GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 97 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise.

There are four features that help you find the topic in which you are interested:

1. The contents list.
2. Cross-references to other relevant articles within each article.
3. A full subject index.
4. Contributors list.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Meat, Animal, Poultry and Fish Production and Management: Antibiotic Growth Promotants.

> *See also*: Chemical Analysis: Sampling and Statistical Requirements; Standard Methods. Foodborne Zoonoses. Growth of Meat Animals: Metabolic Modifiers. Microorganisms and Resistance to Antibiotics, the Ubiquity of: Antibiotic Resistance by Microorganisms. Residues in Meat and Meat Products: Feed and Drug Residues; Residues Associated with Meat Production

3 Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

PREFACE

The Encyclopedia of Meat Sciences, second edition, an extensive revision of the first edition published in 2004, covers all the essential meat topics, ranging from animal production, processing, analytical procedures, and food safety, to final consumption including health issues and nutritional aspects. There are more than 230 articles and these provide a greater breadth of coverage than any existing work on meat science. In addition to publication in print, the Encyclopedia is also available for licensing online that can allow regular updating. The articles are designed to bring a nonexpert up to a level of understanding the interactions among the various disciplines covered in the articles. Most articles are 3000–4000 words long and include a list of Further reading and Websites to expand the content beyond the immediate scope of this work. The Encyclopedia is, therefore, a valuable resource for several levels of education and experience.

The Editors gratefully acknowledge the contributions of the authors of the articles and the Editorial Advisory Board. The board not only proposed subjects to be covered, but also found contributors and then reviewed the articles. The work involved in an Encyclopedia such as this requires an extensive interactive cooperation among the Editors, the Editorial Advisory Board, the contributors, and the publishers, particularly the staff of the Major Reference Works division of Elsevier. The staff included Nancy Maragioglio, Donna de Weerd-Wilson, Anna Gebicka, Cari Owen, Will Bowden-Green, Sam Mahfoudh, Zoey Ayres, and Marise Willis.

The Editors are particularly grateful to Cari, Will, and Sam, who worked very closely with us and who diligently pursued all avenues to obtain contacts with contributors, maneuvered around obstacles, facilitated the day-to-day management, and linked everyone together to meet the deadlines.

Michael Dikeman and Carrick Devine
Editors, August 2014

INTRODUCTION

Meat consumption by hunter–gatherers predated the agricultural revolution. Consumption of meat and fish runs in parallel with human development that is still in process. Humans and animals have now coexisted for thousands of years for their mutual benefit, even though their relationship is changing. Meat does not come from a single, or even a few, animal species, but is derived from a wide variety of species ranging from poultry to pigs, cattle, sheep, goats, and wild game to thousands of species of fish. While many of these species are now intensively farmed, some still coexist with nomadic tribes, whereas, others are raised by families in small village communities, or are even hunted by remnants of hunter–gatherer communities. The second edition of the Encyclopedia of Meat Sciences discusses how the domesticated species evolved; the wide range of harvesting methods for animals, poultry and fish; the historical changes in production, processing and nutritional value, including the beneficial effects of optimum amounts of meat in a diet.

The meat industry is based on obtaining animals, poultry, and fish from pastures, feedlots and specialized intensive production systems, and from extractive industries such as fishing. It is understandable, therefore, that the genetics and management of animals and production systems are prominent in the Encyclopedia. However, the broad field of meat science is much more than harvesting animals and processing meat from them. It includes issues such as preslaughter stress and its effects on meat quality; religious issues; animal welfare; and humane slaughter techniques, all of which are extremely important to ensure that meat quality, cultural issues, and market requirements are harmonized.

Processing methods for the various species are different, but they have all historically developed to ensure, either by conscious design or by experience, that the underlying principles of physiology and biochemistry in the conversion of muscle to meat are optimized. Biochemistry and physiology are extremely important and fundamental disciplines, because they explain how unfortunate, undesirable processing defects such as PSE or cold shortening and toughening can occur and can be avoided. Progress in this area has also enabled significant changes in production and subsequent quality since the first edition of the Encyclopedia of Meat Sciences in 2004.

Understanding these changes requires an appreciation of the structure of carcass tissues, from gross carcass attributes to consideration and understanding of changes at the ultrastructural level. The form and function of muscle tissues, how they change through growth, how they impinge on meat quality, and the way that connective tissue and fat can be major contributors to the final product quality are all covered in these pages. Topics such as cold shortening that can cause meat toughening or inhibition of tenderisation are explained, as well as how procedures such as electrical stimulation evolved to prevent these problems. Assessment of meat quality from measurements such as muscle pH, tenderness prediction through spectral measurements on uncooked meat, color changes on display and storage, and reduction of microbial contamination are critical for many aspects of the meat industry and are also discussed.

There have been many and significant advances in meat animal production based on genetic, nutrition, growth biology, and metabolic modifier research. In regard to meat processing, advances in refrigeration and freezing technology, which is the foundation of perhaps the most important changes ever encountered for food is discussed. Even so, such advances also depend on the way in which microbiology and packaging are integrated to ensure wholesome products with a long shelf life, minimal spoilage, and desirable sensory attributes. However, there are many other ways to preserve food that are also important. Of ever-increasing importance is the topic of food safety, which must receive extensive attention because meat is a perishable product and is critical for a high quality of living and even for human survival. Meat marketing and pricing in all its forms, from wet markets to hotel, restaurant and institutional trade, and transportation are also important. Whole-tissue meat is usually cooked, so, many of the desirable attributes such as flavor development relate to the temperature interactions with various proteins and sugars during cooking. Other cuts are processed in various ways, from smoking to mincing to sausages and the technologies involved are covered.

Not all muscles or cuts of meat are suitable for the same cooking and preparation methods. Therefore, out of necessity, a vast range of highly desirable products has evolved with variations from one ethnic background to another. Other products are merchandized through fast-food restaurants. One can now consume a hamburger in China that is almost identical to that in Chile or in the United States owing to a consistency of product specifications that has become universal. Meat is not only a major source of quality protein and some vitamins and minerals; it often forms the central part of a meal, and is desirable to have the appropriate flavors, aromas, and appearance to conform to the expectations and the way meat is used in various cultures.

This second edition of the Encyclopedia of Meat Sciences also covers controversial health-related aspects of meat consumption and this aspect needs considerably more research. In recent years, the ready availability of meat and other foods has given rise to some health concerns. However, the issues are not always what they seem. The positive and potential negative health-related aspects of meat eating are addressed by experts in dietary and health aspects of meat consumption, but the effect of a single food item should not be considered in isolation.

The wide coverage of topics will ensure that this second edition of the Encyclopedia of Meat Sciences will be an important resource for students or professionals with an interest in meat science or those engaged in the livestock and meat industries. Most of the articles in the second edition are not only a revision of those in first edition but there are additional areas covered. The relatively short nature of the articles makes the Encyclopedia easy and interesting to read.

This article is a revision of the previous edition article by E Mills, volume 1, pp 6–11, © 2004, Elsevier Ltd.

Glossary

Casein The predominant protein in milk.
Collagen The predominant structural protein constituent of muscle connective tissues, the principle protein component of food grade gelatin.
Gluten A protein component separated during milling of grain, dietary concerns with respect to gluten focus on that from wheat, barley, rye, and oats.
Gums and hydrocolloids Long-chain polysaccharides derived from various plant sources or fermentation processes, give high viscosity in aqueous foodstuffs, for example, alginate, carrageenan, guar gum, locust bean gum, and xanthan gum.
Inulin and oligosaccharides Medium chain length polysaccharides comprised of glucose and fructose subunits.
Nonfat dried milk solids (NFDMS) Manufactured by drying skim milk, contains 52% lactose, 36% protein, and 8.4% mineral (predominantly potassium and calcium).
Retrogradation The viscosity decline in starch gels that occurs if the linear glucose chains reform into granules, accelerated by freezing and thawing.
Soy flour Milled soy grits derived from dehulled, defatted soy beans, contains 47% protein, 38% carbohydrate.
Starch Polysaccharide composed of glucose molecules arranged in linear and helical (amylose) and branched (amylopectin) structures.

Introduction

Extenders are added to meat products to reduce formulation costs or to contribute a variety of functions in the product. The effect of an extender on formulation cost may be significant especially when it facilitates increased product yield via addition of water. Nevertheless, nonmeat ingredients may be added to ground, comminuted, or whole muscle meat products for a variety of reasons including increased shelf-life, reduced fluid purge, increased slicing yield, improved flavor and juiciness, improved color, or cost reduction among others.

Ingredients described as extenders typically allow for reduced product cost while serving other important functions as well. A common functional property of most extenders is water-holding. Water-holding capacity is an especially important property because most cost reduction comes from the addition of water along with the extender. Ingredients are sometimes called binders when they are used primarily for increasing the water-holding capacity of a product or also if they improve fat-holding and emulsion stability. Thus, the terms extender and binder are often interchanged when referring to various ingredients. Extenders used in a particular meat product are

chosen based on their specific functional properties, compatibility with the product, and cost.

Functional Properties

A functional property is the ability of an ingredient to impart an economically important characteristic to the finished product in which the ingredient is used. Functional properties of extenders used in meat products include, for example, water-holding, texture modification, improvement of flavor or appearance, improvement of sliceability for luncheon meats, reduced cook loss or fluid purge, modification of heat-set or cold-set gelation, emulsification of fat, or simply improvement of flowability or mixability of a seasoning mix Table 1.

Many of the functional properties of extenders depend on the ability of the material to interact with water, protein, or fat. Water-holding by an extender material is largely dependent on available charged groups and void spaces within granules of the material. Interactions of extenders with meat protein often involve charged groups along with hydrophobic interactions. Interactions with fat are largely hydrophobic but, an extender may help emulsify fat if it includes both hydrophobic and hydrophilic regions. Protein-based extenders such as soy or milk proteins may interact with meat proteins to increase cohesiveness or with fat to increase emulsion stability. Starch-based extenders such as corn or potato starch increase water-holding but may interfere with protein–protein interactions, thus weakening the protein matrix within the product. By selecting the right extenders the manufacturer can increase or decrease specific product properties to achieve a desired functional result, often with a concurrent reduction in formulation cost.

Choosing the best extender for a particular application is a complex process. An ingredient such as starch may be chosen for its low cost and water-holding ability but it also imparts other properties such as pale color and a tendency to soften the product by interfering with protein–protein interactions. Another, more expensive, ingredient such as soy protein concentrate also holds water while increasing protein–protein interactions and emulsion stability.

Addition of extender ingredients changes the nutrient profile of the meat product. The change may be desirable with low use rates of protein ingredients such as soy or milk increasing the protein content and often changing the amino acid composition to improve biological value. At high use rates, approaching 50% extension, protein digestibility and biological value may be decreased. Milk ingredients also add calcium, which is often lacking in meat products. Even calcium-reduced milk ingredients have enough remaining calcium to measurably raise the calcium content of the meat product. Extenders usually reduce the fat content of the meat product by simple dilution. However, most extenders, except cellulose ingredients, are digestible and contribute to the total calories of the product.

Another significant consequence of extender addition is possible allergic responses. Soy, wheat, and milk proteins are common allergens but any protein ingredient may be allergenic in sensitive individuals. It is critical that extender materials be adequately described on the product label to let consumers know what they are buying.

Table 1 Functions of extenders in meat products

- Reduce formulation cost
- Increase water-binding
- Modify texture
- Improve flavor
- Modify appearance
- Modify cohesiveness
- Provide for heat-set or cold-set gelation
- Improve nutrient profile

Extender Addition to Meat Products

Extenders may be added to meat products by direct addition to comminuted meat or, for intact muscle, by injection along with water, or by surface application in a marinade and massage system.

Extenders are commonly used in certain sausage or sliced luncheon meat products where they are added along with seasonings and incorporated during mixing or chopping. In such applications the extender may be in a range of forms from finely milled powder to coarse grits or flakes. The dry extender may be rehydrated with water to form a slurry before adding it to the meat. Extender ingredients added as larger pieces such as grits or textured flakes may be visible on close examination in the finished product. Hamburger extended with soy grits and water has a different appearance than ground beef without an extender. However, the extender is usually not intended to be visible in the finished product.

For whole muscle products such as ham or chicken breast extender is added as a solution or suspension in water. In this process, the ingredients are commonly referred to as binders instead of extenders. The liquid containing the binder is injected into the muscle using the same techniques as in meat curing. Only finely milled or soluble materials are suitable for this application. Care must be taken to control rehydration, swelling, or gelation of the binder in the injection system as these may lead to fouling of the injector or loss of yield control. Continuous agitation is often needed to prevent the binder from settling out of the water as the liquid sets in the injector reservoir. Additionally, binders or extenders injected into muscle tend to remain in the channels made by the injector needles. When the product is sliced the bands of binder material may be visible within the muscle. This problem is minimized by increasing the number of injection needles and decreasing the amount of material delivered by each.

In some types of products the functional benefits of extenders can be realized by applying the material to the product surface as part of a marinade. Mechanical action in the form of tumbling, massaging, or mixing is required to promote incorporation of the extender material into the surface of the muscle. Penetration depth is minimal, only a few mm. Nevertheless, this approach can be used to modify surface properties of a product to improve color, texture, or reduce fluid loss.

Functional Components of Extender Ingredients

A variety of nonmeat ingredients may be used as extenders in meat products. Sources may include plant seeds, tubers, milk solids, or fermentation processes among others. But, in spite of their varied origins, the functional properties of most extenders are provided by their protein and carbohydrate components. Extender ingredients generally contain little or no fat. Water-holding capacity, flavor, texture, and visual effects of extenders in meat products depend on the types and amounts of carbohydrates and proteins present.

The proportions of carbohydrates and proteins vary greatly with the plant source used. Flour, commonly milled from wheat, contains significant amounts of both starch and protein (gluten). The variety of wheat and the milling process determine the proportions of starch and protein in the flour. More complex separation processes may be used to produce specific, concentrated components from the milled seeds. Wheat gluten, a by-product commonly removed during milling of wheat flour for baking purposes, is widely used as a meat product extender, especially in European countries.

Starches are commonly derived from corn, potato, rice, or wheat using specialized procedures that separate starch granules from protein and other carbohydrate components. The separation is achieved based on density or viscosity differences between starch and protein granules. Modified starches are manufactured using chemical or physical processes that impart unique functional properties to the starch and increase its cost.

High-protein ingredients such as soy protein, wheat gluten, or corn protein are also produced following additional processing steps. By combining these separated, purified components, a meat extender may be created with a unique set of properties that fit a specific product. Of course, the cost of such a specialized extender would be greater than that of a simple milled flour Table 2.

Ingredients Used as Meat Extenders

The list of ingredients that may be used as meat extenders is almost limitless. However, in practice only a few ingredients have found wide acceptance as extenders. Some of the more commonly used ingredients are described in the sections that follow. This is not intended to be a comprehensive listing. Instead, it is a collection of examples of commonly used ingredients or ingredients that demonstrate a unique principle.

Table 2 Types of meat product extenders

- Flour – milled whole grain or grain with seed coat or germ removed
- Proteins – protein fractions of grains, milk, or animal products
- Native starch – starch granules fractionated from grain or tubers
- Modified starch – starch granules pretreated to improve functionality
- Dextrin – from partial cleavage of starch
- Cellulose – long chain complex carbohydrate, dietary fiber
- Hydrocolloids – longer chain, charged side groups, high hydration

Soy Ingredients

Soy protein products represent a great model for discussing extenders in meat products. They are commonly used extenders in many countries. Soy products come in various types and physical forms and serve several different functions.

