and separated into its constituent frequency components over the NIR range of the spectrum.

The discriminative power of NIR lies in the very high signal-to-noise ratio (SNR; typically many orders of magnitude, with some of the newer systems claiming 10^6 or greater), which enables subtle differences between signals, invisible to the naked eye, to be reliably used to discriminate between samples. This precision of NIR instrumentation means these subtle changes can be measured even in the presence of gross spectral changes unrelated to the target parameter(s). Any spectral changes caused by one difference in sample composition may be independently extracted, enabling NIR to measure an enormous range of tests from a scan of a single sample.

Generally, NIR requires relatively little sample preparation, is nondestructive and very fast, compared to the traditional base tests. The test may take only a matter of seconds per sample. Equipment may be deployed much closer to the sample itself (field, conveyor, etc.) than would be possible for the normal complex, laboratory-only equipment used to perform the base test, which generally requires more complex sample preparation. It is possible to measure a wide range of chemical elements and physical characteristics of a material simultaneously. NIR has been implemented on-line to measure composition in homogenous product streams (e.g., ground or boneless meat streams) but for whole cuts or carcasses it still requires either a sample to be taken or the instrument applied to the product at a predetermined location, in order to perform a measure. Therefore, it is still currently considered an 'at-line' rather than 'on-line' technology.

Fundamental to NIR is the calibration of the instrument. The calibration must be prepared in advance using statistical methods to match subtle features of the NIR spectra to the effect of the various components of the samples. The accuracy of this calibration is, therefore, limited by the accuracy and precision of the base test used to calibrate.

There are over 10 000 published papers on NIR and a high proportion of these are directly associated with agriculture. NIR has been used to predict protein in fresh beef and chicken carcasses and chicken breast with standard error of performance (SEP) of 0.809, 2.03, and 2.04, respectively. Good predictions of fat, moisture, protein, collagen, starch, collagen-free protein, iron, and iodine have also been reported, and NIR is an accepted and established rapid technique for the basic chemical composition of red meat and pork, with calibrations delivering $R^2 > 0.95$ and prediction errors of less than 2% by mass, respectively.

A recent trend has been the use of NIR to determine the fatty acid content and composition in raw meat as a technique for inferring quality parameters to complement compositional analysis. Although published results indicate that NIR is generally less accurate for predicting different attributes of meat quality, it nonetheless is promising when categorizing meat into quality classes on the basis of quality traits. The ability to develop calibrations for quality as well as compositional attributes from a single spectral measure and instrument offers significant potential to develop on-line solutions, limited only by the reliability of the method of calibration.

The majority of NIR instruments are designed as laboratory instruments and are not particularly suited to on-line implementation, due to issues around sample size, presentation, scan time, sample preparation, and the delicate nature of the fundamental mechanisms. However, on-line instrumentation and applications are becoming more prevalent. NDC Infrared Engineering (Irwindale, CA, USA) currently market the *MM55plus*, an NIR food sensor for a variety of on-line food analysis applications. This filter-based reflectance NIR device has been installed at the outlet of a meat grinder and is used to collect measurements continuously. Industrial scale meat batches of beef and pork, with chemical compositions of 7–26% fat,

58–75% water, and 15–21% protein, were measured in an industrial environment. Prediction errors (SEP) for these sample sets were in the ranges of 0.8–1.5% for fat, 0.9–1.5% for water, and 0.4–0.7% for protein (dependent on sample set and species), respectively. This system has been implemented for regular use in a Norwegian meat manufacturing plant.

FOSS and Wolfking (Slagelse, Denmark) have developed a continuous fat analyzer (CFA) to control fat content in ground meat products on-line in real time. The CFA samples meat directly from the blender every three seconds, measures the sample for fat, moisture, and protein, and returns the sample to the blender. It uses NIR and neural-network technology to standardize lean-to-fat ratios, controlling the in-feed conveyors so as to maintain the desired fat content. Wolfking claim accuracies of 0.3%.

Modern diode-array NIR instrumentation is becoming more prevalent in off-the-shelf commercial equipment, with diode-array instruments from manufacturers such as FOSS (Hillerod, Denmark) and Perten (Huddinge, Sweden). Although generally not as accurate as more established fixed grating and scanning monochromator instrumentation, their robust nature means they are more suited to on-line industrial applications where sampling is a major challenge. Installed over a continuous meat product streams moving at linear rates in the order of 1 ms^{-1}, SEPs of 2.15–2.28% have been reported, with predictions for fat content of standard 27 kg blocks of 0.7–1.05%. This work clearly shows the potential of this technology to on-line large-scale measurement using NIR that more modern and robust diode-array NIR technology offers.

A recent development is the application of hyperspectral instrumentation to the measurement of meat composition and quality by NIR. Hyperspectral NIR instruments produce an individual spectrum for each picture element within an image, thereby adding an additional dimension of spatial resolution to the data acquired. Using hyperspectral NIR imaging with a spatial resolution of 0.38 mm per pixel, good calibrations for saturated and unsaturated fatty acids have been reported for intact raw beef cuts ($R^2 = 0.87$ and 0.89, SEP of 1.7% and 3.4%, respectively) of Wagyu beef.

Total Body Electromagnetic Conductivity

Total body electromagnetic conductivity (TOBEC) utilizes the fact that lean meat conducts electricity better than fat. This technique and technology is more than 30 years old. The EMME Company (EMME standing for electronic meat measuring equipment) originally patented a 'method and apparatus for measuring fat content in animal tissue either in vivo or in slaughtered and prepared form' in 1973 (US patent number US3735247).

TOBEC uses a varying electromagnetic field, generated by applying a radio frequency signal to a solenoidal coil, through which the animal or meat product passes longitudinally. Because of difference of electroconductivity and dielectric properties between various body components, the load observed by the source that drives the solenoidal coil takes on a different value from that of the empty sample zone. By utilizing other predetermined parameters of the sample, the load difference may be utilized to infer the fat-to-lean ratio to a commercially acceptable standard. Because water content is highly correlated to lean content of meat, either attribute can be inferred.

TOBEC technology has been developed for both meat processing and medical applications. Numerous publications document the investigations of TOBEC for meat-related applications. These include the evaluation of carcass composition in pig and lamb carcasses, the prediction of commercial yield and lean in beef hindquarters and pig carcasses, the assessment of live lamb chemical composition, and the measurement of compositional differences in hams, loins, and bellies in pigs.

A number of TOBEC machines, specifically targeting the measurement of CL in boxed manufacturing meat, have been commercialized. Much of the published market assessment of these devices has been undertaken by the Meat Research Laboratory of the CSIRO (Cannon Hill, Australia), reflecting Australia's position as the world's largest exporter of manufacturing meat (predominantly beef). One of the first systems developed was the EMME Model M60. In an industrial trial in 1977, the device demonstrated an accuracy of ±7.68% against the manufacturer's claimed accuracy of ±2% of the value determined chemically 'with appropriate temperature control' due to the technology being very sensitive to the operating environment.

In 1991, the EMME-M60 was compared with a second generation TOBEC machine, the MQ-25 (Meat Quality Incorporated (formerly Agmed Incorporated), Springfield, IL, USA) was assessed for measuring cold-boned beef. The MQ-25 operated at throughput rates in excess of 16 cartons per minute and demonstrated SEE for single cartons ranging from 1.34 to 1.91 dependent on meat piece size. A further evaluation in 1994 of a more recent model (MQ-27) for monitoring lean meat content of hot-boned beef concluded that results (SEE of 1.71) were comparable with results previously obtained for cold-boned beef. Chemical evaluation of CL was implemented by core sampling frozen cartons, taking two 20 g subsamples from each core and testing for fat content using the microwave drying procedure described by CSIRO. The MQ-27 is marketed on the basis of an achievable accuracy (SEE) per carton of between 1.5% and 2%.

An important tennet of TOBEC is the direct relationship between the temperature of the meat product and its electroconductivity. The vast majority of published prediction equations include product temperature as an independent variable. In the 1991 trial, the temperature of the meat near the geometric center and at four other points was measured using a digital probe thermometer for each carton. The arithmetic mean of these values was used to correct the mean electrical conductivity measurement for the temperature of the meat according to a formula provided by the manufacturer of the equipment.

The hot-boning trial in 1994 found that temperature did not play a significant role in the performance of the machine. Note, however, that this trial was on hot-boned meat, which would have been a temperature somewhere between 10 and 20 degrees warmer than the equivalent cold-boning operation. Ongoing anecdotal evidence from numerous installations within Australasian meat plants (predominantly cold-boning plants) indicates that the temperatures both of the product

and the operating environment are critical to maintaining accurate and consistent operation of TOBEC equipment.

Contaminant Detection

The fundamental principle of TOBEC has also been utilized to detect metallic contaminants. There is a wealth of manufacturers providing this technology, with an example in place in the majority of meat-processing plants around the world.

Radioactive Isotopes

In the early 1990s, a radioactive isotope-based approach was developed for measuring the percentage, by weight, of fat and boneless meat. Using the radioactive isotope Californium-252, the Institute of Geological and Nuclear Sciences Ltd. (Wellington, New Zealand), in conjunction with the Meat Industry Research Institute of New Zealand Inc. (MIRINZ, Hamilton, New Zealand) developed a system called NEUGAT that used the relative transmission of neutrons and gamma rays emitted by the isotope to measure meat composition.

The system demonstrated an accuracy of 1.1% CL in validation trials over trial periods of at least 1 h duration at throughput rates of 15 ton h^{-1}. However, due to the advent of electronic X-ray generation technology, this technology was not commercialized because of the technical complexity and safety issues regarding permanent radiation isotopes.

X-Ray Systems

Single-Energy X-Ray

Single-energy X-ray systems for measuring meat and meat product composition have been available for many years. These systems operate on the principle of the differential X-ray absorption between lean and fat due to their elemental composition. Devices such as the Anyl-Ray (Packaging Technologies, KartidgPak, Davenport, ID, USA) shine a collimated beam of broad energy X-rays onto the product and detect the amount of X-rays that penetrate completely through to the other side. The use of a conveyor enables two-dimensional images of meat products to be created using a single row of X-ray detectors aligned at right angles to the direction of travel. The intensity of the signal from each detector is proportional to both the density and the thickness of the product between the detector and the X-ray source.

The Anyl-ray is not an on-line device. It requires a specific weight sample to be taken from the product stream, minced to create a degree of homogeneity, then packed into the sample presentation tray and analyzed. Standard deviations have been reported to be between 0.6% and 0.8%. In spite of quite high acceptance in the industry, anecdotal evidence from operational sites often indicate much higher error levels, highlighting potential issues regarding sampling, sample preparation, calibration development, and the effects of operator experience, or lack thereof.

More recently, Robotics Technology Limited (RTL), a joint venture between Scott Automation Limited (Dunedin, New Zealand) and Silver Fern Farms Limited (Dunedin, New Zealand), have developed a proprietary single-energy X-ray scanning system. The first of its kind in the world, this system takes two separate single-energy X-ray scans of each carcass as it enters the boning room and determines cut planes for primal cutting to maximize the saleable yield of each carcass. Although the system is commercially available in conjunction with RTL's primal cutting technology, there is no published data on its ability to estimate carcass composition or yield. The RTL X-ray system is also used as a stand-alone grading system to predict primal weight proportions.

X-Ray based Contaminant Detection

A similar principle is used in systems developed for identifying contaminants in food products. Examples include the Eagle range of X-ray based food product inspection systems (Eagle Product Inspection, Tampa, FL, USA) that can detect and reject foreign body contaminants such as metals, glass, stone, bone, PVC, teflon, and stainless steel in pumped and packaged meat product streams.

Applied Sorting Technologies, Pty. Ltd. (Melbourne, Australia) have developed the XR-2000 and XR-3000 series of food inspection machines. Production machines have now been supplied to 20 leading Australian food producers, chiefly meat works in Queensland and NSW inspecting carton meat automatically at the rate of approximately 40 cartons per minute. Cartons with detected contaminants such as lead shot and other embedded foreign objects are automatically rejected. These machines have been tested by Meat and Livestock Australia to successfully detect and reject 27 kg meat cartons with 2 mm diameter lead shot in the meat at high production rates.

X-ray systems have also been developed to detect and reject bone in poultry, fish, and red meats. Companies such as Marel (Marel, Gardabaer, Iceland) and Meyn (Meyn Food Processing Technology B.V., Oostzaan, The Netherlands) produce systems for bone detection with stated accuracies of up to 98% detection rate with a 3% false detection rate.

Dual-Energy X-Ray

Single-energy X-ray systems have proven effective for at-line meat composition measurement but the inherent dependence on product thickness has limited their adaption to on-line measurement applications. Advances in dual-energy X-ray (DXA) systems, both in the security and medical areas, have recently been investigated for meat measurement applications.

In DXA systems, two sets of X-ray detectors are used, each with a sensitivity distribution centered around a different X-ray energy (approximately 50–70 keV and 100–120 keV). This effectively produces two images of the product – one for the higher-energy X-rays and another for the low-energy X-rays. Each image is effectively a density map of the product scanned at the X-ray energy level determined by the X-ray response of the detector. Because the relative absorption of X-rays by different materials (having fundamentally different elemental composition) varies with X-ray energy, the effect of thickness can be eliminated as a dependent variable. However, these two X-ray measures are still highly correlated with each other (as

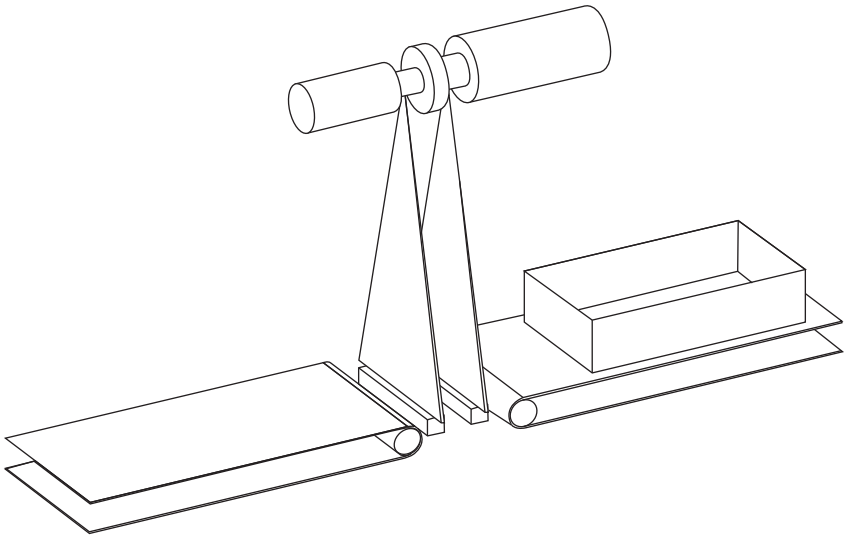

Figure 5 Setup of the FOSS MeatMaster™ instrument, illustrating the two X-ray sources and corresponding detector arrays. Reproduced from Hansen, P.W., Tholl, I., Christensen, C., *et al.*, 2003. Batch accuracy of on-line fat determination. Meat Science 64 (2), 141–147, with permission of Elsevier Science Publishers.

with spectral data points within NIR spectra). The advent of complex data analysis techniques, such as those used in the area of NIR spectrum analysis, has enabled DXA systems to provide rapid and accurate assessment of meat and meat product composition.

The Anyl-Ray2 (Packaging Technologies, KartidgPak, Davenport, ID, USA) utilizes DXA technology. Using two levels of X-rays has reduced the necessary sample size and the sensitivity to packing density, air pockets, precise sample weight, and surface (thickness) uniformity. However, the fundamental operational mode of the device has not changed from its predecessor and it is still an at-line instrument.

FOSS (MeatMaster™, FOSS Electric A/S, Denmark) and EAGLE (Eagle-FA, EAGLE Product Inspection, Tampa, FL, USA) produce DXA-based systems for measuring the fat content of fresh, frozen, boxed, and loose meat on-line. The MeatMaster™ system incorporates two X-ray generators whereas the Eagle-FA uses a single broad-spectrum X-ray generator with high- and low- X-ray detector arrays superimposed over each other (Figure 5).

The Foss MeatMaster™ can measure meat in cartons or boxes as well as continuous product flow of meat loose on the conveyor at rates of up to 38 ton h^{-1}, and comes in standard and compact machine footprints (Figure 3). The MeatMaster™ is capable of repeatabilities (one standard deviation) of $\leq$0.5% for fat and weight and accuracies (RMSEP, one standard deviation) of between 1% and 1.5% absolute for fat and 1% and 2% relative for weight, dependent on product format, over a fat range of 2–85% (Figure 6).

Mettler Toledo acquired the Smiths Detection X ray-based food inspection business in 2011 and rebranded it as EAGLE Product Inspection. The EAGLE-FA System can measure CL to ±1% accuracy at-line speeds of up to 30 cartons per minute or 108 ton h^{-1} (Figure 7).

The DXA technology also enables metal contaminant detection down to diameters of 4 mm and bone detection down to 10 mm to be performed simultaneously.

Figure 6 FOSS MeatMaster II. Courtesy of FOSS Analytical, Denmark (http://www.foss.dk).

More recently, DXA has also become readily accepted as a technique for determining carcass composition in sheep and pigs and carcasses. A wide range of commercial medical full body DXA scanners have been used to measure carcass attributes such as total, lean, and fat tissue mass with very high correlations in sheep and pigs ($r2 \gg 0.9$). However, it is important to note that DXA estimates do inherently differ from chemically determined values, due to fundamental difference in the measurement systems. In particular, DXA

Figure 7 Eagle-FA720. Reproduced with permission from Eagle Product Inspection (http://www.eaglepi.com).

estimates of bone mass do not correlate as well with chemical ash, because DXA measures bone mineral content. This has been addressed by researchers by applying corrections to the algorithms built in to medical DXA scanners. Further, meat and fat content are estimated in regions where bone is not present and extrapolated to produce full carcass assessment.

In 2012, five new X-ray systems have been built by Robotics Technology Limited for installation in existing lamb plants to undertake lamb yield analysis, as part of FarmIQ (a 7-year partnership between the New Zealand Primary Growth Partnership Funding program and New Zealand's largest meat exporter, Silver Fern Farms Ltd.). These systems are likely to incorporate DXA technology to further enhance their ability to measure carcass composition as part of estimating carcass yield and meat/fat/bone ratios.

Computed Tomography

The use of CT as a virtual dissection tool and its correlation to manual dissection has been well documented in the literature and has been shown to be more precise and reliable than manual dissection. Although the scanning aperture of commercial CT scanners is increasing, largely driven by the need to cater for ever-increasing human body sizes, cost and technological complexity mean that it has yet to reach a size where on-line carcass scanning is commercially practicable. When compared with the European Union's EUROP carcass classification system, CT analysis of rib cuts generated a higher predictive value in estimation of carcass tissue composition.

More recently, spiral CT has been investigated as a potential technology for assessing carcass tissue volume and weights of sheep, pigs, and cattle as well as fatty acid and meat quality characteristics. With the ongoing advancement of CT technology, the Danish Meat Research Institute (now part of the Danish Technological Institute) have recently announced a development program that aims to implement a prototype CT scanner in a pork deboning line capable of measuring 700 middles per hour.

Summary

Although a number of technologies have been investigated for measuring meat composition, and in particular fat, on-line, no one technology has proved to be comprehensive in providing a complete solution. Of the technologies currently in application within the industry, DXA provides significant advantages of 100% inspection and CL measurement combined with metal contaminant detection. NIR offers significant advantages in accuracy and in more specific compositional measures such as protein, water, collagen, and iron, but current off-the-shelf technology still requires sampling and must be thus considered an at-line technology at best. Recent developments in fast, wide-area scanning, diode-array NIR technology and spiral CT may well offer opportunities in the future for on-line inspection of continuous product with a high level of accuracy.

ON-LINE MEASUREMENT OF MEAT QUALITY

C Borggaard, Danish Meat Research Institute, Maglegaardsvej, Roskilde, Denmark

Glossary

At-line A site for obtaining measurements from samples removed from the processing line.
Boar taint An unpleasant odor that can be experienced during cooking of pork from some (not all) uncastrated pigs.
Dark, firm, and dry (DFD) A condition in meat with an elevated ultimate pH (from preslaughter stress resulting in low glycogen).
Electrical impedance The measure of opposition that a circuit presents to a current when a voltage is applied; it extends the concept of resistance to AC circuits.
Electronic nose A device intended to detect odor or flavor (electronic tongue) using sensor arrays and pattern recognition systems.
Hyperspectral imaging Hyperspectral imaging uses cameras with carbonate compensation depth or complementary metal-oxide semiconductor area sensors to acquire images at a number of specific wavelengths (usually between 350 and 1000 nm). These systems can give information on both structure and chemical composition.
In-line A site for obtaining measurements on the processing line.
Marbling Marbled meat contains various amounts of intramuscular fat, giving it an appearance similar to a marble pattern.
Microwave A form of electromagnetic radiation (frequencies between 300 MHz (0.3 GHz) and 300 GHz).
Optical measurements A collective term, used here, covering spectroscopic techniques involving the wavelength regions from the ultraviolet through the visible and the near-infrared parts of the electromagnetic spectrum using one or more wavelengths.
pH A measure of acidity or basicity of an aqueous solution.
Pale, soft, and exudative (PSE) A condition in meat, especially pork.
Tenderness A sensory panel evaluation (a subjective measure) of one of the sensory properties of meat in contrast to a shear value (an objective measure).

Introduction

Meat quality assessment is highly subjective and what is considered 'good quality' is dependent on the consumer and may vary according to culture. There are, however, a number of important traits that industry and consumers can agree on as being important indicators of meat quality.

These include:

- tenderness and juiciness,
- appearance (color and structure),
- fat content, including subcutaneous fat (if it has not been trimmed) and intramuscular fat,
- drip loss/weep/cooking loss caused by pale, soft, and exudative (PSE) or red, soft, and exudative meat,
- fat quality (problems with soft fat related to the degree of saturation of the fatty acids and oxidative stability of fat),
- protein content (composition can be measured online by various instruments), and
- off-odors (e.g., rancidity due to fat oxidation or boar taint).

For a long time, there has been a desire to be able to measure some, if not all, of these traits very early in the slaughter process and preferably at-line speed. If such assessments were feasible, sorting into quality classes would be possible and the individual carcasses could be designated to products in an optimal fashion.

This article focuses on instrumental measurements of meat quality that can be made in-line or at-line at industrial speeds in an abattoir or in a meat processing plant and will be limited to instrumental methods that in most cases are nondestructive, although not necessarily noninvasive. An at-line measurement is characterized by the sample being physically removed from the process line before measurement. The removal can be made either automatically or manually. At-line measurements are often only used as spot wise tests and results are usually not available in real time. In contrast, in-line measurements are made by instruments that are placed on the line or that have been built into the process line. In general, this enables measurements to be taken in real time, thus obtaining data on the entire production flow.

In the following, the quality measurement methods are grouped according to measurement principle. It should be noted that, because of the inhomogeneous nature of meat and the speed of operation required, many useful laboratory methods for determining meat quality have proved extremely difficult to implement as in-line applications.

Optical Measurements

Optical measurements, including fiber optic probes, are used for measuring the reflectance either on the surface or inside an intact muscle. Either the measurements can be made at a single wavelength or an entire wavelength region can be scanned. In this context, the term optical will be limited to refer to measurements that can be made within the wavelength regions 200–1700 nm of the electromagnetic spectrum. These regions cover the long-wavelength ultraviolet (UV) (200–400 nm), the visible (VIS) (400–700 nm), and the short-wavelength (700–1700 nm) near infrared (NIR). The UV part of the spectrum can typically be used to make various contaminants or certain chemical constituents fluoresce. This property can be used as an aid for highlighting organic contaminants on the surface of entire carcasses (e.g., the VerifEYE Solo Inspection System for finding fecal remains on beef carcasses) or for nonquantitatively detecting the presence of lipid peroxidation in fat samples.

The short-wavelength part of the infrared spectrum is used extensively for analytical purposes in the field of NIR spectroscopy. With this technique, it is possible to quantify the macroconstituents (e.g., protein, fat, and water) of food products. The short-wavelength infrared range is also utilized in thermographic or infrared cameras. In the slaughter industry, these cameras are being used as a research tool for specialists working with animal welfare. The heat-sensitive cameras make it possible to measure slightly elevated body temperatures of the pigs that are in lairage at the slaughter house, thereby quantifying possible stress conditions among the animals.

The visible part of the electromagnetic spectrum can be used for measuring color and surface texture, which are especially valuable for assessing meat quality. Measurements on raw meat with visible light and short-wavelength infrared can be made in both reflection and transmission modes. However, due to the strong light-scattering abilities of meat, it is not possible to make transmission measurements with path lengths exceeding a few millimeters except in the wavelength region from 850 to 1000 nm, where transmission is measureable even through 2–3 cm of meat.

If spectra are to be acquired from inside a muscle, it is necessary to use an insertion probe-type arrangement. With probes, it is possible to acquire images of the meat only in one-dimension along the line of insertion. When using probe-type instruments that are based on a single wavelength, it is also difficult to distinguish meat that is PSE or dark, firm, and dry (DFD) from meat that is either pale or dark due to low or high pigment content. If structural properties of the meat are to be separated from differences in chemistry, more than one wavelength will be required. Most VIS–NIR spectroscopic techniques are applied as reflectance measurements of a cut surface. The advantage is that a large surface area can be viewed. The disadvantage is that the reflected image will be strongly influenced by specular reflection, which does not contain chemical information about the object being observed.

Measuring Pale, Soft, and Exudative

The first probe-type instrument for measuring meat quality to emerge was the TBL Mark II fiber optic probe, made by MacDougall in the late 1970s. Although it only used a single wavelength, it was designed to measure the paleness of meat, and because PSE meat is notoriously pale, muscles with this defect could be detected using the instrument. The instrument was handheld and self-contained with a numeric display for the operator. The light source was a light-emitting diode (LED) operating at a single wavelength in the visible region. A needle-shaped steel tube containing optical fibers brought light from the LED to a point inside a muscle. Another optical fiber guided reflected light back to a detector. The registered intensity of the reflected light could then be related to the paleness of the meat at the point of measurement. With this type of instrument where the reflectance of the meat is only measured at a single wavelength, one must be aware that high brightness can be due to several effects: the presence of scattering centers (as in PSE meat) and by low pigment concentration. In dark-cutting beef, the meat is very translucent, that is, the light from the transmitting fiber is not reflected back to the receiving fiber. This gives the meat a dark appearance. However, a dark appearance may also be due to a high myoglobin concentration (deoxymyoglobin), which absorbs light in the wavelength region 520–590 nm before it can be registered at the receiving fiber. Arrangements of in- and outgoing fibers as in the TBL Mark II are commonly used in present day visual and NIR spectroscopic applications.

A major problem with the probe measuring at a single point is that that the sampling area inside the muscle is very small. As previously mentioned, an insertion probe can at most acquire data only in one dimension. This is a serious problem in nonhomogeneous media, such as meat.

The Canadian Colormet handheld probe used a xenon flash as light source and had a photodiode array as detector. For the first time, this permitted full spectra (400–700 nm) to be obtained. It was tested successfully for color measurements on veal and pork as well as for PSE occurrence in pork. Even though the Colormet and TBL Mark II had excellent potential as a tool for sorting, they gained only sporadic acceptance by the industry.

Measuring Pale, Soft, and Exudative and Marbling in Pork

The next logical step after the development of the TBL Mark II was to select an LED light source that operated in the NIR region and to select a wavelength in the NIR region that was reasonably independent of meat color, in order to measure marbling or lean meat percent. In the Danish optical probes, an LED with a wavelength of 950 nm is used (corresponding to a strong water absorption band). The system developed at the Danish Meat Research Institute and named the MK probe (manual classification) was originally designed for measuring lean meat percentage in pork on the killing line. It was equipped with a depth measurement device that enabled the reflection to be measured continuously along an insertion line while the probe was inserted into the muscle. From the resulting reflection profile, the thickness of subcutaneous fat could easily be measured and related to carcass composition. The choice of an NIR light source also meant that the instrument (with a modified software) was well suited for detecting PSE meat; introduction of the depth-measuring device also offered a tremendous improvement in sampling area

compared with the TBL fiber optic probe. When configured as a meat quality-measuring device, the Danish manual system was called meat quality and marbling (MQM). The hardware of this system is basically equivalent to the present day Fat-O-Meater II for carcass grading from the company Carometec Food Technology®.

In profiles from the MQM instrument, marbling is seen as small spikes (reflection peaks) on an underlying curve representing the reflection from the meat. Results obtained with the MQM instrument demonstrated that the system could be used to sort porcine carcasses in two groups with high or low intramuscular fat in the loin muscle. The main limiting factor on the achievable accuracy is once again the limited sampling volume that is measured.

A probe similar to the Danish was developed in parallel by a New Zealand company called Hennesey Grading Systems. This instrument contains all the same features as that of the MQM, the differences lying mainly in the choice of LED wavelength and software. The Hennesey probe uses a green light (550 nm) LED and is, therefore, optimized especially for distinguishing between fat and meat for grading purposes (meat is very dark in green light, whereas fat is very bright).

Near-infrared Spectroscopy for Measuring Connective Tissue, Protein, Myoglobin, and Tenderness and its Future Applications

Spectroscopic techniques have been used for the direct and indirect quantification of collagen in carcasses or cuts. Published work includes measurement of connective tissue in beef by UV fluorescence and NIR reflectance. Also, measurement of myoglobin in both pork and beef by VIS-wavelength spectroscopy and measurement of protein content in intact pork muscles by NIR spectroscopy have attracted some attention. However, apart from color-measuring systems using non-spectroscopic techniques, these procedures have never been commercialized for online use at abattoirs due to the inhomogeneity of the muscle. For ground meat where the sampled volume is representative of the entire batch, spectroscopic methods working in reflectance or transmission mode have proven to be both reliable and fast and are used routinely by many suppliers of ground meat and for measuring fat and protein content of diced meat samples on a conveyor or in pipeline systems. These applications of NIR spectroscopy are typically used in-line on mixers and grinders and as at-line measurements.

Work has been published on the application of NIR spectroscopy for measuring hydroxyproline in pork sausages under laboratory conditions. In chorizo-type sausages with hydroxyproline concentrations varying from 0.2% to 0.8%, a standard error of 0.05% and an R^2 of 0.8 were achieved. However, it is unlikely that NIR spectroscopy will be able to be used online for measuring connective tissue due to lack of homogeneity in meat, and because of the fact that NIR spectroscopy lacks specificity, the method in general will not be able to distinguish between different types of animal protein.

In the future, research and development within spectroscopic methods should be directed toward imaging spectroscopic techniques called multiwavelength imaging or hyperspectral imaging. The difference between these techniques and classical spectroscopy is that with hyperspectral imaging it is possible to acquire an image of a large area of the sample that contains multiwavelength spectral information in each pixel as opposed to the classical spectroscopy, where a spectrum is acquired at a single point or is the average over a larger area. The links in the 'See also' section gives an idea of the types of instrumentation that are available. The main advantage of these types of systems is that classical image analysis and spectroscopy can be combined, giving much more detailed information about the product being studied than either of the two techniques can give separately.

Research has been conducted on using NIR reflectance spectroscopy for the online measurement of tenderness, as defined by shear force measurements or a sensory panel. Several promising results have been reported, but the main obstacles are the lack of reproducibility of the reference methods (e.g., Warner–Bratzler shear force and sensory panel measurements) and the sampling being representative of the muscle or carcass being evaluated. Work at MIRINZ and AgResearch in New Zealand demonstrated the possibility for using NIR for measuring tenderness (shear force) with a reported R^2 in excess of 0.6. The results of the NIR method are limited by the inaccuracies of the reference method that in this case is notorious for its lack of reproducibility. However, the result will be sufficient for sorting (e.g., the tenderer one-third cuts for a select quality) but will be improved with better standardization.

Measuring Surface Meat Color

Surface measurements of color are difficult to make in a well-defined manner unless working under strict laboratory conditions. However, if conditions at the slaughter facility or processing plant can be reasonably standardized, one can choose to use the semiobjective color comparison blocks (such as the Japanese or Australian systems).

When using these color blocks, it is important that measurements are made under exactly the same lighting conditions every time, because the color blocks have spectra in the visible region that look nothing like meat spectra.

The handheld Minolta systems for color measurements constitute an objective way of measuring color of meat surfaces and have been used at line speed in the pork industry. They have gained considerably in popularity because of their small size, low cost, and ease of operation. However, a standardized measurement procedure taking the blooming process into consideration is of utmost importance for reliable results.

Finally, color vision sorting systems that rely on images acquired by ordinary color cameras and image analysis are to be mentioned. These are marketed by companies such as e+v Technology® from Germany (VPS 2000) and do a fair job in assessing the color of, for example, freshly cut surfaces of primal cuts. These systems are being used at meat processing plants, especially in southern Europe for sorting hams of high-quality products according to color uniformity.

A couple of instruments based on vision technology have been developed for assessing marbling, meat and fat color,

area of the eye muscle, and saleable meat yield on quartered beef carcasses. These include the VIAscan® Chiller Assessment System made by the Cedar Creek Company in Australia and the VBG 2000 made by e+v Technology. Both systems are widely accepted for grading purposes in larger beef-producing countries such as the US and Australia. Both instruments are handheld and are placed on the freshly cut surface of the loin muscle, where important information on carcass value can be gained.

Measuring Fat Softness in Pork

In the past years, pork farmers have seen a considerable rise in feed prices, especially high-protein feeds like soy beans. For this reason, producers have increased the content of maize in the feed used for rearing pork. The downside of this increased use of maize is that the back fat becomes more unsaturated, which is undesirable for producers of high-price products like Parma- and Serrano-type hams. The back fat is also used in the production of salami sausages, where unsaturated fat causes problems with rancidity. In the production of bacon, the sliceability of the product is degraded with increased degree of unsaturation in the fat due to the fat becoming softer.

Unsuccessful attempts have been made to measure the softness of fat using mechanical and ultrasonic devices. The propagation of ultrasound through subcutaneous fat is dependent on the fatty acid composition. The speed of sound is slightly larger for hard fat than for soft fat. However, this method is difficult to use online at the slaughter line, as the fat thickness at the point of measurement also has to be known with good accuracy.

Another approach to measuring fat softness was made at the Institute of Food Research in Bristol, UK, in the 1980s. The instrument consisted of a handheld device with two needles that, when inserted into the subcutaneous fat of the carcass, could determine the softness by measuring the force necessary to change the distance between the needles. However, this type of measurement was not reliable as the measured force also was dependent on fat thickness and the amount of connective tissue present.

Fat softness is strongly correlated to the relative amount of unsaturated fatty acids in the back fat; therefore, this trait should be measurable by using spectroscopic techniques, especially NIR spectroscopy. The reference methods for unsaturation of fatty acids to measure the iodine number for the fat sample either by titration or by the more elaborate method using gas chromatographic techniques to determine the fatty acid composition. NIR spectroscopy has been used for online determination of the softness of the back fat on pork carcasses. It should be noted that NIR cannot, with any accuracy, assess the fatty acid composition. What it actually does is predict the iodine value, which correlates well with softness.

In the mid-1990s, an online method based on the use of NIR spectroscopy was developed in a joint effort by Mitsubishi Rayon Engineering in Japan and the Danish Meat Research Institute. This handheld device was capable of sorting the warm pig carcasses 40 min after slaughter into three groups of softness judged by an expert classifier providing the 'ground truth' reference values. Reflection readings were acquired at 12 wavelengths provided by narrow band pass filters almost evenly spaced in the wavelength region 450–1215 nm. For illumination, a broadband filament lamp was used. The instrument was tested on 580 carcasses, of which 160 were labeled as unacceptably soft by the classifier. The instrument misclassified 10 of these as being firm. Four out of 124 carcasses with firm fat were misclassified by the instrument as soft. The measurements were made by placing the instrument directly on the surface of the fat. The main problems with this type of surface measurement are again the variations in fatty acid composition between the various fat layers of the subcutaneous fat, making it difficult to achieve a representative assessment for the entire carcass. The VIS–NIR measurements only penetrate 1–3 mm, and with a probe area of roughly 3 cm^2, the sampling volume was rather small.

The way to overcome the problem of variability in fatty acid composition as one moves through the layers of subcutaneous fat is to combine a multiwavelength transmission measurement in the NIR part of the spectrum (1100–2200 nm), with a depth-measuring system similar to the one used in the Fat-O-Meter system. Using two thin probes spaced in parallel by only a few millimeters, it is possible to acquire a full NIR spectrum for every 0.25 mm. Light is sent, via optical fibers, through one of the probes illuminating the meat around its tip. The other probe collects the transmitted light and returns it to a monochromator via other fibers. One example of such a system is the NitFom developed by the company Carometec Food Technology. However, a slight drawback of the NIR transmission technology is that the transmitting and receiving probes cannot be more than 1–2 mm apart due to the strong absorptions of light by water in the wavelength regions above 1400 nm. This small distance between probes can make it difficult for the operator to use, as the force needed to penetrate the carcass rind is substantial. This system has now become available in a fully automated version to be used on the slaughter line.

Electrical Measurements

pH

pH is measured routinely at many meat processing plants. Manufacturers of sausages and cooked and uncooked hams usually test the pH of the incoming raw materials. Measuring pH gives important information about color and water-holding capacity of the meat, and in beef it can give information on problems with dark, firm, and dry (DFD) meat. pH measurements are also an important parameter in the fermentation processes of meat products, where pH is measured to establish whether the fermentation is proceeding as expected.

Many abattoirs, meat processors, and meat researchers routinely use standard laboratory combination electrodes combined with portable pH meters for performing the measurements. This type of equipment works well, but extreme care must be taken due to the risk of electrode breakage and glass splinters ending up in products. In recent years, manufacturers of these combination electrodes have developed them to ensure that they are more robust and easier to insert into meat. However, for routine online use at production plants, one

must consider using electrodes that are more robust than the standard laboratory glass combination electrodes. The pH meter/electrode pH-K21 from NWK®-Technology GmbH, Germany is a good solution for industry. With its metal casing, it is as close as one can get to a truly shock-resistant and watertight system. A steel shell encases the measuring probe, which is specially developed for measuring pH values in meat, with telescopic protection reducing the risk of the tip of the electrode breaking during operation. The manufacturer claims that the electrode enables up to 600 measurements per hour in a measuring range of pH 2–14 and 0–80 °C and it can be operated on batteries for up to 10 h. Although 600 measurements per hour seem unrealistic, as it only allows 3 s for response time per measurement, the pHK21, in fact, has the fastest response time of any pH meter/electrode systems tested. Furthermore, generally meat pH measurement of carcasses involves a subsampling of carcasses, such as 20%, for quality control measures.

From the mid-1980s, several companies started to manufacture pH electrodes based on ion-selective field-effect transistor (ISFET) technology. One example of this type of instrument is made by the company DeltaTrack®. The biggest advantages of the ISFET electrodes are that there is no glass in the electrodes, making them almost unbreakable, and contrary to glass combination electrodes, they can be stored in a dry state. Two main disadvantages are that the ISFET electrodes cannot be used with standard pH meters and also that they have major problems with proteins clogging the ion-sensitive part of the transistor in the tip. Although the electrode tip can be cleaned with a toothbrush, it appears to suffer from permanent and irremovable clogging after approximately 800 measurements, in the author's experience. Thus, although the technology was initially seen as an attractive alternative to standard electrodes, it is not seen as reliable as the combination electrodes, due to the clogging of the electrodes by proteins, which results in inaccurate measurements.

Impedance

Handheld electrical impedance probes were in use as early as in the 1970s for measuring the lean meat content in porcine carcasses. Instruments of this type consisted of a probe that at the tip had a number of small electrodes in the shape of rings. Each ring was electrically insulated from the others. By measuring the electrical impedance (resistance to alternating current (AC)) between electrodes while the probe is inserted into the carcass, one is able to tell when the tip of the probe is moving from a fat layer with high impedance into muscle with low impedance. This probe system was then combined with a depth-measuring device like the one used in the Fat-O-Meater-type systems, thereby enabling simultaneous measurements of impedance and depth.

Pale, Soft, and Exudative and Water-Holding Capacity

In the early 1980s, a system called the Testron MST Impedance Tester was developed in Germany for sorting porcine carcasses according to their condition as PSE or normal. The instrument, which is handheld, consisted of two parallel blades at the tip that can be inserted into the muscle to be studied. An alternating potential difference with a frequency of 1500 Hz was applied between the two blades and the resulting current monitored. From this, the impedance could be calculated and used as a means of sorting meat according to water-holding capacity. The main reasoning is that meat with a low water-holding capacity also exhibits lower impedance toward an applied electric current, due to a loss in membrane integrity.

A problem with this instrument is that a large part of the drop in potential between the two electrode blades takes place not in the meat between the blades but in the transition between blade and meat. Thus, a large part of what the instrument is measuring is due to the buildup of a shielding layer of ions in the transition layer between the instrument and the meat. The logical way to overcome this contact problem is to use four electrodes. Two of the electrodes are used to apply an AC (approximately 0.01 A) to the meat while the resulting potential difference between the other two electrodes is measured. From the size of the potential and the phase shift between applied AC current and measured AC potential difference, the impedance of the meat can be calculated. This technique has two major advantages. First, as the measurement of the potential difference can be made without drawing any current (at least less than 1 nanoampere (10^{-9} A)), it is ensured that there is no measurable drop in potential at the meat–electrode interface. Second, use of constant current amplitude instead of constant potential amplitude ensures that the buildup of ions around the electrodes does not influence the measurement.

Scientists at Purdue University developed a so-called tetrapolar electrical impedance-measuring device based on the above principles. This instrument was configured with four electrodes placed as rings on a needle-shaped probe in much the same way as in the grading systems from the 1970s. The probe was equipped with a thermometer, so that impedance recordings could be temperature corrected. This instrument gave some very promising results in measuring PSE in pork.

In both of the above-mentioned systems, measurements were made using only a single frequency. This technique warrants further investigation as it is used by researchers to identify PSE and low water-holding capacity carcasses and shows a lot of potential.

Marbling in Beef

In the late 1970s, a method named electrical impedance tomography (EIT) was developed as a medical imaging technique. This method uses many electrodes to measure the electrical impedance in a patient for acquiring a three-dimensional image of, for example, the patient's lungs. In terms of resolution, it is vastly surpassed by more sophisticated methods, such as CT-scanners, and has, therefore, been of little use as a diagnostic tool. However, it is inexpensive and robust and thus has some potential as a means of measuring intramuscular fat in beef loin muscles.

At the Danish Meat Research Institute, EIT was tested as a handheld method to predict marbling. Twelve electrodes (thin needles) were arranged on the periphery of a circle 70 mm in diameter and an AC with constant amplitude could be applied between any two of the 12 needles and the resulting phase shift and potential difference between any other needle combinations measured. Simultaneously, it is possible to scan the

entire frequency range from 10 Hz to 150 kHz. This electrode arrangement was calibrated on fillet muscles from 100 animals with intramuscular fat ranging from 1% to 10%. Measurements were made on the hot carcass approximately 40 min postmortem. The reference method was the intramuscular fat determination by the Schmid–Bondzynski–Ratzlaff method. An independent test of this instrument showed that the intramuscular fat content in the fillet muscle could be estimated with accuracy better than 1% (standard error of estimation).

Microwaves

Microwaves are a part of the electromagnetic spectrum and are situated in the wavelength region 1–300 mm (300 GHz down to 1 GHz) between the so-called terahertz region (used at air ports in the security check) and radio waves.

For spectroscopic applications, microwaves are used in rotational spectroscopy. In this part of the electromagnetic spectrum, the photons do not have enough energy to cause vibrational transitions within molecules as do NIR or infrared lights, but the energy in microwaves is enough to make molecules rotate. The only requirement for rotation to occur is that the molecule has a dipole moment. In foods and especially meat, water is abundant and the water molecule has an extremely strong dipole moment. This strong dipole moment is the reason why water completely dominates the spectra of meat all the way from the NIR part of the spectrum over the mid-infrared to microwave region.

These strong water absorptions, which usually are a nuisance in NIR and IR spectroscopy, can be utilized in the microwave regions for measuring the water content of a product. Luckily, in the case of meat, for each animal species, there is an almost fixed ratio between protein content and water content (roughly 0.3) and the rest is fat. If the water content of a meat sample can be measured, then the fat content can be estimated. The greatest advantage of microwave spectroscopy over NIR and IR is its ability to penetrate a sample in much greater depths. The sampling volume with microwaves can thus be many liters at a time. The limitations are that the measurements are strongly affected by variations in salt content and whether the meat samples are frozen or not.

Microwaves for Measuring Fat

In-line systems for measuring fat in meat are commercially available. One system is from Thermo Scientific applies guided microwave spectroscopy. In the meat industry, this system can be placed on the outlet from a mixer or a grinder where the product is pushed through a steel compartment where a microwave spectrum is acquired. From this, the water content can be calculated on the basis of a calibration made for this type of product. Accuracies for 800 kg batches of meat are of the order of 1% fat under routine use of the instrument.

Another instrument based on microwaves, which may be used by smaller butcher shops for measuring fat, is from the Scottish company Distell and is named the Fish Fatmeter. It is handheld and was originally developed for measuring fat content in, for example, Salmon. However, calibrations have been made for ground pork, beef, and lamb. The operator presses the flat sampling head of the instrument onto the surface of the sample of ground meat and a fat percentage in the underlying product is measured. Owing to the nonhomogeneity of the ground meat, up to eight repeated measurements (subsamples) have to be made in order to get a reliable result on a 500-g sample. The main problem with this instrument is the presence of air pockets in the sample, which will strongly influence the reading. Also, the product thickness over the point of measurement must be at least 5 cm, otherwise the measurement is influenced by the container/tray. If proper care is taken during measurements to get good contact with the product, accuracies of approximately 1% can be achieved on 500-g trays of ground meat.

Dual-Energy X-Rays

In the meat industry, X-ray systems are being used extensively for detecting the presence of foreign bodies. Usually, X-ray images are acquired using only a single X-ray tube operating at a fixed electron acceleration voltage. In recent years, dual-energy X-ray systems have become available. Here, images are acquired with either two X-ray tubes operating at different voltages or with two detector systems, one sensitive to high-energy photons and the other to low-energy photons. The technology is comparable to the dual-energy X-ray analysis systems used for many years at hospitals for measuring bone density and quantifying obesity in patients. A number of companies that have been active in marketing foreign body detectors have switched to using X-rays at two energies. The advantage of using dual energies is that it makes it easier to find certain low-density foreign bodies in the products. At the same time, the systems can be used to find the fat content in boxes of meat or in bulk products on a conveyor. Some examples of these systems are the MeatMaster™, from the company Foss, and the Eagle FA. These instruments can analyze 100–150 ton h^{-1} of fat content and are able to measure through boxes of meat with thicknesses up to 20 cm. During routine operation, accuracies of 0.8–1% fat are achievable. A few of the Japanese suppliers of X-ray inspection systems will be presenting similar dual X-ray energy machines in the very near future.

Mechanical Measurements of Toughness in Beef and Lamb

Researchers have investigated the measurement of meat tenderness using a system that measures the force necessary for a blunt rod to penetrate a muscle. Such 'penetrometer' systems are made by combining a depth measurement system (such as the ones used by Fat-O-Meater-type instruments) with a force-measuring device (strain gauge) on the rod, achieving simultaneous measurements of force and distance. These two quantities can be directly related to the work necessary to push the rod through the muscle. It was postulated that the penetrometer system could be used online as a (reasonably) nondestructive version of the well-known shear force measurements (e.g., Warner–Bratzler or Meat Industry Research

(MIRINZ) tenderometer) used in the laboratory. The most prominent of these is the Tendertec developed in Australia in the early 1990s. With this instrument, correlations to meat toughness of $R^2 = 0.78$ have been reported, but this is on beef from a very wide range in age, which is hardly relevant in most countries. Newer experiments have shown that the method is unable to detect differences in tenderness in loin muscles from younger beef carcasses.

Another system has been developed by MIRINZ in New Zealand for testing lamb, which is different from the shear force instrument mentioned above. It is also called a tenderometer and consists of two concentric rings of needles, with the inner ring able to turn relative to the outer ring. When inserted into meat, the instrument measures the torque necessary to turn one of the rings a given number of degrees relative to the other.

Recently, the viscoelastic (or biomechanical) measurements of meat have been investigated for their ability to assist in online measurement of tenderness. Viscoelasticity is a property of deformable materials, like meat, that can behave both as a liquid and as an elastic material. The measurements can be performed by applying a periodic force over a relatively small surface area of the meat. The difference between this approach and the standard shear force measurement is that the deformation force can be applied at varying frequencies typically in the interval 0–10 Hz. This enables the measurement of the amount of energy that is disseminated in the meat sample during a compression/relaxation cycle as a function of frequency. For predicting sensory tenderness of beef loin muscles, viscoelastic measurements have been reported as being superior to ordinary shear force measurements. However, it remains to be seen whether or not Viscoelastic measurements have potential for being commercialized in a handheld, noninvasive, online instrument.

Chemical Analysis of Odors

Among the positive-quality characteristics of meat is the absence of any off-odor and this is normally considered a given property of unspoiled meat or meat products. Off-odors due to feed ingredients can be controlled via advice to farmers and feedstuff companies. However, the situation is somewhat more complicated when slaughtering uncastrated male pigs, older sheep or goats, or sheep grazing some types of forages/pastures.

Boar Taint

In the European Union, concerns about animal welfare have resulted in an agreement with farmers to stop surgical castration of male pigs before the year 2020. In some countries, such as Australia, castration of male pigs has not occurred for a number of years, due to increased growth rates, higher percentage of lean in the carcass, and healthier status of entire males, which all provide economic advantages. It is undisputed that meat from a small percentage of uncastrated male pigs exhibits an unpleasant odor when heated, and this so-called boar taint has until now prevented large-scale production of 'entire males' in many countries, in spite of the growth advantages. Consequently, the economic incentive to avoid castration is strong, and so, of course, is the animal welfare aspect. Australia has focused heavily on reducing boar taint in entire males for a number of years, through strategies such as immunocastration (Improvac) and specialist feeds such as inulin. Certainly, it will be increasingly important to be able to identify carcasses with boar taint in pig-producing countries around the world.

A mixture of chemical compounds probably causes boar taint, and much effort has been devoted to elucidating their individual structures. The two main candidates are skatole and androstenone. Skatole is a metabolite of the essential amino acid tryptophan, and androstenone is a metabolite of a male sex hormone. In some parts of the world, most attention has been focused on skatole, whereas experience gathered elsewhere seems to indicate that androstenone is equally important. This is perhaps because of differences in slaughter weight, breeds, feed, tradition, etc. Interestingly, skatole can occur in the fat of female pigs and strategies to reduce skatole taint include keeping pens clean. This emphasizes the importance of an online method for taint, for both entire male and female pigs.

Some years ago, Danish scientists developed a high-capacity (180 determinations per hour) automated analytical procedure based on spectrophotometric determination of skatole in back fat. Fat samples (approximately 1 g from each pig) are collected on the slaughter line and analyzed in an on-site laboratory. Turnaround from the time the sample is extracted from the carcass until the result is received is approximately 12 min, which is more than adequate for sorting tainted carcasses after the chilling tunnel under Danish conditions; however, serious logistic problems may arise at higher line speeds. This system is still in operation at a large Danish abattoir.

At the moment, there is no at-line sampling for an androstenone assay able to keep up with line speeds at a normal slaughter house (up to 600 male pigs per hour). However, a number of promising instrumental techniques are available. Potential methods should be able to measure the amount of skatole and androstenone in the headspace over a heated fat sample. Androstenone has a molecular mass approximately three times greater than skatole and it is much more lipophilic, thus its concentration in the headspace over a heated fat sample is very low. An instrumental method must, therefore, be extremely sensitive.

Sheepmeat Taints

The characteristic mutton odor, associated with the cooked meat of older sheep, can be problematic for some consumers who find the odor disagreeable. Branched chain fatty acids (BCFAs), particularly 4-methyloctanoic 4-ethyloctanoic acid and 4-methylnonanoic acids, have been implicated as the main compounds responsible for this aroma. The concentrations of these compounds increase in sheep fat as an animal ages but can also be influenced by breed and diet. Another odor associated with sheepmeat is 'pastoral' odor, and this odor becomes evident as a result of cooking the meat of pasture-fed ruminants. 3-Methylindole, also involved with 'boar'

taint in pigs, and to a lesser extent 4-methylphenol (p-cresol) are the main compounds implicated as contributors to 'pastoral' flavor. The odor is unacceptable to some consumers, although those habituated find it acceptable.

The availability of instrumentation to measure these odiferous compounds would allow segregation of unacceptable and acceptable carcasses. All of the instrumental measures in the next section have shown potential for measuring both the 'mutton' and 'pastoral' odors in sheepmeat. Furthermore, as illegal substitution of mutton (older sheep) for lamb (young sheep) occurs in some markets, such as Australia, online tests for BCFAs have potential for eliminating this from occurring.

Potential Instrumentation for Odor Compounds

Electronic noses have been proposed as a candidate for at-line sampling and delivery of samples to instrumentation and measurement. However, electronic noses all suffer from the fact that it takes up to several minutes to purge the detector before a new measurement can be made. Another possible candidate is a time-of-flight mass spectrometer. These systems are already used to monitor airborne pollutants (including toxic gasses) in the field and have a very high sensitivity. One version of these instruments known as the proton transfer reaction – time-of-flight mass spectrometer (PTR-TOF-MS) has been tested on fat samples for measuring boar taint components with encouraging results. Another possibility is rapid methods using solid phase micro extraction (SPME), and these methods also show some promise. The SPME is usually implemented as a small fiber coated with one of a range of available polymers. The idea is to place a SPME fiber in the headspace over the fat sample to be analyzed for odor components for a well-defined length of time. The polymer coating can be selected in such a way that it will preferably adsorb molecules that are polar or nonpolar or volatile or nonvolatile. The amount of material adsorbed on the fiber coating will be proportional to the concentration of the substances in the fat sample if equilibrium has been reached. The process can be made to work within minutes. When the fiber is inserted into the injection system of, for example, the mass spectrometer (or GC–MS) and heated, the adsorbed materials will be released and made available for measurement. With the PTR-TOF-MS gas analyzer, the time from insertion of the SPME fiber to a result is given can be done within 2 s. Sensitivity of such an arrangement can be as low as a few parts per trillion. The advantage of the SPME technique is that if the headspace from a heated sample was to be measured directly, fat and water vapor would be drawn into the PTR-TOF-MS, where it over time will cause problems. However, much work remains to be done if such a system was to be implemented as an automated at-line method.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 97 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise.

There are four features that help you find the topic in which you are interested:

1. The contents list.
2. Cross-references to other relevant articles within each article.
3. A full subject index.
4. Contributors list.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Meat, Animal, Poultry and Fish Production and Management: Antibiotic Growth Promotants.

> *See also*: Chemical Analysis: Sampling and Statistical Requirements; Standard Methods. Foodborne Zoonoses. Growth of Meat Animals: Metabolic Modifiers. Microorganisms and Resistance to Antibiotics, the Ubiquity of: Antibiotic Resistance by Microorganisms. Residues in Meat and Meat Products: Feed and Drug Residues; Residues Associated with Meat Production

3 Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

PREFACE

The Encyclopedia of Meat Sciences, second edition, an extensive revision of the first edition published in 2004, covers all the essential meat topics, ranging from animal production, processing, analytical procedures, and food safety, to final consumption including health issues and nutritional aspects. There are more than 230 articles and these provide a greater breadth of coverage than any existing work on meat science. In addition to publication in print, the Encyclopedia is also available for licensing online that can allow regular updating. The articles are designed to bring a nonexpert up to a level of understanding the interactions among the various disciplines covered in the articles. Most articles are 3000–4000 words long and include a list of Further reading and Websites to expand the content beyond the immediate scope of this work. The Encyclopedia is, therefore, a valuable resource for several levels of education and experience.

The Editors gratefully acknowledge the contributions of the authors of the articles and the Editorial Advisory Board. The board not only proposed subjects to be covered, but also found contributors and then reviewed the articles. The work involved in an Encyclopedia such as this requires an extensive interactive cooperation among the Editors, the Editorial Advisory Board, the contributors, and the publishers, particularly the staff of the Major Reference Works division of Elsevier. The staff included Nancy Maragioglio, Donna de Weerd-Wilson, Anna Gebicka, Cari Owen, Will Bowden-Green, Sam Mahfoudh, Zoey Ayres, and Marise Willis.

The Editors are particularly grateful to Cari, Will, and Sam, who worked very closely with us and who diligently pursued all avenues to obtain contacts with contributors, maneuvered around obstacles, facilitated the day-to-day management, and linked everyone together to meet the deadlines.

Michael Dikeman and Carrick Devine
Editors, August 2014

INTRODUCTION

Meat consumption by hunter–gatherers predated the agricultural revolution. Consumption of meat and fish runs in parallel with human development that is still in process. Humans and animals have now coexisted for thousands of years for their mutual benefit, even though their relationship is changing. Meat does not come from a single, or even a few, animal species, but is derived from a wide variety of species ranging from poultry to pigs, cattle, sheep, goats, and wild game to thousands of species of fish. While many of these species are now intensively farmed, some still coexist with nomadic tribes, whereas, others are raised by families in small village communities, or are even hunted by remnants of hunter–gatherer communities. The second edition of the Encyclopedia of Meat Sciences discusses how the domesticated species evolved; the wide range of harvesting methods for animals, poultry and fish; the historical changes in production, processing and nutritional value, including the beneficial effects of optimum amounts of meat in a diet.

The meat industry is based on obtaining animals, poultry, and fish from pastures, feedlots and specialized intensive production systems, and from extractive industries such as fishing. It is understandable, therefore, that the genetics and management of animals and production systems are prominent in the Encyclopedia. However, the broad field of meat science is much more than harvesting animals and processing meat from them. It includes issues such as preslaughter stress and its effects on meat quality; religious issues; animal welfare; and humane slaughter techniques, all of which are extremely important to ensure that meat quality, cultural issues, and market requirements are harmonized.

Processing methods for the various species are different, but they have all historically developed to ensure, either by conscious design or by experience, that the underlying principles of physiology and biochemistry in the conversion of muscle to meat are optimized. Biochemistry and physiology are extremely important and fundamental disciplines, because they explain how unfortunate, undesirable processing defects such as PSE or cold shortening and toughening can occur and can be avoided. Progress in this area has also enabled significant changes in production and subsequent quality since the first edition of the Encyclopedia of Meat Sciences in 2004.

Understanding these changes requires an appreciation of the structure of carcass tissues, from gross carcass attributes to consideration and understanding of changes at the ultrastructural level. The form and function of muscle tissues, how they change through growth, how they impinge on meat quality, and the way that connective tissue and fat can be major contributors to the final product quality are all covered in these pages. Topics such as cold shortening that can cause meat toughening or inhibition of tenderisation are explained, as well as how procedures such as electrical stimulation evolved to prevent these problems. Assessment of meat quality from measurements such as muscle pH, tenderness prediction through spectral measurements on uncooked meat, color changes on display and storage, and reduction of microbial contamination are critical for many aspects of the meat industry and are also discussed.

There have been many and significant advances in meat animal production based on genetic, nutrition, growth biology, and metabolic modifier research. In regard to meat processing, advances in refrigeration and freezing technology, which is the foundation of perhaps the most important changes ever encountered for food is discussed. Even so, such advances also depend on the way in which microbiology and packaging are integrated to ensure wholesome products with a long shelf life, minimal spoilage, and desirable sensory attributes. However, there are many other ways to preserve food that are also important. Of ever-increasing importance is the topic of food safety, which must receive extensive attention because meat is a perishable product and is critical for a high quality of living and even for human survival. Meat marketing and pricing in all its forms, from wet markets to hotel, restaurant and institutional trade, and transportation are also important. Whole-tissue meat is usually cooked, so, many of the desirable attributes such as flavor development relate to the temperature interactions with various proteins and sugars during cooking. Other cuts are processed in various ways, from smoking to mincing to sausages and the technologies involved are covered.

Not all muscles or cuts of meat are suitable for the same cooking and preparation methods. Therefore, out of necessity, a vast range of highly desirable products has evolved with variations from one ethnic background to another. Other products are merchandized through fast-food restaurants. One can now consume a hamburger in China that is almost identical to that in Chile or in the United States owing to a consistency of product specifications that has become universal. Meat is not only a major source of quality protein and some vitamins and minerals; it often forms the central part of a meal, and is desirable to have the appropriate flavors, aromas, and appearance to conform to the expectations and the way meat is used in various cultures.

This second edition of the Encyclopedia of Meat Sciences also covers controversial health-related aspects of meat consumption and this aspect needs considerably more research. In recent years, the ready availability of meat and other foods has given rise to some health concerns. However, the issues are not always what they seem. The positive and potential negative health-related aspects of meat eating are addressed by experts in dietary and health aspects of meat consumption, but the effect of a single food item should not be considered in isolation.

The wide coverage of topics will ensure that this second edition of the Encyclopedia of Meat Sciences will be an important resource for students or professionals with an interest in meat science or those engaged in the livestock and meat industries. Most of the articles in the second edition are not only a revision of those in first edition but there are additional areas covered. The relatively short nature of the articles makes the Encyclopedia easy and interesting to read.

Glossary

Barrier property A measure of a packaging material's resistance to a permeant, such as a gas, moisture vapor, or a sensory trait like aroma.

Blooming Exposing fresh meat surfaces to air to allow the oxygenation of myoglobin on the surface of meat cuts, which changes the color of the meat from purple to bright red or pink; cuts are usually allowed to bloom for 30 min in order to obtain the desirable color.

Case ready Retail-packaged meat products that are cut and packaged in a centralized facility and shipped to stores, where they are ready to be placed directly in retail cases.

Controlled-atmosphere packaging The gaseous environment surrounding the product is altered and maintained at a specified composition. Oxygen present is completely removed and subsequent oxygen produced through respiration is removed using oxygen scavengers.

Modified-atmosphere packaging Retail packaging with an oxygen-impermeable package and a headspace that allows introduction of a specific atmospheric environment to control spoilage. It is sometimes termed controlled atmosphere.

Mother bags Large oxygen-impermeable packages in which several case ready, oxygen-permeable packages can be placed to allow a controlled atmosphere during shipping and storage.

Myoglobin Protein pigment found in muscle that gives meat its color. It contains an iron (Fe) held within a heme ring. The chemical state of the iron largely dictates the color of the meat. Myoglobin may be present in the following forms: Oxymyoglobin, oxygen is attached to the iron, which is in the reduced state (Fe^{2+}). It is red or pink in color; Deoxymyoglobin, iron is deoxygenated and in the reduced state (Fe^{2+}). It is purple in color; Metmyoglobin, iron is in the oxidized state (Fe^{3+}). It is brown in color; Carboxymyoglobin, carbon monoxide is attached to the iron, which is in the reduced state (Fe^{2+}). It is bright cherry red in color.

Overwrap packaging Retail cuts are placed in foam trays with a soaker pad and the product and the tray are incased in a clear, flexible, and oxygen-permeable film allowing exposure to ambient air.

Oxidation The loss of an electron from an iron molecule (resulting in Fe^{3+}) of myoglobin. It results in the brown metmyoglobin pigment.

Oxygenation The attachment of oxygen to the iron in the heme ring of myoglobin.
Oxygen permeability The amount of oxygen allowed through a packaging film, usually expressed as ml per m^2 per 24 h at a specific temperature.
Oxygen scavenger A material that actively removes oxygen from an environment.
Preformed trays Rigid trays, of specific size and shape, commonly used in modified-atmosphere and controlled-atmosphere packaging systems. Trays will incase the product in its entirety, allowing a headspace of gas around the cut. Rigid trays are typically impermeable to oxygen.
Reduction The gain of an electron by an iron molecule (resulting in Fe^{2+}) of myoglobin. It results in the red or pink oxymyoglobin or the purple deoxymyoglobin.
Shrink tunnel or bath A steam tunnel or water bath within the production line that exposes the packaged product to a high temperature for a short time. This highly controlled heating shrinks the polymer package tightly around the meat product.
Skin packaging A process of packaging in which a flexible barrier film is rolled onto a meat product, which is then heated and vacuum sealed, forcing the softened film to mold itself into the shape of the meat.
Thermoformed packaging A process of packaging in which products are placed into heat-softened films, formed into a desired shape, and sealed with a nonforming layer over the top of the formed film. The intrapackage environment may be vacuum or gas flushed.
Two-phase packaging The gaseous environment surrounding the product is changed from anaerobic, for transport and long-term storage, to aerobic, for short-term storage and display.
Vacuum packaging A process of packaging in which retail or wholesale cuts are placed in oxygen-impenetrable bags, all air is removed from the bag, and the bag is sealed.

Introduction

Although fresh meat is highly perishable, its packaging has, until recently, been a matter of only minor concern to meat traders, health officials, and consumers. Unwrapped fresh or frozen meat has been the currency of the wholesale and retail meat trade. Small meat species, such as rabbits and poultry, are, in many parts of the world, still traded commercially in their natural packaging, that is, their own skin.

Packaging is not just the materials immediately surrounding a product but rather is the synthesis of the product, its processing, and labor and machines required in order to address specific functional and marketing requirements. These functions relate to all aspects of distribution, storage, and merchandizing along with containment, protection, preservation, portioning, unitization, convenience, and communication.

For meat and meat products, packaging should provide the customer with an appropriately portioned product in a safe and wholesome condition. Meat packaging has to protect the product from a physical environment that threatens product safety, product damage, and loss of pack integrity.

The functional requirements of meat packaging systems are dictated by the required marketing performance. For example, the packaging requirements for international trade in chilled meat differ from those for domestic supply. The overriding performance requirement is, however, the same in both cases – adequate storage life insuring product resilience to meet customer expectations. Briefly, packs for retail display should facilitate contact of meat with oxygen to allow blooming, whereas those for transport and extended storage should preclude such contact.

The packaging technologies required to meet the varied customer expectations are numerous and the machinery commonly used are discussed below.

Nonpreservative Packaging

This type of packaging contains the product and protects it from contamination and moisture loss without creating in-pack conditions very different from the ambient conditions. Consequently, unless microbial growth is prevented by freezing, addition of preservatives, or is retarded by chilling, the product in such a pack is highly perishable with a very short shelf life and would only be appropriate for domestic supply.

Wrapping

The simplest form of flexible packaging – wrapping – does not require machinery at all. A meat product is simply placed on a sheet of material, often greaseproof paper or plastic cling film, which is wrapped around the product to protect it from the environment and vice versa.

Tray Overwrap

Overwrapped trays are widely used in supermarkets for fresh meats, processed meats, and poultry. Fresh meats are placed on a semirigid tray, often incorporating some drip-containing device, and overwrapped with a plastic film of high-oxygen permeability. As with general wrapping, overwrapped trays are not sealed and, because of the high-oxygen permeability of the films used, provide ambient aerobic conditions around the product, giving the product a limited shelf life. The machinery available for overwrapping trays varies from hand wrapping as it ranges from a roll of cling film, through wrapping aids, to fully automated wrapping machines (Figure 1).

Preservative Packaging

Packaging in this group is characterized by its ability to extend product life over that achieved by simple overwrap technology. This is achieved by creating and maintaining in-pack conditions that differ markedly from those of the ambient environment, thus, creating conditions that modify or restrict microbial growth.

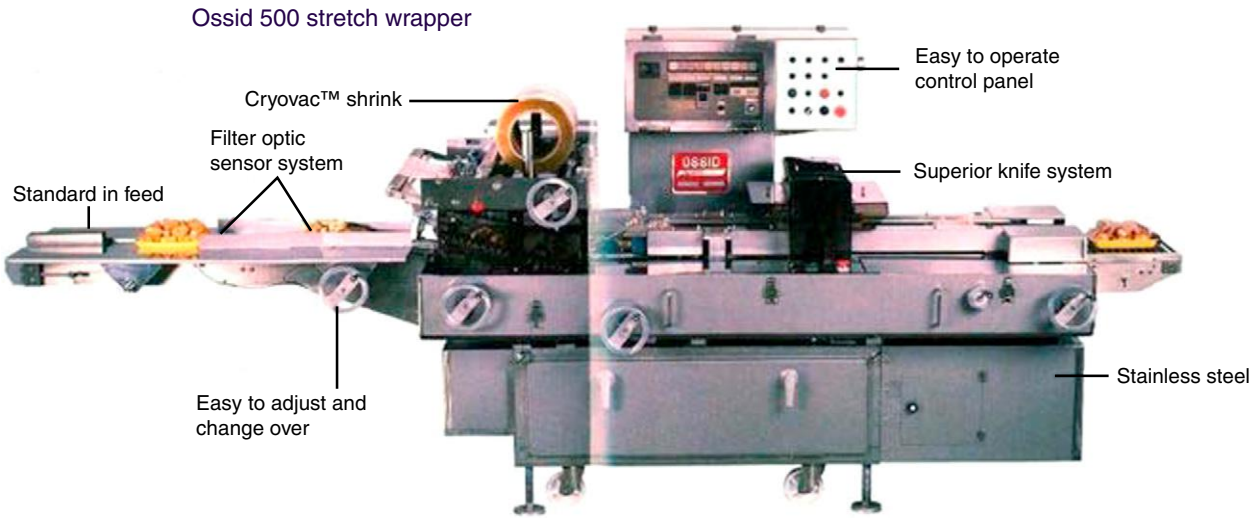

Figure 1 Ossid 500 stretch wrapper. Fresh meat on semirigid trays is feed into the wrapper, on the left, where it is wrapped in oxygen-permeable stretch film, weighed, labeled, and priced, emerging on the right ready for the display case. Vacuum Packaging

The basic principle of vacuum packaging is quite simple and has been successfully used commercially for approximately 40 years. The preservative effect in vacuum packs is achieved by removing air from within the pack and maintaining an oxygen-deficient environment around the product by sealing the product in a flexible film of low oxygen permeability. This oxygen-deficient in-pack environment extends the product's storage life by selecting a slower growing anaerobic spoilage microflora and preventing the proliferation of the fast-growing aerobic spoilage organisms. The technologies and machinery used to achieve this are in large amount and varied.

Vacuum clip

A vacuum pack is achieved, using this technology, by placing a piece of fresh meat or meat product into a tube of oxygen-barrier film that has been sealed at one end with a metal or plastic clip (Figure 2). A vacuum nozzle is placed at the open end of the tube and a vacuum is applied to remove air from within the pack. While the pack is under vacuum, the packaging material is gathered around the nozzle and sealed with another metal or plastic clip. Fresh meat packages prepared in this way can then be heat shrunk to give a tight pack of attractive appearance. Processed meat, such as luncheon meat, could be cooked with this type of packaging.

The machinery available for vacuum clip ranges from a simple hand-operated model to fully automated models mounted in-line for 'chub' packed sausage manufacture.

Vacuum chamber

The most common technology used in the fresh meat industry is the vacuum chamber. Fresh or processed meat is placed into a flexible pouch made of an oxygen-barrier film, which is then placed into a chamber with the open end of the pouch positioned over a seal bar. The chamber is closed and a vacuum

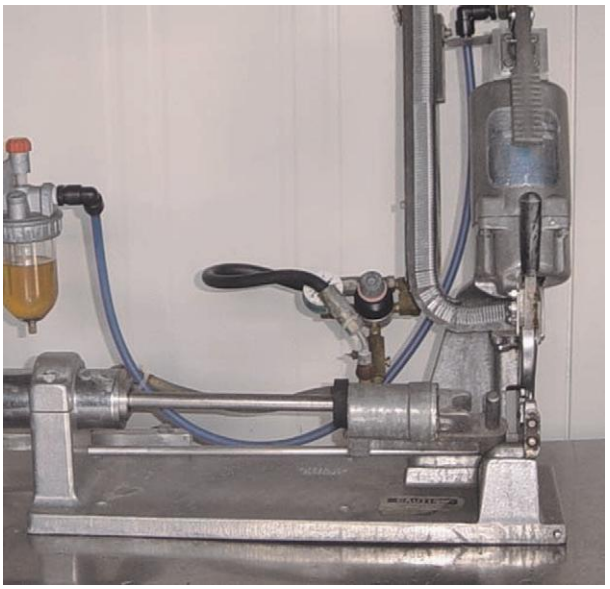

Figure 2 Hand-operated Clippertie vacuum clip system. Meat product packaged in oxygen barrier is sealed with a metal or plastic clip (contained in the reverse-J-shaped formation) around the gathered packaging material.

applied. The chamber is then evacuated to a level where water vaporizes from the meat surface, insuring that an oxygen-free atmosphere is maintained around the product. At this stage, the open end of the pouch is hermetically sealed and the vacuum released, which results in the film collapsing tightly around the product (Figure 3).

Close contact between the meat and the packaging film can be enhanced by heat shrinking the packaging on the product after heat sealing. Packaged product is passed through a shrink tunnel or bath that subjects the packaging material to temperatures between 80 and 85 °C, depending on film formula,

Figure 3 Twin vacuum chamber machine. Meat in oxygen-barrier bags is placed on one platform. The chamber hood is lowered, a vacuum is applied within the chamber, and the vacuum-barrier bag is sealed and the camber is vented. for 1–2 s. This treatment causes the packaging material to shrink in two dimensions.

There is a vast range of vacuum chamber machinery available, from small single-chamber machines to handle 1–2 kg cuts for the corner butcher, through twin chamber (Figure 3), to multichamber rotary machines that can process 100 tons of cuts over a day's production (Figure 4).

In large high-throughput meat plants, modern vacuum chamber machines form the central part of an integrated meat packaging system, where the meat cut is measured, a barrier bag is constructed to size from a roll of barrier tubing, and the product is automatically loaded at the packaging station before normal chamber evacuation and sealing.

Figure 5 Flow wrap. Flexible-barrier film is passed through a former (on the left of figure), producing a tube around the meat (center) before vacuuming and sealing. Reproduced with permission from Cryovac Sealedair Corporation, Hamilton, New Zealand.

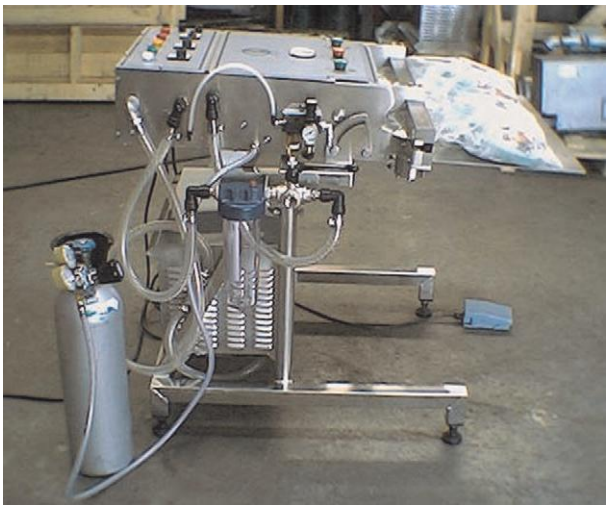

Figure 6 Snorkel machine. Barrier bags of meat are clamped over snorkels (on the right of figure). Air is evacuated through the snorkels before sealing. Reproduced with permission from Oakham Industries, Auckland, New Zealand.

An alternative, recently introduced, in-line system uses a vertical form-fill and seal principle that employs a single roll of flexible-barrier film passed through a forming tool, which forms the material into a tube around the meat cut. The two edges and one end of the formed tube are hermetically sealed to enclose the product in a custom-made barrier pouch. The enclosed product is then conveyed to a vacuum chamber and vacuum sealed or gas flushed automatically (Figure 5).

Snorkel

An improvement on the vacuum clip is snorkel technology (Figure 6), in which the meat is placed in a flexible-barrier pouch and the open end of the pouch is placed over two evacuating snorkels and clamped to make the pack airtight. As the vacuum is drawn, the packaging material collapses around

the product and, when all air has been removed, the snorkels retract and the pouch is hermetically sealed.

Vacuum skin pack

Vacuum skin packaging is a variant of vacuum chamber packaging (Figure 7). Meat cuts or sliced processed meats are placed on trays or flat sheets of flexible-barrier material before being introduced manually or automatically into a vacuum chamber. A flexible-barrier film is fed from a stock rolled over the trayed product. The upper film material is softened by heating; the skin is formed by drawing a high vacuum on the inner and outer sides of a barrier film and subsequently venting the upper side to atmosphere, forcing the softened film down so that the soft film molds itself to the shape of the product and adheres to the lower film or tray to produce a skintight leakproof package. Vacuum skin packaging is particularly useful for irregularly shaped product when the product shape needs to be maintained.

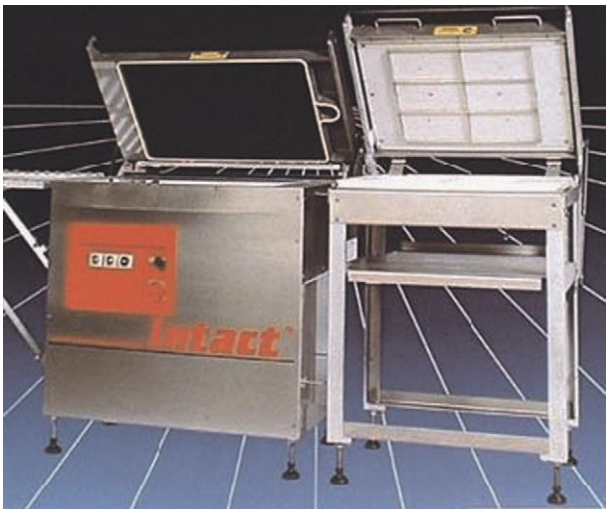

Figure 7 Vacuum skin packaging machine. Trays of meat are placed on magazine (right) before being placed in chamber. Barrier film is softened by a heating element in lid before being molded to trays below. Reproduced with permission from Cryovac Sealedair Corporation, Hamilton, New Zealand.

Vacuum skin packaging machinery ranges from small bench-top models, allowing small butchers to package one or two trays at a time, to fully automated continuous-flow models, packing many hundreds of packs per hour.

Pi-Vac

Pi-Vac is a development that extends the vacuum clip technology, which has recently been marketed in Europe. This technology claims to be a 'vacuum-free vacuum pack'. The film is fed into tubes (Figure 8(a)) and the film edge is stretched over fingers in such a way that it allows the open tube to have meat placed in it (Figure 8(b)).

The oxygen-free atmosphere around the meat product is achieved by using the specially constructed barrier tube of film that is stretched before the meat is introduced into the tube. The stretched film contracts over the meat to its prestretch dimensions, forcing air out and bringing the film into close contact with the meat product. The open end of the tube is clipped or heat sealed, producing an air-free meat pack.

Controlled- and modified-atmosphere packaging

In modified-atmosphere packaging (MAP), the gaseous environment around the meat is modified before heat sealing, and then gradually changes as a result of the interaction between the product and the packaging. For meat, the in-pack environment is usually altered by evacuation followed by backflushing with the desired gas mixture.

For fresh meat, oxygen mixtures are used for retail display packs, whereas oxygen-free mixtures are used for transport/storage packs. Subsequently, changes in the composition of the in-pack atmosphere are determined by the gas barrier properties of the packaging material; the metabolic activities of the product; its microflora; and the solubility of components of the gas mix in the product. For processed meats,

(a) (b)

Figure 8 (a) A Pi-vac machine with three tubes. Barrier film is prestretched inside one of the three tubes with the edges placed over 'fingers' (middle tube) that are stretched to enlarge the opening before introduction of meat. (b) Meat is placed in a tube of prestretched film pulled open by the fingers. Reproduced with permission from Pi-Patente GmbH, Wettenberg, Germany.

where meat bloom is not an issue, oxygen-free mixtures are used.

As in MAP, in controlled-atmosphere packaging (CAP) the gaseous atmosphere around the meat is altered, but it is then maintained at a specified composition – effectively zero oxygen – regardless of product or microbial respiration or any other environmental changes. To maintain complete anaerobic environment, oxygen scavengers are used. In a mother bag/overwrap system, the oxygen scavenger is added to the mother bag and never comes in contact with the consumer. Some processed meats, such as jerky or pepperoni, may contain an oxygen-scavenging sachet in the package labeled 'DO NOT EAT.' Other packaging systems may use an active oxygen-scavenging layer in a multilayer film.

Thermoforming

Thermoforming involves the use of a semirigid base material that is drawn from a feeder reel into a heating station where the material is softened. The softened material is drawn into a mold by application of a vacuum to form the base of a meat tray. In some machine models, the tray formation is mechanically aided by the insertion of a tray-shaped die.

The formed trays are part of a continuous sheet and move onto the product-loading station, as the next cycle commences, with product loaded either manually or, in some cases, automatically (Figure 9). Forming film can be rigid, allowing minimal flexibility, semiflexible, allowing some flexibility, or flexible. These films can be used in combination with colored or clear nonforming films for customized packaging options.

The filled web of trays is indexed to the vacuum, flushing, and sealing chamber, where a barrier lidding material is simultaneously fed into the chamber above the trayed product. A vacuum is applied in the chamber and the ambient atmosphere is removed. The machines can be configured to produce either vacuum packages or MAP trays depending on the product requirement. The sealed web of MAP packs then passes through a series of knives that separate the individual packs before cartoning and distribution to retail. Many products packed in a thermoform pouch require gas flushing; however, many fresh meat products are packed in vacuum using thermoform equipment. Thermoforming equipment allows processors to reduce labor and increase throughput when packaging meat products.

Preformed trays

MAP machines that use preformed trays have many similarities with the thermoforming machines without tray material reel feed and heating and forming station. The use of preformed trays allows a greater variety in tray sizes, designs, colors, and materials to suit changing market demands.

The trays can be filled with product and placed into the vacuum, flushing, and sealing chamber. There can also be an attached tray denester, from which the trays are placed automatically into an indexed in-feed system, fed to the loading station, and then into the vacuum, flushing, and sealing stage, similar to that of the thermoforming machines. The excess lidding film is trimmed from the tray flange before cartoning and dispatch. An example of a machine using preformed trays is shown in Figure 10.

CAPTECH chamber snorkel machines

This technology extends the use of CAP and is known as the CAPTECH system. It is used for very low oxygen/carbon dioxide CAP for extended shelf life where very low oxygen levels are required to be maintained over a long storage period. Meat cuts

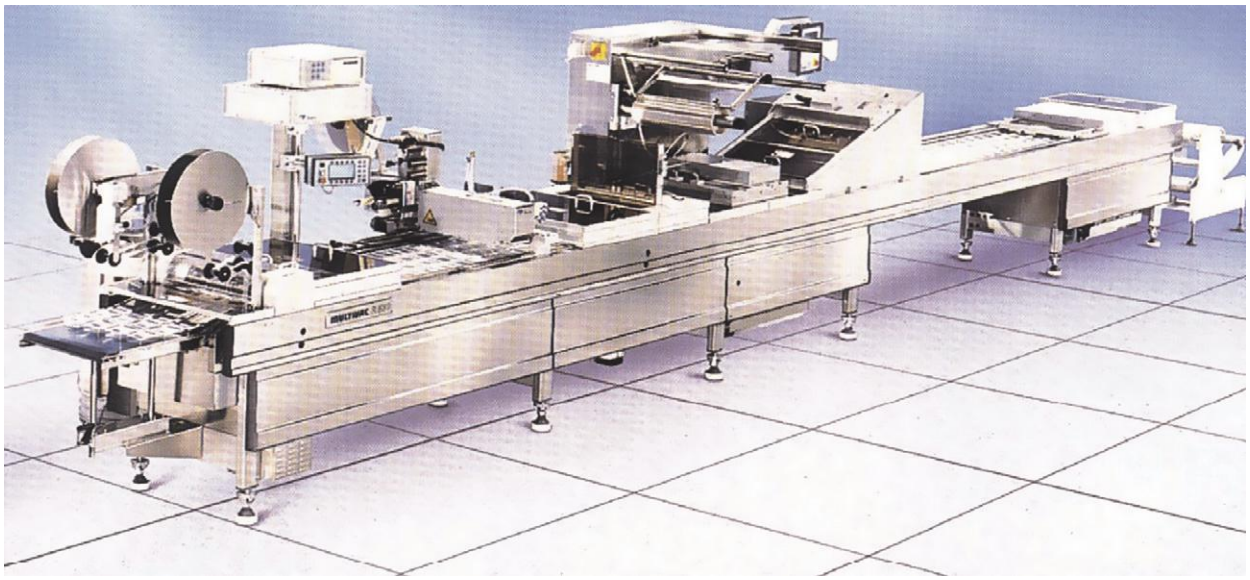

Figure 9 Thermoforming machine. Semirigid base material (far right) is drawn into the heating station (right), where the material is softened and a tray is drawn. The product is loaded into the trays and moved onto the gassing and lidding station (middle), where the pack atmosphere is modified and the pack is lidded. The packaged product is trimmed (far left) for dispatch. Reproduced with permission from Cryovac Sealedair Corporation, Hamilton, New Zealand.

or display packs are placed into high-oxygen barrier bags and the open end of the pouch is placed over the internal snorkel before the chamber lid is lowered. A vacuum is applied to both the chamber and the snorkel at the same time to maintain equal pressure within the chamber and the bag, thereby preventing any distortion of the packing materials or the product. When the vacuum reaches the predetermined level, the chamber is slowly vented and the pack gas is injected into the meat pack through the evacuation snorkel at a rate that prevents pack damage. When the preset level of gas is reached, the pouch opening is hermetically sealed and the chamber is fully vented and opened. The equipment is shown in Figure 11.

Mother bag snorkel machines

This technology does not rely on chamber evacuation to remove air from the package and can be used for products that may be damaged by vacuum; however, the amount of air removed from the pack may vary and may not be suitable for packs that require accurate control of pack gas atmosphere.

Meat cuts or display packs are placed in an oxygen-barrier pouch. The open mouth of the barrier pouch is stretched over the flat snorkels and is clamped to make an airtight seal. The clamping action initiates a vacuum in the snorkels and the air within the pack is removed, collapsing the packaging material around the product. After a preset time, the evacuation is stopped and the pack is backflushed with the required MAP gas.

If more accurate control of the gas composition in the pack is required, the vacuum and backflush cycle can be repeated, further diluting ambient air remaining within the pack. In very low oxygen mother bag packaging, oxygen scavengers are typically used to sequester residual oxygen that may be present in the package. The machinery is similar to that shown in Figure 6.

Figure 11 CAPTECH machine. Meat is placed in very high-barrier bags. The open end of the bags is placed over one of the three internal snorkels. The chamber is lowered, a vacuum is applied, and the storage atmosphere containing carbon dioxide is injected into the pack before sealing. Reproduced with permission from Securefresh Pacific Ltd., Auckland, New Zealand.

Mother bag flow wrap

Mother bag flow wrap uses a vertical form-fill and seal principle that employs a single roll of flexible-barrier film passed through a forming tool to form the material into a tube. A number of case-ready trays are transported into the tube as it is formed. The two edges, and one end of the formed tube, are hermetically sealed to enclose the product in a custom-made barrier pouch. The pouch with the enclosed product is then flushed with the required MAP gas mix and sealed automatically. The machinery is similar to that shown in Figure 5.

Two-phase packaging

The general principle of two-phase packaging is to change the gaseous environment surrounding the meat from anaerobic to aerobic between the transport/storage and the storage/display phases.

One system uses a vacuum chamber to replace the ambient air in a ridged-barrier tray with low oxygen, carbon dioxide, or nitrogen, or a mixture of both, and seal a ridged, domed lid onto the ridged tray to enclose the CAP atmosphere. After transport and storage, the dome is removed to allow air into the pack, which will effectively 'bloom' the meat for an attractive retail display.

Another system uses the same principle to produce an anoxic atmosphere around the product but seals the pack with a multilayer peelable-barrier film. After transport and storage, the top barrier layer of the lidding film is removed to expose the oxygen-permeable layer, which allows the anoxic transport atmosphere to be replaced with ambient air, resulting in meat 'bloom' for retail display.

In a third variation, the 'windjammer,' meat is placed in a preformed tray. The ambient atmosphere in the tray in the chamber is replaced with a nitrogen–carbon dioxide mix in a vacuum chamber where the 'transport atmosphere' is replaced with a 'display atmosphere' and sealed with a high-barrier film.

When the pack is required for retail display, a septum is placed on the lidding film and a needle is inserted through it. The meat pack is then transferred to a vacuum chamber where the anoxic transport atmosphere is replaced, through the needle, with a high-oxygen display atmosphere. The needle is then removed and the product is ready for retail display.

Glossary

Carboxymyoglobin A form of myoglobin that results in red color due to carbon monoxide.
Controlled atmosphere packaging (CAP) A package with an atmosphere that is intentionally controlled to remain approximately the same during the package life.
Deoxymyoglobin A form of myoglobin responsible for purple color due to absence of oxygen ligand.
High-oxygen packaging A gas mixture of up to 80% oxygen and 20% carbon dioxide.
Low-oxygen packaging A gas mixture of up to 80% nitrogen and 20% carbon dioxide.
Methemoglobin A form of hemoglobin in which the iron is in the ferric state, not the ferrous of normal hemoglobin, and is responsible for marrow color.
Metmyoglobin A form of myoglobin responsible for brown discoloration due to ferric iron.
Modified atmosphere packaging (MAP) A barrier package where the initial atmosphere is removed, then the package is refilled with a single gas or a combination of gases.
Oxymyoglobin A form of myoglobin redox responsible for red color due to effects of oxygen ligand.
Peelable films An oxygen-permeable package contained within an outer oxygen impermeable barrier that is removed (peeled) at the retail market to enable oxygenation.

Introduction

Both modified atmosphere (MAP) and controlled atmosphere packaging (CAP) systems have gained popularity because of centralized preparation of retail meat cuts and distribution over increasingly longer distances. These factors require meat in packages to have a shelf life that is greater than that provided by overwrapping and require packaging to provide benefits different from those offered by vacuum packaging. Case-ready meat programs have been in wide use in Europe for several decades but are a relatively recent part of meat retailing in the US. Nevertheless, case ready is experiencing phenomenal growth in the US, accounting for nearly 65% of fresh meat retail cases.

Modified Atmosphere Packaging

MAP involves placing product in a barrier package, removing the existing initial atmosphere with a vacuum pump or by gas flushing, and then refilling the package with a single gas or a combination of gases. Although the gas composition within the package after sealing is typically not altered, oxygen scavengers as well as muscle and microbial metabolism may reduce residual levels of oxygen in some types of MAP.

Controlled Atmosphere Packaging

CAP implies that the package atmosphere after air evacuation is intentionally controlled to remain approximately the same during the package life. Another term sometimes used is 'intelligent' packaging, which may include monitoring the package and possibly making adjustments based on this information. These package adjustments could deal with oxygen scavenging or control, moisture and gas permeability, ethylene control, temperature control, odor removal, aroma emission from plastics, microbial growth, product freshness or spoilage, and package integrity. To meet this very demanding requirement, a film that is completely impermeable to gases must be used.

Proponents of CAP advocate the use of

1. A film with a layer of nonplastic material, such as aluminum;
2. Heat seals on all package perimeters; and
3. Complete evacuation of air because product color is significantly affected by even minute amounts of oxygen in the package. Antimicrobials and antioxidants also can be incorporated into films to improve shelf life.

Purposes of Modified Atmosphere Packaging and Controlled Atmosphere Packaging

Both MAP and CAP have the ability to prolong product shelf life and thus are very useful when meat must be transported to long distances. This technology is primarily used for the distribution of fully prepared case-ready retail packages either as individual packages or as several retail packages in a master or mother package. In addition, distribution of carcasses or larger cuts to the location where retail cuts are prepared and retail packaged is possible. For example, lamb carcasses can be shipped in CAP and larger pork wholesale products (loins, shoulders, or spare ribs) packaged in MAP can be shipped to retail locations for further processing. In addition to improving color life, modifying the within-package atmosphere can influence the time before microbial growth and lipid oxidation cause spoilage.

Color Properties

Packaging systems need to promote both the development and the stability of an attractive, bright, fresh saleable appearance when meat products are cut into retail cuts and placed on display. This should provide sufficient display life by allowing products to be sold and used by the consumer with minimal loss. Desirable appearance relates not only to muscle color but also to color of fat, bone marrow, and liquid purge, which all can influence consumer purchasing decisions. As a result, discoloration can decrease shelf life more quickly than microbial deterioration or spoilage. Packaging should also provide a barrier to water vapor transmission in order to control surface dehydration of the meat.

Advantages and Disadvantages of Case-Ready Meat and Central Processing

MAP systems have been essential to the development of case-ready meat programs. The benefits of the case-ready method include better control of sanitation and use of Hazard Analysis and Critical Control Points principles at a centralized processing facility; improved product safety resulting from less handling; a lower requirement for skilled labor at individual retail stores; more consistent and high-quality products; greater marketing flexibility (the retail manager can order product to fit anticipated individual retail store needs); the ability to rapidly replenish case items that are out of stock or in short supply; and more accurate records of sales, purchasing patterns, and inventory.

The case-ready programs that are made possible primarily by MAP have some disadvantages and challenges, such as a higher per-package cost because more specialized films and packages are needed to maintain desired quality and safety for the longer time from initial fabrication to purchase by the customer. Although MAP can reduce food loss and waste, the impact of packaging material waste, such as trays and film, on the environment can be a concern. As a result, environmentally friendly packaging materials that are biodegradable have received interest. Other disadvantages to case-ready systems using MAP can include the effect of oxygen level on bone marrow discoloration and cooked color development.

Role of Gases in Packaging

Modified Atmosphere Packaging

The initial gas atmosphere for MAP is obtained by removing air from the package followed by refilling the package with a desired gas blend mix such as high oxygen, low oxygen, ultralow oxygen, and carbon monoxide at a low level (0.4%). High-oxygen MAP involves a gas mixture of up to 80% oxygen (65–80% is most common) and 15–30% carbon dioxide. Complete air evacuation is not as critical for high-oxygen as for low- and ultralow-oxygen MAP because of the final oxygen level. Low- and ultralow-oxygen MAP uses a gas mixture of carbon dioxide and nitrogen. The purpose of this system is to minimize oxygen exposure during storage and distribution. This will slow the onset of microbial spoilage and lipid oxidation while promoting myoglobin oxygenation (bloom) before display. Merely assuming that packages have the proper gas composition may lead to serious consequences, even if the deviations in composition are small. In addition, leak detection is extremely important.

Peelable packaging includes a retail package with an inner film that is oxygen permeable and contained within a second outer layer of barrier film that maintains a low-oxygen condition. This outer oxygen-impermeable barrier is removed (peeled) at the retail market to enable oxygenation (blooming) of the meat to a desired bright color. Alternatively, individual oxygen permeable retail packages can be sealed in an individual outer 'master' or 'mother' bag that is oxygen impermeable. The inner package is then removed at the retail location to facilitate product oxygenation. Minimizing both storage time and oxymyoglobin formation before packaging in peelable films is critical because the conversion of oxy- to deoxymyoglobin is not direct but through metmyoglobin. More specifically, deoxymyoglobin regeneration requires both oxygen consumption accompanied by subsequent metmyoglobin reduction. This reaction tends to decrease with storage time, suggesting that oxygenation, or bloom, after peelable films are removed at retail and the product is exposed to air will be greater for product that has spent less time in the oxymyoglobin redox state before initial packaging.

Oxygen

Oxygen is essential in fresh meat packaging to both develop and maintain bright red meat color. Its use at 65–80% of in-package gas helps to drive the oxymyoglobin pigment layer deeper into meat. This extends the time until metmyoglobin approaches the surface of the meat, which results in discoloration. Although color life is dependent on numerous factors, 80% oxygen:20% carbon dioxide can increase color stability up to three times of that expected with aerobic packaging. However, the primary disadvantage of the high-oxygen packaging is lipid oxidation and the development of oxidized off-odors. To counteract this, product enhancement with a solution containing an antioxidant may be useful. High-oxygen packaging can also predispose product to marrow discoloration and cooked color defects such as premature browning.

Residual Oxygen Effects

Sufficiently low levels of oxygen are necessary for the success of ultralow-oxygen packages because partial oxygen pressure as low as 1.4 mmHg will favor metmyoglobin formation. Nevertheless, low levels are difficult to achieve with initial package evacuation of air and thus a low level of oxygen may persist in the in-package atmosphere until it is used by muscle or microbial metabolism or is removed with an oxygen scavenger. For example, simple gas displacement may result in residual oxygen of up to 10%, whereas chamber evacuation can achieve 0.1–1% oxygen, depending on evacuation cycle time. As a result, residual oxygen in low- and ultralow-oxygen packages is typically present shortly after package closure and is often used for both muscle and microbial metabolism. This produces carbon dioxide, which can be an asset in lessening

aerobic microbial growth and may favor a more desired microbial population. However, at low oxygen levels, the formation of metmyoglobin is favored, resulting in surface discoloration. With time, oxygen may be used up by the meat and metmyoglobin may return to purplish-red deoxymyoglobin via metmyoglobin reducing activity (MRA). Oxygen scavengers can also be used to minimize the amount of muscle metabolism necessary to result in suitably low oxygen levels and MRA.