Soy flour is produced by pressing dehulled soybeans with a solvent to separate the soy oil. The resulting soy grits may be used directly or milled into soy flour. Soy grits or flour contain approximately 45–50% protein along with carbohydrate that imparts a distinctive 'beany' flavor to products. Soy flour may be heated and extruded to produce textured soy flour with a more meat-like texture compared to plain soy flour. Soy flour is an effective water-holder but in spite of its high protein content it has limited ability to participate in protein–protein interactions or fat emulsification. Soy flour may be partially purified by removal of much of the carbohydrate. The resulting soy protein concentrate (SPC) is approximately 70% protein, has much less beany flavor, and has improved protein functionality. SPC is often jet-cooked to further improve its protein functionality. Jet-cooked SPC exhibits excellent ability to interact with meat protein contributing to product firmness. It also has improved capability for fat emulsification. SPC may also be texturized by heating and extrusion to give a meat-like texture.

An extraction process is used to dissolve and then precipitate certain protein fractions from the soy flour to produce isolated soy protein (ISP). This material contains 90–95% protein and exhibits almost no 'beany' flavor. ISP has excellent protein functionality with capability for fat emulsification and increased fluid viscosity and gelation. Like soy flour and SPC, it may be texturized by thermal extrusion. It is also used to produce spun fibers, with improved meat-like texture, which perform nicely in production of meat analogs.

With each successive step from soy flour through isolated soy protein the cost of the material increases. In specific meat products or situations the improved functional properties and reduced flavor intensity of soy concentrate or isolated protein may justify the cost. However, soy flour or grits are most widely used as meat extenders. The beany flavor may become part of the product's flavor profile or seasonings may be used to mask the flavor. Dry soy flour is commonly rehydrated with 2.5–3.5 parts water for one part soy flour. The resulting slurry is added to the meat in the mixer or chopper. The added soy flour slurry may represent up to 50% of the finished meat product. Of course the amount used must be in compliance with applicable ingredient and labeling regulations. In the USA soy flour, SPC, and ISP are limited to 3.5%, 3.5%, and 2.0%, respectively, in cooked sausage products.

Milk Ingredients

Milk proteins are relatively expensive but are chosen by meat processors because of their unique ability to interact with meat protein to form heat-set gels and contribute to stable emulsions. Nonfat dried milk solids (NFDMS) are derived from fluid milk by fat separation and drying. It contains approximately 36% protein including casein and lactalbumin among others. NFDMS is used in meat products to increase water-holding and reduce cook loss. In finely comminuted products it contributes

to improved emulsion stability. Water-holding and emulsifying capabilities of NFDMS may be improved significantly by replacing much of its calcium with sodium. For this reason, the so-called calcium-reduced NFDMS is preferred for use in meat products even though it costs more. The high lactose content of NFDMS, approximately 52%, contributes to flavor and texture of the finished product and may be considered as undesirable in certain products. In the USA, NFDMS utilization is limited to 3.5% of finished product for comminuted meats.

Casein may be precipitated from milk and then resuspended as sodium caseinate. This process produces a concentrated protein (approximately 90% protein) and eliminates most of the calcium and lactose. Sodium caseinate has excellent water-holding and emulsifying properties, a mild flavor, and pale color. It tends to impart a smooth mouthfeel to fine ground sausages. In the USA, this ingredient is limited to 2.0% of finished product for comminuted meats and 1.5% of finished product for water-added ham.

The whey remaining after manufacture of cheese or precipitation of casein contains whey proteins, primarily lactalbumin. The whey may be dehydrated for use as a food ingredient but the dried whey contains up to 75% lactose and over 8% ash. Instead, whey protein concentrate is often produced using an ultrafiltration system to remove lactose and minerals. Dried whey protein concentrate is approximately 80% protein, 4.5% ash, and 6% lactose. It exhibits good water-holding capacity and forms an irreversible heat-set gel when heated above 70–75 °C.

Starch Ingredients

Various starches may be used as extenders in meat products. Starches are generally less expensive than protein ingredients and have low flavor and color intensity. Native starches represent stored carbohydrate in cereal grains and tubers. They are composed of two types of glucose chains, amylose (unbranched glucose) and amylopectin (branched glucose). The glucose chains are packed into starch granules within seeds (grains) or roots (tubers). The size and amylose/amylopectin makeup of the starch granule varies with plant source. Potato starch has larger granules whereas corn starch granules are small. Waxy corn starch contains only amylopectin although most starches include a mixture of amylose and amylopectin.

Starch granules are insoluble in cold water. On heating in water the granules suddenly swell and hydrate, eventually producing a viscous solution in a process called gelatinization. This process accounts for the high water-holding, increased viscosity, and gelling ability of starches. The gelatinization temperature varies for starches from different plant sources. In general, starches with larger granules swell and gelatinize at lower temperatures compared to those with smaller granules. Water-holding or viscosity of starch gels may be lost if the linear glucose chains reform into granules. This process called retrogradation leads to release of water and loss of product quality. When unmodified starch is used in meat products, retrogradation is likely during extended refrigerated storage. Starch retrogradation is accelerated by freezing and thawing.

Native starches are classified on the basis of their properties (viscous, watery, or stringy paste and strong or weak, clear or opaque gel on cooling) with cereal starches (corn, wheat, rice, and sorghum) setting to a strong opaque gel on cooling. Root and tuber starches (potato, cassava, and tapioca) are highly viscous and set to a clear, weak gel on cooling. Waxy starches (waxy corn, sorghum, rice) produce very high viscosity but do not form a rigid gel.

Native starches may be chemically modified to reduce gelatinization temperature or to alter viscosity or gel strength and to control retrogradation. Because most native starch granules do not gelatinize at typical meat cooking temperatures, modified starches are generally preferred for meat applications. Starch may be modified by acid or enzyme treatment, oxidation, or heating among others. Most modification processes involve partial cleavage of the starch to produce shorter glucose chains. This weakens the starch granule allowing for reduced gelatinization temperature. Viscosity and cooled gel strength are affected and the tendency for retrogradation is reduced.

Modified starches are used in meat products to increase cook yield, reduce fluid purge, increase product firmness, and improve sliceability. Overall firmness of the product may be increased due to reduction in free water. Certain starches may be used along with added water as fat replacers. Starches generally do not interact well with meat proteins so they can be used to reduce rubbery character in very low-fat products. The increased fluid viscosity produced by the starch is said to contribute an oily texture during chewing. This property is useful in fat replacement. Under some circumstances starches may cause reduced adhesion among meat pieces in restructured products. This is especially true if the starch is not injected but added in the blender or massager. The combination of starch source and modification process is critical in determining the performance of starch in a meat product.

Some practical issues arise when using starches in injection systems. Because the granules are not soluble, there is a tendency for rapid settling of the starch in the injector reservoir or other containers where the brine is allowed to set. The starch may settle out in the brine pump itself if it is stopped for a time. Continuous agitation is needed to keep the granules suspended during operations and the pump should be rinsed immediately after use. When using modified starches, care must be taken to assure that the temperature in the pumping system does not rise high enough to trigger gelatinization. The resulting change in viscosity can lead to loss of process control and possible equipment damage.

Inulin and Oligofructose

Some plants such as chicory, garlic, or onion do not produce much starch but instead store carbohydrate in the form of inulin and oligofructose. These are polysaccharides comprised of glucose and fructose subunits with varying chain length. Nutritionally, inulin and oligofructose are considered soluble dietary fibers. They are only minimally digested and do not elevate blood sugar levels. Inulin from some plants such as chicory root has a slightly sweet taste. When dissolved in water they impart a slippery, oily mouth-feel that may be quite beneficial in low-fat meat products. Thus, use of inulin in meat products is mostly as part of fat replacement system with

water. Inulin gel improves the texture of low-fat meat products. It also improves water-holding and has been shown to stabilize foams and emulsions in nonmeat food systems.

Gums and Hydrocolloids

Gum is a term that refers to a group of long-chain polysaccharides characterized by the ability to give highly viscous solutions at low concentrations. Ingredients in this group include exudate gums, seaweed gums, microbial gums, seed gums, and certain starch or cellulose derivatives. Ingredients in this category are used throughout the food industry but have found only limited use in processed meats. Unlike classical meat extenders, gums are commonly used at very low concentrations to improve yield, texture, and sliceability and to reduce fluid purge in products with high added water. The cost of gums is usually higher than for other extender ingredients but their exceptional performance may offset the cost.

The most commonly used gum or hydrocolloid in meat products is carrageenan. Carrageenan is a seaweed-derived gum extracted from red kelp. It is composed of linear galactose chains with varying amounts of sulfate side chains that contribute to its water-binding and gelling properties. There are three types of carrageenan, identified as kappa, iota, and lambda. On cooling, kappa carrageenan forms a rigid, brittle gel that tends to release fluid during storage. Iota carrageenan forms a weaker, more elastic gel that is reasonably stable through refrigerated storage, freezing, and thawing. Carrageenan gels may be melted and reformed repeatedly. Lambda carrageenan is used for thickening and viscosity but does not form a cold-set gel. In meat products, mixtures of kappa and iota carrageenan are combined in varied proportions for different applications. Benefits expected from use of carrageenan include improved cook yield, reduced fluid purge, improved sliceability and cohesiveness. Carrageenan has been used along with water in reduced fat products to improve juiciness and texture. Carrageenan is often used at a concentration of approximately 1% of meat weight. Highly refined carrageenan ingredients may give satisfactory results at concentrations of less than 0.5% of meat weight. USDA limits use of carrageenan to 1.5% of finished product for cured meat products.

Flavorings and Seasonings as Extenders

Proteins from plant or animal sources are commonly subjected to partial hydrolysis or other modifications to develop flavorings for food products. Such flavor ingredients appear on the product label and are regulated separate from similar proteins used as extenders. In most cases flavoring ingredients are considered to be self-limiting and thus are allowed at concentrations 'sufficient for purpose.' The hydrolysis process may be quite minimal and the flavor intensity low so that a considerable quantity is needed to alter product flavor. In this situation the meat processor may also consider water-holding and texture benefits in addition to the flavor contribution of the ingredient.

Seasoning ingredients may be an unconventional source of extender materials. An example is mustard seed. Ground mustard is a high protein (26–38%) ingredient with water-holding, gelling, and antibacterial properties. It is used in processed meats as a binder and extender and to enhance product flavor. Deheated mustard is a common ingredient in cooked sausages where it contributes to water-binding, fat emulsification, color, and flavor.

Animal-Derived Extender Ingredients

Consumer resistance to other-species ingredients has reduced the popularity of several animal-derived extender ingredients. Nevertheless, these ingredients are still available and in use for many meat products. Gelatin is probably the most widely used of these ingredients. Most gelatin protein is extracted from animal skins, bovine or porcine. Gelatin takes up water on heating and forms a reversible cold-set gel. It is typically added to processed meat products to reduce purge during refrigerated storage. Raw collagen in the form of powdered skin or muscle-connective tissue is also utilized. It has much lower cost than gelatin and reduced functional properties. This material takes up water on heating but is not soluble, so it is not easily used in injection systems. Blood serum proteins have excellent water-binding, foaming, and emulsifying capabilities. They may be particularly useful in hotdogs and luncheon meats where all these properties are desired.

Functional

E Mills, Penn State University, PA, USA

This article is a revision of the previous edition article by E Mills, volume 1, pp 1–6, © 2004, Elsevier Ltd.

Glossary

Bacteriocin An antimicrobial protein produced by certain bacteria.
Comminuted meat The meat that has been ground or otherwise divided into very small particles.
Essential oil A volatile oil comprising aromatic components of spices that are responsible for distinctive aroma or flavor.
Maillard browning A chemical reaction between carbohydrates and proteins leading to a brown color with development of cooked flavor.
Monosodium glutamate A sodium salt of glutamic acid and a potent activator of umami taste sensor.
Myoglobin A red pigment found in meat, especially red meat.
Nitrosamine A compound resulting from reaction of nitric oxide with secondary amine, some of which are carcinogenic.
Nitrosylhemochrome The compound responsible for the familiar pink color of cured meat.

Regulations

Regulation of functional ingredients in meat products is quite variable around the world. No attempt will be made here to address specific regulatory issues for functional ingredients. Nevertheless, some general observations might be appropriate. Ingredients that impart obvious flavor or visual properties, such as salt and spices, are often considered to be self-limiting and are often unrestricted. Ingredients, such as sodium nitrite and sodium nitrate, can be quite toxic and thus are closely regulated in most parts of the world. Certain ingredients that might be improperly used to deceive an unwitting customer are also regulated in most countries. Examples in this category include sodium phosphates that contribute to increased water-holding ability or reducing agents that may stabilize color, even when the product is noticeably spoiled. In addition to these intuitively obvious regulations, the decisions to regulate specific ingredients are often a matter of tradition or circumstance. Thus, meat manufacturers often encounter a confusing patchwork of regulations when they market their products in other countries.

Adding Functional Ingredients to Meat Products

The addition of functional ingredients to meat products may be achieved using various methods, depending on the properties of the functional ingredients and the meat products. For comminuted or heavily macerated meats, all types of ingredients are easily dispersed by mixing or massaging. Mixing is a rapid process requiring only minutes to achieve uniform distribution of ingredients. Addition of ingredients to intact muscle is more complex. Low molecular weight, easily soluble ingredients such as salt or nitrite may be added by surface application of the dry ingredients, by injection of a water solution into the meat, or by immersion of the meat in a water solution. Injection is quite rapid whereas surface application or immersion requires days or weeks for ingredients to diffuse throughout the intact muscle. Larger molecular weight or insoluble ingredients might be added by injecting a suspension of the ingredients. Continuous agitation is needed to keep the ingredients in suspension during injection. Also, the suspended materials tend to remain in the path opened by the injection needle and become visible when the finished product is sliced.

Functional Ingredients

Salt

Salt (sodium chloride) is the most commonly used functional ingredient in meat product manufacture. It is used primarily for flavor with microbial inhibition, extension of shelf life, and increased protein hydration as secondary functions. Choices relating to the amount of salt to formulate in a product are usually based on taste preferences of customers. Finished product salt concentrations of 1.5–2.5% are common for processed, ready-to-eat meat products. Microbial inhibition and extended shelf life from salt addition are achieved by reducing water activity and, in some cases, by increasing the chloride ion content in the product. With very high salt content (6% or more), the product may be made shelf-stable due to reduced water activity. Such a product would have an intense salty flavor. Salt increases water-holding in meat protein systems and soluble protein in comminuted meat products. Much of the protein that is brought into solution with addition of salt is myosin. Soluble myosin has excellent emulsification and gelling properties. As a result, salt addition is critical for creating a stable and emulsion-like structure in finely comminuted products such as hot dogs.

Nitrite

Nitrite (sodium nitrite or potassium nitrite) is included in many processed meat products for the purpose of inhibiting

spore-forming microorganisms, especially *Clostridium botulinum*, and for stabilizing color and flavor. Meat products containing nitrite are commonly referred to as cured meat products. On addition to meat products, nitrite is reduced to nitric oxide, and this reactive intermediate accounts for most of the functions of nitrite. When nitric oxide from nitrite binds to the iron atom within myoglobin, its pigment properties are changed to a heat-stable form. This so-called pigment stabilization due to nitrite/nitric oxide leads to meat products that retain their pink color even after heating to well done. This heat-stable pink color, nitrosylhemochrome, is an identifying character of products cured with nitrite.

In addition to its effect on meat color, nitrite also influences meat flavor. Although nitrite or nitric oxide, at the low concentration used in meat curing, do not directly impart much flavor, it plays an important role in controlling lipid oxidation. When fresh meat products are cooked, a number of physical and chemical changes lead to accelerated oxidation of unsaturated fatty acids. This oxidation pathway is initiated, in part, by iron released from myoglobin and perpetuated by continuous formation of free radicals from the oxidized fatty acids. The resulting off-flavors are sometimes called warmed-over flavor. In cured meats, two mechanisms cooperate to limit lipid oxidation. First, nitric oxide stabilizes the heme iron in myoglobin and second, nitric oxide reacts with the free radicals to produce a nonreactive product and effectively stop the oxidation chain reaction. These important functions help cured meat products maintain their desirable flavor through extended storage.