Oxygen Scavenging

To rapidly attain and then maintain zero oxygen in MAP, oxygen absorbers or scavengers are often needed to remove residual oxygen. The most common oxygen scavengers are reduced iron powders mixed with acids, salts, or both that can be oxidized in the presence of oxygen, usually on the addition of a wetted humectant. Active packaging may use a polymeric oxygen scavenging system that both absorbs oxygen within the package and serves as a barrier film. The oxygen scavenging layer consists of three components including an oxidizable polymer that binds oxygen molecules, a photoinitiator, and a catalyst. After the package is sealed, it passes under an ultraviolet light, whereupon the photoinitiator provides energy to start the reaction and the catalyst speeds up the oxygen scavenging. Another important consideration is immediate packaging after fabrication to minimize the uptake of oxygen by meat. Increased time before packaging will more likely result in oxygen release into the within-package atmosphere as well as slow metmyoglobin reduction and bloom.

Carbon Dioxide

Carbon dioxide is a component typically used in modified atmosphere packaging to slow bacterial growth; thereby extending the time until spoilage. Carbon dioxide is more effective with low levels of initial contamination and also at cold temperatures. Its effects include altered cell membrane function, nutrient uptake and absorption, and enzyme functions.

Carbon dioxide is very soluble in both the muscle and fat components of meat, especially at cold temperatures and increased pH. This can diminish the volume of gas within the package headspace, resulting in package collapse because of a loss of gas volume. As a result, enough carbon dioxide must be added to the gas mix to account for absorption into meat and its consequent loss from the within-package atmosphere. Adding nitrogen to the gas blend lessens the possibility of package collapse.

Nitrogen

Nitrogen is essentially inert in a meat package and is frequently used as a filler gas to dilute oxygen. It is especially used with cured product to provide conditions under which cured color does not fade very rapidly and where nitrite is an ingredient used for microbial control.

Carbon Monoxide

The use of carbon monoxide (CO) in modified atmosphere packaging results in a stable bright red color via the formation of carboxymyoglobin. There was early concern that this stable color would mask microbial spoilage, but at the 0.4% use permitted in the US, this was not found to be a problem when retail packages are removed from the master pack before display. Nevertheless, the use of expiration dates on labels has been recommended. Although carbon monoxide can result in cooked color defects, such as persistent pink color, consumer apprehension toward CO is more likely the limited factor preventing its use in modified atmosphere packaging.

Gas Effects on Bone Marrow

In addition to muscle color, packaging can influence the color of bone marrow because hemoglobin oxidation results in bone marrow discoloration, sometimes referred to as bone darkening. This has been particularly problematic in high-oxygen packages as the 80% oxygen tends to increase methemoglobin formation. Low-oxygen and CO packaging can minimize marrow discoloration by maintaining hemoglobin in a ferrous redox state.

Gas Effects on Cooked Color

Packaging atmosphere can influence cooked color in addition to raw color. In particular, premature browning of cooked product before pasteurization temperatures has been associated with high-oxygen packaging. Before cooking, myoglobin redox form influences the protein's stability toward heat induced denaturation. Oxy- and metmyoglobin are less heat stable than deoxymyoglobin. As a result, the increased depth of oxygen penetration in high-oxygen packaging can predispose beef to premature browning. Vacuum packaging, which maintains deoxymyoglobin within the interior of steak/patties, can prevent premature browning. Meat packaged in CO will often remain red/pink after cooking because carboxymyoglobin is relatively stable against heat denaturation.

Film Composition and Gas Permeability

To adequately maintain the desired gas composition during storage, distribution, and display, packages must consist of materials that are effective barriers to the transmission of gases and water vapor. Gas transmission rates are affected by film material(s) and thickness, environmental temperature, and the difference in partial pressures of the appropriate gas between the inside and the outside of the package. Most barrier packages are constructed of three layers of film. The outer layer is designed to be scuff and abrasion resistant; the middle layer provides barrier properties; and the inside layer is the sealant layer. More details on film materials, how they are manufactured, and their functions and limitations are given in another article.

Enhancement of Meat

Injection enhancement of meat includes the incorporation of ingredients such as water, salt, phosphate, lactate, and

antioxidants via injection and/or physical manipulation. This process can increase yield of saleable product, create a more uniform tenderness, and improve color stability. Ingredient-based effects on color can be packaging dependent. For example, lactate tends to improve color life in high-oxygen packaging but not in CO or vacuum. Other ingredients added via injection enhancement can negate lipid oxidation associated with extended storage of MAP.

Key Factors for Success in Product Quality Using Modified Atmosphere Packaging and Controlled Atmosphere Packaging

The essential keys to success of both MAP and CAP operations include:

- Using clean, acceptable quality product.
- Rapid completion of packaging after meat fabrication.
- Temperature control during storage and display.
- Complete evacuation of air before filling the package with the desired atmosphere.
- Use of packaging materials with appropriate gas and moisture transmission rates.
- Packaging that remains sealed until opened at the point of use.
- Other considerations are package cost, package reliability, the storage and display life provided, acceptability of the retail package to the customer and to the meat marketing manager, packaging speed (productivity), equipment efficiency, and the required headspace gas.

Glossary

Blooming Exposing fresh meat surfaces to air to allow the oxygenation of myoglobin on the surface of meat cuts, changing the color from purple to bright red or pink, cuts are commonly allowed to bloom for 30 min to obtain the desirable color.

Carboxymyoglobin Carbon monoxide is attached to the iron and it is in the reduced state (Fe^{2+}), bright cherry-red in color.

Case pulls The packages removed from retail case due to discoloration, package failure, or being past the 'sell-by' date.

Case-ready The retail packaged meat products that are cut and packaged in a centralized facility and shipped to stores, ready to be placed directly in retail cases.

Modified atmosphere packaging Retail packaging with an oxygen-impermeable package and head-space that allows for the introduction of a specific atmospheric environment to control spoilage, sometimes termed controlled atmosphere.

Mother bags Large oxygen-impermeable packages in which several case-ready, oxygen-permeable packages can be placed to allow for a controlled atmosphere during shipping and storage.

Myoglobin A protein pigment found in muscle that gives meat its color, contains an iron (Fe) held within a heme ring. The chemical state of the iron largely dictates the color of the meat. Myoglobin may be present in the following forms: cholemyoglobin, hydrogen peroxide is attached to the iron and it is in the oxidized state (Fe^{3+}), brownish-green in color; cyanmetmyoglobin, cyanide is attached to the iron and it is in the oxidized state (Fe^{3+}), red or pink in color; deoxymyoglobin, iron is deoxygenated and in the reduced state (Fe^{2+}), purple in color; metmyoglobin, iron is in the oxidized state (Fe^{3+}), brown in color; oxymyoglobin, oxygen is attached to the iron and it is in the reduced state (Fe^{2+}), red or pink in color; and sulfmyoglobin, sulfide is attached to the iron and it is in the oxidized state (Fe^{3+}), brownish-green in color.

Oxidation The loss of an electron from a molecule, in myoglobin, from the iron (resulting in Fe^{3+}), which results in the brown, metmyoglobin pigment.

Oxygenation The attachment of oxygen to the iron in the heme ring in myoglobin.

Oxygen permeability The amount of oxygen allowed through a packaging film, usually expressed as ml per m^2 per 24 h at a specific temperature.

Psychrotrophs The bacteria that prefer to grow in cold environments.

Reduction The gain of an electron to a molecule, in myoglobin, to the iron (resulting in Fe^{2+}), which results in the red or pink oxymyoglobin or the purple deoxymyoglobin.

Retail cuts The cuts of meat produced from wholesale/primal/subprimal cuts, that are small enough for one serving or one meal. Consumers purchase retail cuts for preparation at home.

Shrink The value of meat lost in the retail case. This may be due to repackaging, lower the price, further processing (trimming, flavoring, or grinding), or completely discarding.

Wholesale/primal/subprimal cuts Large cuts of meat removed from the carcass in a specified manner. Several retail cuts will be produced from each wholesale/primal/subprimal cut. The terms wholesale and primal are synonymous and subprimals are cut from primal. Examples would be a ribeye roll, or a lamb loin.

Introduction

In the US and in many other countries, the majority of retail food stores changed from butcher service to largely self-service meat departments after World War II. Customers selecting individual meat packages from an array of product offerings by meat retailers led to the passing of perceptions from generation to generation about various meat quality attributes. In particular this 'knowledge' meant that bright red color for beef and bright pink for pork became the most important quality factors in choosing fresh-chilled or frozen meat at the self-service counter. Ensuring that the customer gets this desired meat color became a prime objective in presenting meat to the public, and led to overwrapping of meat with plastic film that allowed sufficient oxygen penetration but prevented moisture loss. Presentation of meat with the most acceptable color became all-important in meat merchandising.

This article presents an explanation of the chemical forms of myoglobin, the major pigment of meat, and its change from one form to another, as well as those factors that influence pigment change. Controlling the chemistry of myoglobin, achieved by proper use of overwraps, has a critical influence on acceptable meat color life. Requirements for functional overwrapped packages are also dealt with to help readers understand how to meet customer expectations, as well as the requirements of special plastic films to meet the needs of marketing, including the effects of type of packaging on microbial flora and, thus, its impact on spoilage and safety. Also discussed are management practices that will minimize 'case pulls' and discards. Case pulls are packages that are withdrawn

from the retail case for reworking and repackaging or are discounted in price. These steps impact the financial contribution to overhead and net profits of the meat segment of retail business. Systems to lengthen product life and provide a reasonable display life are also presented.

Meat Pigment Chemistry

A brief explanation of myoglobin chemistry, the major chemical forms of myoglobin and related pigments, and a description of pigment layers will be helpful in understanding the impact of the packaging on the color of fresh, chilled meat. An illustration of the meat color (myoglobin) triangle is provided elsewhere in the encyclopedia. The three major chemical forms of myoglobin in fresh meat include deoxymyoglobin, which contains iron in the reduced or ferrous state (Fe^{2+}) and has a darker purple-red color. Its formation is favored at extremely low oxygen partial pressures (1.4 mm Hg or less) and, when exposed to air or another source of oxygen, it combines very quickly with oxygen to form the bright red or pink color of oxymyoglobin, which also has iron in the ferrous (Fe^{2+}) state but has oxygen attached. Oxymyoglobin is stable at high partial pressures of oxygen but, if relatively low oxygen partial pressure develops, it is vulnerable to oxidation with conversion to brown metmyoglobin and resultant discoloration.

Oxygenation or Blooming

Because of the anaerobic condition of muscle before cutting, the fresh cut surface of meat will briefly present the purplish-red (beef) or purplish-pink (pork) color of deoxymyoglobin. Immediately after cutting, myoglobin at the newly cut surface will begin to react with oxygen of the air to form oxymyoglobin. This reaction is called oxygenation or blooming and proceeds for at least 20–30 min to a point where the meat may be considered sufficiently bright to be placed in display. This surface layer of oxymyoglobin gradually becomes thicker and thus extends deeper from the surface. This change occurs more rapidly at colder chilled temperatures. Although oxygen diffusion into muscle should theoretically be faster at warmer temperatures, such as 4.4 °C (40 °F) versus 0 °C (32 °F), the competition of meat enzymes for oxygen is greater at the higher temperature, which works against oxygen penetration at the warmer temperature; thus, oxygen penetration is greater at the colder temperature. Relatively fresh muscle (that with a good supply of reducing-capacity enzymes) will have two pigment layers: oxymyoglobin toward the surface and deoxymyoglobin at deeper locations. For intact muscles, oxygen diffuses more deeply into the muscle with longer time after initial exposure to air. This increasingly deeper penetration may continue for several days, depending on the microenvironment surrounding the muscle and the status of the reducing capacity of the muscle.

Discoloration

When the reducing mechanisms of the muscle are approaching depletion and the oxygen supply favors neither deoxymyoglobin nor oxymyoglobin, a third layer of pigment, brown metmyoglobin, begins to form between the other two pigment layers. This brown layer becomes thicker with time and moves toward the muscle surface. This brown layer is frequently not uniform in its closeness to the surface, so that spotty, nonuniform discoloration may be apparent at the surface. At some point, both the human eye and reflectance instruments begin to 'see' the brown discoloration. The perception of surface color is not only due to the chemical form of myoglobin immediately at the surface, but is also influenced to a limited degree by subsurface chemical state of myoglobin. Meat with a high degree of light scattering, such as pale, soft, exudative meat, allows less subsurface contribution to perceived color than does meat with less light scattering, such as dark, firm, dry (DFD) muscle.

Consumer Reaction

Some studies report that consumer discrimination begins when 20% of the detected pigment is metmyoglobin. A distinctly brown color is perceived with 40% metmyoglobin, and a brown to gray-greenish color is related to 60% of myoglobin being in the metmyoglobin form. Meat with 20% metmyoglobin is accepted about equally with bright red meat, according to one study; yet, other studies report a linear increase in consumer rejection as the percentage of metmyoglobin increases. Meat cubes, such as used for stew meat, present a greater opportunity for oxygen penetration from the much greater surface area of these small pieces.

Effects of Cutting/Mincing on Meat Color

Intact muscle that has been treated to improve tenderness with mechanical needles, knives, or the rotating knives of a cubing machine also has multiple entry points for oxygen penetration. Although the pigment layers are not clearly defined in these situations, the same principles seem to be involved.

Meat that has been minced, flaked, or made into small particles presents a more complicated case of multiple loci of different chemical forms of myoglobin, because multiple surfaces have been exposed to oxygen. In the extreme case of minced meat, all particles are susceptible to oxygenation during any exposure to oxygen, such as during mincing, but when they are packed into a solid mass for packaging the chemical form of myoglobin at any location in the mass depends on the continuing pattern of oxygen level, which is affected by muscle metabolism, consumption of oxygen, and the availability or depletion of reducing capacity. Often the center of a minced meat mass, given sufficient time, will revert to deoxymyoglobin while the surface continues to be in an oxymyoglobin state. Because so much of meat mass has been exposed to oxygen, and because of the small particle size and the enormous surface area, the process of converting oxymyoglobin to metmyoglobin to deoxymyoglobin may use up enzymatic resources of reducing capacity. A condition is quickly reached in which the metmyoglobin reducing ability is depleted, and some of the ground meat will revert to the oxidized metmyoglobin state. This leads to brown pigmentation becoming evident at locations where conditions favor the oxidized chemical state of myoglobin.

Other Color Effects

When fresh meat surfaces are exposed to carbon monoxide (CO), a very stable, bright cherry-red pigment is formed, known as carboxymyglobin. Even with very low concentrations of CO, the carboxymyoglobin pigment will form and is much more stable than oxymyoglobin. Green discoloration in fresh meat has been attributed to altered heme structure, possibly from choleglobin or sulfmyoglobin forms of myoglobin. Choleglobin results from the reaction of myoglobin with hydrogen peroxide, which may have been produced by microbial metabolism or chemical reactions. Sulfmyoglobin results from the reaction between hydrogen sulfide and myoglobin. Hydrogen sulfide can result from microbial metabolism or sometimes from chemical residues from certain treatments of carcasses or meat cuts.

Requirements for Overwrapped Packages

Customers have expectations of safety and quality both for the package and for the meat within the package. The package should have a solid backing so that it can withstand the frequent and occasionally abusive handling by customers. On at least one side it should be transparent to provide for a viewing of the product. Antifog or other anticondensation properties are also desirable. A leaky, messy package is very undesirable, as customers will not accept meat juice dripping on their clothes, in their automobile, or in their kitchens or refrigerators. Bacteria associated with raw meat may contaminate kitchen surfaces and cause infection or illness. Packages should also be resistant to puncture, whether from sharp edges of bone inside the package or from any sharp or pointed object outside the package, as puncture can lead to leaking or to dehydration of meat in the package. The integrity of the seal is also important.

The package must provide the proper internal microenvironment to ensure a muscle color that is acceptable to the consumer, and also acceptable color of fat and bone that may be part of a cut. Providing meat with expected color is critical, as this is used by the customer to determine freshness and acceptable quality. For overwrapped meat cuts, this requires an acceptably bright red (beef or lamb) or pink (pork) muscle color and an absence of brown, green, or dehydrated appearance on the meat surface. Fat color is expected to be white with perhaps a slight red or pinkish cast, whereas yellow, green, tan, or brown fat colors are undesirable. Bone color is expected to be white to gray, with possibly a reddish cast; yet, tan to black or green are undesirable bone colors.

Because much of the overwrapping packaging is done by machine, important factors in film selection are its suitability for use on machines, as well as optical clarity, sealability, and cost.

Types of Trays

Meat is customarily presented for retail sale on trays of rigid or expanded plastic, frequently with a soaker pad to absorb liquid (absorbent area of the pad not against the meat), and overwrapped with a clear film that is usually sealed by heat. Paper pulp trays were used at one time but have been replaced by expanded polystyrene, oriented polypropylene, or clear polystyrene, which have the advantages of not sticking to meat and not absorbing moisture; thereby becoming weak and less sanitary. The drip pad is likely to contain absorbent cellulose, with the side toward the meat being the nonabsorbent layer that keeps the pad from sticking to the meat. Recently, companies have been developing renewable foam trays for meat packaging, such as the NatureTRAY™ from Cryovac, which is made from a biopolymer that is compostable. Absorbent pads are also available consisting of renewable and biodegradable materials. The properties of these trays and pads are similar to their polystyrene counterparts, but the use of these more environmentally-friendly packaging materials is limited due to their higher cost.

Films Used

The first film used was cellophane, which was coated with nitrocellulose on one side for permeability to oxygen but impermeability to moisture. Pliofilm was next introduced, but its use has given way to plasticized polyvinyl chloride, which is the major overwrap film used in the US. In a stretch form, it may be approximately 0.017 mm (0.000 7 in.) thick and the high degree of plasticization provides excellent oxygen permeability, very good conformation to the outer contour of meat pieces, and superior gloss and clarity. Polyvinyl chloride should have a low moisture transmission rate and an oxygen permeability of at least 5000 ml m^{-2} per 24 h at 23 °C, but many films have oxygen transmission of up to 10 000. Low-density polyethylene is used in many countries at thicknesses of 0.025 4 mm (0.001 in.) and has sufficient oxygen permeability if no thicker than this. Modifying it with vinyl acetate increases oxygen permeability. It is a suitable barrier to moisture but needs treatment to overcome surface condensation. It shows somewhat marginal clarity and gloss.

Duration of Acceptable Retail Display

The major disadvantage of packaging by overwrapping is the relatively short time before meat becomes unsalable. With suitably low temperatures, overwrapped meat may be microbiologically acceptable for a week, but its display life is limited by appearance to perhaps 3–5 days at the very longest for intact muscle cuts. Many stores withdraw discolored or otherwise unsalable cuts, but may also have a 'case pull' policy at 2 or 3 days. Ground meat has a much shorter display life, and some stores may have a 1 day or even shorter 'pull' policy. Many stores prepare ground meat several times a day. Stores can also have a set time at which packages are price discounted, with the purpose of selling at a lower price rather than discarding them.

Problems Encountered with Overwrap

Overwrapped packages are not well suited for taking home and placing in a freezer, at least for not more than a few days. The meat and fat are vulnerable to oxidation, with rapid development of rancid aroma and taste. Meat in these packages may also develop 'freezer burn,' a brown dried-out condition,

because of the suboptimal protection provided by overwrap films in freezer conditions, especially with temperature fluctuations in the freezer.

Other Purchase Considerations

When purchasing meat, customers have numerous other considerations that go beyond the influence of the packaging on the perceived quality of the meat. These might include the number of chops or steaks per package or the size of a roast. Closeness of fat trim is important at a time when many customers are 'fat conscious.' The cost of packages is definitely considered. Market managers are faced with the challenge of meeting these varied customer expectations, but are also limited in the number of options that can be presented to the customer.

Microbial Effects

Microorganisms that cause spoilage or foodborne diseases are those that grow best under the conditions of packaging and the microenvironment surrounding the packaged product. With overwrapping, the high-oxygen permeability of the film strongly favors aerobic bacteria and, because meat is usually kept reasonably cold, psychrotrophs are also favored. Thus, the predominant spoilage organisms are the strictly aerobic pseudomonads, which can utilize the highly available glucose but, because the amount of glucose is limited, can also use amino acids for their nutrition. Metabolism of amino acids leads to putrid odors and flavors typical of this kind of spoilage. For DFD product, metabolism of amino acids occurs earlier and there is thus an early indication of spoilage. These organisms compete very aggressively, so that foodborne pathogens are less likely to grow in such an environment.

Management Practices and Systems to Enhance Overwrapping

Three keys words of advice for meat retailing have long been the three 'keeps': keep it clean, keep it cold, and keep it moving. Keeping the product clean should mean that there will be fewer microorganisms to multiply and cause discoloration or other deterioration and pose food safety problems. Keeping the product cold is critical in slowing microbial growth and maintaining acceptable quality. Keeping it moving reflects the importance of products being sold and consumed before the occurrence of any discoloration, other spoilage, or foodborne disease problems. Inventory control, or selling product in the order it was received at the store (first-in and first-out), is an important principle in managing a meat retail operation. The first two 'keeps' contribute to the strategy of delaying the onset of discoloration so that the product may be sold at full value instead of at a discounted price or being reworked, trimmed and repackaged, or perhaps discarded.

Retail Losses

Loss of saleable product is called shrink, and it has a definite impact on the net profit of the meat operation. In a 2008 estimate, 5% of value was lost to waste at the retail level. Retail loss (shrink) estimates are scarce in the literature and difficult to obtain, but one study reported 3.1% and 4.6% case pulls for beef retail packages in two different stores. It further cited the disposition of pulled packages from three stores as follows: converted (probably ground) and repackaged (4.1%), trimmed and repackaged (2.9%), rewrapped (2.9%), price reduced for quick sale (0.6%), and discarded (0.2%). Each of these steps results in an added cost or a loss in product value. In a survey of 10 large supermarkets in the US, another study reported shrink, defined as losses due to reduced value, to be 6% for beef cuts compared to 4% for overall market operations. However, when summarized, these losses were as high as 23% for one high-value beef cut, and 19 retail beef cuts exceeded 10% loss. The market manager would like to display a good selection of high-priced cuts for customer consideration, but these cuts also have a higher risk of shrink.

Historically, the lowest shrink at local retail stores over a number of years in this author's experience was represented by a retail company that, surprisingly, had a central retail cutting plant that delivered overwrapped meat to stores located as far as 128 km from the central cutting plant. This company developed and maintained an outstanding program of sanitation and cold temperatures and the bottom line was a shrink (loss of value) less than one-half that of other stores in the area. A temperature of −2.2 to −1.1 °C (28–30 °F) was consistently maintained in the holding coolers, the cutting and packaging room, the shipment assembly area, and on the delivery trucks. On delivery to local stores, the first priority was to immediately place the containers of retail packages in the chill room, without lingering on the loading dock. The company also operated another management practice extremely well, as they kept detailed computerized records of packages delivered to stores on each delivery and thus, had excellent information about likely anticipated needs for future deliveries. These practices are a good example for any store or meat market to follow.

Large processing companies adopted this practice in the late 1990s and early 2000s with the case-ready retail products packaged in high-oxygen, modified atmosphere packages, delivered directly to the store. Quality issues with the high-oxygen packaging caused processors and retailers to move back to a more traditional, aerobic overwrap package. This product was still cut and packaged at a central, case-ready facility, but the packages are stored and transported to retail stores in mother bags containing a mixture of nitrogen (N), carbon dioxide (CO_2), and a small percentage of CO. The growth of spoilage and pathogenic bacteria is controlled by the high levels of CO_2, whereas the carboxymyoglobin formed due to the exposure of the cut surfaces to the CO will allow for a stable, bright cherry-red meat color. According to the 2007 National Meat Case study, 64% of the total fresh meat case was made up of case-ready products and it is likely that those percentages have increased in the years since.

Cutting and Display in Local Outlets

Individual stores that prepare their overwrapped retail cuts in their back room can also use records to improve their

efficiency, but they need to recognize that the sale of any retail cut can be influenced by price, by whether a 'special' is being offered on that cut, and by a holiday period or time of year that can affect sales of any particular cut. Certain times of year lend themselves to promotion of certain cuts, such as the summer outdoor grilling season. Good market management involves the use of good sales records, but it also involves a perceptive sense of judgment about customer demand. If a cut is not available in the display case when a customer would like to buy it, it takes several minutes to unwrap a subprimal or wholesale cut, make retail cuts and package them in an overwrap package. A market would always like to have available on display a selection of cuts that meets the needs of its customers and would not like to have a costly 'out-of-stock' situation or make customers wait until their choice is available. Good records can help in anticipating sales and providing a reasonable assortment of packages without 'overcutting the case' (having too much of a given product on display) and perhaps having packages become reduced in value or unsalable.

An analogy regarding product life is that the 'alarm clock' which begins counting down to the end of product life immediately postmortem, or at the time the animal source of meat is stunned and bled. This clock can be slowed by cold temperature and good handling practices and sped up by warm temperature and inappropriate handling at critical points of product preparation and distribution. When a wholesale, or subprimal, cut is fabricated into retail cuts, the clock runs faster. When retail cuts are placed under display lighting, the clock runs much faster owing to the photochemical and sometimes warming effects of lighting. This adds up to the importance of planning the cutting, packaging, and display so that meat cuts will have a minimum time in the conditions in which they are most vulnerable to developing discoloration and other deterioration. In other words, the clock is always ticking toward a point at which product history adds up to discoloration and the alarm goes off. With good management, deterioration can be slowed so that the meat can be sold and consumed well before that point is reached. The case-ready system allows meat to be processed and cut in the highly-controlled and sanitized conditions of a processing plant. Furthermore, the mother-bag packaging and controlled atmosphere inhibits the growth of microorganisms and allows for the formation of a very stable, red color that consumers will choose to purchase.

Improving Overwrap Systems

Some very effective systems are in place that will make the sale of overwrapped cuts more profitable and will reduce shrink. Early practices, such as wrapping pork loins or other fresh uncured cuts in parchment paper and putting them in a box with exposure to air, have been partially replaced by bulk gas flushing, with perhaps five pork loins placed in a large barrier bag inside a box, with air withdrawn and replaced, usually with a mixture of CO_2 and N, before the bag is sealed. These bulk gas-packed loins maintain quality and food safety requirements much better and longer than those wrapped in parchment. As an example, stores promoting a 'red hot' special on pork loins might get part of their loin shipment packaged aerobically and cut that first, but have gas-packed loins as a hedge when sale of loin cuts might be unpredictable. The fact that gas packaging will maintain acceptable quality longer allows the product to be kept for the possible business the following week.

Commercial Packaging Situations

Some processors are experimenting with cutting bone-in and boneless pork loins in a central processing facility, reassembling and packaging these loins in a vacuum bag, and shipping them to a retail facility. At retail, the chops are removed and repackaged in an overwrap system. This system reduces the need for knives and saws at the retail store and improves the safety for store workers. Furthermore, the sanitary conditions at the cutting facility would be improved, greatly reducing bacterial contamination.

One rather comprehensive study done under commercial cutting and packaging conditions used a single gas flush of 0.61 l of CO_2 per kilogram of meat and storage for up to 19 days before cutting pork loin chops and overwrapping them for display. The initial CO_2 concentration of 78.5% of the within-bag atmosphere decreased to 55.1% by day 3 and to 41% by day 19, partially due to CO_2 absorption into the meat. Oxygen, which was 3.1% initially, increased to 7.1% during the storage. The increase of oxygen was partially due to oxygen that had been absorbed by the meat before packaging later coming out of the meat into the within-package atmosphere and partially due to ingress of oxygen through the large area of the bag. Although microbial counts increased from day 3 to day 19, they were still less than 5 $\log_{10}$ colony-forming units per square centimeter surface area. With longer storage, loin weight loss and discoloration increased. At day 19, off-odor was acceptable but discoloration at some locations was the limiting factor in shelf life. Loin eye (longissimus) color for chops cut and overwrapped in polyvinyl chloride and placed on a soaker pad on a styrofoam tray was acceptable through 3 days of display after the 19-day storage time. The psoas major (tenderloin) still had acceptable visual color for two display days when it had been stored in the gas pack for 10 days, and muscles from the sirloin end of the loin had acceptable color for 2 days of display if the loins had been stored in gas-pack for up to 11 days. The color stability of the psoas major was the limiting factor of pork chops in this study.

Another pork loin study compared gas mixes of 100% CO_2, 75% CO_2–25% N, 50% each of CO_2 and N, 25% CO_2–65% N–10% oxygen, and another sample stored in a vacuum package. Gas packages were triple-flushed using a Corr-Vac Mark III packager (M-TEK Inc., Elgin, IL, USA). Loin sections were stored at 1.1 °C (34 °F) for either 14 or 22 days, after which chops were cut, placed on soaker pads on polystyrene trays and overwrapped with polyvinyl chloride film, and displayed at 2.7 °C (37 °F) under 1076 lx (100 foot-candles) of warm white fluorescent (3000 K) display lighting. Oxygen concentration in bags flushed with CO_2 and N was very low (0.1%–0.4 %). The gas mix containing 10% oxygen resulted in chops with more graying and greening, stronger off-odors, and higher psychrotrophic microbial counts by over 1 $\log_{10}$. Drip loss from loins stored in the 100% CO_2 was higher than from loins receiving other treatments. The display life of chops was similar for all treatments, except shorter for those stored in

the gas mix containing 10% oxygen. Another study found no advantage for triple-flush over single-flush gas-pack for display life of overwrapped chops. This study also compared gas-to-meat ratios of 0.7:1, 1.3:1, and 3.0:1 for gas-pack pork loins that were cut into chops and displayed, and found no advantage for any particular ratio.

Other Packaging Systems

Other gas-pack systems are used to deliver wholesale cuts to retail stores where retail cuts are prepared and overwrapped. These include the CAP-TECH system used to deliver lamb carcasses and wholesale cuts, packaged in high CO_2 atmospheres, many thousands of miles to their destination. Compared to vacuum packaging, the CAP-TECH system extended the shelf life of fresh lamb from 12 to 30 weeks.

Vacuum-packaged distribution is used less for pork, perhaps because the pressure results in large amounts of purge. Vacuum packaging is widely used for beef subprimal cuts that are placed in a box, and hence called 'boxed beef', for distribution to retail stores where retail cuts are prepared and overwrapped for display. Boxed beef has been enormously successful as a part of the system that markets overwrapped retail cuts to the final consumers. Vacuum packaging is discussed in another part of this encyclopedia.

Glossary

Active packaging Systems that actively alter the meat products' environment to improve the shelf life of the product. Examples include gas scavengers, temperature control and monitoring, or antimicrobial properties.
Barrier property A measure of a packaging material's permeability, whether a gas, moisture vapor, or a sensory trait such as aroma.
Blooming Exposing fresh meat surfaces to air to allow the oxygenation of myoglobin on the surface of meat cuts, changing the color from purple to bright red or pink; cuts are commonly allowed to bloom for 30 min to obtain the desirable color.
Modified-atmosphere packaging (MAP) Retail packaging with an oxygen-impermeable package and a head-space that allows for the introduction of a specific atmospheric environment to control spoilage; sometimes termed controlled atmosphere.
Myoglobin The protein pigment found in muscle that gives meat its color, contains an iron (Fe) held within a heme ring. The chemical state of the iron largely dictates the color of the meat. Myoglobin may be present in the following forms: Oxymyoglobin, oxygen is attached to the iron and it is in the reduced state (Fe^{2+}), red or pink in color; Deoxymyoglobin, iron is deoxygenated and in the reduced state (Fe^{2+}), purple in color; and Metmyoglobin, iron is in the oxidized state (Fe^{3+}), brown in color.
Overwrap packaging Retail cuts are placed in foam trays with a soaker pad and the product and tray are incased in a clear, flexible, oxygen-permeable film allowing exposure to ambient air.
Oxidation The loss of an electron from a molecule, in myoglobin, from the iron (resulting in Fe^{3+}), which results in the brown, metmyoglobin pigment.
Oxygenation The attachment of oxygen to the iron in the heme ring in myoglobin.
Oxygen permeability The amount of oxygen allowed through a packaging film, usually expressed as ml m^{-2} per 24 h at a specific temperature.
Polymers A material containing a large number of repeating units (monomers) bonded together to make up a large part of the molecule. Polymers may be one of three types: homopolymers, made with one type of monomer (e.g., polyethylene and polyvinylchloride); copolymer, made with more than one type of monomer (e.g., polyvinylidene dichloride (saran)); and polyblend, made with two or more different types of polymer chains.
Reduction The gain of an electron to a molecule, in myoglobin, to the iron (resulting in Fe^{2+}), which results in the red or pink oxymyoglobin or the purple deoxymyoglobin.
Thermoformed packaging Products are placed into heat-softened films, formed into a desired shape, and sealed with a nonforming layer over the top of the formed film. The intra-package environment may be vacuum or gas-flushed.
Vacuum packaging Retail or wholesale cuts are placed in oxygen-impenetrable bags, all air is removed from the bag, and the bag is sealed.

Introduction

Packaging can be defined as the enclosure of products or items in any containers, such as bags, bottles, boxes, cans, pouches, trays, tubes or wraps. Packages contain the product and assemble it into units for storage, distribution, and offering for sale; and, in an increasing number of cases, they are used as a cooking utensil. Package sizes vary from single-serving units to very large units for distribution or transport. The primary goal of packaging is to maintain the product at a suitable quality level, frequently defined as freshness, as well as assure the safety of the product to the consumer at the point of ultimate consumption.

This article deals with functions of packages, including special properties and factors that influence these properties. It also deals with the chemistry of films and how this influences the many characteristics of packages, as well as discuss traits of individual polymers and deal with multilayer films. However, applications of packaging for meat products, including overwrapping, vacuum packaging, and modified-atmosphere packaging (MAP) will be covered in detail in other articles. Steps of the packaging process will be presented for thermoformed meat packages, and some elements of active packaging will also be discussed.

Functions of the Package

Protective Functions and Labels

A major function of the package is to serve as protection from environmental variables, which include temperature, moisture or humidity, oxygen, airborne particles, and light. It must also protect against biological contamination, such as that from humans, microorganisms, rodents, insects, and other pests. A package further serves as a marketing tool because it must provide space for a label that carries information, such as product identification, ingredients, nutritional information, net weight, verification of inspection, cooking instructions,

promotional material, company name and location, and instructions on how to contact the processor (such as a 'hot line' contact number). Labels today frequently display the ubiquitous universal product code, which is critical to laser scanning at the check-out counter in virtually all stores and also plays an important role in inventory management.

The package must protect against loss or gain of moisture and regulate permeation of gases such as oxygen, carbon dioxide, and nitrogen. This allows the package to function in managing meat color and appearance by minimizing oxidation, which can influence color, odor, flavor, and safety, and also provide the environment to discourage microbial growth, which in turn delays the occurrence of spoilage and lessens the impact of foodborne pathogens.

A critical consideration in designing a packaging system is to quantify the rate of change of the most limiting quality or safety factor, and develop requirements for the package so as to minimize change in this most critical characteristic so that the product's shelf life might be extended. The package cannot improve or completely stabilize the product quality, but it can only slow down quality loss. Chemists or packaging engineers can design and build films with marvelous properties, but some alternatives are costly and may not be economically justified. A major consideration is product's shelf life, especially in the light of long distances for distribution of product to the ultimate consumers. These economies must be weighed against the costs of improved packages.

Other Package Requirements

Considerations in selecting and designing a package include strength factors, which include tensile, elongation and tear (both initial and subsequent) strength, and resistance to puncture, all of which should be considered at all temperature and humidity conditions expected. The shelf life of the film itself is important. Permeability to gas, moisture, grease, and odor are important. Machinability factors include stiffness (flowability), static accumulation, and slip (which affects the ability of people to open bags); and merchandising factors not only include stiffness and static accumulation but also clarity or transparency, gloss (sparkle), absence of an undesired film color, and antifogging characteristics. The most widely considered factor, or the bottom-line trait, is the cost! Obviously, cost is much more than film cost and includes equipment costs and labor involvement or savings. Losses due to the consequences for the product of package failure must also be strongly considered in determining cost.

Barrier Properties

The barrier property of a packaging material is a measure of the resistance offered to a permeant, irrespective of it being gas like oxygen, carbon dioxide, nitrogen, or carbon monoxide; or moisture vapor; or a sensory trait such as aroma. This information is a very important part of a film or package specification. Oxygen permeability is usually expressed as cm^3 per 24 h m^{-2} at 0% relative humidity. Sometimes the film area used in the specification is 100 $in.^2$: an area of 1 m^2 is 15.5 times as large as 100 $in.^2$; so, one must be very careful in reading specifications. For some purposes, it can be critical if the permeability given as 3 cm^3 for the smaller area of 100 $in.^2$ is mistakenly taken to refer to 1 m^2; 3 cm^3 per 100 $in.^2$ corresponds to 46 cm^3 m^{-2}. Oxygen and moisture transmission values for some films are given in Table 1.

Factors Affecting Permeability

Permeation decreases as the thickness and density of the film and cross-linking and crystallinity of the polymer increase, whereas it increases as the permeant solubility in the polymer, pressure of the permeant, temperature, amount of plasticizers and fillers, and affinity for water decrease. Depending on their affinity for water, the relative humidity of the environment affects polymeric materials differently. Hydrophilic films, such as nylon and cellophane, have increased permeability at higher humidity, whereas hydrophobic films, such as polyethylene and polyvinylidene chloride, are not affected by humidity. The permeability to carbon dioxide may be 2–10 times that to oxygen for some polymers.

Other Important Properties

Other important properties of films include flowability, machinability, printability, stability over a wide temperature

Table 1 Typical oxygen and water vapor permeability transmission values for some film

Film	*Oxygen permeability (cm^2 per 24 h, 22.8 °C (73 °F), 0% RH)*		*Water vapor transmission (g per 24 h, 37.8 °C (100 °F), 90% RH)*	
	m^{-2}	*100 $in.^{-2}$*	*m^{-2}*	*100 $in.^{-2}$*
Ethylene vinyl alcohol	1.55	0.1	–	–
Polyvinylidene dichloride (Saran) coating	7.75–15.5	0.5–1.0	13.95	0.9
Nylon (0.0254 mm; 0.001 in.)	31–46.5	2–3	–	High
Polyester (0.0254 mm; 0.001 in.)	139.5	9	43.4	2.8
Oriented polypropylene (0.0190 mm; 0.00075 in.)	3100	200	–	0.4
Surlyn (0.0508 mm; 0.002 in.)	4650	300	10.85–17.05	0.7–1.1
Polyethylene (EVA) (0.0508 mm; 0.002 in.)	–	–	7.75–10.85	0.5–0.7

Abbreviation: RH, relative humidity.

range, shrinkability, thermoformability, hot tack, and seal strength. Visual traits, such as clarity, sparkle, absence of color, and antifog (minimizing of condensation on the inside of the package), can be very desirable. Some marketing options include packages with zip openers and resealable packages, such as luncheon meat packaging, with resticking properties that allow it to be reopened and sealed multiple times.

Film Chemistry

Polymer Chemistry

Plastic film materials are made up of a large number of small repeating units (monomers) bonded together to form a polymer, usually making up a large part of the molecule. Polymers may be classified as (1) homopolymers, which are made up of only one type of monomer in the chain; (2) copolymers, which contain more than one type of monomer in the chain; and (3) polyblends, which contain two or more different types of polymer chains. These materials may be further classified according to the backbone architecture as linear (containing a single backbone chain), branched (with regularly occurring branches), and cross-linked or networked (where the backbone chains are interconnected to form a single molecule). Polymers formed by addition reactions, in which one monomer is added to another without the formation of any by-product, include vinyl and diene compounds, whereas some important polymers, such as polyesters, polyamides (nylon), and polyurethanes, are formed by condensation reactions, which means that they are built from monomers with functional groups (such as –COOH, C–OH, and $–NH_2$), with small molecule by-products also being formed in these reactions.

Polyethylenes and Copolymers

Polyethylenes, the most abundantly produced plastics, are polymerized from the monomer ethylene (C_2H_4) and can be produced as low-, intermediate-, or high-density polyethylenes. The higher density forms have more crystalline regions and exhibit greater tensile strength, stiffness, and barrier capabilities, but decreased impact and tear resistance. High density also contributes better heat and grease resistance and improved compatibility with acids and alkalis; however, lower density confers greater clarity and low-density forms can form a strong seal at lower temperatures. These are relatively inexpensive plastic materials. An additional modification that results in linear low-density polyethylene imparts greater tensile and impact strength and elongation and puncture resistance than that found in other polyethylene films.

'Polyethylene copolymer with ethylene vinyl acetate' is polyethylene copolymerized with 5–20% ethylene vinyl acetate, which lowers the sealing temperature and improves seal performance, especially when lower temperatures are used in sealing; thus, it is often used in the food-contact layer. With a higher proportion of vinyl acetate hot tack, impact resistance, adhesion, low-temperature toughness, and stress crack resistance are improved, whereas stiffness, seal temperature, chemical resistance, and barrier properties are decreased.

Ethylene Vinyl Alcohol

Ethylene vinyl alcohol, a crystalline copolymer produced by saponification of vinyl acetate, vinyl alcohol, and ethylene, has high barrier characteristics but is moisture sensitive. It has greater oxygen permeability at high humidity and is frequently used in multilayer films, where it can be protected from moisture influences by the other film layers or by drying agents added to the laminate structure. This film can also be produced with a biaxial orientation to reduce moisture sensitivity. This plastic works well for packages for hot-fill products and is widely used for meat packages needing a good oxygen barrier.

Polyvinyl Chloride

Polyvinyl chloride (PVC), polymerized from vinyl chloride monomer, has very high oxygen permeability and excellent transparency and, if plasticized, is very flexible and a good heat sealer. This is the film of choice in the US for overwrapping of chilled fresh meat cuts that are sold in the bright red (beef) or pink (pork) condition, but product packaged in this film has relatively short display life.

Saran

Polyvinylidene dichloride (Saran) is produced by polymerization of polyvinyl chloride and polyvinylidene chloride, and is a dense, highly crystalline material that is a very good barrier to oxygen and moisture, is resistant to grease, and is a tough, abrasion-resistant film with good clarity. It is frequently used in meat packaging as a layer in multilayer pouches, bags, chubs, and thermoformed packages. It is most often used for modified-atmosphere applications.

Ionomers

Ionomers are sodium or zinc salts of ethylene/acrylic acid polymers and contain low levels of covalently bound ions. Ionomers are frequently used in laminate structures to give adhesion to aluminum foil. They are often used as the inside or meat-contact layer because of their wide heat-sealing temperature range and excellent hot tack. Ionomers work well in high-speed operations and provide good seal integrity under these conditions. They also have good grease and chemical resistance.

Polyesters

Polyesters are produced by the condensation of ethylene glycol and teraphthalic acid. They are widely used in food packaging because of their superior mechanical properties, good barrier to gases, resistance to high temperatures, and maintenance of excellent tensile strength over a wide temperature range, as well as having good clarity and resistance to many chemicals. Polyesters accept ink well for printing and also adhesives for lamination. They work in heat-shrinkable films, but are not readily heat-sealable if uncoated. Some processors have started using polyesters for thermo-formed cook-in-bag retail items.

Nylons

As films, nylon polymers, manufactured as a condensation product of a diamine and a diacid, possess good oxygen and aroma barrier properties. They are tough and abrasion-resistant, easily thermoformed, heat-resistant, and resistant to most chemicals, except for acids. They are usually part of a laminate structure with polyolefins to give moisture resistance and heat sealability. Nylons are widely used for vacuum packages for beef subprimal cuts, blister packs, and 'cook-in-the-bag' products because of their toughness and heat resistance.

Polypropylenes

Polypropylenes, polymerized from propylene monomer, have a wide range of uses, as they can be copolymerized, coextruded, surface-coated, and modified to give heat sealability. Their properties of good moisture barrier, resistance to high temperature, grease compatibility, stiffness, and clarity are appropriate for use in preparing cook-in steam-processed products.

Acrylonitriles

Acrylonitriles, when converted into film, have good gas barrier properties, fairly high tensile properties, and good chemical resistance. The major use is in thermoformed plastic containers because of their rigidity.

Polystyrene

Polystyrene is used primarily to make thermoformed trays, both clear and foam, for overwrapped meat products. Clear, thermoformed polystyrene trays have high oxygen permeability, excellent clarity, good stiffness and tensile strength, and are resistant to both acids and alkalis. Their special property is adequate melt strength for processing into foam trays.

Special Film Properties

Plasticizers are added to film resins to make the final package more flexible at the temperature of use. Stabilizers are used to prevent degradation of plastics when they are exposed to heat and light, either during processing or during the commercial life of the film. Light degradation can lead to a rapid loss of mechanical properties. Antioxidants can minimize these light effects and also rancidity of fat, which may be absorbed from the product into the film. Release agents help to overcome the sticky or tacky nature of films and make them easier to work with. Pigments are sometimes added directly to film resins and inks are used in printing directly onto packages.

Multilayer Films

Very few polymers have all the properties desired in a packaging film, regardless of the product or packaging system. However, combinations that have appropriate properties can be built using layers of different films that can be produced in thicknesses commonly ranging from 0.0254 mm (0.001 in.) to 0.3054 mm (0.012 in.). Film materials may be reinforced, coated, coextruded, laminated, and printed before they are formed into packages.

Coating

Coating may be done with a variety of materials, such as hot melt, waxes, emulsions, or solvent coatings, which improve one or more of the properties of barrier, scuff resistance, printability, adhesion, or sealability. The term coating implies applying a relatively thin layer to a much thicker base structure.

Lamination

Lamination is often preferred to achieve functional traits for many purposes. When base structures of different polymers or materials are combined, barrier or mechanical properties, sealability, printability, and machinability can be improved. An adhesive material may be placed between two base structures to form a single material. Additional layers may be added using adhesive for each new layer. Adhesive lamination, especially with solvent-borne adhesives, is decreasing in use because of health and pollution concerns. However, water-based and high-solids adhesives are increasing in use. In extrusion lamination, a polymeric resin is melted and extruded as a thin film between two base materials. This process uses less solvent material.

Coextrusion

In coextrusion, multiple extruders are connected to a single die. Molten resin from each extruder is forced through the die simultaneously with material from one or more extruders, sometimes as many as seven. The heat of the process causes the surfaces of the individual layers to interact and bond on cooling. Coextrusion is preferred for combining layers, provided they bond with each other.

Film Layer Arrangement

The arrangement of layers from the outside to the inside (next to the product) should use selection criteria of scuff/abrasion resistance and printability traits for the outer layer, barrier properties and mechanical structure in the middle, and heat sealability and compatibility with the layer adjacent to the product. Bags can be manufactured by extruding as a tube, cutting into appropriate lengths, and heat sealing one end of each bag. Pouches and bags are very similar, with a three-side seal sometimes being used. Adaptability to a high-speed operation must be considered, with filling and sealing being critical steps.

Sealing

Sealing is important, both in forming the empty package and in sealing with the product inside. The goal is a hermetic seal, which consists of a fusion weld of compatible thermoplastic materials produced by thermal heat sealing using hot bars or

hot wires or by thermal impulse sealing. Thermal impulse sealing controls thermal input by pulsing electric current. With impulse sealers, the materials can be cooled while still under jaw pressure, but this also means that impulse sealing is normally slower. The success of sealing is affected by the melt temperature of the material to be sealed, by the jaw pressure that forces the sealing layers into close contact, and by the dwell time (the time the material is heated under pressure). Too much jaw pressure can result in undesired thinning of films at the seal.

Three materials often used as the heat-sealing layer are polyethylenes (all density levels), ethylene vinyl acetate, and ionomers. More dense polyethylene has a higher melt temperature and, thus, requires more heat for sealing. Ethylene vinyl acetate requires less sealing time and energy than polyethylenes to produce an acceptable seal. Ionomers weld together well, even in the presence of contaminating or interfering materials, and also form strong seals at somewhat reduced sealing temperatures. Their exceptional hot tack allows packages to be filled and sealed at high speeds.

Thermoforming

Thermoforming is the forming of heat-softened films into a desired shape into which product may be placed before sealing a nonforming film layer over the top of the formed film. The process is done by equipment that performs the following steps: (1) heats the forming film by a top heater, single or double preheating, or sandwich (both sides) heating, or a combination of heating methods, (2) forms into the cavity of a die into the desired size and shape, (3) provides a loading area where the product can be placed into cavities either mechanically or by operatives, (4) brings the top layer (usually nonforming film, although it could be another formed film) in place over the formed film, (5) removes air from the inside the package either by pulling a vacuum or by gas flush, (6) introduces a gas or gas mixture into the package, (7) hermetically seals the package with a heat-seal bar that welds the films together under pressure, and (8) cuts or trims the excess film.

Forming can be negative, which means the heated film is pulled into the mold by vacuum or pressed-in by compressed air. Forming to too great a depth may result in overthinning of the film so that the desired barrier properties may be lost. Positive forming, used only for rigid films, uses a male-forming plug, and thickness is precisely controlled and detailed shapes can be formed on the bottom or walls.

Gases introduced into the package are often mixtures. These can be purchased premixed, or proper proportions from individual gas tanks can be accurately controlled with a gas mixer. Special problems may be encountered in evacuation of product with a high liquid content or a partly liquid product, which may bubble up. A longer pouch may be the solution to this problem, or steam flushing (an evacuation system) can solve the problem of boiling or bubbles associated with packaging of ready meals or other hot precooked products in either vacuum or modified-atmosphere packages.

Printing and labeling are important 'late in the process' steps in the packaging process. Personnel who assemble and pack boxes are responsible for detecting leaker packages.

Forming films often consist of nylon/barrier (often Saran)/sealant from outside to inside. The thickness of film layers must be adjusted for depth of the cavity because a greater drawdown may result in thinning of film, which can alter film effectiveness or even result in a package 'blowout.' In summary, the degree of thinning and also the uniformity of the formed film are affected by the type and original thickness of the forming film, the size of the cavity area, the depth and contour of the cavity, and the procedure used to heat and to draw or push heated film into the cavity.

Anaerobic Packaging with Blooming Agents

The Curwood packaging company offers meat suppliers a best-of-both-worlds package known as FreshCase®, which allows fresh meat to be vacuum packaged in a centralized facility in a thermoformed package but maintains a bright-red oxymyoglobin fresh meat color. According to their patent, this package is made up of a multilayer film in which the meat-contact layer contains a myoglobin-blooming agent. The myoglobin-blooming agent may be any agent or precursor that binds to undenatured myoglobin producing a desirable fresh meat color. These myoglobin-blooming agents may include a nitric oxide (NO)-donating compound, such as a nitrate or nitrodisulfide; an inorganic cyanide (MCN); a nitrogen heterocycle, such as pyridines or purines; a carbon monoxide (CO)-donating compound; or niacin. Additionally, the package would contain an oxygen-barrier layer to allow for vacuum sealing. The vacuum seal increases the refrigerated shelf life of retail-ready fresh meat products from a few days to several weeks. The thermofilm packaging reduces packaging waste compared to modified-atmosphere packaging and foam tray/PVC overwrap packaging. This system minimizes labor and potential for mishandling in the retail store, and the vacuum seal eliminates purge leakage in the retail case, the shopping bag, and the consumer's home, which would reduce the possibility for cross contamination.

Cook-in Packaging

As consumers demand more convenience from their food, processors must become more creative with their offerings available to consumers. Consumers demand minimal preparation time for 'home cooked' meals that they can simply fix and forget. Furthermore, research has shown that today's consumers prefer not to touch raw meat with their bare hands, and eliminating the handling of raw meat products in consumers' kitchens will greatly reduce cross contamination.

Perhaps the most demanding requirement for forming films is for applications in which thermal processing (cooking) is done in the same package that is used for distribution and merchandising. This film must shrink down onto shrinking product as the product is cooked and cooled, otherwise purge and cookout liquid will be evident. This film must also have good visual properties and be tough enough to withstand the rigors of shipping and abusive handling. Ham may be cooked in stainless steel molds that protect the film during cooking. A film construction of nylon/sealant or nylon/barrier/sealant is often used. An ionomer (Surlyn) sealant is commonly used and this gives a slight bond to the product, which minimizes purge of cooking. Packaging for poultry breasts is more

complicated, especially if skin is still attached. Surlyn sealant, as used for hams, adheres too tightly to poultry skin, so that skin comes off with the film when packaging is removed. The forming film for poultry breasts may use a nylon that is less sensitive to moisture or use a polypropylene/nylon/polyethylene, where the polypropylene protects the nylon layer from steam used for cooking. For poultry products, a special polyethylene may be used for sealant.

Retort Pouch

The retort pouch is a very demanding package that consists of a three-layer laminate that will be processed like a can, will be shelf-stable, and allows the convenience of frozen boil-in-the-bag products. It may be composed of an outer layer of polyester film, a middle layer of aluminum foil, and an inner layer of modified polypropylene. Material for retort pouches must provide superior barrier properties over a long shelf life, seal integrity and toughness/puncture resistance, and must withstand the thermal rigors of a canning process, which might have temperatures up to 135 °C (275 °F). The advantage of the retort pouch over a can is its flatter shape compared to the round shape of a can; thus, a more uniform heat and less heat is required to bring the temperature in the product center to the safe level.

Ovenable Films

Packaging companies are now offering vacuum bags and pouches made from films that allow the product to be packaged in a vacuum-sealed bag or pouch, and the subsequently packaged products can then be placed directly in the oven for cooking or used in sous vide cooking. These packages allow the product to be marinated, tumbled, seasoned, and packaged at a highly sanitized meat processing facility, and then the product may be shipped, stored, frozen, and cooked at a later date either in a restaurant or in the consumer's home. When processing steps, such as cutting, marinating, and seasoning, are limited to a processing facility, and consumers do not have to handle the uncooked product, the likelihood of mishandling or contamination is greatly decreased. During cooking, the packaging expands away from the meat, allowing for browning and reducing meat adhesion that makes the product easier to remove from the package after cooking. Cooking in bag allows for a juicier product and greater cook yields than when done in a typical oven cookery.

Quality Assurance in Film Production and in Packaging

Film Quality Assurance

Even though the processes in film manufacture seem highly automated and immune to process errors, considerable checking should be done to assure that specification requirements, such as film thickness and absence of defects, are met. Each step in the production of resins and films requires careful monitoring, so that the undesired by-products are washed away or separated from the film. Occasionally, a distinctive and undesirable odor may be transmitted from the film to the product, which can be costly both to film supplier and the meat processor.

Package Quality Assurance

Quality assurance regarding packages of product should include an inspection by the individuals placing packages in boxes, as this will allow detection of obviously defective packages that are fast leakers. Pulling samples at intervals for close inspection by quality assurance personnel for proper seals and absence of damage to packages can be useful and allow for adjustments or repairs to the packaging machine to minimize problem packages. In addition, good quality assurance programs include a next-day random checking of the product within boxes on pallets to detect slower leakers, and determine the level of compliance with company-stated goals regarding absence of bad packages.

Flexible Film Package Defects

Some packaging manufacturers have published charts of flexible package defects that are very helpful to companies using their film products and packaging equipment. Class 1 defects (the most serious defects) include a patch of nonbonding across the width of the seal, creating a leak; a mechanical slash into the package, resulting in the loss of hermetic integrity; a fracture or break through the packaging material; unsealing of the pouch or bag; failure of two sealant films to combine; mechanical piercing into the package; a leak at a manufactured notch that had been placed for easy opening; any other break through the package material; and a swollen package, indicative of gas formation within the package, usually a sign of serious microbial problems. Each of these leaks should lead to careful analysis and correction of the cause of the problem as well as rejection of the failed package. Discovery of Class 2 problems should also be quickly addressed. These may include a scratch or abrasion through part of the film; a blister that is not in the seal; a contaminated seal that might easily lead to a leaker; film delamination in the seal area; a compressed seal resulting from too much jaw pressure; a misaligned seal that might lead to the loss of hermetic integrity; seal creep, which is a partial opening of inner border of the seal; or a wrinkle that is greater than half-way through the seal. These can result in hermetic failure quickly or too early in the journey of the package to the ultimate consumer.

Active Packaging

Active packaging systems include oxygen scavengers, carbon dioxide scavengers or emitters, chemical preservative films, ethanol or ethylene emitters, temperature control and monitoring systems, and time–temperature integrated monitors. Oxygen and carbon dioxide levels are important in MAP (systems that affect their level are discussed in another part of this encyclopedia). Some processed meats have the potential for very long shelf-lives, especially when packaged in completely anaerobic conditions. Oxygen-scavenging films have

the potential to eliminate oxygen from a package without the use of a sachet labeled "DO NOT EAT." These triple-layer films have a middle layer that scavenges oxygen and plastic layers on either side for product contact and consumer handling. In some cases, the oxygen-scavenging properties are activated with a ultraviolet light during the packaging process.

Antimicrobial packaging is receiving much interest; a long list of possible ingredients for this purpose include anhydrides, bacteriocins, antimicrobial enzymes, radiation emitters, silver ions, zeolite products, sorbic acids, and interesting combinations. New innovations using essential oils, such as thyme, in a packaging system have shown promise as antimicrobials.

New packaging innovations have also resulted in the development of intelligent packaging. These products may feature time and temperature indicators to detect mishandling or temperature abuse of a product or to indicate when a cook-in bag product has reached a proper temperature. Other possibilities include freshness indicators in packaging that may detect levels of volatiles in a product. Other 'active' possibilities are odor removers or odor emitters.

Conclusion

Any packaging process involves a careful consideration of the package–product–process interaction. An excellent example of this is consideration of packaging for irradiated meat products, where migration of certain compounds or the possible effects of irradiation on the film may be important.

Consideration of raw materials for producing films will be more important in the future as one thinks about renewable resources versus petroleum-based raw materials. Considerable research is being focused on this, with some of the effort dealing with edible films and the challenges in their production and use. The issues of whether a packaging material can be recycled or whether it is biodegradable will be even more important in coming years.

Glossary

Blooming Oxygenation of deoxymyoglobin to form oxymyoglobin.
Coextruding Extruding multiple layers of plastic material simultaneously; the individual layers typically have specific properties of interest, such as O_2 impermeability or puncture resistance.
Deoxymyoglobin Myoglobin form resulting from H_2O bound to reduced or ferrous iron; it is of visual purple color.
Metmyoglobin Myoglobin form resulting from –OH bound to oxidized or ferric iron; it is of visual gray or brown color.
Oxymyoglobin Myoglobin form resulting from O_2 bound to reduced or ferrous iron; it is of visual red color.
Permeability The ability of a gas (i.e., O_2) to seep through a film.
Shrink packaging Polymer thermoplastic films designed to shrink on application of heat at approximately 80–90 °C.
Skintight packaging A specialized form of shrink packaging that uses thinner films to create a package that contours very closely to the product, so tightly that the texture of the product can often be detected through the package.

Vacuum/pressure

- Inches and mm Hg: Units of pressure; 29.9 in. or 760 mm Hg represent a pressure that is equivalent to 1 standard atmosphere or 760 Torr and can be related to other units;
- mbar: Unit of pressure; 1013 mbar is equivalent to 1 standard atmosphere or 760 Torr;
- mm Hg: Unit of pressure; 760 mm Hg pressure is equivalent to 1 standard atmosphere or 760 Torr;
- Pascal (pa): Unit of pressure; 101.3257 Pa is equivalent to 1 standard atmosphere or 760 Torr;
- Torr: Unit of pressure; 760 Torr is equivalent to 1 standard atmosphere or 760 mm Hg;
- Vacuum: Gaseous pressure within a space that is less than atmospheric pressure; 0% vacuum is equivalent to 1 standard atmosphere or 760 Torr; 99.9% vacuum is equivalent to 1 Torr.

Introduction

Vacuum packaging is usually described as packaging in a container, either rigid or flexible, from which substantially all air has been removed before sealing of the package. It is a good system for distribution and long-term storage of fresh meat cuts, providing longer product life and, if chilled and handled properly, allowing meat color to return to a highly desirable bright red or bright pink form in retail offerings, where retail cuts are packaged with oxygen-permeable film. With good vacuum packaging, the very low oxygen level obtained coupled with production of carbon dioxide in the bag discourages growth of aerobic microorganisms that cause spoilage odors and flavors. These processes also encourage more favorable conditions for anaerobes with production of lactic acid. Vacuum packaging is also very useful for many cured meat products in providing an environment that prolongs the cured meat color before fading occurs and also maintains other quality factors at an acceptable level.

This article covers what constitutes vacuum and the basics of myoglobin chemistry that influence color in vacuum-packaged products. It deals with the major uses of vacuum to deliver high-quality, safe meat products to the consumer. The less than hoped for success in retailing vacuum-packaged chilled or frozen meat is also discussed. Films and important film characteristics for successful use of vacuum packaging are described. The essentials of a good vacuum package are delineated, along with key aspects of management to optimize success in vacuum packaging. Systems for achieving desired results with vacuum are also discussed.

Measurement of Vacuum

The degree of vacuum or pressure can be expressed in a number of ways (Table 1). From the table, 100 Torr (or 100 mm Hg pressure) is equivalent to 26.0 in. of mercury, 87.0% vacuum, and 13 332 Pa, which can be expressed as 133.3 mbar. The importance of this table is that research studies often indicate that vacuum packaging is used, with no further indication of the degree of vacuum or pressure. This is a serious omission, which is indicated in the Section Myoglobin Chemistry. A vacuum/pressure of 50 Torr or 93.5% vacuum allows 6.5% residual air within the package that can represent an oxygen partial pressure, which is very favorable to the formation of metmyoglobin and to discoloration. Thus, an unknown vacuum level may allow unfavorable conditions in some research studies or commercial situations. The capability of a vacuum packager can be measured by the use of a device to measure vacuum in a bag, such as a Kennedy gauge, often used in the United States.

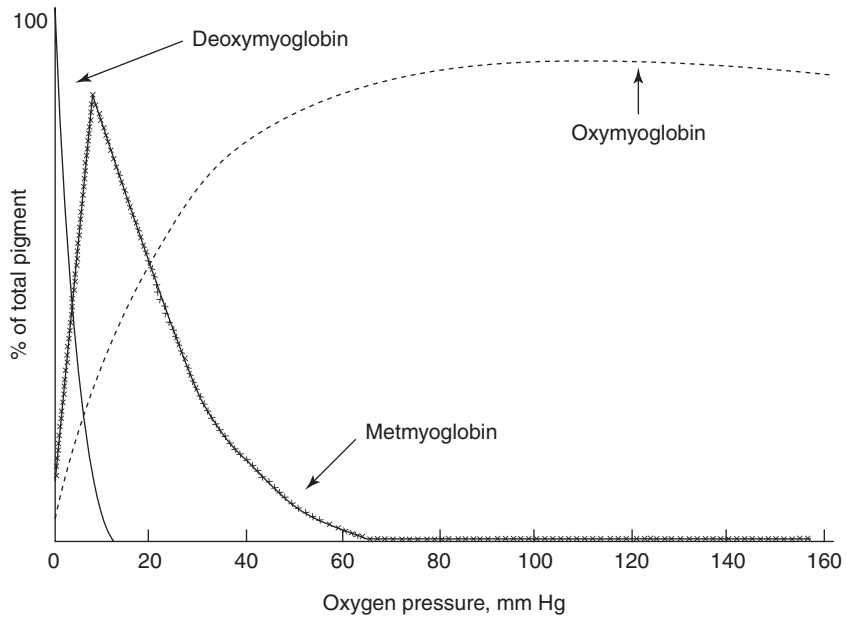

Figure 1 Forms of myoglobin at different oxygen partial pressures.

Myoglobin Chemistry

An understanding of the three major chemical forms of myoglobin is important to making decisions and determining major points of emphasis essential to achieving successful results with vacuum packaging. The three major chemical forms of myoglobin in fresh meat, irrespective of whether it is chilled or frozen, include deoxymyoglobin, which has iron in the reduced or ferrous state (Fe^{2+}) and exhibits a somewhat darker, purplish red color. Vacuum-packaged meat frequently has a preponderance of myoglobin in this form owing to the natural scavenging of oxygen within the vacuum package, provided that the film sufficiently limits the ingress of oxygen into the package. This is because deoxymyoglobin formation is favored at extremely low oxygen partial pressures (1.4 mm Hg or less). Figure 1 illustrates the relationship of oxygen partial pressure to the relative proportions of myoglobin forms. Early in the development of vacuum packaging, users apparently did not realize that very low partial oxygen pressures were needed to assure long product life and also to have fresh meat cuts, especially beef, retain the ability to bloom.

Blooming and Fresh Meat Color

On exposure of meat to air or another source of oxygen, deoxymyoglobin combines with oxygen to form the bright red

or pink oxymyoglobin, which also has iron in the ferrous state (Fe^{3+}) but with oxygen attached. This reaction is called oxygenation or 'blooming.' Oxymyoglobin formation is favored with high partial pressures of oxygen (Figure 1). There is no valid reason to have meat in the oxymyoglobin state until it is presented in a retail package for display. Even though some degree of blooming quickly occurs on the surfaces before freshly cut meat is vacuum packaged, this time of exposure and the amount of brightening should be kept to a minimum, because more brightening at this time can limit ability to brighten at a later time, preferably as cuts are being prepared for display. As illustrated in Figure 2, which depicts the fresh meat color (myoglobin) triangle, myoglobin in meat in the oxymyoglobin state must go through the oxidized state of metmyoglobin to get back to the deoxymyoglobin form. This is expensive in terms of reducing capacity, and the ability to achieve this change is limited and should be conserved. Otherwise, a point may be reached where the reducing capacity of the muscle is exhausted and the change to deoxymyoglobin may no longer be possible. When this happens at any location in the muscle, the formation of the brown metmyoglobin is inevitable and the ability to oxygenate is lessened. As illustrated in Figure 1, metmyoglobin formation is maximally favored at an oxygen partial pressure of 4 mm Hg, but it occurs at pressures as low as 1.4 mm Hg and can also occur at up to 25 mm Hg. An important point to be emphasized is that a very good vacuum must be achieved and maintained for products, such as beef subprimal cuts, not only to maximize product life but also to retain a high ability for the meat to bloom.

Pigment Layers in Meat

The three myoglobin pigment layers discussed in the article on overwrapping also occur in vacuum-packaged cuts. In relatively fresh meat that has not been mishandled, only a small proportion of oxymyoglobin occurs initially, but primarily deoxymyoglobin will be observed at a later time interval after vacuum packaging. During the time delay before this happens, small amounts of residual oxygen within the bag create areas where the partial pressure of oxygen favors formation of metmyoglobin. The surface of vacuum-packaged ground or whole-muscle product may become totally brown for a while. With sufficient time, the natural oxygen-scavenging ability of the muscle should return oxygen partial pressures to the very low levels that favor formation of deoxymyoglobin. This metabolic activity of the muscle also produces carbon dioxide inside the bag. Drawing an insufficient vacuum or placing highly oxygenated meat in the bag means that more oxygen has to be scavenged, which will delay appearance of the desired purplish red color. If a film bridges (over a space) to produce a void, these voids may have an atmosphere that favors oxidation to metmyoglobin and also a space for purge to accumulate. With good oxygen scavenging by the muscle, the surface oxymyoglobin layer will largely revert to the deoxy form and the vacuum-packaged cut will assume the purplish red color of this pigment. This color is good evidence of a successful vacuum package for fresh meat.

Discoloration of Vacuum-Packaged Meat

The occurrence of brown metmyoglobin on the surface of a vacuum-packaged cut too early in the package life may indicate that the degree of vacuum achieved by the vacuum pump/packager combination was not sufficient or that the film is not a sufficient barrier to ingress of oxygen (<30 ml per 24 h per m^2, or less, is the target for domestically marketed beef in countries such as the United States). This coloration also occurs when meat is exposed to air for too long after cutting and before packaging and absorbs too much oxygen, which can later be released into the within-package environment. The brown color might also indicate that the meat has been held in vacuum too long and has used up all of its metmyoglobin-reducing capacity, thereby losing its ability to return to the reduced deoxymyoglobin form. It could also be a consequence of a leak in

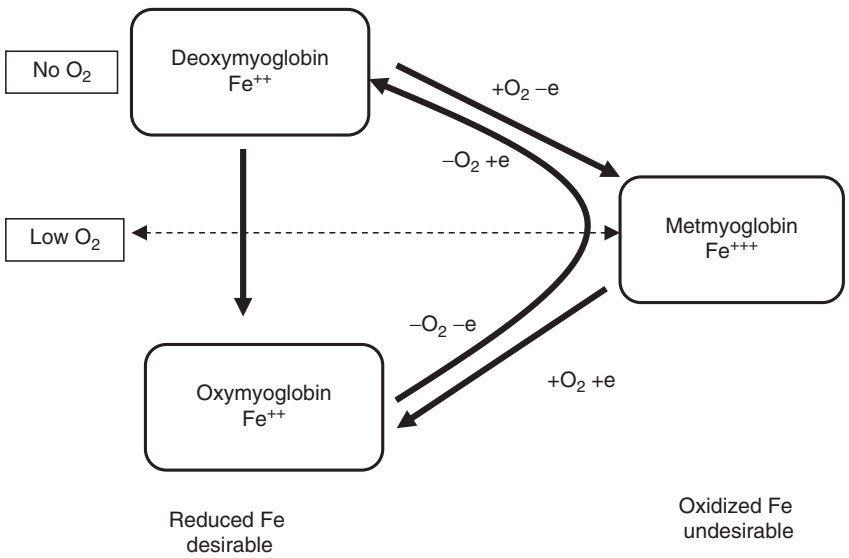

Figure 2 Fresh meat color (myoglobin) triangle.

the package. The results of a poor vacuum or a leak in the package can frequently be observed when these newly vacuum-packaged cuts are placed in the box; however, a slow leaker may not be noticeable for several hours. Some company's quality assurance programs for packaging include next-day random sampling of a predetermined number of boxes on so many pallets as a check for unsatisfactory packages, usually leakers. This procedure is used more for vacuum-packaged cured products than for vacuum-packaged fresh meat.

Increased meat surface area, such as six sides in small meat cubes cut for stew beef or with meat that has been tenderized by penetrating needles or knives or with the rotating knives of a meat cuber, may allow a great deal of oxygen to diffuse into the structure of meat to react with myoglobin. This oxygen is included with meat placed in the package and can later be released from the meat into the sealed package, where it alters the partial oxygen pressure enough to favor metmyoglobin formation.

Delay before Packaging

A classic study was reported, in 1970, in which beef semimembranosus muscle samples were exposed to air for 2, 6, 24, or 48 h at 3.3 °C before vacuum (anoxic) packaging. Samples held aerobically for 2 h and then vacuum packaged maintained a high level of metmyoglobin-reducing ability and underwent a rapid conversion of pigment to deoxymyoglobin, with no visible or instrumental manifestation of metmyoglobin at any time. The conversion to the deoxy form went so completely that there was never enough brown pigment to be detected. With the 6 h exposure to air before vacuum packaging, a similar ability to change oxymyoglobin to deoxymyoglobin was noted, with a small amount of brown metmyoglobin being detected for approximately 4 h after the vacuum packaging. However, muscle samples held in air for 24 h before vacuum packaging took approximately 2.5 times as long (10 h) for the metmyoglobin to become reduced and 20% metmyoglobin was reported at 5 h after vacuum packaging. Moreover, muscles exposed to air for 48 h before vacuum packaging took 20 h for maximum conversion back to deoxymyoglobin, but only 80% of the total myoglobin reverted to the deoxy form. Analysis showed that up to 60% of the myoglobin was in the met form at 4 h after vacuum packaging. This study emphasizes the importance of vacuum packaging cuts rapidly after they have been fabricated. Ideally, plant organization and product flow should be organized to facilitate rapid packaging and cuts should never be held overnight or even for several hours before vacuum packaging. Stacking or throwing retail cuts into a combo or lug before vacuum packaging might result in partial blocking of the surface of some cuts so that part is exposed to oxygen and part is blocked from exposure. With some time in this condition, a single cut may demonstrate color variation on its surface, because different areas of the surface are in different stages of the change of myoglobin from one form to another. This could be a negative factor when product is displayed for sale.

Curing and Vacuum Packaging

In the curing process, nitric oxide formed from nitrite reacts with myoglobin to form red-colored nitric oxide myoglobin, which, on heating and in favorable conditions, is converted to nitrosohemo- or nitrosomyochrome, a pink-colored pigment. Although this cooked form is frequently described as relatively stable, it is susceptible to oxidation, leading to fading of the pink to a gray, tan, or sometimes colorless appearance. The oxidation is catalyzed by contact with oxygen, exposure to light, and higher temperatures. Such a product is especially vulnerable to ultraviolet (UV) light, especially shorter UV wavelengths. Packaging plays a critical role in stabilizing the cured meat pigment by keeping the within-package levels of oxygen low and by having a very small amount of headspace. A vacuum of 77–93.5% should be drawn for processed meat packages. The greater value is a much-preferred target to sustain product for a long shelf life and display life. Thus, very good evacuation of air or an effective gas flush, as well as having a package that is a good barrier to oxygen, is essential.

Choosing Vacuum or Gas Packaging

For a retail package, vacuum is useful for more solid or chunky cured products, such as ham pieces or even frankfurters and similar sausages, but gas packaging works better for sliced or fragile products. Fragile products may be broken by the pressure of vacuum packaging, whereas thin slices may be very difficult to separate if they are pressed together by the force of vacuum packaging. Gas packaging may also be favored over vacuum for product with uneven surface contour, as it may be difficult to draw the vacuum film down into a depression on the product surface. For example, products such as chicken are not well suited for vacuum packaging because of their very uneven contour and their relatively soft texture and also because of their small product mass in relation to surface area, which result in diffusion of larger amounts of oxygen into the meat surface proportion to scavenging of oxygen by the muscle.

Considerations whether vacuum can be used or whether gas packaging would be more appropriate depend on product characteristics. Size, shape, and regularity of product may determine whether an effective vacuum can be drawn; if not, these products should be considered for gas packaging.

Essential Film and Package Traits

Properties of Films and Oxygen Permeability

Important requirements for films used for vacuum packages include good barrier properties, for both gas and moisture, because of the necessity of minimizing oxygen permeability for chilled or frozen fresh meat and also when using film for cured meat packaging. Specifications for bags used for packaging beef subprimal cuts for domestic use in the United States frequently require permeability not exceeding 30 ml per 24 h per m^2. Some countries and some meat exporters favor or require an oxygen permeability not exceeding 3–4 ml per 24 h per m^2.

Some variation from the requirement for very low oxygen permeability might be in order for frozen meat packaging. When skintight film for frozen meat was used, a brighter red beef color was maintained with somewhat greater oxygen

permeability. Another approach to providing a bright red color, in this case for ground beef, was to expose the ground beef to hyperbaric oxygen immediately before packaging and freezing. Both approaches require acceptably cold freezer temperatures for storage, distribution, and display, because this product might be more vulnerable to oxidation; thus, resulting in an oxidative or rancid taste sooner than expected in product life.

Permeability of Films

To maximize storage life of fresh meats through marketing channels, permeability of films should be minimized. The literature suggests that greater than 15 weeks of storage life can be attained when permeability is 190 ml per 24 h per m^2 or less. Films that allow greater permeability will likely result in greater counts of *Pseudomonas* and putrid odors.

Films used for cured items also require very low oxygen permeability because of the vulnerability of the nitrosohemochrome pigment to oxidative fading. One study, reported in 1985, compared films ranging in oxygen permeability from 0.1 to 1600 ml per 24 h per m^2 and vacuum levels ranging from approximately 60.2% to 96.7% to determine the effects on color stability and rancidity in sliced bologna. Color was most stable with the highest-barrier film but remained acceptable for 35 days of storage if oxygen permeability was 7 ml per 24 h per m^2 or less. Vacuum at approximately 89.8% or higher resulted in the best cured color stability in all films, but if film permeability exceeded 60 ml per 24 h per m^2, color became unacceptable in only 10 days. At the lower vacuum levels in this study, only the best barrier film, one that had a foil layer and oxygen permeability of 0.1 ml per 24 h per m^2, retained acceptable color, whereas at 77–84.9% vacuum a film permeability of <60 ml per 24 h per m^2 was needed. Thiobarbituric acid residue measures of oxidation did not become significantly greater until a vacuum of 77% or less, or a film allowing more than 120 ml O_2 per 24 h per m^2, was used. A similar study with bacon showed no large effects, although a vacuum of 75% and a barrier film allowing 10.6 ml per 24 h per m^2 or less showed a somewhat better color. These authors suggested an 89.8% vacuum as a good target. The product life reported in these studies has been improved, and many commercial products today have a 'sell by' date based on a product life of 70 days or longer.

Physical Traits of Films

Materials must be flexible so as to conform closely to the shape of product being packaged and must have the ability to shrink and to be heat sealed. It must also be strong and puncture resistant. Special bone guard materials are sometimes used to cover sharp bone edges and some films are available that are very resistant to such punctures. Details of films and film uses are given in the article.

Research in Denmark showed that holding vacuum-packaged cured meat in the dark long enough for the meat to deplete oxygen stores by its metabolism before placing product under display lighting was very helpful in reducing cured color fade. Processed meat is frequently packaged in heat-shrinkable and heat-sealable bags with three layers, such as ethylene–vinyl acetate, polyvinylidene dichloride, ethylene–vinyl acetate or nylon, ethylene–vinyl alcohol, and ionomer coextrusions. Ionomers with zinc or sodium are very good in heat-sealing layers. These products are also packaged using thermoformed packages.

Vacuum Packaging Operations

Benefits of Vacuum Packaging

Vacuum packaging offers some special benefits because of the extended product life, reduced weight loss through the control of evaporation, protection against contamination, preservation of color, and improved eating characteristics because of the longer aging that is possible in vacuum bags. These benefits led to the 'boxed beef' program (vacuum packaging and placing beef subprimal cuts in conveniently sized boxes) developed originally by Iowa Beef Processors (later named IBP, Inc. and, today, Tyson Foods, Inc.). This system offered huge benefits because bones and fat trim were retained at the slaughter–fabrication plant and not shipped to retail stores. This allows huge savings in transport space and in cost and results in fresher fat trim and bones for rendering. Vacuum-packaged subprimal cuts in boxes holding approximately 9–27 kg were more easily handled at individual stores and their use facilitated quicker cutting and retail packaging of retail cuts. The system also lends itself to enhanced marketing flexibility, as individual retail market managers can order a product mix to suit their anticipated business.

Creating the Vacuum Package

Vacuum packaging can be accomplished by several techniques. The simplest method involves mechanically collapsing the film around the product, which does not result in a very satisfactory package or degree of vacuum. Steam evacuation or hot filling of the product can force atmospheric gases out of the package headspace, and a vacuum develops when the product cools and steam condenses. More commonly, vacuum packaging involves pumps to withdraw air from the package to create a negative pressure before sealing. For a very high degree of vacuum, multistage pumps may be needed. Mechanisms of air withdrawal include a snorkel device or single- or double-chamber systems. The snorkel has a tube or nozzle that is placed into the package to enable withdrawal of air, which is then withdrawn when package sealing is performed. For a single chamber, the package is placed in the chamber, a vacuum is drawn in the chamber so that the package atmosphere is drawn out, and sealing is performed inside the chamber. The double chamber is set up so that external pressure outside the bag produces better evacuation before sealing, resulting in a tighter drawdown. Although an earlier study indicated little difference in storage life of product from nozzle compared with chamber evacuation machines, and no major difference between nozzle/clip and chamber/heat seal for vacuum packages, the chamber-type approach seems to be highly favored.

An interesting and effective way to extend the vacuum clip technology is Pi-Vac, a 'vacuum-free vacuum pack,' which has recently been marketed in Europe. The film is fed into tubes and the film edge is stretched over 'fingers' in such a way that meat can be placed in the opened tube. The specially constructed barrier film is stretched while meat is introduced into the tube and the stretched film then contracts to its prestretch dimensions over the meat, forcing out air and bringing the film into close contact with the meat. The open end of the tube can be clipped or heat sealed to produce an air-free meat package.

Effective Sealing of Vacuum Packages

Technique is important in effective vacuum packaging. The heat seal bar should be as close as possible to the product in the vacuum bag to avoid collapse of the bag between the product and the seal bar resulting in trapping air in the bag. A clean bag at the seal location is highly desirable to produce a better closure, although some sealing systems are designed to function even with some interfering meat or fat in the seal location. Proper adjustment of seal temperature is important as some films can melt at high seal temperature, whereas others require a higher temperature to obtain a hermetic seal.

Shelf Life and Microbiology of Vacuum-Packaged Product

Shelf life of vacuum-packaged meat depends a great deal on the microbiological condition of the meat at the time of packing. Residual oxygen is metabolized by enzymes in the meat and carbon dioxide is produced. The resulting conditions severely limit the growth of aerobic microbes; thus, the growth of *Pseudomonas*, responsible for spoilage of meat under aerobic conditions, is lessened and lactic acid bacteria predominate. Holding vacuum-packaged product at very low temperatures favors growth of lactic acid bacteria more than that of *Brochothrix thermosphacta* and enterobacteriaceae, which can also grow under these anaerobic conditions. The more desired lactics are also favored by film with very low oxygen permeability, and these same conditions favor the formation of deoxymyoglobin. A lactic acid aroma on opening a vacuum bag of meat is a good sign of growth of lactic acid bacteria. This odor quickly dissipates on exposure to air. Beef of normal pH and of good condition could be stored for up to 12 weeks, but high-pH beef spoils much more rapidly due to growth of *Alteromonas putrefaciens* and of psychrotropes, such as *Serratia liquefaciens* and *Hafnia* and *Enterobacter* species. The latter two are detected by greening of the meat surface and off-odors, mainly from sulfur-containing compounds. The hydrogen sulfide produced results in green sulfmyoglobin and sometimes even further degradation of myoglobin to porphyrins and bile pigments. When the pH of beef is higher than 6.0, it should not be kept more than 2–3 weeks and actually should not be vacuum packaged at all. An important consideration in vacuum-packaged meat is the possible growth of psychrotropic pathogens, including *Yersinia enterocolitica*, *Listeria monocytogenes* and *Aeromonas hydrophila*, although *L. monocytogenes* grows very slowly below pH 6.0.

Vacuum Packaging of Larger Cuts

Many studies, especially with beef and pork, have been done on vacuum packaging, and its major commercial use has been for the distribution of larger cuts that are later cut into retail cuts and probably overwrapped for display. Major results include lower weight losses after 21 days of storage, less weight loss because less trimming is required, reduced discoloration, less off-odor and off-flavor, and improved palatability of the product. Some studies report an additional day of display time for cuts from a vacuum-packaged larger cut. Beef cuts produced under commercial conditions were reported to have a 70-days storage life, whereas another study reported an 11-weeks storage life when held at 0 °C, although undesired color was sometimes noted after 8 weeks. Black or brownish spots were noted on the fat at 6 weeks of storage, and authors attributed them to myoglobin breakdown products in the purge. On rare occasions, boxes of beef subprimal cuts were lost in the huge boxed beef warehouses, despite digital records of boxes and their locations. Sometimes product as old as 84 days had been 'found,' but was still able to be successfully used. Several reports have noted that a shorter storage life is appropriate for lamb with higher psychrotropic counts. Perhaps the smaller muscle mass in relation to surface area has an influence. One study indicates that the optimum time to vacuum package lamb cuts is at 4 days postmortem, and further delay before vacuum packaging reduces the intensity of later bloom and encourages metmyoglobin formation.

Some interest has been developed in the possibility of precutting wholesale or subprimal cuts into retail cuts and then placing chops or steaks back in their order and vacuum packaging them collectively. When these packages are opened on delivery at retail stores, they need no further cutting and are retail packaged. This approach is probably considered periodically by the industry, but a recent test of the procedure again resulted in considerable brown and green discoloration on most of the individual steaks within the vacuum packages. A likely contributing factor is rapid diffusion of oxygen into each retail cut so that, when these were vacuum packaged, some locations within the vacuum package have partial oxygen pressures that strongly favor oxidation.

Reducing Headspace with Shrink Packaging and Skintight Packaging

Alternative methods for reducing headspace in a package include shrink packaging and skintight packaging, which use oriented thermoplastic films that shrink onto the product surface or are drawn tightly around the product when they are in the heat-softened state. Skintight packaging is an appropriate method for packaging frozen meat, as the closeness of film to the meat does not allow buildup of ice between meat and film, so that product visibility is very good. The skintight film is also effective in minimizing desiccation of the meat surface, even under conditions where freezer temperature may have considerable variation. A concern with skintight packaging is having enough initial film thickness so that, when the film thins in the shrink process, it does not thin so much that it causes a blowout or reduces barrier properties to an extent that package barrier needs are compromised.

Frozen Meat Packaging

For frozen meat packaging, a more snug fit of film to meat should occur if packaging is done before freezing. However, packaged meat should be taken to the freezer immediately after packaging and subjected to rapid freezing, because muscle metabolism may cause a rapid darkening of color to dark red or even brown unless meat is quickly frozen to stop metabolic activity. A frozen meat retailing effort in Manhattan, Kansas was not successful because many cuts became too dark in color, and management failed to emphasize initiation of rapid freezing immediately after vacuum packaging. Cryogenic freezing via liquid nitrogen or carbon dioxide is highly recommended. Retailing of frozen, raw meat cuts has been relatively unsuccessful, even though with good management and handling, beef, pork, and lamb cuts can show an attractive color in display. A possible reason is that meat purchasers felt unable to evaluate quality in frozen meat and perhaps too many had experienced unfavorable impressions of discolored chilled meat that had been discounted in price and placed in a freezer case for quick sale.

Heat-sealable film bags are useful in packaging frozen meat. Heat-shrinkable polyolefin bags are appropriate for packaging frozen poultry products. Low-density polyethylene has a relatively low cost but needs improvement as an oxygen barrier. Coextruding or laminating these films or ethylene–vinyl acetate with barrier materials, such as polyvinylidene dichloride or ethylene–vinyl alcohol, creates a film that functions well to prevent oxidation and desiccation.

Choosing Proper Bag Size

An important consideration in vacuum packaging is to use the smallest possible size of bag into which the meat cut can be placed. The obvious justification is that larger bags are more costly, but another consideration is having the least possible bag surface area to reduce the area available for oxygen ingress. Although a larger bag might be shrunk onto the product, this larger area can still be a factor in allowing more oxygen into the package.

Commercial Difficulties in Marketing Vacuum-Packaged Fresh Meat

A major effort was made some years ago to market chilled vacuum-packaged cuts in retail stores by one of the largest US meat companies and offered in stores of a large retail chain in Midwest United States. Retail beef cuts were fabricated and packaged in a mid-western state and marketed in several states. As expected, the meat color was darker purplish red, which proved to be a large obstacle, even though a very strong effort was made by college students hired by a local retail store to educate consumers. The quality of the meat was very acceptable other than in terms of color, which did not meet expectations of many customers. Color was stable for a week, except for more rapid discoloration in stew beef and in steaks tenderized in a rotating-knife cubing machine. Both the large amount of surface related to meat mass for stew beef and the facilitation of oxygen diffusion into the tenderized beef created conditions favorable to early formation of metmyoglobin.

Recently developed technology has incorporated small quantities (5–90 mg m^{-2}) of sodium nitrite into the film. In a vacuum, oxymyoglobin is oxidized to metmyoglobin due to the low level of oxygen remaining in the package and ultimately converted to deoxymyoglobin via the natural reducing activity of the muscle. On reduction, nitrite forms nitric oxide in the meat that binds with deoxymyoglobin to form nitric oxide myoglobin, providing a red color visually similar to that of oxymyoglobin. The quantity of nitrite in the film does not cure the meat, nor does it provide antimicrobial properties.

In the authors' experience, vacuum-packaged pork retail cuts have an attractive meat color. Even though the muscle has darker color of deoxymyoglobin, the lower myoglobin content of this meat creates a situation in which the color is very acceptable. One negative aspect of vacuum-packaged retail pork cuts is that the purge may take on a greenish color.

In summary, vacuum packaging has added a new and very useful dimension to the distribution and marketing of red meat with benefits for food safety, appearance, and eating satisfaction.

PARASITES PRESENT IN MEAT AND VISCERA OF LAND FARMED ANIMALS

A Broglia, European Food Safety Authority, Parma, Italy
W Basso, University of Zurich, Zurich, Switzerland

Introduction

The purpose of this article is to give an overview about the main zoonotic and nonzoonotic parasitic infections affecting meat and viscera (excluding gastrointestinal tract) of land farmed animals (cattle, small ruminants, swine, solipeds, poultry, and lagomorphs), providing insights on the main drivers for their transmission. As part of the Encyclopedia, this article is not intended to be exhaustive about all parasites associated with meat or viscera in all land farmed animal species, but up-to-date literature will be indicated for further information.

Ecological Patterns of Meatborne Parasite Transmission and Maintenance of Life Cycle in Farmed Animals

From the ecological viewpoint, parasites can shape host population structure through their effects on food webs, competition, and biodiversity. In the case of parasites encysted in muscle or in viscera, their development is necessarily based on carnivorism or scavenging behavior of at least one host in the life cycle. These parasites have generally indirect life cycles and are usually characterized by complex trophic interactions between different hosts and the environment. Infectious stages present in the environment (i.e., larvae, eggs, and oocysts) are ingested by the suitable intermediate hosts, where further development of the parasites and encystations in muscle or viscera occurs. The encystation usually occurs in the most oxygenated muscles (e.g., the diaphragm, tongue, masseter muscles, and heart) and in selected viscera that are usually the top choice for predators (e.g., the liver and the lungs). These evolutionary patterns are intended to maximize the survival of the parasitic larvae and their protection in privileged sites inside the host and to maximize the chance of transmission to the definitive carnivore or omnivore hosts. In the definitive hosts, the sexual maturation and reproduction of the parasites take place, and dissemination stages (i.e., eggs, larvae, oocysts, and sporocysts) are produced and shed to the environment, commonly with the feces. The number of stages disseminated by the definitive host is generally high, which guarantees the survival of sufficient number of parasite stages to be transmitted to the next intermediate hosts. In case of parasites with an indirect life cycle, the presence of a determined parasite in a host indicates that other required hosts are also present in that biotope. These facts should be taken into consideration when setting prevention programs, which should aim at interrupting the parasitic life cycle at the most convenient stage. Humans may serve as definitive, intermediate, or accidental hosts for several meat-associated parasites. The pathogenic impact of these parasites can be related to the different role of humans in the life cycle. Generally, the pathogenic impact is higher when humans act as intermediate or accidental hosts (i.e., larval encystation in meat or viscera) than when they are definitive hosts (harboring adult parasite stages in the gut) of these parasites.

A special case is represented by some parasite species that may also occur in the viscera of farmed animals (i.e., *Fasciola hepatica*, *Dicrocoelium* sp., Protostrongylids, *Dictyocaulus* sp., and *Eimeria stiedae*) but developed other evolutionary strategies other than carnivorism for their spread. These parasites affect mainly lungs or liver in their adult phase, and the dissemination stages (i.e., eggs, larvae, and oocysts) can reach the environment through the host feces and further develop into a direct or an indirect life cycle involving one or more intermediate hosts.

In Table 1, the main parasite species associated with meat or viscera of farmed animals are listed.

Farmed Animals as Intermediate Hosts

Because most farmed meat-producing animals are herbivores or omnivores, their role in the life cycle of parasites associated with meat is mostly as intermediate hosts (harboring parasite stages in muscles or organs), whereas definitive hosts are generally represented by domestic carnivores (i.e., dogs and cats), wild carnivores (i.e., foxes and wolves), or humans (i.e., for *Taenia saginata* and *Taenia solium*), which account for contamination of the farm environment with parasite stages, generally shed with the feces.

Farmed Ruminants

Farmed ruminants can harbor stages from several parasite species in edible tissues (meat and viscera). The most important zoonotic parasites affecting ruminants include *Taenia* and *Echinococcus* species and *Toxoplasma gondii*. Humans get infected orally by consumption of raw or undercooked tissues harboring immature stages of these parasites (i.e., cysticerci, *T. gondii* tissue cysts). Some trematodes, such as *F. hepatica*,

Table 1 Main parasite species that can be present in meat or viscera of farmed animals

Parasite group	*Parasite species*	*Definitive hosts (DHs)*	*Localization and size of adult stages in DHs*	*Intermediate (IH), accidental (AH), and paratenic hosts (PH)*	*L = Larval stage (size); main localization in IH and AH*	*Zoonotic potential*[a]/ meatborne[c]	*Geographic distribution*
Cestodes	*Taenia solium* (pork tapeworm)	Humans	Small intestine; length: 3–4 m	Domestic and wild pigs (IH), humans, dogs, cats, and ruminants (AH)	L: Cysticercus cellulosae (0.5–1.5 cm, sometimes bigger in CNS); skeletal and cardiac muscle, seldom CNS, eye, subcutis, liver, kidney, and lung	Yes/yes	Latin America, Asia, Africa, and very rare in Eastern and Southern Europe
	Taenia saginata (beef tapeworm)	Humans	Small intestine; length: Up to 10 m (seldom longer)	Cattle, buffaloes, and other bovids (IH)	L: Cysticercus bovis (0.3–1 cm); skeletal and cardiac muscle, seldom esophagus, subcutis, and adipose tissue	Yes/yes	Worldwide
	Taenia asiatica	Humans	Small intestine; length : 4–8 m	Domestic and wild pigs, seldom cattle (IH), goats, monkeys (AH)	L: Cysticercus viscerotropicus (0.2 cm); liver, seldom other organs (lung and omentum)	Yes/yes	Asia
	Taenia hydatigena	Dogs, foxes, wolves, and other canids, and cats	Small intestine; length: 0.5–2.5 m	Domestic and wild ruminants, swine, and equines (IH)	Cysticercus tenuicollis (1–7 cm); liver, subserous tissues in abdominal cavity, and seldom thoracic cavity	No/no	Worldwide
	Taenia ovis	Dogs, foxes, and wolves	Small intestine; length: 0.6–1.5 m	Small ruminants (IH)	Cysticercus ovis (0.2–3.5 cm); skeletal and cardiac muscles	No/no	Worldwide
	Taenia cervi (for some authors syn. of *T. ovis)*	Dogs and foxes	Small intestine; length: 2–2.5 m	Cervids (IH)	Cysticercus cervi; striated muscles	No/no	Europe
	Taenia pisiformis	Dogs, foxes, wolves, and seldom cats	Small intestine; length:0.3–1.5 m	Rabbits, hares, rodents (IH), dogs, goats, and equines (AH)	Cysticercus pisiformis (0.5–0.7 cm); liver and subserous tissues in abdominal cavity	No/no	Worldwide
	Taenia multiceps	Dogs, foxes, wolves, and other canids	Small intestine; length: 0.2–1.2 m	Domestic and wild ruminants, swine, equines (IH), dog, and humans (AH)	Coenurus cerebralis (2–6 cm, sometimes bigger); brain, seldom spinal cord, in AH also subcutis and eye	Yes (rare)/no	Worldwide, but not in Central and Northern Europe, Northern America, and Australia
	Taenia serialis	Foxes, wolves, and seldom dogs and cats	Small intestine; length:0.2–0.7 m	Rabbits, hares, seldom rodents (IH), dogs, and humans (AH)	Coenurus serialis (1–6 cm, sometimes bigger); connective tissue and muscles (CNS in AH)	Yes (rare)/no	Worldwide
	Taenia brauni	Canids	Small intestine	Rodents (IH) and humans (AH)	Coenurus brauni; subcutis and eye	Yes (rare)/no	Africa
	Taenia polyacantha	Foxes, seldom dogs, and other canids	Small intestine; length:0.1–0.14 m	Rodents, rabbits, and hares (IH)	Cysticercus (up to 3 cm); body cavities	No/no	Northern hemisphere

Parasite group	*Parasite species*	*Definitive hosts (DHs)*	*Localization and size of adult stages in DHs*	*Intermediate (IH), accidental (AH), and paratenic hosts (PH)*	*L = Larval stage (size); main localization in IH and AH*	*Zoonotic potential*[a]/ meatborne[c]	*Geographic distribution*
	Echinococcus granulosus (sheep strain G1; Tasmanian sheep strain G2; buffalo isolate G3)	Dogs, dingoes, and jackals	Small intestine; length: 2–7 mm	Small ruminants, cattle, buffaloes, yaks, and pigs (IH); humans and other mammals (AH)	Hydatid cyst (few mm–> 20 cm); liver, lung, and other organs	Yes/no	Worldwide
	Echinococcus equinus (horse strain G4)	Dogs	Small intestine; length: 2–7 mm	Equines (IH)	Hydatid cyst; liver	Unknown/no	Europe, Africa, and the Middle East
	Echinococcus ortleppi (cattle strain G5)	Dogs	Small intestine; length: 2–7 mm	Cattle, small ruminants, buffaloes (IH), and humans (AH)	Hydatid cyst; lung and liver	Yes (rare)/no	Europe, Asia, Africa, and Central and South America
	Echinococcus intermedius (camel strain G6; pig strain G7; strain G9)	Dogs	Small intestine; length: 2–7 mm	Pigs, goats, camels, cattle (IH), and humans (AH)	Hydatid cyst; liver and lung	Yes/no	Europe, Asia, and South America
	Echinococcus canadensis (cervid strain G8, 10)	Wolves and dogs	Small intestine; length: 2–7 mm	Cervids (IH) and humans (AH)	Hydatid cyst; lung and liver	Yes/no	Northern Eurasia and North America
	Echinococcus multilocularis	Red foxes, arctic foxes, wolves, raccoon dog, dog, and cat	Small intestine; length: 1.2–4.5 mm	Rodents (IH), pigs, horses, humans, and other mammals (AH)	Alveolar hydatid cyst; liver and other organs	Yes/no	Northern hemisphere
	Spirometra spp.	Dogs, cats, and other carnivores	Small intestine; length: 0.1–1 m	Copepods (1st IH) ; reptiles, amphibians, birds, and mammals (i.e., rodents, pigs, humans, dogs, and cats) (2nd IH)	Procercoid in 1st IH, plerocercoid (syn. sparganum) in 2nd IH (1–40 cm); body cavities, viscera, subcutis, intermuscular connective tissue, CNS, and eye	Yes/yes	Europe, Asia, and America
Trematodes	*Alaria alata*	Foxes, wolves, raccoon dog (dog and cat)	Small intestine; length: 2.5–6 mm	Planorbid snails (1st IH) ; frogs (2nd IH) ; amphibians, reptiles, birds, and mammals (i.e., wild pigs and humans) (PH)	Cercaria (1st IH), mesocercaria (2nd IH and PH) (0.4–0.7×0.2 mm); striated muscles and associated connective tissue	Yes (rare)/yes	Europa and Asia
	Fasciola hepatica (common liver fluke)	Domestic and wild ruminants, horses, pigs, rabbits, hares, humans, and other mammals	Liver (juveniles in parenchyma and adults in bile ducts); length: 2–5 cm	Snails (IH) (*Lymnaea* spp.)	Sporocist, redia, and cercaria	Yes/no–yes[b]	Worldwide

	Parafasciolopsis fasciolaemorpha (moose fluke)	Moose, bison, cervids, and sheep	Small intestine and liver (bile ducts and gall bladder); length: 3–7 mm	Snails (IH) (*Planorbarius corneus*)	Sporocist, redia, and cercaria	No/no	Eastern and Southeastern Europe
	Fascioloides magna (large American liver fluke)	Cervids; moose, bison, and domestic ruminants: Parasites do not reach maturity	Liver (juveniles in parenchyma and adults in cysts communicated with bile tract); Length: 7–10 cm	Snails (IH) (*Lymnaea* spp.)	Sporocist, redia, and cercaria	No/no	North America and Europe
	Fasciola gigantica (large liver fluke)	Cattle, buffaloes, sheep, goats, horse, camel, humans, and other mammals	Liver (juveniles in parenchyma and adults in bile ducts); Length: 2.5–7.5 cm	Snails (IH) (*Radix auricularia*-complex)	Sporocist, redia, and cercaria	Yes/no–yes[b]	Subtropical and tropical regions in Africa and Asia
	Dicrocoelium dendriticum (lancet fluke)	Domestic and wild ruminants, camelids, rabbits, hares, horses, humans, and other mammals	Liver (bile ducts); length: 0.5–1 cm	Snails and slugs (1st IH); ants (2nd IH)	Miracidium, sporocyst, and cercaria in 1st IH; cercaria and metacercaria in 2nd IH	Yes (rare)/no	Regional in North America, Europe, North Africa, Asia, and some South American countries
Nematodes	*Trichinella* spp.	Domestic and wild pigs, horses, dogs, cats, foxes, raccoon dogs, rat, other wild animals, and humans (AH)	Small intestine; length; 1–3. 7 mm	The whole cycle occurs in the same host	Encapsulated larva I (nonencapsulated for some *Trichinella* spp.) (capsule: 300–700×200–300 μm; larva I up to 1 mm); skeletal muscle	Yes/yes	Worldwide (some *Trichinella* species have regional distribution)
	Protostrongylus sp., *Muellerius* sp., *Cystocaulus* sp., and *Neostrongylus* sp. (small lung worm)	Small ruminants, cervids, rabbits, and hares	Lungs (parenchyma, small bronchi, and bronchioles) length: 0.5–3 cm	Snails and slugs (IH)	Larvae I–III	No/no	Regionally worldwide
	Dictyocaulus filaria (large lung worm)	Small ruminants and cervids	Lungs (trachea and bronchi); length: 5–10 cm	No	No	No/no	Worldwide
	Dictyocaulus viviparus (large lung worm)	Cattle, other bovids, and cervids	Lungs (trachea and bronchi); length: 3.5–7 cm	No	No	No/no	Worldwide
	Metastrongylus spp. (swine lung worm)	Wild and domestic pigs	Lungs (trachea and bronchi); length: 2.5–5 cm	Earthworms (IH)	LI–III	No/no	Worldwide
Pentastomids	*Linguatula serrata*	Dogs, foxes, wolves, and humans (AH)	Nasal cavity and paranasal sinuses; length: 2–13 cm	Domestic and wild ruminants, pigs, horses, and rodents (IH)	Encysted larva (up to 5 mm); abdominal and thoracic organs	Yes (rare)/yes	Regionally worldwide

Manual of Diagnostic Tests and Vaccines for Terrestrial Animals, third ed. Paris: OIE (World Organisation for Animal Health); and Schnieder, T., 2006. Veterinärmedizinische Parasitologie. Stuttgart: Parey.

Fasciola gigantica, and *Dicrocoelium* sp. that are present in the liver of ruminants can also be zoonotic, but they are usually not transmitted directly to humans by consumption of infected tissues. These parasites undergo an indirect cycle with involvement of one (*Fasciola*) or more (*Dicrocoelium*) invertebrate intermediate hosts (i.e., snails and ants). Definitive hosts (humans and ruminants) get infected by accidental ingestion of larval stages (metacercariae) present mainly on vegetables (*Fasciola*) or in ants (*Dicrocoelium*).

Ruminants are intermediate hosts of many *Taenia* species and harbor the larval stages or metacestodes (cysticercus or coenurus depending on the *Taenia* species) in their tissues. These vesicular stages have a macroscopic size and can be detected during meat inspection at slaughterhouse. Humans are the definitive hosts of *T. saginata*, whose larval stages, Cysticercus bovis, are found in skeletal and cardiac muscle of cattle, buffaloes, and other bovid species worldwide. Cysticercus from other *Taenia* species (i.e., *Taenia hydatigena* and *Taenia ovis*) or coenurus present in ruminants' tissues are infectious for their definitive canid hosts but normally not infectious for humans. Humans can be accidental hosts of some *Taenia* species from canids (i.e., *Taenia multiceps* and *Taenia crassiceps*) and some cases of larval development in human tissues after ingestion of eggs from canids' feces have been observed. Ruminants are also intermediate hosts for *Echinococcus* species (i.e., *Echinococcus granulosus*, *Echinococcus ortleppi*, and *Echinococcus canadensis*), with development of hydatid cysts mainly in the liver and the lungs. Dogs and other canids get infected through ingestion of these larval stages with development of adult worms in the small intestine and shedding of eggs with the feces, accounting for environmental contamination. Humans, who serve as accidental intermediate hosts, can develop hydatidosis after ingestion of *Echinococcus* eggs, with development of hydatid cysts in the liver, lung, central nervous system (CNS), or other tissues.

Toxoplasma gondii is a worldwide-distributed, cyst-forming protozoan parasite that affects warm-blooded animals and humans. Ruminants get infected during grazing through ingestion of sporulated oocysts shed by the definitive hosts (cats and wild felids). Sheep along with goats possess the highest incidence of cysts in meat, playing an important role as a source of infection for humans. In these animals, the parasite can persist asymptomatically in the form of microscopic bradyzoite-containing tissue cysts, mainly in the brain and muscles. *Toxoplasma gondii* is morphologically similar to *Neospora caninum*, a nonzoonotic parasite that can occur in ruminants' tissues (mainly CNS and muscle) and represents a major cause of abortion in cattle worldwide and can also affect small and wild ruminants and other animal species. Cattle can harbor cysts of zoonotic (*Sarcocystis hominis*) and nonzoonotic *Sarcocystis* species (*Sarcocystis cruzi* and *Sarcocystis hirsuta*), mainly in striated muscle tissue. Humans get infected by ingestion of undercooked meat containing cysts of *S. hominis* and can develop gastrointestinal signs. A differentiation of these species is important from a public health and economic point of view because only *S. hominis* is zoonotic. *Sarcocystis cruzi* and *S. hirsuta* are highly prevalent worldwide; they have canids and cats as definitive hosts, respectively, and have no clinical consequence for the definitive hosts. Therefore, condemnation of meat infected by nonzoonotic *Sarcocystis* species not affecting meat quality (i.e., microscopic cysts and no visible macroscopic changes) would not be required. Tissue cysts of *Sarcocystis* species can be differentiated by microscopic and electron microscopic examination and by molecular methods. Small ruminants can be affected by many *Sarcocystis* species, sometimes with macroscopic cysts (i.e., *Sarcocystis gigantea*), but they are not zoonotic.

Farmed Swine

All major meatborne parasites of public health importance (*Trichinella* spp., *T. solium*, *T. gondii*, and *Sarcocystis suihominis*) are associated with pork from domestic pigs and wild boars. Although the risk of porkborne parasites, particularly for *T. solium*, may be currently considered limited in countries with high sanitation standards and where pigs are mostly raised under controlled housing conditions, these parasites are still endemic and highly prevalent in humans in some geographical regions, representing important public health concerns.

Owing to its public health importance and ubiquitous pattern, *Trichinella* is one of the most-studied parasite worldwide affecting domestic and wild swine. Its low host specificity and wide distribution increase opportunities for interspecific transmission, whose patterns have been extensively studied. At the present time, it is recognized that the epidemiology of trichinellosis is characterized by a considerable complexity with 12 *Trichinella* taxa described so far.

Trichinella spp. is one of the few meatborne parasites with all developing stages occurring within one host. It has a very broad range of host species (mammals, birds, and reptiles), mainly those with cannibalistic and scavenger behavior; however, only humans become clinically affected. Because *Trichinella* transmission involves carnivorism at each stage, the only farmed animals involved in the transmission are swine apart from accidental ingestion of contaminated feed by herbivores (horses). Following ingestion of infected raw or undercooked meat containing larvae, these are released in the stomach, they mature in the small intestine developing to adult female and male worms, and reproduce and give progeny to new larvae (LI) that enter the blood circulatory system and invade skeletal muscle. Here most of the *Trichinella* species/genotypes become encapsulated (excluding *Trichinella pseudospiralis*, *Trichinella papuae*, and *Trichinella zimbabwensis*) until being ingested by the next host. The tongue, diaphragm, and masseter muscles are considered sites of choice for *Trichinella* encystation, but this may vary according to the host species.

Among the cestode species associated with pork, *T. solium* is one of the most investigated due to its peculiar public health implication where humans act both as definitive and intermediate hosts. In fact, the larval stage (Cysticercus cellulosae) can develop in swines and humans after accidental ingestion of eggs shed by humans harboring adult parasites in the small intestine; moreover, autoinfections are also possible. *Taenia solium* as adult and larval infection (leading to taeniosis and cysticercosis, respectively) is estimated to infect millions of people worldwide, particularly in countries with inadequate sanitary infrastructure and insufficient health education.

Cysticercus cellulosae in humans develop mainly in the muscles, eyes, and the CNS, causing neurocysticercosis, which is one of the most serious parasitic diseases characterized by a wide range of neurological disorders.

The relatively new species *Taenia asiatica* has also been found to infect humans in addition to *T. solium* and *T. saginata*, whose distribution is restricted to Asian countries. Although according to the World Health Organization (WHO)/Food and Agriculture Organization (FAO)/ World Organization for Animal Health, *T. asiatica* does not cause human cysticercosis, due to its similarity with *T. solium*, humans could be potential candidates as *T. asiatica*'s intermediate hosts.

Pork is considered one of the major sources for *T. gondii* infections in humans. The infection in swine is generally asymptomatic, but in some occasions clinical disease (anorexia, apathy, fever, cyanosis, dyspnea, hind limb weakness, and even death) and abortion or neonatal mortality were reported. The prevalence of infection in swine varies enormously according to the categories and age of pigs tested, for example, piglets versus market pigs or sows, and the management system, for example, free range versus biosecure indoor systems. *Toxoplasma gondii* infections have also been described in wild boars.

Among the species of *Sarcocystis* found in pork, *S. suihominis*, with humans as definitive hosts, is of public health importance and can cause gastrointestinal symptoms, whereas both *S. suihominis* and *Sarcocystis miescheriana* (syn. *Sarcocystis suicanis*) with dogs and other canids as definitive hosts can be pathogenic for pigs, causing myositis, myocarditis, lameness, dyspnea, thrombocytopenia, disseminated intravascular coagulation, and even death.

Equine Species

Horses and donkeys are considered meat animals in many European, South American, and Asian countries; however, in some parts of the Western world, particularly in the US, the UK, and Ireland, they are forbidden food because of the role of equids as companion animal. In Europe, France, and Italy account for 71% of the total horsemeat consumed in the European Union (EU).

The parasites associated with horsemeat of public health importance are *Trichinella* spp. and *T. gondii*. Concerning *Trichinella*, as equine species are herbivores, the possible ways of infection are grazing in pastures contaminated with infected carcasses or ingesting infected flesh from pigs and wild carnivores, even as practice of using carcasses of carnivores bred in captivity, or hunted for their fur, for a mash to fatten horses before slaughter. Human cases of *Trichinella spiralis* in Western Europe have occurred in Italy and France in the 1990s due to consumption of meat from horses imported from Eastern Europe.

Toxoplasma gondii is uncommon in horses, although viable cysts have been isolated from horses slaughtered for export. Three cases of human toxoplasmosis caused by atypical strains probably acquired by ingestion of raw horsemeat imported from Brazil and Canada were detected in France.

Sarcocystis bertrami, *Sarcocystis equicanis* (with canids as definitive hosts), and *Sarcocystis neurona* (with opossums as definitive hosts) can infect equids, although the latter does not encyst in muscle but affect nervous tissue.

Poultry

Parasites are rarely found in poultry meat with the exception of some *Sarcocystis* species and *T. gondii*. Free-range chickens can be considered indicators for environmental contamination with *T. gondii*, but the infection rarely causes clinical disease. Ingestion of infected (raw or undercooked) chicken meat can be a potential source of infection for *T. gondii*.

Besides, poultry organs (mainly the liver and the lungs) and muscles can harbor *Toxocara canis* and *Toxocara cati* larvae and are potential sources of human toxocariasis if these tissues are ingested raw or undercooked.

Histomonas meleagridis is a frequent protozoan parasite of turkeys. It is not zoonotic but induces macroscopic changes in the liver, characterized by round (3–10 mm) necrosis foci that can be seen during inspection at slaughter. Histomoniasis may have high morbidity and mortality, mostly in young birds, and can cause important economic losses.

Farmed Lagomorphs

Protozoa, such as *T. gondii* and *E. stiedae*; larval stages of cestodes, i.e., cysticerci of *Taenia pisiformis, Taenia serialis*, and *Taenia polyacantha*; liver flukes, such as *Dicrocoelium dendriticum* and *F. hepatica*; and lung nematodes, such as *Protostrongylus pulmonalis* are among the most common and studied parasites present in meat and viscera in rabbits and hares.

Detection at Slaughter: New Approaches

Parasitic meatborne infections that can be detected macroscopically, such as cysticercosis in cattle and pigs, are traditionally controlled at the end of the meat production chain by visual inspection of single carcasses. Nevertheless, such an approach may be obsolete in countries with high biosecurity farming systems (e.g., swine production) where prevalence of meatborne parasites in farmed animals and the risk of human infection may be very low. This consideration is also valid for the monitoring of individual swine carcasses to control and prevent trichinellosis in humans, as currently prescribed in Europe as described by the EU legislation 2075/2005, where the current examination method for the detection of *Trichinella* spp. larvae is based on isolation of the larvae by artificial digestion and microscopic identification. Although derogations from the testing program for herds or regions where the risk of *Trichinella* infection in domestic swine is officially recognized as being negligible can be foreseen, the *Trichinella* monitoring program imposes huge economic costs. Modern food production requires a risk-based approach in which several critical control points are monitored and where quality assurance systems are designed considering cost effectiveness. These are some of the factors leading the European regulatory body to revise the current meat inspection practice. As a consequence, the European Food Safety Authority (EFSA) is performing a systematic risk assessment for the modernization of meat

inspection in the EU in order to introduce a risk-based approach to meat inspection at all relevant stages of the meat production chain.

Drivers for Transmission of Meatborne Parasites among Farmed Animals and to Humans

The maintenance of the life cycle of meatborne parasites among farmed animals and their transmission to humans is influenced by, for example, farming system and eating habits, both factors facilitating transmission to intermediate and definitive host, respectively.

Farming System

Farming and agriculture systems represent a major artificial ecosystem in which parasite development and transmission among farmed animals can be influenced by many factors. Because meatborne parasites are transmitted to farmed animals through carnivorism, scavenging on infected preys, or through feeding on pasture or feed contaminated with infective eggs or oocysts, parasite-free farming implies strict indoor housing of animals, including pest control, proper feed preparation and storage, proper slurry management, and general good hygiene. Nevertheless, where biosecurity regimes are not sufficient, meatborne parasite transmission may be facilitated. This may be even truer where the intensification of agriculture is increasing rapidly, especially for poultry and pigs. Moreover, with increasing ecological awareness and request for higher animal welfare standards, food production is evolving toward more sustainable agriculture and organic farming. This increased environmentally sound or animal-friendly livestock production often implies outdoor rearing, which brings livestock in close contact with both the environment and wildlife and may increase the liklihood parasite transmission.

Eating Habits

Among the raw and undercooked foods that may pose a risk for parasitic infection to humans, meat preparation plays a major role. Meat consumption from different animal species is strongly influenced by religious and cultural factors. Pork, which may be a source of infection with *Trichinella* spp., *T. gondii*, and *T. solium*, is avoided by Jews, Orthodox Christians in Ethiopia, and Muslims due to religious beliefs. Beef, which may contain cysticerci of *T. saginata*, is not consumed by Hindus as cows are sacred in their culture. This has a major impact on distribution of infections in various societies throughout the world.

Public Health Impact of Zoonotic Meatborne Parasites from Domestic Animals

The major contributors to the global burden of parasitic zoonoses are cysticercosis, echinococcosis, toxoplasmosis, foodborne trematode infections, leishmaniosis, and zoonotic schistosomosis. In the long list of approximately 100 foodborne parasite species of zoonotic importance, meatborne parasitic species represent a minority and could be restricted to *Trichinella* spp., *T. gondii*; *S. hominis* and *S. suihominis*; and *T. saginata* and *T. solium*. Nevertheless, in a recent evaluation of the global public health impact of 24 preselected foodborne parasites by the FAO/WHO experts, three of the above-mentioned meatborne species are ranked in the top 10 foodborne parasitic species, namely *T. solium* (1st place), *T. gondii* (4th place), and *T. spiralis* (7th place). Public health importance was the primary driver of ranking with almost equal importance given to illness and severity of disease. The disease burden of the above-mentioned species has been thoroughly studied worldwide.

PATENTING PRODUCTS, PROCESSES, AND APPARATUSES

B Myrup and M Rachlitz, Danish Patent and Trademark Office, Taastrup, Denmark

Introduction

Inventors have always, exclusively, wanted the right to own their inventions since time immemorial, but the evolution of a justice system, with statutory rules for the protection of rights, is more recent.

The modern democratic political principles of the nineteenth century brought new legislative initiatives, which also embraced patent law. Today, patent law comes under the law governing intellectual property, which in turn comes under property law.

Intellectual property is so called because it is intangible. Intellectual property law grants the exclusive right to that which one person or group of persons have personally created through intellectual effort, for example, an invention.

However, it was not until the end of the nineteenth century, when industrialism was well established, that patent law succeeded as an important, general legal discipline, marked by international agreements and conventions. As a result, the countries of Europe (cf. the European Patent Convention (EPC)) have experienced an overall harmonizing of their patent rules.

Legal Requirements for Patentability of Inventions

Patents are an integral part of the world of technology. According to patent law, an invention is defined as a technological product capable of being reproduced. For an invention to be deemed patentable in Europe, three criteria must be adhered to:

- The invention must be new, i.e., it must never have been publicly disclosed anywhere in the world.
- The invention must comprise an inventive step, i.e., it must differ essentially from the state of the art before the date of filing of the patent application.
- The invention must be capable of industrial application.

Patents are granted for products, methods/processes, apparatuses/devices, and use of products. Each country has certain exceptions to the rule as to what can be regarded as inventions, for example:

- plant or animal species;
- essentially biological processes for the production of plants or animals; and
- inventions, the commercial utilization of which is contrary to the morals and public order of society.

Patent – An Exclusive Right

A person who obtains patent protection for an invention gains an all-embracing exclusive right, as others are forbidden from producing, marketing, importing, or selling the invention for commercial purposes. In return, the invention becomes publicly available by way of the patent application, allowing anyone the opportunity, on the basis of the invention, to further develop the technology. The application is published 18 months after the filing date. This is the price the inventor pays to society for his protection.

Patent protection is thereby a contract between the inventor/company and the rest of society. Inventors and companies are given the incentive to develop their products, as the return on development costs is achieved by preventing competitors from copying. In return, the publication of the invention allows society to be fully informed about the invention, thus promoting technological development.

The patent is a legal document valid for 20 years commencing from the date the application is filed, on the condition that the annual fees are paid to maintain the patent. Should it be decided that maintaining the patent during its term of validity is no longer advantageous, the patent can be allowed to expire by ceasing payment of the annual fees.

Nowadays, the vast majority of inventions are built on other patented inventions. This could necessitate being involved with other patent holders, i.e., agreements will have to be made with the parties concerned before being able to utilize one's own patent rights. In fact, this rule applies whether one owns a patented product or not. Therefore, it is always wise to be sure there is no risk of infringing the rights of others, as this can cost dearly if investing in production equipment and marketing only leads to the discovery that one does not have the right to produce or sell the product.

In addition, a patent does not provide its owner with the right to utilize the invention if it opposes other laws or rules of society.

Patents are important to economics. First, companies increase their expenses for research and development when innovations can be protected. This gives rise to new inventions and higher levels of productivity. Second, patents increase the spread of knowledge by the publication of the patent. The disadvantage of the patent system is the lack of competition owing to the patentee's (time-limited) exclusive right. However, most economic literature points to the economic advantages of patenting clearly outweighing the disadvantages;

 doi:10.1016/B978-0-12-384731-7.00168-9

i.e., a stronger patent protection system provides the means for greater economic growth.

The Patenting Process

The patenting authority examines the patent application, and determines whether a patent can be granted for an invention. The patent authority determines whether the invention is new (novelty search) in relation to that which already exists, and then decides whether the invention differs essentially from prior art (inventive step) in such a way as to achieve a surprising technical effect. The invention must not be an obvious adaptation of prior art. Finally, it is determined whether the invention is capable of industrial application. An element of the examination looks to recognize the invention as progressive improvement on prior art. Depending on the conclusions of the examination, the application is either approved or refused. Before the decision is finally made, a series of correspondence may be made between the parties. A refusal can be appealed against to the appeal board.

Regardless of whether a patent application is approved or refused, it is published 18 months after the filing date, unless the applicant has withdrawn the application before this time.

The invention is protected from the day the patent application is filed. It is very important that the invention has not been made public in any way whatsoever before filing the application, as this could affect the novelty of the invention and lead to refusal of the application. Once the application has been filed, as far as novelty is concerned, the application can be made public, but many choose not to do so, as this could damage the possibility of patenting further development of the invention.

Patent Strategy

A patent is only valid in those countries where the patent has been granted.

Therefore, careful consideration must be given to determining in which countries a product is to be produced and sold. In addition, the cost of patenting depends on the number of countries designated for patent protection.

There are three ways of applying for a patent:

- national patent application;
- European patent application (EPC); and
- international patent application (PCT).

A national patent application is filed separately in each of the countries where patent protection is required.

EPC stands for the European patent convention. A patent application filed under this convention, via the European Patent Office (EPO) will, if the patent is granted, be effective in all of the member countries of the EU, or in those countries specifically designated. For each country designated, a translation of the application is required, plus the payment of an initial fee and subsequent annual fees.

PCT stands for the Patent Cooperation Treaty. The PCT is a collaboration between 120 member countries. The aim of the PCT is to centralize the examination of patent applications. The PCT carries out a novelty search and on request, serving as a guide, a patentability evaluation. After this, the applicant forwards the application to each of the countries designated in the application. The patent authority of each country, according to its own national law, will decide whether or not to grant the patent.

These international patenting systems offer different options for combining the application filing process. Which process is selected depends on the company's individual needs and economic means.

Figure 1 shows an example of a common patent strategy.

The process begins with the filing of a national patent application in the country in which one resides. The patent authority will, within the first 12 months, perform a novelty search and a patentability evaluation. Based on the information obtained from this examination, a decision can be made as to whether one wishes to file the application internationally (e.g., PCT or EPO) or nationally to those countries

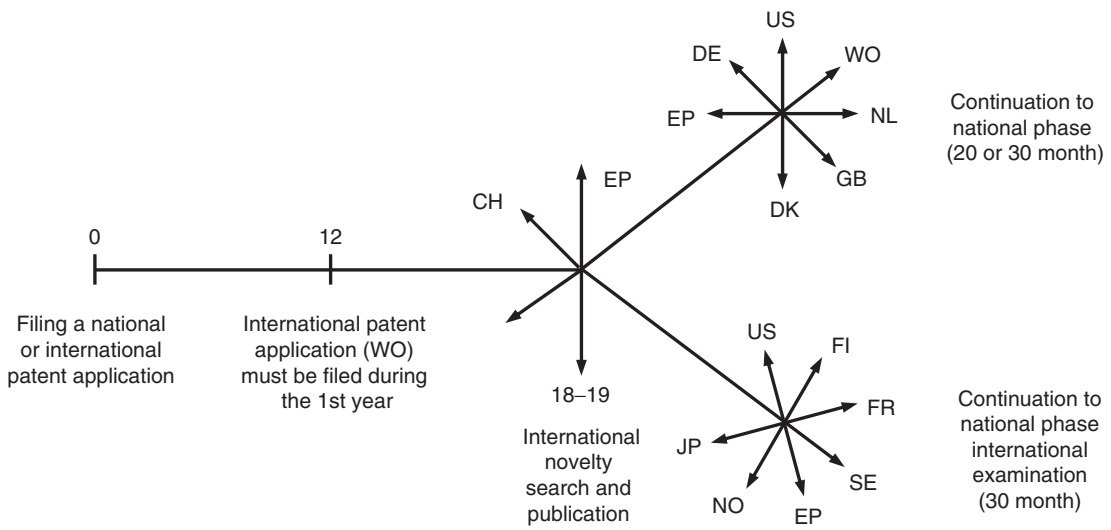

Figure 1 An example of a common patent strategy.

of market interest. The further-extended application, if filed within a 12-month period from the initial date of filing (parent application), will be given the priority date of the first filing date, i.e., the application is deemed valid from the date the application was first filed. Extending the patent application to a PCT application allows a 30-month period in which to decide in which countries the application is to be continued.

Patents as a Source of Information

Nowadays, patent applications that have been published are registered in databases, where they are systematically filed so that they are easy to locate. Apart from using the databases when examining new patent applications for the novelty and inventive step, it is also possible to use them for extracting useful information on, for example:

- innovative activity within a specific field;
- which companies are key players;
- technical areas of current interest; and
- markets of interest to competitors.

The many million items of information in the patent system provide countless opportunities for every company individually to gather invaluable knowledge about the market and the competition.

In the patent applications, the inventions are thoroughly described so as to allow clear insight into new technology, thereby stimulating the inspiration to formulate new ideas that can then be developed.

Patenting in the Meat Technology Field

The field of meat technology has seen a steady rise in patenting worldwide, depicted in Figure 2.

Patent activity varies greatly from country to country. Overall, the US, Japan, and Germany are substantially more active in the meat area than other industrialized countries. This activity can be seen in Figure 3.

Typically, patents are products, processes/methods, and apparatuses/devices and parts/components thereof. The patents span a broad spectrum of technologies from the anaesthetizing of animals before slaughter to processed meat products.

1. Patented slaughter processes: equipment and methods directly associated with the slaughtering process, for example:
   - slaughtering pens and fettering;
   - stunning;
   - fixing;
   - antimicrobial treatment of the carcass;
   - cutting and slaughter equipment and methods with simple tools such as knives, fetters and hooks, and more complex slaughterhouse machinery, for example, for splitting or eviscerating;
   - identification systems; and
   - meat quality measuring equipment.
2. Patenting for meat processing: equipment, methods, and products, for example:
   - cutting meat or bones, bone cleaning, cutting off rind;
   - hanging up meat or sausages;
   - pounding, forming, pressing, tenderizing, or mixing meat;
   - sausage-making;
   - sausage casings;
   - cleaning or working up intestines;
   - marking of meat;
   - extrusion of meat;
   - processing poultry; and
   - working up protein from meat.
3. Patents for meat preservation processes, for example:
   - preserving by heating;
   - irradiation;
   - drying;
   - smoking;
   - freezing/thawing;
   - preserving by inorganic salts, acids, or other chemicals; and
   - preserving with microorganisms or enzymes.

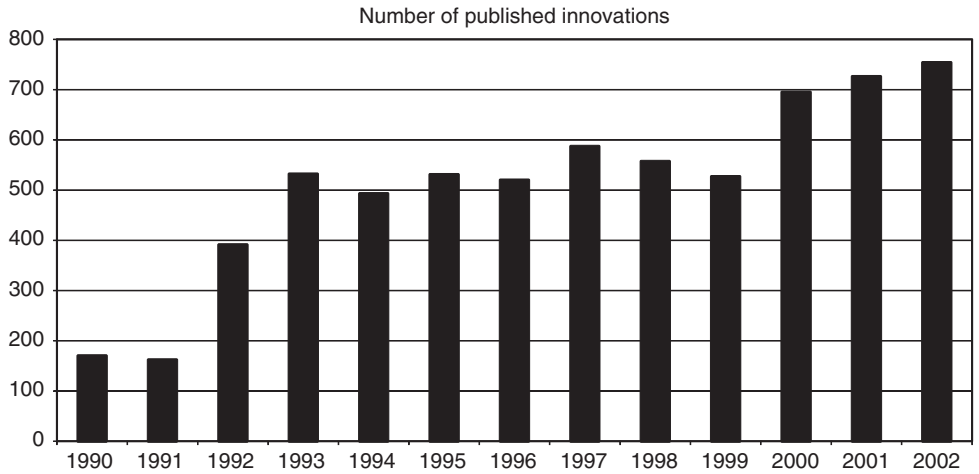

Figure 2 Inventions in the meat technology field registered in the *World Patents Index* from 1990 to 2002.

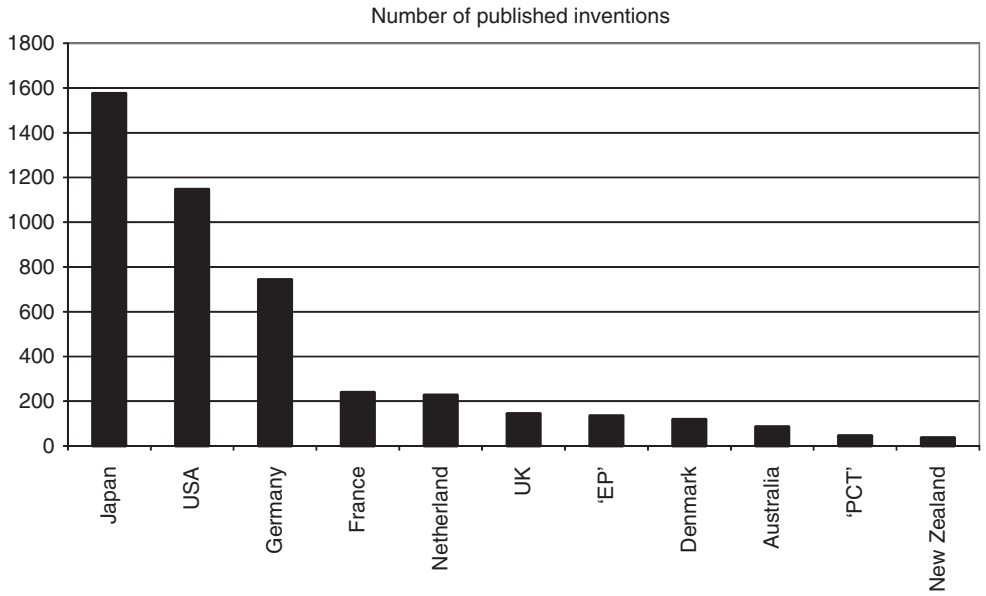

Figure 3 Country of priority for the 6645 meat technology inventions from 1990 to 2002.

4. Patents for meat products, for example:
   - meat meal, convenience food;
   - meat extract;
   - tenderized or flavored meat pieces; and
   - comminuted or emulsified meat products including sausages.

Also patented are methods and equipment for analysis, packaging and packaging methods, food additives, etc.

Activity in the different areas of meat technology is shown in Figure 4, where it can be seen that inventions are far more abundant in the areas of preservation and meat products. As in many other fields of technology, the inventions are typically for optimizing processes and apparatus, for example, to achieve greater cutting precision, simplified processes, improved quality sorting of meat, and easier cleaning, as well as products with improved shelf-life, taste, and appearance.

Examples of Patents

As mentioned earlier, to achieve patent status, an invention must be new and differ essentially from that which is already known (prior art). This means that the invention must comprise a novel technical feature (improvement on a product's properties) in relation to the known product, process, or apparatus.

The following gives a number of examples to illustrate the types of technical features necessary for obtaining a patent for an invention. The examples are divided into products, processes/methods, and apparatuses/devices. Note that the patents/applications in each of these categories may also contain other categories. Therefore, an application for a product can also incorporate the production method and the production apparatus/device. Patents for product use can also be included in the same application.

Products

Patented products are characterized by their composition, for example, providing improved taste, shelf-life, appearance, or texture, or easier and quicker handling of products, such as convenience products.

Low-fat meat product

There is an ever-increasing interest among consumers in food products containing less fat than products having a traditional, full-fat content. Unfortunately, merely eliminating the fat from minced meat food products results in a disagreeable chewy texture as well as a bland taste. There are many inventions in this area aiming to solve the problem, for example, an American patent describes low-fat minced meat products. The products comprise particles of minced meat and fat-like particles made of hydrolyzed milk protein gel particles. The low-fat products have much of the flavor, texture, and appearance of comminuted meat products that have a traditional full-fat content. The hydrolyzed milk protein gels can be combined with meat and processed into meat products using conventional techniques.

Low-fat meat product

An American patent describes a fat-free ham product. This product is made from whole muscle meat cuts and finely textured reduced fat meat combined with brine to give a meat product block. The product is not comminuted or minced, thus giving a more acceptable score at taste testing. Appearance and texture are more acceptable than in comminuted products.

Pizza topping

An American patent describes an uncooked meat product for topping pizzas. It comprises nuggets with a sealing layer containing denatured protein on its external surface and an uncooked central portion. The nuggets retain their shape, do not stick together, and have an improved texture.

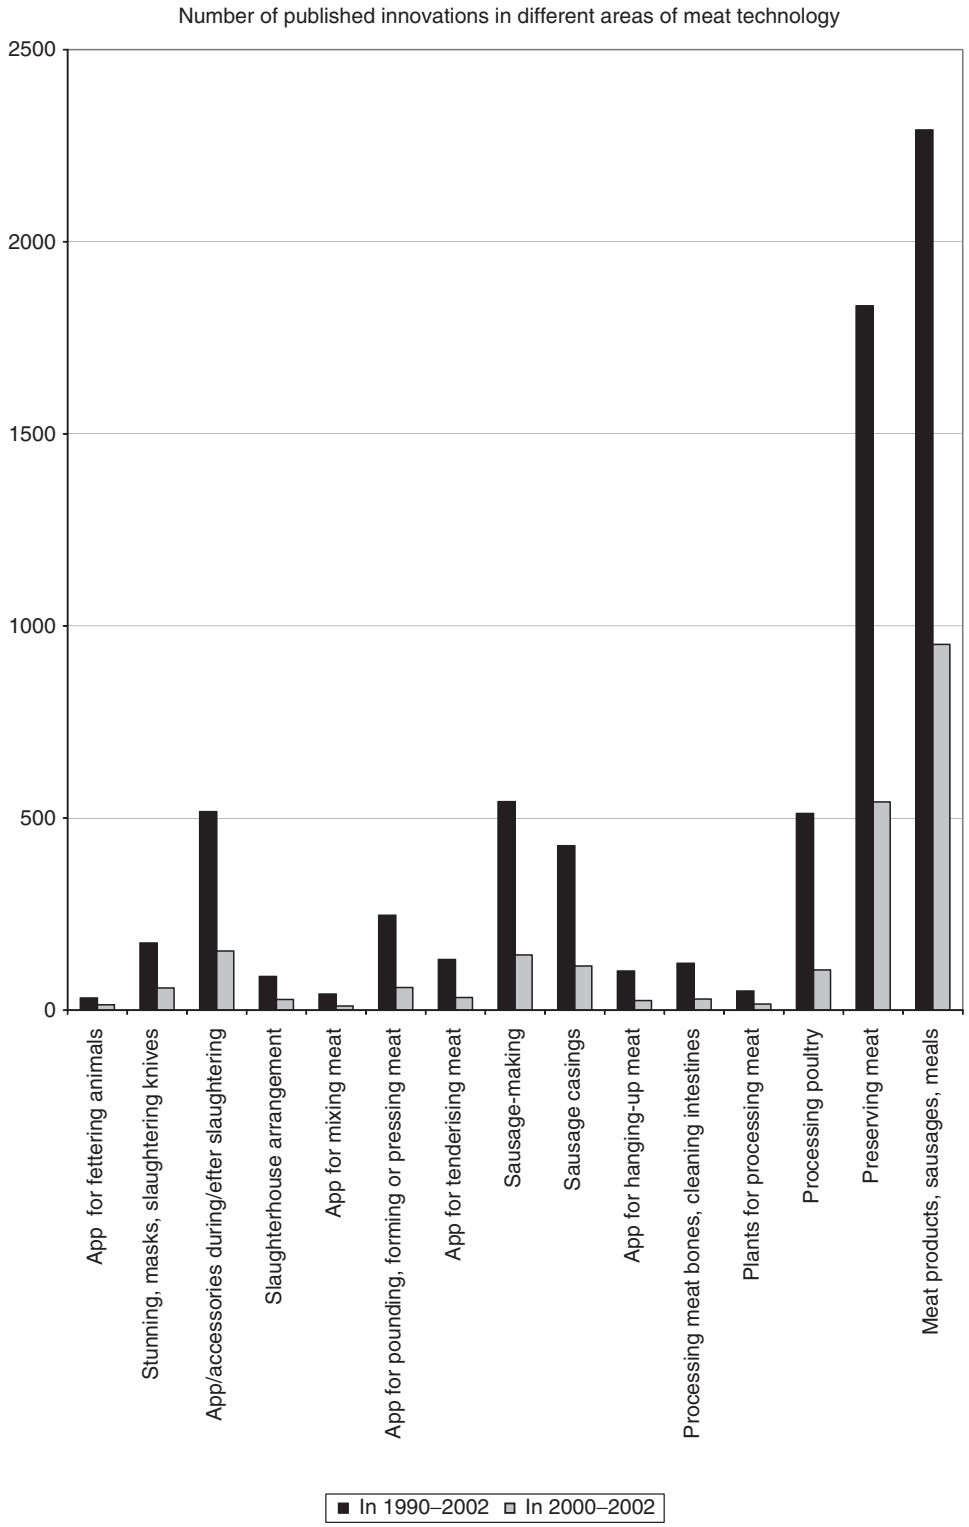

Figure 4 Distribution by area of meat technology of the inventions for the period 1990–2002 (**Figure 2**) and for the subperiod 2000–2002.

Composition for meat

A European patent describes a composition comprising an inorganic propionate salt and a bacteriocin from *Pediococcus acidilactici* and a method comprising inoculation of unspoiled processed meat at pH 6.0 to pH 6.5 using the composition. The composition inhibits the growth of spoilage bacteria in meats, allowing storage at temperatures above freezing. The propionate salts and bacteriocin do not impart any taste to the meat and the additives may be incorporated in a marinade or sauce that dresses a packaged meat.

The method/process and the apparatus for producing the product can also be patented, and can also be included in the same application as for the product.

Processes/Methods

Processes/methods are characterized as those steps that are necessary for achieving the desired technical effect, for example, in the form of a better product or quicker, simpler, or cheaper product production.

Preserving meat by microorganisms

During the past few years there has been increased attention to the occurrence of pathogenic germ cells in food. An international patent application describes a method and an apparatus for the production of sliced food, for example, meat products. During slicing, sufficient amounts of a preparation inhibiting the development of pathogenic germ cells are automatically added and spread onto the surface of the cut-off slices, which results in a product that is safe to use after having been stored for a considerable amount of time at refrigeration temperature. The preparation-inhibiting pathogens may comprise bacteria that are directly or indirectly, via a manufactured bacteriocin, effective against pathogenic germ cells, for example, listeria organisms.

Preserving meat by salts

The treatment and packaging of fresh meat has been a subject of intense research and development for many years. An American patent describes a method for packaging fresh meat. The fresh meat is treated with a predetermined amount of aqueous solution consisting of water, alkali metal lactate, and alkali metal diacetate microbial growth inhibitors in order to increase the weight of meat to approximately 125 wt% of its original weight. The treated meat is then packaged in a closed film package. The shelf-life, taste, tenderness, and freshness of the packaged meat are improved.

Preserving meat with high pressure

A German patent describes a process for production of stable meat and sausage products prepared in the presence of microorganisms, subjected to maturing and drying, wherein on reaching the desired pHs, the semifinished product is exposed to a high-pressure treatment at room temperature and then further processed in the usual way. The method is useful for fixing the pH. The high-pressure treatment kills microorganisms, insects, and parasites present in the product and inactivates enzymes without the formation of toxic components or off-odors.

Prefermentation of meat

A European patent describes the production of a fermented, protein-based meat product – comprising a prefermentation step to reduce the length of the subsequent fermentation. The starter culture comprises a mixture of *Pediococcus pentosaceus* and *Staphylococcus carnosus*. The fermentation step used is shorter without compromising the quality or microbiological safety of the product.

Sausage production

A European patent describes a method and an apparatus for coagulating sausage skins uniformly by spraying brine over extruded sausage as it passes down a serpentine conveyor. The sausage strand is not stretched during transport, and precise weight control is therefore possible. The time during which the sausage is exposed to the brine is precisely controlled, unlike the situation with known methods.

Ham production

A European patent describes a method and an apparatus for curing and cooking of hams without churning and tenderizing as the meat is vacuum-packaged and placed in stackable molds and vibrated. The churning and tenderizing stages of curing meat are replaced by vibrating, which greatly reduces the handling requirements, especially as the meat can be cooked and chilled while still in the molds.

Process for classification of meat

A German patent describes a visual imaging process for the evaluation of slaughtered pig carcass. In an imaging process to assess the distribution of meat, especially pork, within a slaughtered animal carcass, the image is fully assessed and evaluated solely using an electronic data processing system. The process provides reliable classification of the meat for retail purposes.

The product that is being produced by the new process and the apparatus can also be included in the same application as for the process.

Apparatus

Apparatus/device is characterized as the constructive means necessary for the apparatus/device to function as intended, i.e., a description of the precise structural form. This could, for example, be a new apparatus for a new product, or a simplified or in some way changed apparatus or parts thereof that facilitate, speed up, or enable continual production, facilitate cleaning, improve safety, fine-tune the process, improve hygiene, improve the fixing/holding of the product, etc.

Apparatus for evisceration

A European patent describes an apparatus for evisceration of carcasses, especially pigs. The apparatus cuts open the abdomen and breast, allowing the intestines to hang from the abdominal cavity before being separated from the carcass. The need for manpower and heavy work is reduced, and better hygiene is achieved than in traditional organ removal, whereby the connection between the pluck set and the intestines is cut through inside the carcass.

Cutter for splitting animals

A Dutch patent describes a cutter for dividing an animal carcass. The apparatus has a bracket positioning the carcass and a knife driven in a continuous movement to cut longitudinally through the bone. The device makes the carcass division proceed steadily and reliably, avoiding bone splintering, smearing, and cutter-jamming. Sideways displacement

of the cutter can be prevented and replacement of the cutter is easy.

Guide wheels

A European patent describes a guided cutter for dividing animal carcasses into two equal parts. The apparatus has guide wheels that pass either side of the outer surface of the animal's spine, keeping the cutter central with the spine. The guide wheels ensure that the carcass is cut into two symmetrical parts, each with an equal ratio of flesh to bone. The cutting operation can be carried out at high speed.

Sausage-cutting machine

A German patent describes a sausage-cutting machine for cutting strands, especially with natural gut skins, into individual sausages or sausage links. The cutting machine has cutting elements preceded by mold elements holding the sausages apart during cutting. The machine provides reliable cutting of sausages, independently of the link joint properties and without damaging the individual sausages.

Apparatus for antimicrobial treatment

A European patent describes an apparatus for antimicrobial treatment of animal carcasses with directed sheets of heated water. The apparatus comprises housing and two sets of distributing elements for dispensing water sheets downwardly and upwardly on top/under the carcass and systems for supplying water. The apparatus accepts carcasses of variable geometry without significant modification.

Markings for identification

A German patent describes identifying carcasses in slaughterhouses by applying machine-readable markings to abattoir hooks. The hooks can be machine-identified in a rational and inexpensive manner without the need for detachable reusable labels.

Product Use

Product use is defined as the product's specific intended purpose. However, patents for product use are rare in the meat technology field.

How to Prepare a Patent Application

A patent application must, apart from the formalities of name of applicant and inventor, contain the following:

- a title;
- a description of the invention;
- drawings or photographs where necessary to understand the inventions;
- a set of claims; and
- an abstract.

The application must only concern one invention.
The title must be short and specific.

The description must state the technical area with which the invention is concerned and the technique on which the invention builds. The invention must be explained in such a way that the technical problem and its solution can be comprehended, and it must be stated what, specifically, can be achieved by the invention based on prior art, and the means necessary for achieving this. The invention must be supported with examples, and should not be obvious from the nature of the invention, it must be stated how the invention can be industrially applied.

The claims of the patent must state concisely the technical features necessary to achieve the intended effect. There are two types of claims: independent and dependent. A dependent claim states the features that are additional to the features comprised in the independent claim. An application may contain several independent claims as long as there is technical unity between them. The independent claims can be of the categories: a product, a method of production, a production apparatus and a product use for a special purpose.

The abstract must be constructed in a clear and precise manner to cover the technical problem for which the invention has been designed, the method for solving the problem, and the scope of the invention.

The Patent Subsequent to Publication

Opposition

Once the patent authority has completed the examination of the application and the patent has been granted, the patent will be published. It will now be possible to file opposition against the patent within a period of no more than 9 months from the date of publication. Anyone, even the applicant, can oppose the patent, subject to payment of a fee. However, oppositions are usually filed by competitors.

Oppositions are filed in 10% of European patents and many of these lead to the patent being revoked, either in part or entirely.

Glossary

Absolute humidity Ratio of the mass of water vapour in the air to that of the other gases, expressed as kilogram moisture per kilogram dry air.
Dew point Temperature to which the air has to be cooled before moisture starts to condense out.
Frost point Temperature to which the air has to be cooled before moisture starts to freeze out as frost.
Humidity ratio See absolute humidity.
Relative humidity (RH) Ratio of water vapour pressure in the air to the saturation water vapour pressure at the same temperature, usually expressed as a percentage.
Water activity RH of air in equilibrium with a product with a given moisture content, usually expressed on a scale from 0 to 1.
Wet bulb depression Difference between temperature of the air and that of a wet surface.

Measurement of Humidity and Water Activity

What are Humidity and Water Activity?

Air humidity influences microbial growth, drying rate, evaporative weight loss, condensation, the heat load on cooling coils, the performance of dryers, and the comfort of workers. Air humidity can be expressed in several ways. Absolute humidity or humidity ratio is the ratio of the mass of water vapor in the air to that of the other gases, expressed as kilogram moisture per kilogram dry air (sometimes also as gram moisture per kilogram dry air or as ppm). Relative humidity (RH) is the ratio of water vapor pressure in the air to the maximum possible (saturation) water vapor pressure at the same temperature, usually expressed as a percentage. Humidity can also be expressed as dew- or frost-point, the temperature to which the air has to be cooled before moisture starts to condense out or freeze out, as the case may be. The relationships between these concepts are illustrated in Figure 1, where air at 25 °C and 60% RH is shown to have an absolute humidity of 0.012 kg kg^{-1} and a dew point of 16.7 °C.

The water activity (a_w) of a product is defined as the RH of air in equilibrium with that product. Conventionally, water activity is measured on a scale from 0 to 1 rather than 0–100%. Water activity measures the degree to which water molecules in the food are free and available to biological processes, rather than bound to other molecules. As such, water activity is a critical factor in determining the shelf life of

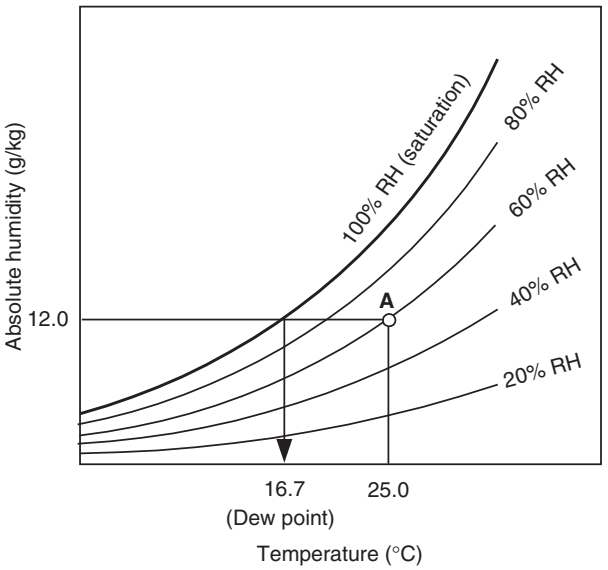

Figure 1 Relationships between dew point, absolute humidity, and RH.

 doi:10.1016/B978-0-12-384731-7.00075-1

foods. Most bacteria do not grow at water activities below 0.91, and most molds and enzymatic reactions cease at water activities below 0.80. The range of water activity of most interest to meat technologists is from 0.6 to 1. Fresh meat has a water activity close to 1, whereas below 0.6 most biological reactions cease.

Water activity also determines the transfer of moisture (by evaporation, absorption, and desorption) between different food components and between food and the air. In an isothermal environment, moisture always moves in the direction of decreasing water activity or RH, irrespective of the absolute moisture content. This is important to consider if meat is mixed with other ingredients.

Water activity measurement usually involves equilibrating the product in a small air space and then measuring the humidity of that air space. Water activity measurement will therefore be treated together with air humidity measurement.

A review in 1881 by Symons listed no fewer than 138 devices and methods for humidity measurement, and more have been invented since then. This article will review only the most common methods.

Types of Humidity Instruments

Psychrometers (wet and dry bulb thermometers)

A psychrometer consists of two thermometers, one of which is covered with a wet wick. The wet sensor will read a lower temperature owing to the cooling effect of the evaporating water. This 'wet bulb depression' is a function of the air temperature and humidity, and can be converted to a humidity reading by using a psychrometric chart.

The psychrometer is inexpensive and very popular. It is rather inaccurate at low temperatures, where wet bulb depression tends to be small. Using thermopiles to multiply the temperature difference signal can overcome this drawback, even at subzero temperatures. In general, for reliable results, the following precautions must be taken:

- The wick and water must be clean and free of solute. To ensure this, the wick can be boiled in water for several minutes.
- The wick must be completely wet but not dripping.
- There must be sufficient air velocity (3 m s^{-1} or more) over the wet bulb. In still air, a fan is used or the thermometer is whirled manually.
- The sensors must be shielded from thermal radiation.
- The air must be clean and free of volatiles that may condense on the sensors.

Psychrometers are obviously not suitable for measuring food water activity owing to the requirement for a high airflow over the sensor.

Salt dew cells

These are also called thermoelectrolytic sensors or Dunmore sensors. A cloth impregnated with a hygroscopic (strongly moisture-absorbing) salt is heated by passing an electric current through it. When the salt's dew point temperature (the temperature to which it has to be heated before it stops absorbing moisture from the air) is exceeded, the cloth starts to dry and its electrical resistance increases. This causes the electrical power to fall (according to $P=V^2/R$) and the cloth starts to cool, causing moisture to be absorbed and electrical resistance to fall. Eventually the system comes to equilibrium and its temperature is then equal to the salt's dew point, which is related to absolute humidity (Figure 1).

Because these instruments have a simple control circuit and need no cooling, they are robust and relatively inexpensive. An accuracy of approximately 0.5–1 °C is usually obtainable. Salt dew cells are usable over the dew point range −40 °C to +70 °C, but their response is slow at low temperature (up to 30 min). It is important to ensure that the cloth is clean and free of solutes other than the salt being used. At high air velocity, a windshield has to be used to avoid excessive cooling and temperature gradients in the probe. If current to the sensor is cut off for half an hour or more, water may condense on the cloth and drip off, leading to loss of salt and corrosion problems. Salt dew point instruments are not used in water activity instruments owing to their heating effect.

Capacitance and resistance hygrometers

Capacitance and resistance hygrometers measure the variation in the capacitance or resistance of a material (such as metal oxides or polymers) with the amount of absorbed moisture, itself a function of RH of the air. These hygrometers, therefore, give a reading of RH. They are relatively inexpensive and are widely used in industry. Their accuracy varies from approximately 1–3% RH depending on model and RH range. Exposure to high RH (more than 95%) may affect their calibration but in any case they should be regularly calibrated. Capacitance and resistance sensors can be used in water activity instruments.

Chilled mirror dew point meters

These instruments have a mirror that is cooled until dew or frost forms on it. This is detected by a change in the intensity of a reflected light beam. An electronic controller maintains the mirror at the dew or frost point. Chilled mirrors use a very fundamental and stable measurement principle and the best models are very accurate, though rather expensive. Their accuracy can be as good as 0.1 K dew point. When used for water activity measurement, this would lead to errors of approximately 0.005 in a_w for most meat products. Less well-built models have a greater temperature measurement error for the dew point and may also have systematic errors owing to temperature gradient in the mirror.

Larger errors might be introduced by soluble impurities on the mirror (e.g., salt solution may have been splashed on it during calibration) and its cleanliness should be checked. In the range of approximately −20 to 0 °C, there may be uncertainties as to whether the mirror is covered with frost or (supercooled) dew; for example, if air at 0 °C is being monitored with a chilled mirror instrument and a reading of −10.0 °C is obtained, this could indicate an RH of 42.5% or 46.9%, depending on whether frost or dew has formed on the mirror.

Direct dielectric measurement

If the air being measured is hot and moist (as in most dryers), the moisture in it can be measured directly by a capacitance

instrument without first absorbing it into a solid sensor (as in most capacitance hygrometers). The Dewcon humidity meter uses this principle. The gas is filtered through a self-cleaning membrane and passed between two capacitor plates. The instrument is claimed to be linear, drift free, and resistant to dust.

Selection of Hygrometers

The price, performance, and application range of hygrometers, including water activity instruments, vary widely, and it is important to select one that is suited to the application and the budget. The user should ask the following questions:

1. What is the purpose of measuring humidity/water activity?
2. What are the temperature and humidity ranges likely to be encountered?
3. What is the most important variable: dew point, absolute temperature, or RH?
4. What accuracy is required?
5. How maintenance-free should the instrument be? How frequently can calibration be done?
6. Are there special environmental problems, such as dirt, solvent-rich atmosphere, high or low pressures, or widely fluctuating temperatures?
7. Is continuous monitoring required?

At this time, capacitance and resistance sensors are the most widely used industrial hygrometers. Chilled mirrors occupy the top-of-the-range position, but their limitation in the dew point range immediately below 0 °C owing to dew/frost point uncertainty must be kept in mind. In any case, all hygrometers should be regularly calibrated.

Using Hygrometers to Measure Air Humidity

Sensors that measure RH directly (e.g., capacitance and resistance sensors) should be put directly in the air to be measured. Those that measure dew point (salt dew cells, chilled mirrors) or wet and dry bulb temperatures can be used on air sampled via a tube, because changes in air temperature will not affect their reading. If air is sampled in this way, the following must be kept in mind:

- The tube should be made of nonmoisture-absorbent material. Stainless steel, glass, and nickel alloys are best, but polyethylene or Teflon is acceptable at higher dew points. Most other plastics or rubber should be avoided.
- Air tightness is essential when the system is at neutral or negative pressure.
- To avoid condensation, the air sample must not be cooled below its dew point at any point.
- Large pressure drops in the sampling line should be taken into account.
- The air velocity requirements of wet and dry bulb psychrometers and salt dew cells must be satisfied.

Using Hygrometers to Measure Water Activity

Because a_w sensors actually measure the humidity of the air surrounding both sample and sensor, the main problem is in ensuring that temperature and humidity of sample, air, and sensor are the same, i.e., equilibration is as complete as possible. At 25 °C and 0.9 a_w, a temperature difference of 0.1 K between sensor and sample will cause an error of 0.005 in a_w. As far as possible, the sensor must be surrounded by sample and there must be no leakage from the chamber containing both. For faster response, the volume of the measuring enclosure must be as small as possible and the product should occupy a significant fraction of the enclosure's volume. Some a_w meters have a small fan that circulates air in the chamber (Figure 2), but even this may not guarantee equilibration in the air. Equilibration of the product is another limitation, because the diffusivity of water in meat is very slow, of the order 10^{-10} m^2 s^{-1}. It may take up to an hour or more for a_w in meat as thin as 1 mm to equilibrate. Thus, if a reading is taken within a few seconds, it will be the a_w at or near the surface that will be obtained. This effect may be used to advantage if it is the surface value of a_w that is wanted (e.g., when surface microbial growth at the surface is the main concern, as it is for carcass meat): a sensor contained in a cup that is pressed against the meat surface will give a reading of the surface a_w within a few seconds.

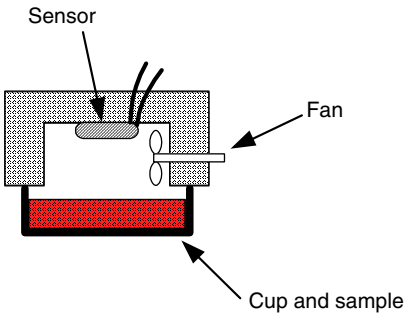

Figure 2 Water activity (a_w) measuring chamber.

Calibration of Hygrometers

For best results, the calibration of hygrometers should be checked immediately after the instrument is purchased and then at least annually. This is particularly important for instruments that rely on changes in the resistance, capacitance, or other physical properties of the sensor.

Salt solution method

The most common way to calibrate hygrometers is to put the sensor in a flask over a saturated solution of a salt for which the moisture sorption isotherm is known. Equilibration can be slow, and complete airtightness must be ensured. Several salts can be used to cover the whole range of RH. To ensure that the solution is saturated, some solid particles must be observable. Nonsaturated salt solutions can also be used if changes in concentration can be avoided. Users can make their own calibrating flasks, but to obtain good results and quick equilibration, the flasks must be as small as possible, leakage must be minimized, and the sensor must be as close to the solution as possible. Extreme care must be taken to ensure that

the solution does not splash on the sensor. Most hygrometer manufacturers supply a range of calibrating cells.

Two-pressure RH generator

In this method, air at high pressure is saturated by bubbling it through water, and then expanded to a lower pressure. If the air temperature is constant, the RH obtained is the ratio between the two pressures.

Dew- or frost-point generator

Air is saturated by bubbling it through water or columns of crushed ice, and then heated and passed over the sensor.

Chilled mirror dew point meter

Because it uses a fundamental measurement principle, a good-quality chilled mirror dew point meter can be used as a secondary standard for calibrating other sensors.

Measurement of Product Moisture Content

Product moisture content can be measured in kilogram water per kilogram wet product, kilogram water per kilogram dry product, or any multiple of these. Although there are very accurate analytical methods for moisture measurement, this article will consider only common industrial measuring instruments.

Gravimetric Method

Modern computerized moisture balances will weigh a sample, dry it under an infrared lamp, and reweigh and display the moisture content. They are more expensive than hygrometric instruments but are not subject to calibration changes owing to variations in composition or temperature.

Water Activity Meters

All a_w meters can be used for measuring product moisture content because the a_w of a given material depends on moisture content and temperature. This relationship is termed the 'sorption isotherm' of the material. An example is shown in Figure 3. A calibration of reading versus moisture content, the latter being measured with the gravimetric method, must be carried out. The sorption isotherm can also be obtained by a dedicated method such as a dynamic vapor sorption instrument. For best results, certain conditions must be fulfilled:

- The product composition must be reproducible.
- The temperature must not vary too much (normally, isotherms are not greatly affected by a few degrees' variation)
- The moisture content must be in a range where a_w is highly sensitive to moisture content. For fresh meat, a_w changes very little with moisture content in the range 0.9–1.0 a_w, and therefore moisture content cannot be measured by this method for that range (Figure 3). However, for dried meat or meat meal, a_w is highly sensitive to moisture content.

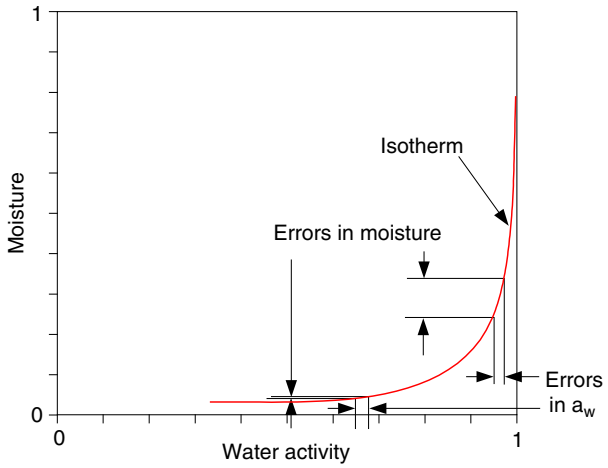

Figure 3 Typical isotherm for fresh meat and errors in using a_w to measure moisture content.

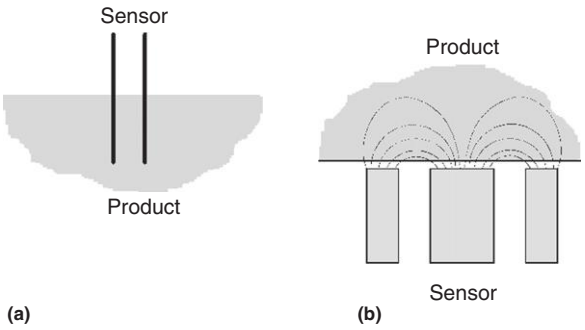

Figure 4 Dielectric moisture sensors: (a) immersed; (b) external.

Dielectric Moisture Sensor

Water molecules are highly polar and tend to reorient themselves in an alternating electromagnetic field. This principle can be used to directly measure the moisture content of foods. The basic sensor consists of an electrode transmitting a radio frequency electric field and a sensing electrode. Both electrodes may be inserted into the product or be outside the product for noncontact measurement (Figure 4). The electric field is wholly or partly immersed in the product and is affected by its dielectric properties. The moisture content being measured is averaged over the domain of electric field, not necessarily the bulk value, and hence the reading is reliable only if the moisture content is uniform.

Microwave absorption instruments are a subclass of dielectric sensors. A microwave transmitter is positioned on one side of the product and a sensor on the other, and the attenuation of the microwave beam by water is measured. Microwave attenuation measures the average or bulk moisture content of the product. Measures should be taken to minimize the effect of scattering and reflection of microwave by the product and surrounding objects, as well as variations in product temperature, composition, thickness, and shape. Microwave absorption works best when the thickness of the product is constant and much smaller than other dimensions, such as with sheet materials or layers of particles.

Near-Infrared Reflectance

A near-infrared beam is shone on the product and the reflected light is analyzed for absorption in certain wavebands owing to water. These instruments measure only surface moisture. For best results, the material should be in powder or flaky form. In a high-humidity environment, accuracy might be affected by infrared absorption by water vapor in the air. Dust or condensation must be avoided.

Determining Moisture Content from Product Temperature

When food is heated by hot air, its temperature will vary between the wet bulb and dry bulb temperature of the air, whereas if it is heated by contact with a hot surface, its temperature will be governed by the boiling point elevation relationship. The higher the moisture content, the lower the product temperature (owing to evaporative cooling); hence, other things being equal, temperature will give an indication of moisture content. This method will work only if

- operating conditions are similar to those under calibration conditions,
- the product is communited and well mixed, so that temperature is uniform, and
- material composition remains constant.

Measurement of Air Velocity

Types of Anemometers

Air velocity sensors in common use include Pitot tubes, mechanical anemometers, thermal anemometers, ultrasonic anenometers, and Laser Doppler anemometers (LDA).

Pitot tubes

Pitot tubes (Figure 5) measure the pressure difference owing to the kinetic energy of the moving gas. The Pitot tube is pointed directly against the airflow so that air impinges on a hole at the tip of the tube. Immediately in front of the hole, the air is stationary and its pressure increases as a result of the conversion of kinetic energy to pressure. Other holes on the side of the tube measure the static pressure. Velocity is related to the pressure difference by eqn [1].

$$v = C\sqrt{2\Delta P/\rho} \qquad [1]$$

where ρ is the gas density in kilogram per cubic meter, ΔP is measured in Pascal, and C is a constant ranging from 0.98 to 1.0. The pressure difference is very small at low air velocities. At $v = 1\ \mathrm{m\ s^{-1}}$ it is only 0.6 Pa or approximately 0.06 mm of water. The resolution of a Pitot tube therefore depends on what is used to measure the pressure difference. An inclined U-tube can at best be read to a few tenths of a mm (1 Pa), whereas micromanometers have resolutions down to 0.1 Pa or less. Pitot tubes are therefore not useful at low air velocities.

Pitot tubes are inexpensive and do not need calibration. They are highly directional instruments (they should be aligned to within 5°) and can be used only when the airflow direction is well defined and accurately known, as in pipes and ducts.

Mechanical Anemometers

Mechanical anemometers measure the rotational speed of vanes or cups driven by the wind. Because of static friction, they only operate at air velocities above approximately 0.2–0.3 $\mathrm{m\ s^{-1}}$. Vane anemometers (Figure 6) are highly directional. As with all mechanical devices, they should not be subject to shock, dust, etc. that may affect bearing friction. Cup anemometers (Figure 7) consist of three or more cups mounted symmetrically about a vertical axis. They are insensitive to airflow direction as long as it is horizontal, and are therefore widely used in meteorological measurements.

Thermal Anemometers

Thermal anemometers measure the cooling effect of airflow over an electrically heated sensor. There is a vast difference in price and performance between laboratory thermal anemometers and industrial models, this article being only concerned with the latter. Thermal sensors come in several shapes: hot wire, hot film, or hot bead (Figure 8). A hot wire sensor consists of a very thin wire made of a noble metal such as platinum or tungsten, tensioned between two metal prongs. A hot film sensor consists of a thin film of a noble metal usually

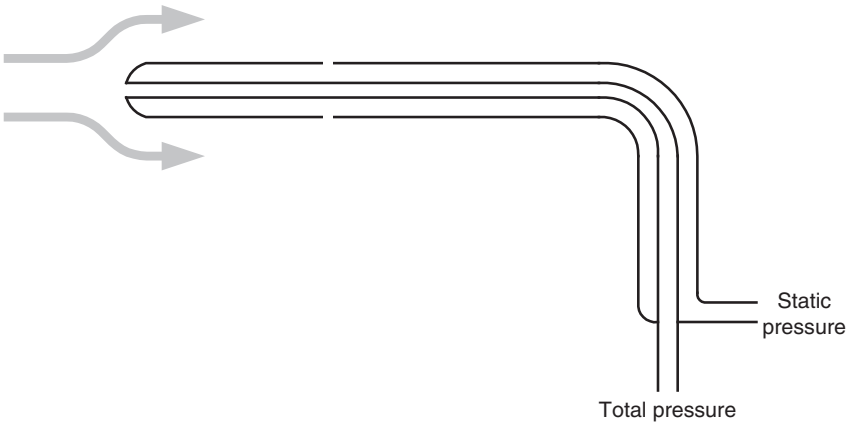

Figure 5 Pitot tube.

Figure 6 Vane anemometer (TSI Inc.).

Figure 7 Cup anemometer.

deposited near the tip of a thin ceramic probe. A hot bead sensor usually consists of a thermistor because of the requirement for high resistance in spherical shape.

Thermal anemometers are better at low velocities than vane anemometers. Good instruments will provide temperature compensation to ensure that the calibration is independent of air temperature. Hot wire and hot film sensor readings are dependent on airflow direction, whereas hot beads are almost omnidirectional, except when a probe component is in the way. All thermal anemometers are affected by turbulence in the air, which increases the cooling rate.

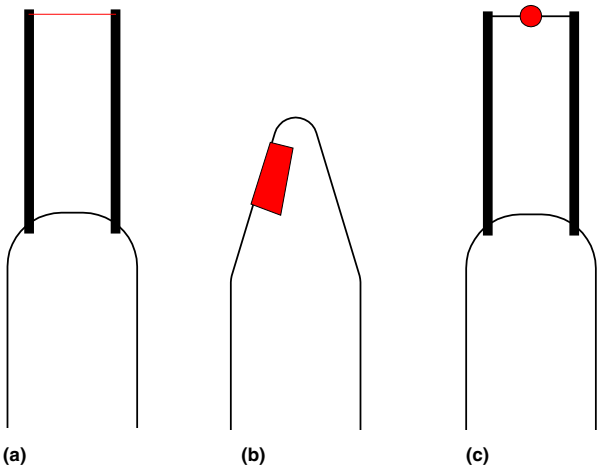

Figure 8 Thermal anemometers: (a) hot wire; (b) hot film; (c) hot bead.

Ultrasonic anemometers

Ultrasonic anemometers measure the effect of wind on the speed of sound traveling between a pair of transducers. By using three orthogonal pairs of transducers, they can measure all components of velocity. Some models can measure air turbulence as well as mean velocity. These anemometers are robust, do not suffer calibration shift, have no moving parts, and can measure quite low velocities (0.01 m s^{-1}). They are still fairly expensive but are gaining popularity, especially in meteorological applications.

Laser Doppler anemometers

LDA use two laser beams that intersect to create a fringe pattern. As a micron-sized particle passes through these fringes, the scattered light from it fluctuates in intensity. The frequency of this fluctuation is measured with a photodetector and converted to particle velocity. Laser Doppler systems are very accurate and can measure very low velocities, down to a few millimeter per second, but they are very expensive and require expertise as laser beams are dangerous to handle.

Practical Guidelines in Using Anemometers

To measure airflow from a fan, coil, or in a duct, several readings must be taken to take into account the nonuniform airflow profile. The flow cross-section area should be divided into several equal subareas. How this is done depends on the geometry of the flow. In a pipe, the variation is mainly in the radial direction and the cross-section should be divided into annuli of equal areas. A rectangular duct or a coil face can be divided by a rectangular grid. Air capture hoods and airflow horns are devices that, in combination with an anemometer, will give the total flows from diffusers, fans, etc.

When the airflow direction is not well known, a nondirectional instrument such as a bead-type thermal anemometer should be used.

In fluctuating flow, modern instruments often have an integrating or averaging capability to give a steady reading. Most thermal anemometers, however, will give high readings in strongly turbulent flow.

All mechanical and thermal anemometers will be adversely affected by dirty or corrosive environments. In such cases, a noninvasive method such as ultrasonic measurement is recommended.

Low air velocities are difficult to measure. Many manufacturers specify a range from 0 m s^{-1} upward for their thermal and mechanical anemometers, but readings below 0.2 or 0.3 m s^{-1} (depending on the model) are unreliable. If it is absolutely necessary to measure at these low ranges, an ultrasonic anemometer or Laser Doppler system may be necessary.

Calibration of Anemometers

Pitot tubes use a fundamental physical principle and do not need to be calibrated. Mechanical and thermal anemometers are usually calibrated in wind tunnels that are carefully designed to give very low turbulence and a flat velocity profile. The air enters via a bellmouth and several turbulence-reducing devices with mesh screens and honeycombs. After the measuring section, the flow is channeled into a smaller tube where the velocity is increased and measured with an accurate flowmeter. Such equipment is not widely available, although some models are now sold commercially and, therefore, anemometers must usually be calibrated professionally in scientific laboratories. For best results, calibration should be checked immediately after the instrument is purchased and then annually thereafter, or more frequently if in heavy use.

Glossary

Electromotive force (Emf) Voltage generated by a circuit.
Ice point Freezing temperature of water.
PRT Platinum resistance thermometer.
Stem error An error due to conduction along the stem or lead wire of a temperature sensor.
Stray voltage Unexpected or undesired voltages caused by imperfections in the electrical circuit or exposure to electrical fields.
Thermal center The location in an object where temperature change is slowest during heating or cooling.

Types of Thermometers

Liquid-in-Glass (or Liquid-Filled) Thermometers

Liquid-in-glass thermometers consist of a glass bulb attached to a glass stem containing a narrow bore channel. As temperature rises, the liquid expands and rises along the channel. It must be borne in mind that, when temperature rises, both the liquid and the glass containing it expand to different extents. Good quality thermometers are constructed of high-quality glass that has been properly annealed to avoid changes in volume after manufacture. Precision liquid-in-glass thermometers may be designed for total immersion or (more commonly) partial immersion, and it is important that the correct immersion mode is used, because they have been calibrated in that mode.

Liquid-in-glass thermometers can lose their calibration when exposed to very high temperatures due to changes in the volume of the bulb, which may not relax back to its original dimensions. Liquid-filled thermometers also tend to have large response times, corresponding to the time it takes for the liquid in the bulb to equilibrate. Another limitation is the size and shape of the bulb, which means that measurement of surface temperature, for example, is not very accurate. Also, liquid-in-glass thermometers must be read by eye and do not produce an electric signal. Safety is a concern because they break easily.

Owing to these disadvantages, liquid-in-glass thermometers are not widely used in industry, except in a laboratory environment.

Thermocouples

When two dissimilar metal wires are joined, the difference in the energy levels of the electrons in each metal causes electrons to migrate from one metal to the other and a voltage (EMF) develops. This voltage is dependent on temperature. When a circuit is formed by joining the wires at both ends (Figure 1), providing the junctions are at the same temperature, equal but opposite EMFs appear at the two junctions and cancel each other. However, if one junction is hotter than the other, the EMFs will be of different values and a net EMF will develop in the circuit. If the temperature at one junction is known, the other junction's temperature can be found from the circuit voltage by using a conversion equation, reference table, or chart specific to the two metals used.

Several types of thermocouple material pair are in common use, each identified by a single letter: T (copper/copper–nickel), J (iron/copper–nickel), K (nickel–chromium/nickel–aluminum), and so on.

In practice, thermocouple circuits are seldom as simple as shown in Figure 1. To be able to use thermocouples correctly in a variety of situations, a number of 'laws' have been proposed but the most important one to remember is: "A homogeneous piece of wire of any material inserted into the circuit will not change the EMF, if the two ends of this wire are at the same temperature."

An application of the above law is in the use of compensating or extension wires. Ideally, there should be only two metal wires in a thermocouple circuit. However, often the measured temperature is far away from the voltmeter, and it would be prohibitively expensive to use high-quality thermocouple wires all through. In such case, wires of lower quality and cost may be used (Figure 2). These wires, A' and B', are usually made of the same materials as the instrument wires A and B, but to less stringent standards. As long as the temperatures at the terminal blocks 1 and 2 are not very different, the error introduced will be negligible.

A thermocouple only measures the temperature difference between two points. To determine the actual temperatures, that of at least one point (known as the reference junction) must be known. In Figure 3, the reference junction is kept at a known temperature, such as a mixture of ice and pure water (0 °C). This is the most accurate method for measuring temperature with a thermocouple. To measure several temperatures, the circuit of Figure 4 is used. All the wires made of

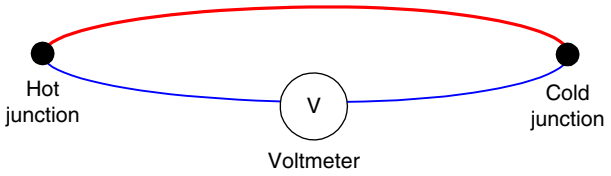

Figure 1 Basic thermocouple circuit.

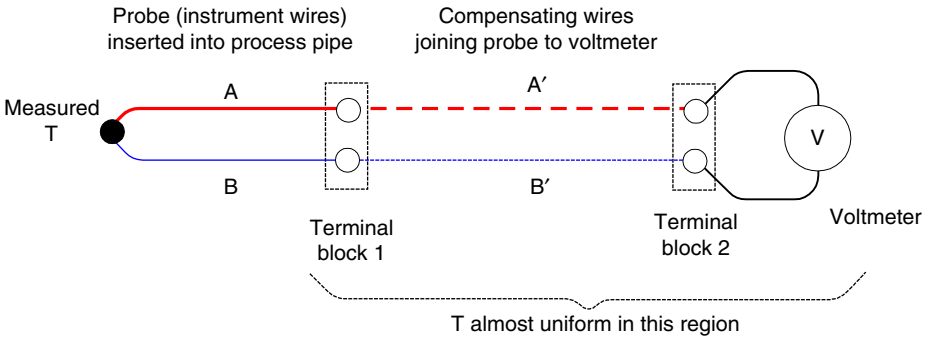

Figure 2 Using compensating wires.

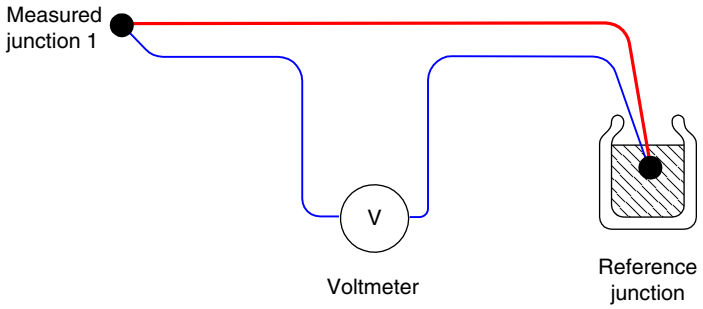

Figure 3 Measuring temperature with thermocouples and external reference.

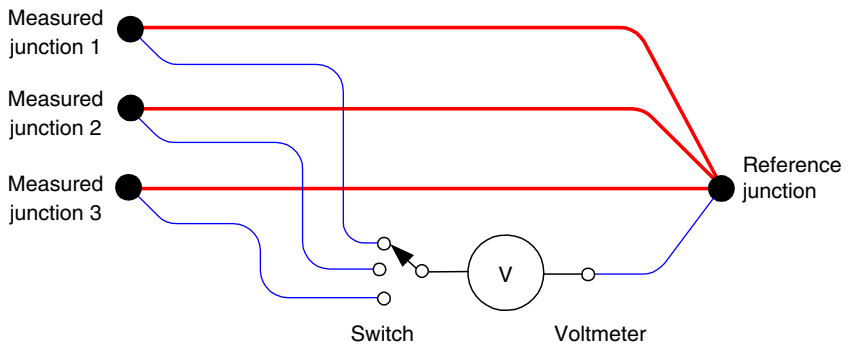

Figure 4 Measuring multiple temperatures with external reference.

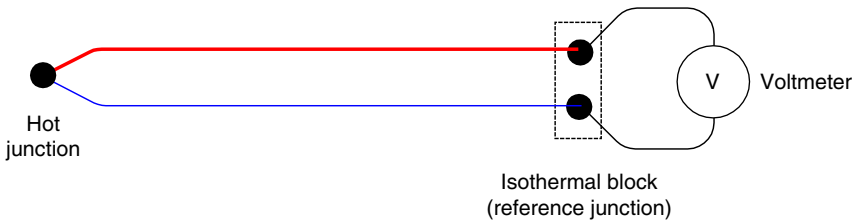

Figure 5 Measuring temperature with thermocouples and internal reference.

material A are joined together at the reference junction, and a single wire of material B connects this junction to a voltmeter. The voltmeter is connected to any of the measured junctions via a selector switch, which may be manual or automatic (automatic switching is standard in commercial dataloggers).

Modern instruments often have internal temperature compensation, which dispenses with the need for an external reference junction (Figure 5). The two ends of the dissimilar thermocouple wires are connected to an isothermal connector block in the instrument, which serves as the reference junction.

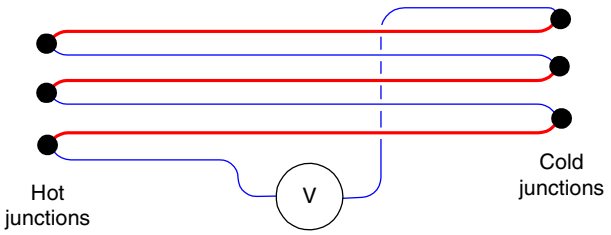

Figure 6 Thermopile.

The temperature of this connector block is measured with, for example, a thermistor, and the instrument computes the temperature of the hot junction from the voltage difference. However, this method is less accurate than using an external reference junction, due to uncertainty about the temperature of the connector block.

In some applications, such as when measuring wet bulb depression or heat flux, one may be more interested in measuring 'temperature differences' rather than temperature. Thermocouples are ideally suited for this. For measuring very small temperature differences, a 'thermopile' made of several pairs of junctions connected in series can be used. The voltage will be multiplied by the number of thermocouple junction pairs present; thus the voltage obtained from the six-junction circuit of Figure 6 is three times that of a single pair. It is vital that the junctions are electrically insulated from each other.

Thermocouples are widely used because of their low cost, robustness, wide range, and flexibility. They are sufficiently accurate for most industrial purposes but can also be used for high-precision measurements. An inherent error in thermocouples is due to the variation in the composition of the wires and this is given in the manufacturer's specification. However, there are many other possible sources of errors that should be taken care of:

1. Reference junction error: In single-junction instruments, the temperature of the terminal block is used as reference temperature. The accuracy then depends on how isothermal the terminal block is and how its temperature is measured. Typically, a 0.5–1 K error is involved. Sometimes the reference temperature sensor can be several centimetres away from the terminal block and the error can be higher (this happens in dataloggers with long arrays of terminals). External references using an ice point can be much more accurate, but this depends on the experience of the user (see Calibration and Use of Thermometers).
2. Short circuiting between different parts of the thermocouple circuit, or between the thermocouples and the electrical ground of the measuring instrument. If there is any possibility of this happening, the junctions must be coated with an electrically insulating coating.
3. Electromagnetic interference causing stray voltage.
4. Changes in sensitivity caused by aging of the thermocouple wires.
5. Stresses in the wires (kinking, work hardening), which cause local changes in composition.
6. Using low-grade (compensating) wire in a highly non-isothermal environment. Compensating wires should be used only if no significant temperature variation is expected along these wires.

Resistance Thermometers

There are two types of resistance thermometers: pure metal resistance thermometers and thermistors.

The platinum resistance thermometer (PRT) is the most well known and accurate of the first type. The resistance of a pure platinum wire increases almost linearly with temperature (the temperature coefficient specified in international standards is 0.385% per Kelvin; however, it should always be checked with the manufacturer). In the past, a Wheatstone or Mueller bridge was used to measure the resistance. Modern instruments measure resistances by sending an accurately known electric current through the sensor, and measuring the voltage across it. For maximum accuracy, a four-wire connection must be used (Figure 7). Two of the wires carry the current, the other two connect the ends of the sensor to a high impedance (low current) voltmeter. If the sensor is close to the voltmeter, or if high accuracy is not needed, a two-wire connection can be used (Figure 7). The resistance measured will then be that of the sensor plus those of the lead wires, which will decrease accuracy. Another source of errors in using a PRT is ohmic heating by the measuring current. If the PRT is in good thermal contact with the product being measured, this may not matter but, if thermal contact is poor (e.g., if the sensor is in still air), the error may be more significant – although still small in most cases. PRTs are highly accurate and stable but costly.

Thermistors come in various sizes and shapes and are usually made of some semiconducting material. Their advantages over PRTs include lower cost, smaller size, and much higher sensitivity (several percent per Kelvin). The accuracy and stability of thermistors vary, but the best models can be comparable to those of PRTs. They have high resistances (thousands of ohms, vs. 100 Ω for standard PRTs) and large temperature coefficients, so that a simple two-wire measuring circuit can be used (Figure 7b). They are very nonlinear and require linearizing hardware or software; however, that is not a big problem these days. They should not be exposed to high temperatures. Thermistors are widely used in hand-held industrial instruments and miniature loggers. Thermistors are not as highly standardized as PRTs, so it is important to use the correct hardware, calibration curve, or equation, as supplied by the manufacturer. As resistive devices, they are subject to the same self-heating problem as PRTs.

Infrared Thermometers

Infrared thermometers measure temperature by sensing the infrared radiation emitted by a surface. For a given surface, the amount of radiation, I, increases with temperature according to Plank's equation, $I = \sigma\varepsilon T^4$, where σ is Plank's constant, ε the surface's emissivity (which can have a value between 0 and 1), and T the absolute temperature. Surfaces differ in their emissivity and emission spectrum; therefore, the infrared sensor must be calibrated for each product surface. The surface can be coated with a paint or tape of known emissivity to ensure reproducible readings. Unwrapped meat and other unwrapped

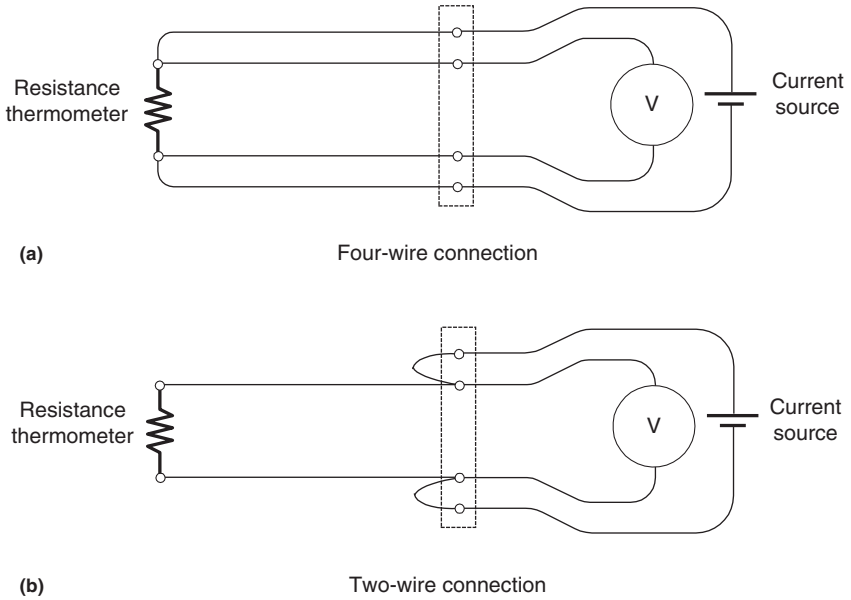

Figure 7 Connecting resistance thermometers.

foods usually have high emissivities (above 0.9), which make them suitable for infrared measurement.

The sensitivity and resolution of infrared thermometers fall off at low temperatures. Most models have a lower limit of −20 or −30 °C, although some will work down to −50 °C, whereas upper limits of up to 400 °C are common. At a low temperature, the error may be ±2 K or more. In view of the difficulties in measuring true surface temperature by other means (location errors and stem errors), this is not as bad as it sounds.

Errors arise when changes in emissivity are not taken into account, for example, when a surface fogs up as it cools below dew point. Smoke, dust, and vapors in the atmosphere can also affect the reading. For wrapped product, it is the wrapping's temperature that is read, even if it is optically transparent. With low-emissivity surfaces such as polished metal, reflected radiation may cause large errors.

There is a wide range of infrared sensors in the market, differing in size, capabilities, and cost. Technical factors that should be considered in purchasing a unit include accuracy, range, response time, emissivity adjustment, distance to target size ratio, availability of a targeting aid such as a laser spot, and portability. Instruments with wider temperature ranges and which can focus on smaller targets at larger distances will be more expensive.

For accurate measurement, the infrared thermometer should be aimed perpendicular to the surface. The field of view must be adjusted to avoid viewing unwanted areas. The thermometer itself should not be exposed to subfreezing temperature.

The advantages of infrared sensors are as follows:

- They are noninvasive – no hole drilled, no damage to wrapping, no contamination.
- There is no contact with food, hence no danger of contamination of the food or risk of burns in the case of very hot surfaces (e.g., charcoal, cooked meat, hot soup).
- They can be used to scan the surface quickly and locate hot or cold spots. Thus, they can be used for scanning product in a cold room or a retail display, or hot spots on the wall of a cold store, which indicate heat leaks.
- They can measure the temperature of objects that are moving or vibrating.
- They can measure very high temperature (e.g., burning charcoal).
- Their field of view can be adjusted (like a camera lens) for a small or large target area.
- They can read the true surface temperature of meat and other surfaces, unaffected by location errors or stem errors as with other instruments.

Bimetallic Thermometers

Bimetallic thermometers consist of two strips of metals with different thermal expansion coefficients, joined side by side. When the temperature changes, differential expansion causes the strips to bend. For increased sensitivity, the bimetallic strip may be formed into a coil or spiral. Bimetallic thermometers are not particularly accurate (typically ±1 K to several Kelvin), but they involve no electrical parts, hence they are robust and popular as cooking indicators, oven indicators and thermostats, and freezer thermometers.

Thermochromic Materials

Thermochromic materials, whose color changes with temperature, are used as temperature indicators in the food industry. There are two basic types, liquid crystals and leuco dyes, the former being more sensitive and accurate. Thermochromic indicators are available as dyes, inks, paints, paper, tapes, sticky labels, and so on. The color change may or may not be reversible. Some materials change color at a sharp temperature and can only be used as single temperature

indicators, whereas others (known as thermochromic materials), such as some liquid crystals, go through a range of colors as temperature changes and can be used for quantitative measurement.

Color change sensors can be used as disposable temperature indicators with respect to some critical temperature. Sensors that change colors irreversibly are used to detect and record temperature abuse in packaged foods during storage and transport, or to indicate that a cooking or sterilization process has reached a specified temperature. Color change materials usually measure surface temperature but have also been used in cooking probes to indicate when meat has been properly cooked.

Temperature Logging

Data loggers are widely used in industry to collect data on the cold chain. The data are stored in nonvolatile memory for downloading later to a computer. Some data loggers may also be accessed remotely via telephone lines, mobile phone, or the Internet for continuous or intermittent downloading. Data loggers range from miniature (as small as 16 mm diameter × 5 mm thickness) low-cost portable units with one or a small number of inputs, often used in the transportation industry, to larger modular units that can be expanded to many channels. Miniature loggers are often dedicated to one type of input (such as temperatures), have lower accuracy and can store less data. Larger units can usually handle multiple types (temperature, humidity, voltage, current, and so on). Some data loggers have a digital display allowing instant reading, as with an ordinary digital thermometer. Because digitization normally converts a temperature or other signal into an electrical signal using a high-precision digital voltmeter, some data loggers – especially those of the generic input type – may record temperature or other variables to several decimal places more than would be justified by the inherent accuracy of the sensor. Caution must be exerted in interpreting these outputs.

Calibration and Use of Thermometers

Thermometer Calibration

In any physical measurement, the signal from the sensor must be processed into an analog (dial) or digital reading. This processing may introduce errors of three different kinds (Figure 8): 'zero error,' 'span error,' and 'nonlinearity error.' A zero error remains constant throughout the measuring range. It can be corrected for by doing a single temperature calibration. A span error is an error in the sensitivity of the instrument. Calibration consists of taking the reading at two known temperatures (e.g., the ice point and the boiling point of water). To correct for nonlinearity, more reference temperatures have to be measured.

An ice point reference is obtained by filling a vacuum flask with a crushed ice-distilled water mixture. To ensure equilibrium, it is important that both phases are present. If liquid is not present, the ice may be below freezing point, which can be detected by a frosty appearance, whereas a two-phase

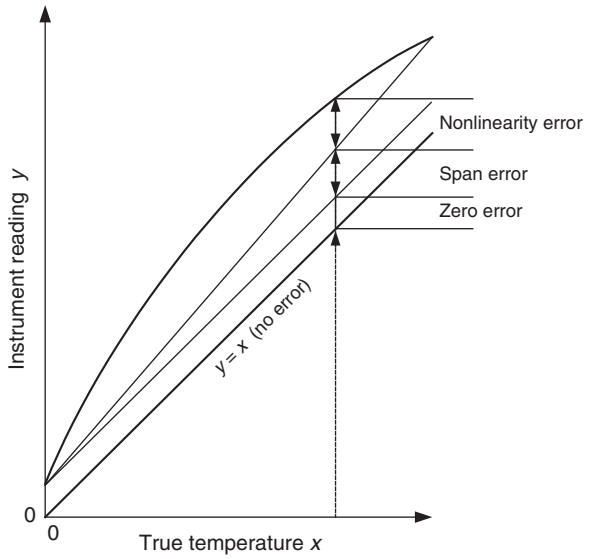

Figure 8 Types of calibration errors.

mixture will be transparent. If there is too much liquid, the ice will float on top and the liquid below may be above freezing point due to conduction from the wall. The sensor must be immersed into the ice slush as much as possible and kept away from the wall of the container.

The ice point is fairly insensitive to atmospheric pressure. On the contrary, the boiling point is highly sensitive to ambient pressure, a +1% change in pressure causing a +0.28 K change in boiling point. Thus, when calibrating a thermometer with boiling water, it is important to measure the ambient pressure and correct for its effect.

Commercial thermometer calibration units are now offered by many manufacturers. Calibration can also be made against a reference thermometer, usually liquid-in-glass or platinum resistance. To ensure that the two thermometers are at the same temperature, they should be inserted into a well-stirred bath or an insulated block of aluminum with holes drilled for the sensors. Good thermal contact between the aluminum block and the sensor must be ensured.

Reading Digital Displays

Except for liquid-in-glass thermometers, bimetallic thermometers, and thermochromic indicators, practically all commercial thermometers use a digital display. The number of displayed decimal digits may be greater than the accuracy of the sensor, especially when the latter varies over the range. The user should always refer to the manual to get an indication for accuracy and, if necessary, perform a calibration or commission an accredited laboratory to do it.

Error Sources in Temperature Measurement

Many factors will influence the reading of temperature, including sensor location, type, and construction of the probe used, and method of probe insertion. To get reproducible results, it is important when developing a protocol for

measuring product or environment temperature to pay attention to all these factors.

The temperature at the center (more accurately the 'thermal center') of the product is of interest because it is often used to define the end of a cooling or heating process. However, it is not always easy to locate the thermal center. This problem may arise because of the irregular shape of meat components (leg, shoulder, or loin), irregular packing, or asymmetrical ambient conditions (e.g., when a carton is cooled mainly from the bottom due to an air gap at the top) (Figure 9). In these cases, the thermal center must often be found by trial and error. Fortunately, a small error in locating it will usually not lead to very large errors in temperature, because the temperature profile tends to be flattest around the thermal center (Figure 10). Often, the best one can do is to define a protocol that will measure temperature at a reproducible location. With beef, pork, and lamb, the temperature next to the bone in the thickest part of the hind leg is usually taken as the 'deep meat' temperature.

A frequent source of error is 'stem errors.' Stem error is a combination of two effects. First, sensors do not 'sense' the temperature at one point; rather, the sensor's temperature, which we read is an average of both the product surrounding it (what one wants to read) and the stem of the thermometer or thermocouple/thermistor wires to which it is attached (which one does not want). Second, the stem is a heat leakage path, which will modify the temperature of the product surrounding the sensor (Figure 10). An error of several degrees may result when measuring food cooling. Stem error is more severe when the stem is larger and a better heat conductor, immersion is shallower, and the length exposed to ambient is longer. Stem error is also worse in sheathed sensors, because thermal contact between the sensor and the product immediately around it is not as good as with unsheathed sensors.

To ensure the most accurate possible measurement, the following precautions must be taken:

1. If necessary, the thermal center must be located by trial and error.
2. The thermometer stem or leading wires must be parallel to isotherms within the meat (i.e., perpendicular to the direction of heat flow) (Figure 10). In an elongated product, the wires should lie in the major direction.
3. The leads should be as fine as possible.

The steeper the temperature gradient (small products, high cooling rates), the more difficult it is to minimize measurement errors. For large products, such as a beef leg, errors due to stem conduction are usually negligible, but some experience is still needed to locate the center accurately.