In spite of its various benefits, nitrite is a toxic material with a lethal dose for humans of 22–23 mg per kg of body weight. The low amounts used in cured meat products, 200 mg per kg or less, virtually eliminate any risk of toxicity through consumption of cured meats. In addition to its direct toxicity, nitrite might react with certain amino acids to produce nitrosamines, some of which are carcinogenic. The nitrosamine-producing reaction is favored by high temperatures and acidic conditions. The high temperature developed when frying sliced bacon is known to lead to nitrosamine formation if the residual nitrite content is high. This occurrence is minimized by using a lower ingoing nitrite level for bacon and by including reducing agents that help deplete residual nitrite before frying.

Nitrate

There is currently little use of nitrate (sodium or potassium nitrate) in cured meat products. Nitrate is a precursor of nitrite in meat curing. Unlike nitrite, nitrate is comparatively stable in meat products. It reacts slowly, through reduction by microbial enzymes, to release nitrite over an extended period of time. Nitrate use is limited to products such as dry sausage, Prosciutto or Parma ham, and dry cured products that require long curing and aging times. Nitrate is much less toxic than nitrite and is found in many foods including fresh vegetables and drinking water.

Nitrate from Plant Sources

Consumer interest in 'Natural' labeled products in the USA has lead meat processors to manufacture products using nitrate found in certain plant-derived ingredients. Dehydrated celery juice powder is one commonly used ingredient. Such meat products, manufactured without the use of pure sodium nitrite or sodium nitrate, must be labeled as 'Uncured.' Nevertheless, the naturally occurring nitrate in celery juice powder may be converted to nitrite leading to typical cured meat properties. The shelf life, however, and especially cured color, of these 'Naturally Cured' products are considerably reduced compared with conventionally cured products.

Phosphate

Phosphates used in meat processing are usually alkaline polyphosphates. Sodium tripolyphosphate is a very commonly used linear polymer of three phosphate units. Other longer chain polymers can be used, but pH and buffering benefits of phosphate are reduced at longer chain lengths. On addition to meat products, the alkaline phosphate raises the pH away from the isoelectric point of meat proteins and thus increases the water holding. Over time, enzymes in the meat convert longer-chain polyphosphates into diphosphate (pyrophosphate). Pyrophosphate has the ability to break actomyosin cross-bridges that have not transformed into full rigor cross-bridges. Thus, pyrophosphate is the most effective form for increasing water holding and emulsifying ability of meat proteins. However, pyrophosphate has low solubility in water and tends to settle out of brine solutions as insoluble aggregates. Thus, meat curing brines are typically prepared using longer chain, more soluble polyphosphates. Even when using more soluble phosphates, great care must be taken to assure that the phosphate goes into solution before other ingredients, especially salt, are added. For sausage products, where phosphate solubility is not an important issue, it is common to utilize phosphate blends with a higher proportion of pyrophosphate. Thus, the maximum benefit of the phosphate may be realized immediately.

In addition to their influence on water binding and protein hydration, polyphosphates are also able to chelate metal ions that might otherwise catalyze lipid oxidation. Cooked meat products containing alkaline polyphosphates exhibit less lipid oxidation and flavor loss during storage than similar products without phosphate. Phosphates have also been shown to reduce microbial growth, especially that of Gram-positive bacteria. The effect is most pronounced for longer-chain polyphosphates but is also detectable for pyrophosphate.

Erythorbate

Erythorbate (sodium or potassium erythorbate) is a reducing agent used in cured meat products to facilitate the reduction of nitrite to nitric oxide. Sodium erythorbate and erythorbic acid are isomers of sodium ascorbate and ascorbic acid (vitamin C), respectively. Some manufacturers prefer to use the more expensive ascorbic acid in place of erythorbate because they want to list vitamin C on the ingredient statement. As reducing agents, erythorbate, erythorbic acid, ascorbate, and ascorbic acid are chemically equivalent.

Erythorbate is quite important in the curing reaction as it promotes the production of nitric oxide that binds to and stabilizes myoglobin. This is especially beneficial in products

such as frankfurters that might be manufactured and cooked in a very short time, less than 2 h. Use of erythorbate is also beneficial in products such as bacon where elevated residual nitrite might lead to formation of undesirable nitrosamines. In the USA, bacon is required to have 550 mg kg^{-1} of sodium erythorbate or equivalent in the formulation in order to reduce residual nitrite. Because nitrite is quickly converted into nitric oxide, its concentration has to be reduced before the high temperature of frying can lead to nitrosamine production.

Erythorbic acid or ascorbic acid may be used as reducing agents and oxygen scavengers to slow down light-induced fading of cured meat color. For this application, a solution is used to spray or dip the product before vacuum packaging. The application must not add appreciable weight to the product but can be quite helpful in extending the color shelf life of a cured meat product.

Sweeteners

Sucrose, dextrose, and corn syrup products, among others, are commonly used as sweeteners in manufactured meat products. These carbohydrate materials are usually included to impart a desired degree of sweetness. However, properties such as surface browning, water binding, mouthfeel, or smoothness, and the ability to be fermented by microorganisms are also important considerations in choosing the right sweetener. Nonnutritive sweeteners such as saccharin, cyclamate, aspartame, and sucralose have not been widely utilized in the meat industry due to high cost and limited functional benefits.

The sweetness of sugars is usually described in reference to sucrose (cane sugar). Considering sucrose to have a sweetness value of 100, the sweetness of some other sugars is as follows: fructose = 173, dextrose = 74, glucose = 74, and lactose = 16. Corn syrup and dried corn syrup products may be manufactured with a wide range of sweetness, depending on the degree of starch hydrolysis and dextrose isomerization to fructose. High fructose corn syrup with sweetness of approximately 130 is made by complete hydrolysis of corn starch to dextrose and maximal enzymatic conversion of dextrose into fructose. Low sweetness corn syrup products would be manufactured using only partial hydrolysis of corn starch to dextrose and no conversion of dextrose to fructose. Low sweetness corn syrup products are utilized more for their water-binding abilities than for sweetness.

Surface browning of meat products during cooking is a desirable process involving sugars in the product. Caramelization of sugars might lead to surface browning if very high temperatures greater than 190 °C are achieved as with radiant heat cooking. However, the Maillard browning reaction between protein and a reducing sugar is much more common in meat products. Dextrose, glucose, and corn syrup sweeteners all participate in the Maillard browning reaction. However, sucrose does not participate much in Maillard browning. The use of sucrose alone may lead to insufficient surface color during cooking and smoking of meat products.

Seasonings

Seasoning is the general term for ingredients used primarily to impart or modify flavor of food products. Many seasonings also contribute to product color. Seasonings include spices, herbs, and vegetables among others.

Spices are aromatic parts of plants. The particular part may be the fruit, seed, bud, flower, stem, leaf, or root of the plant. Herbs, a subclass of spices are dried aromatic leaves. The flavor or aroma intensity of natural spices varies with season, geographic source, and cultural conditions. Thus, the flavor and aroma of seasoned meat products may vary also. To improve product consistency, many processors have chosen to use essential oils or oleoresins of spices with standardized flavor and aroma intensities.

Essential oils include only the volatile, aromatic components extracted from the natural spices. They generally have little color and may not have a typical spice flavor because nonvolatile taste components are not included. Essential oils are usually extracted using steam distillation to recover the volatiles from the natural spice. Essential oils are widely used in the fragrance industry but are less common in the food industry.

Oleoresins are derived from natural spices by solvent extraction. They include both volatile and nonvolatile components of the spice. Thus, their flavor and aroma might closely match that of the natural spice. The solvents selected for extraction can greatly influence the content of the oleoresin. A low-polarity solvent, such as petroleum ether, will recover a different set of components than a higher-polarity solvent, such as acetone. Solvents are generally chosen so that the oleoresin includes the principal flavor, aroma, and color components of the natural spice.

Natural spices are harvested, dried, and ground with minimal heat treatment in order to protect the important volatiles present. The lack of a thermal kill step means that many bacteria, especially spore formers, survive on the ground spices. For many years, an ethylene oxide gas fumigation treatment was used to sterilize natural spices. Presently, irradiation is replacing ethylene oxide as the preferred sterilization technique. Both techniques are effective for destruction of bacteria. However, concerns with respect to dangers from small residual amounts of ethylene oxide are motivating many companies to switch to irradiation sterilization.

Flavorings

The term 'flavoring' is usually reserved for manufactured ingredients intended to impart or strengthen a specific flavor or flavor note. Most flavorings are made from high-protein materials such as soy protein, yeast extract, milk protein, or blood serum proteins. The protein is partially hydrolyzed to produce a mix of peptides that impart a particular flavor, such as beef or pork flavor.

The hydrolysis and chemical modification process used in preparation of flavorings is a highly protected art with much of the technology developed by trial and error. Flavor chemists share few of their secrets but some generalizations are well-established. Extensive hydrolysis to produce many short peptides tends to heighten the overall intensity, especially the bitter aspect of the flavoring. Complete hydrolysis of a protein with a high content of glutamic acid leads to production of monosodium glutamate (MSG). MSG is an effective flavor

potentiator and activates the umami receptor to give a savory note central to meat flavor. Very mild hydrolysis leads to a flavoring with low flavor intensity. This ingredient might be used when the processor wants to take advantage of other protein properties, i.e., water holding, in addition to the flavor.

Tenderizers

Tenderization of meat products can be achieved in several ways. Some of the ingredients used for tenderization include proteolytic enzymes, acids, salt, and phosphate, among others. See 'Tenderizing mechanisms: (c) Chemical/enzymatic' in this encyclopedia for a detailed discussion.

Antimicrobials

Many of the ingredients used in meat processing, for example, salt, nitrite, and phosphate, have antimicrobial properties. Nevertheless, only a few ingredients are used primarily for their antimicrobial capabilities. These are the focus of this section.

For many years, mold inhibitors were the principal class of antimicrobials used in the meat processing industry. Products in this category include potassium sorbate and propyl paraben. They are used in dry sausage manufacture to control surface mold growth. Casings for dry sausage may be dipped in a solution before stuffing, or the chubs or links may be dipped after stuffing.

Recent regulatory changes, including a zero tolerance for certain pathogens, especially *Listeria monocytogenes* and *E. coli* O157:H7, have led to a greatly increased interest in antimicrobials for fresh and ready-to-eat meat products. Many new ingredients or new applications of existing ingredients are in use or under investigation. Laboratory findings often fail to hold true in the field; so some or most of today's new antimicrobial ingredients might survive the test of time. Following is a description of some of the antimicrobials of interest.

Most of the recent work with antimicrobials has focused on surface sprays or dips that kill or limit growth of bacteria on fresh meat or ready-to-eat product surfaces. Organic acids, such as lactic, citric, and acetic, fall in this category along with sodium diacetate, acidified sodium chloride, acidified calcium sulfate, and cetylpyridinium chloride. Activated lactoferrin may also be used as a surface treatment to prevent bacteria from attaching to the meat surface, thus making them more susceptible to removal or destruction. Sodium or potassium lactate might also be used as antimicrobial ingredients in formulation of meat products, especially ready-to-eat items.

Bacteriocins, small proteins or peptides produced by certain bacteria, are another new type of antimicrobials of interest in the meat industry. Nisin, a bacteriocin produced by the lactic acid bacteria *Lactococcus lactis*, is used in the food industry as an inhibitor of Gram-positive organisms. When incorporated into the casing or packaging material of a processed meat product, nisin helps control bacterial growth on the product surface. Other bacteriocins also show promise for helping control pathogens or spoilage organisms in meat products.

Antioxidants

Lipid oxidation is a considerable problem for flavor of precooked meat items. On heating, physical and chemical changes take place in meat, making unsaturated fatty acids susceptible to rapid lipid oxidation. Oxidation also occurs slowly in fresh meat exposed to light and air. Initiation of oxidation may be controlled by limiting exposure to light and oxygen. The focus of this entry is control of lipid oxidation using antioxidant ingredients.

Lipid oxidation includes initiation and propagation events. Antioxidants work by preventing initiation or by stopping propagation. Initiation of oxidation in meat usually involves oxygen and a metal catalyst, such as iron or copper. The first step is the metal-catalyzed production of a free radical. Antioxidants that chelate metals prevent initiation by keeping the catalysts away from the substrate. Citric acid, polyphosphates, and EDTA (ethylene diamine tetraacetic acid) prevent oxidation by chelating metal ions that might otherwise catalyze initiation of lipid oxidation. Propagation of lipid oxidation over time occurs as free radicals formed during initiation react with oxygen and move on to attack another fatty acid double bond. This attack produces a new free radical that can repeat the process. This cascade process can be stopped by providing free radical acceptors that reduce the free radicals to a nonreactive form. BHA (butylated hydroxyanisol), BHT (butylated hydroxytoluene), TBHQ (tertiary butyl hydroquinone), PG (propylgallate), alpha tocopherol (vitamin E), nitric oxide from sodium nitrite, and the natural antioxidant in the spice rosemary, all act as free-radical scavengers donating electrons to reduce the free radicals to a stable form.

Lipid oxidation naturally occurs in the lipid, hydrophobic portion of meat products. Nevertheless, oxidation intermediates, such as free radicals, might be quite hydrophilic and move into the water portion of the product. Many antioxidants (BHA, BHT, PG, and tocopherols) segregate into the lipid portion whereas citric acid, polyphosphates, EDTA, and nitric oxide localize in the water portion. For best control of oxidation, it might be beneficial to include both a hydrophobic and hydrophilic antioxidant.

Control of lipid oxidation in cooked meat products often involves a combination of control measures. For example, smoked ham contains polyphosphates that control initiation and nitrite (nitric oxide) that acts as a free radical acceptor. In addition, ham usually contains ascorbate or erythorbate, an oxygen scavenger, and is vacuum packaged to limit oxygen exposure. When all these measures are in place to protect against oxidation, smoked ham might be stored under refrigeration for months without appreciable loss of flavor due to lipid oxidation. The same muscle cooked as a pork roast without any added antioxidant protection would exhibit detectable off-flavor within a few hours after cooking.

Acidifiers

Acidifiers are added to meat products to impart a tangy or tart flavor note, to extend shelf life, to tenderize fresh meat, or to promote protein denaturation and moisture release in dried snack products. Acidification is achieved by natural fermentation in traditional, long-process fermented sausages

(Hard Salami), and some whole-muscle products (Proscuitto Ham). However, direct addition of an acidifier allows the process to proceed more rapidly, achieving the desired pH reduction in a matter of minutes. Direct acidification allows the manufacture of many products that would not be practical using natural fermentation.

The most commonly used acidifiers in meat products are lactic acid and citric acid. Lactic acid is favored in products intended to compete with naturally fermented products because it has the same flavor profile. Citric acid is usually less expensive than lactic and is preferred in products such as dry sausage where its antioxidant properties are beneficial. Other acidifiers include acetic, adipic, fumaric, malic, phosphoric, and tartaric acids. Glucono-delta-lactone (GDL) is a unique acidifier sometimes used in the meat industry. It has little effect on pH until it is hydrolyzed to produce gluconic acid. This delayed acid release may be quite beneficial as discussed below.

Several important properties of meat, including color, water-binding ability, and protein functionality, are influenced by pH. Thus, addition of an acidifier to a meat product might have a variety of effects, both expected and unexpected. The normal pH of postmortem muscle is 5.6–5.8. This is somewhat above the isoelectric pH of muscle proteins. With addition of acid, the pH declines toward the isoelectric point where water binding is at its minimum and protein denaturation proceeds more rapidly. Below the isoelectric pH, protein denaturation continues with loss of fresh meat color and reduced protein solubility. Acid-denatured proteins are less able to bind water, emulsify fat, or form a heat-set gel that adheres meat pieces together.

The timing of acidification is often critically important in determining product properties. If acid is added at the start of the mixing process for a ground meat batter, the surface proteins on each meat particle will be denatured, causing bind failure. The finished product will be crumbly or mealy, and fat will separate during cooking. This problem may be managed by using GDL or an encapsulated acid and adding the acid very late in the mixing process. As mentioned above, GDL is acidic only after hydrolysis to gluconic acid. Encapsulated acid is similarly delayed from contact with the meat by virtue of a lipid coating around acid droplets. Encapsulated acid is not released until the cooking process when elevated temperature leads to melting of the lipid coating. At this point in the process, acid and heat denaturation of protein lead to a firm, cohesive texture.

DNA Markers and Marker-Assisted Selection in the *Genomic* Era

EA Navajas, Instituto Nacional de Investigación Agropecuaria, Canelones, Uruguay

This article is a revision of the previous edition article by Navajas and Simm, volume 1, pp 19–27, © 2004, Elsevier Ltd.

Glossary

Breeding value Sum of average effects of alleles, summed over the pair of alleles at each locus and over all loci affecting a trait. It is traditionally predicted based on the performance of the individual and relatives for the trait.

Genomic breeding value Prediction of the genetic merit of the animal based on information provided by high density panels of DNA markers (genomic information).

Genomic selection Selection is based on breeding values predicted from a very large number of estimated DNA marker effects across the whole genome. It is also a marker assisted selection because genomic data is combined with other sources of information to enhance accuracy of breeding values at an early age and facilitate the selection of new traits.

Marker-assisted selection (MAS) The process of using information provided by DNA-markers to predict the genetic merit, assisting the identification of the best animals to be used as parents of the next generation. The DNA marker information should contribute to improve the accuracy of selection and increase the rate of genetic progress by identifying animals carrying desirable genetic variants for a given trait at an earlier age.

Molecular marker Identified segment of the DNA in the genome with known sequence and location on a chromosome. Nowadays, single-nucleotide polymorphisms (SNPs) are commonly used markers in association studies and genomic selection.

Quantitative trait Phenotypes (characteristics) that vary in degree and can be attributed to polygenic effects and their environment.

Quantitative trait loci (QTL) Chromosome segments containing or linked to the genes that underlie quantitative traits.

Introduction

Most economically relevant traits in livestock production systems are under genetic control, which implies that they can be genetically improved by exploiting the genetic variability within and between breeds. Significant genetic improvement rates have been reported in many characteristics such as growth performance, wool production, and milk composition. Less emphasis has been given in selection schemes in livestock species to those attributes which are related to carcass composition, meat quality in particular. This is partially explained by the difficulties and high costs of measuring them.

However, more attention has lately been given by breeders and geneticists to carcass and meat quality traits due to the stronger influence that consumer satisfaction has had on the supply chain in the past few decades; consequently, increased efforts are being directed toward the genetic improvement of carcass traits and meat quality.

Advances in molecular genetics are leading to valuable applications in the meat industries, such as providing accurate paternity tests or certifying the origin of specific products. The limitations of identifying superior genotypes for meat quality, due to the difficulties of collecting phenotypic data on these traits, may be overcome by molecular genetics. The very recent developments in structural and functional genomics, as novel and promising techniques, will provide a more comprehensive understanding of the genetics and metabolic paths, with direct application on genetic improvement. This article presents main concepts on deoxyribonucleic acid (DNA) markers and marker-assisted selection with emphasis on carcass and meat quality. The potential of the novel genomic tools and their implications for the genetic improvement of these traits are discussed.

 doi:10.1016/B978-0-12-384731-7.00002-7

Role of Molecular Markers on Genetic Improvement of Carcass and Meat Quality Traits

Most of the relevant carcass and meat quality characteristics are quantitative traits whose phenotypic expression is the result of the joint action of several genes and environment. In general, the evaluation of the genetic merit of individuals and breeds is based on the analysis of phenotypic records plus pedigree information.

Although phenotypes are not perfect predictors of breeding values, conventional animal breeding methodologies have been effective in the genetic improvement of traits under selection. The limitation on obtaining phenotypic information of carcass and meat quality is a significant restriction for their genetic improvement, especially for meat quality. Modern *in vivo* noninvasive techniques allow the inclusion of carcass composition in the selection schemes using measurements on breeding animals, but the assessment or prediction of meat quality traits still relies on the implementation of siblings or progeny tests, which lead to longer generation intervals and, consequently, slower genetic progress.

The inclusion of the genetic information provided by molecular markers can make a significant contribution to the genetic improvement of carcass and meat quality traits. Estimations of genetic merit can be available for breeding animals at younger ages with levels of accuracies that were not possible before. Higher selection accuracies and shorter generation intervals will lead to higher rates of genetic improvement. In addition, it would be possible to consider in breeding programs some very difficult and expensive traits to measure, such as fatty acid composition or flavor. Furthermore, it will be possible to investigate the differential expression of genes in different muscles and different *in vivo* and postmortem phases, by the application of transcriptomics and proteomics. Based on the information provided by the transcriptome and the proteome, these new 'omics' give insight into the genes being expressed and the proteins influencing metabolic pathways, thus complementing the understanding achieved through genomics.

Markers and Quantitative Trait Loci

Genetic variability at DNA level can be directly assessed by using genetic markers. They are segments of DNA with a known position in the genome, which can be identified by laboratory tests (genotyping). By analyzing DNA samples that are very easy to extract from tissue samples, such as hair, blood, or meat, the variant (allele) of each genetic marker which an animal carries can be detected. Markers are of different types. In the recent past, markers called microsatellites were the ones of preference because they were very polymorphic (many alleles) and, therefore, highly informative. However, the genotyping of this type of marker is relatively expensive and difficult to standardize. Nowadays, single nucleotide polymorphisms (SNP) are extensively used. They are abundant and the genotyping shows low rate of errors at a low cost with current technologies.

In some cases, the marker is the gene of interest, or it is a fragment of DNA within the gene. If this is the case, knowledge of the marker variant directly indicates which the gene's variant (direct marker) is (**Figure 1**). However, in most cases, genetic markers are nonfunctional or neutral genes, which are linked to the gene of interest (indirect marker). Despite being nonfunctional, indirect genetic markers can provide valuable information not only for the identification of the target gene but also for selection on the trait of interest. Direct and indirect genetic markers can be used in genetic improvement schemes, although they require different strategies and lead to different responses to marker-assisted breeding, which will be discussed in the Section Identification of QTL and Genes.

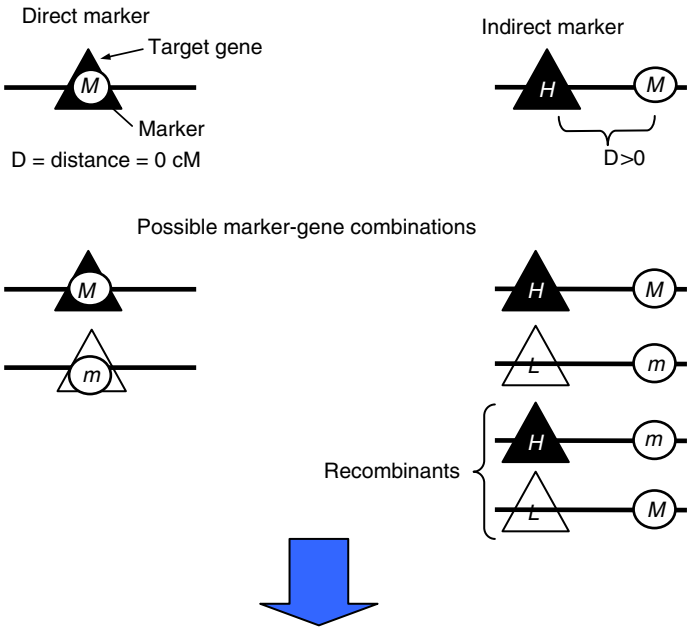
Genetic markers have become strategic tools for the identification of loci underlying the expression of quantitative traits, known as quantitative trait loci (QTL). Methodologies used in genetic evaluations are based on the assumption that quantitative characteristics are controlled by an infinite number of genes, each with infinitesimal (very small) effect. Nevertheless, genes or QTL with moderate effects have been identified. In general, important progress has been made in the identification and location of QTL affecting traits that are economically relevant for livestock production systems, including carcass and meat quality attributes. Information on QTL identified in cattle, sheep, pigs, and chickens are available on online databases with free access (AnimalQTLdatabases www.animalgenome.org/QTLdb). Other very useful public databases on genes and markers are also available (i.e., GenBank, www.ncbi.nlm.nih.gov/genbank; FunctSNP, www.csiro.au/science/FunctSNP).

QTL and Genes Affecting Carcass and Meat Quality

Quality is a complex concept that is a function of several traits that vary according to the species and target markets. **Table 1** presents some carcass and meat characteristics for which significant QTL have been identified, whereas **Table 2** summarizes significant findings for muscularity and tenderness, which are major carcass and meat quality traits, respectively.

Tenderness has been defined as one of the most important eating quality traits for consumer. Important efforts have been dedicated to unravel the genetic background of this attribute. The genes responsible for μ-calpain (CAPN1) and calpastatin (CAST) with effects on meat tenderness have been identified and SNP markers associated with them have been reported. The role of the calpain/calpastatin system on tenderness is described in other article. Although independent validations have confirmed the effect of these markers, their effects need to be validated in different commercial populations, because of differences in genetic frequencies in *Bos indicus* and *Bos taurus* breeds and the likely interaction between these genes.

Muscle development and shape in the carcass are relevant to define value in terms of actual meat yield or conformation and muscularity. The Myostatin (*GDF8*) gene has been associated with double-muscling phenotypes in some European breeds of cattle, such as Belgian Blue, Charolais, and Piedmontese, and with improved muscularity in sheep. The larger muscle development is due to an increased protein synthesis translated into a higher number of muscle fibers (hyperplasia). In the case of this gene, in most of the studies, neutral or favorable effects on meat tenderness were reported.



Marker genotype	Inferences on genotype with	
	Direct marker	Indirect marker (D=10 cM)
MM	HH ✓	HH ✓ (20.7%) HL × (4.1%) LL × (0.2%)
Mm	HL ✓	HH × (4.1%) HL ✓ (41.3%) LH × (0.4%) LL × (4.1%)
mm	LL ✓	HH × (0.2%) HL × (4.1%) LL ✓ (20.7%)
Total ✓	100%	83%

Figure 1 Direct and indirect genetic markers. When a direct marker is available for the gene of interest, the marker variants indicate precisely the allele of the target gene. The genotypes for the genes of interest can be inferred directly from the marker genotypes. In this example, the marker alleles M and m are associated with the high (H) and low (L) performance alleles, respectively. Therefore, an MM genotype in a direct marker indicates accurately that the animal is homozygous for the favorable allele (HH), whereas Mn and mm imply that the genotypes for the gene of interest are HL and LL, respectively. An indirect marker is located close to the gene, but it is not the gene itself. The distance D between marker and gene will determine the magnitude of the linkage. It is considered that M and H and m and L are linked. However, recombination events can lead to new combinations of marker and gene alleles (M–L and m–H). Owing to these possible combinations between marker and target alleles, it cannot be surely told that which marker allele is associated with the gene variants, and thus the confidence in the inference from marker genotypes is lower. Considering D = 10 cM, 83% of our inferences are correct, but in 17% cases, marker genotypes indicate the wrong allele is the gene of interest. Obtaining markers closer to the target genes will reduce this uncertainty because recombination rates are lower.

In sheep, the Callipyge gene (*CLPG*) has a pronounced effect on hindquarter muscularity. Characterization of Callipyge lambs indicates greater dressing percentages and heavier and leaner carcasses than in normal lambs. However, the gene also has a severe detrimental effect on tenderness of high-value muscles. The increased toughness of Callipyge meat has been explained by a reduced rate and extent of postmortem proteolysis that results from increased levels of calpastatin. Carwell is another gene in sheep that increases muscle development, but its effect is limited to the longissimus muscle. Although it may have a mild unfavorable effect on tenderness, this is not commercially relevant and can be removed by postmortem treatment.

Identification of QTL and Genes

The traditional approach used to map QTL in livestock species is termed as genome scan. In previous approaches, markers were selected to cover the whole genome with an average distance of 20 cM between them. An extensive list of major DNA-marker trials in farm livestock developed in the 1990s is presented in Table 3. The identification of QTL is based on the combined analysis of molecular and phenotypic information by searching for significant associations under specific experimental designs. One common design in farm animals was to map QTL segregating in crosses based on parental populations that are highly divergent for the traits of interest. Figure 2 shows the general concept that underlies the identification of QTL linked to genetic markers.

Although QTL experiments provided very valuable information, only few QTL with moderate or larger effect were

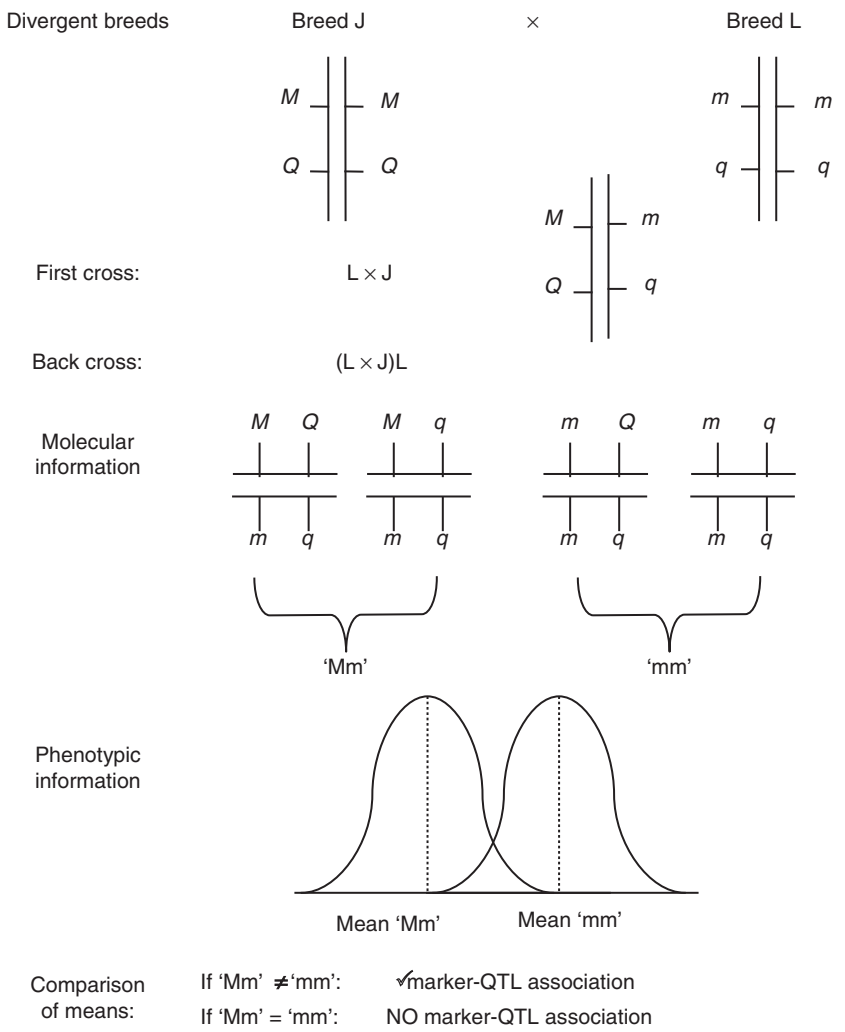

Figure 2 Searching for QTL–genetic marker associations in a backcross design between two breeds. Breeds L and J are two divergent breeds, which are assumed as homozygous for different alleles of both QTL (Q, q) and genetic marker (M, m). F1 animals are heterozygous for the marker and linked QTL. Backcrossed animals are obtained by mating F1 crosses to L individuals. There are four classes of gametes formed by the F1: the parental gametes MQ and mq and the recombinant gametes Mq and mQ. Because parental breeds are homozygous, L gametes are all mq. The resulting segregation in the backcross may allow the identification of the QTL. Genotyping provides the information of marker genotypes and phenotypic recording supplies data on the trait of interest. If the average of the Mm individuals is significantly different from the average of those with mm genotype, it is then concluded that the QTL affecting the trait of interest is linked to the genetic marker.

detected and mapped, given the power of the QTL experiments. In addition, further studies were needed before incorporating QTL into breeding programs to confirm that QTL mapped in crosses between divergent breeds or in a different breed were relevant to the genetic variation within the target breeding population. The size of the effects of an identified QTL is needed to be reestimated in commercial populations because they may differ between genetic backgrounds, environments, or production systems.