Surface temperature is difficult to measure with a probe. Temperature will vary along the surface depending on shape, airflow pattern, and so on. In air blast cooling, for example, the surface will cool fastest on the upstream side. For irregular products, thinner parts cool more quickly than thicker parts. Temperature gradients tend to be largest near the surface and in the boundary layer (Figure 10), so errors due to sensor location and stem conduction are more severe than when measuring center temperature. The sensor should be as small as possible and inserted at a shallow angle, to be located as close to the surface as possible (Figure 10). Gluing or taping the sensor to the surface with adhesive tape may alter the surface temperature, especially if evaporative cooling is taking place. The same problem arises when using a thermochromatic material. An infrared thermometer is perhaps the best choice but, for good accuracy, the emissivity should be determined. For a spot manual measurement, it may be possible to sandwich the probe between two pieces or packs. The probe should be as thin as possible (a thermocouple is best) because a thick probe may not fit snugly and will change the surface temperature. A reading must be taken quickly before the surface temperature changes, due to the change in surface heat flux.

The mean product temperature cannot be measured with an ordinary thermometer. However, by leaving the product to equilibrate in an insulated box, it will eventually reach the average temperature (allowing for some heat loss or gain). A microwave attenuation detector developed by AgResearch-MIRINZ (New Zealand) can give an approximate indication of the mean temperature of a frozen carton by measuring its microwave transmittance, which depends strongly on the ice content.

When measuring air temperatures in chillers, cold stores, transport vehicles, and retail displays, temperature variation is a big problem. With cold rooms, temperatures tend to be highest above doors, near ceiling and walls, in dead spots shielded from the airflow by stacked products, near lights, and near warm product. For control purposes, the temperature

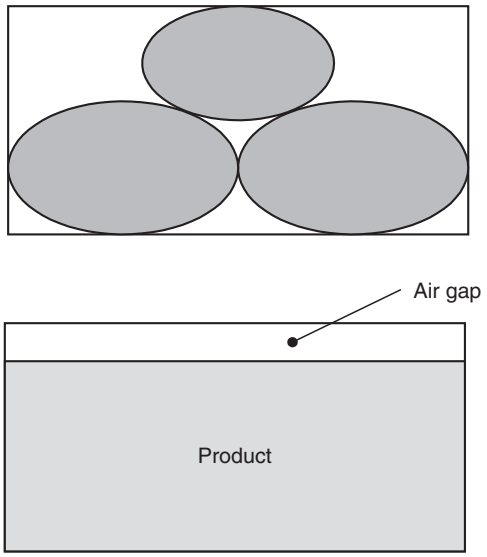

Figure 9 Causes of error in locating thermal center.

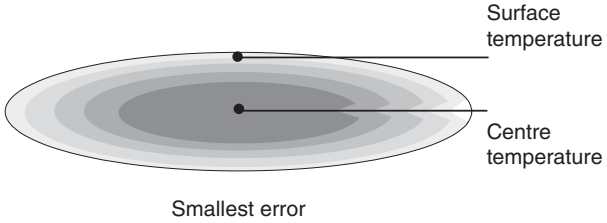

Figure 10 Measuring surface and center temperatures.

sensor should be on the return air to the cooling coils, but there should be other sensors at critical spots if product is stacked nearby. In transport vehicles and containers, the highest temperatures are found at the door end, especially toward the top, due to air infiltration through the door seals and the distance from the cooling unit. Retail display units are particularly susceptible to large temperature variations, which depend on cabinet design and the stacking of product. One cost-effective method may be to use color change temperature indicators at various positions to locate hot spot areas. With chilled meat, the coldest temperature is also of interest, because freezing must be avoided and therefore product should not be allowed to go below −1 °C.

Advances in sensor technology and computer miniaturization have enabled the development of inexpensive miniature loggers that can accompany the product during storage and transport, which is important in the long distance transport of temperature-sensitive product such as chilled meat.

POTENTIAL CHEMICAL HAZARDS ASSOCIATED WITH MEAT

R Nova, University of Nottingham, Nottingham, UK
F González-Schnake, Universidad de Concepción, Chillán, Chile

Glossary

Antibiotics Chemical substances used to inactivate bacteria.
Antihelmintics Chemical substances used to inactivate parasitic helminths (worms).
Curing A method of food preservation that, by the addition of curing agents (salt, nitrites, nitrates, and sugar) occasionally in conjunction with smoking, results in reduction of water activity as well as in desirable organoleptic changes in the food product.
Hazard Analysis Critical Control Point A systematic approach in food safety that aims for the reduction of biological, physical, and chemical risks in food products to negligible levels.
Maximum Residues Level The upper legal concentration of residues of veterinary medicinal products in food of animal origin for human consumption.
Nitrates and nitrites Salts used as curing agents in food products. They not only have antimicrobial activity, especially against *Clostridium botulinum*, but also give food organoleptic characteristics that improve acceptability of cured products (color and flavor).
Quaternary ammonium compounds (QACs) The most commonly used chemicals in industrial environments worldwide. These amphoteric compounds have a broad-spectrum bactericidal effect, which is related to disruption of cell membranes, resulting in cytolysis. However, if QACs are used on an unclean surface, the contact time required for them to be effective could be as long as 10 min. If QACs have been used for disinfection of food contact surfaces, these should be rinsed before use in order to reduce the risk of toxicity.
Smoking A method of preservation of food products. The two most common smoking methods are cold and hot smoking. The process not only acts as a flavor enhancer but also has antimicrobial and antioxidant effects.
Standard Operation Procedures (SOPs) In the food industry, SOPs are written procedures that aim to produce safe food products. The SOP written document must include the purpose and frequency of a task, who is responsible to execute the task, a description of the procedure to be performed (which must include all the steps), and corrective actions to follow if problems are identified in the running of the task.
Standard Sanitation Operation Procedures (SSOPs) In the food industry, SSOPs are written procedures for sanitation (cleaning and disinfection) of food processing facilities.

Introduction

Paracelsus in the fifteenth century stated, "The dose makes the poison;" hence, depending on the level of exposure to a specific substance, any substance could have a detrimental effect on health. When talking about food products in general, and specifically meat and meat products, it is important to assess not only the potential chemical risks but also the likelihood of these risks to be harmful for human health (the hazard level).

Chemical risks in food products are not easy to evaluate. Chemical contaminants do not always produce clinical signs/conditions that can be identified during antemortem inspection in abattoirs, neither organoleptic alterations of the food product that can be detected during postmortem inspection or during consumption. Unfortunately, most of the current protocols for surveillance in chemical residues in food products require costly equipment and highly trained personnel; prerequisites can be found mostly in developed countries but not necessarily in the developing ones, where the population could be, unknowingly, exposed to unsafe levels of chemical contaminants.

For some chemicals, there is a lack of evidence on the risk level for human health; for other chemicals the risks might be related to the accumulation of that substance over a long period of time, rather than being the result of a single exposure. Hence, Maximum Residues Limits (MRLs) are not always available, and some countries have decided to use a precautionary principle banning the use of some chemical compounds in food-producing animals. However, these precautionary measures can be considered and can be used as a tool to protect local markets, instead of human health. Strong scientific evidence is required in order to carry out proper risk assessments, evaluate the impact on human health, and choose the most appropriate tools to control and reduce these chemical risks.

Veterinary Drug Residues

The kind and amount of veterinary drugs used in meat-producing animals vary, amongst other factors, with the species of animals used for production, the production system

 doi:10.1016/B978-0-12-384731-7.00215-4

in which these animals are bred, and also the country where these animals are produced. The veterinary drugs covered in this section include the following: antibiotics, antihelmintics, and growth promoters.

There are multiple reports highlighting the potential detrimental effects on human health when consuming products of animal origin that contain veterinary drug residues at unacceptable levels. Some of the potential effects and examples are as follows:

Anaphylactic reactions: Allergic reactions after consumption of food products of animal origin have been reported primarily for dairy products. Nevertheless, meat products could potentially trigger an anaphylactic shock in susceptible consumers.

Antibiotic resistance: Presence of antibiotic resistance in intestinal microflora has been reported in animals after ingestion of subclinical doses of antibiotics. However, the impact of antibiotic resistance in animal intestinal microflora on human health is not yet fully understood.

Chronic and acute toxicity: Human health problems have been reported after consumption of meat products from animals that have been administered growth promoters, such as clenbuterol, a drug currently banned for use in food-producing animals in the United States, European Union (EU), and other countries. Toxicity problems associated with clenbuterol include neurological signs (gross tremors of the extremities), tachycardia, nausea, headaches, and dizziness.

Imbalance in human intestinal microflora: Reports show that human intestinal microflora might change not only after ingestion of food products that contain antibiotic residues but also when working in an environment where antibiotics are used in large amounts as prophylactic treatment on food-producing animals. The presence of antibiotic residues might affect the balance of not only intestinal microflora but also oropharyngeal, skin, and vaginal microflora. However, more research is needed to elucidate whether these changes might affect animal and human health.

The EU periodically reviews new information available on veterinary drugs in order to revise the list of veterinary drugs included in the list of forbidden substances, whereas an MRL is established for other substances. A conscientious checking of drug residues by national surveillance systems is not easy, as it may result not only in a large number of samples to analyze but also in a wide variety of residues to check for, long waiting times for results, and a high economic cost. Additionally, the accuracy on the detection of noncompliances can be affected by the mixing of drugs at smaller doses by unscrupulous people, in order to get a synergistic effect of some drugs as well as avoiding detection of residues by the current analytical methods. Hence, the existence of fast screening techniques is critical for the implementation of effective residues control.

Antibiotics

Antibiotics are widely used in meat-producing animals to control bacterial diseases, and in some countries they are also used as growth promoters. Regardless of the positive effect on animal health and welfare, food production, and human health, indiscriminate use of antibiotics might result in undesirable effects, such as bacterial antibiotic resistance, technological problems in food production (Figure 1), or anaphylactic reactions in consumers. To reduce the risk of human health problems associated with the presence of antibiotics in meat products, antibiotics should be used responsibly in food-producing animals, and withdrawal periods should be respected.

Figure 1 Damage in ovine carcase in an injection point due to bad practice.

There is a great concern about antibiotic resistance in human pathogens due to use of these drugs in animal production. For example, resistance to beta-lactamic antibiotics due to the presence of extended-spectrum beta-lactamases (ESBLs) enzymes in food-producing animals could potentially be extremely detrimental for human health as these proteins provide resistance to bacteria against antibiotics used in the treatment of humans affected by bacterial infections unresponsive to first-generation antibiotics. There is, however, no clear evidence that bacteria carrying ESBLs in animal and human infections are genetically related.

Efforts have been made to reduce the use of antibiotics used in veterinary medicine. For example, in the EU it is not possible to advertise prescription only veterinary drugs to the general public; that restriction includes animal keepers. The ban aims to reduce pressure on veterinary professionals by animal keepers to prescribe antibiotics that might have a short withdrawal period, instead of an election drug. Also, at EU level there is a legal requirement to monitor resistance levels in *Salmonella* obtained from food-producing animals. Moreover, from 1 January 2014, that requirement will include the monitoring of antibiotic resistance levels in *Campylobacter* spp. and in commensal *Escherichia coli* isolated from food-producing animals.

Additionally, the World Health Organization (WHO) and the World Organisation for Animal Health (OIE) have produced guidance documents of international relevance on the responsible use of antibiotics considered critically important antibiotics (CIA) for human and veterinary medicine. This high-priority antibiotic group includes fluoroquinolones, third and fourth generation cephalosporins, macrolides, and glycopeptides. CIAs should be used only in veterinary medicine in clinical cases unresponsive to other antibiotic groups. Furthermore, antibiotic sensitivity tests must be carried out before using a CIA. Fortunately, in EU, level CIAs are not normally used, where tetracycline and penicillins are the most widely used antibiotics in food-producing animals.

Although in developed countries there is awareness, monitoring, and enforcement on antibiotic residues in products of animal origin, in many developing countries that might not be the case. This situation does not necessarily affect only human health but also the potential presence of antibiotics in food products of animal origin for human consumption. In addition, factors such as lack of strength of veterinary services, animal health status, and traceability of food chain could reduce the chances of some developing countries to commercialize food products in international markets. Although the antibiotic residues situation in developing countries is widely unknown, some studies in cattle abattoirs report levels as high as 44% of positive samples for antibiotic residues, with penicillin (14%), tetracycline (8%), and streptomycin (4%) the most common antibiotics found in the analyzed samples, and with 18% of multidrug resistance. This example clearly highlights that more international support is needed to encourage responsible use of antibiotics.

Antihelmintics

Antihelmintic drugs are widely used in food-producing animals to increase animal production by reducing animal disease burden (Figure 2). Some of the most widely used antihelmintics are benzimidazoles, such as triclabendazole (effective against *Fasciola hepatica*), and drugs from the avermectin group, such as ivermectin (effective against nematodes and ectoparasites).

Although there are reports of toxicity in animals and humans due to treatment with antihelmintics, the risks for human health due to the presence of antihelmintic drugs in meat products are either low or unknown. In fact, there are many studies in the pharmacokinetics of these drugs, but not many studies have been carried out in the potential human side effects after ingesting meat with residues. More importantly perhaps, from the point of view of human health, is the fact that missed doses might result in the selection of resistance for these parasites with drugs that might be an elected treatment for human health.

Figure 2 Applying antihelmintics in beef cattle.

Growth Promoters

Growth promoters are drugs used in meat-producing animals in order to get higher meat yields and better feed conversion in a shorter period of time. Antibiotics, hormones, and beta agonists, amongst other drugs, have been used and are used in animal production with that aim. The legal frame that allows or bans the use of these compounds in food-producing animals varies. These variations are related not only to scientific evidence but also in the precautionary principle and pressures from consumers.

Owing to the increased risk of antibiotic resistance, and the associated risk for animal and human health, using a precautionary principle, from 1 January 2006, the EU has implemented a wide ban on the marketing and use of antibiotics as growth promoters, allowing the use of antibiotics in feed for only veterinary purposes. However, countries such as the United States still widely use antibiotics as growth promoters is some species. Nevertheless, the United States has also started its own initiatives, where the Food and Drugs Administration has proposed a voluntary program on labeling and use of antibiotics in food-producing animals. More evidence is needed on the use of antibiotics as growth promoters for food-producing animals and on the risk to generate antibiotic resistance in potentially dangerous human pathogens.

Hormones are widely used in some countries as growth enhancers for food-producing animals. The five hormone types most commonly used in meat production, either as injection or as ear implants (slow release), include three natural hormones, oestradiol 17-β, testosterone, and progesterone, and two synthetic substances, trenbolone and zeranol.

In the United States and other countries, natural and synthetic hormones are normally used as growth promoters in cattle, whereas in the EU for decades there have been concerns about the potential human toxicity risk associated with the likely presence of extremely minute quantities of exogenous hormone residues in meat products of animal origin for human consumption. However, there have not been any human health issues associated with consumption of beef from cattle properly implanted with hormone implants. Furthermore, as a result of these concerns in food-producing animals in the EU, these chemicals can be used for only therapeutic purposes and there is a wide ban on all hormone products to be used as growth promoters. Meat produced in non-EU countries where hormones are used as growth promoters cannot be exported to the EU.

It has been suggested that hormone growth promoters would pose endocrine, developmental, immunological, neurobiological, immunotoxic, genotoxic, and carcinogenic effects, particularly for prepuberal children. However, because there is

no conclusive scientific evidence on the human health impact, market restrictions imposed by the EU have resulted in a long international debate.

There are a number of beta agonists currently in use as growth promoters in the farm industry in some countries. Some of the most commonly used are ractopamine hydrochloride and zilpaterol hydrochloride. These drugs enhance feed conversion to muscle, with a faster growth, better yields, and leaner meat. Although improper use of these two drugs might negatively affect meat quality, they do not have a reported detrimental effect on human health as other beta agonists, such as clenbuterol. Nevertheless, some countries do not allow their use and will not allow imports of meat from animals fed with ractopamine hydrochloride and zilpaterol hydrochloride.

Disinfectants

To obtain the desired effect and to ensure food safety and health, cleaning and disinfection procedures in the meat industry should follow specific written protocols (Hazard Analysis Critical Control Point, standard operation procedures, and standard sanitation operation procedures), and these protocols should be carried out only by trained personnel. Additionally, the election of a specific chemical product must consider the material of which the surface is made, the nature of the contamination to be removed, the effectiveness at reducing microbial contamination under specific conditions, risk assessment, feasibility to use, cost of the product, and whether or not there is a need for rinsing before reusing the food contact surface.

Chemical risks associated with the presence of disinfectants are mostly related to human exposure during cleaning and disinfection processes rather than intoxications due to the presence of residues on food products. After exposure to some of these chemicals, people could suffer from skin, eye, and respiratory irritation; also, some disinfectants can have a corrosive effect on the material being cleaned, or can have a carcinogenic effect in humans.

Some disinfectants, like quaternary ammonium compounds (QACs), one of the most widely used sanitizers in the food industry, when used in the appropriate concentrations, have a low toxicity risk, and additionally they are biodegradable (Figure 3). However, there is a number of other cleaning/disinfection products, such as sodium hydroxide, which might represent a higher risk for toxicity for humans, even when used at the recommended concentrations.

Figure 3 Use of QACs foam products for disinfection of food processing premises.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) comprise a group of chemical compounds widely distributed in the environment. PAHs are mostly produced as a result of incomplete combustion; in food production, there is a latent risk that these chemicals could be present in a larger than recommended amount in smoked products.

For decades, concerns have been raised on the genotoxic and carcinogenic risk for humans exposed to PAHs. However, the tolerable daily intake for PAHs has not been set yet; as a result, the current recommendation is that human exposure to PAHs through consumption of food products should be as low as reasonably achievable. However, exposure to PAHs has been related to a higher risk to develop lung, skin, and bladder cancer. When a case of toxicity occurs, it is not easy to relate human health problems to PAHs present in a specific food product, as the clinical effects are a result of an accumulation of these residues during a period of time (chronic cases rather than an acute intoxication).

Previous EU legislation targeted only the presence of benzo(a)pyrene in food products, which was used as an indicator of PAHs; hence, maximum levels in food were regulated only for that compound. However, after a scientific opinion of European Food Safety Authority suggesting that benzo(a)pyrene on its own was not a good indicator of PHAs, current EU legislation requests to monitor PAHs concentration in food products by measuring the levels of a combination of four substances (PAH4) (benzo(a)pyrene, benz(a)anthracene, benzo(b)fluoranthene, and chrysene) while maintaining a separate maximum level for benzo(a)pyrene.

Other Chemical Risks

Lead

Lead is a heavy metal that can affect animal and human health. The highest frequency of intoxication with lead in animals is associated with the use on farm buildings of paints that contain a lead base as well as the rare instance of animals grazing in areas where car batteries might have been disposed. Although there are more important routes of human exposure to lead, consumption of contaminated meat products can pose a risk for human health. However, human consumption of game meat might represent a higher risk for human health than consumption of meat produced from farmed animals; that higher risk is related to the use of bullets that contain lead for hunting.

Signs of acute lead poisoning include not only gastrointestinal signs, such as abdominal pain, nausea, vomiting,

diarrhea, and constipation, but also neurological signs, which are associated with encephalitis. Signs of chronic lead intoxication might have a similar presentation as acute intoxication; however, neurological problems (short memory loss, depression, lack of concentration, and stupor) and anemia can also be seen.

Dioxins

The presence of these chemical compounds in food products is generally associated with industrial processes. In fact, dioxins can be produced as a by-product of waste management through incineration. Animals can be easily exposed to dioxins present in the environment, and as these molecules are lipophilic, they will accumulate in fatty tissues.

If humans consume food products contaminated with a higher than acceptable amount of dioxins, they might be affected by an acute intoxication, where skin lesions as well as alteration of liver function could occur. As dioxins are ubiquitous in the environment, human health can also be affected by long-term exposure not related to meat from contaminated animals. A chronic intoxication might result in an impaired immune system, endocrine and reproductive system, and in younger people could result in alteration in the development of the nervous system.

A number of episodes of dioxin contamination in meat products have occurred in the past years; hence, official contingency plans in order to identify, detain, and dispose of contaminated feed and food products should be in place in each country in order to reduce human and animal health risk. However, the current laboratory methods required for dioxin detection are expensive and not necessarily available worldwide.

Mycotoxins

Mycotoxins are metabolites produced naturally by fungi and molds. They have a special relevance for animal and human health as many of these mycotoxins have a carcinogenic effect. The highest risk for animals is by consumption of feed that has neither been prepared nor stored properly, allowing the growth of microorganisms, such as *Aspergillus* spp. Although human health can be at risk by the consumption of food products of animal origin that contain mycotoxins, the highest risk of exposure is not through meat consumption but through the consumption of contaminated cereals.

Nitrites/nitrates

Nitrates and nitrites are food additives used during curing of meat products in order to extend their shelf life. They are used for improving organoleptic characteristics of products (redness) and palatability as well as for the control of bacterial pathogens (*Clostridium botulinum*). Human consumption of food products that contain a high concentration of these chemicals might result in nausea and vomiting, dizziness, headaches, confusion, cyanosis, and methemoglobinemia. Additionally, nitrites and nitrates can be metabolized in the organism and produce nitrosamines, a potential carcinogenic compound.

PREDICTION OF MEAT ATTRIBUTES FROM INTACT MUSCLE USING NEAR-INFRARED SPECTROSCOPY

MM Reis, AgResearch Limited, Hamilton, New Zealand
K Rosenvold, ANZCO Foods Limited, Waitara, New Zealand

Glossary

Chemometrics A science discipline dedicated to develop and apply multivariate data analysis, numerical analysis, and statistics to interpret data from chemical systems.
Isosbestic A point where extinction coefficients are the same.
Metmyoglobin Ferric state (Fe^{3+}), the oxidized form of myoglobin responsible for brown–red oxidized surface color.
Myoglobin The primary oxygen-binding pigment protein found in the muscle tissue of animals.
Near-infrared spectroscopy A spectroscopic technique that uses the near-infrared region of the electromagnetic spectrum (from 700 to 2500 nm).
nm and cm^{-1} The units of wavelength (λ) and wavenumber ($\tilde{\nu}$), respectively, used to identify the frequency of the electromagnetic radiation in spectroscopy ($\tilde{\nu} = 1/\lambda$).
Oxymyoglobin Ferrous state (Fe^{2+}), the reduced form of myoglobin responsible for bright-red bloomed surface color.
Principal component analysis (PCA) Multivariate data analysis technique based on data reduction, which is able to compress and organize most of the information using a few variables, thus facilitating the interpretation of the data.
Water-holding capacity The ability for fresh meat to retain its own water.

Introduction

After slaughter, the muscle undergoes a series of biochemical and structural changes until it reaches the state of rigor. Following rigor a new series of changes take place, including proteolysis. The combination of these pre- and postrigor changes define the meat quality attributes in muscle from that carcass. Although there are processes to control and direct these changes toward consistent meat quality, not all factors affecting the final meat quality can be controlled in the slaughter plant as it is also influenced by preslaughter factors such as breed, sex, weight, and environment, which can lead to inconsistencies of the final meat quality. A strategy to deal with these inconsistencies is to identify abnormal carcasses early on in the process and manage them to achieve a desirable set of attributes. To be successful, this strategy requires the carcass to be evaluated within a time frame that allows it to be managed toward a desired use.

Near-infrared spectroscopy (NIR) is a technique based on the interaction of a radiation with the sample through an absorption and scattering process. As a result, the NIR spectrum is a rich source of information about the chemical composition of the sample as well as its microstructure. NIR is a rapid, noninvasive, and nondestructive spectroscopic method suitable for online measurement and has become widely used across the food and fiber industries including dairy, grains, oil, meat, and wool industries for proximate analysis. For the meat industry, however, there is no current commercial online NIR measurement system to accurately predict key meat quality indicators (pH, glycogen, and temperature) and/or meat quality attributes (tenderness, color, or water-holding capacity).

A large number of studies have investigated NIR technology for this purpose showing variable results. Hence, this article focuses on application of NIR spectral measurements taken from intact muscle and placed in a controlled environment to evaluate changes in meat during its conversion from muscle to meat as it relates to a meat quality indicator and the attributes relating to the conversion process The underlying principles enabling NIR to be used as an assessment criterion for the evaluation of meat quality attributes are presented to understand and develop the opportunities for the use of NIR by the meat industry.

Near Infrared

NIR spectroscopy is based on changes in vibrational status of molecules resulting from interaction with incident radiation. These changes are detected in the form of bands associated with vibrational modes of the molecules (Figure 1). Within the NIR spectral range, overtones and combinations of fundamental vibrations are observed, which lead to high degree of overlap between bands. The water molecule, for example, has the fundamental vibrations shown in Figure 1. In bulk water, the band observed at approximately 840 nm

 doi:10.1016/B978-0-12-384731-7.00250-6

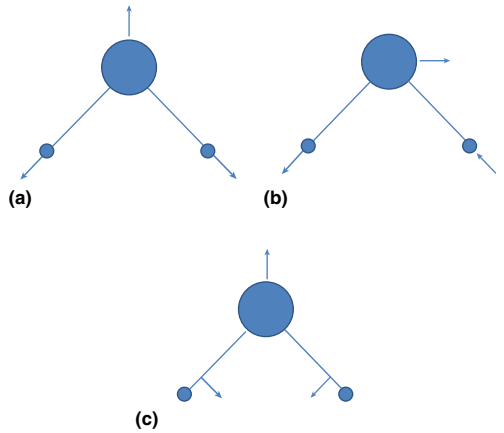

Figure 1 Fundamental vibrational modes of water (a) symmetrical and (b) asymmetrical stretch and (c) scissoring.

results from the combination of the asymmetrical stretch (Figure 1(b)) at 3500 cm^{-1} (2860 nm) and the scissoring (Figure 1(c)) band 1645 cm^{-1} (6079 nm), i.e., 3500 +1645 = 5145 cm^{-1} (1943 nm). Although molecules containing C–H, N–H, S–H, and O–H are highly active in the NIR region, the interpretation of NIR spectra is rather complex due to overlap among bands resulting from overtones and combinations.

NIR allows high penetration of the incident radiation into the sample, allowing the noninvasive detection of the backscattered radiation or transmitted radiation through the sample. For complex solid samples such as meat, the radiation–sample interaction involves mainly two principles: scattering and absorption; the former related to the microstructure of the sample and the latter resulting from the chemical composition of the sample. This allows NIR to be applied for the study of meat attributes, which depend not only on the chemical composition of meat but also on structural components.

In the NIR instrument, a beam of light from a powered radiation source (a tungsten coil or halogen lamp) is directed at the meat sample and the transmitted or backscattered radiation from the sample is returned to the spectrometer (Figure 2). The ratio between the intensity of returning radiation and the intensity of incident radiation is obtained for a range of light wavelengths to produce the NIR spectrum.

A wide range of detection systems is available to NIR spectroscopy and in particular, those based on sensor arrays without moving parts are portable so that the spectrum is collected in milliseconds. In this type of instrument, the returning radiation, following interaction with the sample, is diffracted and directed to a sensor(s) with a series of independent elements, which thus allows the scanning of an entire spectrum to be captured in a few milliseconds (Figure 3). A range of measurement modes are available, including: transmittance, where the radiation is transmitted through the sample, and reflectance, where the radiation penetrates the sample and the backscatter radiation is detected by the spectrometer (Figure 2). Reflectance mode is the type more commonly used for measurement of meat, as it allows a noninvasive evaluation of the sample.

Although these instrumental characteristics allow NIR to be used as a noninvasive fast technique for evaluation of meat attributes, its spectrum is rather complex to easily interpret. This has restricted the interest in NIR for decades until the development of chemometrics that expanded the use and interpretation of NIR spectra in wide range of applications. Chemometrics utilizes multivariate data analysis to extract information from NIR spectra and to develop mathematical models for the prediction of attributes. In the approach based on the use of exploratory data analysis to extract information, a series of spectra are analyzed, and features, or responses, from the spectra associated to sample traits are identified and interpreted. The most popular methodology is based on

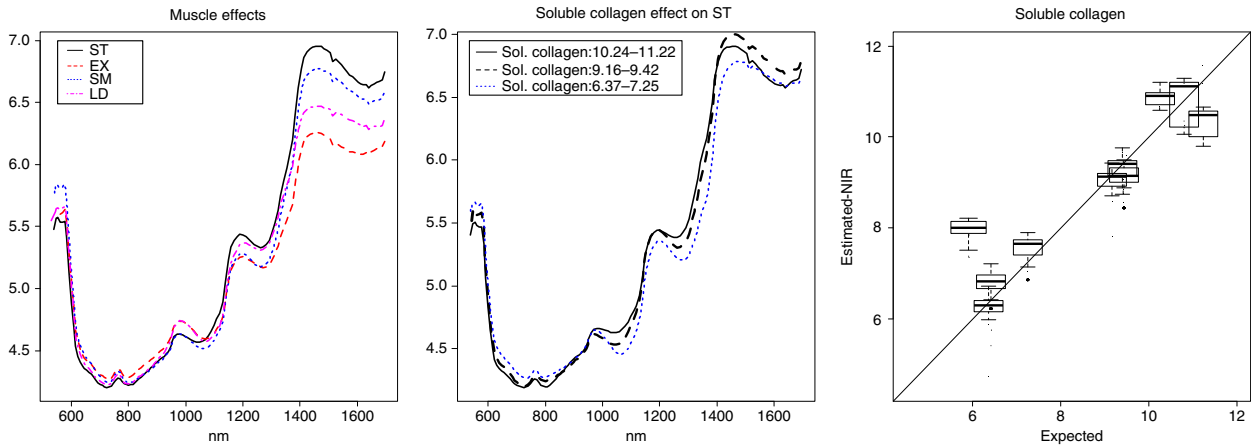

Figure 4 Effect of muscle type and concentration of soluble collagen on NIR spectra. On the left-hand side, the effect of muscle type on NIR is shown. ST, Semitendinosus; EX, Extensor capri; SM, Semimembranosus; LD, Longissimus dorsi. In the middle, a set of spectra is averaged according to range on soluble collagen content (solid line 10.24–11.22, dashed line 9.16–9.42, and dotted lines 6.37–7.25). On the right-hand side is shown the predictions of soluble collagen in ST, showing that NIR is able to predict the presence of soluble collagen, for details of the experiment see Reis *et al.* (2012).

principal component analysis (PCA). The second approach enabling the rapid prediction of sample attributes from NIR spectra involves the development of a chemometric model used to translate the NIR spectrum into the property of interest (e.g., tenderness).

The NIR spectrum is affected by different characteristics of the sample, such as chemical composition, microstructure, temperature, homogeneity, to mention a few. All of these effects may not be required for a given application. Thus, the NIR spectrum is corrected before the multivariate analysis. This correction is also known as preprocessing, with the most common being multiplicative light scattering used to reduce effect of unwanted light scattering.

The development of prediction models from NIR spectra requires a representative dataset that includes similar sources of variation to those found in new samples. Once a representative dataset is obtained, the development of the model is performed in two steps: calibration and validation. To perform these steps, one part of the dataset, the validation dataset, is initially put aside. The other part called calibration dataset is used to fit the model, which can involve different mathematical techniques such as partial least squares, neural network, and others. Once the best calibration model is selected and the model is applied to the validation dataset, its performance is assessed. There are several processes to perform the model selection. Among them, cross-validation is widely used. In this case, the calibration dataset used to develop the model is split in subsets of samples. One subset is used to fit a calibration model, which is then applied on the cross-validation subset of samples left out. This process is repeated until all samples are left out once. The predictions of these samples are then used to evaluate the performance of the model. In the meat science literature, it is common to use cross-validation to assess the ability of NIR to predict a given attribute. This is not an ideal process as cross-validated samples are not completely independent and care must be taken when interpreting these results.

Meat Microstructure and Near Infrared

As the NIR portion of the incident radiation penetrates the meat, it undergoes light scattering and absorption. In particular, light scattering is dependent on the microstructure of the meat and absorption results from the chemical composition. In Figure 4, for example, the effect of four different muscle types on the NIR spectra and the effect of three different concentration ranges of soluble collagen on the NIR spectra are shown. Although muscle type is associated to an additive effect on spectral range over 1200 nm, the effect of soluble collagen does not show such additive effects. It has been found that distinction between muscle types is related to the light scattering (Figure 5) and that the amount of scattered light is associated with shear force (Figures 6 and 7). This ability to capture two types of information makes NIR a useful tool for meat quality evaluation where most of quality attributes evolve from changes in the chemical composition as well as in the meat microstructure.

Pre- and Postrigor Changes

PCA of NIR spectra collected on beef M. longissimus lumborum from slaughter up to 90 h postmortem is shown in Figure 7. The scores of first principle component (PC1) are separated between pre- and postrigor, where prerigor samples present negative scores and postrigor samples have positive scores. The loadings from PC1 show high positive values for bands associated with the OH (water) functional group and negative values for bands in the visible region and CH functional group (Figure 8). This suggests that postrigor samples (positive scores) are associated with more water when compared with prerigor samples. It also indicates that prerigor samples (negative scores) are richer in the CH functional group compared with postrigor (positive scores), i.e., postrigor must present a higher degree of breakdown of its

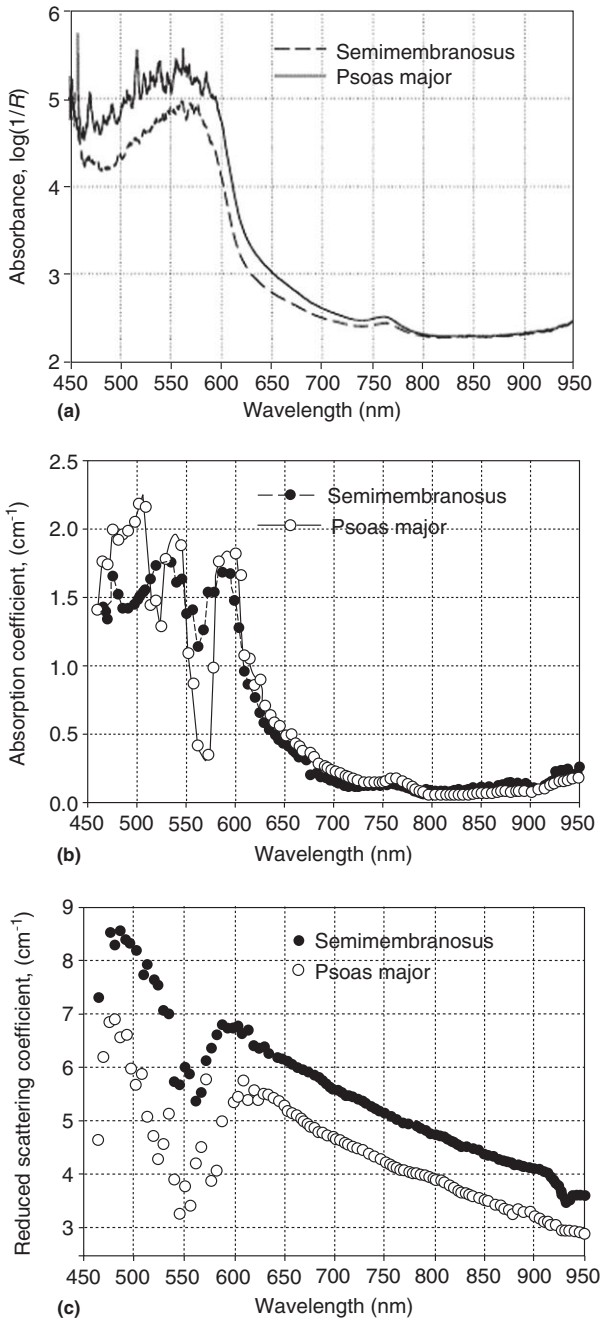

Figure 5 (a) NIR spectra of samples of two different muscle types, (b) absorption coefficient, and (c) scattering coefficient. The scattering coefficient corresponds to an additive effect over spectral range as the two scattering spectra are similar in shape but shifted by an additive constant. Reproduced from Xia, J.J., Berg, E.P., Lee, J.W., Yao, G., 2007. Characterizing beef muscles with optical scattering and absorption coefficients in VIS–NIR region. Meat Science 75, 78–83.

microstructure that reduces the level of the CH functional group. The bands in the visible spectral range (below 600 nm) are associated with oxidation status of myoglobin where 572 and 600 nm are the isosbestic points for deoxymyoglobin/oxymyoglobin and metmyoglobin/oxymyoglobin, respectively. The reflectance at the isosbestic point is the same for the two or

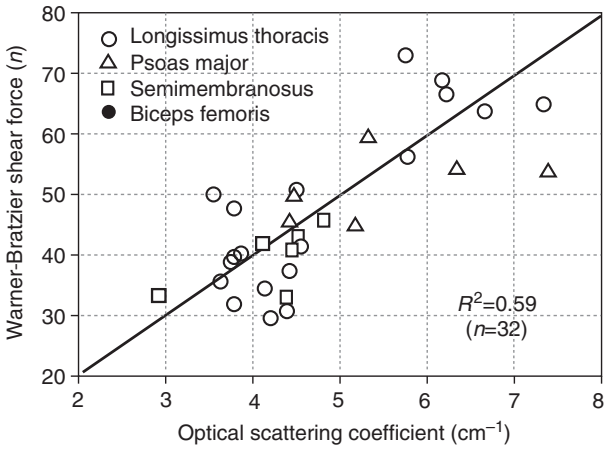

Figure 6 Relationship between scattering coefficient and shear force. The values for M. longissimus are spread over the whole range of shear force, showing the relationship due to confounding between muscle type and shear force. Reproduced from Xia, J.J., Berg, E.P., Lee, J.W., Yao, G., 2007. Characterizing beef muscles with optical scattering and absorption coefficients in VIS–NIR region. Meat Science 75, 78–83.

three forms of myoglobin, which suggest that the negative loadings at 572 and 600 nm are an indication of higher degree of oxidation of myoglobin for the postrigor samples that would reduce the overall reflectance in this spectral region (Figure 7).

Prerigor Changes

Figure 7 also shows that NIR is associated with pH as there is a trend in prerigor samples where the decrease in pH is related to an increase the scores of PC1. To investigate this relationship, a quantitative approach was applied to the data shown in Figure 7. This experiment included carcasses electrically stimulated and nonstimulated with samples kept at three different temperatures, resulting in six rates of pH decline. The pH predictions by NIR, from 1 to 90 h postslaughter, demonstrate the ability of NIR to capture the temporal variation as well as the differences among the applied treatments (Figure 9).

It has been shown that NIR is able to predict glycogen in prerigor meat (R^2 validation 0.72, RMSEP = 2.68 mg g^{-1}), which combined with the ability to predict pH might underlie key principles that allow NIR to be used prerigor to predict ultimate pH.

Postrigor Changes

The development of full rigor occurs as each muscle fiber sequentially enters rigor over the preceding period. At this point, new changes take place in the meat, especially in its microstructure. During postrigor aging, meat loses increasing amounts of water and an increase in drip with aging is most likely due to the release of water tightly bound up in the cytoskeletal proteins as they degrade and progressively unravel, releasing their bound water. In a study on lamb, NIR was

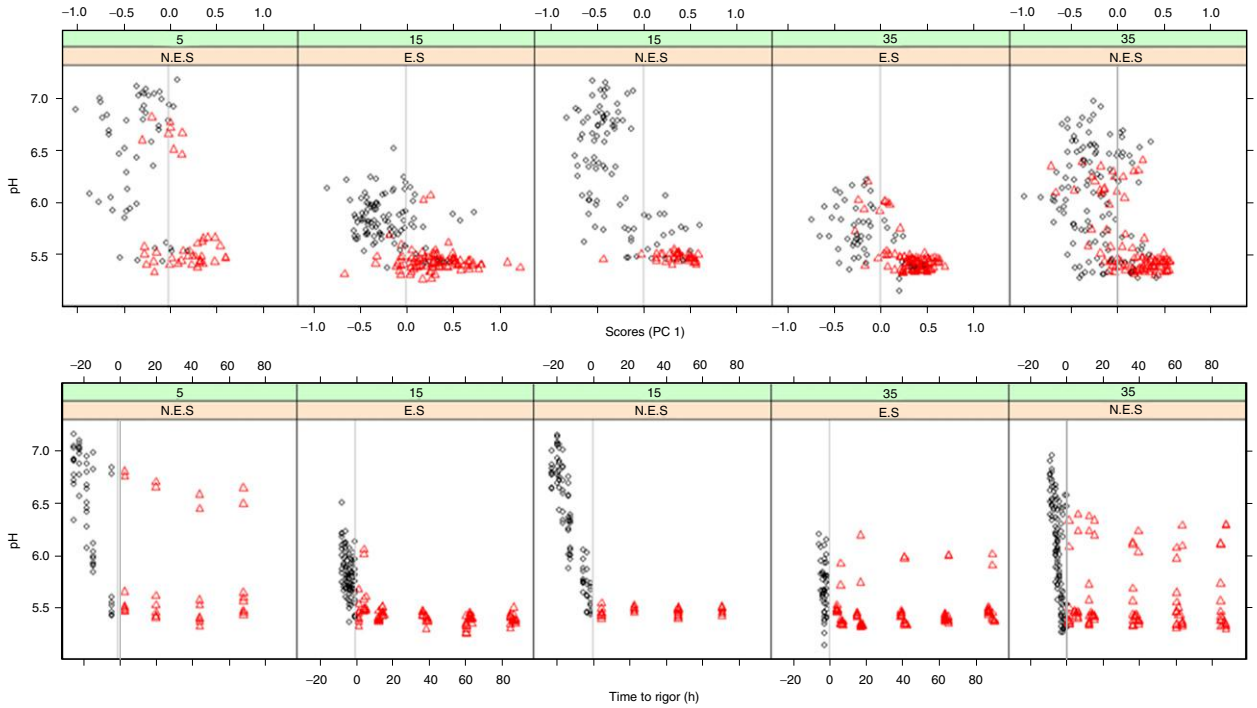

Figure 7 Relationship between scores of the first PC1 with pH and time to/from rigor. Open circles represent spectra collected prerigor and triangles correspond to samples postrigor. The temperature of the samples is shown on the top of each panel, whereas E.S and N.E.S refer to electrical and nonelectrical stimulated carcasses, respectively, for details of the experiment see Rosenvold *et al.* (2009).

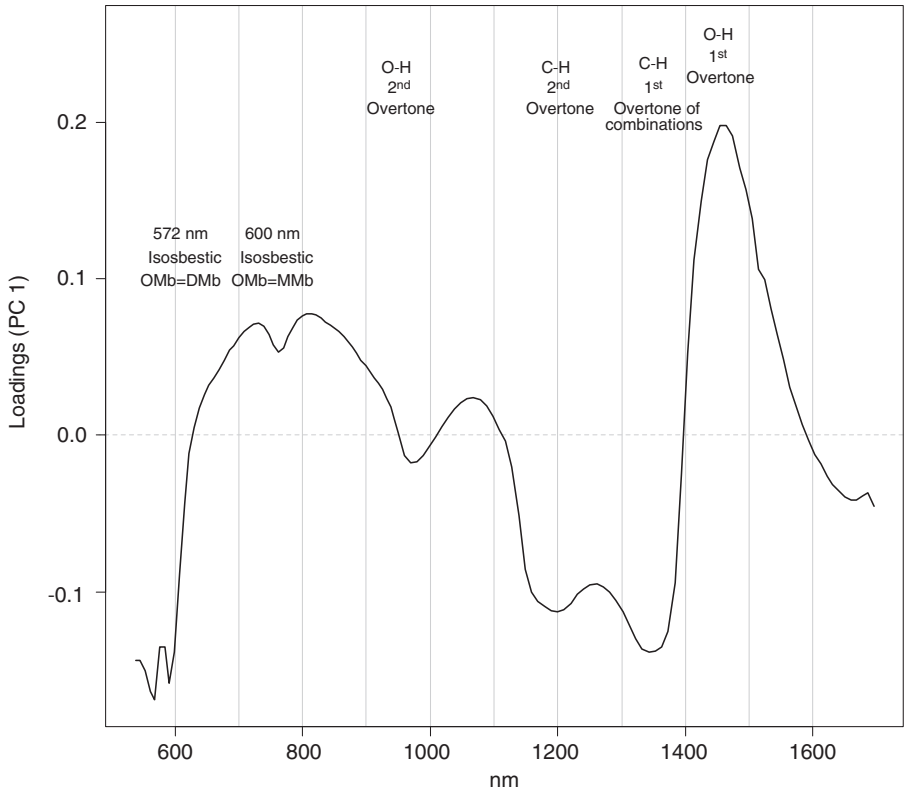

Figure 8 Loadings for PC1 shown in **Figure 7**. The isosbestic points for deoxymyoglobin, oxymyoglobin (OMb), and metmyoglobin (MMb) occur at 572 and 600 nm. 'O–H' and 'C–H' refer to spectral region where there are overtone and combinations of fundamental molecular vibrations for the functional groups 'O–H' and 'C–H'.

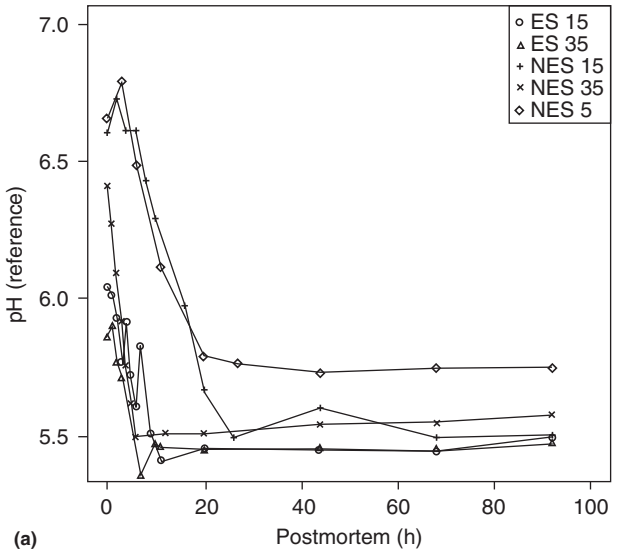

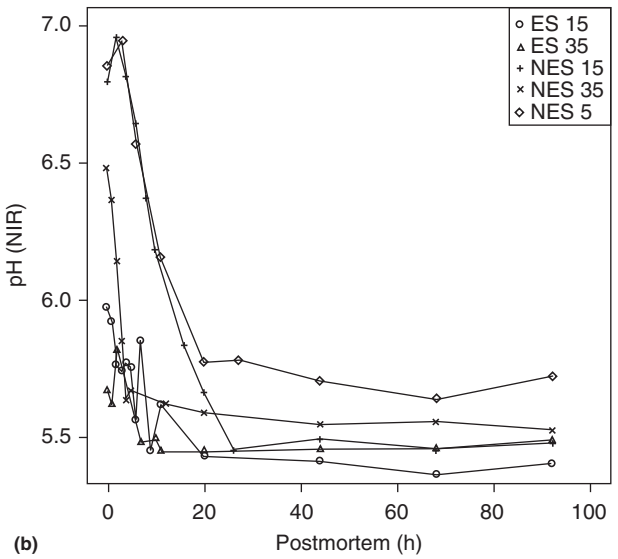

Figure 9 (a) Reference measurement and (b) NIR measurement of pH. ES15: electrically stimulated and held at 15 °C until rigor. ES35: electrically stimulated and held at 35 °C until rigor. Reproduced from Rosenvold, K., Micklander, E., Hansen, P.W., *et al.*, 2009. Temporal, biochemical and structural factors that influence beef quality measurement using near infrared spectroscopy. Meat Science 82, 379–388.

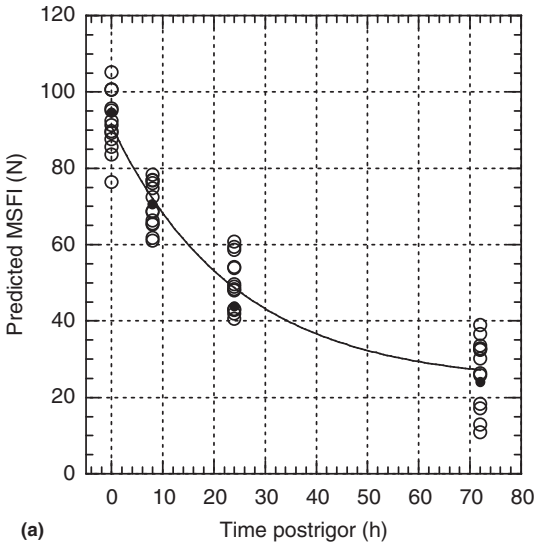

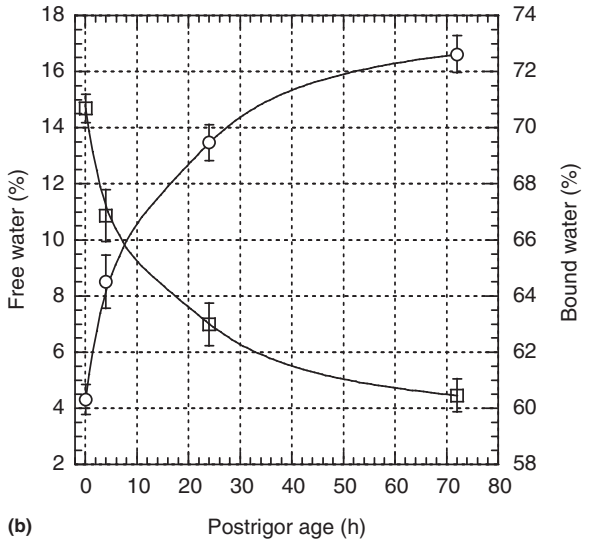

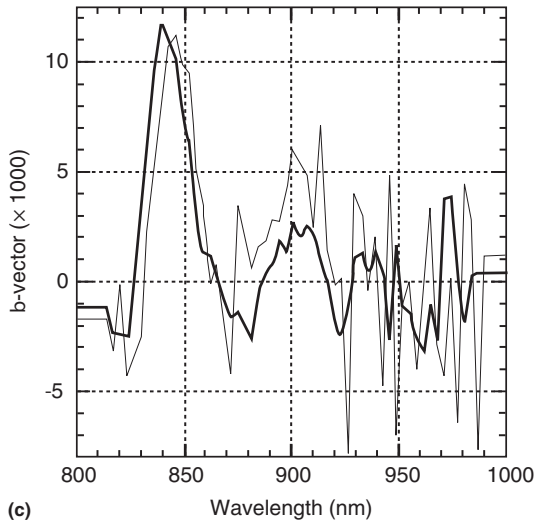

Figure 10 (a) Scatterplots of predicted Mean Shear Force index (MSFI) versus postrigor age for a validation subset. The curve was generated using an exponential model. (b) Mean percentages of free (○) and bound (□) water plotted against postrigor age for the same data as in (a). (c) Regression coefficients for the models to predict shear force from NIR from two independent datasets. Error bars represent ±1 standard error of the means. Reproduced from McGlone, V.A., Devine, C.E., Wells, R.W., 2005. Detection of tenderness, postrigor age and water status changes in sheep meat using near infrared spectroscopy. Journal of Near Infrared Spectroscopy 13, 277–285, with permission from IM Publications.

able to predict the drop in shear force during the aging process (Figure 10(a)). In this model, the dominant feature was the OH band at 840 nm, suggesting that the underlying chemistry is related to the postrigor changes in the water status of the meat. These samples also showed an increase in the amount of free water and a decrease in the amount of bound water (Figure 10(b)). It suggested that drip was related to a degradation of the tertiary structure of the cytoskeletal proteins during aging. This observation is in agreement with Figure 8, where NIR was able to identify reductions of CH, more likely to happen due to degradation, and there was an increase in the amount of water in the postrigor samples. Figure 8 shows that key difference between pre- and postrigor samples in NIR is associated with higher amount of water and reduced amount of CH in the samples. To further investigate this observation, an experiment was set up with three different treatments applied to the carcass/sample: electrical stimulation, wrapping, and prerigor temperatures. The results from six aging regimes were obtained, where shear force was monitored with a conventional tenderometer and predicted by NIR. In this experiment, each sample was monitored to identify starting point of rigor. NIR was able to predict the time from rigor (Figure 11) and the decline of shear force similarly to measured values (Figure 12), i.e., NIR was able to predict the stage and monitor the aging process.

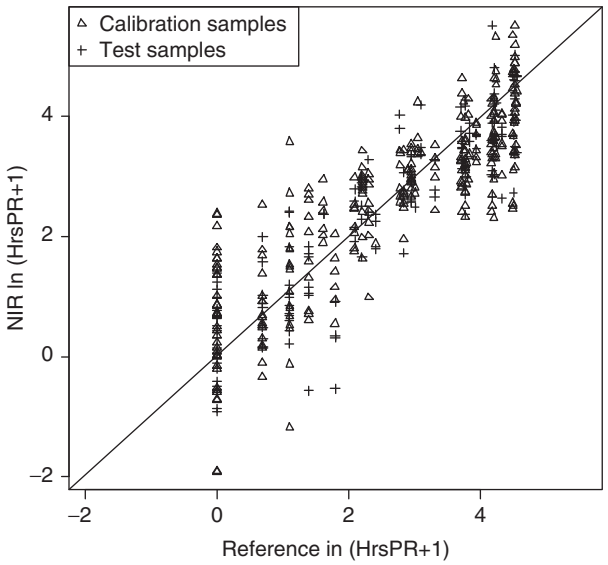

Figure 11 Prediction of time from rigor measured as ln (HrsPostRigor+1) in beef M. longissimus lumborum samples from rigor mortis to 90 h postrigor from the same samples as in Figure 12 Reproduced from Rosenvold, K., Micklander, E., Hansen, P.W., *et al.*, 2009. Temporal, biochemical and structural factors that influence beef quality measurement using near infrared spectroscopy. Meat Science 82, 379–388.

Use of Near Infrared to Predict Meat Quality in Commercial Situations

The experiments described in this article show the ability of NIR to capture changes in the meat throughout the conversion of muscle to meat that are related to final quality attributes. This ability to predict pre- and postrigor changes enables NIR to be considered as:

1. a tool to monitor rigor and aging processes to manage carcasses in order to set quality standards,

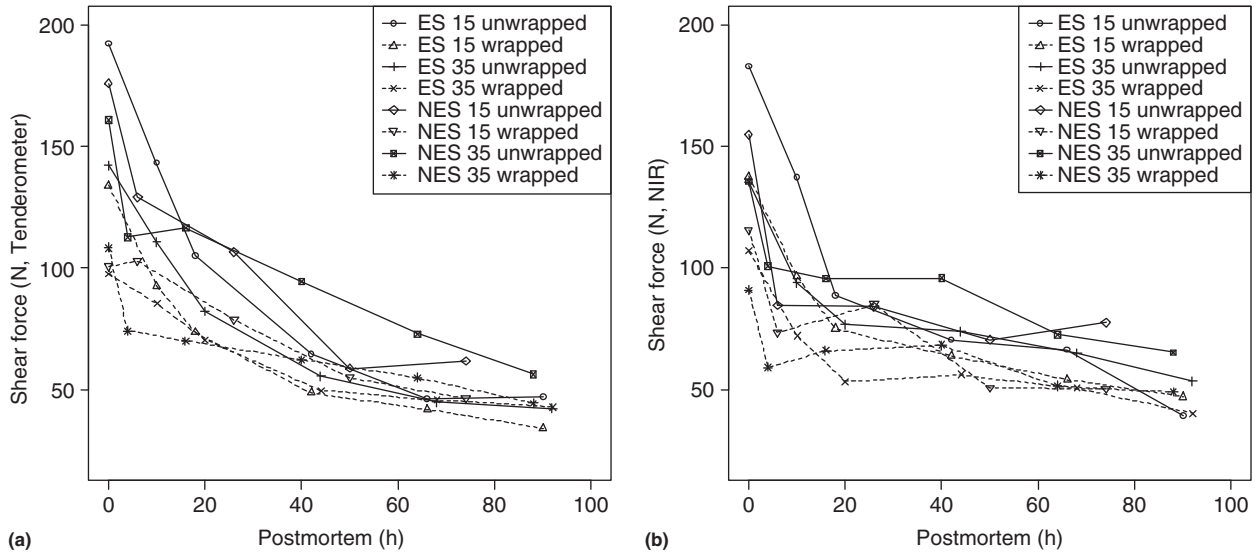

Figure 12 Shear force measured from rigor mortis to 90 h postmortem in steer M. longissimus lumborum samples to which electrical stimulation, wrapping, and prerigor temperatures were applied to create a variation in meat quality. (a) Reference measurement and (b) NIR measurement. ES15: electrically stimulated and held at 15 °C until rigor. ES35: electrically stimulated and held at 35 °C until rigor. NES15: nonstimulated and held at 15 °C until rigor. NES35: nonstimulated and held at 35 °C until rigor. NES5: nonstimulated and held at 5 °C. Unwrapped/wrapped refers whether the muscles were wrapped or not. The calibration for shear force (N) measured in beef M. longissimus lumborum used samples from rigor mortis to approximately 90 h postrigor. Reproduced from Rosenvold, K., Micklander, E., Hansen, P.W., *et al.*, 2009. Temporal, biochemical and structural factors that influence beef quality measurement using near infrared spectroscopy. Meat Science 82, 379–388.

2. a grading tool to identify quality carcasses for sale into higher value markets (e.g., higher quality bulls with normal pH),
3. a filtering tool to pick out a small percentage of inferior quality carcasses to ensure that they do not go to discerning customers (e.g., dark cuts identified from NIR prediction of ultimate pH), and
4. a selection tool for producers and processors, leading to improved quality over time through better genetic selection, improved finishing regimes, or process control.

NIR has been investigated for prediction of meat quality attributes for more than two decades, where a variety of independent studies have been carried out. Results are not always in agreement across studies, and it is very rare to identify studies using similar experimental design and processing conditions, which makes it difficult to evaluate and compare outcomes. Indeed, the development of meat quality attributes involves a complex biological process affected by several factors (e.g., seasonality, processing factors, and animal-to-animal variation). Thus, the success of any of NIR applications to predict meat quality attributes will rely on the design of experiments which must necessarily accurately represent the environment in a meat-processing plant. Good experimental design will lead to representative datasets which account for most of the factors affecting the conversion of muscle into meat, such as environmental (e.g., seasonality) and processing factors (e.g., chain speed and temperature) must be taken into consideration and included in the final analysis. Thus, the variation of results observed in the literature should not deter the development science underpinning NIR spectroscopy for application in meat industries and shows that there is need of some harmonization of the measurement of meat quality attributes.

PRESERVATION METHODS OF ANIMAL PRODUCTS

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

Glossary

Binders Reduce cost and some have water binding and emulsifying properties.
High-pressure food preservation Extremely high pressure can preserve fresh appearance and reduce microbial content.
Hurdle technology Using several bacterial limiting factors in one product to reduce bacterial growth.
Irradiation Used to reduce the microorganisms content for feed, spices, and meat.
Modified atmosphere packaging Reduction of oxygen and replacing it with carbon dioxide or nitrogen within a package.
Reducing compounds Ascorbic acid and erythorbic acid and their salts have antioxidant effects and resist color fading.
Smoking Placing in an environment with smoke to improve flavor, color, and to obtain a slight bacteriostatic effect.

Introduction

Animal products preservation is the system of treating and handling these products to stop or retard spoilage, loss of quality, oxidation while maintaining the nutritional value and desirable edibility, and extending shelf life.

Preservation usually involves prevention or reduction of growth of microorganisms (although in some cases benign bacteria are taken advantage of to achieve desired results). Preservation can also include inhibiting or retarding color deterioration, which may be caused by pigment oxidation, heating, the nonenzymatic Millard reaction (combination of an amino acid and a reducing sugar), or enzymatic action (however, enzymes can be helpful in tenderizing meat). Maintaining or improving nutritional value, texture, and flavor is also important in preservation. Some preservation techniques drastically alter product characteristics, and these changes are often desirable. Many other preservation techniques are often combined (hurdles) to accomplish the desired results. For example, a few of the hurdles might include cooking, reduction in water content, additives such as salt or nitrite, and modified atmosphere or vacuum packaging.

Individual Techniques Utilized

Drying

Drying is one of the oldest preservation techniques and reduces water activity to a level in the product that will prevent bacterial growth (Table 1). American-Indians hung meat in their campfire smoke not only to smoke it but also to dry it (reduce water activity, a_w), so that it would keep for later use. Today, jerky is an example of this dehydration. Modern dehydration is normally carried out by blowing filtered warm air over the product until the desired water activity level is achieved (Table 1). Even though bacterial growth will not occur if the water activity is low enough, recent discoveries reveal that some of the bacteria may still survive. Therefore, combined treatments are now required, and a moist high temperature treatment must also be

Table 1 Influence of water activity (a_w) on microorganism's growth

$a_w = \frac{\text{55.5 mol of water per kilogram}}{\text{Number of moles of solute} + \text{55.5 mol of water}}$	a_w *or minimum* a_w *for growth*
Fresh meat (optimum for most bacterial growth)	0.99
Most bacteria	0.90
Molds	0.85–0.60
Yeast	0.01–0.88
Rapid spoilage can occur	1.0–0.92
Spoilage can occur, but few pathogens will grow	0.85–0.92
Some spoilage can occur, but generally the product is stable without refrigeration	0.85–0.80
Spoilage is greatly delayed	0.7–0.65

Source: Reproduced from Ockerman, H.W., 1996. Chemistry of Meat Tissue, eleventh ed. Columbus, OH: The Ohio State University.

 doi:10.1016/B978-0-12-384731-7.00207-5

included in the drying procedure, for example, for jerky. As a_w is lowered below the optimum, it will increase the lag phase, decrease the growth, and decrease the amount of cell substance synthesized. Each organism has its own a_w range of growth. Combinations of environmental factors (surface drying and migration of salts to the surface, curing salts, pH, and temperature) influence a_w effect.

Water activity is usually obtained by measuring the relative humidity of the atmosphere in a sealed container in equilibrium with the food in the container.

Refrigeration

Microbial growth and the action of enzymes are primarily controlled by time and temperature. In some areas of the world, refrigeration (both commercial and domestic) is utilized, giving food a longer shelf life and improving diets by allowing fruit, salads, dairy products, and meat to be safely stored for longer periods, particularly when the weather is warm. Meat freezes at −2.0 °C and the closer the refrigerated food can keep to this temperature, the longer the food will be protected. The food danger zone is between 4.4 and 60 °C (40 and 140 °F), so food should not be kept in this temperature range for any extended period of time. In other areas of the world, time is controlled and little refrigeration is utilized, lowering the carbon footprint. This practice requires early morning slaughter, meat sales by noon, cooking for lunch or early afternoon, and consumption that day. This is particularly important if the weather is warm. Lack of refrigeration also requires daily shopping, which reduces human efficiency.

Freezing

Freezing is a continuation of refrigeration except at a lower temperature, with an even greater extension of the food's storage life. In evaluating storage temperature, usually colder is better; however, the colder temperature requires a greater expender of energy, so a compromise must be achieved and usually −23.3 °C (−10 °F) is recommended. The rate of freezing is also important; the faster the better (less time for water migration and production of large ice crystals, which causes dehydration of other areas). In most cases, microorganisms will not grow at recommended freezer temperatures and therefore the food is usually safe to eat. However, oxidation, even though retarded in frozen products, will continue and off-flavors will develop. Oxidation rate is not only reduced at lower temperatures but is also controlled by a substrate that is susceptible to oxidation, such as unsaturated fat, so higher fat content will result in shorter acceptable storage life. Also, sodium chloride (salt) added to food will speed up oxidation. Therefore, different products have different recommended frozen storage times. Food packaging is also important, and a material with reduced moisture transmission is desirable. If this is not used, dehydration will occur and in extreme cases freezer burn will produce a white area that will allow oxygen penetration and increased oxidation. The product is usually still safe to eat but flavor and texture is reduced.

Vacuum and Modified Atmosphere Packaging

Vacuum packaging in an oxygen impermeable package will exclude most of the oxygen, thus reducing oxidation and off-flavors and retarding the growth of microorganisms that require oxygen for growth (aerobe). This will significantly extend the shelf life of refrigerated, frozen, and dried foods. Vacuum packaging changes the color of muscle tissue. Tissue that has been exposed to the oxygen changes from myoglobin (purplish red) to oxymyglobin (bright red), and consumers associate this bright red color with a fresh product. When meat is vacuum packaged, this reaction is reversed and a purplish-red color is obtained. Modified atmosphere packaging changes the environment around the food in the package. In this system the oxygen (O_2) concentration is often reduced and the carbon dioxide (CO_2) concentration is increased. Increase of CO_2 may be obtained by depositing a block of dry ice in the package before sealing or more frequently the food container can be purged by gaseous carbon dioxide from a cylinder. The reduction of oxygen reduces oxidation. Nitrogen (N_2) gas is also sometimes used instead of CO_2. Various combinations of gases are currently being researched to find the ideal mixture for each type of product and storage condition.

Salt

Salt is one of the oldest additives to extend the shelf life of a food item. It also alters flavor, which is desired by most humans, decreases the water activity value, which gives better bacterial protection, extracts protein, and assists in emulsion formation. If salt is placed on the outside of food, it attracts food moisture by osmosis and dehydration results. If mixed with the food, salt will retard bacterial growth. When salt is added to muscle tissue, the tissue will have a higher salt concentration than the bacterial cell; most bacterial cell walls are semipermeable, which will allow water but not salt to pass through. Water will pass from the less salt dense concentration (bacterial cell) to the more salt dense concentration in the food, and the bacterial cell will become dehydrated, shrivel, and die. Other effects of salt addition include toxicity of the chlorine ion, reduced oxygen solubility in food, and reduced effectiveness of bacterial proteolytic enzymes. Table 2 indicates the approximate salt level for bacterial inhibition.

Because this high salt level is objectionable for most products, it is usually used in combination with other bacterial

Table 2 Upper limits of salt for bacterial growth

Microorganism	*Salt (NaCl)*
Clostridium botulinum	10%
Staphylococcus aureus	15%
Salmonellae	8%
Most bacteria	8%
Fermentative yeast	10%
Oxidative yeast	Up to 25%
Molds	18%, some up to 22%

Source: Reproduced from Ockerman, H.W., 1996. Chemistry of Meat Tissue, eleventh ed. Columbus, OH: The Ohio State University.

inhibiting factors. Disadvantages of salt are that it promotes oxidation and fades desirable meat color to a stale one. Owing to the fact that many people consume more salt than they require, most processors are trying to reduce the salt level in their products to promote better health.

Sweeteners

Sugars (sucrose, glucose, corn sirup solids, corn sirup, glucose, sirup, and malt sirup) and artificial sweeteners are used in food to contribute to flavor. Sugars result in food energy, altered color on cooking, and reducing conditions, which aid in color development in meat. The level of sugar needed to retard bacterial growth is from 20% to 80%, which is used in jams and jellies, but this level is too high for most animal products. The only exception to this rule in the meat area is some mincemeat. In fact, the 1–10% sugar level usually used in meats will encourage bacterial growth.

Smoking

Smoking is used primarily with meat (including sausage), fish, and cheese and is usually, but not always, combined with heating. Its main purpose is to add flavor and produce a desirable external color. The smoke usually affects only the external surfaces and has little penetrating power. Smoke has a slight bacteriostatic effect, adds a protective coating that acts as a physical barrier for the product and retards penetration of undesirable microorganisms, and deposits some phenol compounds, which retard oxidation. However, smoking alone does not have much preservative power unless it is combined with heating or drying. Sausages that are moist cooked, showered, or sliced after smoking lose some of the advantages of smoking. Liquid smoke, which is obtained by burning hardwood and capturing a fraction of the smoke volatiles in a suitable solvent, can be mixed with the food, resulting in more penetration into the product. Liquid smoke is usually acidic and the lowering of pH can result in some preservative effect. As smoking is a potential carcinogenic risk, it is continuously evaluated for its safety.

Additives

Many food additives influence preservation, of which two (salt and sweeteners) have already been mentioned. Many additional food additives make present day food formulations possible, and without additives many products would be difficult to manufacture and most animal food products' shelf lives would be drastically affected. A few of the more important and often used food additives are listed here.

Nitrite (nitrate that can be converted into nitrite in the meat and its typical microbial environment) and salt (sodium chloride) convert fresh meat into cured meat. Sodium (Na) or potassium (K) nitrite is primarily used. Na and K nitrates are primarily used as a reservoir for nitrite in long-cured meat (e.g., dry-cured meats that will keep without refrigeration). These cured meat products are not as easily found today as in the past. In meat curing, the nitrite is partly converted into nitrous acid, which is then converted into nitric oxide, which combines with the muscle pigment (myoglobin) to form the desirable pink color of cured meat. In addition to the color change, nitrites are highly bacteriostatic (retard bacterial growth). Five percent salt plus 200 ppm of nitrite is equivalent in preserving effect to approximately 15% salt in meat products. A number of genera of bacteria are retarded by nitrite in the pH 5.7–6.0 range. Flavor is also altered by nitrite to produce the desirable, typical, cured meat flavor. Nitrite is also an excellent antioxidant, which reduces 'warmed-over flavor' and other oxidation problems, giving cured products a much longer shelf life than their uncured counterparts. Nitrite usage in the US is limited to 156 ppm (in some countries this value is lower) in most products and 120 ppm in bacon. After heat processing and storage, this level is usually reduced to much less than 50 ppm. In fermented products, the nitrite is used at a lower level to keep it from deactivating the starter culture bacteria. Nitrite in large dosage is toxic, but there are several safeguards built into its usage in meat processing. Nitrite is kept in a locked 'bonded room,' and if nitrite is used in excess in a product, 'nitrite burn' will result in an undesirable color, which would warn the processor. Nitrite is usually mixed with salt (Europe, 0.6% and USA, 6.25% nitrite), and if too much is added, the product would be too salty to eat. This mixture is also colored pink so it would be difficult to confuse it with 100% salt or sugar. Nitrite oxide (HNO_2) could also combine with secondary amines (R_2NH) to produce nitrosamines ($R_2N–NO$), which are carcinogenic. Till date, these have only been found in extremely low levels in sausage products. In a few cases, fried bacon has been found to have slightly higher levels, so to combat this, you can only add 120 or less ppm of nitrite and must also contain 500 ppm of erythorbate (a reducing compound to retard this nitrite/secondary amine combination). Also, new processing techniques are now required to reduce this possibility. In the US, products are sampled periodically by the inspection service to make sure that they do not contain excessive levels of nitrosamines and are, therefore, safe.

Reducing Compounds

Ascorbic acid, erythorbic acid (isoascorbic acid), and their salts (sodium ascorbate and sodium erythorbate (sodium isoascorbate)) are used in cured meats (not allowed in the US in fresh meat products) and have water-soluble antioxidant effects, which result in faster color development and resist color fading during storage. These compounds can be used at 500 ppm (some countries allow higher levels); this quantity is required in bacon. Citric and fumaric acids (acidulates) lower the tissue pH, influence the flavor, reduce bacterial growth, and speed up color development. Glucono delta lactone (GDL) has a neutral pH when added to meat but is slowly converted to gluconic acid, which causes a delayed influence in meat due to a delayed pH decline that speeds up color development similar to the other acid compounds. GDL can be added in the US at the rate of 8 oz per 100 lbs of meat. In several countries, the permissible rate is much higher. Sodium (or potassium) lactate (salt of lactic acid) lowers water activity,

which has an antimicrobial effect, without changing the pH or color of the meat tissue.

Phosphates (Na or K) fall into two categories: those that raise pH, increase water-holding capacity, increase juiciness, reduce cooking shrink, reduce cooking time in mature poultry and white tuna, have antioxidant properties, and reduce refrigerator and thaw drip. The greater the pH increase, the greater the effect. The other category is acid phosphate, which lowers pH, speeds up color development, reduces bacterial growth, increases muscle texture and emulsion stability, and improves sliceability but does not increase water-holding capacity. Phosphates in the US may be added at the rate of 0.05% but are usually used at a 0.03% level. In the EU, the maximum level is 5 g kg^{-1} (0.5%), but the amount used is usually 2.5 g kg^{-1} as phosphor pentoxide.

Binders

Binders that can be added to sausage emulsions include corn, wheat, oats, rye, rice, sunflower meal, vital wheat gluten, corn gluten, potato, barley, rapeseed, rusk, soya, and possibly many more. Many of these have subdivisions depending on how they are processed. In addition to the plant kingdom, many animal additives are also used, such as nonfat dry milk, sodium caseinate, calcium-reduced dried skim milk, dried whey, gelatin, and blood. Binders and additives are added to reduce the cost per unit weight. A few have emulsifying power and several of the dried products can absorb moisture and/or fat, reduce shrinkage, increase juiciness, and alter color and flavor.

Spices

Spices (whole or extract) incorporated into sausage often determine its characteristic (flavor, visual effect, flavor impact, and label requirements), and the addition of spices supplies a tremendous variety of products.

Color

Color additives are usually placed on the surface and can be extracts of plant material or coal tar dyes, titanium dioxide, or caramelized material. Other color additions such as hydrogen peroxide (used to bleach tripe), federal inspection ink, and branding ink are utilized and approved as safe.

Other Additives

Other additives include starter cultures (that cause fermentation) and/or added acid to produce a tangy flavor.

Antioxidants are sometimes used to reduce rancidity and are usually selected for their 'carry through' effect, which will be determined by the environment in which the product is stored.

Meat tenderization can be improved by weak acids or by mechanically breaking the fibers or enzymes (both naturally in the meat or added). A few preservatives are legal in the US primarily to reduce mold growth on the surface of dried products.

Casings to contain sausage fall into three major categories: natural casing obtained from animal intestines or internal organs, collagen made from cotton linters (often removed before sale), or cellulose (extracted from animal tissue). Each casing category has its market place. Stockinets from knitted cotton are often used to maintain the meat's shape during cooking and smoking.

Pickling

Pickling is used more in the vegetable area than in animal products, but a few examples can be found, such as corned beef, muscle tissue from many species, herring, and eggs. Pickling can be divided into two main categories: chemical pickling and fermentation pickling. In chemical pickling, the food is placed in an edible liquid that kills microorganisms and includes brine (high in salt), vinegar alcohol, or oil. Pickling often involves heating or boiling so that the food becomes saturated with the pickling agent. Fermentation pickling involves microorganisms (starter culture or natural culture) that on growth lower the pH to such a point that bacteria will not grow. This type of pickling is used extensity for fermented sausages.

Canning

Canning in the meat area is most successful with cured products, such as canned or chopped ham (e.g., spam) or fish or poultry. With uncured products, the time/temperature requirements for sterilization are so high that the flavor is not very acceptable. A few products have been successful by masking this flavor with spices.

The classic example for bottling is dairy products that are pasteurized and, along with refrigeration, allow the product to have several days of shelf life. Conditions often used are 71.7 °C (161 °F) for 15–20 s or for ultra-high temperature processing, the milk is exposed to a temperature of 135 °C (275 °F) for a minimum of 1 s. Some countries use sterilized milk, but in most cases due to heat-induced flavor, the milk is used for cooking and usually not for drinking. Condensed milk is cow's milk from which some of the moisture has been removed. It is most often found in the form of sweetened condensed milk, in which sugar has also been added.

Irradiation

A very wide range of dry herbs and spices can be processed using irradiation or treated with ethylene oxide gas to reduce microbial contamination. Irradiation is frequently used in spices utilized in the food industry and usually not used in spices sold in the supermarket.

Irradiation effectively controls or eliminates microorganisms in animal feeds and is approved by the US Food and Drug Administration (FDA) to treat feeds for any animal. The irradiation of poultry feed to control *Salmonella* is approved by

the FDA (21 CFR § 579.40). The FDA is amending the food additive regulations to allow safe use of irradiation on unrefrigerated (as well as refrigerated) uncooked meat, meat byproducts, and certain meat food products in order to reduce levels of foodborne pathogens and to extend shelf life. The FDA also increased the maximum dose of ionizing radiation permitted in the treatment of poultry products and clarified packaging requirements.

Pulsed Electric Fields Processing

Use of pulsed electric fields (PEFs) for inactivation of microorganisms is a nonthermal processing method. Microorganisms are exposed to high-voltage PEFs that react with the electromechanical instability of the bacterial cell membrane. Electric field strength and treatment time are the two most important factors involved. This system works with liquid and semiliquid products and encouraging results are reported at the laboratory level, but scaling up to the industrial level escalates the cost. A successful continuous PEF processing system for industrial applications is currently in the design stages. The high initial cost is the major obstacle.

High-Pressure Food Preservation

High-pressure food preservation (high hydrostatic pressure processing; high-pressure pasteurization) refers to placing food inside a vessel and exposing it to 70 000 lb per square inch or more. Food processed by this technique retains its fresh appearance, flavor, texture, and nutrients while disabling harmful microorganisms and delaying spoilage. A few of the foods preserved by this method include fruits, juices, vegetables, sea food, sauces, and ready-to-eat meats. Average high-pressure pasteurization systems employ pressures up to 700 MPa (100 000 psi) to destroy many foodborne pathogens, such as *Listeria*, *Escherichia coli*, and *Salmonella*, with little or no change in the organoleptic properties or nutritional value. Products may be packaged in consumer packaging before processing, thus eliminating recontamination problems. A good fact sheet on this process can be located at Ramaswamy *et al.* (2012).

Biopreservation

Biopreservation is the use of natural or controlled macrobiotics or antimicrobials as a way of preserving food and extending product shelf life. Desirable bacteria or the fermentation products produced by these bacteria are used in biopreservation to control spoilage and to inactivate pathogens in food. This is a benign ecological approach that is gaining increasing attention. Lactic acid bacteria (LAB), which have antagonistic properties that make them useful as biopreservatives, are the organisms mostly used. When LAB compete for nutrients, their metabolites often include active antimicrobials, such as lactic and acetic acids, hydrogen peroxide, and peptide bacteriocins. Some LAB produce the antimicrobial nisin, which is an effective preservative. Fermented (usually dried) sausage is a classic example of this type of preservation. Fish preservation is achieved by adding antimicrobials or by increasing the acidity (lowering the pH) of the fish muscle; most bacteria stop multiplying when the pH is less than 4.5. Traditionally, acidity has been increased by fermentation, marination, or by direct addition of acetic, citric, or lactic acid to food products, but most consumers do not like the flavor of the acid-added products as well as naturally fermented products. Other preservatives include benzoates, essential oils, nitrites, sorbates, and sulfites, to name but a few. This type of processing is fundamentally in the dairy industry and, currently, is being extended to other fermented foods, such as meat, spirits, vegetable products, and juices.

Hurdle Technology

Hurdle technology means combining various bacteria-inhibiting or bacteria-killing factors (some of the 'hurdles,' e.g., are salt, reduced pH, reduced water activity, heat treatment, and appropriative packaging) to achieve a safe product with acceptable shelf life and an acceptable taste and consistency. This means that the level of an individual hurdle can be reduced from the height (intensity or contrition) it would require for the same safety if used alone. An appropriate combination of hurdles can work in synergy and provides a good antibacterial effect, even though the 'height' (level) of each individual hurdle may be smaller than would be appropriate by itself.

Behavior of Cattle, Pigs, Sheep, Bison, and Deer during Handling and Transport

T Grandin, Colorado State University, Fort Collins, CO, USA

Glossary

Crowding pen A small pen for directing animals into a single-file race. It may also be referred to as a forcing pen, push pen, or funnel pen. In systems where animals are stunned in groups for controlled gas atmosphere stunning, the crowd pen is defined as the last small pen before the animals enter the gondola or other apparatus that conveys them into the gas.

Driving aids These are the tools for moving livestock. Some examples of acceptable driving aids are flags, plastic paddles, solid panels carried by the handlers, plastic bags, or trained leader animals.

Electric prod (goad) A stick that delivers a shock for moving animals. Other driving aids for moving animals are preferable because electric prods are stressful.

Flight zone An animal's safety zone or personal space. Animals that are not completely tame will move away when a handler enters their flight zone.

Lairage These are the pens for holding animals after they have been unloaded from the trucks. They are sometimes called stockyards, holding pens, antemortem pens, or yards.

Point of balance All types of farm animals will move forward when a person is located behind the point of balance at the shoulder and they often back up when a person stands in front of the shoulder.

Race An alley where animals move to the stunner while walking in single file. It may also be called a chute or a lead-up alley. Single-file races are also used in some countries as the loading ramp for loading animals onto trucks.

Staging alley An alley for holding animals that is located between the lairage pens and the crowd pen.

Stunner A device or method for rendering animals insensible to pain and unconscious before slaughter.

Stunning box A small stall or restrainer where an animal is held for application of the stunning method.

Introduction

This article is concerned with behavior of cattle, pigs, sheep, bison, and deer during handling and transport. However, this is only part of the way animals need to be handled and this article needs to be read in association with design of stockyards, lairages, corrals, races, chutes, and loading ramps to facilitate the movement of animals for both optimum welfare and productivity.

Behavior Is Important

People who understand animal behavior will be able to move all species of livestock more easily. A skilled person uses behavioral principles instead of forcing the animals to move. The use of behavioral methods will also help to improve animal welfare. Animals that become stressed shortly before slaughter will have higher lactate levels and be more likely to have tougher meat. A calm animal that has not become agitated and fearful will also move more easily and be safer for people to handle. Handlers should be aware of the behavioral signs of fear and distress in the different species of animals.

Behavioral Indicators of Stress

Behavioral indicators of stress can be used to detect welfare problems during preslaughter handling. One of the most obvious and useful indicators of stress in cattle and pigs is

 doi:10.1016/B978-0-12-384731-7.00251-8

vocalization during handling and restraint. In both cattle and pigs, high levels of distress are associated with vocalization (moo, bellow, and squeal) during handling and restraint. Research studies have shown that vocalization during handling, restraint, or surgical procedures is associated with physiological indicators of stress, such as increased levels of cortisol, lactate, or glucose in the blood. A basic principle is that measuring glucose or lactate within 5 min after a stressor is applied will result in higher levels. When lactate and glucose are measured several hours after a stressor is applied, such as truck loading at the farm, they will be lower in stressed animals. Cortisol is a time-dependent measure and requires 15–20 min to peak after a stressor is applied.

In cattle and pigs, vocalization during movement by a person through the race and vocalization in the stunning box or restrainer are associated with aversive events. Some examples of aversive events are use of electric prod, excessive pressure from a head holder or body restraint, slamming gates on animals, or being held too long in a restraint device. There are species differences in vocalization behavior. Sheep are the most defenseless prey species animal and they do not vocalize when painful or distressing stimuli are applied to them. Goats will often vocalize loudly when they are distressed by either handling or restraint. When vocalization is being used as an indicator of poor welfare and distress during handling, it should only be measured when people are actually moving animals or when the animal is being held in a stun box or restraint device. It should not be measured in the lairage where animals are quietly resting. Animals will sometimes vocalize to each other during lairage. This often happens in bulls and it is not associated with the stress of preslaughter handling.

There are other less obvious signs of stress in animals. When the whites of an animal's eye show, it is starting to become fearful. In cattle, eye white will often be shown before the aversiveness of the situation becomes high enough to elicit vocalization. Scientists were able to verify that eye white is associated with fear because antianxiety drugs will block the eye white response. The best scientific documentation for eye white is in cattle. The author has also observed eye white during handling and restraint in horses and bison. Other obvious indicators of distress are struggling during restraint and increased heart rate and respiration. Tail switching in cattle and raised tails in bison are also signs of stress. Heart rate can be easily monitored with electronic monitors designed for athletes. Handlers should be observant for struggling and behavioral agitation associated with a slippery floor. A common problem is an animal that refuses to stand still in the stunning box. This is often due to a slick floor and one or more of the animal's feet doing a series of rapid small slips. Providing a nonslip floor in the stunning box will prevent this and the animal will remain still and be calmer.

Stress during Slaughter

A common question that people ask is, "Do the animals know they will die?" The author has observed that the behavior of animals moving to the stunning area at a slaughter plant is the same as animals moving into a veterinary restrainer on the farm. Data collected during many studies, both on the farm and in slaughter plants, indicate that the level of cortisol is similar after stunning and after restraint on the farm. However, epinephrine (adrenaline/adrenalin) will be elevated after stunning compared with on-farm restraint, and it increases almost instantly after the brain is disrupted by stunning. This does not cause an animal welfare issue, because correct application of either electrical stunning or a captive bolt shot will render the animal instantly unconscious. Cortisol measures taken immediately after slaughter will not be affected because cortisol takes 10–20 min to reach peak values.

Researchers have found that the novelty of the new environment at the slaughter plant may be associated with stress at slaughter. Cattle that had the biggest reaction to a sudden novel stimulus on the farm also had the highest physiological indicators at slaughter in the plant.

Animal Perception

Vision Affects Livestock Movement

Cattle, pigs, bison, deer, and sheep all have wide-angle vision. Panoramic vision enables them to see all around themselves. Farm animals are also dichromatic and they do not see the color red. Dichromatic vision improves both night vision and seeing contrasts of light and dark. All the species discussed in this article are sensitive to visual distractions that can slow down animal movement through handling facilities. In many existing slaughter plants, locating and removing one or more visual distractions greatly facilitated the movement of cattle and pigs. In one pork plant, moving ceiling lights to eliminate a sparkling reflection on a wet floor improved movement through the single-file race. Modification of lighting can often greatly improve animal movement. All animal species will often refuse to enter a dark race or stun box. Indirect illumination of the entrance of the race or stun box encourages the animals to enter. The basic principle is that livestock are attracted toward more brightly lighted areas, but they will not walk toward a blinding light. People should experiment with portable lamps to find the best position for additional illumination. Sometimes turning off a ceiling light will improve movement. Animals are often attracted to a 'light at the end of the tunnel' effect. It is also essential to prevent animals from seeing moving equipment or people up ahead. The installation of solid panels or curtains made from discarded conveyor belting can be used to block these visual distractions. Large pieces of cardboard can be used to experiment with shields for blocking the view of moving people or equipment. At one cattle plant, four different distractions had to be located and fixed before the animals would move easily.

The four modifications were:

1. block sunbeams from a hole in the lairage roof;
2. block the cattle's view of a person checking cattle ID's with cardboard;
3. install a light on the restrainer entrance;
4. install a curtain to prevent seeing people walking by.

People need to be observant. A calm animal will stare directly at a distraction such as a reflection, a hose on the floor,

a coat on a fence, or dangling chains. Frightened agitated animals are too stressed to stare at the distraction. Instead, they will immediately balk and turn back.

Auditory Effects

Yelling at livestock is stressful and raises the animal's heart rate more than the sounds of gates slamming. One study showed that yelling in the ear of a cow was as stressful as an electric prod. Handlers need to be quiet with no yelling, whistling, or banging on the side of the race.

Effect of Odor

Novel odors will often make animals balk and refuse to move. The author has observed that both odors from the slaughter process itself and odors such as fresh paint that are not related to the slaughter process will both increase balking and retard animal's movement. Two studies have shown that cattle or pigs that have been stressed for 10–15 min with aversive stimuli will secrete substances that will be avoided by other animals. During numerous new equipment startups, the author has observed that if an animal got jammed in a malfunctioning piece of equipment for 10–15 min, other animals would refuse to enter the equipment. The next day after the equipment was completely washed, cattle would enter easily. A single poke with an electric prod is usually not sufficient to cause this effect. At one plant, the author observed that after one steer had flipped over on its back in the race and was stuck for 10–15 min, the other cattle refused to walk over the spot in the race where this severely stressed steer had urinated and salivated. After the race was washed, the cattle started moving easily again.

Behavioral Methods for Moving Livestock

People who work with animals at a slaughter plant and during loading of animals onto trucks need to use and understand some basic principles of animal behavior. Two of the most important principles that apply to all species are flight zone and point of balance. These two principles are used in all livestock species. The only time they do not work is in very tame animals that are trained to lead. Tame animals have no flight zone and they can be led into the slaughter plant or onto a truck instead of being driven. The flight zone and point of balance principle should be used in all animals that are not completely tame.

The Flight Zone

The flight zone is like a bubble around the animal. When a person enters the flight zone, the animal will move away and when a person retreats from the flight zone, the animal will stop. A major cause of animals rearing up in stun boxes and races is due to a person being deep in the flight zone. The animal will often settle back down and stop rearing if the handler backs away. The handler should back away instead of attempting to push the animal back down. The size of the flight zone is determined by both the animal's genetics and its previous experience with people on the farm of origin. Animals that live in close contact with people will have smaller flight zones than extensively raised animals that seldom see people. Species such as deer and bison often have larger flight zones than cattle and pigs. Covering the side of the race with a solid panel will also reduce the size of the flight zone. Even a partial solid side where the animal can still see over the top will usually reduce the flight zone compared with a completely open-sided race.

Animals tend to have a larger flight zone when approaching novel new things compared with familiar things. For example, cattle or pigs that are accustomed to people walking through them will have smaller flight zones than animals that are not accustomed to. The reactions of animals are highly specific. Cattle that have become accustomed to a person on a horse may have a small flight zone of 2 m, but when they are suddenly confronted with the novel experience of a man on foot, the flight zone may expand to more than 10 m. On pig farms, it is important for people to actually walk through the fattening pens; walking only in the aisles is not sufficient. On farms where the caretakers have only walked in the aisles, the pigs may become agitated and pile up the first time a person enters their pen. This is especially a problem with certain genetic lines of lean more excitable pigs. To reduce stress during truck loading, for several months before shipment, the producer should walk quietly through the pens and get the pigs accustomed to quietly moving away when a person walks through them.

Point of Balance

One of the most common mistakes that handlers make when moving an animal through a single-file race (chute) is to stand at the animal's head and attempt to make it go forward by poking it in the rear. To induce all species to move forward, the handler should be positioned behind the animal's point of balance at the shoulder. When a person is standing close to an animal in a single-file race, the point of balance will usually be at the shoulder. If the handler is in the lairage and further away from the animal, the point of balance may be just behind the eye. The point of balance will never be in front of the eyes. All handlers should be trained on how to use the point of balance. One of the most effective methods for inducing all species to move forward in a race is to quickly walk back past the shoulder in the opposite direction of desired movement. This seems counter intuitive, but it really works. To make it work, the handler must walk quickly. If the handler walks too slowly, the animals will back up. The forward movement will start when the point of balance is crossed. If the handler stops in front of the point of balance, the animal will back up.

Species Differences in Behavior between Sheep and Other Livestock

Most basic principles of moving animals are the same for all species, but there are some important differences. Sheep are intense followers and they can be moved in large groups. They will keep following and can be moved through a handling

system in a continuous flow. They have an intensive behavioral motivation to follow other sheep. On progressive farms and slaughter plants, specially trained lead sheep are used to lead sheep out of pens, unload trucks, and move sheep through the race to the stunner. There are two basic methods for using lead sheep. On some large farms, the trained lead sheep is led like a dog with a lead rope and a halter (head collar). Another method is a trained leader that knows the routine when it is released by a handler. In one well-run large sheep plant, they had three types of specialist leader sheep.

They were:

1. truck unloaders,
2. leaders to lead sheep out of the lairage pens, and
3. a leader that led sheep up the race to the stunner.

To avoid being slaughtered, the trained leader escaped through a side door. Each leader is trained for its specialist job. The most progressive sheep slaughter plants have stopped using dogs.

Move Small Bunches of Other Species

Cattle, pigs, goats, bison, and deer should all be moved into the crowd pen in small separate bunches. This applies to both handling systems that have a single-file race (chute) and systems where the animals are stunned in groups. One of the most serious handling problems is moving groups that are too large. Good handling is going to require more walking to bring animals up to the staging alley to the crowd pen. Each plant will need to determine the correct number of animals that should be moved through each stage in the handling system. The most common mistake is to overfill the crowd pen that leads to the single-file race. Animals need to have room to turn. If animals balk and refuse to move out of the crowd pen into the race, there is probably a distraction that needs to be removed. One of the most common distractions is an antibackup gate. Try tying it open. If animals constantly back up, there is a distraction in the race that needs to be removed.

Use Following-Behavior

Animals will enter the single-file race (chute) more easily if there is space in the single file before the crowd pen is filled. This will enable the animals that are entering the crowd pen to move into the race without stopping. If the crowd pen is filled when the race is full, the animals may turn around. They turn around because it is natural behavior to return to where they came from. This same principle applies to truck loading. Before the animals are brought to the crowd pen, the truck should be backed up and ready to receive them. The animals can then be moved through the crowd pen and onto the truck without stopping.

Isolated Lone Animal Problems

All species get frightened and agitated when they are isolated from their herdmates. Many accidents have occurred that have injured both people and animals when a single isolated animal charges fences or attempts to jump out of a facility. Handlers should never leave a single animal alone in a race or a stun box during breaks. If a lone animal becomes agitated, some other animals should be put in with it.

Use of Electric Prods (Goads)

This is a controversial area from an animal welfare standpoint. The OIE World Animal Health Organization bans their use on horses, sheep, small calves, and piglets. Only battery operated electric prods should be used. They should be applied no more than three times on the hindquarters. An electric prod should never be a person's primary driving tool. In the most progressive slaughter plants, electric prods are banned in the lairage and in the truck unloading area. A single electric prod is kept at the stunner entrance. It is only picked up to move a stubborn animal and then put away. If animals refuse to enter the stun box, it has either too many distractions or design problems that must be corrected.

Recommended Driving Aids

Some of the recommended driving aids for cattle, sheep, or bison are plastic paddles or flags. A plastic paddle looks like a small boat oar. Flags of various types are also excellent for moving animals. A simple, easy-to-use driving aid is a plastic bag tied to a light stick. These driving aids should be used to quietly guide animals. When animals are calm, they can be turned by moving the flag or paddle next to the eye. The handler should not wildly wave the driving aid. Blocking the animal's vision on one side will make the animal turn. If the animals are agitated and fearful, they will stick together and be hard to turn. Good driving aids for pigs are solid panels and large flags. The following aids for driving animals are not acceptable – iron rods, bats, sticks with nails in them, heavy whips, or electric prods wired into the main current.

Abusive Acts that are Detrimental to Welfare

The following abusive acts are banned according to many international and private standards. They are dragging downed nonambulatory animals, throwing animals, dropping animals off the back of a large truck, beating animals, poking sensitive areas such as the rectum, nose, ears, or eyes, deliberately driving animals over the top of downed animals, and deliberately slamming gates on animals.

The Need and Impact of Understanding Animal Behavior

Animals have been part of human culture for thousands of years and to a large extent pastoralists have understood much of what was required for domestication. With intensive farming systems and a large focus on production and processing in modern abattoirs, the need has arisen for a better understanding behavior for welfare and sensible movements of animals through various facilities. This article and its companion article have pulled together many aspects of behavior

Table 1 The impact of Temple Grandin's work

Design of animal handling facilities	Dr. Grandin is one of the world's leaders in the design of livestock handling facilities. She has designed livestock facilities throughout the USA and in Canada, Europe, Mexico, Australia, New Zealand, and other countries. In North America, almost half of all cattle-processing facilities include a center track restrainer system that she designed for meat plants. Her curved chute systems are used worldwide and her writings on the flight zone and other principles of grazing animal behavior have helped many producers to reduce stress during handling. Temple has also designed an objective scoring system for assessing handling of cattle and pigs at meat plants. This system is being used by many large corporations to improve animal care.
Industry consulting	Dr. Grandin has consulted with many different industry organizations each year for the past 10 years. These efforts represent the majority of her time as she has a part-time appointment at Colorado State University but a thriving business as a consultant. The majority of her work is involved with large feedlots and commercial meat packers. She has worked with Cargill, Tyson, JBS Swift, Smithfield, Seaboard, Cactus Feeders, and many other large companies. Her company also does design work for many ranches. She was also involved with several major packing companies. Her consulting has led to work with companies such as Wendy's International, Burger King, Whole Foods, Chipotle, and McDonald's Corporation, where she has trained auditors regarding animal care at processing plants. She also has consulted with organic and natural livestock producers on animal care standards The animal handling guidelines that she wrote for the American Meat Institute are being used by many large meat-buying customers to objectively audit animal handling and stunning.
Research	Dr. Grandin maintains a limited number of graduate students and conducts research that assists in developing systems for animal handling and, in particular, with the reduction of stress and losses at the packing plant. She has published her research in the areas of cattle temperament, environmental enrichment of pigs, livestock behavior during handling, reducing dark cutters and bruises, bull fertility, housing dairy cattle, and effective stunning methods for cattle and hogs.
Media exposure	Dr. Grandin has provided worldwide media exposure for the livestock industry and, in particular, with issues relating to animal care. She has appeared on television shows such as 20/20, 48 h, CNN Larry King Live, 60 min, and has been featured in People Magazine, the New York Times, Forbes, U.S. News and World Report, and Time magazine. Interviews with Dr. Grandin have been broadcast on National Public Radio (NPR) and she has been taped for similar shows in Europe. She was named one of Time Magazine's 100 Most Influential people. HBO has made a movie about her life starring Claire Danes.
Outreach	Dr. Grandin maintains an appointment with Cooperative Extension at Colorado State, where she has been active in making presentations to Colorado ranchers and farmers as well as those interested in the packing industry. She is sought after to discuss issues of quality assurance. Privately, she has developed her own website (www.grandin.com), which has been expanded to include information on livestock handling in addition to information relative to the design of handling systems. A section on bison handling and one in Spanish have been popular. More than 2000 people visit the website every month and approximately 1000 download significant amounts of information. As many as 1431 files were downloaded daily and more than 42 000 have been downloaded in a single month. The website has been accessed by people from more than 50 countries worldwide. She also did a TED talk in 2010 entitled, 'The World Needs All Kinds of Minds.'
International activities	It is clear from the wide variety of information accessed via the website, presentations made in international settings, and interest in livestock handling systems developed by Dr. Grandin that her work has reached an international audience. She typically travels to make presentations internationally three to five times annually.

of animals and design of facilities for optimum handling of animals. The author, Dr. Temp"le Grandin, has had a major impact on the meat and livestock industries worldwide and the editors have compiled six specific examples that document this influence from student involvement to international presentations – these provide a template on Table 1 for others to follow and improve.