Fine mapping of QTL was used to reduce the broad chromosomal region derived from genome scans. Additional markers in the flanking region were tested in QTL linkage studies, thus improving the precision of QTL location. Furthermore, the fine-mapping approach has the potential of narrowing down the number of candidate genes and eventually identifying the causative polymorphism. A candidate gene is a known gene in another species that is related to the physiology underlying the trait of interest. After the candidate gene is chosen, the association between polymorphism/alleles for that gene and the phenotypic expression of the trait is investigated. It is important to mention that the assistance provided by genetic markers in terms of genetic improvement does not necessarily require the identification of the causative genes. Nevertheless, the detection of the gene and the development of direct marker tests were expected to lead to a more effective utilization of DNA technology in genetic improvement.

Only a few commercial DNA tests are available for economically relevant traits, although many of them are related to carcass or meat quality traits. Examples for beef tenderness are the DNA tests Pfizer GeneSTAR® and Ingenity TenderGENE®, which include the CAPN1 and CAST genes. In sheep,

LoinMAX® and MyoMAX® provide information for carcass quality based on the Carwell and Myostatin gene, respectively. In addition to these tests, there are new tools which can take into account simultaneously the information captured by hundreds or thousands of markers after their calibration using training populations. These genomic tools are explained later in this article.

Despite considerable efforts in QTL mapping and application of marker-assisted selection, the incorporation of DNA markers into the breeding programs has been low and the general impact poor. Under the QTL mapping approach previously described, marker densities were insufficient to find markers that were linked with QTL at the population level (population-wide linkage disequilibrium). Owing to the low marker densities, QTL of minor effect were not detected or their effects were overestimated, leading to inconsistent results across QTL mapping studies and reinforcing the relevance of carrying out independent validations studies before utilization in breeding programs.

Validation studies of commercial DNA tests for economically relevant traits showed that effects were not necessarily similar in all populations. On the basis of phenotypic data and DNA samples from reference cattle populations, a very interesting initiative was put in place by the US National Beef Cattle Evaluation Consortium (NBCEC) to independently verify the associations claimed by commercial genotyping companies. The results are in the public domain and can be found in the NBCEC web page.

Table 4 SNP Beadchips available for cattle, pigs, and sheep

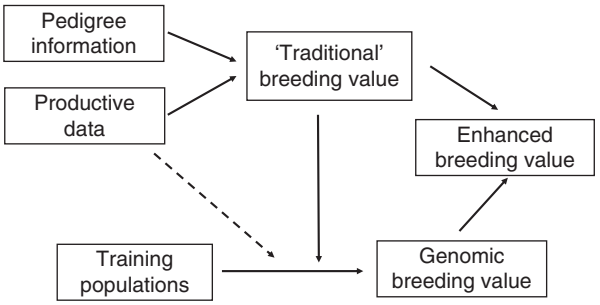

Figure 3 Combining genomic information in breeding programs. Breeding values are predicted on the basis of phenotypic (performance records) and pedigree data. The enhanced breeding values result from adding the genomic breeding values. The estimation of genomic breeding values relies on the genomic information of the animals and the SNP effects. The analysis of the genomic and phenotypic data of training populations provides the magnitude of the SNP effects.

Genomic Selection

Recent developments in DNA technology and genome sequencing have led to the detection of thousands of SNPs, making possible a very dense coverage of the genome, at affordable genotyping costs. Dense arrays of SNPs (SNP chip) have been developed for many livestock species that are commercially available (Table 4).

The availability of genome-wide dense markers has allowed the implementation of genomic selection in which the estimation of the genetic merit is assisted by the information provided by thousands of markers. Based on this methodology, and because of the high density of markers used, every QTL would be in population-wide linkage disequilibrium and all QTL affecting any trait would be considered simultaneously, independently of the magnitude of QTL effects.

The implementation of genomic selection can be defined in two steps. In the first step, the SNP effects are estimated in a training population that comprises animals with genomic data as well as with information on the relevant traits. The second step is to use the estimated effects of the SNP to predict the genetic merit of the breeding animals. Using genomic information, it is possible to estimate genetic merit just with the information obtained from a DNA sample, for very young animals. This information allows making earlier selection decisions that will reduce the generation interval. It may also increase the number of animals with information of their merit, which will have a positive effect on selection intensity.

In practice, genomic information is integrated to the genetic evaluation engines in addition to pedigree and phenotypic data, which are the 'traditional' sources of information to predict the genetic merits. The flow of information is illustrated in Figure 3. The higher accuracies in this case due to more precise relationships will also contribute to obtain higher rates of genetic progress.

Genetic evaluations including genomic information are already in place in many dairy cattle, pig, and poultry breeding programs. Regarding beef cattle breeds, the American Angus Association, using SNP data, is publishing estimations of genetic merit (www.angus.org/Nce/WeeklyEvalGenomicData.aspx), whereas other breeds such as Hereford are developing their training populations in the context of their international genetic evaluation program, which involves USA, Canada, Uruguay and Argentina Hereford data simultaneously (www.hereford.org/static/files/0711Genomics.pdf). Genomic breeding values are also now available in the sheep genetic programs run by Sheep Improvement Limited in New Zealand (www.sil.co.nz/News/Sheep50k-breeding-values-available.aspx).

In contrast with marker-assisted selection, genomic selection does not require a QTL detection step, as all markers, either significant or not, are considered. In fact, a one-step methodology to estimate enhanced breeding values (traditional plus genomic breeding values) is being implemented in some dairy cattle and in pig breeding programs. Nevertheless, the improvement of accuracy due to the genomic information can be enhanced by ensuring that markers linked to relevant QTL are present in the SNP chip being used.

Genome-Wide Association Studies and Functional Genomics

The information provided by the high density SNP chips enables not only the implementation of genomic selection but also genome-wide association studies that provide very valuable information for the identification of specific polymorphism with favorable effects on carcass and meat quality. Fine mapping, however, may not be sufficient to achieve this objective. A more comprehensive understanding is possible by combining the information provided by functional genomic tools to high-density genotyping or DNA genome sequencing data. Gene expression/transcriptomic profiling can give new insights to the actual SNP with influence on the traits of interest. The contribution of proteomics to meat quality is discussed in other article.

For both genomic selection and genome-wide association studies, the size of the training population and the quality of the data being recorded are of relevance. The volume of carcass and meat quality information with genomic data have a direct association with the accuracy of genomic breeding values and, therefore, on the additional genetic progress to be achieved. Similarly, the power of the genome-wide association studies will be stronger, and more accurate findings will be obtained. In this sense, the availability of accurate, less expensive, and time consuming methods to assess carcass and meat quality will make a significant contribution. New methods such as near-infrared spectroscopy and video-image analysis for the prediction of carcass and meat quality, respectively, will be useful sources of data to be collected directly in abattoirs in large number of animals. A comprehensive characterization of meat and carcass quality attributes using more expensive and laborious evaluation methods will be always very valuable, particularly as part of more detailed studies exploiting the potential of all new genomic tools.

This article is a revision of the previous edition article by Lambe and Simm, volume 1, pp 11–19, © 2004, Elsevier Ltd.

Glossary

Best linear unbiased prediction A statistical procedure for predicting the breeding values of animals.
Estimated breeding value (EBV) An estimate of an individual's true breeding value (genetic merit) for a trait, based on the performance of the individual and its relatives for the trait, and for genetically correlated traits.
Expected progeny difference It is EBV divided by two. The difference in expected performance of future progeny of an individual, compared with expected performance of future progeny of an individual of average genetic merit.
Heterosis Advantage of crossbred progeny over the average performance of the individual parent breeds.
Intermuscular fat It is defined as the fat deposited between muscles.
Intramuscular fat It is the fat deposited within muscles.
Subcutaneous fat It is defined as the fat deposited under the skin.

Introduction

Meat production can be influenced to a large extent by animal breeding and genetics. Several breeding strategies that can affect carcass composition and meat quality will be reviewed in this article, that include (1) selection between breeds within species; (2) crossbreeding to combine desirable characteristics from more than one breed or strain, or to exploit heterosis in crossbred progeny; and (3) genetic selection of superior breeding stock within a breed. Genetic influences on carcass and meat quality and selection programs designed to improve these traits will also be discussed.

Differences among Breeds

When selecting among breeds within a species, it is important to choose a breed that is able to perform well within the relevant environment as well as meet the appropriate market demands. Differences among breeds are only relevant in the environments in which they have been measured, because of possible genotype by environmental interactions. Most breed comparisons of carcass composition and meat quality have been performed in temperate climates, using animals on a high level of nutrition. Studies performed in more extreme environments (e.g., tropical or subtropical), or when food is less abundant, have been fewer in number and have shown less convincing evidence of breed differences. It is also of note that any breed comparison is a snapshot in time, as breeds evolve as a result of selection, so results from breed comparisons may change over time.

Carcass Composition

Large between-breed differences exist within all farm animal species for growth and carcass composition traits. As an animal matures, it undergoes an increase in the ratio of muscle to bone, followed by a decrease in muscle growth rate and an increase in the ratio of fat to muscle. However, breeds vary in their rate of maturation and average mature weight. Therefore, standardizing measurements of body composition (proportions of muscle, fat, and bone) to the same stage of maturity of body weight (ratio of actual weight to expected mature weight) results in much less variation in carcass composition than standardizing to the same age or weight. One exception to this rule is the Texel breed of sheep, which shows less total body fat than expected for its mature size (Table 1).

In beef cattle, late-maturing breeds, such as the Continental European breeds, are often preferred under conditions of good nutrition, producing heavier carcasses with little fat. Early-maturing beef breeds, such as the traditional British breeds (e.g., Angus, Hereford, and Shorthorn), can be harvested at lighter weights and may be preferred for grass-based systems, when food supply is limited or for certain markets such as those rewarding higher intramuscular fat. Similarly, in lamb production systems, the use of early-maturing breeds (e.g., Southdown) will allow faster finishing of small lambs with good carcass composition. However, the use of larger breeds that mature later (e.g., modern Suffolk strains) will result in heavier lambs with less fat. Traditionally, early-maturing pig breeds (e.g., Middle White) were used for pork production and late-maturing breeds (e.g., Large White) for bacon production. Strains and hybrids of improved pig breeds that are now used in pork and bacon production (e.g., Piétrain, Landrace,

Table 1 Heritability ranges for carcass composition traits across species

Trait	*Heritability*[a]
Ultrasound muscle depth/area	Moderate–high
Ultrasound fat depth	Moderate–high
Carcass weight	Moderate–high
Carcass length	High
Dressing percentage	Low–moderate
Lean yield	Moderate–high
Lean:bone ratio	Moderate–high

[a]Low = 0–0.25; moderate = 0.25–0.5; and high = 0.5–1.

Hampshire, and Large White) have better carcass composition than that of traditional British pig breeds (e.g., Tamworth, Gloucester Old Spot, and Saddleback), owing to reduced fat levels and increased muscle percentage.

Breeds may partition fat and muscle differently between body depots. Dairy breeds of sheep and cattle have a higher proportion of body fat in internal depots than meat breeds, which have higher proportions of subcutaneous fat. In general, maternal sheep breeds that have higher reproductive rates and higher levels of milk production also have increased proportions of noncarcass fat. During growth and development, intermuscular fat is deposited before subcutaneous fat, which is deposited before intramuscular fat. Therefore, relative to subcutaneous fat, large late-maturing cattle breeds have a higher proportion of intermuscular fat than small early-maturing breeds, which have increased levels of intramuscular fat (e.g., British beef breeds vs. Continental European breeds). Breed comparisons in pigs have found that the Duroc, Meishan, and Berkshire breeds have a high proportion of intramuscular fat compared with other improved breeds, and for some markets, the level of intramuscular fat in pure Duroc and Berkshire pigs is too high for consumer acceptability.

Meat Quality

In addition to yield and carcass composition, meat quality is determined by traits such as color and composition of muscle and fat, level of intramuscular fat, juiciness, tenderness and texture, and flavor and aroma. Objective laboratory-based techniques that are discussed in other articles have been developed to quantify many of these traits. These measurements are often referred to as technological traits and some examples are listed in Table 2. The most widely used of these techniques is 'shear force,' which measures the force required to cut through samples of cooked meat. Trained sensory panel analysis is still considered the most relevant measure for many meat quality traits and Table 2 also gives examples of some of these sensory traits. There is substantial evidence of between-breed variation in technological and sensory meat quality traits. Examples include the following:

- Paler, more watery muscle, with more exudation of fluids during storage, in 'improved' pig breeds compared with traditional British pig breeds (e.g., Pietrain vs. Bekshire).
- Yellower fat in Channel Island cattle breeds compared with other cattle breeds.
- More tender, fine-grained meat in smaller breeds of cattle, owing to smaller muscle bundles.
- More tender meat in 'double-muscled' Piedmontese cattle compared with some other breeds.
- More tender meat in *Bos taurus* cattle breeds than in *Bos indicus* (humped cattle) breeds. *Bos indicus* cattle show increased calpastatin activity in the muscle, which is known to inhibit postmortem tenderization.
- More tender meat in Duroc pigs compared with most other breeds, owing to an increased amount of red muscle fibres and increased intramuscular fat.
- Increased flavor, juiciness, and tenderness in pigs with an increased percentage of Duroc, Berkshire, or Meishan genes.

Table 2 Heritability ranges for meat quality traits across species

Trait	*Heritability*[a]	
	Technological (objective)	*Sensory (subjective)*
Color		
Lean color		Low–moderate
Fat color		Low
Lean color reflectance	Low–moderate	
Myoglobin content	Moderate–high	
Juiciness		Low
Water-holding capacity	Low	
Drip loss	Low–moderate	
Tenderness		Low–moderate
Lean texture/firmness		Low–moderate
Shear force	Moderate–high	
Calpastatin activity	Moderate–high	
Myofibrillar fragmentation index	Moderate–high	
Intramuscular fat content		
Marbling score	Moderate–high	
Chemical intramuscular fat %	Moderate–high	
Ultimate pH	Low–moderate	
Flavor		Low
Overall acceptability		Low

[a]Low = 0–0.25; moderate = 0.25–0.5; and high = 0.5–1.

Breeds can also react differently to on-farm management, transport, preslaughter, slaughter, and processing methods. For example, leaner and lighter animals are more likely to suffer from cold shortening in the carcass post-mortem.