Conclusions

Improvements in animal handling of all species of livestock will have benefits for the welfare of the animals, quality of the meat, prevention of bruises, and safety for plant employees.

Introduction

The behavioral principles of animal handling have been discussed in the article 'Behavior of Cattle, Pigs, Sheep, Bison, and Deer during Handling and Transport'. In addition, the cross-references in 'see also' and the websites cover the design and layout of chutes and races and these references are an important supplement to this article. Visual distractions discussed in this article can ruin the efficiency of a well-designed facility because animals constantly balk, back up, or turn around. Low stress humane handling will be impossible until the distractions are removed. The distractions that inhibit animal movement are the same for all species. Some of the most common distractions that must be removed are:

1. Air blowing into the faces of approaching animals – This must be stopped. Airflow at the entrance of a stun box or restrainer must either be still or move with the flow of the animals.
2. The 'dark movie theater' Effect – When animals are moving from bright sunlight into a dark building, they will often balk because they cannot see where they are going. This can be fixed by building a shade over the entrance to reduce the brightness of the sunlight.
3. Seeing Moving People or Equipment – Look through the chutes and races and if moving people or equipment is visible, solid shields should be installed. Experiment with cardboard.
4. Indoor Dark Race or Chute Entrance – In indoor facilities where the animal's eyes have adjusted to lower light levels, lamps can be installed to attract animals into a dark stun box or race. Experiment with portable lights.
5. Reflections on shiny metal or wet surfaces – Reflections can often be eliminated by either moving existing ceiling lamps or turning off selected lamps. Experiment with lighting while a person looks through the facility at an animal's eye level. Some shiny surfaces will need to have a dull nonreflective finish applied.

Further information and photos can be found in the websites.

A Case Study of A Beef Plant

It is often required to find and fix two or more distractions before animals move easily through a plant. Below is the list of distractions that had to be eliminated at one plant that processed cattle.

1. Installed 80% light-blocking shade cloth over the single file chute that led up to the stun box. This blocked bright sunlight and eliminated the 'dark movie theater' problem. The shade cloth was stretched very tightly to prevent flapping. Flapping materials will cause balking.
2. Installed an easy-to-use latch so the one-way backstop gate between the crowd pen and the single file race could be held open. This facilitated cattle entry into the single file because it prevented approaching cattle from seeing the moving gate.
3. Installed a solid shield to prevent cattle entering the stun box from seeing moving people and equipment up ahead.
4. Installed nonslip flooring in the entire facility.

Stun Box and Restrainer Design for Cattle, Pigs, and Sheep

Drawings of restrainers, head-holders, and other equipment for holding animals for stunning or religious slaughter can be found in websites, and other articles.

1. Nonslip flooring is essential – Animals become agitated when they slip. Agitation in stun boxes is often caused by a series of small rapid slips. Pictures of good nonslip flooring are on the websites and references. Steel rods welded to the floor of the stun box make a good nonslip floor. Embossed steel or broom finish concrete is too slick. When steel rods are used, do not crisscross them. This will damage hooves. The rods must flush against the floor.
2. The stun box must not be too wide – Average sized cattle will fit in a 76 cm (30 in.) wide box (Figure 1). Larger bulls and some European Continental cows will require more width. A good design is to have an adjustable side.

Figure 1 Well-designed stun box that is the correct width to prevent animals from turning around. A common mistake is to make stun boxes too wide. Stun boxes must have nonslip flooring. Animals remain quieter on nonslip flooring.

 doi:10.1016/B978-0-12-384731-7.00252-X

3. Head-holders and other mechanical restraint devices must not cause stress – If cattle or pigs vocalize (bellow or squeal), or struggle when a restraint device is applied, it has a design problem such as excessive pressure or a sharp edge. Animals may also vocalize or struggle if they are held tightly for more than 15–30 s in any mechanized restraint device. This is why stunning or religious slaughter should occur immediately after animals are fully restrained. There is a problem with the design or operation of the device if animals struggle or vocalize in direct response to application of the restraint of which there are several designs (see 'Relevant Websites'). Hydraulic or pneumatic systems that control rump pusher gates, head-holders, and other devices for restraining animals should move with steady, smooth motion. Sudden jerky motion frightens animals.
4. Use features of design which will encourage animal entry into a restrainer – Prevent the incoming animal from seeing the visual cliff effect under a conveyor restrainer. The installation of a false floor will facilitate entry because it prevents the animal from seeing that the conveyor restrainer is high up above the plant floor and drawings are on websites. Incoming animals must not be able to see out onto the slaughter floor. A shield should be installed to prevent incoming animals from seeing activity on the slaughter floor.
5. Engineer equipment to reduce noise – On pneumatic equipment, either pipe air exhausts outside or install silencers. Silencers (mufflers) need to be replaced periodically because over time they lose their ability to reduce noise. Use rubber stops to reduce metal to metal clanging and banging. Noise from moving parts of equipment can be reduced by using plastic for door tracks. Plant buildings constructed from foam core cooler boards are often quieter than prestressed concrete. Hydraulic pumps should be located away from the animals. Use larger diameter plumbing to reduce high pitched noise that occurs when hydraulic fluid moves rapidly through smaller diameter pipes.

Layout Principles for Races, Chutes, and Crowd Pens

Chutes or races leading up to the stun box or restrainer must be laid out correctly. Layout mistakes can wreck the efficiency of the system. Below is a list of layout principles.

1. Never, never dead-end the single file chute or race – The design of the junction between a single file race and the crowd pen is very critical. When an animal is standing at the entrance of either a single file or double file race, it must be able to see three body lengths up the race. If the single file or double file race is bent too sharply where it joins the crowd pen, animals will back up or turn back because it looks like a dead-end. Diagrams of correct and wrong layout of this critical junction can be found in references.
2. Correct crowd pen/forcing pen angle at the single file race/chute entrance – For all species, a transition that is angled too gradually will cause jamming. For cattle and sheep, the best angle for the transition between the single file race and the crowd pen is one side straight and the other side on a 30° angle. For pigs, the transition should be abrupt because pigs jam in a funnel-shaped transition. Diagrams can be found in references.
3. Proper layout of curved races – Curved single file or double file races work well for cattle and sheep because they take advantage of the animal's natural tendency to go back to where they came from. They also prevent the animals from seeing activity up ahead (Figure 2). To be effective, they must be laid out correctly. Diagrams can be found in references.
4. Never build a crowd pen or forcing pen on a ramp – Cattle, pigs, sheep, and other animals will stand quietly if they are held in single file on a ramp. Groups of animals that are held standing on a wide, 3° or greater sloped alley will tend to pile up on the back gate. Crowd pens and the wide staging alleys before the single file part of the system should be level. If there is a ramp in the system, it should be in the single file race part of the system. For pigs, complete elimination of ramps is recommended. Pigs handle best in level systems. A slight drainage slope will be required for washing in all facilities.
5. Design of ramps to the stunner – Stair steps are recommended (designs are covered in references). The advantage of stair steps is that when they wear out, the animals can still walk on them without slipping. Ramps with grooved concrete without stair steps wear out and get slick. Dimensions for stair steps for cattle are 3.5 in. (10 cm) rise and 45 cm long or longer tread length. A 30 cm (12 in.) tread length will work if space is restricted. For pigs and sheep, use a 2.5 cm rise and 8 in. (25 cm) or longer tread width. Maximum ramp angles to the stunner are: cattle 20°, pigs 15°, and sheep 25°. More gradual ramps are strongly recommended.
6. Crowd pen and forcing pen layout – If a circular round crowd pen (tub) is used, it should be laid out in a 180° full half circle to take advantage of the natural behavior of animals to go back to where they came from. The recommended radius for the crowd gate is 12 ft (3.5 m) for cattle, and 8 ft (2.5 m) for pigs and sheep. Longer and shorter lengths can be less efficient.
7. Use solid fences – There are many activities and distractions in a meat plant, so the use of solid fences on the

Figure 2 Well-designed, curved cattle race/chute with high solid sides. A curved race prevents the cattle from seeing activity up ahead.

single file races and crowd pen is strongly recommended. The most important fences to make solid is the outer perimeter to prevent animals from seeing people, moving vehicles, or equipment. The crowd gate in the forcing pen or crowd pen should be solid. This will help prevent animals from turning back towards the yards.

8. Correct single-file race length – The chute or race for holding animals in single file should be long enough so that natural following behavior can be used. Cattle and pigs will enter a single file race more easily if they keep moving through the crowd pen without stopping. When a group of animals can enter a partially empty, single file race, natural following behavior will facilitate movement. If animals are allowed to stand in a crowd pen, they tend to turn around. The recommended capacities for single file races for cattle and pigs are shown below. For sheep, shorter races can be used because sheep can be handled in continuous flow. Cattle and pigs are moved in small, separate bunches.

   Under 25 per hour – should hold 3 or 4 animals
   26–100 per hour – should hold 6–10 animals
   Over 100 per hour – should hold 10–15 animals

   For large plants over 200 per hour, the single file race should hold 15 cattle.

   For higher speeds, do not make it longer. This will require handler to walk too far. These capacities are recommended in systems where the stunned animals are indexed onto a power chain at fixed intervals. In pork systems, with loose shackles, batches of pigs can be handled with a waiting period between batches. In these systems, a shorter race might work because the processing floor is kept supplied by the stunned pigs that are batched on the rail. These capacities will make it easier to use following behavior because the races can be allowed to become partially empty before more animals are brought up. To determine the correct length, one market weight pig that weighs 275 lbs. will fit in a 4 ft (1.2 m) section of single file race. One adult bovine will fit in an 8 ft (2.5 m) section of single file race. One lamb will fit in a 3 ft (1 m) section.
9. Batch floor stunning systems – In these systems, the single file race is eliminated. This system is used mainly for pigs or lambs in smaller plants. In these systems, a group of 5–10 animals is held in a small pen. Electric stunning tongs are applied to the head. To prevent return to sensibility, a second stunner application should be applied to the chest to stop the heart. To allow enough time to do an initial head stun and then a second cardiac arrest stun, 10 s per animal will be required. Group electric stunning should be used in systems processing less than 120 pigs or lambs per hour. Larger plants should install a V-conveyor or center track conveyor restrainer system.
10. Do not exceed these maximum capacities – On a single line, the following maximum capacities should not be exceeded:
    - Pigs and sheep – 800 per hour
    - Cattle – 390 per hour

Exceeding a speed of 800 pigs per hour on a single V-conveyor restrainer will cause serious handling problems. Faster speeds more than 800 per hour exceed the normal slow walk of the pig. In plants that use CO_2, when the line speed going into the cooler is 1000 per hour, two large group CO_2 machines with separate handling systems will be required. For plants using electrical stunning, two V-conveyor restrainers and two complete handling systems will be required.

Design of Stockyards and Lairages

Diagrams are available in references (Figure 3). A well-designed beef stockyard with a herringbone layout can be seen on YouTube Beef Plant video Tour with Temple Grandin. Different countries have different requirements for the capacity of stockyards. In the US, the minimum stockyard or lairage capacity is 4 h of production, which is equal to half a production shift. In countries where longer times in the lairage are required, stockyards with greater capacity will be needed. More space will also be required if deliveries of animals all occur during the same time of the day. For all species, there should be sufficient space in the stockyard so that all the animals can lie down. This is especially important for animals that are held overnight or on weekends. Below are recommended space requirements.

- Adult cows and fed cattle 20 ft^2 (1.85 m^2). Cattle that weigh over 1200 lbs (545 kg) will require more space.
- Market weight pigs 6 ft^2 (0.55 m^2). Very large pigs over 275 lbs will require more space.
- Sheep – 5 ft^2 (0.46 m^2).

The US Humane Slaughter Act requires that every holding pen has a waterer. Hanging nipple waters will work well for pigs. Cattle and sheep should have water troughs. It is best to lay out the pens so that each pen holds either one truckload or two truckloads of animals. This will prevent the problem of jamming too many animals in a pen that holds a fractional proportion of a truckload. In plants where many small groups are processed, some smaller pens will be required. Boars or bulls that are mounting other animals or fighting will need to be put in a separate small pen.

Flooring Surface in the Stockyards

For cattle and other large animals, grooved concrete should be used. The recommended grooving pattern is an 8 in. (20 cm)

Figure 3 Herringbone stockyard/lairage with long narrow pens. Cattle enter through one end and exit through the other end. The correct angle for the pens is 60–80°.

diamond or square pattern. V-shaped grooves that are 1 in. (2.5 cm) to 1.5 in. (3.5 cm) deep are recommended. Instructions and pictures for making a grooving tool are in the references. For sheep and pigs, a good concrete finish is to print the pattern of expanded metal mesh into the wet concrete. For the small animals, epoxy grit finishes can also be used. Epoxy grit is not recommended for cattle because it will not provide sufficient traction. Do not use a broom finish. It will wear out quickly and become slick. In the United States, mats made from woven tire treads are available. They provide excellent nonslip flooring on unloading ramps. Some plants have installed a custom-made woven tire mat on the stun box floor. Unfortunately, these mats are more difficult to clean than grooved concrete.

Layout of Stockyards

The best stockyards have one-way traffic through the yards. Animals enter through one alley and leave to go to the stunner through an alley that is at the other end of the pen. Pens can be laid out either straight or on an angle (herringbone). Angled pens work well but they must be laid out correctly. The correct angle for all species is pens on a 60–80° angle (Figure 3). Never use a 45° angle. Animals might get stuck in the corners. To further eliminate corners, gates can be built that are longer than the width of the alley so that they open on an angle. The recommended alley and gate lengths are:

- Cattle – 10 ft (3 m) alley with 12 ft (3.5 m) gates
- Pigs and sheep – 8 ft (2.5 m) alley with 10 ft (3 m) gates

Some plants use narrower alleys for pigs. When narrow alleys are used, pigs should be moved in much smaller groups of 10 or less.

The Use of Powered Gates

Gates that are operated by either pneumatics or hydraulics are used in some facilities. In group CO_2 stunning systems, powered gates are used to move pigs up to the chamber and into the chamber. There is a tendency to use too much automation, which is expensive and completely unnecessary. In the group CO_2 pig stunning system, only five powered gates are required. They are:

1. A powered push gate to bring pigs up the main alley
2. Entrance gates to the holding pen by the stunner entrance
3. Indexing gate
4. Push gate to move the pigs into the chamber
5. A vertical sliding gate on the chamber entrance. Additional powered gates are a needless expense.

A video of a well-designed CO_2 with powered gates is on YouTube (use keywords Temple Grandin, pigs). If the pigs are difficult to handle, automated push gates might need to be converted from fully automatic to manual. A hand switch that is controlled by a person is used to start and stop gate movement. Even if fully automated gates have controls to prevent excessive pressure from being applied to animals, they still tend to overcrowd the animals. Powered gates must not knock animals over or push a fallen animal along the floor. This is abusive and must be corrected. This applies to all species.

There are often many problems with powered vertical gates (guillotine gates) on the entrance of beef stun boxes. When poorly designed and operated, they can cause many bruises on cattle. Shoving an animal down to the floor with a vertical slide gate is not acceptable. Controls should be designed so that the operator can immediately stop downward movement of the gate. The bottom of the gate should be padded. For all species, bruises can also be reduced by making the bottom portion of a vertical slide gate a flexible curtain. Animals will perceive the curtain as a solid barrier and not go through it. For pigs, make the bottom 18 in. (45 cm) from lightweight conveyor belting. For cattle, the bottom 24 in. (60 cm) can be a conveyor belt curtain.

Design of Unloading Ramps

For new construction, it is strongly recommended to eliminate all ramps in the system. In many existing facilities, ramps will be required to unload trucks and for moving animals to the stunner. Diagrams and designs of unloading ramps are available. For all species, concrete ramps for unloading should not exceed 20°. Stairstep ramps described previously should be used. Ramps with less than 20° slope are better. An unloading ramp should have a level dock at the top so that animals step out onto a level surface when they leave the truck. The minimum length of the level dock is 10 ft (3 m), and 20 ft (6 m) is recommended to prevent exiting cattle from jumping on the ramp. Man gates should be installed so that people can easily get away from charging animals.

A well-designed unloading area for all species has unloading pens that hold an entire truckload before they go to the main lairage stockyard pens. The unloading pens must not be on a ramp. Holding groups of cattle on a ramp may cause animals to pile up on the back gates.

Design of Drains and Wash Down

Animals tend to balk and refuse to step over any changes in the floor surface or texture. A drain located in the middle of a drive alley might cause animals to stop moving. Drains should be located outside the areas where animals walk. Many well-designed stockyards are laid out with a concrete ditch drain that is located outside the alley fence. To facilitate washing of the pens, there should be a 12 in. (30 cm) high concrete curb along the bottom of each pen fence. This curb contains the wash water within the pen that is being washed. Pens are much more difficult to clean, if wash water from one pen runs over into the next pens.

Preslaughter Handling

A Velarde Calvo and A Dalmau, IRTA, Girona, Spain

This article is a revision of the previous edition article by P Barton Gade, volume 3, pp 1012–1020, © 2004 Elsevier Ltd.

Glossary

Animal welfare The state of an individual as regards its attempts to cope with its environment.
Journey The entire transport operation from the place of departure to the place of destination, including any unloading, accommodation, and loading occurring at intermediate points in the journey.
Lairaging Keeping animals in stalls, pens, covered areas, or fields associated with or part of processing plants.
Stress Biological response elicited when an individual perceives a threat to its homeostasis.
Transport Movement of animals affected by one or more means of transport and related operations, including loading, unloading, transfer, and rest, until the unloading of the animals at the place of destination is completed.

Introduction

Preslaughter handling refers to the interaction between humans and animals during the phases of preparation for transport, loading, transportation, unloading, lairage, and moving to the place of stunning and slaughter. Stunning and sticking are discussed in other articles. Potential stressors include fasting and water deprivation, mixing of unacquainted individuals, exposure to a different environment, noise, forced physical exercise, and extremes of temperature and humidity. No animal shall be transported unless it is fit for the transportation. Poor conditions during transport might cause high levels of fear and pain, inducing psychological and physical stress or even death, particularly in pigs. These problems can be exacerbated during longer journeys. Lairage at abattoirs permits animals to recover from the stress and physical activity resulting from deprivation of food and water, handling on the farm, loading, transport, and unloading, which can be beneficial to meat quality and welfare. However, the benefit of providing animals with a resting time can be lost if the animals are subjected to poor handling and stressful environmental conditions in lairage. To safeguard animal welfare during transport and at the abattoir, preslaughter handling should guarantee the four basic requirements for animal welfare defined by Welfare Quality®:

1. Good feeding (absence of prolonged hunger and thirst).
2. Good housing (comfort around resting, thermal comfort, and ease of movement).
3. Good health (absence of injury, disease, and pain induced by management procedures).
4. Appropriate behavior (expression of social and other behaviors, good human–animal relationships, and absence of general fear).

Methods of Measuring Preslaughter Stress

The most common definition of animal welfare states that the welfare of an individual is its state as its attempts to cope with the environment. The environmental stimuli that lead to an imbalance of homeostasis are defined as 'stressors' and the corresponding physiological and behavioral defense reaction as 'stress response.' The stress response produces an activation of the adrenal gland, which results in an increase in glucocorticoid and catecholamine secretion. Depending on the nature, duration, and intensity of the stressor, the stress response can vary. Parameters such as heart rate, respiration rate, or cortisol concentration in blood or saliva can be used to assess the magnitude of the stress as they are valid indicators of the levels of activation of different pathways associated with stress responses. Other factors used are the concentrations of some acute phase proteins, such as haptoglobin, pigMAP, or serum amyloid A. In addition, biochemical parameters, such as total proteins in blood, albumin, urea, lactate dehydrogenase, vasopressin, creatine kinase, lactate, free fatty acids, β-hydroxybutyrate, osmolality, packed-cell volume, or glucose also give information about the stress response. Species-specific behavioral responses must be also taken into account, such as vocalizations induced by poor management, fleeing reactions, reluctance to move due to poor design and maintenance of handling facilities, or muscle tremors due to fear. Other factors to be considered are based on the general state of the animals, such as exhaustion, sweating, panting, shivering, lameness, or unable to walk. The presence of deep injuries, bruising, scratches, lacerations, or broken bones are also indicators of poor welfare, as well as high or low body or skin temperature. After slaughter, carcass and meat quality can also be used to assess preslaughter stress. Elevated body temperatures and fast glycolysis (low pH in muscles) just before or after slaughter produce pale, soft, and exudative (PSE) meat in pigs. However, the incidence of dark, firm, and dry (DFD) meat with a high ultimate pH is linked to the depletion of glycogen stores of the muscle before slaughter and can be due to severe and long exercise periods, long fasting periods, or any combination of stressors that lead to a high demand for energy for prolonged time.

Preparation for Transport

Inspection and selection of fit and healthy animals are the most important factors to maintain an adequate level of

Figure 1 Pigs loading on farm. Reproduced from IRTA.

welfare during transport. Animals should be checked at the place of departure and before the loading for fitness for transport. Sick, injured, weak, disabled, or fatigued animals; females in advanced state of pregnancy; and newborn animals with unhealed umbilical cords are unfit animals to be transported as the stress response will be impaired.

Water should always be available at the farm until loading on transport vehicles and in lairage until animals are stunned and bled. However, animals might be fasted to prevent the release and spread of bacterial contamination through feces within the group during transport and lairage as well as through the spillage of gut contents during carcass evisceration. Fasting before transport, within reasonable limits, is also beneficial to the welfare of pigs as it prevents them from chocking due to vomiting in transit or developing hyperthermia. Some studies recommend fasting pigs from 4 to 12 h before transport and a maximal feed withdrawal of 16–24 h before stunning and slaughter. After this time, animals mobilize fat and proteins as the main source of energy, increasing the tendency to form DFD meat and reducing carcass weight.

Pig groups are usually mixed on farm before loading in order to obtain groups of uniform weight and to adjust the group size to that of the truck compartments. Beef cattle are sometimes collected in the same lorry from several farms and mixed together. Mixing unacquainted animals leads to aggression to establish a new social rank. However, it impairs animal welfare. Firstly, aggression may result in injuries, pain and, in extreme cases, the death of animals. Secondly, aggression leads to physiological stress and immunosuppression within the whole group. To avoid fighting, animals should be kept in stable social groups. If mixing is unavoidable, the recommendation is to mix animals at loading rather than later in the abattoir and to maintain in lairage the same groups from the transport. To reduce aggression at arrival in the abattoir, cattle should be grouped again by farm of origin.

Loading and Unloading

Loading and unloading are the most stressful phases of transport (Figure 1). As animals meet new situations, they may be mixed with unknown animals, and finally there is the physical exertion involved with the physical exercise. Animals jumping, running, slipping, or falling might increase the risk of injuries, but also an animal balking, turning back, or going backward are indicators of fear and these behavioral indicators must be observed during loading and unloading, and appropriate actions should be taken immediately to rectify defects.

Cattle, sheep, and pigs go up better than they go down, but they have considerable difficulty negotiating steep ramps. Between 0° and 20°, slope has little effect on the time taken for pigs and cattle to ascend, and the time taken to ascend increases linearly when the slope is above 20°. Furthermore, pigs' heart rates increase as the angle of a loading ramp increases. In pigs, cleats (2.5×2.5 cm) on ramps must be spaced 20 cm on the centers to fit the normal walking stride of animals, and missing cleats can cause leg injuries in the animals due to slipping and falling. In cattle, inter-cleat distances should be at 20–30 cm. Steps between the loading ramp and floor should not be higher than 15 cm. Unloading ramps should have a level dock before the ramps go down so that animals have space to walk on when they exit the truck. Another possibility is the use of a deck lift, in which the whole deck moves upward or downward.

The stockperson and others associated with animal handling should have adequate knowledge and understanding of

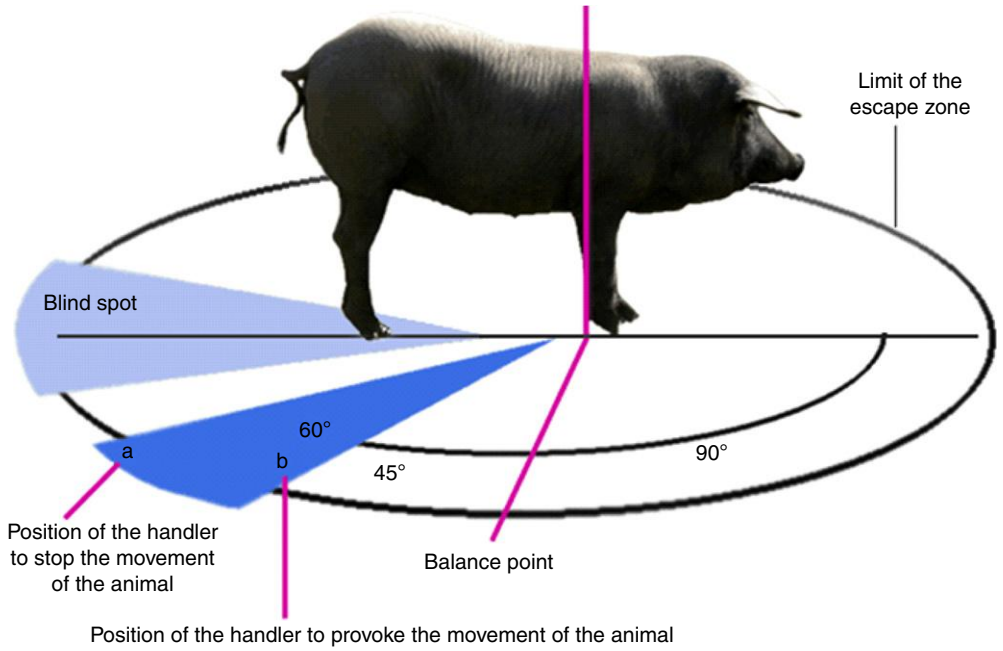

Figure 2 Balance point of the pig. If the intention is to move the pig in a forward direction, the animal handler should be situated at point b. Reproduced from IRTA.

the species-specific behavioral patterns. Red meat animals have wide-angle vision but have only limited forward binocular vision and poor depth perception (Figure 3). This means that they can detect objects and movements in front and beside them but can only judge distances directly ahead. Therefore, animal movements can be affected by shadows, discontinuities on the floor, and lighting. Animals have a tendency to move from a darker area toward a brighter area, but they will not approach blinding light. However, these animals can hear over a greater range of frequencies than humans and are more sensitive to higher frequencies.

Proximity to humans remains to be one of the most potentially alarming experiences for many farm animals that are reared under industrial farming conditions. When a person approaches closer than a certain distance, domestic animals try to escape. This critical distance, which defines the flight zone (Figure 2), varies among species and individuals of the same species and depends upon previous experience with humans. Animals reared in proximity to humans may have a short flight zone, whereas those kept in free range or extensive systems may have more a distant flight zone. The point of balance at the animals' shoulders could be used to move animals by adopting a position behind the point of balance to move an animal forward and in front of the point of balance to move it backward. The sudden penetration of the flight zone may cause a panic reaction. During a threatening situation, animals exhibit adaptive behaviors such as escape, balk, back off, shake, or other fear-induced behaviors including lying down. Social animals such as pigs collaborate with conspecifics in defense against predators and vocalize a lot when caught or hurt. Species that are unable to defend themselves, such as sheep, vocalize far less or none at all (Figure 3).

Transportation

During transport, effective temperature (which is the end result of the interaction between air temperature, relative humidity, ventilation, and flooring), space allowance, vehicle design, driving quality, journey duration, and road conditions are important factors influencing the welfare of animals and resultant meat quality.

The effective temperature inside the transport vehicle generally increases when vehicles are stationary for prolonged periods with lack of forced vents because of the lack of sweat glands in animals. In this case, lying behavior is the most important tool within behavioral thermoregulation. When it is too warm, pigs lie down quickly, maintain relatively wide separation between individuals, and increase their respiration rate. Therefore, high temperature increases the space each animal needs to rest.

In addition, the physical activity and stress response may contribute to the increases in body temperature. The physical activity will depend on the management of the animals during loading, difficulties in maintaining balance, the presence of unknown animals in the compartment, and the general fearfulness and excitability of the animals. Vehicle motion and vibration produces motion sickness in pigs, which contributes to increase in body temperature and the risk of vomiting, which can cause death due to asphyxiation (acute) or aspiration pneumonia (chronic). Practical strategies to reduce the risk of heat stress in pigs include transporting early in the morning or at night, when temperature and humidity are low; substitute deep bedding materials or straw by wet sand or small amounts of wet shavings; use of additional ventilation and showers; reducing stops; and unloading the animals as soon as possible at arrival. Cattle and small ruminants are less

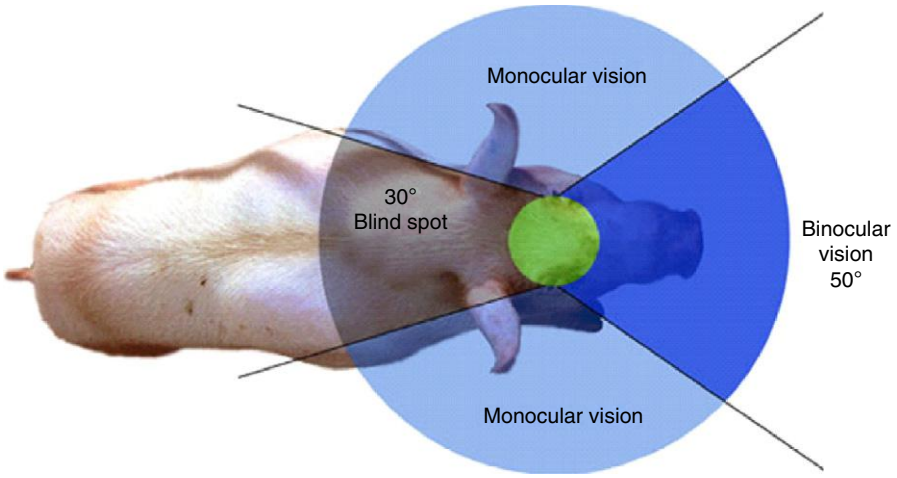

Figure 3 Monocular and binocular vision zones of the pig. Reproduced from IRTA.

vulnerable to high environmental temperatures, but in case of high temperatures it is also recommended to use additional ventilation, reduce stops, unload promptly, and drive during the cooler parts of the day. Low temperatures and wind chills can provoke cold stress, especially in young animals and pigs. Keeping livestock dry is important to protect them from wind chill. Animals can also have frostbite in severely cold weather.

Transported animals require a certain floor space allowance in order to stand comfortably, lie down, and keep their balance during vehicle movement. Once journeys start, pigs explore the compartment in which they are placed and try to find a suitable place to sit or lie down. The space allowance for each animal that needs to lie during transport should allow it to adopt a comfortable lying position without a significant risk of being walked on or smothered by other animals. Cattle usually remain standing during transport of up to 20 h duration, even if the vehicle is driven carefully. The space allowance provided for each animal that prefers to stand during transport should be such that it can adopt a position maintaining balance without any contact with other animals or with the vehicle or partition walls and without a high risk of falling. Avoidance of contact with other animals is also important if overheating is a potential problem in hot climates. Space allowances are calculated according to the size, bodyweight, and type of animal. However, the relationship between bodyweight and required floor area is not linear as the animal's weight is proportional to its volume. For cattle with horns, space allowance should be 7% higher than dehorned/hornless cattle. Attempts to reduce transport costs by overloading in the trucks produce a reduction in carcass weight, downgrading of carcasses due to bruising, and increased risk of injuries or death in worst cases.

Vehicle design and driving quality are other important factors to consider. When animals are transported in vehicles where the internal height is too low, they are prevented from standing in their natural position and may be in constant contact with the ceiling (Figure 4). This may result in wounds and bruises to the animals and may also hinder adequate ventilation above the animals. Furthermore, where there is not enough space between animals and the ceiling, the possibility to access the animals and allow them to be inspected may be reduced.

Figure 4 Transport of sheep with low internal height. Reproduced from IRTA.

The flooring surface should be designed to maintain balance and thermoregulation of animals and minimize the leakage of urine or feces. In motion, truck vibration can be reduced by installing a pneumatic suspension. Overinflated tires must be avoided as it increases severity of vibration, and driving must be with care to prevent bruises and injuries by avoiding sudden stops and acceleration, unpaved roads, and potholes.

Journey time per se is unlikely to be a risk factor but it becomes a risk when other aspects related to transport, such as animal fitness, fasting, vehicle design, driving style, stocking density, weather condition, ventilation, etc., are neglected. According to the EU Regulation 1/2005, journey times shall not exceed 8 h, except when road vehicles meet special requirements. In the EU, cattle and sheep can be transported for 28 h (with a rest of at least 1 h after 14 h, after which they must be unloaded and given food, water, and at least 24 h rest). If the higher vehicle standards are attained, pigs can be transported for 24 h, after which they must be unloaded and given food, water, and at least 24 h rest before continuing the journey.

Lairaging at the Abattoir

It is possible that fit animals at the start of the journey might fall sick, become ill, or be injured during transport. Animals should be inspected while they are still in the vehicle upon arrival at the abattoir for any welfare and health problems (Figure 5). Animals that have an injury or a disease associated with severe pain or suffering, and when there is no practical possibility to alleviate it, should be killed humanely whilst on the vehicle within the shortest possible time.

If animals arrive exhausted, for example, due to prolonged period of deprivation of food and water, long transport distance/time, and adverse weather conditions, their ability to cope with the lairage conditions would be impaired. To avoid the negative welfare effects of lairage, mixed groups of animals should be unloaded as quickly as possible after arrival and subsequently slaughtered without undue delay. In unmixed groups of pigs, however, a short period of lairage permits animals to recover from the stress and activity resulting from transporting and unloading, which can be beneficial to meat quality. A recommendation of a minimum 2–3 h has been made on the basis of physiological measurements in pigs.

The lairage environment should meet the welfare needs of animals in terms of resting and thermal comfort (neither too hot nor too cold) as well as by providing enough space for animals to be able to move around freely. To satisfy its welfare needs, each animal shall have enough space to stand up, lie down, and turn around. High stocking densities also increase aggression because the easy escape of attacked individuals is thwarted. When pigs are kept in small pens without the space and opportunity for attacked animals to escape, it leads to distress and physical damages in them, predominantly caused by dominant animals.

Where holding-pen space is limited, it is important to schedule truck arrivals precisely. Otherwise, animals would have to wait in the truck on arrival at the processing plant, which increases the chances of compromising animal welfare. Longer times in lairaging can demand a great use of energy in all the species due to the fact that animals are in a new situation and usually without food. Under this situation, prolonged periods of preslaughter stress can increase the incidence of DFD meat and, therefore, feeding animals and giving a resting period in lairage would be economically beneficial to the meat industry. EU legislation states that animals must be fed if the lairage time exceeds 12 h.

During transport, animals are usually deprived of water. Therefore, sufficient quantity of drinking water should always be available in the lairage/holding pen. The water supply system should be designed and constructed to allow all sizes of animals easy access (i.e., in terms of comfortable drinking height and number of water troughs or drinkers) to clean water at all times, without being injured or limited in their movements, and so that the risk of the water becoming contaminated with feces or urine is minimized. Suckling animals are particularly susceptible to dehydration because they might not have learned how to drink from a trough and so they fail to drink the water provided at the abattoir.

During hot weather, the practice of spraying pigs with cold water (10–12 °C) at lairage limits the risk of hyperthermia and consequently reduces the mortality rate in lairage pens (Figure 6). Showering also reduces aggressive behavior and facilitates greater ease of handling into the stunning chute. The shower regimen should be intermittent (i.e., once at arrival and once just before moving to stunning) and not longer than 30 min in total in order to get the greatest cooling effect and reduce activity and aggression. For maximum cooling effect, the sprinklers should have a spray coarse enough to penetrate the hair and wet the skin. Sprinklers that create a fine mist can

Figure 5 Inspection of animal at the slaughterhouse. Reproduced from IRTA.

Figure 6 Showering of pigs at arrival to the lairage pens. Reproduced from IRTA.

increase humidity in the lairage pen without penetrating the hair and should not be used. Showering in lairage is not recommended when the ambient temperature is below 5 °C as it causes thermogenesis by shivering to maintain body temperature in pigs.

Lighting/illumination in the lairage area/holding pens should be sufficient to observe all the animals and that they are able to move without fear and distress. All the animals kept in lairages or holding pens should be protected from inclement weather.

Movement from Lairage to Stunning Pen

Pens, passage ways, and races should be designed and constructed to allow the animals to move freely in the required direction using their behavioral characteristics and without distraction. Pigs are calm during handling when they can walk side by side for as long as possible. The flow of animals proved to be better when the corridors are well lit, wide, straight, and with few bends. Solid-walled fences eliminate contact between pigs walking through the alleys and those held in pens and prevent stops due to distraction.

Occasionally, animals are moved too fast through the raceway in order to meet high throughput. The combination of high throughput and poorly designed and maintained handling systems (sharp protrusions on the walls, gaps, and potholes on the floor) lead to rough handling and excessive and inappropriate (e.g., when there is no empty space to move forward) use of electric goads. Application of electric goads, even with low voltages, causes pain and distress as evidenced by significant raises in heart rate, open mouth breathing, squealing (in pigs), and many other physiological measures. The routine and excessive use of electric goads is an indicator of poor attitude of the stockperson and/or serious lack of species-specific infrastructures. Training personnel of the abattoir on the behavioral principles of handling can greatly reduce the use of electric goads. Similarly, abattoirs should be designed and constructed to meet the species-specific demands of handling and throughput rates.

The number of pigs and cattle moved per group can affect stress and ease of movement as any disruption in the movement and consequent distress can spread through the whole group. When animals are handled in large groups, those close to the transporter might be excited whereas there is a lack of control over the animals that are far away. Moving pigs in groups of five or six at a time seems to be optimum. Cattle are calmer and show less turning around when driven in groups with more than three cattle per group and when they have uniform side protections of equal height (minimum 1.5 m). Owing to the flocking and following behavior of sheep, it is better to manage them in big groups and give them a clear and unobstructed view toward the exit.

Body trembling and vocalizations are highly correlated with physiological stress indicators, and the level of squealing in pigs is correlated with meat quality problems. Pig squeals can be measured by determining the percentage of time pigs are quiet in the stunning pen, restrainer, and race and crowd pens, or with a sound meter. Vocalization can also be used in cattle but is not a good stress indicator in sheep. Reduction of noise in the driving area facilitates the movement of animals calmly. In pigs, high sound levels in lairage (>100 dB) increase the levels of lactate and creatine phosphokinase in blood. Noise produced by machinery, pressure hoses, and humans represent a source of stress. Provision of rubber pads on gates help to reduce noise levels. Prevention of noises higher than 80 dB and high-pitched sounds from hydraulic systems must be avoided in the live animal handling area. Lairages with high concrete ceilings and precast concrete walls have more echoes and noise than those built from foam-core insulation board. Races, stunning boxes, and restrainers must be illuminated with indirect, shadow-free light. Any disturbance or distraction, including at the entrance to the stunning box or restrainers, will affect the normal movement of animals and, in turn, will increase the pressure on operatives leading to poor animal welfare.

Improvements in the practical handling of pigs have been achieved with the introduction of the group handling system and lairage design, which incorporate smaller pens holding only 15 pigs, and automatic push gates to move the animals from lairage pens up to the point of loading into the gas stunning system. The lower stress imposed on the pigs and reduced interaction with the handlers have been shown to improve welfare and meat quality.

Effects of Preslaughter Handling on Meat Quality

Stressful conditions during transport and at slaughter adversely affect meat quality. Both PSE and DFD meat are related to poor animal welfare conditions in pigs. At slaughter, the supply of oxygen to the muscle ceases, and any subsequent metabolic process is anaerobic. Therefore, energy (adenosine triphosphate) is generated through glycolysis, which results in the accumulation of lactic acid in the muscle. Because this is not removed by the blood system the muscle gradually acidifies. The drop in the muscle pH causes the denaturalization of the muscle protein and conversion of the muscle into meat. The final pH is inversely proportional to the concentration of lactic acid.

Antemortem short-term or long-term stressors impair normal muscle metabolism and affect fresh meat color, water-holding capacity, shelf life, and yields. Acute stress around the time of slaughter causes PSE meat, determined using a pH at 45 min postmortem of lower than 6. PSE usually occurs in pigs that are genetically sensitive to stress when subjected to acute preslaughter stressors immediately before stunning, though it can occur in normal pigs subjected to stressful conditions before slaughter. The risk of PSE meat decreases with decreased durations of transportation, though its effect depends on the stocking density. For transits longer than 3 h, the risk of PSE increases with stocking density during transport whereas the opposite occurs for shorter transits.

Animals that are subjected to chronic stress before slaughter suffer severe depletion of muscle glycogen, leading to less lactic acid formation during postmortem. DFD meat is often defined as having an ultimate pH, measured after 24 h, higher than 6. The extent of glycogen depletion antemortem depends on physical exhaustion and psychological preslaughter stress in cattle. Various stress factors have been reported as

responsible for glycogen depletion: time and handling during transportation from farm to abattoirs, lairage time, climatic factors, social disruption, and the novelty of the preslaughter environment. In cattle, mounting behavior, stimulated by social regrouping, and fighting are associated with dark-cutting beef.

Welfare Including Housing Conditions

AM de Passillé and J Rushen, University of British Columbia, Agassiz, BC, Canada

Glossary

Catabolism The process of breaking down complex molecules (e.g., starches, proteins, or fats) into simpler ones (e.g., glucose and amino acids) with the release of energy.

Farrowing crate A metal crate or cage in which pregnant pigs are housed for a short period before giving birth and in which they can remain for several weeks after. The crate is narrow so that the sow cannot turn around. Farrowing crates are used with the intent of reducing crushing of the piglets when the sow lies down.

Feedlot A dirt-floored, outdoor pen in which livestock (most often cattle) are fattened by being fed a high grain diet before being sent to slaughter.

Hypothalamic–pituitary–adrenal (HPA) axis It consists of the hypothalamus, the anterior pituitary gland and the adrenal cortex, and controls one of the main sets of physiological responses to stress. HPA activity is most often measured through blood concentrations of adrenocorticotropic hormone (ACTH) and the corticosteroids (e.g., cortisol).

Innate behavior The behavior patterns that are characteristic of a particular species and which are strongly influenced by genetics.

Periparturient The period of time just before and just after birth.

Stereotypic behavior Behavioral patterns that are repeated in a relatively fixed and repetitive manner, and which appear to have little purpose. When seen among captive animals, the occurrence of stereotypic behavior is thought to indicate reduced welfare.

Stress-induced immunosuppression A reduction in the capacity of the immune system to fight against disease as a result of the animal being exposed to stress.

Introduction

Animal welfare is important to meat production because poor animal welfare is associated with poor animal production or health, and because consumers' concerns may influence market access. Throughout the world, animal welfare is the topic of legislation, retailer standards, and codes of practice. An animal has good welfare if it is in good health and feeling good, and the psychological component must not be ignored. Challenges to animal welfare differ between species and production systems. Concern about animal welfare is highest for intensive production but extensively housed animals also have welfare problems. Poor welfare is apparent in the animal's health, behavior, production, and physiology. Different welfare indicators detect specific challenges to animal welfare, rather than measuring the overall welfare.

What Is Animal Welfare?

Healthy animals that are not experiencing unpleasant emotions should be in a good state of welfare. Disease is a major cause of poor welfare but animal welfare is more than just poor health. Animal welfare is at risk whenever animals are suffering as a result of pain, fear, or when they cannot behave in a way that they are motivated to do. Suffering is an emotional state of animals and animals' emotions are difficult to assess. Alternative definitions of animal welfare that ignore animal emotions have been proposed, but these do not address the main concerns of the public.

Various definitions exist for animal welfare. A good inclusive definition is the 'five freedoms' viz: freedom from discomfort, freedom from fear and pain, freedom from thirst and hunger, freedom to express most normal patterns of behavior, and freedom from injury or sickness. Although complete 'freedom' may be impossible to attain, this definition indicates how animal welfare can be improved. The World Organization for Animal Health (OIE) defines an animal experiencing good welfare if it is healthy, comfortable, well nourished, safe, able to express innate behavior, and is not suffering from unpleasant states, such as pain, fear, and distress. The European Welfare Quality project involves 12 animal welfare criteria, namely:

- absence of prolonged hunger,
- absence of prolonged thirst,
- comfort around resting,
- thermal comfort,
- ease of movement,
- absence of injuries,
- absence of disease,
- absence of pain induced by management procedures,
- expression of social behavior,
- expression of other behaviors,
- good human–animal relationship, and
- absence of general fear.

These criteria are grouped into four welfare principles, namely, good feeding, good housing, good health practices, and an environment for natural behavior. The overlap between these definitions shows that there is considerable agreement as to what constitutes good animal welfare.

The Importance of Animal Welfare to Consumers

The existence of animal-friendly niche markets suggests that some consumers are sufficiently concerned to alter their

 doi:10.1016/B978-0-12-384731-7.00019-2

buying habits if not convinced that animals were raised in a way that leads to good animal welfare. However, there is little evidence that animal welfare issues affect the normal buying habits of consumers in general, and most consumers are not willing to pay substantially more for animal-friendly products. Younger generations tend to be more sensitive to animal welfare issues, suggesting that consumer concerns about animal welfare will grow in the future, and 'scandals' or stories of animal abuse reported in the press have potential to affect buying habits of all consumers. Consumer concerns currently impact the meat industry most through legislation or through retailer standards.

Legislation, Standards, and Codes of Practice

The European Union countries have comprehensive animal welfare legislation, focusing on contentious issues, for example, mandatory group housing of calves after 8 weeks of age and prohibiting tethering of pregnant sows. Historically, North American governments were hesitant to pass farm animal welfare legislation, but recent referenda in a number of US states, most notably California, have resulted in welfare legislation being introduced at a state level. Legislation is a direct way of preventing particular unacceptable practices, but has limited ability to improve overall animal welfare. Often, legislation deals with issues that concern the public most and overlooks issues of which the public is less aware. Therefore, legislation might only serve to establish minimum acceptable levels of welfare. In addition, legislation is time consuming to pass, requires public resources to police, and can be inflexible.

Some food retailers have animal welfare standards that their suppliers must meet. Auditable standards are now an accepted way of dealing with animal welfare in North America. A number of food retailers and chain restaurants are promoting 'best practices' for each animal species, with adherence verified through independent audits. Auditable standards are more comprehensive than legislation and often aim at a higher level of animal welfare. Standards can be more flexible and easier to revise, but unless the auditing process is transparent, consumers might have less confidence in them.

Codes of practice are usually comprehensive and cover most aspects of housing and management. These vary from purely voluntary to where compliance is mandated by legislation, as in the UK. Codes often serve as an educational tool helping producers to improve practices and can form the basis of self-audits whereby producers can identify potential animal welfare issues on their own farms. However, the codes are often complex, which makes compliance difficult to assess and it is doubtful whether purely voluntary codes will do much to reassure skeptical members of the public or improve animal welfare when producers are reluctant to implement voluntary codes.

With increased global trade, there is pressure to harmonize animal welfare standards in different countries, and the OIE has included animal welfare in its mandate and has begun to develop international animal welfare standards. The requirement to meet international regulations and standards that deal with animal welfare will be of increasing importance to the meat industries in regions that export meat or animal products.

Animal Welfare and Food Safety

Concern with the on-farm contribution to food safety might increase attention to animal welfare because there are close links between animal welfare and animal health. Endocrine changes that occur when animals are chronically stressed can inhibit immune responses to infection, rendering animals more susceptible to disease. Overcrowding might increase disease transmission within groups of animals but confinement housing might minimize transmission of diseases to other farms. Reduced reliance on antimicrobials will require housing and management techniques that improve the welfare of meat animals. However, some changes in housing or management practices to improve animal welfare might increase on-farm risks to food safety; for example, increased use of group housing might increase disease transmission unless the groups are well-managed. Animal welfare standards and their application must be consistent with on-farm food safety standards.

Threats to Animal Welfare

Challenges to animal welfare vary between species and production systems. The list in Table 1 is not exhaustive but focuses on animal welfare issues that have gained most attention.

The use of surgical procedures that cause pain to animals are of particular concern to the public. These include tail docking, castration, and tooth clipping of pigs; castration, branding, and dehorning of cattle, as well as aversive handling, such as use of electric prods. Dehorning of cattle is done partly to safeguard animal welfare, but pain should be reduced preferably by combinations of local anesthetic, antiinflammatory agents, and sedatives. Dehorning should be done as early as possible, because young animals recuperate better than older ones. Polled cattle breeds are available that perform as well as nonpolled breeds, thus removing the need for dehorning. In other cases, for example, hot-iron branding, the procedures are not done to protect animal welfare and alternative methods of identifying animals should be sought.

Good stockmanship is essential for good welfare, but is often overlooked. Poor handling often arises from mistaken beliefs about the difficulties of handling animals and can be reduced by training. In addition, good stock people recognize the importance of routine tasks, such as cleaning of facilities to protect animal health and welfare. Table 2 shows that poor handling and painful practices can make animals frightened of people and contribute to poor welfare and reduced production, possibly due to the increases in stress hormone levels, like those of cortisol.

Concern about animal welfare is highest when animals are kept intensively. This is particularly true when large numbers are kept in small areas and prevented from exercising their natural behavior. However, intensive housing systems can have advantages for animal welfare if designed and managed properly. Animals under extensive conditions can suffer from inclement weather, natural disasters, poor feeding, parasitism, and predation. These threats might not be the direct result of human action, but because such animals are kept to benefit

Table 1 Some of the more widely recognized animal challenges to animal welfare in meat production

Beef production
Early weaning
Respiratory disease at feed lots
Lameness at feedlots
High grain diets and acidosis
Heat stress (and lack of shelter)
Buller syndrome
Lack of bedding
Concrete and slatted floors
Stocking density
Branding
Dehorning
Castration
Rough handling
Nonambulatory animals
Veal production
Individual housing
Tethering
Stall dimensions
Stall flooring
Ventilation
Group size
Respiratory and GI tract disorders
Low roughage diets
Anemia
Pork production
Breeding animals
Individual housing for gilts and sows
Tethering
Stall dimensions
Lameness in sows and boars
Intestinal torsion in sows
Breeder sow mortality
Tusk removal
Low roughage diets
Lack of bedding
Meat animals
Stocking density
Preweaning mortality
Tail docking
Tooth clipping
Castration
Aggression in groups
Lack of bedding
Concrete and slatted floors
Respiratory disease in weaner/growers
Ventilation
Rough handling
Poultry meat production
Skeletal disorders
Dermatitis and skin disorders
Cardiovascular problems (ascites)
High mortality
Stocking density
Ventilation
Food restriction of breeding animals

their owners, welfare remains the responsibility of the owners. Alternative housing systems might not improve overall welfare but change the nature of the threats to animal welfare. Group housing of pigs and calves provides opportunities for social contact, but increases the risk of aggression, competition, and disease transmission. The increased use of such housing systems requires that effective ways of controlling aggression and disease transmission are implemented. This can be achieved by appropriate group sizes. For example, disease incidences in calves in groups <10 are similar to those of individually housed animals. In addition, appropriate stocking rates and feed space can minimize competition. Among broilers, incidence of mortality and pathologies starts to rise when stocking densities are above 30 kg m^{-2}. Growth rates of 250–500 kg beef cattle are reduced at space allowances less than 3–4 m^2 per animal.

Table 2 Some of the effects of rough handling on swine production and welfare

Variable	*Positive handling*	*Rough handling*
Growing pigs		
Growth 7–13 weeks (g d^{-1})	455	404
Growth 11–22 weeks (g d^{-1})	709	669
Cortisol concentration (ng ml^{-1})	2.1	3.1
Adrenal weight (g)	3.82	4.81
Time to approach human (s)	10	160
Gilts		
Pregnancy rate (%)	88	33
Cortisol concentration (ng ml^{-1})	1.7	2.4
Time to approach human (s^{-1})	48	120

Source: Based on results from experiments described in Hemsworth, P.H., Coleman, G. J., 2011. Human-Livestock Interactions. Wallingford: CABI International.

Providing an appropriate physical environment is essential: animals must be protected against temperature extremes, provided with good quality air, and given stalls and pens that are sufficiently large and designed to avoid injury and ensure comfort. Heat stress is a particular problem for feedlot cattle: providing shade can be necessary to reduce mortality in areas where heat waves are common. A lack of proper, clean bedding and use of concrete floors increase foot and leg injuries in cattle and pigs. Slatted floors in beef production increase mortality and tail tip necrosis. However, excessive mud in extensive systems can result in poor animal welfare.

Farm animals continue to suffer from a variety of endemic diseases that pose a major challenge to their welfare (Table 1). Reducing their incidence will improve animal welfare and profitability. Continued genetic selection for high growth rates can increase the risk of various 'production diseases,' such as leg weakness and osteochondrosis in pigs and leg and cardiovascular problems (ascites) in poultry and may be a risk factor for poor welfare.

Behavioral deprivation is a problem in some housing systems. That an animal on a farm behaves differently from one in the wild does not mean its welfare is threatened: behavior is an adaptation to the local environment and varies between different environments. However, farm animals have retained much of their ancestral behavior and research has identified some behaviors that animals are highly motivated to perform but are unable to perform due to housing environment. Periparturient domestic sows, in the appropriate environment, show the nest building behavior typical of wild boar. In farrowing crates, this behavior is sometimes expressed as rooting and pawing at the floor or chewing at metal bars. Providing

suitable farrowing accommodations or nesting materials does not prevent these behaviors. The sows appear to need to perform the behaviors themselves. However, farrowing crates may help prevent injury or death to baby pigs, which are also major welfare issues. Milk-fed veal calves fed from a bucket will suck at each other or on pen fixtures. The motivation to perform this nonnutritive sucking is reduced by allowing the calves to suck for an adequate period of time, either while drinking milk or by sucking a dry teat after a meal.

Feeding methods and nutrition can be responsible for some welfare problems. Dairy heifers often remain hungry because of restricted milk feeding. Milk-fed veal calves are at the risk of being anemic if hemoglobin levels are not adequately monitored. Beef cattle fed large amounts of grain can develop acidosis and liver abscesses. Broilers grow too heavy without feed restrictions. Breeding sows fed low volume concentrates can remain hungry after the meal and develop stereotypic behavior possibly due to a delay in the physiological signals that register satiety. This behavior can be reduced by increasing the energy content or the bulk of the meal.

Assessing Animal Welfare

Recently, the European Food Safety Authority has begun to develop a risk-assessment approach to identify the most serious threats to animal welfare in various species of farm animals. Many protocols are now available for conducting on-farm animal welfare assessments or audits looking at threats that are apparent in animals' health, behavior, production, and physiology. Animal welfare indicators detect specific challenges to animal welfare, rather than measuring overall welfare and different welfare indicators are required to detect different problems. To provide more positive outcomes, there is an increasing interest in having measures of good welfare rather than measures of poor welfare only. By using certain measurable indicators of animal welfare, different systems or operations can be compared. These indicators or criteria do not measure absolute levels of welfare, nor can they determine whether the level of welfare is acceptable because this is more of an ethical question.

Input- Versus Outcome-Based Criteria

Animal welfare assessment requires a combination of input-based criteria, which describe how animals are kept (e.g., spatial allowances and size of stalls), and outcome-based criteria (or animal-based criteria), which assess the animals themselves. Input-based criteria are easier to audit and can describe the level of risk that exists for poor welfare, but they provide no direct evidence about the actual state of the animals, and it is difficult to compare different production systems. Outcome-based measures are closely linked to the actual state of the welfare of the animals, irrespective of how they are housed or managed, but are harder to audit. Both input- and outcome-based criteria are required for an overall animal welfare assessment but they must be validated, that is, shown to actually measure animal welfare. At present, there is considerable research aimed at developing reliable and outcome-based animal welfare indicators for use in on-farm animal welfare assessments.

Health Indicators

Poor health, measured by mortality or disease incidence, is the least controversial indicator of poor welfare. However, it is unlikely that all threats to animal welfare (such as behavioral deprivation or social isolation) will reduce animal health. Thus, a high incidence of illness is a clear sign of welfare problems, but the absence of illness is not sufficient to determine that welfare is good. Obtaining reliable data on health problems on farms is difficult. Record keeping can be time consuming, but would do much to help farmers control welfare problems and improve production and profitability. Indirect measures of health can be obtained from records of veterinary treatments but underestimate the incidence of illness, and are influenced by the farmer's judgment of the need for treatment.

Behavioral Indicators

Injurious behaviors

The least controversial behavioral indicator is behavior that results in injury (Table 3). Problems arise from the difficulties of recording these behaviors on farms. Usually, injurious behaviors occur sporadically and animals must be observed for long periods to accurately estimate how much aggression is occurring. It is easier to observe the consequences of the behavior, for example, by counting the types of wounds or injuries that are likely to result from aggression.

Abnormal behavior

Farm animals perform a variety of behaviors that appear abnormal, for example, milk-fed veal calves that suck at each other or at metal bars and gestating sows root the floor of the pen or mouth the bars of the cage (known as 'stereotypic behavior'). When these behaviors occur excessively, it can indicate a welfare problem but to use such abnormal behaviors to assess welfare, their causes and consequences need to be properly understood.

Table 3 Some of the more common behavioral indicators of poor welfare

Injurious behaviors
Aggression/bullying
Tail biting (pigs)
Vulva biting (sows)
Bulling (cattle)
Feather pecking (poultry)
Vent pecking (poultry)
Cross sucking (veal calves)
"Abnormal" behavior
Belly nosing (pigs)
Stereotypic feeding behavior (sows)
Sucking pen fixtures (veal calves)

Changes in normal behavior

Changes in normal behavior can be used to assess animal welfare, for example, if animals feed or sleep less. Some behavioral changes are related to illness or disease. Animals respond to illness by feeding less, resting more, and showing less social behavior. These behavioral changes are controlled by cytokines from the immune system and can be considered as part of the immune response. They occur simultaneously with physiological components of the acute phase response to illness and are adaptive responses that help the animals recover from the illness. Therefore, a better understanding of illness behavior can help in the early detection of illness. Some behavioral changes can be monitored automatically so that morbidity can be detected several days earlier than with conventional methods. For example, feedlot cattle suffering from bovine respiratory disease show an increased number of drinking bouts and a reduced number of visits to the feed bunk.

Anatomical problems or injuries could be detected by a change in normal movement of an animal; for example, changes in gait can be used to detect leg problems.

Physiological Indicators

Animals respond to various challenges by physiological responses, which have been used to assess animal welfare. The main components of the physiological response are:

- perception by the animal of the stressor,
- biological defense reactions, and
- long-term consequences of the stress response.

The physiological changes might show that the animal is suffering from some aversive emotional experience, or the physiological changes might themselves result in suffering, for example, stress-induced immunosuppression leading to disease. The main physiological defense responses involve the sympathetic nervous system (SNS) (assessed by heart rate, blood pressure, or plasma concentrations of catecholamines) and the hypothalamic–pituitary–adrenal (HPA) axis (assessed by plasma concentrations of corticosteroids or adrenocorticotropic hormone (ACTH)). Not all changes in SNS or HPA activity are specifically stress responses but occur in many normal physiological events; for example, after feeding or sexual activity. Physiological responses vary between different types of stressors and some stressors require specific measures, for example, heat stress in cattle is detected by changes in tympanic temperature or respiration rates.

An animal's perception of a threat triggers both the emotional and the physiological stress response. Animals respond to pain or fear with increased SNS and HPA activity, which can be used to assess the animals' response to painful treatments or acute stressors (Table 4). However, physiological measures are less useful in assessing longer lasting stress. Firstly, secretion of cortisol is pulsatile and follows circadian rhythms, requiring multiple blood samples over the day. Secondly, HPA activity can adapt when stress is prolonged. For example, when bulls are first tethered, plasma cortisol increases, but this is absent 1 month later due to a reduced sensitivity of the adrenal gland to ACTH.

Chronic physiological changes can lead the animal to enter a 'prepathological' state that can involve increased catabolism leading to weight loss, or immunosuppression. However, stress has complex effects on immune responsiveness, with moderate stress often improving immune competence, and it is still difficult to predict that any change in the immune system will indicate increased susceptibility to diseases. Without better understanding of the relationship between stress, immune competence, and disease susceptibility, caution is necessary when using physiological measures to assess animal welfare.

Table 4 Increases in plasma cortisol concentrations in cattle following various painful or stressful procedures[a]

Treatment	*Increase in plasma cortisol (ng ml^{-1})*
Hot iron branding	26
Surgical castration	31
Castration + LA	21
Castration + AI	3
Dehorning	28
Dehorning + LA + AI	5
Handling (3–4-week-old calves)	6

[a]Comparison of the values gives some indication of the relative degree of pain or stress and shows the relative advantages of providing local anesthetics (LA) and/or anti-inflammatory agents (AI) to reduce the pain.

Journal of Dairy Science 77, 3725–3729.

Measures of Production

Animal productivity is a controversial welfare indicator. Reduced growth rate in pigs and cattle or even weight loss are common response mechanisms to chronic stress. However, measures of the production of individual animals must be used and not measures of profitability. For example, increasing the stocking density of broilers can reduce growth as a result of stress, whereas profitability continues to increase. Figure 1 shows mean body weight of broilers at 7 weeks of age housed at different stocking densities as well as an estimate of profit potential. Although the body weight of individual birds began to decline as space allowance dropped below 0.09 m^2 per bird, the profit potential continued to increase: having more birds in a given area compensates for the reduced gain of individuals. Furthermore, one must understand the cause of the change in productivity, and relate this to the animal's welfare. The reduction in growth that occurs when a calf has diarrhea indicates a welfare problem, but increased growth due to growth promotants would not necessarily indicate improved welfare. Beef cattle respond to high temperatures by reducing feed intake and growth is reduced. This would not necessarily indicate a welfare problem if the reduced feed intake helps the animal adapt to high temperatures by reducing metabolic heat production. Finally, the rapid growth of meat animals can result in welfare problems. Among fast growing broilers, lameness, sudden death syndrome, and cardiovascular disease are serious welfare problems. High productivity can, therefore, be a risk factor for poor welfare.

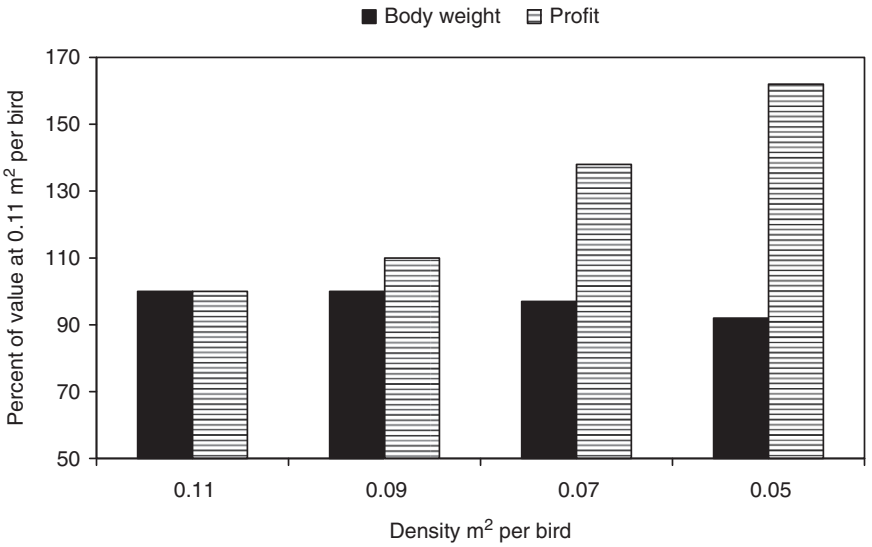

Figure 1 Mean body weight of broilers at 7 weeks of age housed at different stocking densities as well as an estimate of profit potential. The values are expressed as a percent of the value at 0.11 m^2 per bird. Drawn from data presented in Cravener, T.L., Roush, W.B., Mashaly, M.M., 1992. Broiler production under varying population densities. Poultry Science 71, 427–433.

Welfare of Animals

P Lawlis, Ontario Ministry of Agriculture and Food, Woodstock, ON, USA
A Allen, Canadian Food Inspection Agency, Saskatoon, SK, Canada

Glossary

Animal-based measures Scales developed and validated to measure an animal's welfare by observing the animal (e.g., lameness scoring and body condition scoring).

Immunosuppression Something that reduces the effectiveness of the immune system to fight disease or infection.

Management-based measures A method of assessing the level of animal welfare being provided through the verification of select protocols that have been demonstrated to be important (e.g., treatment protocols).

Resource-based measures A method of assessing the level of animal welfare by examining and investigating what has been provided for the animal. The necessary resources for good welfare are established through research.

Sentience The ability to feel or experience.

Utilitarian A term used in the study of ethics to describe an approach whereby a person selects the option which provides most happiness and reduces suffering. Also defined as the practical and material value of animals to serve some human purpose and that the practical demands outweigh emotional considerations, but there is not necessarily lack of affection toward animals.

Introduction

The human–animal relationship is complex. Humans filter information through narratives that are used to make sense of the world, people learn how to think about animals from their parents and elders at an early age. There have been significant changes in agriculture in the last 30 years and there is no longer a definitive universal understanding of how society should see the use of animals for human benefits. There is no single pervasive cohesive world view about how we should think, feel, and behave toward them. Hal Herzog explores many of the paradoxical and inconsistent beliefs we hold in his 2010 book: *Some We Love, Some We Hate, Some We Eat*. Similarly, interpretation of the concepts of animal welfare related to livestock production varies among interest groups and stakeholders who have differing experiences, knowledge, values, and vested interests.

The Evolution of Philosophical Thinking about the Human–Animal Bond

Interest in the human–animal relationship and concern about the welfare of animals is not new – the human–animal relationship has been of interest to concerned members of civil society for generations. Attitudes toward animals and how they differ from humans have been explored by many philosophical thinkers.

The Pythagorean School (Greek) viewed man and animals as having souls (animism). They believed that souls were finite in number and as an animal died, the soul took up residence in either another animal or another human. Followers of Aristotle held the belief that there was a scale or ladder of nature, with humans at the top and lower life forms at the bottom. This theory, known as vitalism, shared many similarities with the (much later) theory of evolution. Teleological anthropocentrism, described by Xenophon, decreed that everything on the earth was put there for the pleasure and exploitation of humans. Later Christian thinkers allowed that animals 'lower' than man could experience pain without fear and anticipation of its future continuation – but this condition was not equivalent to suffering.

Rene Descartes, a prominent French philosopher in the early seventeenth century compared animals to complex organic machines, devoid of mind and consciousness and the ability to feel pain and whose behaviors were dictated by the laws of physics. Descartes believed in a great divide between man and animals and that mankind had the authority to use animals as a means to an end. Like Descartes, Emmanuel Kant believed that animals were not capable of rational thinking and that man was set apart from animals because he possessed a 'categorical self,' which directs him to do the right thing. Although Kant did not consider animals to be moral agents, he did believe that humans ought not to cause suffering in animals because this increased their potential to do so to other humans.

John Locke, an English philosopher in the late 1600s with interests in social contract theory and the definition of consciousness, made some influential observations in his 1693 treatise 'Some Thoughts Concerning Education.' He based his theories on direct observation that animals, unlike machines, are sentient beings: that is that they can feel pain. John Locke was one of the first to highlight that disregarding animal pain had severe consequences for humanity. Locke's sentiments contributed to the development of the societies for prevention of cruelty to animals and to anticruelty legislation in Britain and Europe. Anticruelty legislation mirrors societies' concerns that animals deserve at least this minimal protection.

Jeremy Bentham and Modern Utilitarianism

Bentham was a British philosopher, social reformer, and early advocate of animal rights who argued that the ability to suffer

 doi:10.1016/B978-0-12-384731-7.00201-4

and not the ability to reason should be the benchmark for attitudes toward animals. Bentham introduced the notion of utility as a guide to making moral decisions in 1789. Bentham's principle of utility was based on the desire to produce the greatest happiness for the greatest number. In his view, the calculation of the total amount of pleasure and pain should include all creatures capable of feeling pain, including animals. Bentham raised the question of how the pain of animals should be entered into the calculation of utility (but did not answer it). The difficulty with adopting this utilitarian, cost–benefit calculation approach is deciding what objective method should be used to calculate the experiences of pain and pleasure.

Brumbaugh argues that moral thinking about animals is divided between Descartes approach, a utilitarian, anthropocentric commodification of animals for food production and research, and the philosophical approach more aligned with John Locke's, which is a more animal-centric approach applied to animals that are kept as pets.

Recent philosophers, scientists, and activists have challenged the existing treatment of animals and rekindled the discussion concerning the morality of animal use and why we should care about the animals that we use.

The Animal Rights Movement

Peter Singer advocated for equality for all animals. Singer argued that man's treatment of animals (including intensive agriculture and animal experimentation) arose from our prejudices about them. Tom Regan, an American philosopher, promoted the granting of rights to all animals based on the issue of equality. For Regan, the granting of rights should be based on the similarities between humans and animals, not the differences. The animal rights movement, of which Regan is a prime supporter, is not focusing on larger cages, but cage-free egg production. Proponents argue that "what is wrong is not the pain" but the entire system of animal use.

Bonnie Steinbock argued that the granting of rights to animals would not immediately or directly improve their welfare. Steinbock makes the case that a cow would not benefit from a university education. Steinbock argued that there are valid reasons for treating animals with respect that are independent of inherent 'rights.' Steinbock gives the example that if we punch our neighbor it will hurt him (her), and that this is enough of a reason not to do it. This, Steinbock stated, is the reason that we should not hurt animals.

The Definition of Animal Welfare

A succinct and exhaustive definition of animal welfare is difficult to arrive at, because animal welfare, indeed human welfare, is subjective, i.e., 'in the eye of the beholder.' There are many criteria that influence opinions about animal welfare. Animal welfare is difficult to define because it not only involves information about animals, it also involves values about what is better or worse for them. Swanson asks whether the appropriate term is animal 'well-being' rather than 'welfare.' Swanson points out that definition of animal welfare will depend on such factors as cultural, scientific, religious, and political backgrounds. Broom believes that the welfare of an individual depends primarily on its ability to cope with its environment. Furthermore, intensity, duration, and incidence of any welfare relevant condition need to be considered.

There have been many attempts by governments and policy makers to create a working definition for animal welfare that has the consensus of stakeholders. Article 7.1.1 of the OIE (World Organisation for Animal Health) Terrestrial Animal Health Code provides a good working definition:

> *Animal welfare* means how an *animal* is coping with the conditions in which it lives. An *animal* is in a good state of *welfare* if (as indicated by scientific evidence) it is healthy, comfortable, well nourished, safe, able to express innate behaviour, and if it is not suffering from unpleasant states such as pain, fear, and distress.

The Five Freedoms

The Five Freedoms were first introduced in the Brambell Report that was commissioned by the UK government in 1965 to investigate concerns raised over factory farming. The concept of the five freedoms spawned countless debates and was the underpinnings for new animal welfare legislation in the UK and Europe, and the definition adopted by the OIE. The five freedoms include both physical and mental factors and stress the importance of animals being able to express 'natural behaviors' or 'telos' (see Section Relevant Websites):

1. Freedom from hunger and thirst;
2. Freedom from discomfort;
3. Freedom from pain, injury, or disease;
4. Freedom to express normal behaviour;
5. Freedom from fear and distress.

Animal Welfare Science

The 1990s saw the rise of a new field of Animal Welfare Science, an area of study that David Fraser refers to as "mandated science" because it was deliberately brought into existence to address policy issues and make recommendations to agribusiness and government about if and how changes will be made. Duncan and Fraser stated that animal welfare "is not a term that arose in science to express a scientific concept. Rather it arose in society to express ethical concerns regarding the treatment of animals." Animal welfare science has produced a growing body of objectively verifiable data ascertained using the scientific method, which helped to increase our understanding of how animals perceive the world. The use of quantitative, objective studies and results that can be expressed with a degree of mathematical certainty can provide information about resources required to ensure good welfare (such as stocking density); however, measurements relating to welfare outcomes (such as fear) are subjective and therefore can be influenced by observer bias.

Understanding Animal Welfare

Fraser proposed three different approaches to understanding animal welfare:

1. The 'nature' of animals.
2. Biological functioning.
3. The subjective experience of animals.

Appleby expressed these categories as mind, body, and nature (Figure 1).

The 'Nature' of Animals

This approach begins with the assumption that good animal welfare will flow from allowing animals to act naturally. Acting 'naturally' includes all natural biological functions, such as eating, drinking, and reproduction, so that the 'nature' approach mimics the biological scheme to some degree.

Fraser pointed out that this approach is disappointing, because many natural behaviors, such as sweating, shivering, and fighting, are negative and are not necessarily in the best interest of the animal. McBride stated that the natural approach requires the ability of an animal to adapt to its environment.

Welfare Is about Biological Functioning

Biological functioning is compatible with the 'nature' approach to animal welfare. Many guidebooks and codes on animal care stress the importance of good health and biological functioning. A view of animal welfare based solely on biological functioning is no longer satisfactory. Scientists, ethicists, and others have begun to provide insight into the mental state of animals and how the presence of a mental state must also be included in the evaluation of the welfare of an animal.

The Subjective Experience of Animals

In addition to the physical criteria that affect welfare (e.g., freedom from disease, injury, and hunger) science has demonstrated that animals are sentient beings, that is, they can feel pain and are motivated by the need to avoid suffering. The subjective experience of animals, that they have feelings and emotions, has been ignored, most likely due to the difficulties of defining and measuring these things objectively. Perhaps it has been because its existence or nonexistence cannot be proven in a scientifically recognized way. Fraser pointed out that some advocates of the biological functioning approach claim that the subjective experience of animals is so closely linked with their (animals') biological functioning that the two things are interchangeable. Despite this, many scientists and philosophers have considered the dimensions of a possible mental state of animals and are actively attempting to discover what exactly is going on in the brains of animals.

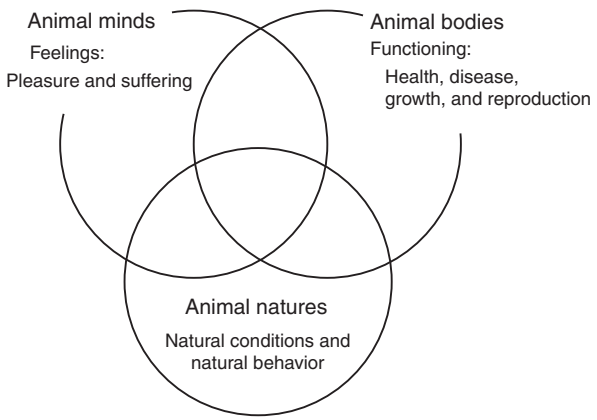

Figure 1 The three approaches to understanding animal welfare. Reproduced from Appleby, M., 1999. What Should We Do about Animal Welfare? Oxford: Blackwell Science, pp. 36–37.

The Welfare Continuum

Seamer argues that welfare means well-being, so that there can be no such thing as 'bad' welfare. However, Broom stated that welfare exists on a continuum from good to bad. Broom used the two extremes, good and bad, as basis points for the assessment and examination of animal welfare. Broom stated that the majority of work done had primarily focused on those conditions (pain, abnormal behavior, etc.) that lead to poor welfare. Broom believed that poor welfare is the result of overtaxing of an individual's ability to cope. Some responses to poor welfare are easy to recognize and assess – like sickness and death. Other responses, such as pain, immunosuppression, and abnormal behaviors, are difficult to measure and assess. Being able to recognize how animals react to certain elements of bad welfare is the key to an appropriate assessment of their welfare. However, it is important to keep in mind that even though an animal may look 'normal' it may be suffering.

Pain and Suffering

Most would agree that pain and suffering would be equivalent to 'bad welfare.' Bath claims that all those working with production animals are ethically bound to make their best assessment of animal pain and act to reduce suffering. Direct measurement of pain is difficult due to its subjective nature and the variability of the pain experience among individuals. How animals experience pain and how they react to it has been studied and this research has led to recommendations and legislation. The behavior of an animal will contribute to how it reacts to pain – prey animals (e.g., sheep) will hide their pain to avoid being picked out as being weak and vulnerable.

Molony and Kent maintain that there is still the thought that some pain is necessary; any pain experienced would be part of a learning experience. Beckoff and Bath suggest that although our (humankind's) ability to assess the pain and suffering might be inadequate, we should always err on the side of the animals and never question the ability of animals to experience pain.

Abnormal Behaviors as Indicators of Poor Welfare

Abnormal behaviors have been used as indicators of poor welfare. There are several abnormal behaviors that can signal to the observer that an animal is experiencing suffering. For example cribbing, weaving, and box walking are abnormal 'stereotypical' behaviors in horses that are associated with the confinement in individual stalls. Stereotypies are fixed sequences of behavior performed repetitively with no obvious function. Stereotypical behaviors are seen in most species and include such things as bar biting in sows and excessive grooming in dogs and cats. Stereotypies indicate that animals are highly motivated to perform a particular behavior, but the opportunity to perform this behavior has been denied to them.

Vacuum activities are another example of natural behaviors that are performed when animals are stressed (e.g., dust-bathing in hens and nest-building in sows that are performed in environments without the appropriate stimuli – dust for hens and straw for sows).

What Is Good Welfare

Duncan introduced the notion that animal welfare (be it good or bad) is what an animal is feeling (mental state). This concept is important because it focuses the debate from the external, physical contributors to welfare including how animals are bred, agricultural practices and management practices that affect disease, injury, and incapacity to the internal, the mental state of sentience; but how can one determine what an animal is feeling?

Using Animal Behavior to Explore Animal Welfare

Through various techniques, researchers have been able to draw conclusions about the relationship between what an animal is experiencing and its environment. Rushen notes that mental states of animals can be better understood by using aversion techniques to measure how an animal is feeling in a particular situation. Rushen looked at various handling and restraint methods of sheep and was able to show that sheep that were treated roughly when passed through a chute were very reluctant (averse) to returning. The difficulty with using aversion techniques to study the mental state of animals is that the results will be affected by the learning abilities of the animals.

Operant methods allow researchers to study how the consequences of a behavior affect future behavior. During operant testing, a particular behavior of an animal is selected – for example, the key-peck of a pigeon or a bar-press by a laboratory rat. Operant technology has been used to obtain information related to preference for prepared feeds, flavors, and on animals' abilities to smell and hear.

Other behavior research involves observation, with no manipulation of animals. Weary and Fraser explored the use of various signals – any feature of an animal or its behavior shaped by natural selection to influence the behavior of other animals – to calculate how animals were reacting to their environment. Weary and Fraser have focused on acoustic signals, as does Grandin in her research on the relationship between vocalization and animal handling during slaughter.

Dawkins asked animals how much they would 'spend' in terms of energy, time, etc., to perform certain behaviors. The cost that an animal is willing to pay for the opportunity to perform different behaviors can tell researchers which behaviors are more important to the animal. Dawkins found that the manipulation of time-budgets (the daily routines of wild animals and the amount of time they devote to different activities) provided the best measure of animal's motivation.

More recent research is combining the measurements from mind, body, and nature to draw conclusions. Bokkers used observation and slaughter data to uncover the suitability of three different environments for veal calves. Zulkifli measured the effects of regular visual contact with human beings on fear, stress, antibody, and growth responses on broiler chickens.

Animal Welfare Legislation and Standards

Laws are created in response to changing attitudes in society. A change in societal attitude comes first, the law follows. Good laws are intuitive, objective, and easy to communicate and can be used to modify human behavior to adapt to societal norms. Until the 1960s anticruelty legislation, transport, and slaughter were the only areas where the welfare of animals was protected.

There have been many changes in international standards and laws related to animal welfare in the last 20 years. The OIE has outlined standards for animal welfare and many countries have reviewed and updated their legislation recently. In some countries, the laws related to animal welfare are prescriptive (e.g., some countries define the required minimum current and voltage to stun animals), whereas other countries define the outcome that needs to be achieved (i.e., that the animals are effectively and immediately rendered unconscious during stunning and do not regain sensibility before death).

Germany's lower house of parliament recently voted in 2002 'to give animals constitutional rights.' The amendment will add the words 'and animals' to a clause in the German Basic Law or constitution that obliges the state to respect and protect the dignity of 'life.'

The Swiss Animal Welfare Act was passed in 1978. The essence of the five freedoms is noticeable in the principles of that Act, although the Act takes the protection of animal welfare much farther:

1. "Animals shall be treated in the manner which best accords with their needs."
2. "Anyone who is concerned with animals shall, in so far as circumstances permit, safeguard their welfare."
3. "No one shall unjustifiably expose animals to pain, suffering, physical injury or fear."

In 1981, legislation was adopted in Switzerland that prescribed that all housing system manufacturers had to submit their designs for preapproval before systems could be marketed. They chose to test proposed animal housing systems

using veterinary, Physiological, and behavioral measurements. Article 5 of the Swiss Animal Welfare Act states that:

> mass-produced housing systems and installations for the keeping of animals for purposes of profit may not be advertised and sold without prior authorisation from a service designated by the Federal Council. Authorisation shall only be granted if such systems and installations provide proper living conditions for animals.

More recently, consumer concerns about animal welfare has contributed to the development of legislation and voluntary industry standards designed to improve food animal welfare. For example, space allowances for production and prescriptive handling and transporting conditions have been legislated in the European Union (EU). Conventional battery cages and gestation stalls for sows are no longer permitted in the EU countries. The Royal Society for Prevention of Cruelty to Animals' 'Freedom Food Program' is an example of animal welfare schemes. The Freedom Foods seal is used by major supermarket chains in the UK to assure consumers that the meat, eggs, and dairy products are from animals reared under specified welfare conditions.

Practical Assessment of Animal Welfare

All segments of the livestock industry, from producers through to retailers, are becoming increasingly interested in animal welfare and some meaningful assessment of an animal's welfare status. Producers position themselves as knowledgeable and rational actors while they dismiss the concerns of the lay person as emotional and uniformed. The public, however, associates industry's interests in animal welfare as economic and profit oriented. The public believes their questioning the methods used in livestock production is ethically based. Spedding advises the industry to address these public concerns if they wish to ensure the sustainability of their industry.

If animal welfare science is to be of any practical use to animals, it must be applicable in the real world. The increased interest in animal welfare in livestock production in Western Society has been driven in part by the fact that the food supply has exceeded demand, which allows the development of demand-driven economies where consumers' needs and preferences have an impact. Animal welfare and acceptable production methods emerge as issues. Economic realities of animal agriculture have created a need for on-farm assurance programs, such as biosecurity and food safety. The knowledge built by animal welfare science can be used in the development of welfare-based quality control procedures. There is a need for cost effective, effective protocols to assess the conditions of good husbandry and for welfare assurance programs that consumers can trust and can use to make decisions about welfare.

There are three methods that can be used to assess animal welfare on-farm: resource-based, management-based, and animal-based measures. The first two measures have several common advantages, the most important being that these types of measures are objective and highly repeatable. Animal-based measures require more training before assessors can reliably use them. Grandin developed a basic 'yes' or 'no' scoring system to eliminate the confounding human factor. Grandin based her scoring system of handling in slaughter plants on one parameter: vocalization. She tabulated the vocalizations of cattle in the forcing pen and stunning box at six commercial slaughter plants ($n=1125$) and determined that a large percentage of vocalizations were the result of the use of excessive force (electric prods) by plant employees. When the use of prods was prohibited, vocalizations dropped dramatically. Therefore, by auditing the vocalization levels in slaughter plants, animal welfare can be assessed. Grandin has reported that the audit system has improved handling practices at some major US plants. Improvements are due to the simplicity of the system (i.e., a yes or no score) and because 'you manage what you measure.'

The type of measure used to assess animal welfare often, though not always, is dependent on the goals of the assessment. Mollenhurst demonstrated that resource-based measures are valid and sensitive enough to show differences in hen welfare between housing systems but not differences in hen welfare within systems.

In 2006, the European Union announced an Action Plan on the Protection and Welfare of Animals. One of the key features of this community Action Plan was the development of an EU-wide animal welfare label. In October 2009, this labeling program, Welfare Quality®, was unveiled. The program assesses animal welfare from farm to fork using animal-based measures – animal-based measures are valued by consumers because they actually assess the animals. The four welfare principles and the 12 welfare criteria of the Welfare Quality® project are listed below:

Welfare principles	Welfare criteria
Good feeding	1 Absence of prolonged hunger
	2 Absence of prolonged thirst
Good housing	3 Comfort around resting
	4 Thermal comfort
	5 Ease of movement
Good health	6 Absence of injuries
	7 Absence of disease
	8 Absence of pain induced by management procedures
Appropriate behavior	9 Expression of social behaviors
	10 Expression of other behaviors
	11 Good human–animal relationship
	12 Positive emotional state

Battering and Breading Equipment

S Barbut, University of Guelph, Guelph, ON, Canada

This article is a revision of the previous edition article by RG Swackhamer, volume 3, pp 1073–1080, © 2004 Elsevier Ltd.

Introduction

Overview

Applying coatings to food substrates has been a common practice for centuries. Most foods are coated just before pan-frying to add texture and flavor. Some of the most popular items in the market at present include chicken nuggets, fish sticks, and cheese sticks, all of which come in various sizes and shapes and are found on menus around the world. They are produced on high-volume fully/semiautomated lines, which basically mimic the traditional hand-coating procedures. Manual coating is still done at home and at some restaurants, but it is too slow, inefficient, and inconsistent for today's high-volume production runs. Battering and breading equipment was first introduced in the 1950s and started the trend of producing low-cost, uniform, and high-quality coated products on dedicated production lines (Figure 1). At present, coated meat, vegetable, and cheese products are very popular throughout the world. This article reviews the range of coating equipment, coating materials, and coating operations found throughout the food industry in the beginning of the twenty-first century.

Why Substrates Are Coated?

Commercial battered and breaded products are considered as convenience foods, which require minimal preparation on the part of the consumer or restaurant. Consumers today expect more and better attributes in the food they purchase. They want food safety, value for their money, and certain preferred sensory properties (texture, taste, color, and smell). Processors have learned to cultivate preferences in their customer base. Processors also extend the yield of their substrates by adding coatings, and can enjoy economic gain by producing differentiated, value-added products.

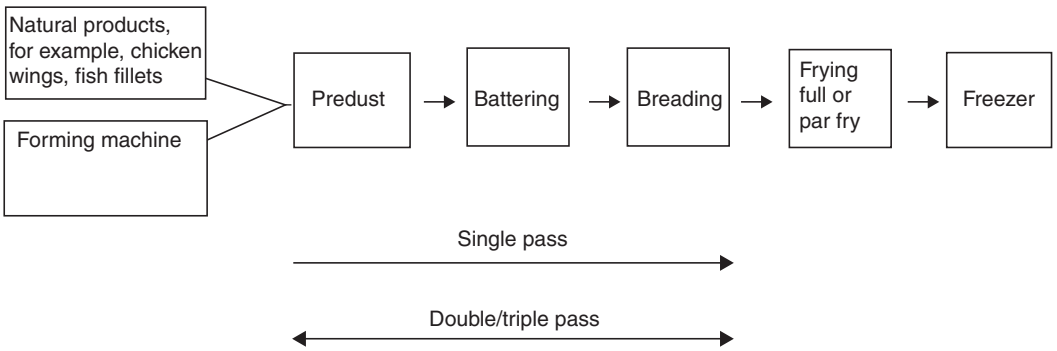

Figure 1 A schematic diagram of a dedicated battering and breading production line for making uniform shaped products such as chicken/pork nuggets, fish sticks, or irregular-shaped products such as coated drumsticks and cordon bleu.

 doi:10.1016/B978-0-12-384731-7.00118-5

Early History and Process Goals

Some of the early pioneering work on coating equipment was carried out in the early 1950s at Syracuse University by Dick Johnson under the guidance of Professor John Hart. Johnson developed a prototype breading applicator for Jean's Beans to use in their outlet stores. As Johnson approached graduation, he was contacted by Sam Stein to bring that breading equipment concept to be used by Grill Meats. That venture proved successful, and in 1953 Sam Stein associates was established to continue the development and marketing of coating equipment. At approximately the same time, the Best Products Company in Chicago, IL, USA, developed a breading machine that claimed to perform the work of 17 people applying coatings by manual methods (Figure 2). Equipment manufacturers and the coating material manufacturers have maintained a mutually supportive relationship with one another throughout their histories. A case in point involves Japanese crumb, a breading that is composed of relatively large, crust-free bread crumbs. This delicate product breaks down quickly in traditional breading machines. New breading applicator designs were needed to successfully bring these crumbs to market. Of course, these new designs would have no demand if these crumbs were not available. So what came first – the new style breading or the new style breading machine? The equipment manufacturers worked closely with the coating suppliers to deliver the total processing solution and thereby ensure that the food processor would have the equipment needed to apply these new Japanese crumbs. Such equipment is now in commonplace.

Processors seek to maintain consistency from one piece of product to the next and from one day to the next. They want to add the targeted amount of coating materials onto each piece of product. They also want to achieve complete coverage, with no voids or bare spots. They demand consistent color and highlights. Their goal is to achieve a product that satisfies consumer demand. They then seek to continue producing identical product. This must all be accomplished in a coating system that provides economic gain for the processor.

Examples of Commonly Coated Substrates

Poultry	Boneless breast fillets, patties, nuggets; bone-in eight cuts (i.e., special splitting of the carcass for fast food vendors), wings, drums
Fish and seafood	Fish sticks, patties, shrimp, fillets, scallops
Red meat	Nuggets, cutlets
Vegetables	Onion rings; mushrooms (poppers), zucchini, French fries
Dairy	Cheese sticks
Combination	Cordon bleu, Chicken Kiev, poppers (breaded mushrooms)

Common Terms

- Batter (n): a suspension of dry solids in liquid that forms either the complete outer coating for a substrate or the binding layer between the food base and the subsequent layer(s) of breading.
- Batter (v): the act of transporting a substrate through a puddle of batter material or carrying the substrate through curtain(s) of the batter material.

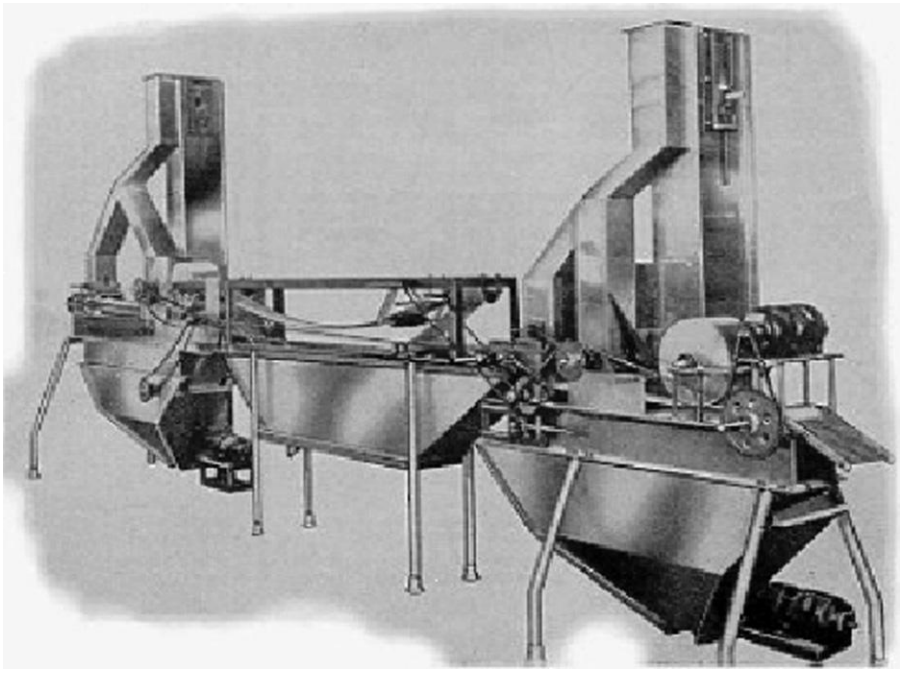

Figure 2 An original 1953 machine from Best Products Co. Chicago, which was claimed to coat shrimp, fish, and chicken up to 17 times faster than hand breading methods.

- Breading (n): a cereal-based, generally thermally processed, ground coating that is seasoned or unseasoned. Breadings are typically applied to moistened or battered food substrates to influence their flavor, color, texture, and appearance.
- Breading (v): the process of applying coating material to a moistened substrate.
- Home style breading: resemble a type of crumb, consumers can prepare at home. The crumb has a distinct crust and provides good highlighting during the frying operation.
- Japanese-style bread crumb (J-crumb): an elongated, typically crust-free crumb with outstanding textural and appearance properties. Generally used as an outside coating in full fry, oven, and microwave applications.
- Pass: the combination of a batter step followed by a breading step. Some products require a double-pass, whereas cheese sticks, for example, commonly require a triple-pass to ensure coating integrity.
- Pickup: a measure of the amount of material added to a product in a given step or in a series of steps, expressed as a percentage of the final coated weight. Pickup percentage is defined as added weight divided by final weight.
- Predust: when the first step in a coating sequence is the application of a dry coating, this is referred to as predusting. This step can improve adhesion and pickup, and also provides a place to bury flavors to protect them from degradation during frying.
- Substrate: the food material that is being coated. Common substrates are poultry, fish, seafood, meat, vegetables, cheeses, and fruit.
- Tempura (puff batter): leavened batters, used as an outer coating.

Coating Materials

Batters

Batters are made of blends of wheat flour, corn flour, starch, gums, browning agents, proteins, flavorings, and leavening agents. They can be divided into the following:

- Adhesion batters, which act as a 'glue' to bind subsequent layers to the substrate.
- Cohesion batters, which form an envelope, or shell, around the food product.
- Tempura batters, which are generally leavened cohesion batters used as the puffed coating.

Breadings

Breadings comprise a range of products from fine flour to granular coatings, including delicate Japanese crumbs. They have various colors, browning characteristics, absorption abilities, and textures. Spices and other ingredients are frequently added to customize taste and performance. Breadings can be divided into four main groups:

- Basic flour.
- Home style/American bread crumb.
- Traditional/cracker type crumb.
- Japanese-style crumb.

The Role of Frying in Coating Systems

Although a few products are chilled or frozen immediately after coating, the majority of coated products are parfried or fully fried before freezing. Two realities support this decision. First, the mechanical strength of the coating is increased by frying, and the crumbs adhere better during handling, transportation (e.g., vibrations on a moving truck), and preparation, as a result of frying. Second, as much as consumers may claim to avoid fried foods, the cooking oil absorbed during frying plays a major role in defining the highly desirable taste profile and the texture, including crispiness characteristics of coated food products. Unfried items that are reconstituted without frying, such as in an oven, can be sticky in the mouth, and less palatable.

Common Line Configurations

Natural and Formed Products

The first step in considering batter and breading applications is to decide about the food product to be coated. This can include a natural cut such as a piece of cauliflower, bone-in chicken wing, boneless pork Schnitzel, fish fillet, or a formed product such as a nugget, a meat patty, or a cheese stick; all of which can come in different sizes and shapes. Each category has its own challenges when it comes to coating. For example, a chicken wing/drum does not have even surfaces, therefore achieving a uniform dry coating layer is not possible by using a conventional belt type preduster. In such a case one needs a drum type preduster, as discussed below.

Forming machines, which are used to produce nuggets and patties can be divided into high- and low-pressure formers. Both machines mimic what people will do with their hands when forming a hamburger patty. However, a machine with multiple cavities can produce hundreds of identical patties every minute. The traditional approach uses a high-pressure former, where meat is pumped into the cavities (usually cut into a metal/plastic plate) and then the patties are 'punched out' by plungers with surfaces very similar to the cavity's shape. The patties are discharged onto a conveyor belt that takes them to the first predusting operation. Low-pressure formers have recently been developed in which cavities are filled with vegetable puree (spinach), meat, or their mixtures, and then gently pushed out by a stream of air from behind. This is typically done using a drum configuration (Figure 3(b)) where porous metal is used to allow air flow over the entire patty area inside the cavity. The advantage of using this technology is the reduced pressure applied to the patty, which reduces the quantity of water squeezed out of the product (i.e., lean meat is 75% water and most vegetables are 95% water) and the ability to form detailed 3D structures.

Nonleavened Systems

The most common coating configuration is a single pass with a preduster followed by battering and breading (Figure 1), which consists of dry–wet–dry applications. The predust

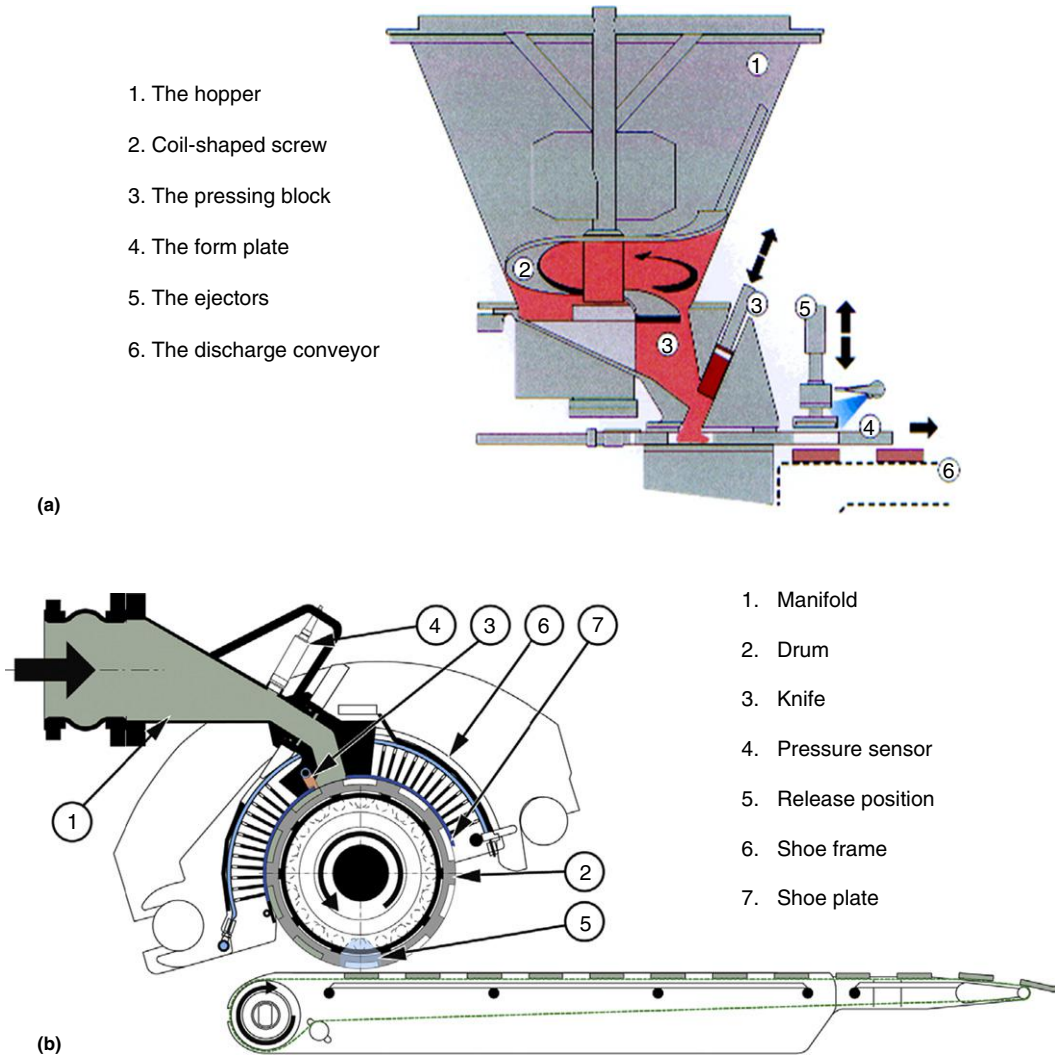

Figure 3 Forming equipment: (a) high-pressure; (b) low-pressure. Reproduced with permission from Marel and Townsend.

material is usually a flour-type coating, sometimes a dry batter mix. Figure 4(a) shows a general configuration of the equipment used to apply this coating. As illustrated, the product is dropped onto a bed of flour, and is moved toward a curtain of flour falling from above to cover the whole product. Then, the product is moved under adjustable pressure rollers that compress the flour onto the product. This is followed by air knives, which blow off excess flour while the product is transferred to a wire belt. When dealing with an uneven product such as chicken wing, a drum applicator (Figure 4(b)) is used, where the product is tumbled for a few revolutions while covered with predust material. The flour that is not picked up by the product is recirculated. This is followed by a batter applicator that in turn feeds the substrate into the final breading applicator as will be discussed in Section Batter Mixers. Many products use a two-pass system to achieve greater pickup levels. Cheese sticks, for example, commonly require a triple-pass arrangement to ensure that the substrate is thoroughly coated and will not leak cheese during the frying phase.

Leavened Systems

Various machine arrangements are included in the category of leavened systems. They all have the application of the wet leavened batter in common as the last step before frying.

There are special challenges in setting up and running these systems. For example, the leavened batter is often viscous, much like pancake batter. It clings to the flat flex belting moving through the puddle in the applicator, and then slowly drains from the belt. This characteristic can limit the system's ability to run properly at higher speeds where batter remains on the belt at the discharge zone near the fryer. Even if the submerger-style batter applicator runs acceptably at a certain speed, it may fail to run at a higher speed because the batter will tend to 'walk' out of the applicator as its available drain time from the belt has been reduced. In addition, the transfer of coated product into the fryer can be another problematic and related issue. Various schemes utilizing wiper bars, 'star' rollers, or 'porcupine' rollers are employed to carry the product the last few centimeters in the tempura applicator and then

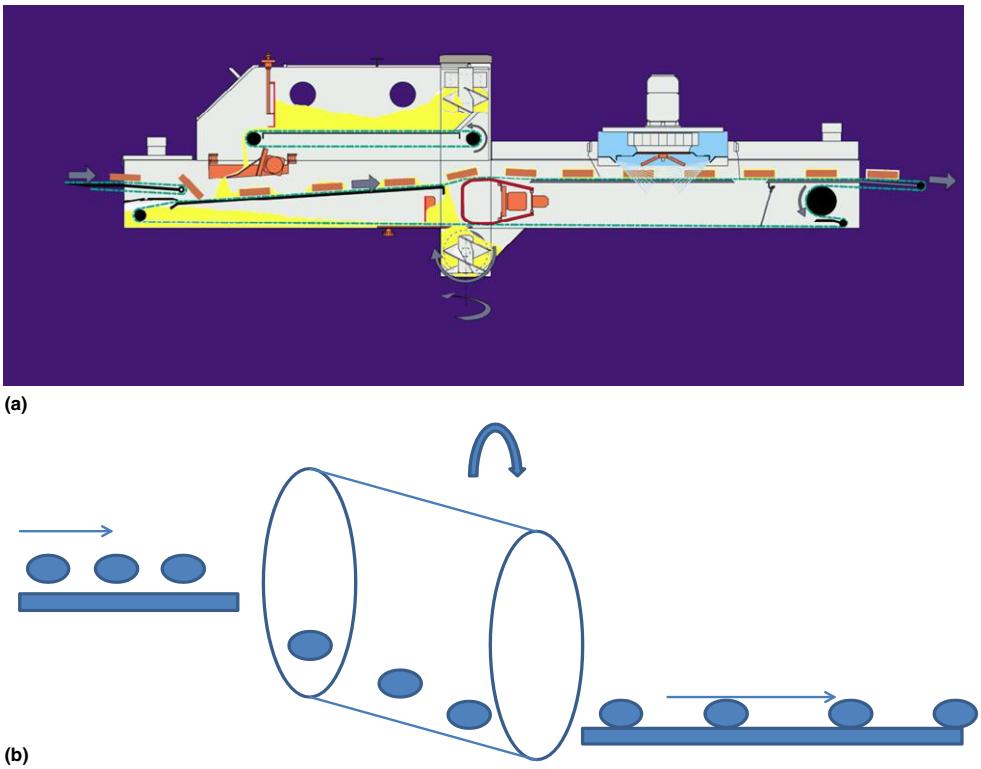

Figure 4 Predust equipment: (a) flatbed and (b) drum. Flatbed – Reproduced with permission from Townsend Further Processing.

to carefully release the coated substrate to drop into the hot oil. The heat coming from the nearby frying oil slowly cooks some of the excess batter to the applicators' components that are hanging over the frying zone, thus necessitating periodic stoppages for manual removal of crusted batter buildup. The goal is to transfer the undamaged product into the hot frying oil, letting it settle for a few seconds on a special Teflon slat conveyor to 'skin' over. After a few seconds, the coated product expands, and then floats off the bottom conveyor in the fryer and floats up against the underside of the hold-down conveyor.

Types of Coating Equipment

Batter Applicators

There are two principal modes of applying batter to a substrate: overflow and submerger.

The 'overflow' method has the batter continually pumped to maintain a curtain of batter falling on the product passing beneath (Figure 5). This system is usually used for nonleavened batters and commonly employs two or four curtains of batter. The product paths through these applicators are fairly flat, making them the preferred choice for high-speed coating lines. Note that the batter is continually being pumped, thus exposing the batter to shearing action and making these machines unsuitable for leavened batters.

The second method is the 'submerger' approach, wherein the substrate is conveyed down into and then up out of a puddle of batter. This is the viable choice for a leavened batter because the batter is not subjected to excessive pumping and shearing, actions that can drive the gases from the batter and render it flat. Some circulation, however, may be required when the submerger method is used for nonleavened batters that are subject to a settling out of their solids. The submerger method is very effective in delivering batter to all surfaces of even complex shapes, making it ideal for products such as bone-in poultry parts and shrimps.

Batter viscosity and batter temperature each play a key role in determining coating line performance. Batter viscosity relates directly to coating pickup whereas batter temperature impacts issues of food safety as well as the required volume of dry batter mix. A given level of batter viscosity can be maintained with less dry mix at lower temperatures than at warmer temperatures. Some batter machines feature cooling coils to help maintain cool batter temperatures, but viscosity can vary when batter is supplied incrementally as is the case in smaller capacity systems. As the product passes through the batter applicator, some of the coating particles may wash off the product and serve as a thickening agent in the batter pool, so monitoring and adjusting viscosity is very important.

High-volume coating lines normally employ batter mixers that continually mix new material, adjust viscosity, and circulate the batter between the mixer and the batter applicator. While the batter is in the mixer it can be chilled as needed, and it can be thickened or thinned to maintain target viscosity levels. The batter is sent to the applicator for a short period before it returns again to the mixer for reconditioning. This batter management system is intended for nonleavened batters only.

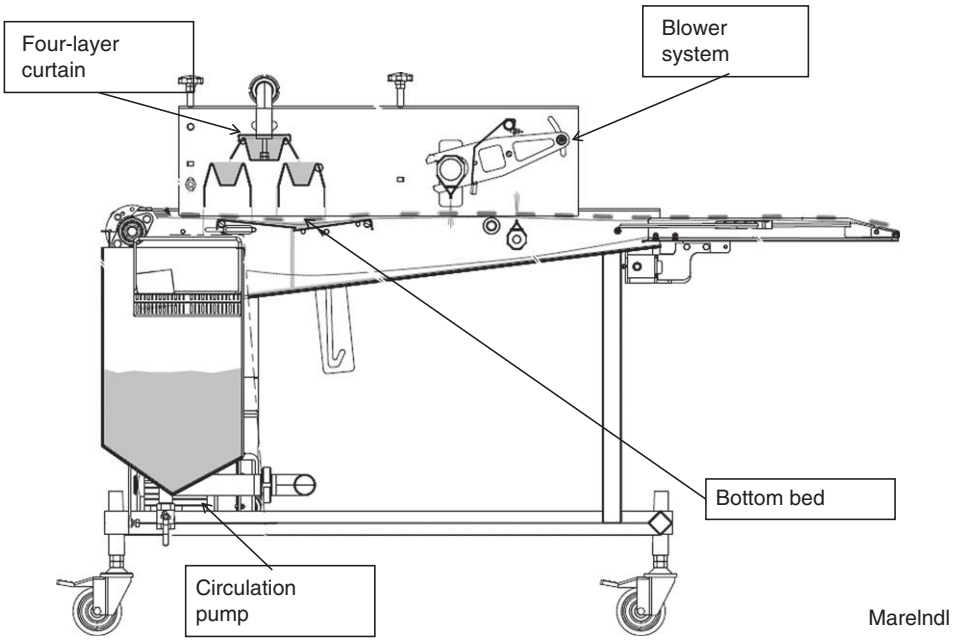

Figure 5 Equipment to apply batter to food products using the overflow configuration. Reproduced with permission from Marel and Townsend.

Batter Mixers

The choice of batter mixer reflects the volume of batter required per hour and the type of batter being produced. Mixers for leavened batters are specialized in that they blend very gently. They mix the dry batter material with water in relatively small quantities, for a short time, and then pump the batter to the applicator. There is no recirculation of the batter after it leaves the mixer. The batter must be used in a short time (minutes after mixing) or it will go flat. Conventional batter mixers for nonleavened products range from simple, low-volume machines to moderate-volume mixers, up to 1000 kg h^{-1} automated mixers that are coupled to the batter applicators and maintain a preset level of temperature and viscosity.

Breading Applicators

Breading can range from very fine particles (flour) to relatively large and brittle bread crumbs (Japanese crumbs). It is interesting to note that with the current economic situation, flour is becoming a popular coating material in places like North America. Overall, the breading material provides a unique texture to the coated product and can also be used to carry spices and flavorings to the product. A typical schematic diagram of a breading machine is shown in Figure 6. The battered product, which is wet on the surface is dropped onto a bed of dry breading material while more breading is sprinkled from the top. This is followed by pressure rollers, which help to push the material onto the product. This configuration provides a challenge for the breading applicator, however, in that breading/flour does not flow well and can easily clog and jam the equipment. Properly designed applicators use powered methods (augers or belting) to move the flour/breading through the machine. Augers, for example, move the flour laterally to feed other augers that lift the flour for returning to the main hopper. Flat flex belting is used to drag the flour out of the hopper and onto the product. This same belting also carries unused flour back to the start of the auger (Figure 6).

Japanese-style crumbs are delicate and cannot withstand the abuse of being powered through their applicators. These crumbs quickly break down in the equipment that uses excessive forces to move the crumb through the machine. Gravity is employed in place of power to move the delicate Japanese-style crumbs. The hopper has sloping surfaces and sifting screens to guide and sort the material wherever possible. Some mechanical powering is still required, however. Minimal use of power in the machine extends the crumb life so that crumbs survive long enough to be applied to the substrate without breaking down significantly.

Some substrates are difficult to lay out on the processing belt and are also difficult to transfer from one machine to the next unless they have picked up some coating material and become less sticky. Chicken tenders and clam strips are two good examples. For these products, a drum breader (Figure 4(b)) allows coating to adhere to the product surface while the product tumbles in breading material. Four to six rotations of the tumbler usually suffice for coating. Unless spreading conveyors are used after the drum breader, the processor can expect to have to assign people to spread the product across the belt, because the product stream emerges from the drum breader in a narrow path.

There are different variations in coating machines that can help to create different effects. One of these is the triple flip at the end of the breading machine, which is used to create a random texture on the surface giving what is referred to as a 'home style' look. This example can be used to understand what happens within a breading applicator. The product is loaded into the machine from the batter applicator. The batter applicator's discharge conveyor reaches into the breader and deposits the product on the lower layer of breading material, which is moving

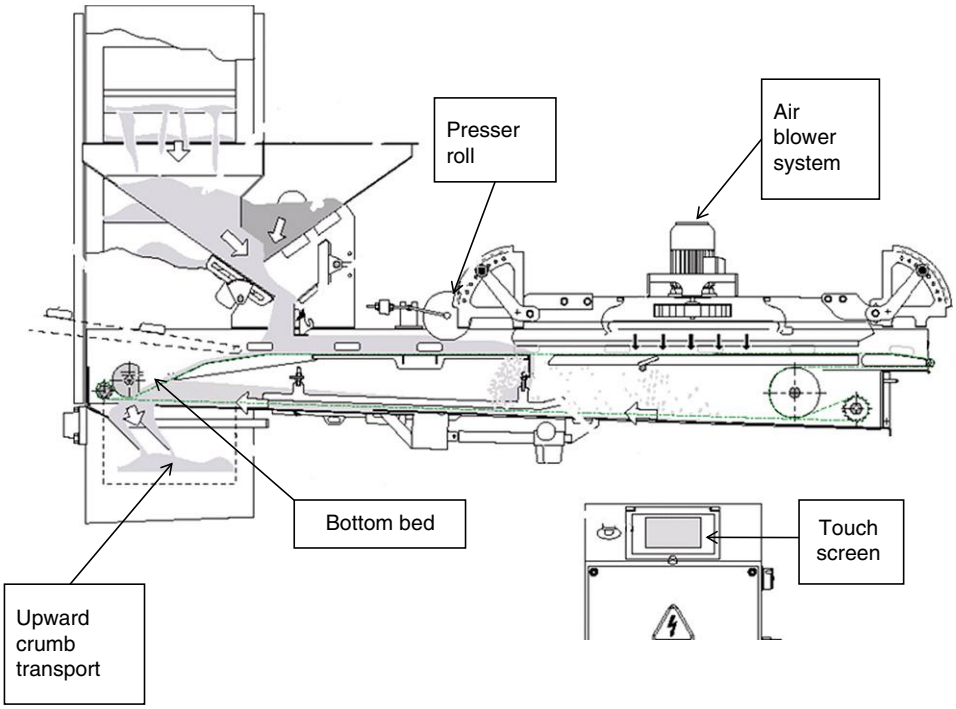

Figure 6 Breading equipment used for different types of crumbs. Reproduced with permission from Marel and Townsend.

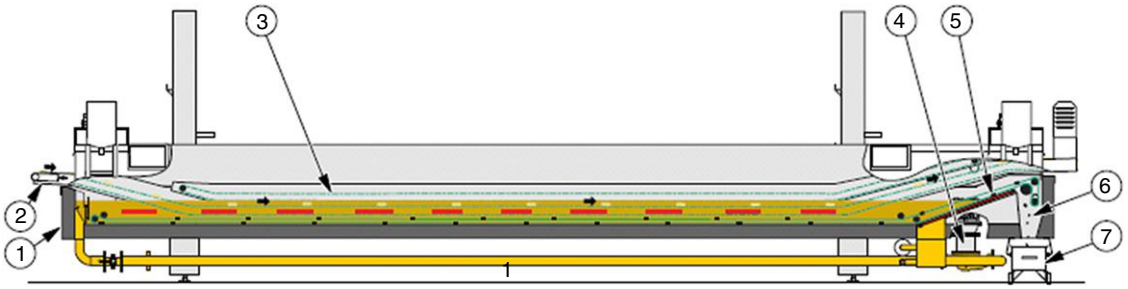

Figure 7 A continuous deep fat fryer, which can be used for a short par fry or fully cooking the product. Reproduced with permission from Marel and Townsend.

with the belting through the machine. Then the top layer of coating material is powered out of the hopper, cascading onto the product as it moves through the machine (Figure 6). The covered product moves under some optional soft rollers to help press and set the coating on the product. The product then travels to the discharge side of the machine, and the excess flour is shaken off as the product is dropped and flipped down through a series of short reversing conveyors, finally discharging from the machine. The product's journey through the flip section normally serves to create the random look of the outside layer.

Frying/Cooking

The coating material on the product at this stage is very soft and prone to deformations if not quickly hardened or 'fixed' to preserve its shape. Most of the products are therefore fried to 'cement' the texture on the surface. The frying operation can vary between flash/parfry (a 30–90 s immersion in 180–190 °C oil) and full fry in oil (time depends on product thickness). At this point the parfried product can also go into a forced air oven to complete the cooking. Most of the time this process is followed by freezing, and in the case of parfry, final cooking is done by the consumer/restaurant. An example of a continuous linear fryer is seen in Figure 7, where the product usually travels on a Teflon belt or a wire mesh belt so it moves at a constant speed (i.e., spends only the required time inside the fryer). An oven (Figure 8) can be used to finish the cook cycle and still provide fried product characteristics. After the initial parfry, the core temperature is still close to 0 °C (i.e., working with cold meat to minimize microbial growth and

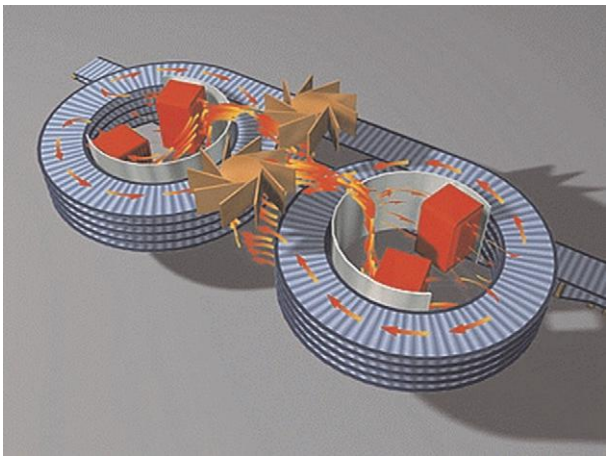

Figure 8 Forced air continuous oven with two separate cooking zones/towers. Reproduced with permission from Marel and Townsend.

maintain texture). Using a forced air oven allows complete cooking without absorbing any additional oil. Currently, there are various oven designs available in the market, mainly linear and spiral ovens (Figure 7), which allow temperature control in different zones. Some also include impingement at the end of the belt to provide a short, high-temperature exposure.

Conveyors

Conveyors may be found in a coating line in any of three places. First, at the beginning, conveyors deliver the product to the first coating applicator. Loading conveyors are used after forming machines and slicers, and are also used in hand-loading operations. Second, conveyors may be located within the line to provide the product some soak (hydration) time between processing steps when this will improve the coating's performance. Third, fryer-feed conveyors are used after the last breading applicator but before the fryer in virtually all nonleavened applications. These conveyors allow for some belt speed adjustments and also allow for some of the loose crumbs to fall free of the product before it goes into the frying oil.

Common Design Goals

The design engineer is charged with delivering a machine that meets several design goals:

- It must support food safety efforts by being easily and effectively cleanable, and by not harboring bacteria or foreign materials.
- It must be easily maintained.
- It must work harmoniously with other equipment in the processing line; addressing issues of belt height, belt width, belt transfers, belt speed, and capacity.
- It must be easy for the operator to learn to operate safely without posing hazards to personnel.
- It must be made from durable food-grade materials that can survive the challenging environment of a processing line.
- It must setup, change over, and tear-down quickly.
- It must handle the product gently, causing minimal damage and rejects.
- It must be easily cleaned, sanitized, and inspected.

Measures of Coating Line Performance

The capacity of a processing line is limited by the machine in the line that has the least capacity. Note that a continuous processing line is made up of short conveyor segments, each working harmoniously within the total system. For any uniformly loaded conveyor running at steady speed, its hourly capacity is defined in eqn [1].

$$\text{Capacity (kg h}^{-1}) = \text{BLD (kg m}^{-2}) \times \text{width (m)} \times \text{length (m)} \times [60/\text{time (min)}] \times \text{yield (\%)} \quad [1]$$

where BLD is the belt loading density, time is the process time for that conveyor's length, and yield reflects weight changes within the process segment (fryer, oven, freezer, etc.).

The reject rate measures the fraction of the production stream that is set aside for any reason: physical damage, falling from the conveyor, or failing to meet safety and quality specifications. Some items are rejected on the basis of value judgments by the line operating staff.

Key Control Points in the Performance of a Coating Line

The quality and safety of the final food product produced on a processing line is related to several conditions and settings throughout the line. When these are maintained as specified, the final product will conform to specifications. Several examples are listed below.

- Substrate temperature: the temperature of the substrate entering the processing system needs to remain constant from piece to piece and from time to time throughout the processing shift. Allowing the temperature to fluctuate will lead to variation in batter performance and coating pickup. Temperature variations can also have a dramatic impact on subsequent cooking operations, perhaps leading to undercooked product. Temperature variations near and below the freezing point are especially challenging because latent heating for a phase change of ice to water may be required in addition to sensible heating of the water. The energy required for this latent heating is typically quite large.
- Belt speeds: the components of a processing system are intended to work harmoniously with one another. Belt speeds for each machine should increase gradually across transfers as the product moves through the system. The basic recommendation is that the belt moving away from a transfer should exceed the speed of the belt approaching the transfer by approximately 0.5 m min^{-1}. This serves to maintain or improve alignment and helps to keep the product separated end-to-end.
- Transfer point setups: the product needs to flow smoothly from the belting of one machine onto the belting of

the following machine. Care needs to be taken to prevent the product from dropping through the belt gap and falling to the floor, or from colliding with the next machine's belting and causing edge damage. The ideal arrangement for belting at a transfer point should take into account the product size and shape, the style and pitch of the belting, and the speed of the line. Commonly, the gap between the machines should be 6–9 mm, and the elevation of the take-away belt should be 3–6 mm lower than the feeder belt.

- Batter temperature: there are several notable advantages to colder batters (5–10 °C). First, cold batter denies bacteria the ideal environment for rapid growth. Second, less dry batter mix is needed when making cold batter than when making warm batter of the same viscosity.
- Batter viscosity: viscosity is the term used in this context to describe a batter's ability to flow. It can be measured precisely with laboratory-quality instruments or quick proxy measures can be made in the processing area. The quickest measurements use either Zahn cups or Stein cups. A Stein cup is a clear plastic cup, approximately the size of a soup can, having a precisely sized drain hole in the bottom and a swiveling wire handle. The first step in using a Stein cup is to immerse the cup in the batter. The operator then starts a stopwatch as the cup is lifted up from the pool of batter. The draining action is allowed to continue until there are breaks in the batter stream coming from the hole in the bottom of the cup. At that moment, the stopwatch is stopped. The drain time is recorded and compared with previous readings (control charted) to provide a measure of the current batter viscosity. Pure water drains in approximately 8 s. Most adhesion batters drain in 10 s; cohesion batters in approximately 30 s; some tempura batters in approximately 45 s or more. Some of the thick leavened batters require other instruments to test their viscosities.
- Batter levels: batter levels in submerger-style batter applicators must be monitored and maintained above a minimum level to avoid failure to apply batter to the top of some products. There are gates to maintain puddle depth that function effectively as long as operators maintain adequate reserves in the machine.
- Breading levels: breading levels must be maintained to a prescribed depth to prevent bare spots on the products and to assure side coverage. At present automated gauges can help or a skilled operator needs to learn the pace for adding breading before the levels become too low.
- Hydration times: the coating and the pickup on some products are improved by providing some 'soak' (hydration) time between coating steps. This can be accomplished by inserting conveyor sections that delay the delivery of the product to the next machine.

Brine Injectors

RE Rust, Iowa State University, Ames, IA, USA
CL Knipe, Ohio State University, Columbus, OH, USA

Glossary

Accumulator tank A receiver tank for injection solution that is not retained in the meat product and is returned to the system.
Brine A solution of salt and other soluble materials that does not contain curing ingredients.
Curing pickle A solution containing nitrate or nitrite as curing ingredients.
Marinade A solution or suspension of materials primarily for flavoring.
Walking beam A series of mechanical arms that advance the material in repetitive steps.

Introduction

Brine injectors are used to incorporate curing pickle, brine solution, or marinade into meat pieces to affect product color, texture, flavor, meat safety, plus protein, and water-binding abilities. In their simplest form, these may consist of a single 'hypodermic' type needle attached to a syringe, or some type of liquid pump capable of delivering the pickle, brine, or marinade under pressure. Another version might be a 'spray' type hollow needle that has a series of holes along its axis that allow the solution to be distributed throughout the product. Sometimes, these needles are in multiples, resembling fingers on a hand. This configuration enables the operator to distribute the curing pickle, brine, or marinade over a larger area.

A single hypodermic-type needle was once used to inject curing pickle into the femoral artery of hams. This practice of artery injecting has fallen into disuse owing to high labor intensity and the potential for problems with uniformity in solution distribution. Even and consistent distribution of these solutions throughout the muscle pieces should be the ultimate goal; proper injection can maximize the uniformity of the solution distribution. Good slicing yields and uniform cured color are two results of uniform distribution of injected solutions. Color defects, poor slicing yields, plus inconsistent texture, and cooking yields are all results of uneven distribution of injected solutions.

Continuous Injectors

There are two types of continuous injectors, those designed for boneless product and those designed for bone-in product. The bone-in injectors have needles that retract if they encounter a bone (Figure 1). The meat to be injected is carried through the machine on some type of stainless-steel or plastic belt (Figure 2) or on a 'walking beam' arrangement (Figure 3). Either of these conveying systems is designed to stop when the needles are in the product. Normally, the needles stop within approximately 5 mm of the conveyor. This needs to be taken into consideration when placing the product in the injector, because the last few millimeters of product will not receive any pickle or marinade.

When injecting bone-in products, it is necessary to be cognizant of the 'bone shadow' that occurs when the needles strike a bone and the material below the bone does not receive any of the injected liquid. In some cases it is necessary to turn the product over, and essentially double pump it, to eliminate this bone shadow.

Figure 1 A bone-in injector with the cover open to show the multiple-needle injection head.

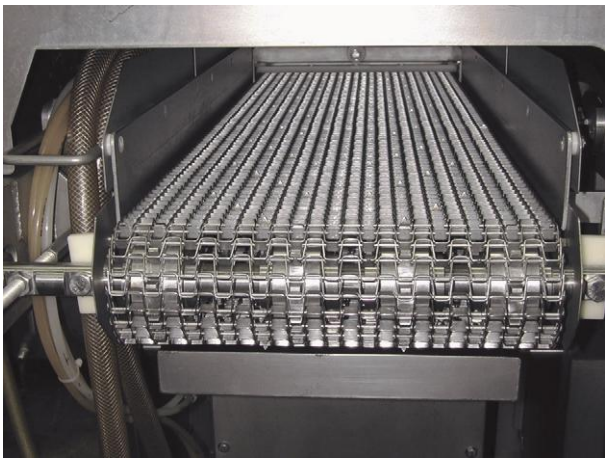

Figure 2 A stainless-steel injector conveyor belt.

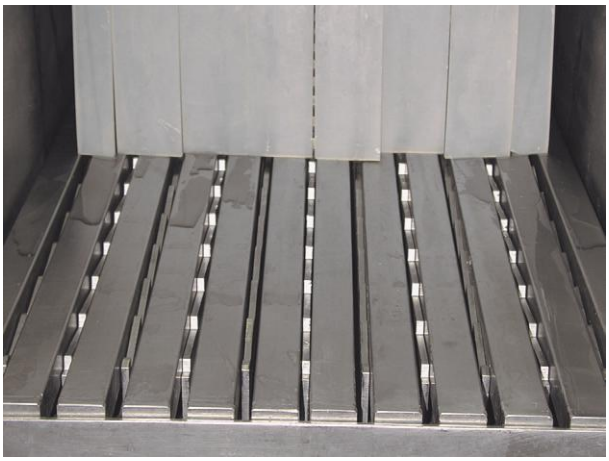

Figure 3 A 'walking beam' injector conveyor.

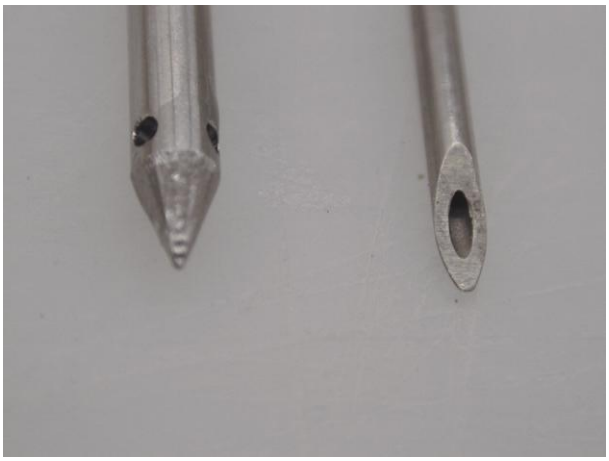

Figure 4 Injector needles. Left, a side-port needle; right, a hypodermic-type needle.

The needles may either be the hypodermic-type or the spray-type needles with side openings (Figure 4). The hypodermic-type needle is widely used in the US for bacon injectors. When using a needle with a bottom opening, care is needed to ensure that cores of fat do not clog the needle. For that reason, together with the fact that the last few millimeters of the product will not receive any injection, it is recommended that meat be placed in the injector fat side down.

Solution Uptake Targets

Meeting injection targets for solution uptake into meat pieces is a result of balancing pump pressure, injection time, and needle design.

Pump Pressure

Balancing injection pressure can be a challenge. Increasing pump pressure has been used in the past as a means to increase injection level. However, injecting at very high pressure may cause quality problems for products. For example, injecting pork bellies at very high pressure will result in solution accumulation in the fat streaks and seams, causing pickle pockets. However, injecting at very low pressure may result in under cured spots because of uneven distribution of the curing solution. It requires some experience in working with the equipment and the product to be injected to determine the optimum pumping pressure.

Injection Time

Injection time involves speed of the conveyor or walking beam, injection method (downstroke versus both down- and upstroke injection), number of passes through an injector or injection heads, injecting on both the up- and downstroke, versus only injecting on the downstroke, etc.

Higher injection levels can be accomplished with lower pump pressures by increasing injection time by methods, such as increasing needle numbers (i.e., closer needle spacing), multiple passes of product through the injector, and reducing the conveyor/walking beam speed. Some injectors are designed with multiple injection heads to simulate multiple passes through an injector. Multiple passes through an injector simulates the effect of closer needle spacing. Other injectors are designed to inject both in the down- and upstroke to increase solution retention. Reducing the speed that meat moves under the injector head will increase the number of times that the meat is injected, allowing for lower pump pressures.

Needle Design

Most injector needles for bacon have holes at the end of the needles. However, needles designed for other whole muscle products have holes along the sides of the needles. Side-port needles direct the solution in multiple directions away from the needle, which improves the solution distribution and retention in larger whole muscle products.

One method of dealing with products requiring a lower level of solution uptake would be to use smaller diameter needles with smaller holes. Larger diameter needles would be used for higher injection level products.

It is advisable to use needles with the smallest possible outside diameters to reduce needle marks in the product being pumped. However, the inside diameter should be sufficient to preclude the need for excessive pumping pressures to deliver the appropriate volume of pickle or marinade.

Pumps

The pickle, brine, or marinade is delivered to the injector needles by some type of pump. Pumping pressure can usually be varied. It is important to maintain the pumping pressure high enough to ensure good distribution, but not so high as to cause 'pickle pockets' to develop in the seams between muscle groups. Most injectors provide some mechanism for bleeding air from the injector head. If air accumulates in the injector, it can cause false pumping pressure readings and result in a lack

Figure 5 An accumulator tank. Note the filter screens and the pickle agitator.

of pumping uniformity. Pumps need to be suited to the type of material being pumped. If the pickle is viscous or contains particulate materials, the pump must have the appropriate capacity.

Accumulator Tanks

Injectors are normally equipped with an accumulator tank (Figure 5) that receives the excess pumping liquid and maintains the supply of liquid for the injector. These tanks have some type of filtration system to keep particles of meat from being recirculated in the pumping liquid. If the material being pumped contains suspended solids, such as soy proteins, it is necessary that the filtration system will not filter these out.

Agitation in the accumulator tank is normally provided by the overflow of the pumping liquid through a bypass from the injector pump. A mechanical agitator may supplement the overflow. Sufficient agitation must be maintained to keep the liquid thoroughly mixed, but it should not be so vigorous as to incorporate air into the pumping liquid.

A sufficient liquid level in the accumulator tank must be maintained to prevent the pump from sucking air when the level drops to near or below the tank outlet. As the accumulator tank can be a source of contamination from materials and microorganisms flushed off the surface of the meat, it is necessary to empty the tank and purge the system periodically. However, the return solution stream can be exposed to ultraviolet light to help reduce microbial contamination.

Product Temperatures

To maximize protein extraction and minimize microbial growth during subsequent processing steps, maximum product temperatures should be 4.4 °C (40 °F) during injection and a more optimal product temperature would be 1.6 °C (35 °F) to maximize protein extraction. However, warmer product temperatures have been shown to result in better uptake and retention of solutions, and in the case of pork bellies higher cooking yields.

Maintenance and Sanitation

Proper maintenance of injectors is critical. A preventive maintenance program should include checks for plugged, broken, or bent needles. All lines leading to and from the pump should be checked to make sure that seals are intact and that air is not being sucked into the brine or marinade. Injectors can provide reservoirs of spoilage and pathogenic microorganisms and a good sanitation program should be part of the daily maintenance schedule and the Sanitation Standard Operating Procedure.

Glossary

Grinder This term is preferred in the USA when referencing a device using a rotating knife and stationary plate to reduce meat particles. Synonymous with mincer.
Meat emulsions Finely comminuted fat particles disbursed in a salt-soluble protein matrix.
Mincer This term is preferred in Europe and the UK when referencing a device using a rotating knife and stationary plate to reduce meat particles. It is synonymous with grinder.
Salt-soluble proteins Myofibrilar proteins soluble in a salt brine.
Vacuumize To remove entrapped air from a meat mixture.

Mixing Equipment

The terms 'mixer' and 'blender' are often interchanged and from an engineering standpoint there seems to be no well-defined distinction. In the meat industry, a blender is usually a device that imparts more mechanical action to the product for the purpose of solubilizing and extracting the salt-soluble proteins. A mixer, however, is used to incorporate and uniformly distribute components of the processed meat formulation.

When using any type of mixing and blending equipment, care must be taken to choose the correct piece of equipment for the particular product being manufactured. For example, the mixer that one would choose for a dry sausage would not be the type that one would choose in a blender/emulsion mill operation for the manufacture of an emulsion-type sausage. In production, care must be taken to ensure that the temperatures of the product are optimum for both the type of equipment and the product being produced.

Paddle Mixers

Paddle-type mixers are most often used where a more gentle handling of the meat materials is desired (Figure 1). These devices consist of a tank or trough with either a single shaft or two intermeshing shafts running through the longitudinal axis. Paddles of varying configurations are attached to these shafts. Rotation speeds are either fixed or variable depending on the type of drive configuration. The drive mechanism can be supplied by either an electric or a hydraulic motor.

Paddle mixers would be the equipment of choice for processed meats such as dry and semidry sausages or coarse ground fresh and cooked sausages where particle distinction is critical. They are also used where the main purpose is to distribute ingredients with a minimum of mechanical action to extract the salt-soluble proteins.

Paddle mixers are more desirable for most meat-mixing applications. Paddle mixers are more efficient in uniformly mixing two or more ingredients. Compared with ribbon agitators, paddle agitators provide more lift and less push to product, which results in less compaction of ground meat, and paddle agitators are preferred when mixing high-viscosity mixtures, such as very cold meat or drier meat blends, such as ground beef, fresh sausage, and dry sausage.

Paddles are typically self-cleaning during the mixing process, so fat buildup is less of a problem. Intermeshing of paddle agitators speeds up the mixing process, reducing the mixing time needed to produce a uniform mixture, which is particularly important when trying to introduce a number of different nonmeat ingredients into meat. This reduced mixing time should also reduce fat smearing for products in which particle definition is important.

There is some debate about this issue; many believe that paddle mixers would be more effective for extracting protein for mixing lean meat in preblends or for mixing blends before emulsification. However, there is little scientific data to support either argument. If the surface area of the paddles moving through the product is increased, by using either larger paddles or even smaller paddles, the mechanical action of meat working against meat is increased, which increases protein extraction.

Paddle mixers run at reduced revolutions per minute (rpms), which can be useful for applying mechanical action to whole-muscle pieces or softer muscle like poultry to produce a

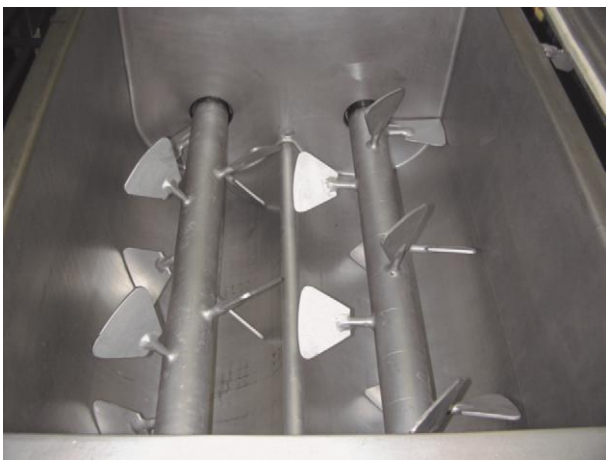

Figure 1 A view of a twin-paddle mixer.

 doi:10.1016/B978-0-12-384731-7.00224-5

surface protein exudate without damaging muscle integrity. Single-shaft paddle agitators are also used in massagers to produce protein exudate and increase water-holding capacity of muscle pieces.

Ribbon Blenders

Ribbon blenders have a similar configuration and drive mechanism to the twin intermeshing paddle mixers (Figure 2). In a ribbon blender, a screw-type configuration is substituted for the paddles. The configuration of these twin screws is such that the meat is conveyed back and forth through the length of the blender tank to enhance the mechanical action being applied to the meat mixture. Ribbon blenders are used where solubilization and extraction of salt-soluble meat proteins is desired. One such application would be preceding an emulsion mill in producing an emulsion-type sausage. Ribbon blenders are used where solubilization and extraction of salt-soluble meat proteins is desired. One such application would be preceding an emulsion mill in producing an emulsion-type sausage.

Ribbon blenders are less effective than paddle mixers in evenly distributing different ingredients that are added to the mixer, unless paddles are added between the shaft and the ribbon. Regarding the protein extraction debate in blends intended for cooked or emulsified sausage, some claim that ribbon agitators are more effective than paddles due to the friction produced.

Ribbon blenders can cause compaction of drier blends, such as ground beef, fresh sausage, and dry sausage. Ribbons can also cause 'log' or 'barrel rolling,' which results in meat packing around the shaft and turning around the shaft with no mixing action. This is particularly a problem when water is added to frozen meat in a blender. Fat buildup is also a bigger problem on ribbon agitators than on paddles.

Fat smearing can be a problem with ribbon agitators because of the meat being slid along the sides of the blender and pinch points between the ends of the ribbons, particularly if product temperature is too warm.

Figure 2 The same mixer as shown in Figure 1 fitted with twin ribbons to function as a ribbon blender.

General Considerations

In addition to the type of agitator, mixing times and temperatures are also very important in getting proper protein extraction, particle definition, and final product texture. Mixing times for hamburger and sausage patties, as well as for fermented and dried products, would be shorter than for cooked sausages, because protein extraction is not important in making these products. Also, for hamburger and sausage patties, overmixing will result in an undesirable, rubbery texture and possibly fat smearing. For all of these products, colder meat temperatures will help to minimize melting of the fat and therefore fat smearing.

For cooked sausage products, where protein extraction is important, the lean portion should be mixed as long as is feasible at the coldest temperatures possible, with the salt (and phosphate, if used), to optimize protein extraction. After the fatter ingredients are added, mixing time should be minimized and product temperatures kept as cold as possible to minimize fat smearing.

When determining the capacity of a mixer, at a minimum, the volume of meat should be at least up to the center shaft of the agitators. Meat should not extend past the tip of the agitators. Bridging can occur with overfilling of mixers, and proper mixing will not occur with underfilling.

The sequence of final grinding versus mixing will also impact product texture and particle definition. Products, where good particle definition is important, should be mixed after the final grinding. This also applies to products that contain cheese, peppercorns, encapsulated acid, etc. For products where protein extraction is important (cooked sausage, emulsion products, etc.), mixing after final grinding is more effective.

Cooking and Cooling

Both mixers and blenders can be equipped with steam or hot-water jackets to heat the meat mixture during this step in processing. The most usual configuration for converting the ribbon blender to a cooker would be to insert scraper paddles between the ribbon flights to prevent the cooked meats from sticking to the heating surface. These jackets can also be used with chilled liquids to help maintain product temperatures.

More effective cooling can be obtained, however, by equipping the mixer/blender with a hood for applying carbon dioxide snow. The use of carbon dioxide as a chilling device is effective because of the large temperature differential between the product and the coolant, plus the fact that nothing is added to the finished product, as would be the case if ice were added. Mixer/blenders can also be fitted with a perforated pipe or bottom injection nozzles for the incorporation of carbon dioxide snow or liquid nitrogen as a coolant. In these cases, the blender needs to be fitted with a hood and an exhaust to vent the carbon dioxide or nitrogen gas.

Vacuum

A lid can be added to mixer/blenders to enable mixing and blending under vacuum. For most cooked products as well as

dry and semidry sausages, vacuum mixing is important, but vacuum mixing would not be recommended for looser textured products, such as ground beef and fresh sausage patties. Vacuum mixing removes air bubbles and pockets, which improves texture and appearance of cooked sausage products. Vacuum mixing is only applicable where it is applied in the final step before stuffing.

Other Types of Mixer/Blenders

Some smaller mixer/blenders use a single sweep arm as the mixing device. This produces a 'kneading' effect on the meat product. Sometimes this single sweep arm is coupled with counter-rotating paddles.

Combination mixer/mincers are available. These are designed to mix the product before the final mincing step. They are most useful in operations such as hamburger mincing, where the coarse-minced lean and fatter meats are being incorporated into a final blend before the final mincing.

Mincers/Grinders

Mincers/grinders are the most widely used particle reduction equipment for meat processing. These comminute the meat by forcing it through a plate with holes of varying sizes and then cutting off the extruded particles by means of a rotating knife. The most common configuration consists of a variable-pitch screw, which serves to deliver the meat to the mincer/grinder plate. Figure 3 shows a diagram of a typical mincer/grinder configuration. Because the screw drives the rotating knife, the knife rotation speed is fixed and the length of the particle being extruded can only be varied by changing the number of blades on the knife. The most common configuration is four knives, although two or six knives are sometimes used. The knives may be solid steel, which require periodic sharpening, or there may be a knife holder with insertable blades that can be replaced when worn.

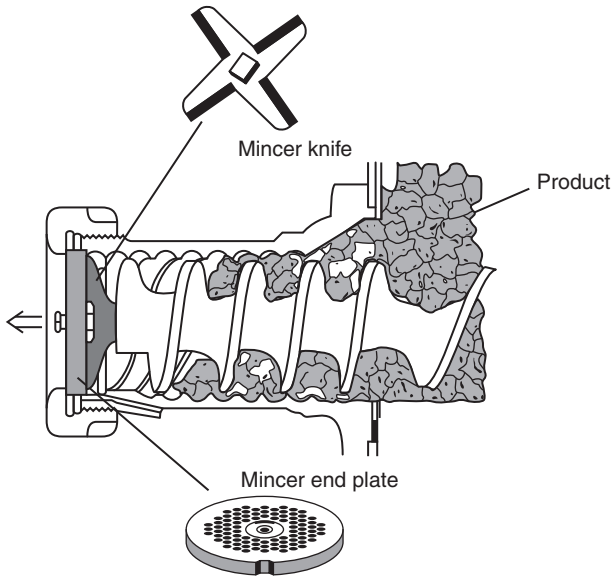

Figure 3 A diagram of a typical mincer/grinder. Reproduced from Aberle, E.D., Forrest, J.C., Gerrald, D.E., Mills, E.W., 2001. Principles of Meat Science, fourth ed. Dubuque, IA, USA: Kendall/Hunt Publishing Co., p. 127.

The particle diameter is controlled by the size of the holes in the mincer/grinder plate. They can vary from very large, the so-called kidney plate (because of the shape of the holes) that produces fist-sized chunks, down to 3 mm.

Some mincers/grinders are designed with a double plate that consists of a double-edged knife or knife holder sandwiched between a coarse plate of, say, 13 mm and a fine plate of 3 mm. The objective here is to complete a coarse mincing/grinding and a fine or final mincing/grinding in one operation. It is common to use a coarse mincing/grinding followed by a fine mincing/grinding to ensure more uniform distribution of fat and lean particles. There are also triple-plate configurations.

It is critical in operating a mincer/grinder that the knives and plates are sharp and carefully matched, so that a clean cut is obtained. The knives should make close contact with the plate for the entire length of each knife. Because the knife and plate are in close contact, the mincer/grinder should never be run empty as this will result in burning of the knife and plate and loss of sharpness. It could also result in metal fragments being incorporated into the product.

To obtain the proper consistency and appearance of the final product, it is important to pay attention not only to the sharpness of the knives and plates but also to the temperature of the meat being ground/minced. Each product has very specific temperature requirements. Large-capacity mincers/grinders can be equipped with screws that are designed to give optimum performance with a specific type of meat. Although there are 'general-purpose' screws, it is best to use a screw designed for a specific purpose – frozen meat, fat, lean, etc.

In general, plates with the largest hole size possible should be used. The first grinding/mincing step in which large chunks or whole muscles are to be reduced, plate hole sizes of 0.5–0.75 inch (13–19 mm) are recommended. Larger plate hole sizes in the first mincing/grinding step improves the uniformity of fat distribution and also increases the efficiency of bone or hard tissue separation in the final grinding process. The final plate hole size affects the texture of the finished product and should be selected accordingly.

Bone Separators

Bone or hard cartilage separators can be fitted to most mincer/grinders. These devices involve designing the knife and plate so that hard particles will migrate to either the center or the outer edge of the mincer/grinder head and there be eliminated. Because some soft tissue is forced out as well, the user has to be prepared to sacrifice some yield in order to eliminate the hazards and annoyance of bone or hard cartilage pieces in the finished meat product. Regulating the discharge rate usually controls the degree of bone removal. At best, bone removal systems can only be expected to eliminate 80% of the hazard. They are most effective when used on final mincing/grinding of 0.125–0.25 inch (3–7 mm). Figure 4 shows a typical mincer/grinder screw, plate, and knife assembly. The plate is designed

Figure 4 A typical mincer/grinder screw, plate, and knife assembly. The plate is designed to allow the bone or hard cartilage to move to the center of the plate where it is discharged under controlled back pressure.

Figure 5 A bowl chopper fitted with a vacuum hood. The knife hood is open to show the six-blade knife assembly. The unloading scoop is to the left of the knife assembly.

to allow the bone or hard cartilage to move to the center of the plate where it is discharged under controlled back pressure.

In-Line or Pump Mincer/Grinder

One of the more recent designs is the in-line or pump mincer/grinder. In these systems, the meat is delivered to the mincer head by a stuffing pump, usually a piston or vane type. A separate drive motor controls the knife rotation so that the relationship of the meat being delivered through the plate to the speed of the knife can be varied infinitely. This allows varying the particle length. Using a pump rather than an auger to deliver the meat mixture to the plate and knife further reduces damage to the fat particles. In addition, these systems can operate as closed systems, reducing contamination risks. These in-line systems can also be vacuumized, a further advantage as it will help to eliminate air particles in the meat mixture. In many cases, these in-line mincer/grinders are connected directly to stuffing and linking devices, making for a continuous in-line, closed system.

Bowl Choppers

These devices have been popular for batch operations for the production of coarse-cut sausages and meat emulsions (Figure 5). They offer the advantage over other systems that the mixing and comminution step can be accomplished in one operation. A disadvantage of bowl choppers is that they are best suited to batch operations as opposed to high-speed continuous operations. Bowl choppers are versatile, permitting a wide range of variability that is operator controlled. They have the disadvantage that particle size is totally operator dependent, making uniformity from batch to batch quite difficult. As contrasted with mincer/grinders, they give better particle distinction and less smearing but produce more variability in particle size. Bowl choppers cannot be fitted with bone removal systems as can mincer/grinders.

The bowl chopper consists of a rotating bowl with a series of rotating knives running in a vertical plane in the trough of the bowl. The knife head speed can be varied, as can the rotation speed of the bowl. Knife heads can vary from 2 to 12 knives, and chopper capacity can range from a few kilograms of meat to well more than 1000 kg. Each chopper will have an optimum capacity range for effective chopping. Overloading and underloading can decrease the effectiveness of the chopper.

In operation, the knives must be kept sharp and uniformly balanced. The knives should be set with minimum bowl clearance to produce effective chopping. As with the mincer/grinders, all types of comminution equipment produce frictional heat. This heating effect must be considered in arriving at the optimum final batch temperature.

Most larger choppers have an unloading device that scoops the finished meat batter out of the chopper as the bowl rotates. They may also be equipped with temperature-measuring devices to monitor the meat temperature during chopping and may be equipped with bowl rotation counters and timers. Monitoring the condition of the meat by number of minutes or number of revolutions of the bowl has severe drawbacks because it does not take into account variations in meat texture.

Other Features

Choppers can be equipped with a vacuum hood to enable the vacuumizing of an emulsion or meat batter during chopping (Figure 5). They can also be equipped with a carbon dioxide snow hood to enable cooling.

Choppers can be equipped with a steam jacket to allow cooking while chopping. This feature is useful in the manufacture of some liver sausages and patés.

Vertical Cutter/Mixers

There are some vertical mixer/cutters that resemble large food processors. In these cases, the knife head rotates in a

horizontal plane. These are usually of relatively small capacity for production use. They are quite useful, however, for preparing samples for laboratory analysis.

Emulsion Mills

These devices are used to convert a meat mixture to a fine batter or emulsion. Although they act to disperse the fat particles in the meat and other protein matrix, they must be preceded by a blender to solubilize the myofibrillar proteins. This is the reason that it is usually referred to as a blender/emulsion mill system.

Emulsion mills accomplish the same basic task as bowl choppers, but they are part of a continuous system. They also have the advantage of producing a uniform particle size, as opposed to a bowl chopper in which the particle size is operator dependent. Emulsion mills can range in capacity, and it is to be expected that the capacities of a continuous blender/emulsion mill system will exceed that of a bowl chopper. For this reason, most high-capacity continuous systems employ a blender/emulsion mill combination. Meats are usually preminced or ground through a conventional mincer/grinder before being introduced into this type of system.

There are two general types of emulsion mills. The most common type uses a plate and knife or multiple plates and knives, not unlike a mincer/grinder. The meat is forced through this plate/knife combination by some type of pump. Because this is a closed system, a vacuumizing device can be included in the system to vacuumize the emulsion. The frictional heat rise must be taken into account before the meat mixture is introduced into the emulsion mill. If additional heating is needed to attain the desired final temperature of the emulsion, this can be achieved by controlling the back pressure on the finished emulsion side. The particle size is controlled by the size of the holes in the emulsion mill plates. As with the mincer/grinders, it is critical to maintain sharp knife and plate sets and the same cautions apply to running the equipment empty.

Another type of emulsion mill uses an impeller to force the meat mixture against stationary blades. This design does not have metal-to-metal contact, so it can be operated without meat in the system. However, it does not have provisions for vacuumizing the emulsion. This must be accomplished later with a separate piece of equipment in the system.

Flaking Equipment

There are various types of equipment designed to cut meat particles into very fine flakes. Such equipment is primarily used where the meat is to be reformed into a solid piece under pressure. The popularity of this technology has diminished in recent years.

Frozen Meat Breakers

There are various types of frozen meat breakers that are used to reduce particle size for chunks of frozen meat. It is advisable to temper the frozen block of meat before breaking it up. This saves energy and prevents the destruction of the texture of the meat. A temperature of −7 °C is advisable. The most common types employ a guillotine-type knife that shaves off a layer of meat. Another type uses a rotating drum with knives attached that chip the meat. A third type is a specially designed mincer/grinder that forces the meat through large holes.

Slicers

Slicers are used in the final processing step. They can range from the small meat slicer in a retail operation to the high-speed slicers used for slicing and portioning ready-to-eat (RTE) meat. The meat is presented to a rotating circular or elliptical knife. The thickness of the slice is controlled by the distance the meat advances before it contacts the knife. Slicers can be linked to portioning devices as well as devices that shingle or stack in exact weight units. In the more sophisticated slicers, the weight of a unit coming off the slicer can regulate the thickness of slices in the next unit to achieve exact weights. The type of product being sliced as well as the configuration of the slicer determines the optimum temperature for slicing. This can range from partially frozen, in the case of bacon, to near the freezing point in the case of RTE luncheon meat.

A relatively new entry into the array of slicers is used to preslice the meat on a boneless or bone-in cooked and smoked ham in a spiral pattern, making it easier for the consumer to carve.

Dicers

Precooked meats and some fresh meats are often diced for further processing or for final use by the consumer. Dicers come in various configurations. Usually the meat is forced through a grid made up of knives or a plate with holes of various sizes. A guillotine or elliptical rotating knife then cuts off the pieces. Each particular dicer has rather specific requirements as to temperature of the material being diced and the adjustments to the machine, such as knife clearance.

Glossary

Conduction Particle-to-particle heat transfer within the product. No bulk movement occurs.

Convection Heat transfer from steam, air, or water to the surface of the product. Convective heat transfer results from the bulk movement of air or water due to natural temperature gradients (free convection) or forced agitation using a fan or pump (forced convection).

Dry-sensor temperature The temperature of air measured using a clean, dry temperature probe.

Forced convection An external source (e.g., fan or stirrer) to aid heat transfer from the heating medium to the product surface. Agitation reduces the thickness of the boundary layer around the product, thus producing higher rates of heat transfer.

Free convection Heat transfer from the heating medium to the product surface from natural bulk movement of air or water.

Impinge To strike, dash, or collide against something. Used in the term 'impingement oven' to describe an oven design where fan-driven air is delivered perpendicular to the product surfaces using air supply ducts located directly above and below the product placed on a wire conveyor belt.

Wet-sensor temperature The temperature of air measured using a temperature probe fitted with a moisture-wicking cloth. Moisture evaporation from the cloth cools the sensor to the wet-bulb temperature. In a steam environment, the dry- and wet-sensor temperatures are equal, but if any drying is occurring, the evaporation will cool the wet-sensor probe to a temperature that is lower than the dry-sensor temperature.

Cooking Equipment

Industrial cooking equipment for meat and poultry processing can be separated into two basic categories – batch and continuous. In batch equipment, the product is loaded, cooked, and unloaded as a single batch (Figures 1–3). Batch oven capacities range widely from small units that hold 100 kg of boneless hams per batch to large ovens that hold 25 000 kg of bone-in hams. Batch ovens are commonly known as smokehouses, even though smoke is not always added. Most batch ovens can be used for both steam cooking and forced-air convection cooking, whereas some are designed as dedicated steam cookers (Figure 2). Kettles or tanks are used for batch cooking using hot water (Figure 3).

In large-scale factories, high-volume continuous systems are often used for cooking and smoking. In these systems, the cooking, smoking, and cooling operations are usually integrated into a single large unit with multiple zones or multiple units integrated into a single production line. The product is loaded onto a conveyor that transports it through one or more cooking zones followed by a cooling zone or a freezing system. Common continuous system designs use chain, a walking beam, or belt conveyors to move the product through the zones.

Chain-conveyor systems may be designed as straight-line tunnels (Figure 4), horizontal serpentines (Figures 5 and 6), or vertical serpentines (Figure 7). In straight-line and horizontal-serpentine systems, strands of sausages are hung on

Figure 1 Large meat-processing batch ovens. Reproduced with permission from Brandt Meats, Ltd, Canada.

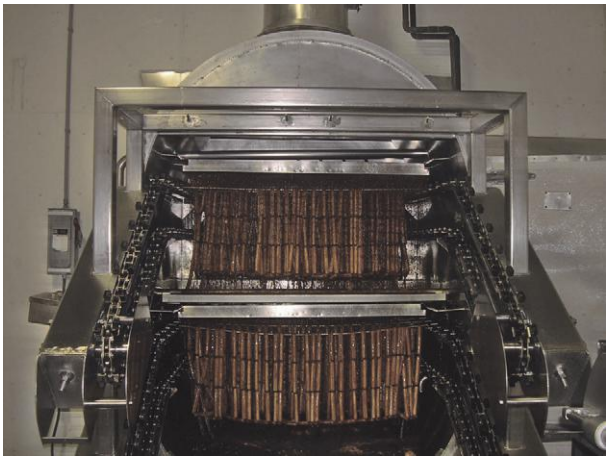

Figure 4 Straight-line chain conveyor – continuous frankfurter cook/chill system. Linked sausages are looped onto sticks and sticks are manually placed on a dual-chain conveyor. The sticks span the gap between the two chains. Reproduced with permission of Cargill, Inc., USA.

sticks or hooks that are conveyed through the system on a slow-moving chain. For vertical serpentine systems, products are often stuffed into casings as individual links, logs, or chubs that are then loaded into trays for cooking and chilling.

Chain-conveyor systems are commonly used for production of small sausages (18–28 mm diameter) such as frankfurters and smoked sausage. Output capacities typically range from 3000 to 8000 kg h^{-1}. For these systems, sausages are stuffed into long cellulose casings and automatically twist-linked into strands. The strands of sausages are either looped onto metal sticks that are placed on a chain conveyor (Figures 4 and 5) or are looped directly onto a J-hook chain conveyor

Figure 5 Horizontal serpentine chain-and-yoke conveyor – continuous small sausage cook/chill system. Linked sausages are looped on sticks and then sticks are manually hung on yokes attached to a mono-rail chain conveyor. Reproduced with permission of Maple Leaf Foods, Inc, Canada.

Figure 6 Horizontal serpentine chain-and-hook conveyor – continuous small sausage cook/chill system. Linked sausages are automatically looped onto hooks attached to a chain. Reproduced with permission of Marathon Enterprises, Inc., USA.

(Figure 6). The conveyors slowly move the sausage strands through a multizone forced-air convection oven and a brine- or water-shower chiller. After cooking and chilling, the sausages are unloaded, stripped, and packaged. Cooking times for these small sausages are typically 30–75 min.

In coextrusion sausage systems, continuous strands of sausage are coextruded with collagen casings made from collagen dough. The continuous strands are automatically cut to length and loaded into trays on a serpentine conveyor (Figure 8). In these systems, the sausages are discharged from the trays after being smoked but only partially cooked to a core temperature of approximately 45–60 °C. The warm sausages are then packaged in plastic film and loaded into a continuous hot-water cooker for final cooking.

Walking beam systems are designed to index product racks through a cook/chill system at preset time intervals (Figure 9).

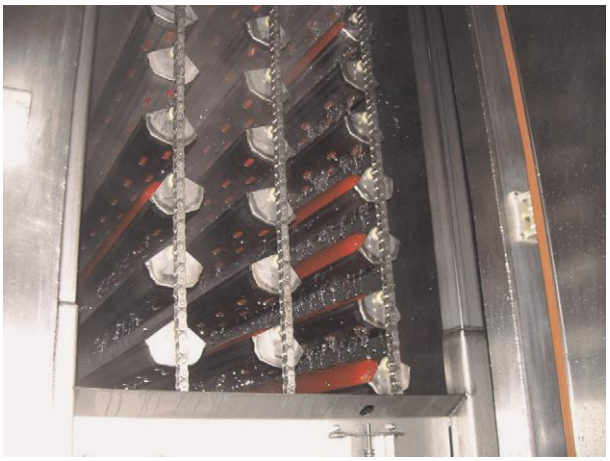

Figure 7 Vertical serpentine chain-and-tray conveyor – continuous large sausage cook/chill system. Stuffed sausage logs are automatically stuffed and loaded into trays that span the gap between two chains. Reproduced with permission of Smithfield Foods, Inc., USA.

Figure 8 Serpentine chain-and-tray conveyor – continuous coextruded sausage system. Blended sausage meat is coextruded with collagen dough to form continuous ropes of sausage encased in a film of collagen dough. Ropes are automatically cut to length, and cut sausages are loaded into trays that span the gap between two chains. Reproduced with permission of Salm Partners LLC, USA.

These systems are commonly used for larger products such as bacon or ham and have output capacities ranging from 5000 to 10 000 kg h^{-1}. These systems can use forced-air or steam cooking, and typical cooking times are 4–6 h.

High-temperature continuous ovens are used to cook a wide range of thin meat and poultry products using spiral-tower or linear (straight-line) belt conveyors (Figures 10–11). Products cooked in these ovens may be either coated or noncoated. Batter, breading, and sauces are commonly used as coatings added before cooking. Typical products include chicken pieces (wings, breast fillets, etc.), formed chicken meat (nuggets, patties, etc.), turkey pieces, sausage links, pizza toppings, meatballs, pork patties, and ground-beef patties. In linear- and spiral-belt ovens, a single layer of product is placed

Figure 10 Spiral-belt continuous oven. Product is conveyed on a belt that is configured as one or more spiral towers. Airflow is horizontal across the belt and parallel to the product. Reproduced with permission of Marel Townsend Further Processing, USA.

on a conveyor belt that carries the product through the oven. Fan-driven air is heated to high temperatures (150–275 °C) and driven through the process zone at high velocities (3–7 m s^{-1}), thus promoting rapid cooking and browning. Typical cooking times are very short at 3–12 min. These products are often conveyed directly from the belt oven into a freezer and then to a packaging machine.

Cooking Processes

Meat-processing ovens are used to cook products to moderate endpoint temperatures of 60–80 °C, thus destroying vegetative pathogens but not spores. As such, these cooking processes are best defined as pasteurization processes because they do not fully sterilize the products.

Although the designs for cooking equipment vary widely, only five heating media are commonly used either alone or in

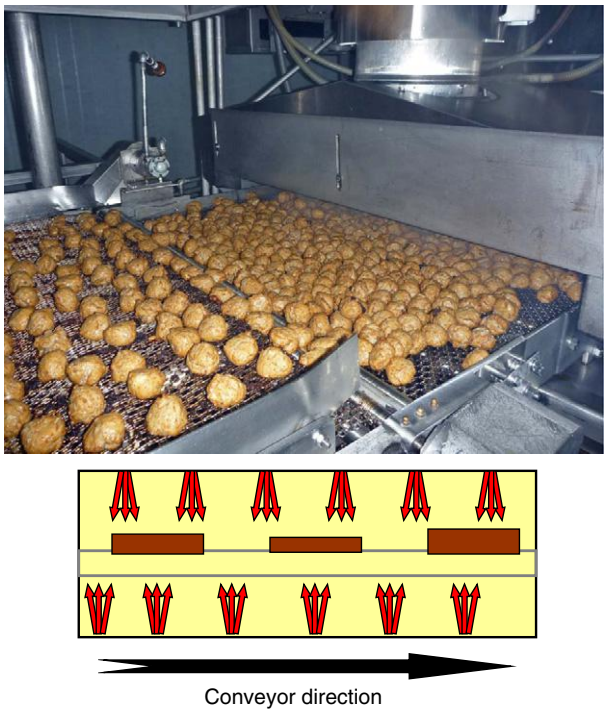

Figure 11 Linear-belt impingement oven. Product is conveyed on a linear-belt straight through a tunnel oven. The airflow is directed perpendicular to the product during cooking from forced-air impingement slots located above and below the belt. combination – (1) hot air (free or forced convection), (2) steam, (3) hot water, (4) infrared, and (5) microwave.

Forced-air convection ovens, steam cabinets, and hot-water tanks are widely used across the industry for cooking and smoking countless types of meat products. Infrared heating is used in specialized applications for rapid cooking and browning of thin products such as beef patties. Microwave ovens are also used in specialized heating systems, and have been widely adopted for continuous cooking of precooked bacon slices.

Steam and Hot Water Cookers

Steam and hot water cookers are used to process products that are not browned. These products are usually encased in plastic film and sometimes placed in stainless steel molds, and then cooked in steam cabinets, hot water tanks, or recirculated hot-water showers. The plastic casings may be coated with liquid smoke to add smoke color and flavor.

Large batch cooking tanks may be individually loaded using manually operated hoists or use automated hoist systems to automatically load and unload the tanks. The hot water may be pumped out of the tanks and replaced with chilled water for cooling. In continuous systems, the product is conveyed through either a steam atmosphere or a hot water shower, and then cooled using a chilled-liquid shower (fresh water, salt water, or propylene-glycol water). Steam and hot water temperatures within batch or continuous cookers are typically uniform, and therefore finished product temperatures are also uniform.

Steam and hot water cooking are simple processes that have only two variables – time and temperature. Condensing steam and hot water both have extremely high surface heat transfer coefficients and are thus highly effective at transferring heat to the product surface. Because the surface heat transfer coefficients are extremely high for both steam and hot water, products cooked at the same temperature in either medium will have approximately the same cooking time.

The basic principles of steam and hot-water cooking are easy to understand. If the steam or hot-water temperature is increased, the product surface temperature immediately increases and – after a lag time for heat conduction to the core – the core temperature cooks faster. If the steam or hot-water temperature is lowered, the surface temperature immediately decreases and the core cooks more slowly. When designing a steam or hot-water cooking process, it is important to consider that the product surface temperature closely tracks the temperature of the heating medium. Meat proteins denature strongly at approximately 55–60 °C. If the steam temperature in the first step of a process is substantially higher than 60 °C, the surface proteins will rapidly denature and cooking yields will suffer. To maximize cooking yields, the first step of a steam or hot-water cooking process should have a temperature set-point of 55–60 °C. This 55–60 °C set-point should be held long enough to slowly denature the surface proteins before increasing the steam or hot-water temperature. The slow denaturation of the surface proteins will improve water-binding ability and yields for the product.

Forced-Air Convection Ovens

Batch, continuous-chain, spiral-belt, and linear-belt ovens that use fan-driven air to cook product are classified as forced-air convection ovens. Regardless of the design, size, shape, or age of an oven, all forced-air convection ovens are designed to control the same four variables: (1) dry-sensor temperature, (2) moisture level in the air (wet-sensor or dew-point temperature), (3) air velocity, and (4) cooking time.

Precooked and smoked meats are often cooked in either batch or continuous-chain forced-air convection ovens. As previously described (Figures 4–6), continuous-chain systems convey the product through a series of smoking, cooking, and chilling zones. Most smoked meat products are cooked using dry-sensor temperatures of less than 100 °C, and therefore the maximum operating temperature for these ovens is usually approximately 110 °C. An exception is that some batch ovens are specially designed for high-temperature cooking or browning at dry-sensor temperatures of up to 260 °C.

Cooking times and air velocities are distinctly different for batch and continuous smokehouses, spiral-belt ovens, and linear-belt ovens. A comparison of typical air velocities through the product zone for various types of forced-convection ovens is shown in Table 1.

Batch ovens are remarkably versatile, and are used to cook products having cooking times ranging from 45 min to over 15 h (Figures 1 and 12). If the products are smoked, the cooking processes will have steps for either liquid or

traditional smoke application. Many smoked products are stuffed in presmoked fibrous casings or nets that are pretreated with liquid smoke, and therefore do not require an external smoke application.

Spiral-belt ovens are used to cook products such as meatballs, links, whole-muscle pieces, formed pieces, and patties that generally have short cooking times of 6–20 min, although longer cooking times are possible. Spiral ovens operate at high temperatures of up to 275 °C. The combination of high temperatures and fan-driven air induces rapid browning of the product surfaces. Airflow is generally horizontal across the belt – parallel to the product surfaces – and therefore the surfaces brown more slowly for a spiral oven than an impingement oven. However, the longer process times allow for better-optimized and thus higher-yielding processes for spiral ovens than for impingement ovens. Because of the horizontal airflow, the edges of the product facing the airflow tend to brown faster than the horizontal surfaces – a phenomenon known as 'edge-browning.'

Table 1 Comparison of typical air velocities through the product zone for various forced-air convection oven designs

Oven design	*Air velocity ($m\ s^{-1}$)*
Batch and continuous smokehouses	1.0–2.0
Spiral-belt tower oven	3.0–5.0
Linear-belt horizontal-airflow oven	2.5–3.0
Linear-belt impingement oven	4.0–7.0

Source: Reproduced with permission from HansonTech LLC, USA.

Linear-belt ovens are generally designed for operating temperatures similar to those for spiral-belt ovens but usually have shorter cooking times of 3–10 min. Many linear-belt ovens use an impingement-airflow design that uses supply-air slots above and below the belt to drive (or impinge) the air directly into the perpendicular surfaces of the product on the belt (Figure 11). The perpendicular impinging action of the air on the product surfaces accelerates the drying and browning of product surfaces in impingement ovens.

High-temperature belt ovens are sometimes used for the surface roasting of large precooked products such as turkey breast, roast beef, and ham to create a roasted appearance. For this application, molded or plastic-casing products are steam or hot water cooked and then cooled. To create the roasted appearance, the casings are stripped off and the product is run through a belt oven for a rapid, high-temperature browning of the surface. Depending on the desired appearance, this rapid-roasting process may take 10–20 min.

In a similar application, belt ovens have been adapted to use high-temperature and high-velocity air to dramatically accelerate the development of smoke color. Molded or plastic-casing products are steam or hot water cooked and then cooled. The product is then stripped, drenched in liquid smoke, and run through a belt oven using high-temperature,

high-velocity forced air for rapid smoke color development. This rapid-smoking process replaces slower conventional batch oven processes, reducing smoking times from 3–6 h to only 15–20 min.

Controls

Electronic controls are used to measure and control the process variables in batch and continuous ovens. These control systems use either a computer or a programmable logical controller to create and store cooking programs and process data. The required oven settings are entered into the control system software and then the cooking programs are saved for repeated use. Depending on how the oven is equipped, the cooking programs may include step times, dry-sensor temperature, wet-sensor or dew-point temperature, intake and exhaust damper position (automatic, open, or closed), main fan speed (one, variable, or multispeed), exhaust fan (on or off), and smoke generator (on or off). An example of a typical cooking program for smoked bone-in hams cooked in a batch smokehouse is shown in Table 2.

Cooking and Smoking Processes

Cooking processes for precooked and smoked meats must strike a balance between dry and wet conditions. Dry conditions promote the development of smoke color, browning, aroma, and firm surface texture. Wet conditions promote smoke absorption, tender surface texture, tender casings, light color, improved yields, good peelability, uniform temperatures, and reduced cooking times.

Air Temperature Measurement

A clean, dry temperature probe measures the dry heat in the oven, known as the dry-sensor or dry-bulb temperature (Figure 13). A wet-sensor probe or dew-point sensor is used to measure and control the moisture level in the oven air. A large temperature difference between the dry- and wet-sensor temperatures indicates that the air is very dry, whereas a small temperature difference indicates that the air is high in moisture.

The wet-sensor probe measures the temperature of evaporating water in the oven air – known as the wet-sensor or wet-bulb temperature. One standard method of measuring the wet-sensor temperature is to fit a wet, moisture-wicking cloth over an ordinary temperature probe, and then drape the cloth

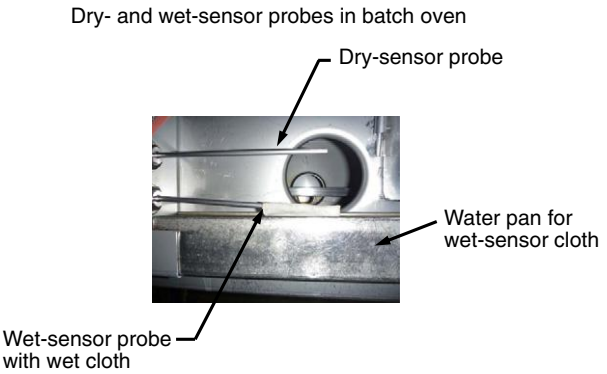

Figure 13 Dry- and wet-sensor probes in mounting bracket. Reproduced with permission of HansonTech LLC, USA.

in a pan of water to keep it wet (Figure 13). Water evaporating from the wet cloth cools the probe to the wet-sensor temperature. The wet-sensor temperature may be equal to but not higher than the dry-sensor temperature. For example, if the air is saturated during steam cooking, no evaporation will occur and therefore the dry- and wet-sensor temperatures will be the same. If the relative humidity decreases to 99% or less, however, moisture evaporating from the wet cloth will cool the probe to the wet-sensor temperature, which is lower than the dry-sensor temperature. Instead of a wet cloth, some ovens spray a mist of water over a probe located in the oven air stream to measure the wet-sensor temperature. This misting method is more reliable than the wet-cloth method because there is no fouling of the cloth from smoke or grease. Some ovens use a dew-point sensor instead of a wet-sensor probe to measure the moisture level in the air.

Relative Humidity

The relative humidity is a measure of the actual moisture content of the air compared to the moisture content of saturated air at the same temperature. It is useful as an indicator of the drying capacity of the air.

The dry-sensor temperature, wet-sensor temperature, dew-point, and relative humidity are all directly related. If any two of these variables are known, then the others can be looked up using a psychrometric chart or psychrometric software. In meat-processing ovens, the dry-sensor and the wet-sensor or dew-point temperatures are usually measured directly, and the control system uses the two values to calculate and display the relative humidity.

Effect of Dry- and Wet-Sensor Temperatures on Drying and Heating Rates

In forced-air convection ovens, evaporative cooling has a strong effect on the product surface temperature and resulting heating rates. Changes in the wet-sensor or dew-point temperatures will strongly affect product drying and heating rates.

An increase in the oven wet-sensor or dew-point temperature will cause an immediate increase in the product surface temperature, thus cooking the product faster. If the dry-sensor temperature is kept the same and the wet-sensor temperature is increased, the product surfaces will dry more slowly, resulting in higher cooking yields but slower surface color development. For smoked meats, if the wet-sensor temperature is increased too soon before the smoke color is fully developed, the result may be a blotchy or pale smoke color. To correct this problem, the product should simply be dried longer to further develop the smoke color before the wet-sensor temperature is increased.

If the wet-sensor temperature is kept the same and the dry-sensor temperature is increased, the higher dry-sensor temperature will dry the product surface more rapidly, resulting in an initially slower increase in the surface temperature that becomes a gradually faster heating rate as the product surface becomes drier. More importantly, the hot, dry conditions will promote Maillard browning, and thus a higher dry-sensor temperature promotes faster browning and smoked color development.

Forced-air convection cooking processes must balance dry and wet conditions to optimize quality characteristics, production efficiencies, and food safety. Dry conditions promote desirable quality and functional characteristics such as faster color development, reduced color variation, improved surface firmness, and casing adhesion. However, too much drying causes undesirable characteristics such as low yields, increased temperature variation, hard-to-peel casings, tough casings, and over-dry texture. Wet conditions generally promote higher production through higher yields, faster cooking times, and reduced temperature variation. Wet conditions also increase destruction of bacteria on the product surfaces and reduce the protective effect of dehydration for vegetative bacteria, thus increasing process lethality. As such, cooking programs must be written to balance and optimize dry and wet conditions. Given the powerful forces at work during forced-convection cooking, even small changes in oven variables may have a large effect on quality, throughput, and food safety.

Heating Systems

To control the dry-sensor temperature to the set-point, the oven control system regulates the heat source to increase or decrease the input of dry heat until the set-point is achieved. The three most common dry-heat sources for meat-processing ovens are direct-fired gas burners, heated coils, and electric heating elements.

- Direct gas: In a direct-gas fired oven, a gas flame is fired directly into the oven air stream to supply dry heat. Direct-gas heat is highly efficient and generally has the lowest cost of operation where natural gas is readily available. It can be used as a heat source for high-temperature operation up to 275 °C. Natural gas and liquid propane are the two most common fuels for direct-gas burners. A negative side effect of direct-gas heat is that the combustion gases are contained in the process air-stream, and these combustion gases often cause pinking in uncured meats.
- Heated coil: In an indirect-heated oven, a heat source such as steam, a gas flame, or thermal oil is used to heat a heat exchanger. The oven air is passed over the hot coil to provide dry heat. Steam coils are inherently limited to ovens that operate at temperatures of 105 °C or less. For higher-temperature ovens, an indirect-gas and thermal-oil coil must be used to achieve high temperatures of 230–275 °C.
- Electric heating elements: In an electrically heated oven, tubular heating elements are used to heat the air. Electric heat is extremely efficient and generally has a low maintenance cost, but it still has a high cost of operation because of the high cost of electricity. For this reason, electric heat is most often used only in small batch ovens (1–4 racks).

Pinking

Combustion gases from direct-gas fired burners will often cause a pink or purple ring to form on the outside edges of uncured meat products such as roast beef, chicken, or turkey. This pink ring is only a problem for uncured products: cured products are already pink and therefore the combustion gases have no noticeable effect. To prevent pink ring in uncured products, an indirect heat source such as a steam coil, thermal-oil coil, or indirect-gas must be used. Alternatively, the product can be encased in an impermeable plastic film to prevent exposure to the combustion gases.

Research has shown that nitrogen dioxide (NO_2) is the combustion gas that results in the pinking reaction. Although natural gas burns very cleanly, low levels of combustion by-products, including NO_2, are contained in the process air-stream during cooking. Nitrogen dioxide is highly soluble in water and thus readily absorbed into the meat surfaces. Nitrogen dioxide results in pinking even at very low concentrations – 0.4 ppm for turkey breast and 2.5 ppm for beef.

Moisture Control

To regulate the moisture level in the process air, oven control systems use a steam humidity valve or a combination of a steam humidity valve and the intake/exhaust dampers to adjust the actual wet-sensor or dew-point temperature to match the controller set-point. In a combination control system, the controller modulates the intake/exhaust dampers to control the amount of evaporated product moisture that is retained in the oven. If the retained moisture with fully closed dampers is not enough to achieve the wet-sensor set-point, then a humidity valve is opened to inject steam into the oven until the set-point is achieved. The humidity valve will then be cycled or modulated to maintain the actual temperature at the set-point. If the oven does not use dampers for moisture control, then the steam humidity valve alone is modulated to control the actual wet-sensor or dew-point temperature to match the

set-point. On-off or proportional on-off controls are sometimes used instead of modulating controls.

In most ovens, saturated steam is used as a humidity source. However, if the oven must maintain a relatively low dry-sensor temperature of, for instance, 42 °C or lower (e.g., for a fermentation process), atomized water is sometimes used instead of steam to prevent overshoot. Atomized water is also used as a humidity source in facilities where steam is not available.

Air Velocity and Airflow Patterns

In most batch ovens and some continuous ovens, the main fan and oscillating dampers are used to control the air velocity in the oven cabinet. The main fan speed can be adjusted using either a multiple-speed fan motor or a variable-speed motor control. The oscillating dampers sweep the air from side-to-side in the oven, thus creating localized changes in air velocity (Figure 14).

In a typical batch oven design, the main fan, heat source, and humidity source are mounted either on the roof of the oven (Figure 12) or on the back of the oven. The main fan supplies air to the supply ducts, where it is delivered to the process cabinet through supply cones or slots (Figure 14). The air is forced down along the side walls and across the floor where the two airstreams meet at what is termed the breakpoint. The air is then drawn up through the product to the return duct. The return duct is on the suction side of the fan and draws (returns) the air back to the fan cabinet to be reheated and rehumidified. Although many variations of this design are used, this basic air recirculation pattern is common to most batch ovens and many continuous ovens.

The point where the two opposing airstreams meet is known as the breakpoint. In Figure 14, the breakpoint is shown at the bottom-center and upper corners of the oven. The airflow at the breakpoint is highly turbulent and is the highest-velocity air in the cabinet. Most ovens use an oscillating damper system to slowly sweep the breakpoint from side-to-side in the oven. Some ovens use dual main fans equipped with variable-speed drives instead of rotating dampers to oscillate the air, but the effect is the same – the air slowly sweeps from side to side in the oven. If the oscillating damper system fails or is out of adjustment, the result will be severe side-to-side color and temperature variation in the oven.

Linear and spiral-belt ovens typically come equipped with variable-frequency drives on the main fans that are used to control fan speeds and air velocities. The fans can be set at any speed between the low and high limits of the drive. In some

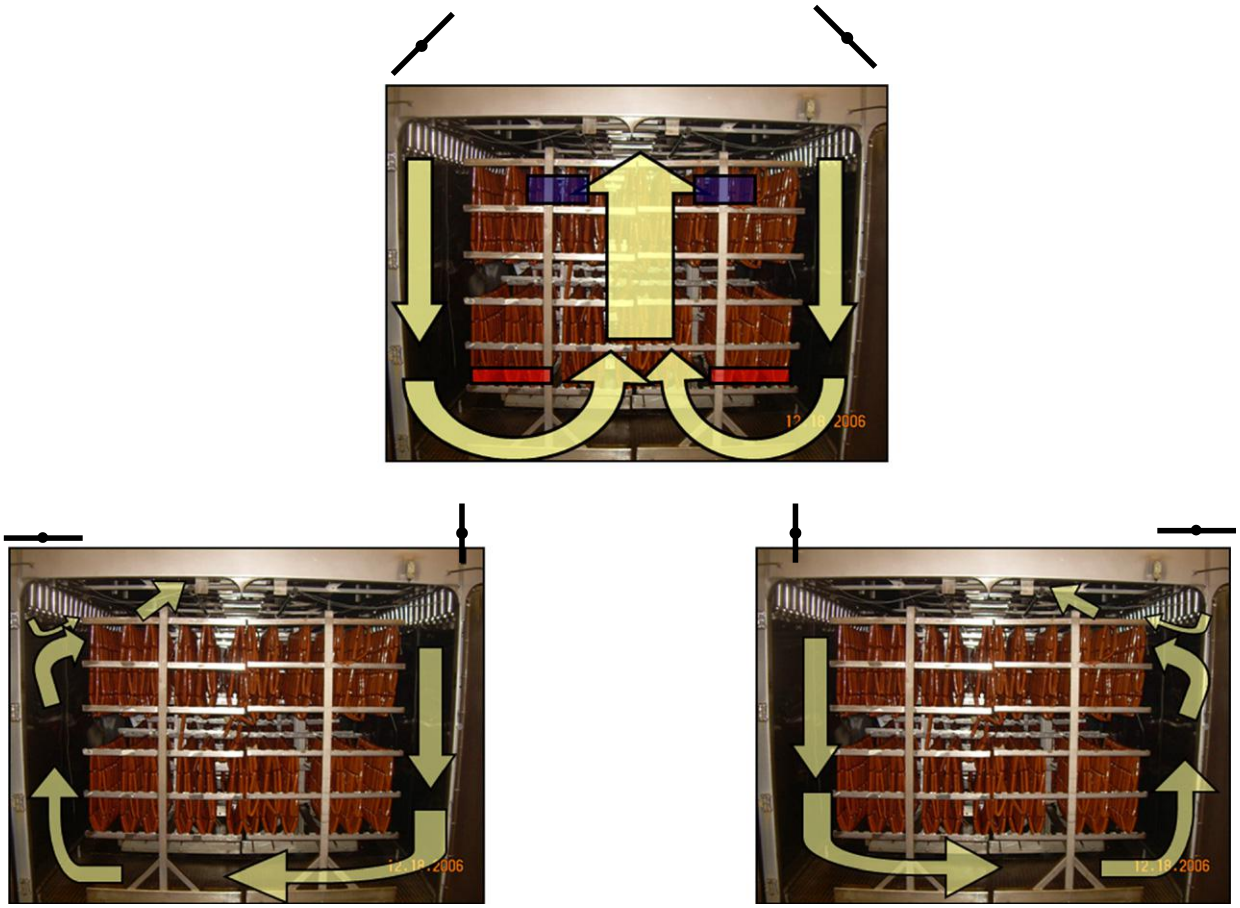

Figure 14 Typical airflow pattern in a batch oven. The point where the two airstreams meet is known as the breakpoint. An oscillating airflow system sweeps the air from side to side during operation. Reproduced with permission of Johnsonville Sausage LLC, USA.

impingement ovens, separate upper and lower fans are used to independently control the air velocities directed at the product from the upper and lower supply ducts. In other impingement designs, a single main fan and drive are used to control the volume of air delivered to a common plenum. A manually set diverter damper then splits the air between individual upper and lower plenums to control the air velocities directed at the product from those plenums.

Cooking Time

The cooking times in batch ovens are typically controlled using an established cooking program that includes several preset cooking and smoking steps (Table 2). The time required to achieve the target endpoint temperature determines the total cooking time for a product. The control system can be programmed to automatically shut down the oven when the target endpoint temperature is achieved. However, most processors use hand-held digital thermometers to manually confirm that the endpoint temperatures are achieved.

Some batch oven controls can be programmed to use 'ramp'-controlled step changes. Using a ramped step change, the come-up rate is controlled or 'ramped' from one set-point to the next instead of the conventional approach of an immediate and rapid temperature change between steps. Ramp-controlled temperature changes are designed to slowly increase the oven temperatures between steps, thereby slowing the denaturation rate of the surface proteins during cooking. Muscle proteins are known to strongly denature between 55 and 60 °C. Research has shown that if proteins are slowly denatured through this critical zone, the proteins will bind water better than proteins that are rapidly denatured in this zone. Ramp-controlled temperature changes in a cooking program, then, can be used to slowly denature surface proteins through this denaturation zone, thereby increasing cooking yields.

The conveyor speed is used to control the cooking times in continuous ovens. Process temperatures and conveyor speed are calibrated to optimize the cooking times in the various zones – balancing the desired quality characteristics with production throughputs while achieving the target endpoint temperature. Endpoint temperatures are manually measured at the outlet of the last cooking zone, and this temperature data is used along with yield and quality data to adjust process variables and conveyor speeds as needed throughout the day.

Temperature Variation

The oven design, product load density, inter product contact, product shape, and cooking program will all affect the temperature variation within the oven.

Oven design

In batch ovens, the oscillating airflow system continually sweeps the air from side to side in the oven cabinet, but the general direction of the airflow is still vertical from bottom to top. The dry-sensor temperature decreases as the hot air passes through the cold product, and thus the hottest air is located along the sides and bottom of the cabinet whereas the coolest air is at the top-center. For densely loaded, small-diameter sausages that have a lot of exposed surface area, this supply-to-return air temperature difference is commonly 8–9 °C and can be as high as 12–14 °C at the beginning of the process when the product is cold and wet. Larger-diameter products such as bone-in hams have less surface area per kilogram, and therefore the supply-to-return air temperature difference is narrower – typically 3–5 °C at the beginning of the process. At the end of the process when the product is warmer and drier, the supply-to-return air temperature difference for most products is typically only 1–3 °C. During steam cooking there is no dry heat and no evaporative cooling, and thus the supply-to-return air temperature difference is negligible.

The supply-to-return air temperature difference in batch ovens causes product at the bottom of the racks to cook faster than the product near the top-center. Therefore, as a good processing practice, endpoint temperature checks should be measured in product in the cold zone near the top-center of the racks. In addition, to minimize temperature variation, the finishing step(s) of a cooking program should use steam or high-humidity conditions whenever possible.

In chain conveyor tunnel and horizontal-serpentine continuous lines, the product is conveyed from front to back in the oven, thus eliminating the front-to-back variation. However, the air-handling systems in these ovens are similar to batch ovens, and therefore a significant top-to-bottom variation will still exist – and the cold zone will still tend to be located at the top-center of the oven. In vertical serpentine chain-conveyor systems, the product is loaded into trays that travel vertically up and down as well as front to back, leaving only side-to-side temperature variation that must be measured.

For belt conveyor ovens, the product is conveyed through the oven as a single layer, and thus top-to-bottom and front-to-back variation are eliminated, but the side-to-side variation is still significant. Furthermore, given the fast, high-temperature cooking processes that are used, even small differences in product thicknesses can cause large differences in endpoint temperatures. For this reason, belt ovens require frequent cross-belt endpoint temperature checks to ensure that final target temperatures are met for all products.

Product loading

For all forced-air convection ovens, product should be evenly spaced leaving adequate gaps for airflow around the product. Touching product (touchers) results in color defects at the touch spots and also tend to come out at lower temperatures than nontouchers. Touchers are an acute food safety and quality problem for belt ovens using processes that depend on dry heat for cooking – pieces that are touching or overlapped dry more slowly than nontouching pieces, resulting in much colder temperatures and distinct color defects for the touchers.

In batch ovens, a minimum clearance of 30 cm should be maintained between the product and the oven floor and side walls to allow free flow of air around the racks. This 30 cm clearance should also be maintained between the rack structural members and the oven floor. Any rack structure that is closer than 30 cm to the floor should be positioned to be parallel with the airflow (i.e., perpendicular to the ovens walls) so that the structure does not impede air circulation around the product. For partial loads, the product racks should be

evenly spaced from front to back in the oven to maintain a balanced airflow from front to back.

Product shape

If the product shape varies significantly from piece to piece, the core temperatures will also vary. Any variation of the product diameter or thickness will cause a corresponding variation in product core temperatures, even if all the pieces are exactly the same weight. In other words, it is the product diameter or thickness that determines the cooking time, not the piece weight. Heat conduction from surface to core takes longer for thicker or larger-diameter pieces. Products that are naturally shaped such as chicken fillets, turkey breast, bacon, bone-in hams and natural-casing sausages have inherently more temperature variation than products with tightly controlled dimensions such as cellulose-casing sausages, fibrous-casing sausages, formed products, or molded hams. Variable product thicknesses are a big concern for fast-cooking processes such as those used in belt ovens. Fast cooking times leave no extra time to equilibrate the temperature differences between the thinner and thicker products, leaving the thicker products more at risk for undercooking. To compensate, belt oven operators typically cook products to high endpoint temperatures and are extremely vigilant about having line workers conduct frequent cross-belt temperature checks.

Cooking processes

Cooking processes that use dry conditions induce more temperature variation than high-humidity or steam-cooking conditions. Higher wet-sensor temperatures during the finishing steps of a process will reduce product temperature variation. As a good processing practice for minimizing temperature variation, in the final step of a cooking process in a batch oven or in the final zone of a continuous line, the wet-sensor temperature should be set equal to or higher than the target core temperature. For example, if the target core temperature for a product is 72 °C, then the wet-sensor temperature in the finishing step or the final zone should be set at 72 °C or higher. This practice will reduce temperature variation, decrease cooking times, and increase yields.

Smoking Equipment

Smoke is added to meat products for the desirable color, flavor, aroma, and preservative effects. Two types of smoke are used extensively throughout the industry: traditional smoke and liquid smoke.

Traditional smoke is produced using one of several different types of smoke generators (Figure 15). Smoke generators use heat to smolder dry or wet woodchips or logs to produce smoke. Various generator designs use different heating methods including electric-heated hot-plates, super-heated steam, direct-gas flames, and friction. The smoke is piped from the smoke generator into the oven where it is absorbed into the moist product surfaces. After the smoke is absorbed, the product is heated and dried to evaporate surface moisture and promote the smoke color reaction.

Using traditional smoke, it is important to measure the amount of smoke exposure for the product. One simple method to indirectly measure the smoke exposure is to hang a permeable, water-filled cellulose casing in the oven with the product during smoking. After smoking, the casing is removed and the titratable acid content of the water is measured. Because traditional smoke contains acid, the acid level in the water will be directly proportional to the level of smoke exposure. Using this method, the smoke exposure can be compared among different products and processes regardless of the size of the oven or number of smoke generators attached.

Figure 15 Dry-sawdust hot-plate smoke generator. Reproduced with permission of Villari Brothers Foods LLC, USA.

Many meat processors have successfully converted from traditional smoke into liquid smoke. Liquid smoke can be applied using several different methods, including atomization, showering, immersion, direct addition, and presmoked casings (or nets). Atomization is a common method for batch ovens (Figure 16). The liquid smoke is atomized into the oven to create a cloud of atomized smoke that is then absorbed into the product surfaces. Much like traditional smoke, the product is then heated and dried to develop the smoke color.

Liquid smoke showers are commonly used in continuous systems (Figure 17). For example, in continuous frankfurter systems, the product is often conveyed under a shower of diluted liquid smoke before entering the first cooking zone where the product is heated and dried to develop the smoke color.

For presmoked casings, the product is stuffed into liquid smoke-treated fibrous casings or nets. After stuffing, the liquid smoke is absorbed from the casings or nets into the product

Figure 16 Liquid smoke atomization nozzle. Reproduced with permission of Red Arrow Products Company LLC, USA.

Figure 17 Liquid smoke shower system. Reproduced with permission of Red Arrow Products Company LLC, USA.

surface. The first steps of the cooking process use hot and dry conditions to promote surface drying and smoke color development on the product.

For direct addition, liquid smoke can be either mixed into injection brines or incorporated into the product during tumbling or massaging. Liquid smokes used for direct addition are specially formulated for this method. Direct addition smoke adds smoke flavor to the entire product, not just the surface, but usually does not contribute significantly to surface color.

For most smoking processes, it is easier to produce consistent smoke color and flavor using liquid smoke than using traditional smoke. Particularly in batch ovens, it is difficult to produce consistent absorption and uniform drying of traditional smoke within an entire load and also from load to load. The use of liquid smoke showers or presmoked casings takes much of the guesswork out of the smoking process. Other operational advantages of liquid smoke include elimination of the smoke generator and lower cleaning and pollution control costs.

Conclusion

Everyday across the meat industry, thousands of different processes are used to cook and smoke a countless variety of meat products. These myriad cooking processes, though, share a few principles of heat and mass transfer that are common to all. Cooking equipment should be designed to take full advantage of our knowledge of the effects of these variables on products during cooking, thus enabling processors to fully optimize processes to ensure safe meat products that meet quality specifications while maximizing throughput. It is crucial, too, that processors gain a thorough understanding of the functions and limitations of their cooking equipment for controlling each key variable, so that the equipment can be optimized to its full potential.