Crossbreeding

Crossbreeding can be used for several reasons that can be exploited simultaneously. One reason may be to combine desirable characteristics from more than one breed or strain. This is termed 'complementarity.' In the pig and poultry industries, different breeds or specialized lines, selected for different characteristics, are commonly crossed to produce commercial hybrids. Sire lines are often selected to be heavier and faster growing, whereas female lines may be selected for reproductive traits, low maintenance requirements, or other economically important factors. An example of such a system for pigs is given in Figure 1. The breeds or strains chosen for crossing depend on their suitability for specific environments as well as market requirements. Crosses between different breeds of sheep and cattle are also used to combine desired characteristics. In the United Kingdom, hill ewes (e.g., Scottish Blackface and Swaledale) are often crossed to rams from upland breeds (e.g., Blue-faced Leicester and Border Leicester) with high maternal performance. The crossbred female progeny are then mated to terminal sire breeds (e.g., Texel, Suffolk, and Down breeds) that have been selected for improved carcass and growth traits, to produce a high number of better-quality lambs.

Another reason for crossbreeding is to exploit heterosis, or hybrid vigor (advantage over the average performance of the

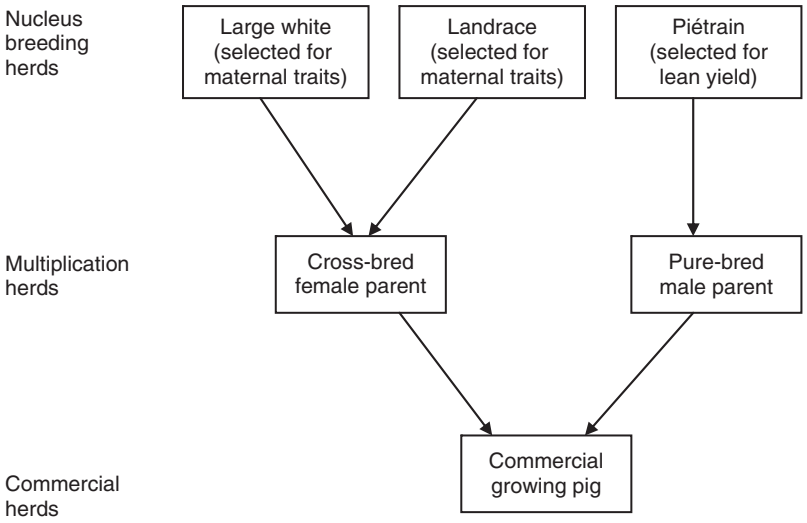

Figure 1 Example of a pig breeding program.

individual parent breeds). Heterosis is widely exploited in the pig, beef cattle, and poultry industries. The 'combining ability' of different strains is tested to increase production. Some strains combine well only when used as the male or the female parent. The pure-bred lines that are used for crossing can be either selected to improve specific traits within line (e.g., meat yield and fertility) or selected on the performance of their crossbred progeny (reciprocal recurrent selection). Heterosis is usually greater for traits with low heritability (see Section Genetic Parameters for Carcass Composition and Meat Quality Traits), such as those affecting overall fitness, reproduction, or survival, and less for production or carcass traits. Some evidence suggests that cross-bred cattle mature more quickly and are thus heavier at a given age, with more marbling fat, total fat, and muscle. However, after adjusting for weight, heterosis for carcass composition traits tends to be low. Effects of heterosis on most technological and sensory meat quality traits have not been studied widely, but available estimates tend to be low for juiciness, tenderness, flavor, cooked color, and overall desirability. Results for the effect of heterosis on shear force in beef are more widely reported and range from slightly unfavorable to moderately favorable.

Differences within Breeds

Substantial genetic improvement can be made within breeds for desired characteristics. This method relies on the fact that the traits to be improved are heritable, and that more animals are produced than need to be kept for replacement stock, to allow selection among progeny for preferred breeding animals.

Genetic Parameters for Carcass Composition and Meat Quality Traits

Heritability is the proportion of the total phenotypic (observed) variation in a trait that is explained by genetic variation. It is, therefore, a measure of how much a trait is controlled by genes (or, more precisely, genes that act additively), as opposed to environmental influences. Heritability is expressed on a scale of 0 to 1, where a value of 1 suggests that the trait is completely controlled by an animal's genes, and management, feeding, and other environmental factors play no part in determining the expression of the trait. Traits with higher heritability allow a higher rate of genetic improvement than traits with low heritability. Estimates of heritabilities for the main carcass and meat quality traits vary between studies but tend to fall in the ranges identified in Tables 1 and 2. There is a good agreement across species for heritability estimates of these traits. Relatively few studies have been conducted on genetic parameters of eating quality traits compared with carcass composition. However, in general, the heritability of most carcass composition traits is moderately high, and objective technological measures of meat quality are more heritable than sensory traits determined by sensory panel analysis. Selection responses in sensory meat quality traits are, therefore, expected to be low because they are less heritable and more difficult to evaluate.

It is important to note that the magnitude of the environmental variation and, therefore, the heritability depends very much on the ability to standardize measurements. The better the meat quality traits are measured, the higher their heritability and the higher the selection success. A low heritability does not necessarily mean that there is too little genetic variance for selection; rather, it may reflect the difficulties in measuring the traits in a standardized, repeatable, and accurate manner. Genetic parameters for meat quality may also differ according to the type of muscle tested within an animal and owing to differences in preslaughter conditions (e.g., stress during transport or at the abattoir) or processing methods (e.g., electrical stimulation, conditioning, and hanging method). For example, shear force has been reported to be more variable in carcasses that have not undergone electrical stimulation. In particular, genetic parameters for meat tenderness vary, probably because this is a very complex trait, depending on many factors (pH and temperature changes postmortem, glycolysis, and processing) and the interactions among them.

Selection on one trait will often lead to correlated responses in other traits, which are not always monitored but could have very important economic consequences. A selection program designed to improve carcass composition should also be concerned with the effects of these changes on sensory meat quality traits and should monitor effects on reproductive traits (e.g., fertility and dystocia) and functional fitness. There are concerns that selection for reduced fat levels may be associated with reduced fertility of females and it may delay puberty, as observed, for example, in pigs and cattle. Genetic improvements in pig and poultry production have also been related to a decrease in meat quality in terms of flavor and texture. In general, intramuscular fat percentage has a negative genetic relationship with meat yield and a positive genetic relationship with total fat. Intramuscular fat in pigs was ignored in early studies, as its importance for eating quality was underestimated. As pigs were selected for reduced back fat, the level of intramuscular fat was also reduced, which was later linked to a reported decline in the eating quality of pig meat. Attempts are now under way in some countries to increase intramuscular fat in pig meat without increasing total fat. Studies in some sheep and cattle populations suggest that this may be possible, as low to moderate genetic correlations have been found between levels of fat in different depots. There is also evidence in pigs that different fat depots are at least partially under different genetic control. This may allow selection in these species to reduce one fat depot (e.g., subcutaneous), whereas maintaining moderate levels of fat in other depots, to reduce or avoid the unintended consequences mentioned, or to maintain marbling and meat quality (intramuscular fat).

Correlations among carcass composition and technological and sensory meat quality traits differ among studies, as a result of which few strong trends have emerged. In general, the literature suggests that selecting for leanness might have slight negative effects on eating quality traits (e.g., water-holding capacity, tenderness, juiciness, pH, and drip loss). Sensory quality traits such as tenderness, flavor intensity, and juiciness tend to be positively correlated to one another, and genetic correlations between these traits and shear force tend to be negative (lower shear force equals more tender). Shear force also has a low to moderate negative genetic correlation with intramuscular fat. Tenderness is widely thought to be the most important determinant of meat quality to consumers. However, genetic parameters for this trait differ, depending on the muscle tested and the method of measurement (myofibrillar fragmentation index, calpastatin activity at 24 h, shear force, or sensory panel assessment of tenderness). The majority of results suggest that calpastatin activity is highly genetically correlated with shear force (higher calpastatin activity = higher shear force), but the phenotypic correlation between the two measurements is only moderate. Correlations of tenderness among different muscles are moderately low and the correlation between shear force and sensory panel evaluation of tenderness also varies between muscles. As a result, selection for tenderness may be difficult and further work is needed to determine the relationships between technological and sensory measurements. (At least in beef, and the research at K-State, the correlation between trained sensory panel tenderness and Warner-Bratzler shear force (WBSF) is high and negative.)

(There are animals that defy the antagonisms between carcass composition and meat quality. For example, the expected progeny differences (EPDs) of an American Simmental bull at ABS global (a company specialising in bovine genetics and reproduction), which has a global rank in the top 5% for marbling, in the top 5% for longissimus muscle area, and in the top 5% for WBSF. In other words, using this bull can simultaneously increase muscling, increase marbling, and decrease WBSF in progeny.)

Selection Programs

In genetic improvement programs, animals are selected on their own performance, on the performance of their relatives, or on a combination of both. First, the breeding goal or goals – i.e., the traits to be improved – must be decided and subsequently the selection criteria determined. The latter are the measurements that will be taken and then selected on in order to improve the breeding goal. In some cases, the breeding goals and the selection criteria are the same, but often they are not, especially with carcass and meat quality traits. Traits to be used as selection criteria must be highly repeatable and practical to measure on-farm or online during animal processing. Selection criteria should be heritable and should show sufficient variation within the population. The design of the breeding program should define the number of male and female animals that are to be selected each year, the age at mating, the generation interval, and other such factors.

Genetic selection programs differ in complexity. A relatively simple approach is to select breeding animals on the basis of their own phenotypic performance (e.g., ultrasound data obtained from selection candidates). However, the impossibility of collecting actual phenotypic carcass and meat quality data on selection candidates has restricted the use of this method of selection for many of these traits. 'Independent culling levels' in one or more traits are often used to improve the genetic merit of the flock or herd. This method involves choosing animals for breeding only if they reach a certain threshold in each trait of interest (e.g., over a certain weaning weight and/or below a certain ultrasound fat depth).

Using a selection index is a more complicated, but effective, method of selecting animals on more than one trait, based on the performance of the individual and its relatives. This method allows selection of traits that can be measured directly or indirectly (using predictor traits) on the selection candidates themselves and also traits that can only be measured on relatives (e.g., slaughter and meat quality traits). Accurate recording of performance data and pedigree structure is vital in these programs. The amount of emphasis or weighting on each trait in a multitrait index can be altered and is usually determined by economic importance. Estimated breeding values (EBVs) for each trait for each animal are produced, and then are combined into an overall 'index score.' Selection decisions are based on these index scores. Response to selection in any individual trait per generation using a multitrait index is smaller than what could be achieved by selecting for that trait alone. However, index selection will lead to the highest rate of change in overall economic merit.

EBVs are calculated, in most selection programs, using a statistical procedure known as best linear unbiased prediction (BLUP). This procedure predicts the genetic effects for each trait separately from management and environmental influences. The EBV is determined by the genetic merit of the animal itself, plus that of its relatives, for the trait of interest and reflects the genetic or breeding merit of that animal compared with the population mean. Because, on average, each breeding animal passes half of its genes to its offspring, the breeding value for each trait is often expressed as the expected progeny difference (EPD), which is half the EBV of the breeding animal.

If the breeding goal of a selection program is to improve carcass composition, the selection criteria will often include predictors of composition taken on the live animal. As live weight is a composite trait (meat, fat, and bone), it is usually not a sufficient predictor of carcass composition. However, carcass composition can be estimated *in vivo* using techniques such as mechanical and optical probes, ultrasound scanning, or computed tomography (CT) scanning. Ultrasound is commonly used in selection programs for sheep, cattle, and pigs to measure depths and areas of subcutaneous fat and muscle (Figure 2) and greatly improves the predictions of body composition above those estimated from live weight alone. In cattle and pigs, intramuscular fat has also been estimated using ultrasound measurements taken on live animals. CT scanning increases the accuracy of predictions of total carcass fat, muscle, and bone compared with ultrasound and allows the measurement of tissues in different body depots and regions (Figure 3). Measurements of average muscle density resulting from CT scanning can also provide moderate predictions of intramuscular fat levels in live sheep and pigs. Two-stage selection can be carried out in sheep and pig populations, where ultrasound scanning is used on-farm to screen large numbers of selection candidates, and then a small number of top-ranking animals are CT scanned to make final selection decisions based on conformation or composition of breeding stock.

Because there are few live-animal predictors of technological and sensory meat quality traits, breeding programs designed to improve meat quality use mainly measurements taken on slaughtered relatives of selection candidates to calculate EPDs (or EBVs depending on the scale used) for these traits. For example, most cattle breed associations in the United States now produce EPDs for marbling and a few have published EPDs for tenderness measured by shear force. Similar traits are included in some cattle breeding programs in the UK and Australia.

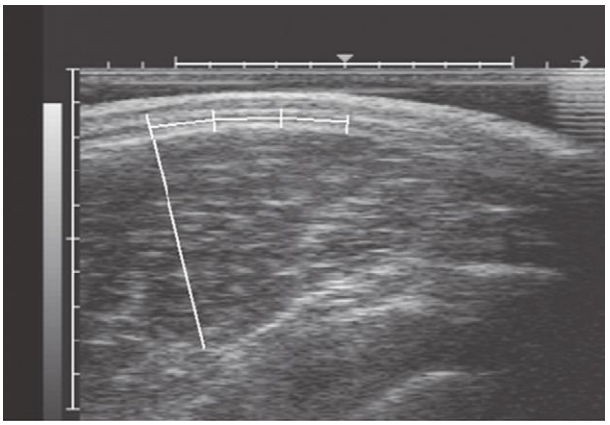

Figure 2 Example of an ultrasound scan taken in beef cattle.

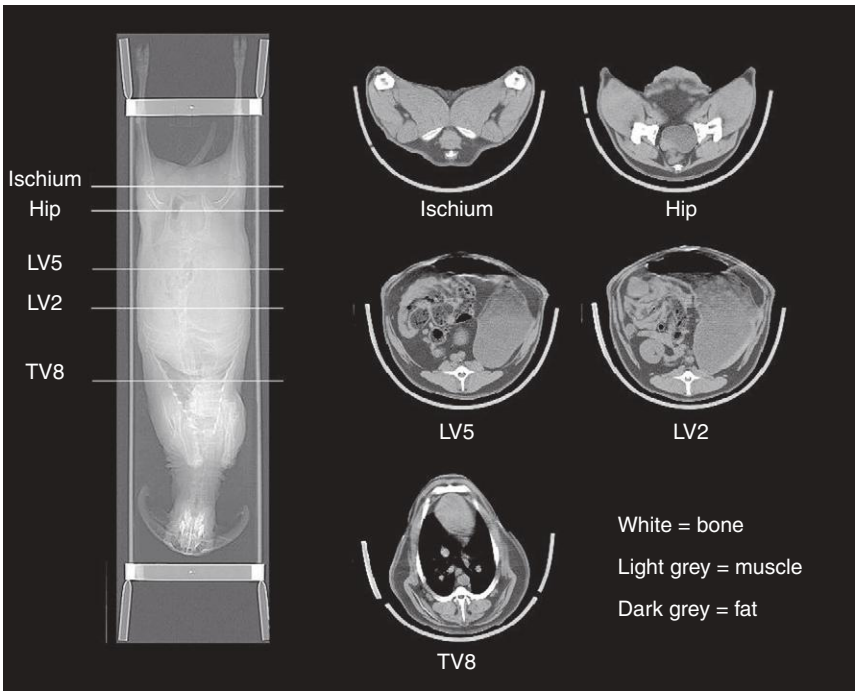

Figure 3 Example of CT scan images from a sheep. LV, lumba vertebra; TV, thoracic vertebra.

In many countries, a relatively low proportion of beef cattle and sheep are performance recorded and, therefore, are included in genetic improvement programs. In these industries, there are many small-scale breeders and although abattoirs usually provide some financial incentives to improve conformation and reduce fat levels, few incentives are given to improve other aspects of eating quality. However, a few countries are now trying to implement grading systems that also reward for improved meat quality traits such as marbling levels, pH, and color (e.g., Meat Standards Australia). There has been considerable genetic progress in lamb and beef carcass composition due to selection programs. In several countries (e.g., United States, Canada, and Europe), 'central testing' has been used to identify sheep or cattle of superior genetic merit, where high-ranking individuals from different farms are tested together at a central station to reduce environmental variation and allow the measurement of 'difficult to measure' traits. There is some concern over the effectiveness of this approach, especially if animals are submitted at later ages, and the use of this method seems now to have decreased. Its importance could, however, increase if genome-wide selection methods are employed. 'Progeny testing' can also identify superior breeding animals by recording data on progeny of high-ranking animals, either at a central testing station or on-farm. This method allows carcass and meat quality traits to be measured directly on progeny of breeding stock. However, central and progeny testing are time consuming and expensive and are only likely to be used to select sires for use in widespread artificial insemination programs. Group breeding and sire reference schemes are now being used by sheep and beef breeders in several countries. Group breeding schemes usually involve a nucleus breeding flock or herd of elite animals taken

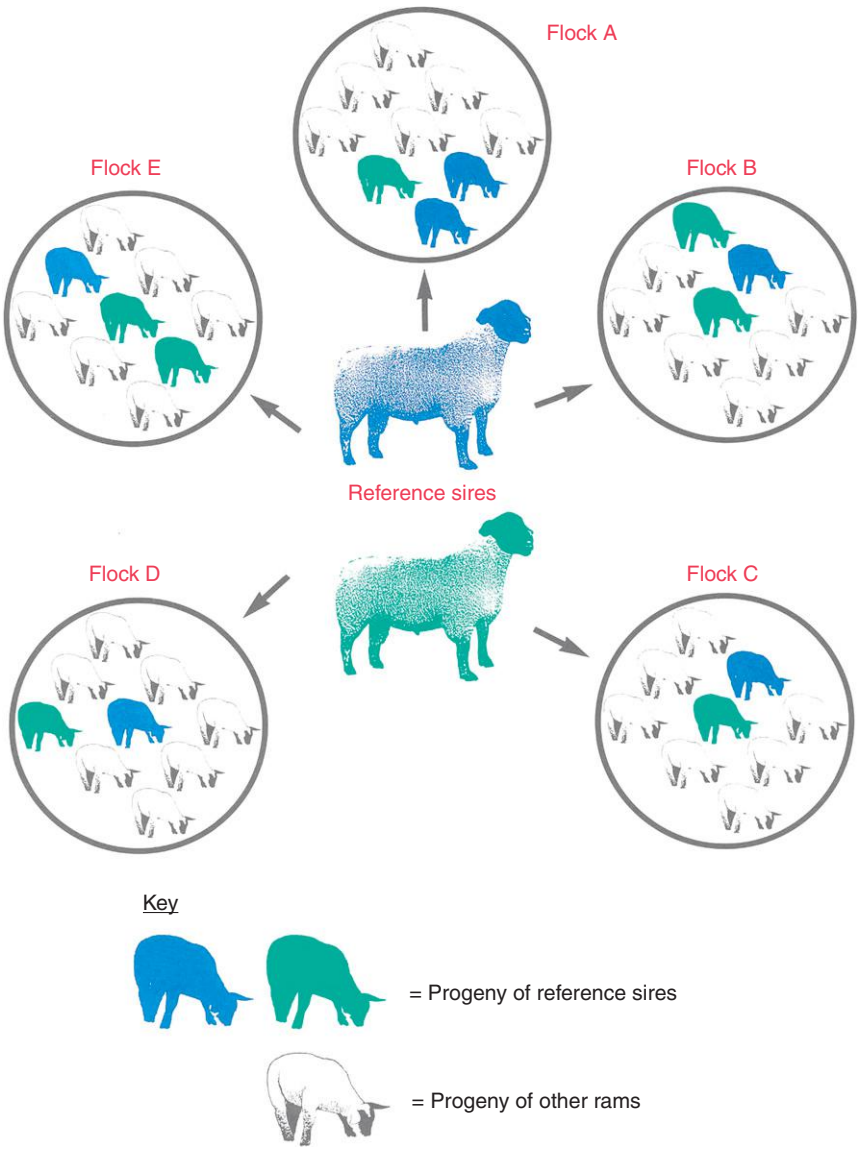

Figure 4 Schematic diagram of a sire referencing scheme (see plate 1). Reproduced from Simm, G., Wray, N.R., 1991. Sheep Sire Referencing Schemes – New Opportunities for Pedigree Breeders and Lamb Producers. SAC Technical Note T264. Edinburgh: SAC.

from different group member farms. This nucleus undergoes intensive recording and selection in order to produce breeding animals (usually males) of high genetic merit so that they can be used on breeders' farms. More popular now are sire reference schemes, in which all flocks or herds are linked by the use of common sires on a proportion of females on each farm (Figure 4). These schemes use BLUP on data from all farms to produce EPDs (or EBVs) that are comparable across all member flocks or herds.

Breeding populations in pig and poultry production are controlled mainly by relatively few large national or international breeding companies. In these industries, 'production pyramids' exist, where intensive selection takes place in the elite breeding herds or flocks. The resulting animals, of superior genetic merit, are multiplied in number and usually crossed to produce commercial animals for meat production (Figure 1). All tiers of the industry are therefore influenced by improved genetics in the top breeding herds or flocks. High selection intensities, short generation intervals, and reduced environmental influences on production in these species maximize the output of high-quality product. As a result of this structure, there have been industry-wide improvements in growth rate, uniformity, muscle yield, feed conversion efficiency, and fat levels in both pigs and poultry.

Major Genes

Most production traits are continuous in their distribution and are controlled by the action of many genes, each having a small effect. These are termed polygenic or quantitative traits. However, some traits are substantially influenced by a single major gene or quantitative trait locus. Some major genes are known to have large effects on carcass composition and meat quality traits in the populations in which they are found. Examples are given in Table 3.

Phenotypic records from relatives can be monitored to detect the presence of major genes and identify individuals and families with the desired genotypes. The use of molecular techniques to identify animals with different genotypes will allow much greater exploitation of these major genes or other genes with smaller, but important, effects. More advanced molecular and reproductive techniques, such as cloning and genetic modification of livestock species, may also play important roles in the meat industry in future.

Future Considerations

Traditionally, the aim of selection was to increase production efficiency and lean yield in farm animals raised for meat production. However, recent consumer preferences for healthy and convenient meat products produced in welfare-friendly systems call for different breeding goals and selection traits. Future selection objectives are likely to incorporate more meat quality issues. Genetic variation has been blamed for an inconsistent product. However, genetic variation provides the opportunity to increase meat quality within livestock populations. The potential to improve meat quality by traditional breeding methods would be greatly increased by the

Table 3 Examples of major genes affecting carcass composition and meat quality

Major gene/Quantitative trait locus (QTL)	*Species: Breed*	*Effects on carcass and meat quality*
Dwarfism	Poultry	*Reduces*: growth rate; mature weight
Myostatin gene ('double muscling')	Cattle: Belgian Blue, Piedmontese, and other breeds Sheep: Texel and other breeds	*Reduces*: subcutaneous fat; marbling; collagen content; lean color intensity; and flavor. *Increases*: muscularity; muscle:bone ratio; muscle:fat ratio; eye muscle area; dressing percentage; and water content
Diacylglycerol acyltransferase 1 (*DGAT1*)	Cattle Sheep	Affects intramuscular fat; marbling; and tenderness (sheep)
Calpain gene (*CAPN1*)	Cattle	Affects tenderness
Calpastatin gene (*CAST*)	Cattle	Affects tenderness
Callipyge	Sheep: Poll Dorset originally	*Reduces*: carcass fat; marbling; and tenderness. *Increases*: muscularity; lean yield; dressing percentage; and connective tissue content
Carwell (Loin-Max)	Sheep: Poll Dorset originally	*Increases*: lean yield; eye muscle depth. *Reduces*: tenderness slightly, but this effect can be eliminated by enhanced processing
Texel Muscling QTL (TM-QTL)	Sheep: Texel	*Increases*: loin muscling. *Reduces*: tenderness slightly, but this effect can be eliminated by enhanced processing
Ryanodine receptor 1, 'halothane gene' (RYR1)	Pigs	*Reduces*: ultimate pH; water-holding capacity. *Increases*: pale, soft, exudative (PSE) meat; meat quality variation
PRKAG3 (new alleles of the 'RN'gene)	Pigs: Hampshire	*Reduces*: processed meat yield; ultimate pH; lean color intensity. *Increases*: drip loss; variation in meat quality
Fatty acid-binding protein (*FABP*) genes	Pigs: Meishan originally Poultry	Affects intramuscular fat and fat deposition
IGF2 gene	Pigs Cattle	Affects weight of primal cuts, lean meat yield, backfat thickness, and eye muscle area

development of tools to measure or predict meat quality *in vivo*. The incorporation of such measures into large-scale, organized breeding programs would allow direct selection for meat quality traits.

Glossary

Hazard identification A process of identifying pathogenic agents that might be associated with the commodity considered in a risk analysis.
Risk A function of the likelihood of an event occurring and the likely magnitude of the biological and economic consequences of that event.
Risk analysis A science-based process composed of hazard identification, risk assessment, risk management, and risk communication.
Risk assessment A process to evaluate the likelihood and biological and economic consequences due to the entry, establishment, and spread of a pathogen in an importing country.
Risk communication The exchange of information, opinions, and results with potentially affected and interested parties during a risk analysis.
Risk management A process to identify, select, and implement measures to reduce identified risks.
Sanitary measures Measures applied to imported goods that protect animal or human health or life in the importing country from risks associated with the entry, establishment, or spread of a pathogen.
Uncertainty A lack of knowledge about a parameter being assessed. Uncertainty can often be reduced by further studies or surveys.
Variability The effect of natural chance on a parameter. Unlike uncertainty, variability cannot be reduced by further studies or surveys.

Introduction

The international trade in animals and animal products presents a degree of risk to the importing country because of the possible presence in the commodity of pathogens that might threaten the resources (human, animal, or environmental) of the importing country, although this risk should not be used as an unjustifiable barrier to trade.

Animal health import risk analysis is a tool that provides an objective and defensible method of identifying and managing disease risks associated with the importation of animals, animal products, animal genetic material, feedstuffs, biological products, and pathological material.

Risk is defined as a function of the likelihood of a disease entering a country and the likely consequences of the disease affecting other animals. Import risk analysis provides a systematic approach to the identification of hazards (pathogens) that might be associated with an imported commodity, assessment of the likelihood and consequences of introducing diseases, formulating sanitary measures to manage this risk, and communicating the findings to others.

Transparency

Although import risk analysis is based on science, the process must accommodate knowledge gaps and uncertainty. Because of this, transparency (the comprehensive documentation of all data, assumptions, methods, results, discussion, and conclusions) is essential. Without transparency, the distinction between facts and the analyst's value judgments might blur.

Uncertainty and Variability

Incomplete knowledge or a lack of understanding of a pathogen will result in uncertainty, which is likely to be present in any risk analysis. This must be distinguished from the natural heterogeneity inherent in any biological system that will result in variability in a risk pathway.

If significant uncertainty is encountered when conducting a risk analysis, a precautionary approach to managing risk may be considered. However, sanitary measures selected must be based on a risk analysis that takes into account available scientific information and any precautionary measures should be reviewed as soon as additional information becomes available. A transparent rationale should always be presented to support selected sanitary measures.

Qualitative and Quantitative Methods

Qualitative risk assessments express likelihood estimates in nonnumerical terms such as high, medium, low, or negligible. This approach is suitable for the majority of risk assessments, and is routinely used for decision making. In some situations, a

quantitative approach might be considered desirable as an adjunct to a qualitative assessment. Quantitative assessments express their inputs and outputs (results) numerically, but are not in themselves any more objective or precise than a qualitative approach. Quantitative models also present significant challenges in interpreting and communicating their results. Regardless of which approach is chosen, it is essential that the analysis is transparently documented and subjected to peer review.

International Obligations

Under the World Trade Organization (WTO) Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement), members can employ sanitary measures to imported commodities but these measures must not be applied arbitrarily, or result in discrimination between members where similar conditions prevail, or constitute a disguised restriction on trade.

The SPS Agreement requires WTO members to base their sanitary measures on international standards, guidelines, and recommendations, where they exist. The SPS Agreement recognizes the World Organisation for Animal Health (OIE) as the international organization responsible for the development and promotion of international standards, guidelines, and recommendations for animal health and zoonoses. However, members may choose to adopt measures that result in a higher level of protection than that provided by international standards, although these must be based on the outcome of an import risk analysis.

The OIE's Terrestrial Animal Health Code provides recommendations and principles for conducting transparent, objective, and defensible risk analyses for international trade. The four components of risk analysis described by the OIE are hazard identification, risk assessment, risk management, and risk communication.

Hazard Identification

To effectively manage the risks associated with imported commodities, any organisms that could potentially cause harm and could be introduced into the importing country must be identified. The potential hazards identified are those associated with the species being imported, or from which the commodity is derived, and which might be present in the exporting country. It is then necessary to identify whether each potential hazard is already present in the importing country, and whether it is subject to control or eradication in the importing country and to ensure that import measures are not more trade restrictive than those applied within the importing country. Hazard identification also needs to consider whether strains of a potential hazard found in the importing country are likely to be less virulent than those reported internationally or in the exporting country, or if the proposed import will increase the exposure to a potential hazard in the importing country.

Depending on the nature of the commodity or the degree of processing, some categories of pathogenic agents may be excluded from consideration. For example, arboviruses such as West Nile virus, which replicate in bloodsucking arthropods and are transmitted by bite to a vertebrate host, need not be considered in a risk analysis for fresh or frozen meat or meat products.

The methods of production, manufacturing, or processing might also exclude certain categories of pathogenic agents. Provided details of these production methods and a verifiable quality control program, which includes testing, are included as part of a commodity description, these pathogenic agents do not need to be considered individually in a risk analysis. Where categories of pathogenic agents are excluded, a description of the category and the justification for their exclusion should be included as part of the hazard identification process. For example, provided meat and meat products have been derived from animals that have been subject to antemortem and postmortem inspection in slaughter and processing plants, which operate effective Good Manufacturing Process (GMP) and Hazard Analysis and Critical Control Point (HACCP) programs, then parasites restricted to the intestinal tract do not need to be considered as potential hazards in these commodities.

If hazard identification fails to identify any potential hazards associated with the imported commodity, then the risk analysis can be concluded at this point. If the importing country adopts international standards recommended in the OIE Terrestrial Animal Health Code, then there is also no need to continue a risk analysis beyond this point.

Risk Assessment

Risk assessment is the evaluation of the likelihood and consequences of an exotic pathogen being introduced into the importing country. A risk assessment consists of four interrelated steps:

- Entry assessment: How likely is the imported commodity to be contaminated with the hazard, leading to its introduction into the importing country?
- Exposure assessment: What risk pathways exist that could lead to exposure of animals and humans in the importing country to the hazard, and how likely are they to occur?
- Consequence assessment: What would be the consequences of exposure to the hazard?
- Risk estimation: A combination of the results from the entry, exposure, and consequence assessment to summarize if the identified hazard presents a risk.

It is important to note that all of the above steps might not be necessary in all risk assessments. If the likelihood of entry is negligible for a potential hazard, then the risk estimate is automatically negligible and the remaining steps of the risk assessment need not be carried out. The same situation arises where the likelihood of entry is nonnegligible but the exposure assessment concludes that the likelihood of exposure to susceptible species in the importing country is negligible, or where both entry and exposure are nonnegligible but the consequences of introduction are concluded to be negligible.

Entry Assessment

Entry assessment consists of describing the biological pathway(s) necessary for an importation activity to introduce

pathogenic agents into a particular environment, and estimating the probability of that complete process occurring. The entry assessment describes the probability of the 'entry' of each of the potential hazards under each specified set of conditions with respect to amounts and timing, and how these might change as a result of various actions, events, or measures.