Tumblers and Massagers

CL Knipe, Ohio State University, Columbus, OH, USA

Glossary

Binding strength The ability of meat pieces to bind together during the cooking process.
Cure migration The migration of curing ingredients (salt, nitrite, phosphates, etc.) throughout the pieces of meat.
Massaging Involves frictional energy generated from meat pieces being rubbed and massaged against each other by rotating paddles.
Pickle A solution containing nitrite that is used to cure hams and other processed meat products.
Protein extraction The process of dissolving proteins from meat by mixing a salt and phosphate solution with the meat.
Protein exudate A protein mixture that accumulates on the surface of meat pieces, during mixing or tumbling processes.
Sliceability The ability to produce slices of meat products that hold together and have good eye appeal during the packaging process.
Stuffing The process of filling a casing.
Tumbling Involves a rigorous physical treatment with impact energy achieved from meat pieces being lifted and falling against each other.
Water-holding capacity The ability of meat proteins to hold water during the application of stresses, such as grinding, cutting, cooking, etc.

Introduction

The mechanical action required for producing high quality, sectioned and formed, whole muscle meat products may be achieved in a variety of ways but most commonly involves the processes of tumbling and massaging. Tumbling and massaging are different physical treatments. Massaging involves frictional energy that is generated from pieces being rubbed and massaged against each other by rotating paddles. There are basically two types of massagers: one with horizontal paddles and the other with vertical paddles (Figure 1). The vertical paddles are reported to give a better, faster massage treatment and cause less damage to meat (or bone) than the horizontal paddles. A massager should have paddles that can be reversed so as to prevent lodging of meat pieces in the corners of the massaging vat and to free pieces that are caught on the paddles. Furthermore, a variable speed drive allows the speed of the paddles to be varied in an attempt to find the optimal treatment for each product.

Tumblers, however, provide a more rigorous physical treatment and involve the impact energy achieved from meat pieces being lifted by baffles along the sides of a rotating drum and falling from the baffles onto the drum or rolling over other pieces of meat as the drum rotates (Figure 2). It has been suggested that the meat needs to drop at least 3 ft (90 cm) in a rotating tumbler to achieve the maximum effect. If a tumbler is filled too full, the meat will only roll around as the tumbler rotates, reducing the physical treatment to the meat. The speed with which the barrel rotates also affects the impact of the falling meat and needs to be adjusted according to the type of meat, size of meat pieces, etc. in order to optimize the effect without damaging the meat.

Rigorous tumbling action causes foaming of the protein exudate that is produced from this physical treatment. Foamy

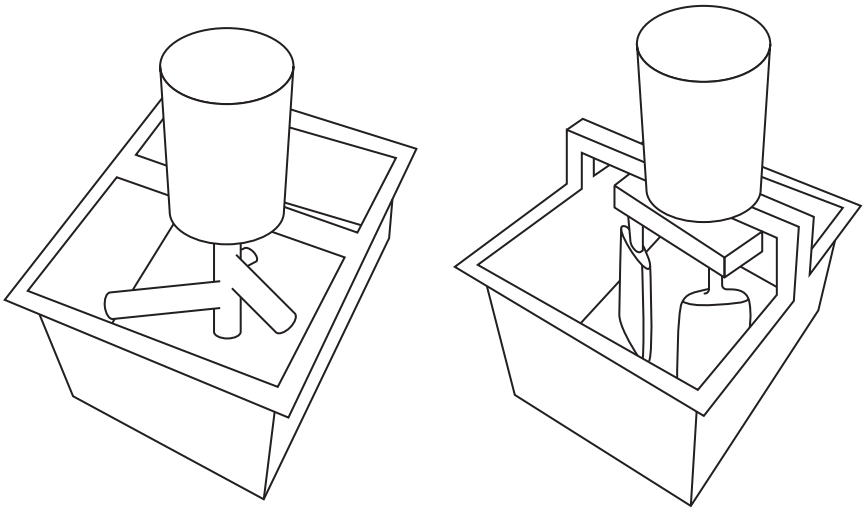

Figure 1 Massagers with horizontal (left) and vertical (right) paddles.

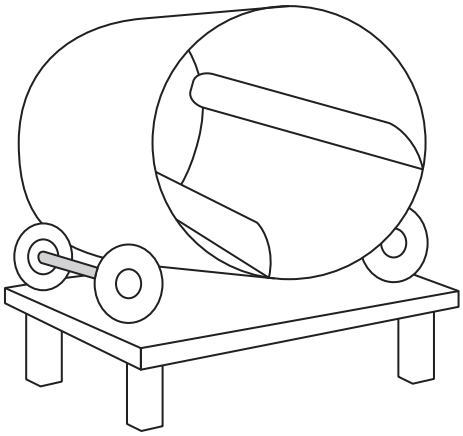

Figure 2 End view of a tumbler.

exudate is not desirable, resulting in the need to vacuumize the lidded drum tumbler before the start of the tumbling treatment. Reducing the speed of the tumbler may also reduce the foaming of the surface proteins.

There are two basic types of tumblers: the rotating drum and the end-over-end tumbler. The rotating drum is relatively gentle in treatment and uses less space per volume of capacity. Although massaging was more commonly used in the early days of this technology, vacuum tumbling is now the most commonly used method.

Mixers can also be used for this process; however, as the mixing action is typically much more damaging to meat pieces (particularly for softer muscles, such as that of chicken and turkey) than tumblers or massagers, care must be taken to adjust the mixers or the total time of the mixing action to avoid overworking the meat pieces. Paddle mixers can be run at reduced rpms to apply sufficient mechanical action to whole muscle pieces or softer poultry muscles in order to produce a surface protein exudate without damaging the muscle integrity. Smaller paddles, fewer paddles, or single-shaft paddle agitators could be used in mixers to produce protein exudate and increase water-holding capacity of muscle pieces without severely damaging the meat pieces.

Owing to the wide variety of equipment that is used to tumble, massage, or mix meat products, it is helpful to refer to the overall process as mechanical conditioning.

Mechanical Conditioning Cycles

The main idea behind mechanical conditioning is to apply a physical treatment to enhance the migration of the curing ingredients (salt, nitrite, phosphates, etc.) that have been either injected into the meat or absorbed into the meat during marination process. This improved migration of ingredients results in increased extraction of proteins from the meat as well as improved color development, if cured. Increased protein extraction increases bind in meat products.

There are two types of binds to consider: one is a protein–protein bind, which is a heat-initiated surface bind or adhesion of pieces, resulting from the protein exudate that is produced. It accumulates on the surface of meat pieces. Larger quantities of exudate are produced when starting with smaller meat pieces in which surface membranes of muscles have been cut. Surface maceration of larger intact muscles may be required to increase the quantity of exudate that is produced during tumbling or massaging.

The other type of bind is the internal protein–water bind that impacts juiciness, texture, and cooking yield. This latter type of bind is produced by cell wall and membrane damage in the center of meat pieces that allow faster migration of water and ingredients, such as salt and phosphates.

The mechanical action of tumbling or massaging involves a time–work intensity relationship. Many different theories exist about the optimal length and aggressiveness of the tumbling and massaging treatments. The length of time required depends on the intensity of the physical treatment imparted to the pieces of meat and is balanced against the desired final product quality. In general, the more intense the mechanical action, the less tumbling or massaging time required. Care must be taken not to overwork the meat, as this will result in a product with a dry surface that may result in meat pieces which are more difficult to stuff into casings or can result in extensive physical damage to the meat.

Although massaging is less destructive to the meat, the resultant protein extraction is typically slower than with tumbling. Binding strength will increase with increased massaging or tumbling time, due to increased exudate formation on the surface of the meat.

Sufficient adhesion of meat pieces may be achieved after 2–3 h of mechanical action, but a longer mechanical treatment may be necessary to obtain a significant yield and quality advantage. To maximize, the internal protein–water bind takes at least 18–24 h, which includes significant rest periods. The use of vacuum while tumbling further decreases the tumbling time required to produce a good bind by preventing the production of foam. Periodic rest periods during the tumbling or massaging processes are important to allow time for adequate cure migration while preventing excessive muscle destruction that could result from a long continuous process and may allow for dissipation of foam in the exudate in the case of nonvacuum tumblers. Holding periods longer than 24 h have been shown to further increase water-holding capacity and internal color development of cured products.

An alternative approach to the periodic rest periods of massagers and tumblers would be to tumble or mix continuously for 1–2 h, followed by a rest period of 18–24 h in a separate combo bin, and ending with a final mixing until sufficient exudate is produced. This approach may give sufficient mechanical action while allowing adequate time for distribution and action of brine ingredients without tying up tumblers and massagers for long periods of time.

Mechanical conditioning may also raise the temperature of the meat. The distribution of ingredients and the curing reaction will occur faster at warmer temperatures; if the product temperature increases above 4.4 °C (40 °F), the time at that temperature should be minimized as much as possible. Colder temperatures, 0 °C (32 °F) or lower, are better for extracting and solubilizing proteins from meat to maximize bind.

The cycle and total treatment times will vary between different pieces of equipment, so every processor needs to

experiment with the equipment available to determine an optimum processing cycle for the desired product. For boneless meat products that are to be sliced, high-speed slicers, more aggressive tumbling, or massaging would be needed; however, the texture of this product would be expected to be more rubbery. For higher quality products, with a more traditional texture, less aggressive tumbling or massaging processes is recommended.

Binding strength also depends on the meat temperature during tumbling or massaging. Salt-soluble proteins are extracted over a wide range of temperatures, but they are most readily extracted from lean meat at 2.2–3.3 °C (36–38 °F). This supports the findings that the bind strength of ham was much better when massaged at −0.9 and 4.4 °C (30 and 40 °F) than at 10 °C (50 °F). In one of the original US patents dealing with mechanical conditioning of meat, the mechanical action was observed to be enhanced by chilling the pieces of cured meat to as low as −3 °C (25 °F), then mixing the product until it reached a temperature of approximately 1.7 °C (35 °F). For protein extraction and functionality, as well as food safety, tumblers and massagers should be operated in refrigerated rooms (4.4 °C/40 °F or colder). This could also be accomplished by using refrigerated tumblers or by direct addition of carbon dioxide to the meat inside the tumblers and massagers. Refrigerated tumblers have circulating refrigerant in jacketed walls of the barrels, which chills the meat as it makes contact with the walls of the tumbler.

Vacuum tumbling or massaging improves bind strength by reducing protein foaming. The development of foam denatures proteins and subsequently decreases bind strength. Vacuum tumbling and massaging have been credited with increasing the amount of protein extracted and decreasing the time required to produce the optimal product. If foaming occurs, when using vacuum tumblers or massagers, faulty seals allow air to leak into the container.

Advantages of Mechanical Conditioning

The advantage of mechanical conditioning that is of the greatest interest to most meat processors is the increased cooking yield and the decreased shrinkage of the final product. The disruption of internal meat tissues due to the mechanical action of tumbling or massaging combined with the addition of salt (NaCl) and alkaline phosphates (most commonly a 90:10 mixture of tripoly- and hexametaphosphates) causes increased protein solubilization. Solubilized proteins in the meat tissues enhance water absorption before heat processing. On heating, the gel formed by the solubilized proteins holds additional water and decreases cooking loss. Typically, proper tumbling decreases cooking shrinkage by 2–3%. Some equipment manufacturers claim that massaging increases cooking yields by at least 4%. Because the amount of added moisture is regulated in many countries for both sectioned and formed whole muscle meat products, the most significant effect of reduced cooking loss is the reduction in injection levels, which makes it easier to achieve the desired injection level.

If the water-holding capacity of meat is improved during the mechanical conditioning process, smoke color development is faster, because drying of the product surface is faster. This results in a more desirable smoked product color, and because the smoking process is faster, the total cooking time should be less than when the product is not tumbled or massaged.

The mechanical action of tumbling and massaging also provides a simple mixing action on meat products. The mixing action causes any loose, available moisture to be absorbed into the muscle. Marination of meat products can be accomplished using tumbling and massaging. The extent to which the marinade is absorbed into the product is based on the time of application and the thickness of the meat. Dry ingredients can also be applied to whole muscle surfaces by the use of a tumbler.

Mechanical conditioning also increases sliceability of sectioned and formed meat products, because of the improved cohesiveness of muscle pieces. This allows smaller, lower value meat pieces to be bound together to produce a more appealing and saleable final product.

Improved pickle penetration also reduces curing time to much less than the 3–7 days, which is traditionally considered necessary to obtain uniform cure distribution by conventional stitch pump curing, especially in the case of dark, firm, and dry hams. This results in a much higher production and turnover rate. Furthermore, improved pickle penetration causes a better, more uniform cured color. Use of vacuum during mechanical conditioning reduces the exposure of lean tissue to oxygen, which results in a brighter, more stable cured color and eliminates pinholes and air pockets in formed products.

Also, mechanical conditioning includes the advantage of more complete and efficient use of available raw meat materials. Imagination is the only limitation to the wide variety of raw meat materials that can be incorporated into sectioned and formed meat products. Some examples include the following: the use of high-quality fresh meat trimmings resulting from meat preparation in food service establishments; the addition of minced or emulsified, cured shank meat to hams during mechanical conditioning; the use of whole hams, with bruises or broken bones removed; the use of heavier primal cuts, which without mechanical conditioning would tend to be tough; the use of meat from poultry carcasses to produce a boneless product of more desirable shape and size; the sectioning of sow loins of various sizes to produce products with less bone and fat and of more desirable and uniform shape; and the use of soy isolates and similar extenders to produce 'combination hams.'

Mechanically conditioned meat also results in greater ease in stuffing. Because the meat is more pliable, it is easier to pump this product through stuffing horns and to completely fill casings or molds of any shape to predetermined weights while eliminating undesirable voids between pieces. This is a temporary softening effect, so if meat products are held very long without any physical action, the meat may need to be retumbled or mixed to make the meat more pliable for stuffing.

Mechanical conditioning has also been found to increase tenderness of cured meats. This is due to the disruption of cellular connective tissue and increased moisture retention after cooking. This tenderizing effect can be applied to heavier primal cuts to produce a more desirable product.

Finally, mechanical conditioning has even been credited with improving the flavor and aroma of the final product. This is best explained by reduced drip loss, which could contain water-soluble flavor compounds and the improved distribution of nitrite and alkaline phosphates. Nitrite and phosphates are both credited with having antioxidant properties and are more likely to reduce off-flavor development.

Disadvantages of Mechanical Conditioning

An obvious major disadvantage of mechanical conditioning is the initial cost of equipment. The equipment is relatively expensive, and one product batch may occupy the unit for 18–24 h. Although the actual expenditure for an individual tumbler is much greater than for a massager, the greater capacity per tumbler can generally make it the more favorable option.

Another disadvantage is the labor required for boning, skinning, trimming, and sorting. The extent of this disadvantage depends on the desired quality of the product. This process does not work miracles. Fat and connective tissue in particular, and muscles of contrasting colors to a lesser degree, can decrease visual attractiveness and esthetic value of the product. The highest quality products demand the time of skilled labor to remove silver skin as much external and seam fat as possible and (in the case of ham) sorting muscles by color.

Finally, the procedure may not work optimally or may even cause excessive muscle destruction if the treatment time and intensity are not carefully monitored. Excessive mechanical conditioning could yield a softer and yet more rubbery finished product, whereas mechanical conditioning cycles that are too short could result in a dense, dry product, which lacks uniformity of pickle distribution.

PROFESSIONAL ORGANIZATIONS

RG Kauffman, University of Wisconsin, Madison, WI, USA

Introduction

The initiative for developing organizations originates from the efforts of dedicated individuals to meet responsibilities, accomplish goals, and become socially involved through sharing, as provided by group interactions and resolutions. For some circumstances (such as food safety), it is appropriate that problems should be solved through group actions.

As long as records have existed, there have been organizational structures of varying designs and complexities for social, political, economic, and scientific groups (and surely others), from elementary and small ones to sophisticated and large ones. Records show that until well into the twentieth century, there were no organizations that formally complimented meat scientists and meat industry groups. The growth of such organizations has more likely resulted because of general prosperity and through technical advancements, such as air travel and electronic communications. This article identifies some of the major meat-related groups (e.g., the International Congress of Meat Science and Technology;

Table 1 Twelve international professional organizations

Name	*Abbreviation*	*Address and/or web site*	*Year began*	*Meeting cycle*	*Characteristics*
American Meat Science Association	AMSA	1800 South Oak Street, Suite 100, Champaign, IL 61820, USA www.meatscience.org	1964	Annual (3 days)	Formal structure and dues required for members worldwide; Reciprocal Meat Conference and proceedings at different universities; Meat Industry Research Conference; and publishes bulletins, brochures, and newsletters
American Society of Animal Science	ASAS	P.O. Box 7410 Champaign, IL 61826-7410, USA www.asas.org	1908	Annual (4 days)	Formal structure and dues required for members; regional meetings; includes a Meat Science and Muscle Biology Section at national and regional meetings; and publishes *Journal of Animal Science*
Central American and Caribbean Symposium on Meat Processing		EARTH Apartado 4442-1000, San José, Costa Rica	1981	Biennial	Conducted by Costa Rican Association of Meat Processors; educates producers, processors, and individuals in meat business about science and technology
European Livestock and Meat Trading Union	UECBV	81 A, Rue de la Loi, (box 9), B-1040 Brussels, Belgium www.uebcv.eu	1952	Annual	Promotes international livestock and meat trade and represents and defends members' interests before European Economic Commission and internationally
European Natural Sausage Casings Association	ENSCA	Gotenstrasse 21, D-20097 Hamburg, Germany	1956	Semiannual	Defends interests of the sausage casings trade
Institute of Food Technology	IFT	525 West Van Buren Street, Suite 1000, Chicago, IL 60607, USA www.ift.org	1939	Annual (5 days)	Formal structure and dues required for its members worldwide; trade show at national meeting; regional meetings; includes all foods and has a muscle foods section; and publishes *Journal of Food Technology and Journal of Food Science*
International Association for Food Protection	IAFP	620 Auroa Avenue Suite 200 W Des Moines, IA 50322-2864, USA www.foodprotection.org	1911		An organization of 3600 food safety professionals from 50+ countries committed to advancing food safety worldwide by providing a forum to exchange information on protecting the global food supply
International Butchers Confederation	IBC	Rue Jacques de Lalaing 4-box 10, B-1040 Brussels, Belgium	1907	Semiannual	Comprised of 14 national butchers' associations and meat traders' federations representing approximately 150 000 companies; defends interests of meat trading and catering through social and economic policy, knowledge, and legislation on meat products; and vocational training
International Congress of Meat Science and Technology	ICoMST	University of Helsinki, Box 66, Viikki EE, FI-00014, Helsinki, Finland www.icomst.helsinki.fi	1955	Annual (5 days)	Informal structure; meetings rotate to countries worldwide by invitation; host country establishes program and fee required for conference and proceedings
International Meat Secretariat	IMS	6 Rue de la Victoire, 75009, Paris, France www.meat-ims.org	1974	Biennial	Represents, promotes, and serves meat and livestock industry worldwide; conducts research and educational programs; provides International Meat Research Award; and meets in different countries by invitation
International Natural Sausage Casing Association	INSCA	18 Zaki Ragab High Class One (1205), Smouha, Alexandria, Egypt www.insca.org	1965	Annual	Importers and processors of natural sausage casings in 40+ countries including 200+ companies and publishes INSCA newsletter and National Link
Liaison Centre of the Meat Processing Industry in the EU	CLITRAVI	Blvd. Baudouin, 18 Box 4, B-1000 Brussels, Belgium www.clitravi.eu	1958	Annual	Represents 16+ countries of the meat processing industry and protects and promotes industry's interests

Table 2 Thirty-seven national professional organizations

Country	*Name*	*Abbreviation*	*Address and/or website*	*Year began*	*Meeting cycle*	*Characteristics*
Australia	Beef Improvement Association of Australia		96 Harbours Road Yenden, VIC 3352, Australia www.beefline.org.au	1968	Annual	Seeks to genetically improve quality of beef in Australia
Australia	Meat and Livestock Australia, Ltd.	MLA	Locked Bag 991, North Sydney 2060, Level 1, 165 Walker Street, North Sydney, NSW 2060, Australia www.mla.com.au	1998	Annual	Provides marketing information and receives funds from livestock sale levies and represents approximately 30 000 livestock producers and has four state offices
Australia	National Meat Association of Australia	AMIC	2nd Floor, 460 Pacific Highway, St. Leonards, NSW 2065, Australia www.amic.org.au	1928		Meat processors, wholesalers, small goods manufacturers, and retailers; promotes increased demand for meat products; gathers and disseminates industry information; and publishes Australian Meat Industry Bulletin
Belgium	National Verbond van Slachthuizen in Vleesuitsnijderijen	NVS	Rue des Deux Eglises 2 G–B4, B-1000 Brussels, Belgium www.unizo.be			Meat processing companies and slaughterhouses in Belgium and publishes monthly newsletter
Canada	Canada Beef, Inc.		#235, 6715-8th Street NE, Calgary, AB T2E 7H7, Canada www.canadabeef.ca	2011		Producers and exporters of beef and related products; promotes international demand for Canadian beef; and represents members' interests before agricultural and industrial organizations, government agencies, and international trade associations
Canada	Canada Pork International	CPI	220 Laurier Avenue, Suite 900, Ottawa, ON K1P 5Z7, Canada www.canadapork.com	1991	Annual	Exporters of pork products; promotes exportation of Canadian pork; facilitates establishment of international business relations; and conducts promotional campaigns
Canada	Canadian Meat Council	CMC	Dow's Lake Court, 1545 Carling Avenue, Suite 407, Ottawa, ON K1Z 8P9, Canada www.cmc-cvc.com	1919		Meat packers and distributors; promotes growth and development of meat industries; and conducts promotional campaigns
Canada	Canadian Meat Science Association	CMSA	4–10 Agriculture Centre, U. of Alberta, Edmonton, AB T6G ZP5, Canada www.cmsa-ascv.ca	1985	Annual	Formal structure of dues-paying members; provides directory, newsletter, and annual technical symposium. Involves support for research, education, and government relations
Denmark	Danske Slagterier – Danish Bacon and Meat Council	DS	Axeltorv 3, DK-1609, Copenhagen V, Denmark www.danskeslagterier.dk	1897	Annual	Pig slaughterhouses and meat processing plants and coordinates joint activities and represents industry (including pig farmers) nationally and internationally

Country	*Name*	*Abbreviation*	*Address and/or website*	*Year began*	*Meeting cycle*	*Characteristics*
Denmark	Danish Livestock and Meat Board	KF	Vesterbrogade 6D, PO Box 438, DK-1505, Copenhagen V, Denmark www.meatboard.dk	1972		Cattle slaughterhouses and represents industry toward governments and EU
France	MHR Group		LeChillenge 17000, La Rochelle, France			Represents all meat groups
Germany	Deutscher Fleischer–Verband (Metzger–Immung)	DFV	Kennedyallee 53, D-60596 Frankfurt, Germany www.Fleischerhandwerk.de	1875	Annual	Gains influence on the economy and government to reduce or block disadvantageous measures
Germany	Federation of Meat Industry and Trade		Postfach 2566, D-53015 Bonn, Germany	1924		Wholesalers of livestock and meat; advises members on foreign trade, customs, and tax issues; and publishes a journal
Germany	National Association of Wholesale Butchers and Meat Merchants		Adenauerallee 176, D-53113 Bonn, Germany www.b-b-b.de	1925	Annual	Wholesalers of meat in Germany; promotes meat industry; and informs members of changes in laws and issues concerning meat industry
Germany	Renderer's Association		Kaisestrasse 9, D-53113 Bonn, Germany www.Fleischmehlindustrie.de	1920		Promotes and protects economic and hygienic interests of meat meal industry and publishes *Die Fleischmehl-Industrie*
Germany	Verband der Fleischwirtschaft	VFD	Sekretariat des 1. Bürgermeisters von Wang, Untere Hauptstraße 17c, 85368 Wang/Volkmannsdorf, Germany www.v-d-f.de	1953	Annual	Represents members of all areas from the meat industry. It considers itself a binding link between the public, the officials, and the 200 companies that belong to this organization
Germany	Biofleischhandwerk		Sekretariat des 1. Bürgermeisters von Wang, Untere Hauptstraße 17c, 85368 Wang/Volkmannsdorf, Germany www.v-d-f.de	2010	Annual	Strengthens environmentally sustainable meat production with high transparency and no or little transportation of the animals in order to produce a healthier product
Germany	Fleischprufring Bayern e. V.		Sekretariat des 1. Bürgermeisters von Wang, Untere Hauptstraße 17c, 85368 Wang/Volkmannsdorf, Germany www.v-d-f.de	1990		Monitors weights, registers, and classifies the butcheries and is under the control of the Bavarian government and a service provider for more than 90% of the butchers in Bavaria
India	All India Meat and Livestock Exporters Association		World Trade Centre, 11th Floor, Center 1, Cuffe Parade, Mumbai, 400005, Maharashtra, India	1987		Wholesalers and exporters of meat and livestock in India
The Netherlands	Koninklijhe Nederlandse Slagersorganischie	KNS	Postbus 1234, NL-2280 CE Rijswyk, The Netherlands			Master butchers and firms selling meat and increases production, consumption, and trade of meat
New Zealand	Meat New Zealand		Box 121, Wellington, New Zealand www.nzmeat.co.nz	2002		Advances domestic meat industry for meat producers and facilitates communication and cooperation among members and represents their interests

New Zealand	New Zealand Animal By-Products Exporters' Association		11 Longchurch Terrace, Box 12–222, Christchurch, New Zealand	1938		Exporters of animal hides, skins, tallow, and other products; seeks to ensure a domestic and international political and economic climate conducive to trade; facilitates communication and cooperation among members and represents their interests; and gathers and disseminates information
Norway	Norwegian Independent Meat Association		Karoline Kristiansens vei 2, Box 6272, Etterstad N-0603 Oslo, Norway			Slaughterhouses and cutting and packing plants engaged in meat industry; represents members' interests before government agencies, international organizations, and the public; and publishes Kjottbransjen
Spain	National Association of Cold Storage Meats and Cutting Rooms		Gran via de les Corts Catalanes 631, 6, E08010 Barcelona, Spain www.anafric.es	1988	Annual	Promotes growth and development of slaughterhouses and cold storage facilities handling meat and meat products; makes available legal and technical services; assists members in conforming to sanitary and other regulations; facilitates establishment of overseas business contacts; and represents members before national and international regulatory bodies, labor organizations, and the public
UK	British Contract Packers Association	BCPA	Syonsby Lodge, Nottingham Road, Melton Mowbray LE13 0NU, UK	2000		Promotes technical, trade, and commercial interests of British contract manufacturers and packers
UK	British Meat Federation		12 Cock Lane, London EC1A 9BU, UK	1934	Annual	Slaughterers and wholesalers of red meat within England and Wales; provides information service; represents membership in government; and publishes monthly newsletter
UK	Butchers' Company		Butchers' Hall, 87 Bartholomew Close, London EC1A 7EB, UK www.butchershall.com	1975		Applies professional code of conduct in meat trading; promotes education and training throughout meat industry; and publishes newsletter
UK	National Association of Catering Butchers	NACB	217 Central Markets, Smithfield, London EC1A 9LH, UK www.Haighs.com/nacb.htm	1983		Catering butchers whose premises have been inspected and approved by NACB Plant Evaluation Committee; raises standards; promotion; and protects interests through negotiations with authorities
UK	National Federation of Meat and Food Traders		1 Belgrove, Tunbridge Wells TN1 1 YW, UK www.Butchers-online.net	1888		Members include independent retail butchers, slaughterhouse operators, bacon curers, meat manufacturers, and

PROTEOMIC TECHNOLOGIES AND THEIR APPLICATIONS IN THE MEAT INDUSTRY

SP Suman, University of Kentucky, Lexington, KY, USA
P Joseph, Kalsec, Inc., Kalamazoo, MI, USA

This article is a revision of the previous edition article by AL Alderton, volume 3, pp 1102–1109, © 2004 Elsevier Ltd.

Introduction

Proteome refers to the set of all proteins expressed in a cell, tissue, or organism at a specific point of time. Essentially, proteome is the protein complement expressed by the genome. Although the genome of an organism is static in nature, the proteome is dynamic and continuously changes over time. Proteomics is the systematic and methodological analysis of a proteome for identification, quantification, and functional characterization of proteins. Because most biological functions in an organism are carried out by the proteins transcribed from the genome, the application of proteomics is necessary to understand the functioning of an organism. The genome of meat animals contains several thousands of genes, and each of them can produce multiple messenger RNA species, which in turn are translated into individual proteins. The proteins, thus synthesized, can further undergo various posttranslational modifications. This, in turn, results in the expression of more than a million different proteins from a genome. Some of these proteins are highly abundant in a cell, whereas others exist only in a few copies.

Tools in Proteomics

Purification, detection, and identification of proteins, usually from a complex mixture, are the major strategies in proteomics. In this perspective, two-dimensional gel electrophoresis (2-DE) is the classical technique widely used for protein purification. In 2-DE, the proteins are separated based on isoelectric points in the first dimension and then separated in the second dimension based on molecular weights. The individual proteins, appearing as spots in the 2-DE gels, are matched on the basis of isoelectric point and molecular weight by imaging software. In addition to 2-DE, new techniques such as difference gel electrophoresis (DIGE) and diagonal polyacrylamide gel electrophoresis (diagonal PAGE) are also becoming common tools in gel-based protein purification. In addition, high performance liquid chromatography (HPLC) renders a valuable tool to separate and purify low molecular weight peptides for proteomic studies. The purified proteins/peptides of interest are then detected by mass spectrometry (MS) and are identified using complex algorithms from the protein databases. Advances in the seamless integration of 2-DE and HPLC with MS, as well as ever expanding protein databases, have significantly contributed to efficiently purify, identify, and quantify several thousands of proteins in relatively short timeframe with high accuracy.

The postgenomic era has witnessed the emergence of MS from an analytical tool for volatile compounds to an application for characterizing macromolecules such as proteins. MS positioned itself as a superior tool to conventional ones in protein biochemistry because it can rapidly and accurately determine the molecular mass of proteins in low abundance and sequence peptides in a proteolytic digest mixture. Developments in ionization techniques, namely matrix assisted laser desorption ionization (MALDI) and electrospray ionization (ESI), contributed profusely to the use of MS in characterizing proteins. MALDI and ESI made it possible to create gas-phase ions from peptides and proteins, and thus became indispensable to the modern day MS. Nevertheless, MS is primarily exploited as a qualitative tool rather than quantitative one due to the unpredictable ionization properties of proteins and peptides.

The proteomic approach in agriculture represents an important cornerstone to characterize and improve the quality of muscle foods harvested from animals. Compared to the conventional techniques in protein chemistry focusing on one or two major proteins in a sample, modern-day proteomic tools enable simultaneous examination of a multitude of proteins and their modifications at a reasonable time and with superior accuracy. The application of proteomics in meat science and industry is in an early stage compared to some other disciplines in life sciences where these tools are extensively exploited. Nevertheless, their application in the meat industry is continuously growing.

Role of Proteome in the Properties of Muscle as Food

Meat, being a protein-rich food, has several attributes influenced by the quantity and quality of the proteins in skeletal muscle proteome. Furthermore, skeletal muscle proteome exhibits dramatic changes during various phases of meat production, harvest, and processing. Proteome of muscle continuously undergoes changes antemortem (different stages of animal growth), perimortem (conversion of muscle to

meat), and postmortem (postharvest storage). This necessitates the use of proteomics to advance our understanding on meat quality and to engineer novel strategies to improve quality and quantity of meat production.

In the meat industry, proteomics can be applied to the pre- and postharvest aspects of meat quality. Preharvest applications encompass growth, metabolism, muscle biology, and genetics of meat-producing animals. From this point of view, proteomic investigations have attempted to explain the molecular basis of variations in meat quality due to diet, gender, genetics, and management. While this approach highlighted the robustness and usefulness of proteomic tools, the primary focus of these investigations was animal production. In this article, application of proteomics in postharvest aspects of meat production is emphasized.

Conversion of Muscle to Meat

Immediately after the harvest, blood supply to various organs stops leading to an anoxic condition. The biochemistry and metabolism of skeletal muscles immediately change in response to the anoxic conditions. These changes continue in postmortem muscles and result in alteration of biochemical and physicochemical properties, ultimately leading to the conversion of muscle (live tissue) to meat (food). Proteins play a major role in the biological functions of skeletal muscles as well as in the conversion of muscle into meat, and proteomic tools are utilized to characterize the cellular changes immediate postmortem. The robustness of 2-DE and MS to interpret changes in muscle proteome became evident more than a decade ago leading to several discoveries characterizing the fundamental basis of conversion of muscle into meat in beef and pork.

Early proteomic investigations in this area demonstrated structural changes in several sarcoplasmic and myofibrillar proteins during conversion of muscle to meat attributing to action of endogenous enzymes. Furthermore, the expression and/or abundance of endogenous enzymes also exhibit changes during this period confirming the shift in the metabolism of muscles. Examination of proteolytic changes revealed the existence of breed-specific mechanism in pigs. The biochemical basis of pale, soft, exudative (PSE) condition in pork, caused by ante-mortem stress, was also studied using proteomics, and the low abundance of heat shock protein 27 kDa was linked to the occurrence of PSE. Heat shock proteins are molecular chaperones that protect cellular proteins from stress-induced denaturation, aggregation, and oxidative damages. While muscle biochemistry was the focus of the majority of these investigations, application of proteomics identified several candidate proteins for meat quality attributes as well as quality defects. The information gathered from these studies can potentially be applied to predict the quality of meat prior to carcass chilling and fabrication, and thus appropriately utilize such meat in suitable products.

Meat Tenderization

Meat tenderness is influenced by the biochemical properties of muscle fibers as well as connective tissue matrix and is improved by aging – primarily due to degradation of cytoskeletal proteins. Tenderness is the major factor contributing to eating satisfaction and consumer acceptance and, therefore, is considered an important trait influencing repurchase decisions. It has been estimated that the inconsistencies in tenderness lead to US$217 million annual revenue loss to the US meat industry. Postmortem degradation of several structural proteins is the major reason for improvement in meat tenderness. Nevertheless, the fundamental mechanisms through which these biochemical changes govern meat tenderization are yet to be completely elucidated.

Improving and predicting tenderness are two factors critical to profitability of the meat industry. Although improvements in tenderness can be made by aging, predicting this attribute is not straight forward primarily due to muscle- and species-specific variations in meat biochemistry. The improvement in tenderness is dependent on the activity of endogenous proteolytic enzymes in postmortem muscles. The interactions between the enzymes and their substrates, primarily cytoskeletal proteins, are complex and are often influenced by different intrinsic (protein oxidation, calcium and vitamin D concentrations) and extrinsic (packaging system, aging condition, brine injection, antioxidant, and electrical stimulation) factors. The fact that the substrates for these enzymes are also proteins makes proteomics an invaluable tool to interpret the biochemistry of tenderness.

Meat tenderness is a muscle-dependent attribute, and significant amount of research has been undertaken to explain the muscle-specific biochemistry of beef tenderness. Use of DIGE to examine the proteolytic changes in beef adductor (tough muscle) and longissimus (moderately tender muscle) revealed that proteins such as actin, myosin heavy chain 1 fragment, myomesin-2, and α-actinin-3 undergo muscle-specific changes during aging; the abundance of these proteins in sarcoplasmic and myofibrillar fractions was different in adductor and longissimus indicating the possibility of using them as potential candidates for further investigations in muscle-dependent mechanism of tenderization. Of specific interest is the fragment of myosin light chain 1, which was more abundant in the sarcoplasmic extracts of tender beef than in the tough beef.

The calpain system is a major enzymatic system responsible for postmortem tenderization of meat and has been extensively studied. Conventional protein chemistry has characterized various calpain isoforms and their biochemical modifications, whereas the use of proteomic tools revealed that μ-calpain undergoes oxidation by forming an intermolecular disulfide bond and that the oxidation results in the loss of proteolytic activity. This finding highlighted the adverse influence of protein oxidation on meat tenderness.

Analyses of muscle proteome identified several proteins potentially associated with the calpains that can influence tenderness in a multitude of ways. These identified proteins included structural proteins, mitochondrial proteins, and proteins associated with calcium and glucose metabolism. The potential association between calcium-regulating proteins and calcium-dependent calpains suggest a complex nature of the mechanisms governing postmortem proteolysis.

Although the role of oxidation in loss of protein functionality has been known for several years, use of diagonal PAGE

and MS demonstrated that myosin heavy chains in postmortem muscles are susceptible to oxidation and that the exposure to an oxidizing environment promotes cross-linking between titin and myosin; both phenomena lead to protein aggregation that subsequently results in an increase in toughness of meat.

Meat Color Stability

Color of meat is the most important quality influencing purchase decisions. Discolored meats are often sold at discounted price leading to revenue loss of more than US$1 billion per year in the US beef industry. Proteomic tools have been utilized extensively to examine the mechanistic interactions between myoglobin and other small biomolecules governing meat color.

The ability of MS to determine the exact mass of proteins has been used to differentiate the myoglobins from various meat animals and for meat species identification. Although conventional gel electrophoresis identifies myoglobins from different species as 17-kDa bands in the gels, MS-based studies revealed that the myoglobins from birds are approximately 300 Da heavier than their mammalian counterparts, offering partial explanation for why certain color phenomena are observed only in poultry whereas some others are reported primarily in red meats.

Lipid oxidation compromises flavor as well as color of meat. MS and proteomic tools demonstrated that the adduction of reactive lipid oxidation products (such as aldehydes) to histidines in myoglobin, especially the proximal (position 93) and distal (position 64) histidines, is responsible for compromising the stability of the heme group and thus favoring formation of metmyoglobin in meat surfaces, eventually leading to brown discoloration. Furthermore, lipid oxidation-induced meat discoloration is species-specific in nature; MS analyses indicated that beef myoglobin is more susceptible to lipid oxidation than pork myoglobin supporting the observation that the color stabilizing effect of dietary vitamin E is more pronounced in beef than in pork. The greater number of histidines in beef myoglobin renders it more susceptible to the nucleophilic attack by reactive aldehydes and subsequent oxidation than its pork counterpart. Recent studies in this area suggested that the susceptibility of myoglobins to lipid oxidation-induced oxidation is governed by the number and location of histidines in the primary structure.

Beef muscles exhibit differences in color stability attributes during retail display, and this has been utilized to categorize some muscles as color-stable and some as color-labile. Studies employing MS and 2-DE revealed differential abundance of antioxidant and chaperone proteins in color-stable (Longissimus lumborum) and color-labile (Psoas major) muscles and concluded that the over abundance of the antioxidant proteins is likely the major contributing factor to the superior color stability in beef Longissimus lumborum by minimizing myoglobin oxidation.

Dry-Cured Meats

Dry-cured meats are traditional products popular in different parts of the world. Degradation of muscle proteins in dry-cured meats generate peptides, which contribute to various product- and region-specific attributes. The degree and nature of proteolysis are influenced by the region's climate, temperature, humidity, and duration of ripening. Furthermore, the chemistry of the peptides is influenced by the conditions of aging and ultimately contributes to the unique savory attributes of products developed in a specific geographical region. Proteomic studies of dry-cured meats demonstrated that myofibrillar and sarcoplasmic proteins are extensively degraded during aging process. In addition, the peptides generated are product-specific and may be utilized as biomarkers for product identity and geographical specification.

Conclusions

With the emergence of proteomics as a robust and high throughput analytical tool in life sciences, its application in meat quality also has grown exponentially. Integration of gel electrophoresis, HPLC, MS, and data-mining algorithms, empowered scientists to explain biomolecular interactions influencing the properties of skeletal muscle as food, to interpret molecular mechanisms governing meat quality, and to solve protein-based concerns in muscle foods.

Glossary

Certification Confirmation that certain characteristics are met by a timely limited certificate.
ISO 9000 series Quality management standards (ISO 9000:2005; ISO 9001:2008; ISO 9004:2009; ISO 19011:2011) providing guidance and tools in order to ensure that customers' requirements are met.
Process control The measures to ensure that processes result in the desired result.
Product testing Analytical procedures for examining products.
Quality assurance Engineering activities, such as measurement and monitoring activities, to fulfill requirements in a quality system.
Quality control Revision activities directed toward the quality traits of the product during production.
System control Control measures comprising several steps within a production chain.
Taylorism A scientific management theory developed by Frederick Winslow Taylor (1856–1915) using process control measures, i.e., analysis and synthesis of workflows in order to improve labor productivity.

Introduction

Meat and meat products are valuable sources of concentrated, easily digestible protein, vitamins, minerals, and micronutrients contributing to a human's balanced diet. Per capita meat consumption varies widely depending on the world's region, but a general trend is that more meat is consumed with increasing personal income. The availability of meat depends also on local agricultural conditions, as animal production may be undertaken in landscapes that are unsuited for crop production.

A great number of trade flows have developed in the global food market that enable the supply of populous and urban regions with food from rural areas all over the world. However, increased transportation distances of easily perishable foods like meat require improved production and handling techniques in order to prevent excessive product losses as well as the risk of foodborne diseases. Systems to effectively measure, manage, and improve product's safety and quality enjoy widespread use. When product losses are reduced, yields and profits may increase; yet, on the other hand, such systems help to assume responsibility for the products that is clearly assigned to the manufacturer by legal standards. As a consequence, the participants of the meat production chain are highly interested in the introduction and maintenance of quality management systems in their processing establishments.

Quality Attributes of Meat and Meat Products

According to the International Standardization Organization (ISO), 'quality' is defined as "the ability of a set of intrinsic characteristics to satisfy requirements" (ISO 9000:2005). With respect to meat and meat products, the intrinsic characteristics are described by several quality attributes. Even though objective quality attributes are analytically detectable, resulting in quantitative or categorized values, subjective quality attributes express the consumer's individual esteem for special product traits.

Objective quality attributes of meat and meat products may be grouped into sensory traits, nutritive values, processing properties, and hygienic-toxicological aspects (Table 1). In subjective terms, the acceptance of the product is also determined by the consumer's attitude toward psychological (nutritional habits, nausea-causing experiences, etc.), ethical (e.g., animal welfare and religious customs), ecological, political, social, and sustainability factors.

Quality Strategies in the Meat Production Chain

Manufacturers must decide which quality traits they wish to attach to their products in both qualitative and quantitative terms. In this decision, they will consider the desires of the target group and market trends, as well as legislative requirements. During production, compliance with these defined quality features, as well as maximal homogeneity of the products, must be guaranteed. For this purpose, quality assurance and quality control measures were introduced in order to fulfill quality requirements. Although the former refers to systematic monitoring, measuring, and threshold comparison techniques for error prevention, the latter comprises observation and steering activities of processes.

Generally, three overall strategies may be distinguished depending on the manner and extent of the quality assurance measures taken: (1) product testing, (2) process control, and (3) system control (Figure 1).

Product Testing

Established in the era of mass production and Taylorism, end-product testing was the accepted concept to guarantee defined product quality features. In other words, products were manufactured by unskilled workers as fast as possible and nonconforming products were sorted out by quality inspectors at the end of the production line. If it is not possible to test each single product (i.e., when complex or destroying testing methods have to be applied), statistically valid sampling plans have to be used to judge the entire production batch.

However, application of valid sampling plans in the meat trade is neither economically nor ethically acceptable. For example, pathogenic microorganisms are most often present in very low numbers and are mostly inhomogeneously distributed in the food matrix. If 5 packages out of 100 contain this hazard, at least 60 packages must be tested in order to detect it with a probability of 95%. If only 5 packages are tested, the probability of finding this health risk is only 23%.

Additionally, the financial implications of the end-product testing concept may be serious. Reprocessing of fresh meat items in order to eliminate risks is not applicable without changing the physical appearance of the product. Thus, serious financial losses up to total destruction of nonconforming batches may have to be borne. Another problem arises when only time-consuming and cumbersome testing methods are available. In particular, this occurs when highly perishable foods, such as fresh meats, have left the producer's site before analytical results become available. If the quality criterion is not reliably met, a cost-intensive and reputation-damaging product recall may be inevitable.

Although product testing will always be necessary in food production, more preventive concepts are required to avoid the occurrence of nonconforming products. Such concepts are primarily based on the control of food production processes.

Process Control

Process control is the second conceptual approach for safeguarding defined quality features. To fulfill the quality criteria, preventive, supervisory, and corrective measures are established in the course of the processes. In this context, a process is described as a "set of interrelated or interacting activities which transforms inputs into outputs" (ISO 9000:2005), or raw material into end products. Process control measures may be restricted to certain quality attributes (e.g., hygienic-toxicological characteristics), may include all quality features of a particular product or manufacturing process, or may cover all internal processes of an enterprise (management, procurement, production, sales, etc.), as in the case of quality management according to ISO 9001.

In recent decades, internal process control has been increasingly requested by food surveillance authorities and food retailers, especially if private labels are manufactured. Operators of meat processing plants worldwide are obliged to safeguard safety and quality of processes and products by identification of critical steps in their processing lines and to introduce effective monitoring and corrective action systems at these critical processing steps. Additionally, documentation of all significant product traits is mandatory.

To support process control, several 'quality management tools' have been developed. This very heterogeneous group of procedures, methods, and techniques are useful for the description, analysis, assessment, regulation, prevention, and visualization of processes. Some quality management tools are rather simple (daily tally sheets), whereas others are quite complex systematic approaches (hazard analysis critical control point (HACCP) concepts). A brief survey of quality management tools throughout different steps in a product's life cycle, beginning with the product idea and ending with maintenance service, are presented in Figure 2.

System Control

Effective quality control measures must also cover preceding and subsequent production steps in order to achieve and maintain the intended product quality characteristics. Although contractual agreed raw material specifications already have a long tradition, the longitudinal integration of quality

assurance activities into a holistic approach was largely developed in the 1980s. Over the intervening years, meat production and marketing chains were established that guarantee certain quality traits and production properties.

Promoted by the rapid developments in the electronic data-processing sector, such integrated quality control systems (longitudinally integrated quality and safety assurance) use interlinked documentation systems that ensure traceability of

the products from the primary production to the consumer's household, concisely depicted by expressions such as 'from farm to fork,' 'from stable to table,' or 'from conception to consumption.'

Standardized Quality Management and Certification

Historical Development

The aim of each business enterprise is for customers to give preference to its products over the products of its competitors. Accordingly, its products must be more favorable regarding price, availability, and/or desired quality features.

At the beginning of the twentieth century, quality features were guaranteed by product inspection. However, in the late 1930s and 1940s, industrial producers realized that preventive process control would allow them to produce better, faster, and with less waste, and this realization was prompted mainly by the needs of the weapons industry. Again in the 1960s, military requirements resulted in the first quality management standards (e.g., the US Mil-Q-9858 and NATO's AQAP 1, 4, and 9). During the 1970s and 1980s, multiple quality standards were developed in many countries for different needs, particularly the nuclear, automobile, and aerospace industries. In 1987, this resulted in the generally applicable quality management standards of the ISO 9000 series. These basic standards have been revised several times, leading to actual version of ISO 9001:2008. In the meat industry, however, these standards were applied only in a reserved way. In France, for example, the first slaughterhouse was not certified before 1995.

Management Systems

The basic rules for introducing directing systems for quality traits are laid down in the ISO 9000 standard series. Herein, quality management systems are defined as "…that part of the organization's management system that focuses on the achievement of results, in relation to the quality objectives, to satisfy the needs, expectations and requirements of interested parties…" (ISO 9000:2005). The ISO 9000 requirements are universally applicable for all kinds of 'organizations' that stand for "…a group of people and facilities with an arrangement of responsibilities, authorities and relationships …," such as companies, corporations, institutions, associations, etc. Requirements for the products themselves are not established because the products' quality features should be stipulated by customers and organizations.

Although ISO 9000 standards are primarily directed toward the satisfaction of customers' needs and expectations, several additional benefits result from the introduction of a quality management system. For costumers, decisive economic advantages arise, thus products reduce the need for retesting. For the organization itself, processes within the organization grow more transparent and responsibilities become more clearly assigned. If there are personnel changes, the know-how remains within the organization and the quality awareness of the employees will be enhanced. The control of the (production) processes will serve as a sound basis for their continual improvement and as proof of due diligence with regard to product liability. Last but not least, positive marketing effects may occur.

The development of a quality management system within an organization takes approximately 6–12 months, depending on the size and complexity of the organization and on the available human and financial resources. At the beginning, a survey is conducted comparing the actual processes and documentation procedures with the requirements of the standards to be applied. To meet the requirements, a hierarchically organized documentation system will be generated. This consists of a statement concerning the quality policy and quality objectives; a quality manual; certain documented procedures as required by ISO 9001; and the documentation needed to ensure the effective planning, operation, and control of the organization's processes. It is indispensable to include the employees in the compilation of the documentation. This helps the acceptance of the quality management system in the organization. An important part of the documentation consists of the records that provide objective evidence of the activities performed or the results achieved. After completion of the documentation, it is officially brought into the organization. The functioning of the quality management system is verified by means of internal audits, being a 'systematic, independent, and documented process' (ISO 9000:2005) for the evaluation of the suitability, adequacy, effectiveness, and efficiency of the quality measures conducted. A description of procedures and requirements to carry out internal audits are found in ISO 19011:2011.

Using common elements, the quality management system will reason for integration into an organization's overall management system, which considers objectives such as economic, social, environmental, and other aims.

Certification Process

If a quality management system is implemented and its functioning has been subjected to several internal audits regarding its usefulness and function, it is possible to have an external survey and certification of the system. Certification (from Latin *certum facere* = to make sure) is a procedure in which third-party experts confirm (in writing) that a product or a process agrees with a certain standard. In case of ISO 9001, it is certified that an organization's quality management system complies with the ISO 9001 requirements – it does not, however, specifically evaluate the technical competence of an organization.

First of all, an external independent organization, a state-approved or accredited certification body, is needed to carry out the certification on the basis of a private law contract. Care and diligence are necessary when choosing a certification body, as the contract period lasts usually several years. Criteria for the choice of certification bodies are, among others, their reputation, their international business activities, their proximity to each other, their competence in the business branch in question, customers' requests, or financial considerations. For example, opting for an international certification body is indicated if the organization itself works internationally. Websites similar to the International Accreditation Forum may be helpful when looking for certification services.

After conclusion of the contract, the quality manual and the relevant documentation are given to the certification body, which chooses an expert audit team. At least one of the audit team should come from the line of business in question. The experts read and review the submitted documentation against an appropriate check list and look for compliance with the requirements of the standard in question. If no deviations are identified, a date for the certification audit will be fixed; otherwise, the organization first has to rework its procedures and documents.

The certification audit is by far the most substantial audit. Its duration and extent depend on the size of the organization (number of employees and locations). At the fixed date, the audit team comes into the organization to conduct a systematic on-site survey of the quality management system. Usually, after an opening session, the quality manager accompanies the auditors through the organization. It is the aim of the audit to find out whether the specifications of the quality manual and the other documentation conform with the day-to-day life within the organization. Additionally, the auditors have to check whether the quality management system has become part of the organization's culture and also whether the stated quality policy and quality objectives are feasible in terms of the processes described. For this purpose, all divisions of the organization are visited, employees are interviewed, activities are observed, and on-site documents (records) are reviewed. It goes without saying that the auditors are bound to professional discretion concerning all of the internal affairs of the organization. At a closing session, the auditors will present the most important audit findings and will draw an audit conclusion. Nonfulfillment of audit criteria will result in written nonconformity reports that are part of the audit report. The auditors and the quality manager will agree on certain corrective and preventive actions, as well as on dates by which the actions have to be established. Depending on the nature and severity of nonconformity, the issue of the certificate may be postponed or linked to an additional audit that deals only with the deviations.

A written audit report will deal with all audit findings. It will include a comparison between the regulations of the quality management system laid down in writing versus the actual quality procedures of the organization, as well as all indications of flaws, weak points, and potential for further improvement. Subsequently, the certificate will be issued and, as a rule, yearly follow-up audits will be performed for renewal of the certificate.

Special Certification Programs

In recent years, globalized trade, legal requirements, and increased liability demands of the food supply chain participants have led to the development of multiple certification standards focusing on different quality traits, products, processes, production plants, and production chain stages within the meat production chain. Owing to its outstanding importance, management systems directed toward food safety aspects enjoy widespread use, especially the British Retail Consortium (BRC) Global Standard, International Featured Standard (IFS), and Food Safety System Certification 22000.

In 1998, the BRC introduced the BRC Food Technical Standard. Because retailers and brand owners are (under the EU food law) legally responsible for their private labels, the evaluation of food manufacturers according to this standard assists private label owners, first to receive food products of consistent safety and quality and second to prove their due diligence in case of a prosecution by the enforcement authorities. The rapid spread and development of this standard has demonstrated its value as the benchmark for best practice in the food industry. During the past decade, the standard evolved into the BRC Global Standards series comprising requirements for the production, packaging, storage, and distribution of food and consumer products. Each of these standards is regularly reviewed, revised, and updated.

A similar standard was launched in 2003 by the French and German retailer federations. Developed for the assessment of food suppliers' safety and quality systems at postfarm gate stages, the IFS have been recently developed to provide uniform safety and quality requirements for food and nonfood products, as well as for related services. As in the BRC standards, the responsibility of the brand owner was the rationale for the development of uniform, common, and internationally accepted audit standards originally meant for products and processes of manufacturers producing those private label products. In the meantime, certification according to the IFS standard requirements is expected from nearly all food manufactures delivering products to wholesalers and large retailers. The latest IFS Food Standard (version 6) has been developed also for certification bodies, food industry, and food service companies from all over the world.

In 2005, the ISO published the ISO 22000 standard. This general derivative of ISO 9001 specifies requirements for food safety management systems to control safety hazards in order to ensure that food is safe at the time of human consumption. For this purpose, the management system requirements of ISO 9001 were merged with food safety requirements of HACCP, good manufacturing practice (GMP), and preventive programs. A certification scheme for such systems was developed by the Foundation for Food Safety Certification and called FSSC 22000. It comprises requirements for management systems to ensure the safety and suitability of food throughout the supply chain.

Although product safety still remains the most important quality trait in the meat supply chain, several other certification schemes have been widely introduced into the meat market. The reasons for the introduction of such schemes were growing quality demands and expanded quality perceptions of the customers. Requirements concerning animal welfare; animal feedstuff composition; environmental aspects like carbon dioxide footprint; organic farming; traceability; sustainability comprising economical, ecological, and social criteria; and/or regional provenance were considered and organized as certifiable private or public quality labels. After successful passing of the certification audit, the issued certificate communicates to the customer that the products comprise the attributes that the certification scheme seeks to affect. This helps the enterprise to be distinguishable from its competitor. According to Bredahl *et al.* such certification schemes can also act as a coordinating mechanism in the supply chain where different levels of the chain are under different ownership. Most of these schemes are related to preceding and subsequent stages of the

production chain; thus, constituting an integrated system control approach. One of the earliest systems in this field was the Dutch 'Integrale Keten Beheersing (IKB)' program (an overview on current European certification systems was provided by Theuvsen *et al.*). Although not yet certifiable, Upmann *et al.* recently presented a standard to evaluate the sustainability status of pig abattoirs and pork processing establishments; hence, the introduction of a sustainability certification programs can be expected within the next few years.

Quality Management in the Meat Production Chain

Aims

In addition to basic meat safety and quality traits presented in Table 1, meat enterprises must consider quality traits, such as animal welfare, organic farming, and sustainability, according to their customers' demands. Thus, quality management activities of abattoirs and meat processing plants nowadays contain a vast variety of quality attributes deriving from different quality programs. Most of them are equally related to preceding and subsequent stages of the production chain, requiring the integration of external data and setting standards for suppliers. The backbone of the activities is, therefore, a sophisticated electronic data-processing system that enables the collection and analysis of data, the traceability of all products on all stages of the production chain, and a detailed documentation of all quality relevant activities.

Activities

First of all, the enterprise must install and maintain a management system. To integrate the quality demands into this management system, all requirements have to be broken down over the whole manufacturing process into single measures at each step of the processing line in order to guarantee that the intended quality traits are maintained throughout the whole process. For this purpose, additional technical production guidelines are followed, supplemental product analyses are performed, additional control points are established, and extra inspection, survey, and monitoring systems are implemented.

Meat plants possess elaborated, often computer generated, product sampling and testing plans that may apply to each single quality characteristic mentioned previously. Sampling for *Salmonella*-monitoring programs may serve as an example. If feasible, the sampled products should be retained from market until the test results are available (sample/test and hold system). Process control measures integrate the technical steering activities during processing that are mandatory in HACCP systems, FMEA, or GMP concepts. Computer-aided survey of chilling or heating processes or online control of exsanguination with respect to animal welfare should also be mentioned. System control measures are equally well introduced in order to integrate all participating enterprises, processes, and products. For instance, abattoirs implement supplier assessment strategies in order to categorize slaughter animals according to their quality deviation risk. Also, individual animal identification systems are maintained to safeguard traceability, and early information transfer between farm and abattoir is mandatory to install logistic slaughter systems. Further, multiple measures are taken during animal transport and arrival, slaughter, meat handling, processing, and meat shipment. As demonstrated in Figure 3, safeguarding upstream and downstream information flows is crucial for the establishment and maintenance of the quality systems, as well as for the transparency and traceability of products.

Last but not least, independent and competent third-party certification services are required to assure compliance with the previously mentioned certification programs. This will increase the number of audits in which the personnel have to participate considerably.

Documentation

Quality management systems require an extensive documentation system. Generally, it is arranged hierarchically following, for example, the structure of the basic certification standard. Some information on the ownership, nature and extent of the production, and organizational structure should be given. A basic description of the available resources (e.g., plant infrastructure, internal/external personnel, etc.), production processes, and supporting processes (such as cleaning and disinfection), as well as the product portfolio should also be provided. The descriptions should be short and precise. For example, a number of resources, such as processing machinery, water supplies, material flows, personnel routes, temperature zones, or clean and unclean areas, can be best represented by a set of ground plans. Description of production processes may clearly be done by process flow charts, and it is recommended to number all processing steps for references.

Specifications must be elaborated for all processing steps laying down the target parameters in order to meet the quality demands at this specific point. Similar specifications must be elaborated for supporting processes, such as personnel hygiene, cleaning and disinfection, pest control, waste removal, and others that indirectly may have an impact on the product quality.

Finally, records must be maintained on the quality relevant activities according to the principle: "Activities that are not documented were not carried out."

Prospect

Definitely, the future will bring further longitudinal integration of the different segments of the agrifood chain. Intelligent information exchange systems, electronic communication, and intense data transfer are prerequisites for the optimization of the different quality management activities.

Multiple concepts and tools can be used to develop an organization's quality management system. Which concepts and tools are employed will depend on the field to cover, the organization's structure and aim, legal requirements, and customers' expectations. Principally, it should be kept in mind that the quality management system should serve the organization and not vice versa. Therefore, implementation of special concepts or tools should always be checked toward their simplicity and suitability for the desired purpose.

Farm Level: Pork Quality

D Newman and J Magolski, North Dakota State University, Fargo, ND, USA

Glossary

Current Good Manufacturing Practices A set of guidelines for processing nonmedicated and medicated feed.

Good Production Practices A set of guidelines for safe, healthy, efficient and humane production of pork.

Hazard Analysis Critical Control Point A production control system for the food industry designed to prevent rather than catch potential hazards; identifies where potential contamination can occur (the critical control points) and strictly manages and monitors these points as a way of ensuring the process is under control and that the safest product possible is being produced.

Pork Quality Assurance® A producer-driven program they can use to ensure US pork products are of the highest quality and safe, and animals raised for food are cared for in a way ensuring their well-being.

Transport Quality Assurance® A program that helps swine transporters, producers, and handlers understand how to handle, move, and transport pigs and the potential impacts of those actions on pig well-being and pork quality. Anyone who handles or transports pigs, or sets protocols for handling pigs, is a potential influencer of animal well-being and pork quality.

Veterinary-Client-Patient Relationship A relationship that exists between a client and a veterinarian where the veterinarian has assumed the responsibility for making medical judgments regarding the health of the animals, has sufficient knowledge of the animals, and is readily available for follow-up consultation.

Withdrawal time Length of time between final administration of an animal-health product and animal harvest.

Introduction

Defining the parameters that encompass the topic of pork quality at the farm level can be a challenging task. Pork quality starts at the farm level and is carried through the food supply continuum. The pork industry maintains its responsibility to support animal well-being and provide consumers with a safe, abundant, and high-quality food. In modern pork production systems, pork producers, and other industry stakeholders have made great strides in improving pork quality at the farm level with attention on such factors as animal health, nutrition, welfare, and proper transportation. Major advances in swine sciences over the past several decades have allowed the pork industry to focus on factors of importance with intensity and the ability to create change. The goal of achieving efficient, safe, and sustainable production of a wholesome pork product has been a focal point for many years and will continue to be critical to pork as a global protein source for a growing world population. This article considers (1) factors of pork quality, (2) how pork quality assurance (Pork Quality Assurance Plus® (PQA Plus®)) in the United States emphasizes quality and integrity, and (3) responsibility of producers to maintain high standards of pork quality.

Pork Quality

To understand the on-farm parameters that can affect pork quality, it is important to define pork quality. Pork quality can be defined as the series of attributes and traits that have a direct influence on the purchasing decision, food safety, and palatability attributes as measured by the consumer. Although pork quality is traditionally thought of as measurements of muscle color, pH, water holding capacity, tenderness, juiciness and flavor, today's consumer also characterizes animal welfare, health, nutrition, and production claims such as 'natural' or 'antibiotic free' as quality attributes.

Because many factors of pork quality begin at the farm level, establishing robust quality assurance programs is critical to ensuring good pork quality for the global pork industry for years to come. A good example that will be outlined throughout this article is the PQA Plus® program in the United States. Many other countries across the world, such as Canada, Germany, the Netherlands, and Denmark also have pork quality assurance programs. These programs all share similar program goals and objectives that help define on-farm pork quality.

Pork Quality Assurance

Developed by the United States National Pork Board in 2007, the PQA Plus® program was designed for continuous improvement and used to identify and educate Good Production Practices (GPPs) that positively affect food safety, animal well-being, and pork quality. The PQA Plus® program combines scientific research with best production practices to educate pork producers about administering proper swine management throughout the lifecycle of the hog. Food safety and animal well-being are the cornerstones of the PQA Plus® program and the pork industry. The PQA Plus® program achieves its goals by educating pork industry professionals during certification sessions. An objective on-farm assessment is also conducted, which, when combined with the individual education certification, results in the production site being granted PQA Plus® site status. This is a very important

 doi:10.1016/B978-0-12-384731-7.00030-1

Table 1 Pork Quality Assurance® Plus 10 Good Production Practices (GPPs)

GPP #1	• Use an appropriate Veterinarian-Client-Patient Relationship as the basis for medication decision making
GPP #2	• Establish and implement an efficient and effective health management plan
GPP #3	• Use antibiotics responsibly
GPP #4	• Properly store and administer animal health products
GPP #5	• Follow proper feed processing protocols
GPP #6	• Establish effective swine identification, medication records and withdrawal times
GPP #7	• Practice good environmental stewardship
GPP #8	• Maintain proper workplace safety
GPP #9	• Provide proper swine care to improve swine well-being
GPP #10	• Utilize tools for continuous improvement

Source: Reproduced with permission from the National Pork Board, Clive, IA, United States.

designation for the production site because site certification is required for swine procurement by most pork processors. On-farm reviews and audits are becoming commonplace throughout the pork industry and are intended to build credibility, trust, and integrity.

Table 1 outlines the 10 GPPs of the PQA Plus® program. According to the PQA Plus® Education Handbook "the GPP's, when implemented, will help ensure pork is free from chemical and physical hazards; that the pigs are raised in a caring, humane manner; that our natural resources are protected by pork producers; and that employees on pig farms have a safe place to work." The 10 GPPs are based on the following objectives:

1. Hazard Analysis and Critical Control Point principles are the standard for controlling hazards in foods produced and processed in the United States and many foreign countries.
2. The Food and Drug Administration's Compliance Policy Guide (CPG) 7125.37 – "Proper Drug Use and Residue Avoidance by Non-veterinarians."
3. The Animal Medicinal Drug Use Clarification Act (AMDUCA) of 1994.
4. Science-based animal care and well-being guidelines.

Production Factors Affecting Pork Quality

There are many factors for a producer to consider when implementing a pork quality assurance program within a production system. This article details some of the most important factors in pork production that contribute to pork quality on the farm level. Many of these factors are major topics included in quality assurance programs. The following list of factors describes a variety of elements necessary to be considered for optimal pork quality.

Barn Management

The most basic aspect of proper swine management comes through the understanding of production systems. Farm setup and design are key components to ensuring both an efficient production system and one that produces a quality product. The production system encompasses barn design, pen size and layout, proper handling facilities, and proper ventilation. Controlling barn environment is a key component of minimizing stress and optimizing animal performance. Barn parameters will vary by region and desired level of biosecurity. Examples of these specific adaptations include the incorporation of cooling cells to maintain comfortable ambient temperature during the summer months and use of body heat and air flow strategies in the winter time to maintain temperatures in the pig's thermal neutral zone without diminishing air quality or increasing energy cost. Even though the system represents a fixed cost in production, proper barn design and setup is the first step in ensuring optimum production.

Genetics

The selection of breeding stock that fit both the rearing environment and the market to which hogs will be sold is critically important. Today's pork industry is very diverse in the genetics available, the production systems where swine are reared, as well as the avenues in which the pork is bought and sold. Production claims such as 'naturally raised,' 'gestation stall free,' 'organic,' 'antibiotic free,' and/or claims of improved meat quality will impact the type of breeding stock used in a production system. The pork industry has observed the development of many high-producing commercial lines of gilts that are designed to maximize the number of pigs weaned and their respective weaning weight. Unfortunately, some of these same females tend to see less parities in a sow herd due to reproductive or body condition challenges. Therefore, it is important to the long-term success of a swine operation that producers find the optimal sow to fit the system.

Modern swine production now utilizes more than 95% artificial insemination. The systematic use of boar lines to improve heterosis for growth, efficiency, and meat quality has been beneficial. Utilization of swine genetics has led to huge gains in production parameters. For example, utilizing Duroc and Hampshire boars on Yorkshire, Landrace, and Chester White base females has led to improved farrowing rates, feed efficiency, and carcass composition while also reducing days to market and overall cost of production. The utilization of the purebred Berkshire breed in niche markets is also very popular. Known for superior marbling capability, higher pH, dark pork color, and recognized palatability attributes, the Berkshire breed retains a reputation for a premium eating experience.

Swine Husbandry

Proper animal husbandry skills are a major component in successful swine operations. A thorough understanding of the production system and ability to recognize challenges are critical to swine welfare and pork quality parameters. Examples of management challenges affecting pork quality could include monitoring animal health, recognizing nutritional deficiencies, changes in air quality or temperature, and animal handling.

Feed and Nutrition

With rising feed costs affecting all livestock sectors, much focus has been turned toward feed efficiency and the utilization of alternative feeds to reduce cost of production in all phases. Producers need to ensure that Current Good Manufacturing Practices are used as guidelines on formulating and feeding both nonmedicated and medicated feed. The importance of high-quality feed to swine operations is essential for growth and maintenance, as well as swine well-being.

Changes in diet formulation can have adverse effects on pork quality parameters. One example of a common feed ingredient used in swine diets to reduce overall cost is dried distillers grains with solubles (DDGS). The use of DDGS in gestation, lactation, nursery, and grow/finish diets has dramatically increased in recent years. This spike in utilization has led to a parallel increase in research in this area. Although cost is reduced, several pork quality challenges have also been observed. Owing to the higher proportion of unsaturated fatty acids in DDGS compared to the traditional corn/soy diet, market hogs fed higher than 20% DDGS have shown significant changes in pork quality and, more specifically, fat quality. An alteration in the fat composition of meat also leads to processing challenges and changes in shelf life and consumer acceptance. Pork with higher concentrations of unsaturated fatty acids undergoes a higher rate of fatty acid oxidation, resulting in off flavor if gone unchecked.

Swine Health

An efficient and effective herd health management plan, coupled with a working relationship with a swine veterinarian, is an essential component of farm management. This relationship is known as the Veterinary-Client-Patient Relationship (VCPR). Without a VCPR, swine herds are put at an increased and unnecessary risk for animal disease and potentially compromised food safety. Herd health is a key to food safety. Animals in good health are more efficient and produce a better end product. The healthier an animal is, the less need for pharmaceutical use, reducing the risk of antibiotic residues while also reducing the associated cost of treating sick animals. A proper herd health protocol should contain regularly scheduled herd evaluation by a veterinarian, as well as biosecurity measures in place to ensure animal safety and well-being.

Regular veterinarian inspections of swine operations are critical in maintaining a healthy herd. Visits by a trained professional grant producers the ability to review their vaccination protocol, potentially observe symptoms previously over looked, and also view the production system from a different vantage point. Many times veterinarians are consulted to address health problems negatively impacting carcass value and quality. These defects are typically brought to the attention of the producer by the pork processor, and in most cases the producer needs to quickly address these issues to improve performance, decrease financial losses, and ensure continued acceptance from the processor.

Sometimes overlooked is the negative impact these health issues have on meat quality. Some examples of common health issues that negatively affect carcass value include abscesses, pneumonia, and arthritis. For example, the presence of pneumonia in swine reduces breathing capacity. Swine can adapt to a more restricted oxygen intake in their normal environment, and, even though a reduction in performance is observed, the animal is still able to cope with its surroundings. However, when swine are exposed to mixing, transportation, lairage, and movement to harvest, the reduced capacity to take in oxygen can cause extreme stress on their system, i.e., not only stress on the circulatory system, but also the musculoskeletal system. The reduction in oxygen consumption and capability to remove by-products from adenosine triphosphate (ATP) hydrolysis out of the muscle creates a challenging metabolic situation. The decrease in muscle pH can lead to fatigue, inferior pork quality, and possibly death.

Biosecurity

Biosecurity is a combination of management practices and protocols designed to prevent the transmission of diseases and disease-causing agents. In general, biosecurity involves restricting the movement of anything capable of carrying disease or disease-causing agents, including people, pigs, birds, other animals, and water. Biosecurity measures can be applied both internally and externally to the facility. For example, an internal biosecurity practice could include an all-in all-out finishing system where any disease cycle present in the facility is confined to the specific group of pigs and the facility is sanitized before another group of pigs enter. This strategy is also observed in the farrowing rooms, where following weaning, all farrowing rooms are washed, disinfected, and have a period of down time before reloading the next farrowing group.

Although internal biosecurity practices are utilized, external measures are more commonly recognized. Some external biosecurity measures include isolation of new animals prior to entering the herd, control of wildlife and pests, air filtration systems, limiting visitors, supplying clean clothes to all guests, shower-in/shower-out, and managing vehicle traffic.

Animal Welfare

Animal welfare is increasingly becoming a focal point of swine production worldwide. There is a wide range of public opinion within and across different countries regarding what constitutes proper animal welfare and humane production practices. Major topics include gestation sow housing, tail docking, physical castration, and immunocastration. Regardless of opinions, providing proper care to improve swine well-being should be the foundation of any livestock producers operation. Swine raised in the proper environment are healthier, perform better, and produce quality pork products. The pork quality assurance programs offered around the world address many factors that directly affect swine well-being at the farm level. Some of these factors are described in more detail.

Recordkeeping

Keeping accurate and consistent records of all procedures and processes within an operation is an essential part of preserving producer/processor relationships and earning the consumer's trust. Documenting the VCPR relationship along with all

medication and treatment records provide a health history on all pigs and help ensure food safety. This documentation process also affords the opportunity to identify trends in animal treatments, helping to identify possible improvement strategies in herd health protocols. All treatment records should be maintained for a minimum of 12 months after marketing of the animal.

Daily Observation

All swine production facilities should be observed daily. Daily observation allows for prompt recognition and delivery of necessary care, as well as detects any facility or management issues present. A daily walk through can also monitor effectiveness of health protocols, current plane of nutrition, and overall animal care. Making sure all feed and water delivery systems and air flow systems are functioning will ensure the utmost care of the hogs.

Daily monitoring should also be used to identify and separate any ill or nonambulatory pigs to an alternative pen. Treatable pigs should be cared for promptly in order for them to fully recover. Any seriously ill pigs should be humanely euthanized following farm protocols.

Animal Evaluation

Evaluating animals on a regular basis will verify that well-being programs are positively impacting the animals. The response of the pigs to human presence alone is an indication of animal well-being. Pigs that are calm and relaxed when someone enters a facility are more than likely beneficiaries of pleasant handling and care. However, pigs that appear afraid and fearful of people may be neglected or may not be in a facility that is meeting their needs.

Specific traits of evaluation include overall performance, physical appearance including lameness, lesions, abscesses, wounds, and prolapses. One of the best indicators of well-being can be measured by pig performance. Changes in average daily gain, feed efficiency, mortality rate, or even farrowing rate are noticeable signs of problems. The ability to benchmark these performance traits and comparing to previous values is essential in monitoring herd performance. All changes in performance should have an explanation as to why, and if not, producers should move swiftly to explore the causes.

Visual appraisal of the animals also serves as a strong indicator of well-being. Lameness, lesions, and wounds can result from many different things. Some of these causes are fighting, biting, and facility problems which can all negatively impact well-being and quality. For example, lameness could be a result of bacterial infections, nutrition deficiency, and (or) genetics.

The presence and location of lesions can be very telling with regard to the problem. Lesions on the main part of the body (shoulder, back, flanks, and legs) are commonly the result of fighting with pen mates. Flooring problems, such as cracks, missing pieces, or raised sections, can lead to lesions primarily on the pig's hooves. Faulty feeding and watering equipment can result in cuts around the head and ears, whereas tail and genital biting is more likely the cause of nutrient deficiencies and overcrowding.

Barn environment challenges can also lead to rectal prolapses in swine. The presence of pneumonia and other respiratory tract infections can lead to excessive coughing, one of the primary causes of prolapses. Piling of pigs to stay warm can also result in prolapse, or it could even be the result of a genetic predisposition to prolapse. Quick isolation and treatment is necessary to prevent further injury and enhance the chance of the pig making a full recovery.

Body Condition Score

Body condition scoring (BCS) is useful in assessing the adequacy of a nutrition program. Literature also suggests that body condition score gives insight to the effectiveness of a barn's heating and cooling strategies. The most accepted BCS system is on a scale of 1–5, with 1 representing a thin, emaciated animal, and 5 being obese. Animals with a BCS less than 2 should receive immediate attention. Poor BCS commonly result from poor or inadequate nutrition or health challenges. Treatment plans may be antibiotic treatment, an increase in caloric intake or total intake, or if not treatable, the animal should be euthanized.

Over-conditioned pigs are also a disadvantage to the producer. On the grow/finish side, high body condition score pigs have reduced growth performance, are less efficient in converting feed to pounds of lean, and have a higher overall cost of production. From a carcass standpoint, these hogs also produce a less desirable and less valuable carcass due to lower lean-to-fat ratio. Breeding stock that deviates from the ideal BCS of 3 also have reduced performance. With regard to welfare, these females also create management challenges with regard to increased incidence of lesions, shoulder and leg sores, lameness, and general welfare concerns. Furthermore, low and high BCS females have reduced conception rates, reduced piglet survivability, and lower weaning weights. There is also evidence that these pigs born from challenged litters have a reduced production performance throughout their lives.

Proper Handling

The proper movement of swine throughout their lives will be important to the overall performance, health, and eventual meat quality of the animal. Having adequate handling facilities along with proven pig-handling equipment and proper handler training will ensure good well-being of the animal and safety for both the pig and the workers. Poorly moved pigs can become stressed, leading to physical injury, increased cases of nonambulatory animals, reduced performance, and increased load and unload times of market animals. These stressors can also lead to increased carcass shrink, increased incidence of carcass bruises and subsequent trim, and decreased pork quality. Improper handling and transport of pigs is one of the largest profit-reducing issues facing the pork industry today. Estimates show that bruises alone cost the US pork industry millions of dollars each year, with overall pork quality defects totaling several hundred million dollars annually. As a general rule, calm, slow, and quiet handling is the best bet for the pig and the handler.

Flight Zone

Flight zone is the imaginary space that surrounds an animal and is considered the animal's 'comfort zone.' Understanding an animal's flight zone and predicting their response to the handler's presence can be very beneficial in moving livestock. When a handler enters the pig's flight zone, the pig will attempt to move in the opposite direction. For example, if a handler approaches a pig from behind it will move forward and if the handler approaches from the right, the pig will try to move left. However, if no escape route is available, the pig will attempt to go back to where it came from. When handling pigs, it is best to use the edge of the flight zone to move them, as this will result in the least amount of stress possible.

Herding Instinct

Pigs are instinctively herd animals. This predictable behavior causes pigs to want to follow each other in order to maintain contact. Understanding this behavior can make it easier to move pigs up and down ramps, through hallways, and into or out of pens and rooms. Many facility designs today use this concept to their advantage by using double alley raceways with a see-through gate in the middle. This allows pigs to see others in front of them as well as next to them, reducing the stress of moving into a new environment.

Using the herding instinct can greatly reduce the potential for stress and injury in pigs. When pigs feel isolated, they will try to escape. This response can lead to injuries caused by nearby gates, feeders, chutes, or other objects. The pig may also try to escape by jumping, increasing the risk of injury to joints, muscles, and bones.

Transport

Loading, transport, and unloading have been identified as high stress events for hogs. These preharvest stressors significantly increase metabolic factors commonly known for quantifying stress and reducing pork quality. Research and anecdotal evidence suggest that transport within different seasons can have a significant effect on animal welfare, survivability of swine, and pork quality. In the United States it is very common for swine to be transported over great distances through vastly different geographic regions. Trailer type, bedding material, and trailer design can influence these transport factors. The National Pork Board manages the Transport Quality Assurance® program in the United States to help those involved in swine transportation understand and manage the factors involved in reducing losses associated with transport, improve animal welfare, and reduce risk of deteriorating pork quality.

Conclusion

There are many farm level factors that affect pork quality. Pork producers can find significant value in quality assurance through quality assurance programs offered by producer groups around the world, such as PQA Plus® in the United States. These programs enable pork producers to participate and engage in programs that benefit the welfare of pigs, reduce costs associated with management, and provide documentation for continuous improvement. As protein consumers become further removed from production agriculture and basic knowledge about food production, it will be critical that swine producers provide customers with factual, science-based information about pork production, pork quality, and food safety. Doing so can add a tremendous amount of value to the entire food chain.

Farm Level: Safety and Quality of Beef

DL VanOverbeke, Oklahoma State University, Stillwater, OK, USA
JK Ahola, Colorado State University, Fort Collins, CO, USA

This article is a revision of the previous edition article by M Upmann, G Wellm, volume 3, pp 1119–1129, © 2004, Elsevier Ltd.

Glossary

Antimicrobial A substance that kills or slows the growth of microbes, like bacteria (antibacterial activity), fungi (antifungal activity), viruses (antiviral activity), or parasites (antiparasitic activity).
Contamination Something that causes a product to be infected, corrupted, or polluted after contact with it.
Hazard analysis critical control point A production control system for the food industry designed to prevent rather than catch potential hazards; it identifies where potential contamination can occur (the critical control points) and strictly manages and monitors these points as a way of insuring that the process is in control and that the safest product possible is being produced.
Resistant determinants Having exact limits that give the ability to ward off bacteria.
Violative residues Residues resulting from the use of animal drugs and pesticides or from incidents involving environmental contaminants that are outside the tolerances established by the Food and Drug Administration, Environmental Protection Agency, and Food Safety Inspection Service.

Introduction

Addressing beef safety and quality on farm has always been a sensitive topic because of the number of producers who are typically involved in the production of animals from conception and birth all the way to harvest. Depending on the production systems involved, cattle might be in as few as one production unit/facility or in as many as three or four during their lifetimes. Regardless, the goal of beef production is to produce a safe, wholesome, quality product that consumers will purchase again and again. In achieving this feat, producers must understand consumer's definition of beef safety and quality and then use production systems that produce a final product which meets that definition.

Definition of Beef Quality

If general consumers are asked to define beef safety and quality, likely responses could be tender, juicy, flavorful, free of defects (residues, lesions, etc.), nutritious, and safe. Although producers might not include safety as a quality measure, consumers commonly do, and hence it needs to be considered. Given such a definition, the beef quality assurance (BQA) program was developed on a national level to help producers identify production practices that impact the factors included in the definition of quality.

Structure and Impact of Beef Quality Assurance Programs on Product Safety and Quality

The BQA program's mission is to maximize consumer confidence and acceptance of beef by focusing cattle producers' attention on daily production practices that influence beef. Ultimately, BQA has the intention of assuring consumer confidence that beef produced by BQA-certified producers and under the program guidelines meets their demands. The BQA program guidelines are simply practices that revolve around five major aspects of production: feedstuffs, feed additives and medications, processing/treatment and records, injectable animal health products, and care and husbandry practices.

The BQA program is implemented on a state-by-state basis; however, the National Cattlemen's Beef Association (NCBA) in the United States provides national leadership and oversight of the program. More than 45 states in the United States have implemented a BQA program. Although the NCBA provides such a leadership, it is important to realize that each state's effort is producer driven, voluntary, and educational in scope. States can vary in terms of their emphasis on 'certification' of educational efforts, but nearly all programs have such a component in them. It is believed that, although voluntary, this effort by the NCBA and each state program will help to avoid government regulation of production practices in the United States.

History

History of BQA dates back to the late 1970s and the early 1980s, when programs such as the Beef Safety Assurance program and the Residue Avoidance Program existed. These programs, although voluntary, focused on one major issue – elimination of residues in the meat supply. This focus was understandable at the time, given the concern of antibiotic residues in beef by the United States Department of Agriculture (USDA) and specifically the USDA Food Safety and Inspection Service. The concepts found in the BQA program are based on the same concepts found in total quality management or hazard analysis critical control point (HACCP) programs – identify potential problems, outline where they can occur, prevent such issues from occurring, and if they do occur, solve the problem.

Goals

According to the national BQA program training manual, the goal of the program is "To ensure consumers that all cattle shipped from a beef production unit are healthy; wholesome and safe; their management has met Food and Drug Administration (FDA), USDA, and Environmental Protection Agency (EPA) standards; they meet quality requirements throughout the production system; and are produced with environmentally-sound production practices." Further, objectives of the BQA program are:

1. Set production standards for quality and safety that are appropriate to an operation and that can be met or exceeded. Key elements that influence production of defect-free food include biosecurity, animal health and well-being, production performance, and environmental stewardship.
2. Establish data retention and recordkeeping systems that satisfy the FDA/USDA/EPA guidelines to help allow validation of management activities and fulfill program goals.
3. Provide hands-on training and education to help participants meet or exceed the BQA program guidelines and help to realize the benefits of the program.
4. Provide technical assistance through BQA program staff, veterinarians, extension specialists, and other qualified individuals working with the BQA program.

Guidelines

The BQA guidelines were developed and evaluated by the national BQA advisory board that consisted of veterinarians, producers, researchers, extension personnel, and beef industry leaders committed to producing safe, quality products for consumers. This advisory board continually reviews and updates guidelines as needed to meet the ever-changing production and regulatory climate of the beef industry. The guidelines, presented by their topic area, of the BQA program can be found in Table 1 and the following paragraphs outline a summary of each category.

Feedstuffs

Although utilization of feedstuffs changes as economic conditions change in the industry, the premise of the guidelines remains the same – maintain a safe feed supply free of contamination by pesticides, herbicides, other feed ingredients, or banned substances and be sure the feeding of such feedstuffs is supported by sound science. An example of this is making sure that producers follow the ruminant-derived protein source feed ban.

Feed Additives and Medications

The emphasis on the category of feed additives and medications is to assure that producers utilize medicated feed additives according to the strict guidelines set forth by the FDA's Good Manufacturing Practices – using them only in accordance with label directions for dose, species, duration, etc. This category also points out that even though producers can work with their veterinarians to use antimicrobials in an extra-label drug use manner, this is not allowed for medicated feed additives.

Processing/Treatment and Records

The emphasis in processing/treatment and records is for producers to understand that records of product – herbicide, pesticide, antimicrobials, etc. – use can benefit them in their production system. Keeping accurate and reliable records help to assure that cattle sent to harvest are free of residues, that feeds are free from contamination, and that ultimately producers meet consumer demands for a safe, wholesome product. Documentation could also help producers to identify trends that might be happening in their own production unit.

Injectable Animal Health Products

Administration of antimicrobials has been the main stronghold of the BQA program since its inception. Although the original focus was on residues, a subsequent focus was on injection site lesions. Early results from the Injection Site Lesion Audits revealed the amount of product loss the industry was suffering as a result of placing injections in the top sirloin butt or the round of cattle and the loss suffered from giving injections in the muscle tissue. The focus in this category is proper placement and administration of antimicrobials. This proper administration includes proper route (giving injection subcutaneous (SQ) instead of intramuscular (IM) if that is a label option), proper location (giving all injections regardless of route in the neck region), and giving low-dosage products (or limiting administration to 10 cc per site) to control the severity of injection site lesions.

Care and Husbandry Practices

The NCBA has taken measures to assure that everyone involved in care, husbandry, and handling of cattle is educated on handling and caring for cattle in a humane manner, inspecting facilities to insure the ease of cattle handling and movement, and to keep equipment clean and sanitary. However, the education in this category goes beyond producers. The NCBA has also developed educational materials for truckers and auction market employees, for example, to make sure that everyone in the production chain from birth to harvest knows the impact they can have on product safety and quality.

Impact of Beef Quality Assurance on Product Quality

Beef quality has been measured over the years through research projects, such as the National Beef Quality Audit (NBQA) and the National Market Cow and Bull Beef Quality Audit. The NBQA was first conducted in 1991 and was followed by audits in 1995, 2000, 2005, and 2011. The focus of the NBQA is to measure and monitor producer-related defects, and then disseminate results through the BQA program to producers on ways management can be improved to decrease the incidence of defects in fed steers and heifers and cull cows,

Table 1 Beef quality assurance guideline categories and guidelines within each category

1. Feedstuffs
   - Maintain records of any pesticide/herbicide use on pasture or crops that could potentially lead to violative residues in grazing cattle or feedlot cattle
   - Implement adequate quality control program(s) for incoming feedstuffs. Program(s) should be designed to eliminate contamination from mold, mycotoxins, or chemicals of incoming feed ingredients. Supplier assurance of feed ingredient quality is recommended
   - Suspect feedstuffs should be analyzed before use
   - Ruminant-derived protein sources cannot be fed as per the Food and Drug Administration (FDA) regulations
   - Feeding by-product ingredients should be supported with sound science
2. Feed additives and medications
   - Only FDA-approved medicated feed additives shall be used in rations
   - Medicated feed additives shall be used in accordance with the FDA Good Manufacturing Practices regulation
   - Follow Judicious Antibiotic Use Guidelines
   - Extralabel use of feed additives is illegal and strictly prohibited
   - To avoid violative residues, withdrawal times must be strictly adhered to
   - Where applicable, complete records must be kept when formulating or feeding medicated-feed rations
   - Records are to be kept for a minimum of 2 years
   - Operator shall assure that all additives are withdrawn at the proper time to avoid violative residues
3. Processing/treatment and records
   - Follow all the FDA, United States Department of Agriculture, and Environmental Protection Agency guidelines for product(s) utilized
   - All products are to be used as per label directions
   - Extralabel drug use shall be used only when prescribed by a veterinarian working under a valid veterinary–client–patient relationship
   - Extralabel drug use of aminoglycosides (a group of antibiotics effective against certain bacteria) is strictly prohibited
   - Employ strict adherence to extended withdrawal periods
   - Individual treatment records shall be maintained. Record the following:
     - Individual animal or group identification
     - Date treated
     - Product administered and manufacturer's lot/serial number
     - Dosage used
     - Route, location, and person administering the product
     - Earliest date animal shall have cleared withdrawal period
   - When cattle are processed as a group, record the following information:
     - Group or lot identification
     - Date treated
     - Product(s) administered and manufacturer's lot/serial number
     - Dosage used
     - Route, location, and person administering the product
     - Earliest date animals shall have cleared withdrawal period
   - All cattle shipped to harvest shall be checked by appropriate personnel to assure that all treated animals meet, or exceed, label or prescription withdrawal times for all animal health products administered
   - Transfer all processing and treatment records with the cattle to the next production level. Prospective buyers must be informed of cattle that have not met withdrawal times
   - Keep records for a minimum of 3 years. Examples would include processing and pesticide application records
4. Injectable animal health products
   - Products labeled for subcutaneous (SQ) administration should be administered SQ in the neck region (ahead of the shoulders)
   - All products labeled for intramuscular (IM) use shall be given only in the neck region (no exceptions, regardless of age)
   - All products cause tissue damage when injected IM; therefore, all IM use should be avoided if possible
   - Products cleared for SQ, intravenous, or oral administration are recommended
   - Products with low dosage rates are recommended and proper spacing (at least 2 in between injection locations) should be followed
   - No more than 10 cc of product is administered per IM injection site
5. Care and husbandry practices
   - Follow the Quality Assurance Herd Health Plan that conforms to good veterinary and husbandry practices
   - All cattle shall be handled/transported in such a fashion to minimize stress, injury, or bruising
   - Facilities (fences, corrals, load-outs, etc.) should be inspected regularly to insure proper care and ease of handling
   - Strive to keep feed and water-handling equipment clean
   - Provide appropriate nutritional and feedstuffs management
   - Strive to maintain an environment appropriate to the production setting
   - Biosecurity should be evaluated
   - Records should be kept for a minimum of 2 years (3 years for restricted use pesticides)

their carcasses, and cuts obtained from their carcasses. In 1991, 22% of top sirloin butts had injection site lesions, whereas less than 2.0% of top sirloin butts had injection site lesions in 2000. In 2000, 100% of federally inspected beef-packing plants had implemented a HACCP system and 85% of all fed cattle was harvested in plants that use a multiple-hurdle carcass decontamination (MHCD) system (both HACCP and MHCD helped to assure that the United States had the safest beef in the world). Cattlemen in all 50 states had access to a BQA program in 2000.

Producers' Role in Beef Quality and Safety

The role of producers seems easy – get involved, attend a training meeting, and implement BQA practices into the production system. Although that might be easier said than done, the NCBA has developed tools to help producers in this manner.

Continual Improvement

Using the HACCP program as a basis, finding improvements in the beef production system requires taking a look at control points throughout the production process. These control points are common management steps, such as calving, purchasing feedstuffs, weaning calves, and transporting cattle, as part of an overall management scheme. It is during these control points that BQA practices should be incorporated in order to limit any potential hazards from occurring to food safety and quality. Table 2 provides some examples of control points impacting the BQA program.

Self Assessments

Three assessments (cow/calf, stocker, and feedyard) are available to producers via the BQA program as an on-site tool for assessment and benchmarking of key indicators of animal care and well-being as well as operational conditions. This tool may be used as a self-assessment or may be conducted by a third-party assessor. The key, regardless of who conducts the assessment, is that the assessment be repeated on a periodic basis so that comparisons can be made, trends observed, and management actions be taken to maximize animal care and well-being and operational efficiency. This assessment is about continuous improvement. However, it can help to identify items and create benchmark points that might need to be improved, including animal handling, facility/equipment maintenance, and recordkeeping/best management practices (BMPs), among other items. Repeating the assessment on a regular basis can help an operation to identify trends and take appropriate management action as necessary. Generally, the assessments focus on three main areas – animals, records and BMPs, and facilities and equipment. The Cow/Calf Assessment consists of multiple assessment points grouped into several categories, or tiers, that are most easily defined by management level and effort. Remember, the assessment tools are available for producers to use to benchmark their production units relative to implementing guideline categories and actual guidelines into practice but not to judge the production techniques in relation to other producers.

Producer Code of Cattle Care

In an effort for producers to be considered accountable for accepting their responsibility to provide proper care to cattle, the Code of Cattle Care was created by the BQA program. Most states require that producers who complete the BQA certification exam also sign a document with the following general recommendations for care and handling of cattle.

- Provide necessary food, water, and care to protect the health and well-being of animals.
- Provide disease prevention practices to protect herd health, including access to veterinary care.
- Provide facilities that allow safe, humane, and efficient movement and restraint of cattle.
- Use appropriate methods to humanly euthanize terminally sick or injured livestock and dispose of them properly.
- Provide personnel with training/experience to properly handle and care for cattle.

Table 2 Use of the hazard analysis critical control points program during on-farm and on-ranch processes to avoid potential hazards that negatively influence the quality and safety of beef

Process	*Control point*	*Potential hazard*
Feeding/supplementation	Purchasing	Antibiotic residues
	Receiving	Chemical residues
	Storage	Feed toxins
	Feeding livestock	
Prevention and treatment of health disorders	Calving	Injection site blemishes
	Weaning calves	Antibiotic residues
	Receiving breeding or stocker cattle	
Processing and cattle handling	Working cows and calves	Injection lesions
	Weaning calves	Bruises
	Shipping calves	Hide damage
		Hide defects
		Poor health
Pasture chemical use	Herbicide/pesticide applications	Water quality
		Soil contamination
	Container disposal	Residues

- Make timely observations of cattle to insure that basic needs are being met.
- Minimize stress when transporting cattle.
- Keep updated on advancements and changes in the industry to make decisions based on sound production practices and consideration for animal well-being.
- Persons who willfully mistreat animals shall not be tolerated.

Unfortunately, participation in BQA programs by cattle producers across the United States has been less than ideal. In recent years, the national BQA program has been evaluated as to its effectiveness at influencing producer behaviors related to beef safety and quality as well as the level of participation among cattle producers in this voluntary program. One of the first evaluations of the program occurred in 2006, in which the Joint Evaluation Advisory Committee (of the Cattlemen's Beef Board and NCBA) requested an external review of the beef checkoff-funded national BQA program by two university faculty members. The authors commended the BQA program for its extensive use of collaboration among diverse groups, a substantial reduction in injection site lesions from 1991 to 2001, existence of BQA programs locally in nearly every state, the BQA certification of approximately 65 000 producers, and the 'ability to educate a large number of producers about BQA in a relatively short time.' However, the authors also indicated that the BQA program could not continue to rely on past accomplishments and redundant training materials and that more standardization in core materials as well as an outline for a future strategy for BQA was needed.

One of the first objective evaluations of the BQA program, including the quantification of beef cattle producer knowledge about BQA and BQA-related issues, was conducted by the USDA National Animal Health Monitoring Service in 2007. When asked about their knowledge of BQA, 51.3% of beef cow/calf respondents indicated that they had heard of BQA, but only 22.2% of those that had heard of BQA had attended a BQA meeting or training session. Moreover, only 57.2% of producers who attended a meeting were actually BQA certified. Ultimately, less than 5% of cow/calf producers were BQA certified – a necessity to insure that producers are aware of BQA guidelines and recommendations. Another evaluation of BQA was conducted in 2011 on a state-by-state basis by surveying state BQA program coordinators. This effort was intended to identify BQA participation levels, characteristics of successful state programs, and future challenges associated with BQA. Results of that survey showed that considerable state-to-state variation exists among BQA programs, including oversight, funding sources, communication methods, and certification requirements. Furthermore, large opportunities existed by increasing the 'challenge' associated with certification (and recertification) tests and offering more BQA-related aspects, including additional levels and an auditing system, as well as dairy-, feedyard-, and youth-oriented BQA programs. It was documented that 709 BQA trainers existed nationwide to offer BQA certification. However, when estimates provided by state coordinators were summarized, just 50 832 producers were actively BQA certified as of 2011 (which equates to approximately 7% of cow/calf producers in the United States). Feedback from state BQA coordinators suggested that successful programs resulted from local trainings, university extension involvement, industry support, and training methods. However, challenges hindering success were related to inadequate funding, competing priorities among trainers, lack of producer participation and buy-in, absent financial incentives, and inconsistent programs across states.

Conclusion

The voluntary BQA program enables producers to improve product safety and quality and, subsequently, acceptance of their beef products by consumers. The guidelines that are outlined in the national BQA program are simply good management practices that will not only help producers to meet consumer demands but also help producers to be more economically viable by maintaining animal health and well-being in the entire production system. In reality, progressive cattlemen have gone beyond certification to actually verify that they are following BQA standards and are using that verification as a marketing tool to add extra value to their production system.

REFRIGERATION AND FREEZING TECHNOLOGY

Contents

Applications

SJ Lovatt, AgResearch Ltd., Hamilton, New Zealand

Glossary

Chilling Cooling an object to a temperature above its freezing temperature.
Freezing A cooling process that results in at least some of the water content of a material becoming solid in the form of ice crystals.
Freezing temperature The temperature at which a material starts to freeze.
Plate freezing Freezing an object by putting it into direct contact with metal plates that are, in turn, cooled by refrigerant.
Refrigeration The process of removing heat from an object.
Refrigeration application A specific use of refrigeration, such as chilling meat, freezing meat, air-conditioning, etc.

Introduction

The main application of refrigeration in meat processing is to cool meat, thereby reducing the rate at which meat deteriorates as a result of microbiological and chemical processes. This process is generally described as either 'chilling' or 'freezing,' depending on whether the aim is to reduce the product to a temperature above or below its freezing point, respectively. Refrigeration is also applied in meat plants as air-conditioning, in order to keep working areas at a comfortable temperature for staff and to limit microbial growth during cutting, boning, or further processing.

The effect that air-conditioning has on meat products is very similar to that of other forms of chilling. Although there are engineering differences between chilling and air-conditioning systems, they are considered together in this article. Freezing, however, has effects on meat products that are quite different from those of chilling, hence that is described in a separate section of this article. The final section discusses some of the important issues that must be considered in designing refrigeration applications.

The Chilling Process

For moisture-rich materials, such as meat, chilling is the process of cooling the material from some starting temperature down to some temperature at or above the freezing temperature of meat. The starting temperature is typically near live animal's temperature of approximately 38 °C in the case of chilling after harvest or near the maximum temperature of 60–80 °C in the case of chilling after cooking. The initial freezing

 doi:10.1016/B978-0-12-384731-7.00123-9

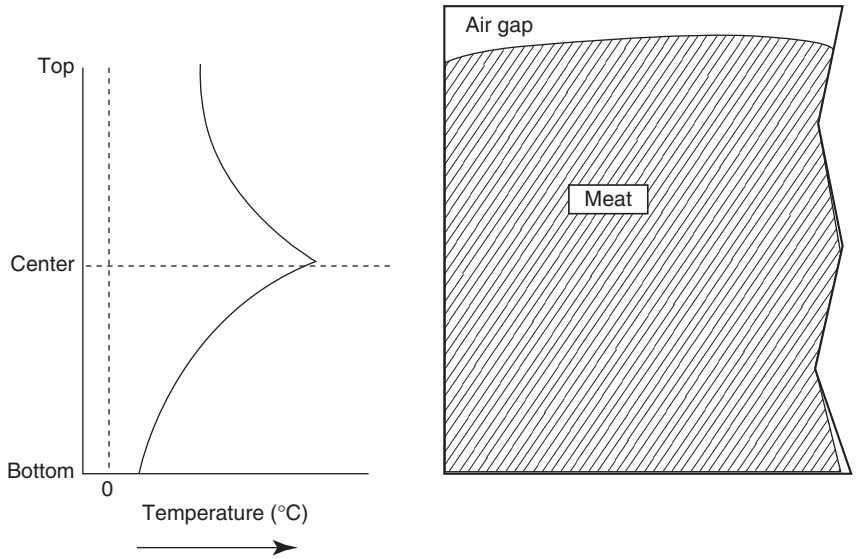

Figure 1 Typical temperature profile through the thickness of a meat carton during chilling. The static air layer in the top of the carton on the cooling acts as a thermal resistance, with the result that the warmest point in the carton is typically above the geometric center.

temperature is typically approximately $-1\,^{\circ}C$ for fresh meat or lower for processed products with some salt added.

To chill any object, the temperature outside of the object must be reduced below its current surface temperature. This will result in heat flowing away from the surface by conduction, convection, or radiation (depending on the chilling method used), causing the temperature of the surface to decrease. When the surface temperature has dropped below the temperature of the deeper parts of objects, those parts will also start to cool by conduction of heat to the surface. The objects will, therefore, develop a temperature profile in which some deep parts of the objects are the warmest, with the temperature gradually decreasing toward the surface, where the objects are the coldest. For a given thermal conductivity, large objects with high rates of heat transfer at the surface have a surface temperature that is proportionately much cooler than the warmest point, whereas small objects with low rates of heat transfer at the surface have surface temperatures that are proportionately only a little cooler than the warmest point.

Temperature Profiles and the Thermal Center

It is useful to define the point in a food material that will remain the warmest at any time during the cooling process or, alternatively, will be the last to freeze in a freezing process. This point is known as the thermal center and, if the temperature of food products is to be measured or predicted, the thermal center is usually the most important point where this should be done.

For homogeneous objects with a simple, regular shape and the same rate of heat transfer over the whole surface, the thermal center corresponds to its geometric center. For complex shapes, or if the rate of surface heat transfer varies from location to location, the thermal center can be at some distance from the geometric center. An example of this is seen in chilling or freezing cartons of meat, where an air gap is often left at the top of the carton and the rate of heat transfer through the top surface of the carton is, therefore, reduced by the insulating layer of static air. In this situation (illustrated in Figure 1) the warmest point during chilling is only a small distance under the top surface of the meat.

The geometry of carcasses or sides and the interplay of the surface heat transfer coefficient with that geometry are both complex and the thermal center must, therefore, be identified from the experience of making many temperature measurements during chilling processes. For example, the thermal center of beef sides is typically in a location known as the 'deep butt,' which can be found near the head of the thigh bone. In lamb carcasses, the thermal center has traditionally been described as being at the 'deep leg,' which is also against the thigh bone but perhaps a quarter of the way down from the pelvis. In practice, however, the low rate of cooling inside the body cavity of lamb carcasses can mean that a point between the thickest part of the shoulder and the inside of the cavity (the deep shoulder), and another point between the deepest part of the loin and the inside surface, can take almost as long to cool as the deep leg. Although the deep shoulder can often be the slowest cooling point in lamb carcasses in some chilling configurations, the deep leg or loin temperatures are measured most often because they correspond with the locations of higher valued cuts.

Chilling Methods

Objects exposed to a fluid that is cooler than objects' surfaces cool slowly by natural convection. This method is uncomplicated and has minimal equipment requirements, so natural convection air cooling was the original way in which meat was chilled – generally in the form of carcasses (for poultry and sheep meat), split or partially split into sides (for pork and beef), or quarters. The cold air itself was typically cooled by coils of tube filled with evaporating refrigerant, generally hanging from the ceiling of the chiller room.

Unfortunately, natural convection air chilling is both slow and relatively uncontrollable, because the rate of chilling is determined only by the thickness of meat and temperature of the air. For a given meat thickness, the rate of chilling can be accelerated by reducing the air temperature. The extent to which this can be achieved is limited because if the air temperature is more than a little below the initial freezing temperature of the meat, the meat surface could start to freeze. This would have detrimental consequences for product quality. As a consequence, the rate of chilling is relatively difficult to control in a natural convection process.

Probably the most common method used to chill food products is forced convection air chilling. In this method, fans are used to blow air over finned tubes filled with evaporating refrigerant. This cools the air, which passes over the food product, cooling the food and warming the air as heat is transferred from the food to the air. The air then passes back to the refrigerant evaporator to be cooled again. Using fans to move the air across the product allows the rate of chilling to be controlled by changing the velocity of the air, which makes a forced convection chilling process much more controllable than a natural convection chilling process.

Although the relationship between fluid velocity and heat transfer coefficient differs between fluids and different heat transfer situations, it is often possible to correlate heat transfer coefficient with velocity using a relationship with a form such as eqn [1].

$$h = av^b \qquad [1]$$

where, h is the surface heat transfer coefficient in W m^{-2} K^{-1}, v is the fluid velocity in m s^{-1}, and a and b are constants. Values of b typically range from 0.5 to 0.8, so (all other things being equal) doubling the fluid velocity in a given situation would typically increase the heat transfer coefficient by between 40% and 75%.

It is important to direct the air flow in a forced convection chiller so that it passes over products as evenly as possible to avoid large variations in chilling rate between different parts of the chiller. This can be achieved by the use of vanes or slotted ceilings that spread the air flow evenly across the product stow.

When moisture-rich food products, such as meat, are not wrapped in waterproof packaging during chilling, or while being processed in an air-conditioned area, the moisture on the surface and within the surface layer of the food can evaporate into the air. Because the air is cooled by contact with the refrigeration system's evaporator coils, its humidity is typically the saturation humidity at the temperature of the air leaving the evaporator. This means that the absolute humidity of the air is usually somewhat lower than that at the surface of the food. The driving force for moisture evaporation is the difference between the absolute humidity at the surface of foods (which is the product of the water activity and the saturation absolute humidity at the food surface temperature) and the absolute humidity of the air passing over the meat surface, so moisture evaporation will frequently occur while chilling unwrapped products. The rate of moisture loss can, therefore, be defined by eqn [2].

$$M = k_Y A(Y_{surf} - Y_{amb}) \qquad [2]$$

where, M is the rate of moisture loss in kg s^{-1}, k_Y is the surface mass transfer coefficient in kg m^{-2} s^{-1} (kg water/kg dry air), A is the exposed surface area of products in m^2, and Y_{surf} and Y_{amb} are the absolute humidities at the surfaces of objects and in the surrounding air, respectively, in kg water per kg dry air. Surface mass transfer coefficients are difficult to measure and few measurements have been made for meat processing situations. Fortunately, for the evaporation of water into air, the mass transfer coefficient can be related approximately to the surface heat transfer coefficient using the Lewis relation, shown in eqn [3], where C_{air} is the humid heat capacity of the air per unit of dry air mass in J kg^{-1} K^{-1}.

$$k_Y \approx \frac{h}{C_{air}} \qquad [3]$$

Moisture evaporation has three key effects on the chilling process:

1. The surfaces of meat will become dry and appearances will be undesirable.
2. The mass of meat products will be reduced by the moisture that evaporates. Because meat is often sold on a weight basis, a reduced mass of meat will result in reduced revenue when the meat is sold.
3. Moisture evaporation increases the effective surface heat transfer coefficient compared with pure convection, thereby increasing the rate of chilling.

Although it is frequently desirable to increase the rate of chilling, substantial increases in chilling rate while chilling in air can usually only be achieved through moisture evaporation. This increase in chilling rate is, therefore, at the expense of significant weight loss and degradation of products' surface appearance – both of which are undesirable. These difficulties can be avoided by spraying surfaces of meat with water intermittently during chilling. Most countries and customers have rules for most meat products that prevent weight from being added to meat before sale, so the amount and frequency of the water sprays are usually arranged to ensure that the product loses a little weight during the process, in order to provide a safety margin that avoids infringing such rules. Exceptions to these rules often include salted products, such as ham.

Spray chilling can eliminate weight losses found in air chilling of carcasses or sides, but experiences with respect to the effect of spray chilling on product surface appearances have been mixed. In some cases, appearances have been reported to be largely indistinguishable from that of air-chilled products, but cases have been reported where meat surfaces developed a streaked appearance and somewhat increased microbial growth. It might be best to conclude that considerable care and perhaps some trial and error may be necessary to achieve the best results with spray chilling.

The last common chilling method is liquid immersion chilling, used for red meats in waterproof wrappings, wrapped cooked products, unwrapped salted products, and (sometimes) bare poultry carcasses. In this method, meat products are immersed in cold liquid (generally water or brine) and cooled quickly as a result of the high heat transfer coefficient that is found between liquids and solids. As with spray chilling, when bare products are immersed in water, it is usually

important to ensure that products contain no more water at the end of the chilling process than they did at the start.

The Freezing Process

The freezing process is similar in most respects to the chilling process described in the Section The Chilling Process, except that the temperature to which the water-rich food products are exposed must be lower than the initial freezing temperature of foods. This leads to the growth of ice crystals in foods during the cooling process.

Ice Crystal Growth

When meat is cooled below its initial freezing temperature, temperature of the meat surfaces must drop somewhat below that temperature before there is sufficient temperature driving force to overcome the energy barrier associated with ice crystal nucleation. This phenomenon is known as 'undercooling' or 'supercooling' and its extent depends on the availability of suitable seed sites for the nucleation process. The extent of supercooling tends to be greater for greater rates of surface cooling, but the abundance of nucleation sites usually present in meat means that the effects of supercooling usually have little practical impact on the rate of freezing or on meat quality in typical meat processing situations.

Once ice crystals start to grow in meat, a freeze concentration process takes place in which the first part of the ice to freeze is almost pure water and solutes diffuse away from the growing ice crystals. As the solute concentration in the remaining unfrozen water becomes higher, the freezing point of the solution is progressively depressed, with the result that ice crystals forming later contain increasing concentrations of solutes. As a result, meat (unlike a pure substance) freezes progressively over a range of temperatures. Indeed, several percent of the moisture content in meat never freezes, even at $-40\,^{\circ}C$.

After freezing starts, it can progress at any given instant either by growing an existing ice crystal or by nucleating a new crystal. The former case tends to occur preferentially when freezing is relatively slow, whereas the latter case occurs preferentially when freezing is fast, with the result that smaller numbers of larger ice crystals are formed by slow freezing and larger numbers of smaller crystals are formed by fast freezing. Both freeze concentration and mechanical damage to cells caused by ice crystal growth can cause some quality degradation in meat, but the macroscale quality changes caused by well-designed freezing processes do not necessarily have demonstrable effects on eating quality.

Whatever the initial size of the ice crystals formed by freezing is, the crystals are relatively unstable and subsequent frozen storage will result in recrystallization, in which large ice crystals grow at the expense of smaller ones. Recrystallization is enhanced by temperature fluctuations, so it is preferable to maintain stable temperatures during frozen storage.

Temperature Profiles in Freezing

A sufficiently high rate of heat extraction at surfaces could make it possible for the surfaces of food products to start freezing while the thermal center is significantly warmer than the freezing temperature of foods. However, in most food freezing situations the rate of heat extraction at surfaces is low enough that the thermal center temperature reaches the freezing temperature almost as soon as the surface starts to freeze. As a result, the whole of food products between the point where freezing commences (known as the freezing front) and the thermal center typically spends much of the freezing process with its temperature equal to the initial freezing temperature. This means that the temperature of the thermal center can remain constant for much of the process and measuring that temperature will give no indication of the extent to which products are frozen. However, once the freezing front reaches the thermal center, the temperature at that point will drop very quickly. A typical thermal center temperature profile is shown in Figure 2.

Freezing Methods

Except for spray chilling, the cooling methods available for chilling processes can all be considered for freezing processes. The fact that the cooling medium in a freezing process must be colder than the freezing temperature of the meat means that some additional methods are available for freezing that are not appropriate for chilling.

The need to transfer heat from products to air or liquid, and then from the air to the refrigerant evaporator, is a drawback of any air- or water-based cooling process. This double heat transfer step can be replaced by a single step if meat can be put in direct contact with the refrigerant evaporator. Plate freezing processes achieve this by clamping slabs of meat (either bare or in packaging) between metal plates filled with evaporating refrigerant as well as by providing the high rate of heat transfer that exists when good solid-to-solid contact is achieved. Eliminating one heat transfer step means that, for a given refrigerant evaporating temperature, the temperature of the environment around the meat product is colder in a plate-freezing system than in an air or immersion freezing system. One drawback to this process is that the product must

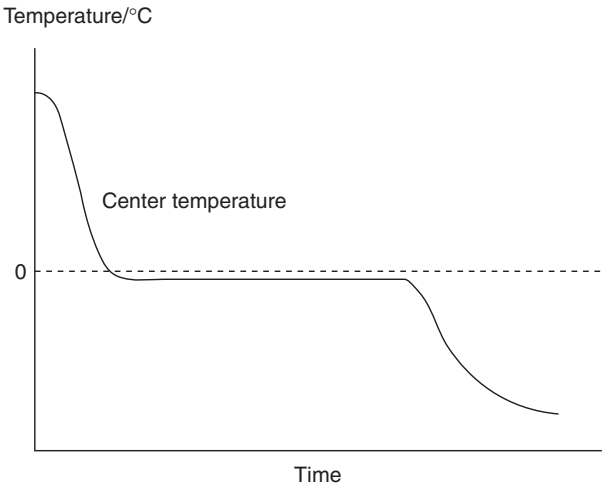

Figure 2 Typical temperature profile at the thermal center during a freezing process.

have flat, parallel surfaces with which the plates can make contact.

Cryogenic freezing, achieved by spraying meat with liquid nitrogen or carbon dioxide, or (occasionally) immersing the meat in liquid cryogen, also results in much shorter freezing times than that of air freezing, both due to the large initial temperature difference between the cryogen and meat products and to the high rate of surface heat transfer resulting from the boiling cryogen. As with plate freezing, the benefits of cryogenic freezing relative to other approaches become smaller as thicknesses of products increase, but the cryogenic freezing has an added advantage that it does not require any mechanical refrigeration equipment – requires only a tank to contain the cryogen and a suitable spraying arrangement. However, the cost of purchasing cryogenic liquid is relatively high in most locations, with the result that it is often prohibitively costly to freeze large quantities of meat in this way.

Designing Refrigeration Applications

In selecting the product temperature profile that should result from chilling or freezing after slaughter, the key quality criteria are that:

- Chilling must reduce the temperature of any meat surface, where spoilage or pathogenic microorganisms might be present, sufficiently quickly so that the number of those organisms does not grow to an undesirable level by the end of the chilling process.
- Chilling must reduce temperature slowly enough so that the biochemical process that converts muscle to meat reaches completion. This process proceeds much more quickly at higher temperatures than at lower temperatures.

For chilling after cooking, muscle has already been converted into meat, so the second criterion is not important, but the higher temperatures involved mean the microbiological growth criterion is even more important. In either case, microorganisms would normally be expected to be present on the outer surfaces of meat, but for meat products or packages that are put together from several pieces of meat, microorganism-bearing surfaces might also exist deep in the combined package. In that situation, microorganisms can be exposed to the thermal center temperature profile rather than the surface temperature profile. During cooling, the center is generally warmer than the surface so this can provide more scope for microbial growth at the center than at the surface for composite meat products.

In some situations, other criteria must be considered in designing a chilling or freezing process, including the health and safety of staff carrying out subsequent processing. For example:

- In carcass chilling processes before cutting or boning operations, it is desirable not to chill carcasses in such a way that the surface fat becomes hard and therefore difficult to cut. Some processes have deliberately reheated surfaces of carcasses so that the fat is warmer and therefore softer, or they have allowed carcass temperatures to equilibrate for some time after chilling and thereby allowed surface temperatures to rise as the thermal center temperatures fell.
- In processes where meat is to be handled afterward, it is desirable for the surfaces of meats to be dried during chilling to make them easier to manipulate. This must be balanced with the desire to retain the maximum amount of moisture in meat.
- Some freezing processes can result in unattractive surface appearances and it is helpful to design the processes to correct this problem. In one case, for example, it was reported that the surface appearance of an immersion-frozen vacuum-packed offal product was unsatisfactory as it emerged from the liquid bath, but this was corrected by spraying the offal packs with water, which briefly thawed the meat surface and then allowed it to refreeze more slowly. The slower refreezing appeared to generate larger ice crystals that reflected light better and provided a more attractive surface.

Many refrigeration processes have traditionally been designed very satisfactorily by designers who use their judgment and experience of many similar processes to ensure that the processes perform as required. However, with the increasing number of different variables that must be taken into account, designers increasingly use mathematical models to complement their judgment. A range of mathematical models from simple (but approximate) to complex (but relatively accurate) exists to calculate temperature profiles of a food product over time during cooling processes. From the temperature profile and other data about the process, mathematical models can be used to predict microbial growth and meat quality at the end of the processes. Models are also available to predict heat loads that must be removed by the refrigeration system, including the products' heat content, heat loads due to equipment in the chiller or freezer (e.g., fans), and heat infiltrating into the room through the walls, ceiling, floor, and doorways. If predicted temperatures and heat load profiles, hygiene, and meat quality resulting from a process are found to be satisfactory to achieve product specifications, equipment can then be selected to meet those requirements. If not, a range of different chilling conditions may be tried until a satisfactory set can be found. The details of models that may be used for refrigeration process design are beyond the scope of this article, but some may be found in other articles and in the Further Reading section.

Glossary

Conduction, thermal Mechanism for heat transfer. The process of heat transfer through a solid material/medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles.

Convection, thermal Mechanism for heat transfer. The transfer of heat from one place to another by the movement of fluids and is usually the dominant form of heat transfer in liquids and gases.

Heat transfer coefficient Coefficient used in thermodynamics to calculate heat transfer, typically by convection or phase change, between a fluid and a solid.

Pasteurization A form of heat treatment that kills certain vegetative bacteria and/or spoilage organisms in milk and other foods. Temperatures less than 100 °C are used.

Radiation, thermal Mechanism for heat transfer. Electromagnetic radiation generated by the thermal motion of charged particles in matter. All matter with a temperature greater than absolute zero emits thermal radiation.

Refrigeration May be defined as the process of removing heat from any substance to: (1) render colder – reduce temperature, (2) change its state – for example, water to ice, and (3) maintain its state – preserving foods, storing ice.

Water activity (a_w) A measure of the available water in a substance. 'High a_w' foods support bacterial growth, whereas 'low a_w' do not. This is not the same as water content. Some foods with a high water content have a relatively low a_w because the water is bound up with dissolved salts or sugar, for example, jam.

Introduction

Refrigeration equipment is required to initially chill or freeze meat and then maintain its temperature throughout the cold chain. After harvest, meat is normally refrigerated in the form of whole carcasses, sides, or quarters. Although some meat is distributed in these forms, a growing proportion is boned out into primal cuts and transported, frozen, or chilled, in 1 t pallets of 25 kg cartons. After further processing, meat and meat products are often stored, transported, and displayed in consumer packs. These can be as small as 50 g vacuum packs, for sliced cooked meat, to modified atmosphere packs containing 3–4 kg meat joints.

Basic Refrigeration System

Mechanical refrigeration systems operate using the same basic refrigeration cycle (Figure 1). A low-pressure liquid refrigerant is allowed to evaporate to a gas within a coil. This process requires heat, which is extracted from (thus cooling) any medium surrounding the 'evaporator' coil. The gas from the evaporator is compressed in the 'compressor' to a high-pressure hot gas. This high-pressure hot gas is then passed through another coil where it condenses, which releases heat into any medium surrounding the 'condenser' coil. This high-pressure, cold, liquid refrigerant then passes though an 'expansion valve,' back to the evaporator.

In a direct expansion system, the evaporator coil is either in contact with the meat to be refrigerated or the media, i.e., air, brine, etc. surrounding the meat. In a secondary refrigeration system, a liquid, i.e., water, brine, etc. is cooled by passing it over the evaporator coil. This cooled liquid is pumped through cooling coils into different parts of the meat plant where it is used to cool air that is subsequently used to cool the meat.

Primary Chilling

Immediately after harvest, red meat and poultry carcasses are at a temperature close to that for the optimal growth of many pathogenic and spoilage organisms. Primary chilling systems rapidly reduce the carcass temperature to a temperature where microbial growth is minimal or does not occur at all.

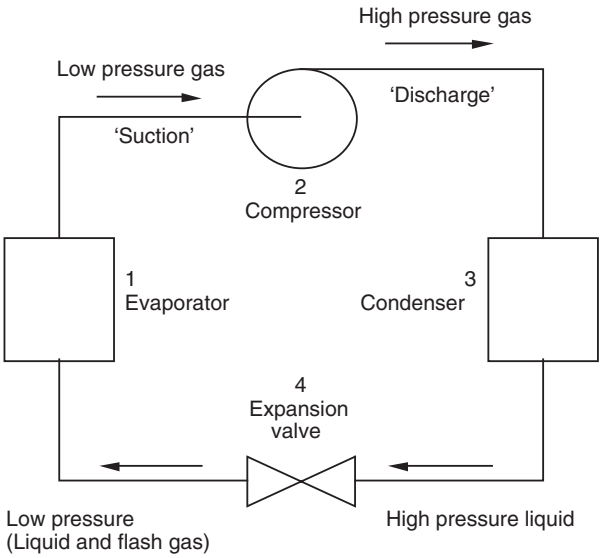

Figure 1 Basic refrigeration system.

 doi:10.1016/B978-0-12-384731-7.00125-2

Red Meat

Most red meat is chilled in large insulated rooms. A steel structure in the roof supports banks of rails from which carcasses or sides are hung. The rooms are usually manually loaded by pushing the suspended carcasses along connecting rails in the abattoir onto the chill room rails. Sets of manually operated points are used to direct the carcasses onto the required rail. When the room is full, the doors are closed and the batch of carcasses is left for a predetermined time before removal. The rooms are then cleaned and the next batch loaded.

Chill rooms are designed in a way that there is free space between the carcasses or sides when they are fully loaded. In practice, they are sometimes badly and/or overloaded such that carcasses are in contact with each other or the walls of the room, which restricts the passage of refrigerated air over the surfaces to be cooled and allows cross-contamination between carcass surfaces.

The cold refrigerated air is produced by evaporator coils that are usually positioned at the top of the chill room above the steel support structure. Fans mounted on the face of the evaporator coils draw or push air through the coils, where it is cooled, and then distribute it over the carcasses to be cooled. As it passes over the warm meat, the air rises in temperature before it is returned to the coil to be recooled.

Simple batch air cooling systems are commonly used because they are economical, hygienic, easy to operate, and versatile. Relatively low rates of heat transfer are attained from product surfaces in air systems and chilling times are consequently long. They are also very dependent on the localized air temperature and velocity over the surface of the carcasses. In simple, in single-stage batch chilling systems, the risk of surface freezing limits the lowest air temperature that can be used.

In high-throughput abattoirs, the carcasses/sides are conveyed through a chilling tunnel or refrigerated room, usually by an overhead conveyor or on a belt. This overcomes the problem of uneven air distribution because each item is subjected to the same velocity/time profile and the carcasses/sides are kept separated so that all the surfaces are exposed. Different air conditions can also be maintained throughout the system. Normally, for pork, the air temperature in the first stage of the process will be less than 0 °C – sometimes as low as −30 °C. This will rapidly reduce the surface temperature of the carcasses/sides, slowing both the rate of weight loss and bacterial growth and increasing the rate of heat loss. In later stages, the temperature is progressively raised to avoid surface freezing. Temperatures around 0 °C are more typical in lamb chilling. In large US beef plants, carcasses are conveyed through a 'hot box' where they are sprayed with cold, often chlorinated, water before being placed in batch chillers.

In the initial stages of chilling, the rates of heat and moisture loss are very high. Consequently, the evaporators have to be very large to remove the heat, and the spacing of the 'fins' on the coils is wide. Moisture from the meat condenses and freezes on the evaporator coil and the ice may block the passage of air through the coil if the spacing is too small.

In some carcasse/side chilling systems for beef and lamb, a spray chilling system similar in principle to that described below for poultry is sometimes used.

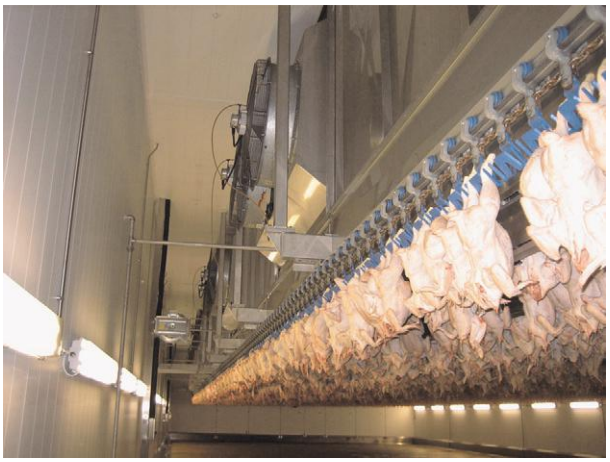

Figure 2 Continuous air chilling system for whole poultry.

Poultry Carcasses

Air, spray/evaporative, and immersion systems are the three most common methods of chilling dressed poultry.

Air

As with red meat, poultry carcasses are often chilled in large insulated rooms. The basic refrigeration equipment is identical to that used in red meat plants. Owing to the scale of production in most poultry abattoirs, the dressed carcasses are normally conveyed on rails through the room (Figure 2) or tunnel.

Spray/Evaporative Chilling

With spray chilling systems, the carcasses are transferred after soft scalding to an air chiller where sprays of potable water are applied at intervals, for example, at 5 and 15 min after the start of air chilling and on four or five more occasions during the whole chilling process. The principle of the process is to increase the rate of evaporative heat loss and, by replacing the water lost during air chilling, reduce the overall weight loss.

Immersion

Most poultry destined to be frozen are initially chilled by being immersed in chilled water or ice/water mixtures. In the US, immersion chilling is also used for poultry destined for sale as chilled birds. The process is normally a counter flow system in which the birds are conveyed in the opposite direction to the water flow to minimize cross-contamination (Figure 3).

Primary Freezing Equipment

Freezing of red meat and poultry in carcass, side, quarter, or boned primal form is normally carried out in an air blast freezer. However, plate freezers are often used for offal and low-value materials.

Air Blast

Systems range from the most basic, in which a fan draws air through a refrigerated coil and blows the cooled air around in an insulated room, to purpose-built conveyorized blast freezing chilling tunnels. The big advantage of air systems is their versatility, especially when there is a requirement to freeze a variety of irregularly shaped products.

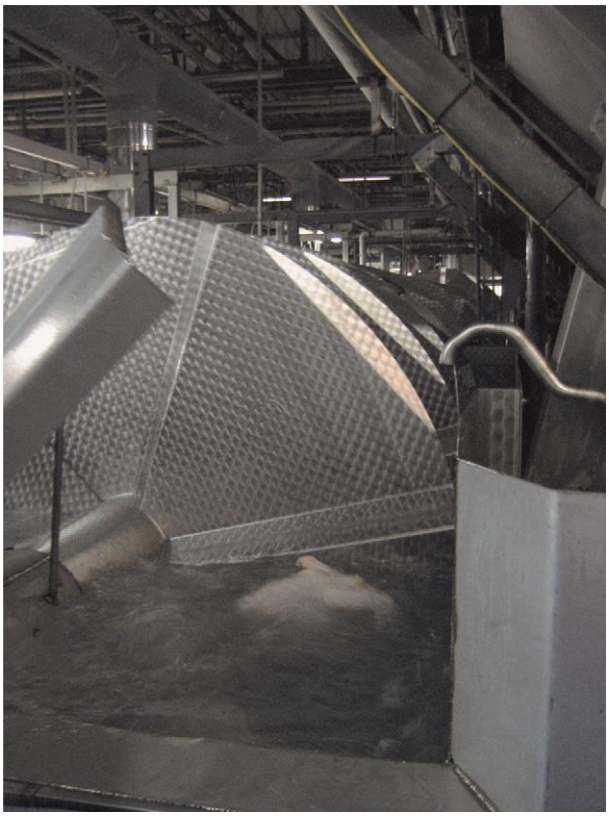

Figure 3 Spin chiller for whole poultry.

Carcass meat is usually hung on rails in order to be frozen and boxed products are carried on racks or trolleys. Freezing times for beef quarters, pork and lamb carcasses and cartons of primals, poultry carcasses, or joints are long, typically 10 h to 3 days. Continuous freezing equipment is, therefore, only used in very high-throughput plants.

In a typical continuous air blast freezer, a shelf is automatically filled with a row of 25 kg cartons. The shelf is hydraulically pushed into the freezing chamber and a second shelf takes its place. A chain system then slowly moves the shelves of cartons through the freezing chamber. Banks of very large evaporator coils with high-powered fans situated inside the chamber circulate air, typically at −35 °C, 3 ms^{-1}, over the surface of the cartons. At the end of the desired freezing period, the shelf automatically emerges from the chamber and is unloaded ready to start the cycle again.

Plate Freezing

Modern plate freezing systems differ little in principle from the first contact freezer patented in 1929 by Clarence Birdseye. Essentially, the product is pressed between hollow metal plates containing a circulating refrigerant (Figure 4). A hydraulic cylinder is used to bring the freezing plates into pressure contact with the product. These plates can be either horizontal or vertical. Contact freezing offers several advantages over air cooling, including much better heat transfer and significant energy savings. However, the need for good contact between the plates and the product necessitates regularly shaped products with large flat surfaces.

Good heat transfer is also dependent on product's thickness and the conductivity of the product. Plate freezers are often limited to a maximum thickness of 50–70 mm to gain the most benefit from the high rate of surface heat transfer. Air spaces in packaging and fouling/contamination of the plates can have a significant effect on cooling time. For example, a water droplet frozen on the plate can lengthen the freezing time of the product in contact with that plate by as much as 30–60%.

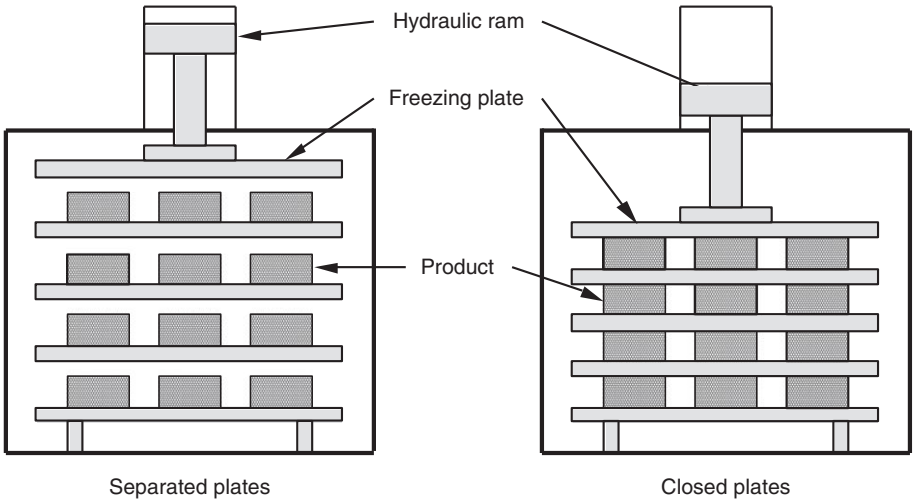

Figure 4 Example of a horizontal plate freezer.

Secondary Chilling and Freezing Systems

After secondary processing, i.e., cooking, portioning, or packing, meat cuts and products require further chilling either to remove the heat gained during the processing, or to be frozen before storage and distribution.

Secondary chilling and freezing equipment tends to be different from primary equipment because the individual items tend to be much smaller and the chilling/freezing times are consequently much shorter. Again, air-based refrigeration systems are the most common, but spray, vacuum, and cryogenic systems may also be used.

Air

In many small operations, cooked products are batch chilled on, or in, racks of trays (2.5–5 m high) that are manually loaded into a chilling tunnel (Figure 5). Very similar systems are often used to freeze batches of small products, the only difference being the temperature employed and the processing time. These systems, however, involve double handling, and it is difficult to achieve even air distribution through the layers. For larger operations, it is more satisfactory to use linear tunnels or spiral chillers/freezers. Linear tunnels are of simpler construction than spirals but are restricted by the length of belt necessary to achieve the cooling time required and the space available in the factories. Spiral chillers are, therefore, often a more viable alternative.

Recently, the use of impingement technology to increase the surface heat transfer in air chilling/freezing systems has received attention. Impingement is the process of directing a jet or jets of air at a solid surface to effect a change. The very high velocity (20–30 ms^{-1}) impingement air jets 'break up' the static surface boundary layer of gas that surrounds a food product. The resulting medium around the product is more turbulent and the heat exchange through this zone becomes much more effective. Impingement chilling/freezing is best suited for products with high surface area to weight ratios (i.e., hamburger patties or products with one small dimension). Testing has shown that products with a thickness less than 20 mm freeze most effectively in an impingement heat transfer environment. The process is also very attractive for products that require very rapid surface freezing and chilling.

Spray

Spraying with ambient or chilled water is an effective method of initially cooling cooked products that can withstand wetting, for example, hams, sausages, chubs, etc. Spray bars can either be fitted into the top of the cooking vessel itself or the hot product transferred to a separate spray-cooling booth.

Vacuum

Vacuum cooling is mainly applied to solid products having a large surface area to volume ratio and an ability to readily release internal water and to liquid or solid/liquid mixtures. Pie and pastry fillings and components of ready meals are commonly cooked in large heated vats under high pressure, and then cooled (often in the same vats) under low pressure. Products are placed in a sealable chamber, which is then evacuated to a pressure of typically 500–700 Nm^{-2} (atmospheric pressure is 101 kNm^{-2}). At reduced pressure, water readily evaporates from the surface of the products, and as it does so, the latent heat of evaporation is drawn from within the products and hence rapid cooling rates are achieved. In general terms, a 5 °C reduction in product temperature is achieved for every 1% of water that is evaporated. As this is a batch process, it requires greater production flexibility and has a high capital cost; moreover, if the pressure is reduced too fast, internal boiling may damage the product.

Cryogenic

Cryogenic cooling uses refrigerants, such as liquid nitrogen (LN) or solid carbon dioxide (CO_2), directly. The method of

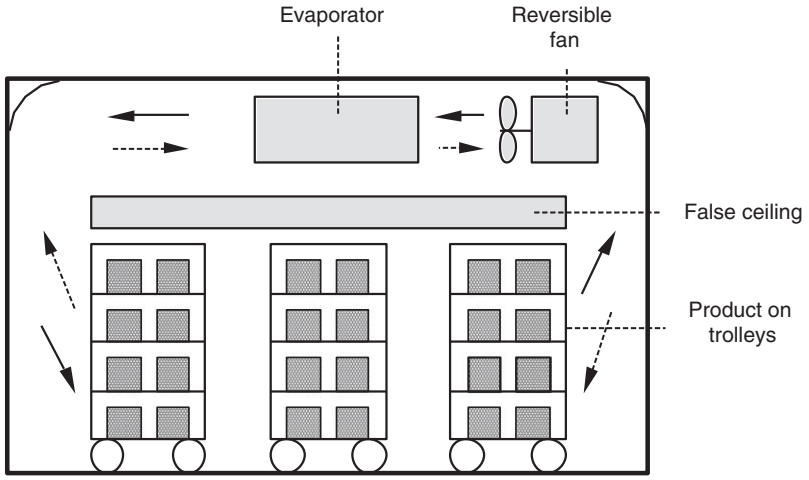

Figure 5 Batch chilling tunnel for cooked products.

cooling is essentially similar to water-based evaporative cooling, i.e., cooling is brought about by boiling off the refrigerant; the essential difference is in the temperature required for boiling. Also, using the latent heat absorbed by the boiling liquid, sensible heat is absorbed by the resulting cold gas.

Owing to very low operating temperatures and high surface heat transfer coefficients between product and medium, cooling rates in cryogenic systems are often substantially higher than other refrigeration systems.

This process is mainly used for small products such as burgers, ready meals, etc. The most common method is by direct spraying of LN onto a food product while it is conveyed through an insulated tunnel. Avoiding surface freezing of the product is the main problem in using cryogens for chilling, particularly when direct spraying; hence, LN is occasionally used indirectly in order to produce cold air that is then blown onto the product.

Cooling of solids and solid/liquid mixtures during cutting and mixing is increasingly common to prevent heating of products due to mechanical movement of the mixing and cutting blades. LN and liquid, or solid CO_2, are commonly employed for such processes.

High Pressure

High-pressure freezing and 'pressure shift' freezing in particular are attracting considerable scientific interest. The meat is cooled under high pressure to subzero temperatures but does not undergo a phase change and freeze until the pressure is released. Rapid nucleation occurs, which results in small, even ice crystals. However, studies on pork and beef have failed to show any real commercial quality advantages, and an increase in toughness was found in one study.

Storage

Most unwrapped meat and poultry and all types of wrapped foods are stored in large air-circulated rooms. To minimize weight loss and appearance changes associated with desiccation, air movement around unwrapped product should be the minimum in order to maintain a constant temperature. With wrapped products, low air velocities are also desirable to minimize energy consumption.

Using a false ceiling or other form of ducting to distribute the air throughout the storage room can substantially reduce variations in velocity and temperature. Using air socks, an even air distribution can be maintained with localized velocities not exceeding 0.2 ms^{-1}.

Transportation

Most International Standard Organization containers for food transport are either 6 or 12 m long, hold up to 26 ton of product, and can be 'insulated' or 'refrigerated.' The refrigerated containers incorporate insulation and have refrigeration units built into their structure. The units operate electrically, either from an external power supply on board the ship or dock, or from a generator on a road vehicle. Insulated containers either utilize plug-type refrigeration units or may be connected directly to an air-handling system in a ship's hold or at the docks. Close temperature control is most easily achieved in containers that are placed in insulated holds and connected to the ship's refrigeration system. When the containers are fully loaded and the cooled air is forced uniformly through the spaces between cartons, the maximum difference between delivery and return air can be less than 0.8 °C. The entire product load in a container can be maintained to within ±1.0 °C of the set point.

Refrigerated containers are easier to transport overland than the insulated types but often have to be carried on deck when shipped because of problems in operating the refrigeration units within closed holds.

For bulk transportation of frozen meat, refrigerated cargo ships are commonly used. Frozen meat is generally stored and transported at −18 °C or below. Unlike chilled meat, small temperature changes during loading and unloading can be tolerated with frozen meat.

The majority of current road transport vehicles for chilled foods are refrigerated using mechanical, eutectic plates, or LN cooling systems.

Mechanical Units

Many types of independent engine and/or electric motor-driven mechanical refrigeration units are available for lorries or trailers. One of the most common is a self-contained 'plug' unit that mounts in an opening provided in the front wall of the vehicle. The condensing section is on the outside and the evaporator on the inside of the unit, separated by an insulated section that fits into the gap in the wall. Units have one or two compressors. Depending on their capacity, these can be belt driven from the vehicle but are more usually driven direct from an auxiliary engine. This engine may use petrol, either from the vehicles' supply or from an independent tank, or may use liquid petroleum gas. Many are equipped with an additional electric motor for standby use or for quiet running, for example, when parked or on a ferry.

Eutectic Plates

Eutectic plate cooling systems are used in refrigerated vehicles serving local distribution chains. The eutectic plate consists of a coil, through which a primary refrigerant can be passed, mounted inside a thin tank filled with a eutectic solution. Standard eutectic solutions freeze at temperatures between −3 and −50 °C. A number of these plates are mounted on the walls and ceilings or used as shelves or compartment dividers in the vehicles. Two methods are commonly used for charging up the plates: (1) when the vehicle is in the depot, the solutions are frozen by coupling the plates to stationary refrigeration plants via flexible pipes, and (2) a condensing unit on the vehicle is driven by an auxiliary drive when the vehicle is in use or an electric motor when stationary. Eutectic systems are chosen for the simplicity, low maintenance, and quietness of their operation but can suffer from poor temperature control.

Liquid Nitrogen

A typical LN system consists of an insulated LN storage tank connected to a spray bar that runs along the ceiling of the transport vehicle. LN is released into the spray bar via a thermostatically controlled valve and vaporizes instantly as it enters the body of the vehicle. The air is then cooled directly utilizing the change in the latent and sensible heat of the LN. Once the required air temperature has been reached, the valve shuts off the flow of LN and the temperature is subsequently controlled by intermittent injections of LN.

Retail Display

In general, display cabinets have to accommodate three types of meat and meat products: (1) chilled wrapped, (2) unwrapped, and (3) frozen wrapped products. Cabinets with a big display area and an absence of doors are generally preferred, but this leads to a higher heat gain and higher operating costs to maintain correct temperatures. Retail display consumes almost 50% of the total refrigeration energy used in the cold chain.

Chilled Wrapped

A typical cabinet has a refrigeration unit behind the display area. Chilled air from the refrigeration unit is blown by a fan and delivered to the relevant area by duct work behind the display area (Figure 6). After the air has been delivered to the display area, it is then drawn back into the duct through a grille and is refrigerated again to continue the cycle.

The duct provides two functions: provides cold air through the holes in the rear panel and provides an air curtain at the front of the cabinet. The holes in the rear panel direct chilled air over the food and the air curtain provides a thermal barrier between the chilled display area and the store.

Chilled Unwrapped

Display cabinets for delicatessen products are available with gravity or forced convection coils and the glass fronts may be nearly vertical or angled up to 20°. Sections through three of the commonest types of delicatessen cabinets are shown in Figure 7. In the gravity cabinet (Figure 7(a)), cooled air from the raised rear-mounted evaporator coil descends into the display well by natural convection and the warm air rises back to the evaporator. In the forced circulation cabinets (Figure 7(b) and (c)), air is drawn through an evaporator coil by a fan and then ducted into the rear of the display, returning to the coil after passing directly over the products (Figure 7(b)), or forming an air curtain (Figure 7(c)), via a slot in the front of the cabinet and a duct under the display shelf.

Frozen Wrapped

There are a number of different types of display cabinets for frozen meat.

Chest cabinets, similar to domestic freezers with products stored generally on one horizontal shelf. Well cabinets have access from only one side of the cabinet, whereas Island cabinets have access to products from all sides. Cabinets can be open or lidded. Air distribution can be forced or gravity.

Multideck cabinets, similar to the chilled cabinets shown in Figure 6, incorporate a number of tiered shelves (graduated or horizontal) with open or glass door front access. Air distribution is often forced.

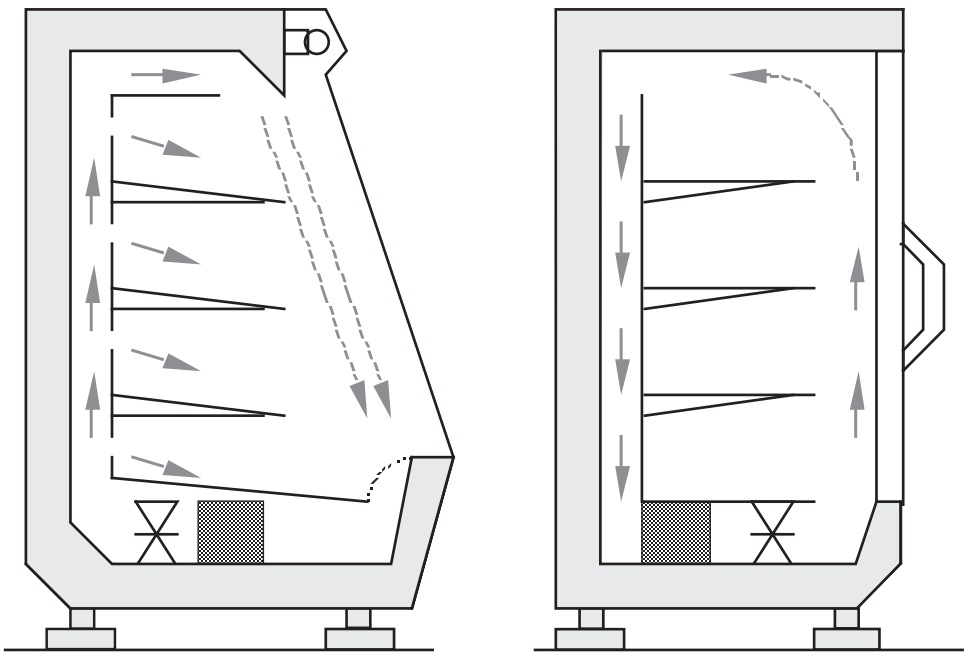

Figure 6 Multideck display cabinet for wrapped products.

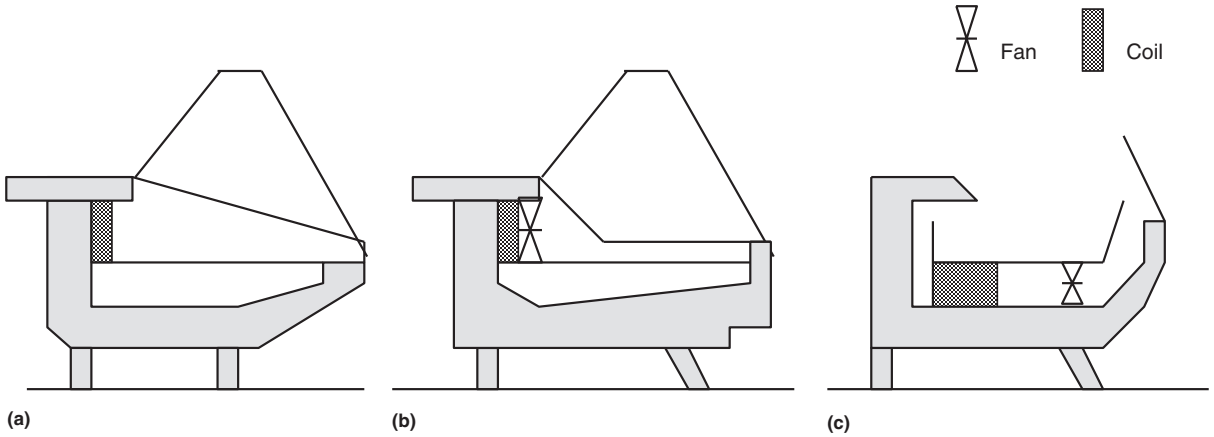

Figure 7 Three types of retail display cabinet for unwrapped products.

Domestic Storage

Consumers commonly store meat and meat products in refrigerators, freezers, or fridge–freezers. These are insulated boxes ranging in size from 0.04 to more than 1 m^3 and they are sold in a range of configurations, which depend on the orientation and type of evaporator coil. Traditional refrigerators with the coil forming an ice box at the top are increasingly being replaced by 'larder' type systems with the coil built into the back of the device.

Freezers are typically the top opening 'chest' design or are 'upright' with one or more doors on the front and internal trays or compartments.

Combination fridge–freezers with a refrigerator mounted above a freezer compartment have taken a majority share of the European market. The large combination appliances with a refrigerator one side and a freezer on the other are common in the USA and are increasingly being sold in other countries.

Glossary

Freezer burn A condition that occurs when frozen meat has been damaged by dehydration and oxidation, due to air reaching the product.

Freezing rate The time to transverse a given temperature range, i.e., freezing time (recommended by the International Institute of Refrigeration). Freezing time for meat is often defined as the time taken to pass from 1 °C (approximately the beginning of freezing in the case of meat) to −7 °C, at which point approximately 80% of the water is frozen.

Lipid oxidation The oxidative degradation of lipids; can result in rancid and other undesirable off-flavors. It may also influence the texture and color of meat products.

Storage life The length of time a food product can be stored under specified environmental conditions, for example, frozen, without being sensorially unacceptable or constituting a health risk.

Introduction

The fundamental reason for freezing meat and other food products is preservation. Traditionally, animals slaughtered for meat were consumed immediately. Preservation was, therefore, not necessary. However, as surplus meat began to be produced, or production peaked at certain times of the year, preservation methods were required, so that excess product could be stored and used later, or – as today – distributed, stored, and sold in a different location, sometimes on the other side of the world.

One of the earliest preservation methods for meat, along with other methods such as salting, curing, and smoking, was through reducing product temperature by packaging products in ice, i.e., essentially refrigeration. The advantage of refrigeration over other early preservation methods was the 'relatively' small change in product quality attributes. Freezing was a natural progression from refrigeration, as technologies evolved that permitted the reduction of product temperatures below the freezing point. This logical progression significantly extended the storage life of meat products.

Today, a substantial portion of the meat consumed around the world has been frozen for storage and/or distribution, particularly in areas where local demand exceeds production. However, for a long time, frozen meat has suffered from a reputation of inferior quality compared with that of fresh 'chilled' meat, particularly in the eye of the general public. This most likely occurred in the first instance because frozen meat was generally frozen without a prior storage period at refrigerated temperatures to allow the meat to tenderize. However, consumers are happy to purchase chilled meat and freeze it at home; possibly because they feel that they are in control of the situation. Notwithstanding this fact, freezing remains the most viable solution for long storage life of meat and meat products. The hotel and restaurant trade is aware of the advantages of frozen product with its associated benefits for inventory control.

As meat is composed of a complex of soluble and structural proteins, fat, and electrolytes, its freezing properties are more complex than a single-phase water-based system. However, many aspects of the physics and freezing of such simple systems are important in freezing meat, and the preceding articles on principles and application of refrigeration and freezing technology as well as 'Further Reading' should be consulted to understand the physics involved. The dynamic changes from the producer through the slaughter procedure, carcass processing, and the temperature control through the whole marketing chain, including freezing, all interact with the unique composition of meat. One must keep in mind how the entire supply chain affects the final quality attributes of the meat.

The areas of the freezing process that have a major impact on product quality consist of three steps: (1) freezing, i.e., reducing the product temperature to the temperature at which the meat will be stored; (2) frozen storage time and temperature characteristics; and finally (3) how the product is thawed before further processing or cooking. The three steps have to be controlled and applied correctly so that they do not negatively affect the quality attributes. However, it should be kept in mind that the quality of frozen meat is also governed by the supply chain preceding the freezing process; in other words, freezing must been seen in the context of the entire supply chain, not merely as an add-on. Ultimate product quality can only be optimized by careful control of the totality of the value chain, rather than any particular operations or steps in the chain.

Packaging Before Freezing

Packaging is crucial in maintaining quality during frozen storage, particularly for cooked products, and performs two basic functions. First, packaging is often the marketing vehicle by which the product is delivered to customers, which means that the package must effectively communicate its content in an attractive way. Second, the package protects its contents from external contamination during shipping and handling and from the environmental factors that cause chemical and

physical changes in the product during storage. The most important factors in the latter group are exposure to oxygen and to low-humidity surroundings. As a result, packages must provide a good barrier to oxygen to minimize oxidation and hence off-flavor development and to moisture loss to avoid dehydration or freezer burn.

To provide the greatest protection, a package must be well evacuated of air (oxygen) using either vacuum or gas flushing and the package must provide an adequate barrier to both oxygen and moisture. For frozen products, particularly cooked products, a complete vacuum coupled with an adequate barrier package that adheres well to the product surface is the most common choice. Avoiding headspace between the product surface and package aids in preventing ice recrystallization and frost formation inside the package during frozen storage that can damage the muscle cells and modify the way the muscle thaws.

'Freezer burn' is the main appearance problem that traditionally affected the appearance of meat in frozen storage. Desiccation from the surface tissues produces a dry, spongy layer that is unattractive and does not recover after thawing. Freezer burn can also lead to accelerated lipid oxidation. It occurs in unwrapped or poorly wrapped meat. The problem is accentuated in areas exposed to low-humidity air at high velocities and by poor temperature control. With improved packaging technologies and temperature control, the issue with freezer burnt meat has been significantly reduced, although it is still prevalent when meat that is bought fresh and is inadequately packaged before freezing is stored in domestic freezers.

Freezing Process

The freezing process starts once the meat reaches temperatures below its initial freezing temperature when ice crystal nucleation will take place. From there, freezing can progress through growth of an existing ice crystal or nucleating a new crystal. Growth of existing crystals tends to dominate when freezing is relative slow, whereas new crystals are more likely to form when freezing is fast. Hence, slow freezing initially results in fewer but larger ice crystals, whereas fast freezing results in more but smaller ice crystals. However, the ice crystals are unstable and, during subsequent frozen storage, recrystallization takes place. In this phenomenon, large ice crystals grow at the expense of small ice crystals – a process that is enhanced by temperature fluctuations during frozen storage.

Freezing itself does not overtly result in poor quality, although undesirable changes can take place in meat during freezing that are associated with the formation of large ice crystals in extracellular locations, mechanical damage by the ice crystals to cellular structures through distortion and volume changes, and chemical damage arising from changes in concentrations of solutes. These changes are related to the rate at which the meat is frozen.

Freezing rate has been evaluated using many different methods. However, a convenient way of expressing freezing rate, which is also recommended by the International Institute of Refrigeration for foods, is the time to transverse a given temperature range, i.e., freezing time. Freezing time for meat has in several studies been defined as the time taken to pass from −1 (approximately the beginning of freezing in the case of meat) to −7 °C, at which point approximately 80% of the water is frozen. At characteristic freezing rates shorter than 10 min, the formation of intracellular ice takes place (several ice crystals in each fiber), whereas at characteristic freezing times longer than 20 min, most ice crystals are extracellular.

Frozen Storage

Meat is not inert during frozen storage; chemical and biochemical reactions continue to take place in frozen meat but at a much slower rate than in fresh and chilled meat. Thus, the physical and chemical properties of meat slowly change with time, and, with extended storage periods, these will ultimately result in detectable quality changes. Ice recrystallization and more pronounced ice crystal growth can occur at higher temperature or due to drastic and repeated temperature fluctuations. This can result in some structural damage and relatively faster quality deterioration. Thus, any perceived benefits of rapid freezing can be easily reversed during frozen storage at high and unstable freezer temperatures.

Chemical and enzymatic reactions during frozen storage can also cause loss of quality, usually through lipid oxidation, which causes rancid odors and flavors to develop, 'warmed-over' flavor in previously cooked meats, and changes in color due to either oxidation of the color pigments or freezer burn (see Section Appearance). In general, these quality-deteriorating reactions occur faster at higher temperatures, especially more than −5 °C. However, some reactions, such as myoglobin oxidation, have maximum rates between −5 and −15 °C.

Thawing

The thawing process is more time consuming and difficult to control than freezing because temperatures more than 0 °C increase the risk of microbial growth; hence, the thawing temperature must, therefore, be kept low. The quality factors most likely to be affected by thawing are microbial growth, drip loss, and appearance and palatability of the product; these changes will be added to the changes initiated before and during freezing.

Appearance

The water-holding capacity of thawed meat is dependent on the rate at which the meat was frozen. The effect of freezing rate on water-holding capacity (measured as centrifuge drip) measured over a wide range of local freezing times is shown in Figure 1. The highest water-holding capacity is obtained with very short freezing times, whereas the lowest is obtained with freezing times of approximately 17–20 min, which coincides with a single ice crystal inside the muscle fibers. Beyond freezing times of 20 min, the water-holding capacity improves again until it plateaus at freezing times more than 30 min,

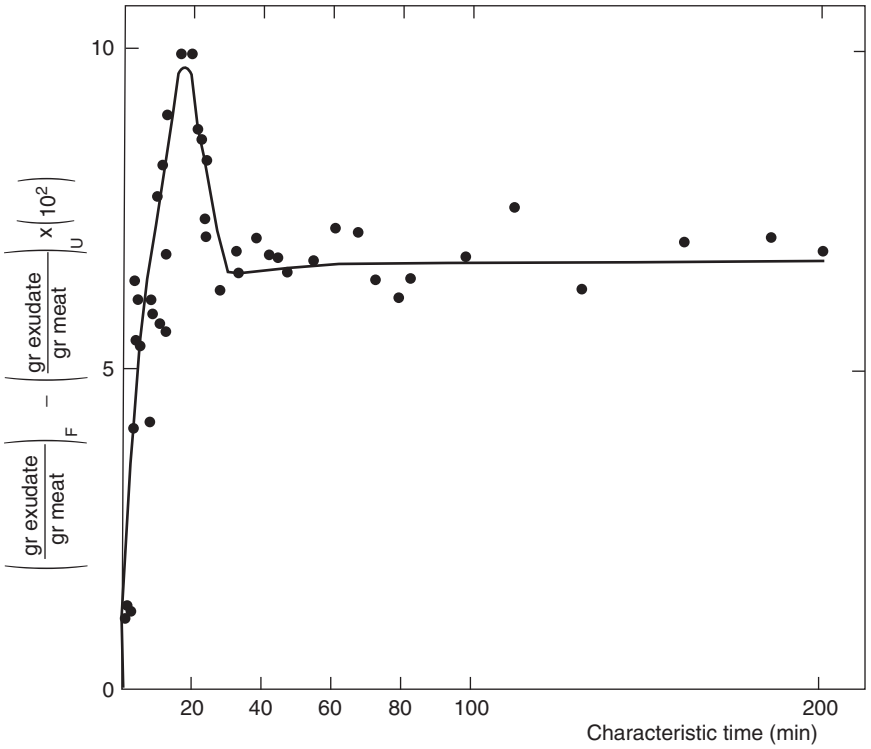

Figure 1 Changes in exudates from thawed meat in relation to the characteristic freezing time. The exudate was obtained by centrifugation. Reproduced from Mascheroni, R.H., Añón, M.C., Calvelo, A., 1980–81. Basis for a method of characterization for quick frozen beef. Meat Science 5, 457–472.

beyond which no further improvement in water-holding capacity is achieved.

A slow freezing rate results in the formation of relatively large ice crystals, which create tissue damage. Temperature fluctuations during frozen storage often result in recrystallization, which influences subsequent thaw-drip losses. Thawing inevitably produces drip, particularly from cut muscle surfaces. However, some uptake of this drip occurs when thawed meat is held at refrigeration temperatures and most of the drip would ultimately be lost during cooking, primarily through evaporation, if it had not already been lost during thawing.

Freezing induces alterations in optical properties and hence a change in meat color when the frozen meat is thawed. Previously frozen thawed meat has been found to exhibit a slower rate of blooming than meat that had not been frozen, because the mitochondrial respiratory enzyme still remains active. Thus, previously frozen meat appears darker in color than nonfrozen meat. Frozen and thawed meat is also likely to be more susceptible to myoglobin oxidation, resulting in a faster conversion into metmyoglobin and hence shorter color display life compared with chilled meat. In addition, the longer the meat is stored frozen, the shorter its color stability is after thawing. Recent studies have found that aging meat before freezing can provide equivalent color and better lipid oxidation stability compared with aged nonfrozen meat. This indicates that aging meat for a certain limited period before freezing can allow oxygenation conditions similar to aged nonfrozen meat, improving meat color and color stability of the frozen/thawed meat.

Eating Quality

Although tenderness has been found to increase following freezing and thawing, this cannot be contributed to proteolysis, because the proteolytic enzymes responsible for the postmortem tenderization process are inactive at commercial freezing temperatures ($<-12\,^{\circ}C$) and proteolysis does not contribute to tenderization to any large extent during frozen storage. For instance, if samples for shear force measurements are cooked from frozen, these will have higher shear force values compared with samples that are thawed before cooking. Rather, the tenderness improvement is ascribed to the loss of structural integrity caused by ice crystal formation. It should be noted that thawed red meat continues to age (i.e., become more tender) unless it is already fully aged before being frozen.

Lipid oxidation occurs not only in fat deposits but also in lean meat tissue through phospholipid oxidation. Lipid oxidation can result in rancid and other undesirable off-flavors and can also influence the texture and color of meat products. Development of off-flavors as a result of oxidation, including rancidity, is common and is a major hurdle to be overcome when producing frozen meat with an acceptable quality. The susceptibility of meat to lipid oxidation and rancidity is related to the fatty acid composition of the muscles, with the polyunsatured fatty acids in the phospholipids being liable to oxidative breakdown. Thus, meat cuts containing more polyunsaturated fatty acids will be more susceptible to oxidation, i.e., when stored under the same conditions, pork, which has more unsaturated fat, will have a shorter shelf life than beef,

which has more saturated fat. In contrast, meat containing antioxidants, such as vitamin E, i.e., meat from animals supplemented with vitamin E or from pastoral systems, will be less prone to oxidation. For detailed information, see those articles on oxidative, enzymatic, and warmed-over flavors.

Microbiological Quality and Safety

Microbial growth can make meat less pleasant to eat (spoilage) and can make the consumer ill if the numbers of pathogenic microorganisms are too high or if too many toxins are produced. Bacteria and molds have a temperature range in which they prefer to grow. As the temperature moves away from this range, their growth rate slows. Once the temperature gets too far away from the preferred range, growth stops completely and the microorganism may die. The growth rate at a given temperature varies between microorganisms, but the principle remains the same. Freezing meat is a very good way to slow or stop microbial growth and thereby reduce the rate of microbial spoilage or the growth of pathogens.

Freezing of Other Flesh Foods

The principles, including packaging, described for red meat generally apply to poultry and fish. However, a few specific characteristics of these foods related to freezing and product quality are described in the Sections Poultry and Fish and Seafood.

Poultry

Similar to red meats, poultry requires a freezing process that is rapid enough to minimize surface dehydration during freezing and decreases drip loss during thawing. With respect to appearance, a light surface color of the frozen product is considered important. This can be achieved with a rapid surface-freezing temperature because supercooling the product nucleates a high number of small ice crystals, which reflect light and appear white in color. Further, young birds are prone to bone darkening following freezing, which is caused by hemoglobin leaching from bone marrow to adjacent muscle as a result of the freeze/thaw treatment. Eating quality is not affected, but the dark bones negatively affect consumer acceptance.

Poultry tend to have fewer tenderness issues than red meat. This is related to the age of the animals (less than 6 weeks) and the fact that poultry are less susceptible to cold shortening and the associated toughening that can occur in prerigor muscle below 10 °C, because the postmortem pH decline is rapid in poultry and leads to a rapid onset of rigor (1–3 h postmortem). Poultry can, therefore, be frozen sooner after slaughter without compromising the tenderness of the product.

Fish and Seafood

In fish, aging is not required to ensure tenderness, and spoilage begins at the time of death, which is usually accompanied by gradual loss or development of compounds that affect fish quality. The most effective way of controlling the spoilage, and hence maintaining product quality, is to either chill or freeze the product soon after slaughter.

Changes in appearance can occur immediately after the fish is caught. Blood pigments become noticeably discolored to various degrees after some period of time. These pigments are subjected to considerable oxidation when the fish is frozen and stored, which results in dark meat color. This discoloration occurs especially when the fish is stored for an extended period of time or during thawing. However, it is highly dependent on storage temperature, with lower temperatures extending the storage period. In shrimp, black pigments can form within a few hours of death and this is enhanced by exposure to oxygen, but rapid freezing to less than −18 °C largely prevents this. In other shellfish, such as crab and lobster, the development of blue or black discoloration is one of the most troublesome quality issues.

A frozen cloudy liquid, known as thaw drip, can sometimes be found in packaged frozen fish. This quality defect is an indicator of inappropriate handling, prolonged storage before freezing, frozen storage at inappropriate cold storage temperatures, or improper thawing.

With respect to eating quality, frozen fish gradually loses its juiciness and texture. The changes are more pronounced in some species than in others. In cod and codfish, for instance, protein denaturation leads to formation of formaldehyde, cross-linking of formaldehyde to muscle proteins, and a 'cottony' or 'spongy' texture. Other fish species and crustaceans such as crab, shrimp, and lobster tend to toughen when stored for prolonged periods.

Changes in the delicate flavor of fish and seafood take place in three steps during frozen storage: first, a gradual loss or decrease in flavor compounds; then neutral, bland, or flat flavors are detected; and finally, off-flavors develop due to the presence of acids and carbonyl compounds as a result of lipid oxidation. Similarly, changes in odor take place in two phases: first, a loss of the characteristic odor and then development of undesirable odors. Generally, fish and seafood have a fresh, seaweedy odor that can be retained even after freezing and frozen storage. Gradually, such odors are lost and unpleasant odors can develop that are often related with inappropriate storage temperatures.

Storage Life of Frozen Foods

However, despite the potential impact of freezing, frozen storage, and thawing on product quality, red meats, poultry, and fish and seafood can be stored in the frozen state for several months or more without appreciable changes in quality, provided the food products are kept under appropriate conditions.

Storage life expectations have been defined by the International Institute of Refrigeration as "the period of frozen storage after freezing during which the product retains its characteristic properties and remains suitable for consumption or the intended process." For frozen meat, the recommended length of storage remains controversial because of the influence of packaging, storage temperature, relative humidity, moisture loss during freezing, and inherent variation in the

Table 1 Practical storage life in months at three storage temperatures

Products	*− 12 °C*	*− 18 °C*	*− 24 °C*

Glossary

Conduction The method by which heat (or another form of energy) is transferred through a solid material or a static layer of fluid.
Convection The method by which heat is transferred from one location to another by a moving fluid.
Heat transfer coefficient The ratio of a heat flux (e.g., the amount of heat flow per unit area of a surface) to the difference in temperatures between a surface and a fluid that drives that heat flux.
Insulation A material with a low thermal conductivity used to reduce the rate of heat transfer.
Radiation The method by which energy is transferred from one location to another as particles or waves.
Refrigeration The process of removing heat from an object.

Introduction

If animals were harvested and consumed almost immediately, there would be no need for any form of preservation. In practice, however, meat that is not preserved in some way will quickly deteriorate in quality and safety to the point where it is both unpalatable and dangerous to consume. Thus, most meat that is produced is subsequently preserved in one way or another.

Historically, meat has been preserved in a variety of ways, with the most common methods being drying, curing, smoking, heat processing, fermentation, irradiation, canning, packaging, and refrigeration.

Of all these alternatives, refrigeration has the key benefit, along with irradiation, that it leaves the form of the meat product almost unchanged and (when carried out appropriately) almost indistinguishable from the original fresh product. In comparison, most other preservation methods can be seen more as ways to change meat into different products that have longer storage lives rather than as genuine methods of preservation. Unlike any of the other preservation technologies, refrigeration is effective in reducing deterioration due to chemical reactions (fat oxidation, for instance) as well as deterioration due to the growth of microorganisms.

Refrigeration is often described as the process of removing heat from an object but, because energy is conserved (i.e., cannot be destroyed or created), it would be more accurate to say that refrigeration is the process of transferring heat from one object to another. Heat flows naturally from hotter objects to colder objects and no mechanism is required to achieve this. With the use of a refrigeration system, however, the object from which heat is removed can be colder than the object to which the heat is added.

At the same time that heat is transferred, masses of material are usually moved around by the refrigeration system. These can include air or liquid in which the heat is carried from the food product to the air or liquid cooler, water vapor and other gases carried in air, and the primary and secondary refrigerants in the refrigeration system itself.

Fundamentals of Heat Transfer

There are three fundamental mechanisms of heat transfer: conduction, convection, and radiation. Of these three, most refrigeration processes involve combinations of conduction and convection, whereas radiation is occasionally significant.

Conduction

The molecules of a solid, liquid, or gas interact with each other, either all the time (as in a solid) or intermittently (as in a liquid or a gas). When two molecules interact, the one with the higher energy level transfers some of its energy to the one with the lower energy level. The relative energy levels are indicated by temperature, with materials at higher temperatures having molecules with relatively higher energy levels and vice versa. Energy (in the form of heat), therefore, flows through a material from areas of higher temperature to areas of lower temperature. In pure metallic solids, heat can also be transferred via 'free' electrons but, again, the direction of heat flow is from higher to lower temperature areas of the material.

The relationship between the characteristics of the conducting material and the rate of heat flow was described by Fourier in 1822. To simplify Fourier's description for a slab-shaped object, such as that shown in Figure 1, when the heat flow is steady over time, the rate of heat flow Q in W (Watts; energy flow per unit time), is given by eqn [1].

$$Q = \frac{kA}{x}(T_1 - T_2) \qquad [1]$$

Here k is the thermal conductivity in W m^{-1} K^{-1}, A is the area over which the heat is conducted in m^2, x is the distance through which the heat is conducted in m, and T_1 and T_2 are the temperatures on either side of the object in K (Kelvin).

Thus, to increase the rate of heat flow due to conduction, one could do one or more of the following things:

- increase the conductivity, k;
- increase the area, A;
- decrease the thickness, x; or
- increase the temperature difference between the two sides of the object, $(T_1–T_2)$.

Typical thermal conductivities for materials of interest in a food refrigeration process include air at 0.03 W m^{-1} K^{-1}, lean meat at approximately 0.5 W m^{-1} K^{-1} when unfrozen or 1.5 W m^{-1} K^{-1} when frozen, steel at approximately 43 W m^{-1} K^{-1}, and copper at approximately 380 W m^{-1} K^{-1}. Thus,

 doi:10.1016/B978-0-12-384731-7.00127-6

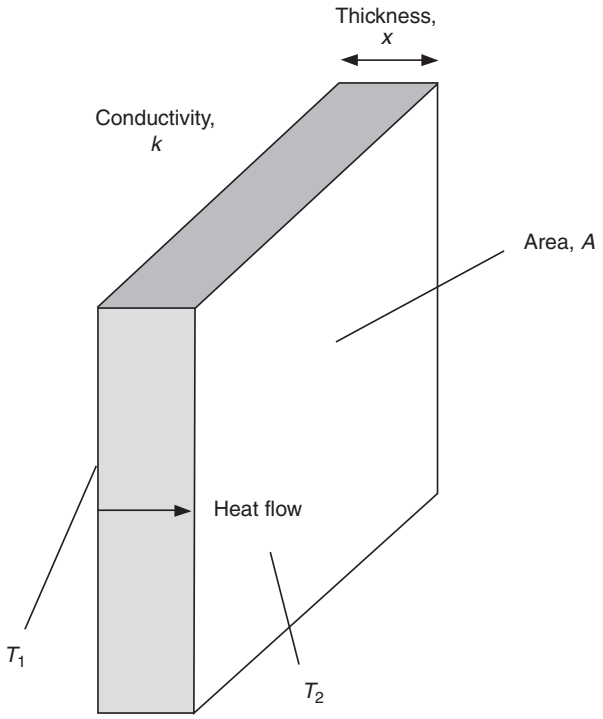

Figure 1 Heat conduction through a slab of material.

the air that frequently surrounds meat products when they are packaged is, when it is prevented from moving, a very good thermal insulator. This is an important consideration in refrigeration process design.

Convection

Although its low thermal conductivity makes immobile air a very effective thermal insulator, the movement of air or any other fluid over a surface is the second fundamental mechanism of heat transfer, known as convection. Convection is the most common practical way in which heat is transferred from a solid to a liquid or a gas (or vice versa) or from one part of a liquid or gas to another part. There are two forms of convection – forced and natural – and both occur as a result of fluid movement.

Forced convection occurs when the fluid is moved by an external force. Examples of forced convection include a fan blowing air across a surface or a pump forcing liquid along a pipe.

Natural convection, however, occurs naturally as a result of the heat transfer process itself. If a warm surface heats some air, the density of the warm air will be less than the density of the surrounding cold air. The warm air, therefore, rises due to its buoyancy in the denser cold air, and surrounding cold air sweeps in from the sides to replace it. This produces air movement around the warm surface without any external force being applied. The rate of this air movement is dependent on the difference between the temperature of the surface and the temperature of the air, so higher temperature differences generate higher rates of air movement.

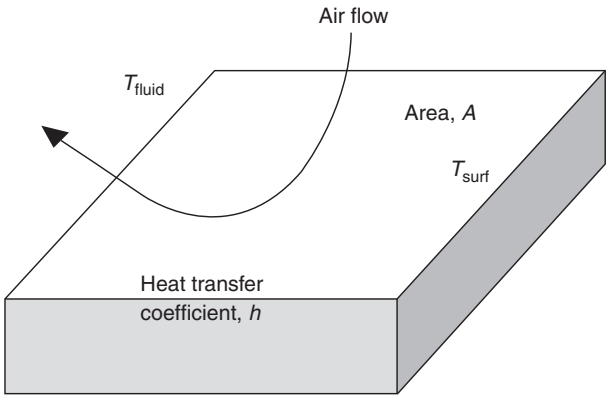

Figure 2 Convection heat transfer at a surface.

The rate of heat transfer due to either forced or natural convection was described by Sir Isaac Newton in 1701 according to eqn [2].

$$Q = hA(T_{\text{surface}} - T_{\text{fluid}}) \qquad [2]$$

here h is the surface heat transfer coefficient in W m^{-2} K^{-1}, and T_{surface} and T_{fluid} are the temperatures of the surface and fluid, respectively in K.

Figure 2 illustrates the conceptual situation. The rate of heat flow in convection is driven by the temperature difference and the surface area, as it is in conduction, and by the heat transfer coefficient, h. Also, h depends on a number of factors, including the characteristics of the fluid, the velocity of fluid flow past the surface, and the level of turbulence. In the case of natural convection, h also depends on the position of the surface (e.g., vertical or horizontal, above or below the fluid) and whether the surface is colder or warmer than the fluid.

Typical values for h in food refrigeration processes include approximately 5 W m^{-2} K^{-1} for natural convection cooling in air, 20–30 W m^{-2} K^{-1} for forced convection cooling in air, 200–500 W m^{-2} K^{-1} for cooling in water and much more than 1000 W m^{-2} K^{-1} if liquid is evaporating or gas is condensing. The value of h can be increased in a forced convection regime by increasing the velocity of flow across the surface. In practice, however, h increases less than linearly with flow velocity whereas the power (and hence the cost of energy and capital equipment) required to move the fluid increases much more than linearly with velocity. This means that it is rarely economic, in a food refrigeration process, to move the fluid fast enough to increase h to more than 5–10 times its natural convection value.

Radiation

Radiation is the last of the three fundamental heat transfer mechanisms. Like convection, thermal radiation transfers heat from the surface of an object but, unlike convection, radiation requires no transfer medium. Radiation actually transfers heat better if there is no intervening fluid. The amount of radiation heat transfer depends on the surface area, as with conduction and convection. Although rates of conduction and convection depend linearly on the difference in temperatures between two objects, radiation depends on the difference between their

absolute temperatures raised to the fourth power and the geometric relationship between the two objects.

Radiation is usually more important in heating processes than in cooling processes, particularly when the source of heating is at a high temperature. This can occasionally be a significant issue during cold storage when radiative heating from lights in the cold store may be sufficient to warm and even start to thaw the top surface of product stacked close to the lights. Radiative heating can also affect the accuracy of air temperature measurements. Radiation is usually not very important in practical chilling and freezing processes, however, so it will not be described further and the reader should refer to an engineering heat transfer text if more information is required.

Refrigeration Systems

As has been noted above in Section Introduction, heat does not naturally flow from a cold object to a warmer object. This means that to cool an object below the surrounding ambient temperature, it is necessary to use some sort of refrigeration system. The types of refrigeration systems that are used for cooling meat range from very simple to fairly complex but their essential principles are similar. The simplest practical system is, therefore, described first and more complex systems are described later in this article.

Cryogenic Refrigeration

When a material changes phase, from solid to liquid, from liquid to gas, or directly from solid to gas, heat must be absorbed in addition to the heat required to raise the temperature of the material. This additional heat is known as the latent heat of fusion (or melting), in the case of the transition from solid to liquid; the latent heat of evaporation, in the case of the transition from liquid to gas; or the latent heat of sublimation, in the case of the transition from solid to gas. Thus, if one has a material that melts, boils, or sublimes at a low temperature, that material will draw heat from warmer objects around it in order to change its phase. By putting such a material in contact with a meat product, it can be arranged that most of the required heat will be drawn from the meat, thereby cooling the meat. This is the principle of cryogenic refrigeration.

Materials that melt, boil, or sublime at temperatures well below normal room temperatures are known as cryogens. Although many different cryogens could potentially be used as refrigerants to cool meat products, the choice of cryogen for food cooling is restricted by food safety, food quality, and environmental acceptability criteria because the cryogen usually comes into direct contact with the food product and much of it is often released into the atmosphere. Two cryogens that meet these criteria, and are, therefore, used most often for food cooling, are carbon dioxide (in either solid form, as pellets of 'dry ice' or as a pressurized liquid) and liquid nitrogen.

Solid carbon dioxide at atmospheric pressure sublimes at $-78.5\,^{\circ}C$. It is, therefore, kept in a thermally insulated container to slow the sublimation process until it is put into physical contact with the food product to be cooled. Liquid carbon dioxide is kept under pressure (at least 6.7 MPa at $27\,^{\circ}C$) to prevent it from evaporating. Liquid carbon dioxide cannot exist in equilibrium at a pressure of less than 0.52 MPa so, when the liquid is released into an atmospheric pressure environment, some evaporates and carries away much of the heat content whereas the rest solidifies in the form of carbon dioxide 'snow.' This 'snow' then sublimes at $-78.5\,^{\circ}C$, drawing heat from its surroundings, until all the carbon dioxide has transformed into gas.

Liquid nitrogen boils at $-195.8\,^{\circ}C$ and its critical point is $-146.9\,^{\circ}C$, so it is kept in a thermally insulated container to slow down the evaporation process or as a pressurized supercritical gas. When liquid nitrogen is put in contact with a warm object, it boils vigorously, drawing heat from the warm object to do so, and thereby cools the object.

Both of these cryogens can be used to refrigerate food products but, whereas such a process requires very little equipment and so has a small capital cost, the cost of purchasing cryogen is typically high. This means that refrigeration with cryogens is mainly used for trial runs in which only small amounts of meat have to be frozen, for products that have very high value or to deal with emergencies when more conventional refrigeration systems are unavailable and there would be a food safety or quality risk if the meat was allowed to warm up.

Two issues make cryogenic refrigeration intrinsically expensive:

- Cryogens are only used once and are then lost into the atmosphere.
- Cryogens are manufactured using very low temperature processes that require a lot of energy.

These two issues can be resolved by a refrigeration system that reuses its refrigerant and that operates at temperatures no lower than it must reach to provide the required amount of cooling. The most common way to achieve these objectives is to use a mechanical vapor compression system.

Mechanical Vapor Compression Refrigeration

The principle of a mechanical vapor compression refrigeration system is to refine the process described above for cryogenic refrigeration in two ways. First, instead of putting the refrigerant into direct contact with the object to be cooled, it is retained inside the tubes of an evaporator, which is part of the refrigeration system. Second, three other pieces of equipment – the compressor, the condenser, and the expansion valve – are used in combination to convert the gaseous refrigerant back into a cold liquid that can be recycled and evaporated again in a continuous cycle. A diagram of a simple refrigeration system is shown in Figure 3.

Starting at the expansion valve, on the left of Figure 3, the warm refrigerant liquid passes through the expansion valve and suddenly reduces in pressure. This results in part of the liquid evaporating, thereby cooling both the vapor and the remaining liquid. This mixture of cold liquid and vapor then passes into the evaporator inside the cold room, where heat is drawn from the room to evaporate the rest of the cold liquid refrigerant. The resulting cold, low-pressure vapor is then sucked into the compressor where energy is applied to raise its pressure. As the pressure of the vapor is increased, its temperature also increases so that the vapor becomes hotter than

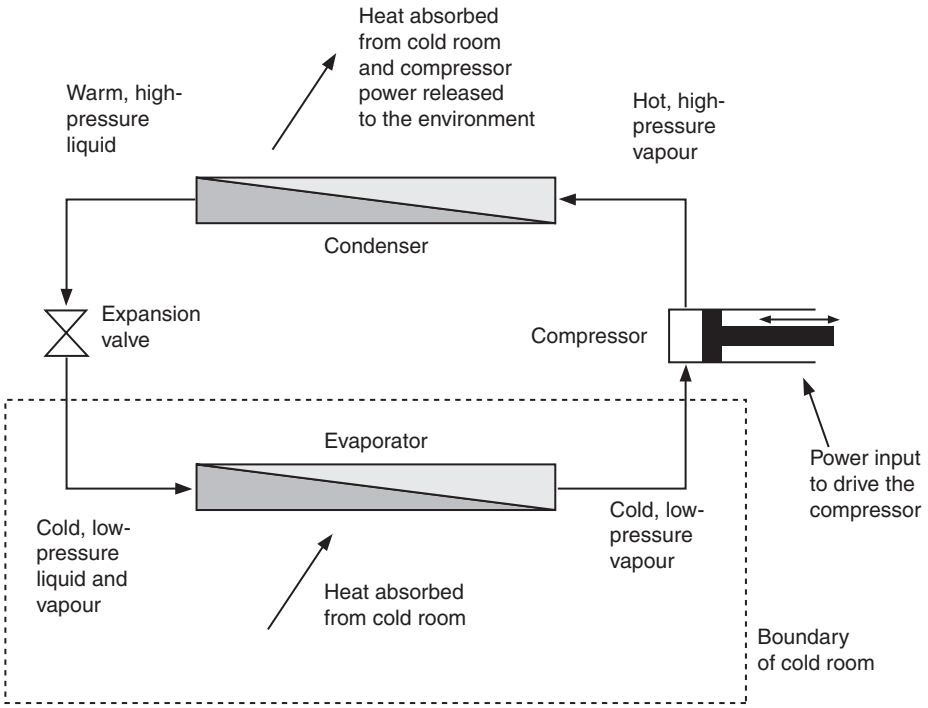

Figure 3 Diagram of a mechanical vapor compression refrigeration system. The arrows show the movement of refrigerant around the cycle, driven by the compressor, and the flows of heat and energy into and out of the system.

the ambient environment. When the hot vapor passes into the condenser, it cools until it reaches its saturation temperature at the pressure in the condenser, and then the vapor condenses, losing some sensible heat and its latent heat to the ambient environment. The warm liquid refrigerant then reenters the expansion valve and the cycle begins again.

By this method, the heat extracted from the cold room is expelled from the system through the condenser along with the energy added at the compressor and a cycle is created that extracts heat from the cold room continuously, rather than being limited by a finite supply of refrigerant. In practice, there are many refinements in real refrigeration systems that make mechanical vapor compression refrigeration efficient, cost-effective, safe, and reliable. For example, most meat plant refrigeration systems would have more than one of each of the components shown in the figure. Almost all mechanical vapor compression systems conform to the general concept shown in Figure 3, however.

The fluid used as a refrigerant must be selected carefully to meet a range of often conflicting criteria. The ideal refrigerant would, among other positive attributes:

- evaporate at the target evaporation temperature above atmospheric pressure, so that air does not leak inward if there are any leaks in the system;
- condense at the target condensing temperature under a relatively low pressure, so that the power required to compress it from the evaporating pressure to the condensing pressure is also relatively low;
- have a large latent heat capacity per unit of vapor volume, so that the compressor would be physically small (and therefore relatively inexpensive) for a given heat extraction rate;
- be compatible with a wide range of materials (e.g., metals, plastics, and lubricants), thus making it convenient and inexpensive to construct and run the refrigeration system;
- be nontoxic;
- be nonflammable; and
- be environmentally friendly.

It was initially thought that synthetic chlorofluorocarbon (CFC) compounds met all of these criteria, and were, therefore, ideal refrigerants. This led to a great many refrigeration systems – especially those with smaller capacities – being constructed to use these compounds. Over time, however, it became clear that CFCs were causing serious damage to the ozone layer, and the Montreal Protocol resulted in CFC production and consumption around the world being phased out by 2000. CFCs were temporarily replaced in many applications by hydrochlorofluorocarbons (HCFCs), which were less damaging to the ozone layer, and in the longer term by hydrofluorocarbons (HFCs) and hydrocarbons, which were not detrimental to the ozone layer.

CFCs, HCFCs, and HFCs are greenhouse gases, and their release into the environment, therefore, contributes to global warming. As was noted earlier, however, the objective of the refrigeration system is to contain the refrigerant and ensure that it is not released so, as long as leakage rates are low, the global warming potential (GWP) of these refrigerants is often considered to be acceptable. Indeed, the most important factor in determining the overall GWP of a refrigeration system is commonly the efficiency of the system. For example, if a

system contains a high-GWP refrigerant, but uses energy more efficiently than another system with a low-GWP refrigerant, the saving in global warming due to the smaller amount of carbon dioxide that would be produced in the electricity generating plant supplying power to the more efficient refrigeration system can often more than make up for the higher GWP of the small amount of refrigerant that will leak out over time.

Several effective refrigerants have little or no GWP. Ammonia is the most important of these in the modern meat industry because it is both a thermodynamically good refrigerant and inexpensive to purchase compared with HFCs. Ammonia is therefore often used in large refrigeration plants, such as meat freezing facilities and cold stores. In these large applications, ammonia's undesirable attributes, such as its toxicity and flammability, can be controlled safely and economically – something that is more difficult in smaller installations. Ammonia also has the advantage of boiling at $-33.3\,^{\circ}C$ under atmospheric pressure. This temperature is often satisfactory for a meat freezing system, so there is often no need to run the evaporator below atmospheric pressure and therefore risk air leaking into the system.

Hydrocarbons (e.g., propane) also have little or no GWP, compared to HCFCs and HFCs and they are often used as working fluids in small- or medium-sized refrigeration systems. Hydrocarbons are highly flammable, however; so careful design and maintenance are required to ensure they are vented safely when they leak and that there is no source of ignition available either in normal operation or in an accident.

Figure 3 shows a reciprocating compressor but many different types of compressor can be used in refrigeration systems. For smaller systems, and where the ratio between the condenser and evaporator pressures is high, reciprocating compressors containing one to eight cylinders are used most commonly. For systems with larger capacities, screw compressors or centrifugal compressors are used. Other types of compressor have advantages under particular circumstances.

For refrigeration systems with larger capacities, it is usual to install several small compressors rather than a single large unit. This allows a compressor to be taken out of service for maintenance without stopping the whole refrigeration system running and it can make the system more efficient when it is run at a fraction of its full capacity. Although many compressors can be controlled to operate with reduced gas throughput, most types of compressor operate less efficiently in that mode. It is, therefore, desirable to achieve most of the required capacity reduction by completely stopping one or more compressors when they are not required.

Although some types of compressor are more tolerant of high pressure ratios than others, the performance of a given refrigeration system always deteriorates as the pressure ratio increases. As a result, refrigeration systems are often designed to compress the refrigerant vapor in two or more stages, with the vapor being cooled between the compression stages. The number of stages is chosen during system design to optimize the added capital cost of additional compressors and the reduced energy cost of a multistage system. A further advantage of a multistage system is that refrigeration in a meat plant is often required at several evaporation temperatures. For example, refrigerant may be needed at $-33\,^{\circ}C$ to cool freezers and cold stores, $-10\,^{\circ}C$ to cool chillers and cool stores, and $0\,^{\circ}C$ to cool air-conditioned processing rooms. If refrigerant can be supplied at each of these temperatures then the energy cost for compression can be reduced when compared with the alternative of supplying all refrigerant at the lowest required temperature.

The condenser is designed to discharge the heat removed from the cold room together with the energy put into the system through the compressor. In small refrigeration systems, the heat released from the refrigerant as it cools and then condenses is released into the air but, for larger systems, the amount of air required for air cooling can be very great and condensers are, therefore, often designed to be cooled by water or by a combination of air and water spray. The latter design results in the water evaporating into the air stream outside the condenser tubes as the refrigerant condenses inside the tubes and it is known, somewhat confusingly, as an evaporative condenser.

The evaporator is the point at which heat is transferred from the object being cooled to the evaporating refrigerant. The simplest way to do this, while keeping the refrigerant sealed inside the refrigeration system, is to put the metal surface of the evaporator in direct contact with the object being cooled – a meat product, for example. This is the principle of the plate freezing system, where meat products are clamped between hollow metal plates that contain evaporating refrigerant.

For meat products that do not have flat, parallel sides suitable for plate freezing, or when the product is to be chilled rather than frozen, the evaporator is usually designed as a set of tubes containing the evaporating refrigerant, with fins mounted outside the tubes to increase their heat transfer area. Air is then blown by a set of fans across the evaporator tubes and fins (where the air is cooled), across the meat product (where the cold air warms and the meat product is cooled), and then back to the evaporator. Although air is the fluid used most often to transfer heat from the cooling object to the evaporator, there are advantages in using liquids such as water or brine to carry out the same function because of their much greater heat capacity per unit volume and the greater heat transfer coefficient between a liquid and a surface compared with that between a gas, like air, and a surface.

Other Types of Primary Refrigeration System

Although mechanical vapor compression is the most common design of refrigeration cycle, there are other alternatives. Absorption refrigeration, for example, uses a liquid solution to absorb the refrigerant vapor while removing heat, the pressure of the liquid is then raised and the vapor is released by applying heat. The vapor is condensed and the liquid refrigerant is evaporated, as in a mechanical vapor compression system, and then the cycle returns to the absorption stage. The advantage of this system is that most of the energy required to run an absorption refrigeration system can be provided in the form of heat rather than as mechanical power. This makes absorption systems ideal for making use of the waste heat that is often available in a meat processing plant. For information on other types of refrigeration system, the reader should refer to the Further Reading.

Secondary Refrigeration Systems

It is sometimes appropriate for safety or cost reasons to separate the evaporator from the point at which cooling is required. A common example occurs where an ammonia refrigeration system is used to cool a processing room in which there may be many staff working and where it is undesirable to risk an ammonia leak from the evaporator into the room. In this case, the evaporator can be used to cool a fluid (usually a liquid), which is pumped to the point where the cooling is needed and then through a heat exchanger to cool air before the fluid is returned to the evaporator for further cooling. A fluid circulated in this way is known as a secondary refrigerant.

Secondary refrigerants are often brines or glycol solutions, but many different fluids can be used, depending on the temperature at which the secondary refrigerant is required. Two-phase secondary refrigerant systems are more complex to design but they make use of the latent heat available when changing phase to effectively increase the secondary refrigerant's volumetric heat capacity. This makes the pumping power and pipe sizes required to circulate a two-phase secondary refrigerant substantially smaller than they would be for a brine or glycol solution with the same refrigeration capacity. One example is an ice slurry (i.e., a mixture of ice and water), in which the ice fraction of the slurry changes around the secondary refrigerant loop, allowing a volumetric heat capacity between four and six times greater than that of water. Another example is carbon dioxide, in which the system pressure is arranged so that the fluid changes phase between liquid and vapor during the cycle, similarly increasing its effective volumetric heat capacity.

Although secondary refrigerants are advantageous for several reasons, they all have an important disadvantage. In any heat transfer situation, the material gaining heat must be colder than the material that is losing heat. For example, the air flowing over a meat product must be colder than the meat product if that product is to be cooled. If a secondary refrigerant is used, the secondary refrigerant must be colder than the air and the evaporating primary refrigerant must be colder than the secondary refrigerant. In contrast, without the secondary refrigerant, the evaporation temperature would only have to be colder than the air. Based on eqn [2], to achieve a small temperature difference in any heat exchange step where a given amount of heat is to be transferred, it is necessary to have a large heat transfer area. A large heat transfer area requires a high cost of manufacture for the heat exchanger or evaporator, so, for economic reasons, the temperature difference at each heat transfer step is typically between 5 and 10 °C.

Using a secondary refrigerant, therefore, incurs additional operating costs because of the lower evaporating temperature required for the primary refrigerant. These costs must be balanced against the benefits of separating the primary refrigerant from the point where cooling is needed.

Glossary

Apparent specific heat The heat required to raise the temperature of a unit mass of product by one degree.
Dielectric heating The heating by high frequency alternating electric field inducing molecular rotation or ionic motion.
Drip The water lost from a product in liquid form during thawing.
Extracellular (ice) The ice formation outside (between) the cells.
Finite element method The method of calculating changes in temperature and other variables in a region of space by dividing it into small elements.
Freezing point depression The lowering of freezing point due to solutes in the water or increase in pressure.
Frozen fraction The fraction of freezable water that has solidified.
Heat transfer coefficient (HTC) The heat transfer rate per unit area per unit time with a temperature gradient between the product and surrounding temperature.
Hot spot A location in the product where the temperature is much higher than average, because of uneven heating.
Tempering The partial thawing achieved by raising the temperature of frozen food near to but still below the freezing point in order to reduce hardness and facilitate processing.

Introduction

Frozen meat must usually be thawed before cooking or further processing. Often only partial thawing (known as tempering) is carried out, as tempered meat is firmer than completely thawed meat and can be more easily sliced or flaked. This article covers both the thawing and tempering processes.

Thawing/tempering is a more difficult process to carry out safely than chilling or freezing because of the high danger of subjecting some parts of the food to high temperature and humidity, which favor microbial growth. A good thawing or tempering regime is one that minimizes process time, microbial growth risks, drip loss, and other quality losses. It is desirable that the product is uniformly treated, and exposure to high temperature is stopped as soon as the desirable endpoint has been reached.

Thawing and tempering may be carried out by industrial, commercial, or domestic users. Food plants may thaw or temper meat for further processing (boning, cutting, grinding, curing, mixing, etc). Shops and supermarkets may thaw frozen meat for retail display. Consumers usually thaw frozen meat before cooking. Although the general principles are the same in each case, different methods and guidelines may be recommended due to differences in circumstances.

This article will examine what happens to meat during thawing or tempering, review the available thawing/tempering methods, and make some recommendations on best practice.

Physical Aspects of Thawing and Tempering

Thawing is more time consuming and difficult to control than freezing. Above-zero environment temperatures must be used, which carries the risk of microbial growth. Because the environment temperature has to be kept low, the temperature gradient that drives the heat transfer is usually much lower during thawing than during freezing, leading to long process times. Furthermore, thawed food has a lower thermal conductivity than frozen food, which slows down the heat transfer even more. Internal heating methods such as microwave thawing alleviate the heat transfer problem but, if the heating is too intense, local hot spots will occur.

Food freezing and thawing do not take place at a sharp temperature, as for pure water, but occur gradually over a temperature range. The amount of residual unfrozen water at any given temperature below the freezing point can be calculated by the law of freezing point depression, and is approximately proportional to T_f/T, where T is the temperature and T_f the initial freezing point of the food, both in degrees C. Thus, for meat, which begins to freeze at approximately $T_f = -1$ °C, approximately half the water in the food (more precisely, half of the water that is not bound to food molecules) remains unfrozen at −2 °C, one-third at −3 °C, one-tenth at −10 °C, and so on (Figure 1). Hence that meat will require almost the same amount of heat to rise from −30 to −2 °C as from −2 to −1 °C. If that meat is being thawed in air, the second part of the process (from −2 to −1 °C) will take longer than the first part because the temperature difference between air and food will be less and less as time goes on. Hence, tempering a food takes much less time than complete thawing, even though the final tempering temperature may be quite close to the freezing point of the food.

The apparent specific heat (the amount of heat required to raise the food temperature by a degree) is greatest just under the initial freezing point T_f, because that is where most the ice thaws (Figure 2). Once all the ice has thawed, the specific heat falls back to a low value. The peak is known as the 'latent heat peak' and means that, while frozen food may take a long time to thaw completely. Those parts of the food that thaw earliest (such as the corners) will rapidly heat up further and stay at