For meat and meat products to act as a vehicle for the introduction of pathogens, the agent must be able to:

- Infect the species from which the commodity is derived from
- Disseminate to those tissues likely to be present in the traded commodity
- Persist in those tissues during the processing and handling conditions to which the commodity is likely to be subject.

The following are examples of factors that might need to be considered in an entry assessment for the importation of meat and meat products:

Biological factors

- The influence of age, breed, and sex of animals on the susceptibility to the potential hazard. For example, only Muscovy ducks and their hybrids are susceptible to Derzsy's disease so the likelihood of entry for this disease is negligible for meat commodities derived from other duck species.
- Means of transmission (horizontal or vertical) of the potential hazard. For example, provided OIE guidelines on breeding flock hygiene are followed, of the OIE-listed avian diseases, only highly pathogenic avian influenza (HPAI), Newcastle disease, and avian mycoplasmosis have a non-negligible likelihood of entry in poultry hatching eggs.
- Infectivity, virulence, and stability of the potential hazard. *Chlamydia psittaci* is an obligate intracellular organism that depends on living host cells for high-energy metabolites, so will not be viable in meat.
- Routes of infection (oral, respiratory, etc). Inoculation of ducks with *Riemerella anatipestifer* via the intravenous or subcutaneous routes results in significant mortality at all challenge doses, whereas very high doses are needed to cause harm by oral challenge.
- Agent predilection sites. Studies have shown that low pathogenicity avian influenza (LPAI) cannot be transmitted to susceptible birds by feeding meat derived from an infected bird because virus replication is largely limited to the respiratory tract. LPAI has a negligible likelihood of entry in imported poultry meat. In contrast, HPAI replicates in a much wider range of tissues and feeding meat from an infected bird is known to transmit virus to a susceptible bird.
- Impact of vaccination, testing, treatment, and quarantine. Vaccination against some diseases, such as leptospirosis, might reduce the excretion rate of the organism and, therefore, the contamination of the environment. Vaccination of poultry has been shown to prevent HPAI virus replication in skeletal muscles.

Country factors

- Incidence and prevalence. The incidence rate of a disease agent affects the probability of a harvested animal being infected. For such information to have value, it should be derived from statistically based surveys reporting the disease prevalence, not just the clinical disease.
- Evaluation of veterinary services, surveillance and control programs, and zoning systems of the exporting country. The quality of information relating to the disease status of a country reflects the standard of veterinary services and the programs they manage.
- Existence of disease-free zones and compartments. If surveillance and disease management procedures allow recognition of such areas, then importation from these reduces the risk associated with that organism.
- Farming and husbandry practices. Traceability is recognized as an important food safety issue. Ruminants reared totally on pasture are exposed to risk factors different from those of ruminants spending part of their time housed or confined and fed concentrates. The likelihood of animals in the United Kingdom in the 1980s being exposed to the bovine spongiform encephalopathy agent depended on whether they had been fed meat and bone meal.

Commodity factors

- Risk increases with increasing volume of trade.
- Likelihood of contamination. Only healthy animals should be presented for harvest and the distance traveled before harvest should be minimized. Quality control techniques such as GMP and HACCP will help minimize contamination at harvest. The recovery of *Salmonella* Gallinarum-Pullorum from poultry meat has only been reported in environments with poor hygiene practices.
- Effect of processing. The pH of meat drops with rigor mortis. If the pH of meat falls below 6.0, then foot-and-mouth disease virus (FMDV) is likely to be inactivated. However, the pH might not fall below 6.0 if an individual is stressed prior to harvest and, as a result, FMDV may persist in the carcass. However, even in healthy animals, the pH will not fall below 6.0 in lymph nodes, blood clots, viscera, and bone marrow, so these tissues pose a risk for the introduction of FMDV.
- Effect of storage and transport. Freezing is recognized to inactivate a number of pathogens such as Aujeszky's disease virus, leptospires, and hydatids. Heat treatment can also be relied on to inactivate a number of pathogens although a few, such as infectious bursal disease virus, are recognized as being able to withstand domestic cooking temperatures.

Several of these factors might be influential in determining the likelihood of a potential hazard entering a country through an imported commodity. Figure 1 illustrates how these factors might impact the likelihood of introducing porcine reproductive and respiratory syndrome virus (PRRSv) in imported pig meat.

Exposure Assessment

Exposure assessment consists of describing the biological pathway(s) necessary for exposure of animals and humans in the importing country to the hazards (in this case the

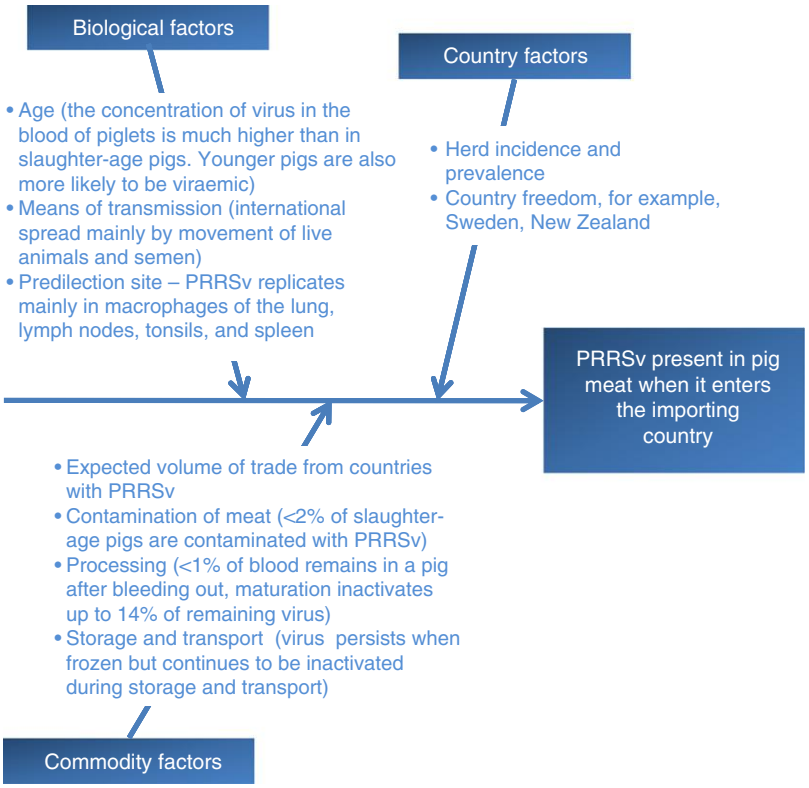

Figure 1 Example of the factors that influence the entry assessment for PRRSv in imported pig meat.

pathogenic agents) associated with the imported commodity, and estimating the probability of the exposure(s) occurring.

The exposure assessment is often the area where there is greatest uncertainty in a risk assessment. For contaminated meat products to serve as vehicles for the introduction of animal disease, the following criteria must be met:

- The pathogen in the meat must be present at an infectious dose.
- Scraps of meat must be fed to a susceptible animal of the appropriate species in the importing country.
- The pathogen must be able to establish infection when given via the oral route.
- If an infection is established in the importing country, local conditions must be such that the disease could spread.

With the exception of pathogens that are able to survive the processes involved in meat and bone meal manufacture, for imported meat to introduce a disease the contaminating pathogen must be able to infect a carnivorous or omnivorous animal when eaten. Ruminants, being herbivores, are extremely unlikely to be infected directly by pathogens carried in meat. The greatest risk of exposure, therefore, occurs in countries with significant pig populations, although imports of poultry meat could expose local poultry to certain disease risks. However, domestic legislation controlling the feeding of waste food to pigs and poultry might have some impact on this risk.

The concentration of the pathogen in meat and the dose of the pathogen required to establish infection via the oral route need to be considered. Continuing the example described in Figure 1 of PRRSv in imported pig meat:

- Meat containing an infectious dose of PRRSv at harvest is likely to come from pigs that are at the peak of viraemia. The mean concentration of PRRSv in the blood of pigs at the peak of viraemia can be estimated from published studies to be approximately $10^{3.18}$ $TCID_{50}$ ml^{-1} blood.
- The residual blood content of lean meat is 2–9 ml kg^{-1} muscle, so the viral titer of meat after bleeding out will be no more than 0.9% of the peak viraemic titer.
- Maturation and the delay before the product arrives at the point of retail result in a further reduction of the amount of viable virus that can also be quantified using published studies.
- The results of experimental studies published in 2005 have established the dose–response relationship between the oral dose of PRRSv and the probability of infection.

Knowing the likely concentration of virus in imported pork at the point of retail (taking into account the effect of bleeding out, maturation, and refrigeration or freezing), it is possible to predict the probability of a known weight of pork taken from a viraemic individual to contain an infectious dose of virus if fed to a susceptible recipient. Furthermore, as the available evidence suggests that only 1.2% of meat samples taken from pigs at harvest are likely to harbor an infectious dose of PRRSv, one can also estimate the probability of a known weight of pork imported from a country where PRRSv is present to contain an infectious dose of the virus. Such calculations have shown that

1 kg of pig meat imported from a country with PRRSv has a probability of 1.8×10^{-3} of containing an infectious dose of virus. However, caution is needed when extrapolating outside experimental results when using purely mathematical models fitted to experimental data. Because of this, the results reported here should be considered highly conservative (i.e., overestimating the probability of infection). For low-dose calculations, a mechanistic model (e.g., β-Binomial, β-Poisson, or Weibull-Gamma) is more plausible. Further discussion of this is beyond the scope of this article.

Consequence Assessment

Consequence assessment describes the relationship between specified exposures to a biological agent and the consequences of those exposures. A causal process should exist by which exposures produce adverse health or environmental consequences, which may in turn lead to socioeconomic consequences. The consequence assessment describes the potential consequences of a given exposure and estimates the probability of them occurring. Examples of consequences that should be considered include:

Direct consequences:

- Animal infection, disease, and production losses
- Public health consequences.

Indirect consequences:

- Surveillance and control costs
- Compensation costs
- Potential trade losses
- Adverse consequences to the environment.

Risk Estimation

Risk estimation consists of integrating the results from the entry assessment, exposure assessment, and consequence assessment to produce overall measures of risks associated with the hazards identified at the outset. Risk estimation takes into account the whole of the risk pathway from hazard identification to unwanted outcome.

For a quantitative assessment, the final outputs might include:

- estimated numbers of herds, flocks, animals, or people likely to experience health impacts of various degrees of severity over time;
- probability distributions, confidence intervals, and other means for expressing the uncertainties in these estimates;
- portrayal of the variance of all model inputs;
- a sensitivity analysis to rank the inputs as to their contribution to the variance of the risk estimation output; and
- analysis of the dependence and correlation between model inputs.

Risk Management

Risk management is the process of selecting and implementing measures to reduce the risk to an acceptable level, whilst ensuring that negative effects on trade are minimized. The objective is to manage risk appropriately to ensure that a balance is achieved between a country's desire to minimize the likelihood or frequency of disease incursions and their consequences, and its desire to import commodities and fulfill obligations under international trade agreements.

Because risk is a function of probability and consequences, risk management may either seek to reduce the probability of an event occurring or the consequences of it occurring. Continuing the example of the risk of PRRSv in imported pig meat, options that could be considered to manage this risk may include:

- Removal of high-risk tissues. PRRSv has a high affinity for lymphoid tissues, although replication does not appear to be significant in bone marrow. Therefore, the removal of major carcass lymphoid tissues, especially those of the head and neck, and also the major regional lymph nodes, can be considered to significantly reduce the risk in meat.
- Stabilized herds. Pigs that are naturally exposed to PRRSv after having recovered from a previous infection with the same virus strain are known to have a shorter duration of viraemia than naïve animals exposed for the first time, providing the basis for the concept of the 'stabilised' herd. Thus, in situations where infection is known to have occurred several months prior to harvest, even if the animals have been recently reinfected, the likelihood of viraemia in harvest age pigs can be considered to be significantly lower than in situations where a herd of naïve animals has been infected just a few weeks prior to harvest.
- Treatment of pig meat to inactivate PRRSv. PRRSv is known to be relatively sensitive to pH; outside the range of pH 6.0–7.5, the virus is rapidly inactivated. On this basis, a wide range of salamis can be considered to pose negligible risk of PRRS. Similarly, holding meat chilled for a week has been shown to reduce the level of infectivity present by 90%, so curing for 12 months such as in the production of Parma ham is considered to result in insignificant levels of infectivity. PRRSv has been shown to be inactivated following exposure to 56 °C for an hour, so pig meat that is cooked at this level or greater is considered to pose negligible risk.
- Measures that reduce the likelihood of exposure. Any form of meat that minimizes trimming or cutting during its preparation prior to cooking can be expected to pose a lower risk than whole carcasses because of the lower likelihood that scraps will be generated prior to cooking that might be fed to pigs in the importing country. For example, quantitative modeling in New Zealand has shown that if imports of pig meat are restricted to consumer-ready cuts weighing less than 3 kg, then the probability of a PRRSv incursion would be equivalent to a mean of once every 1227 years.

Risk Communication

Risk communication is the exchange of information and opinions with potentially affected and interested parties during a risk analysis, and the communication of the results of a risk assessment and proposed risk management measures with

the decision-makers and interested parties in the importing and exporting countries.

A risk communication strategy should be put in place at the start of each risk analysis and this iterative process should continue throughout. The communication of the risk should be an open, interactive, iterative, and transparent exchange of information that may continue after the decision on importation. The assumptions and uncertainty in the model, model inputs, and the risk estimates of the risk assessment should be communicated.

Peer review is a crucial component of risk communication in order to obtain scientific critique and to ensure that the data, information, methods, and assumptions used in a risk analysis are the best available.

Glossary

Christmas tree A vertical stainless-steel rack containing a large number of hooks arranged concentrically around the vertical shaft and used to store and transport a large number of pork hams within a meat processing plant. The Christmas tree is suspended from the top on an overhead rail or chain. It gains its name due to its resemblance with a Christmas tree when fully loaded with cuts.

Feather bones The bone that protrudes vertically from each thoracic vertebra in beef, lamb, and pork carcasses. These are often referred to as baby back ribs, riblets, or button ribs.

Forequarter pistola cut A particular cut of beef incorporating the forequarter, forequarter ribs, and flank after removal of the hindquarter pistol cut from a beef side.

Frenched racks A rack of lamb is a cut that contains a split backbone and 7 or 8 ribs. The rack is often frenched, whereby the rib bones are exposed by removing the fat, meat, and connective tissue from the end of the ribs to a fixed distance from the main muscle (eye muscle or Longissimus dorsi). Rack frenching is the process of removing the intercostal muscles from between the ribs on a 7- or 8-rib rack).

Hindquarter pistola cut A particular cut of beef incorporating the hindquarter, vertebra, and up to 10 ribs, with the flank removed. So-named because of its pistol-like profile.

Line boning The removal of boning involving a number of boning tables arranged adjacent to a central conveyor. Primal meat cuts are placed on the infeed of the conveyor and at each boning table, one or more boners select the appropriate cut, perform a specific operation on the cut, and then return the finished cut to the conveyor for further processing by a subsequent boner further down the conveyor.

Middles The primal cut produced from the middles section of a carcass containing the central vertebral column and the associated ribs.

Pace boning Pace boning is a new boning concept that replaces traditional table boning. Pace boning occupies less floor space and is claimed to result in smoother production and to be more efficient. Individual boning tasks are performed by boners whereas the product remains on a central conveyor, with each boner performing a specialized task, resulting in increased productivity. The decreased throughput time per product on pace boning lines are also claimed to contribute to greater food safety, as the deboned products can quickly be returned to the cold store.

PLC-control A programmable logic controller (PLC) is a digital computer used for automation of industrial machinery and automation.

Primal cuts The basic sections that a carcass is normally cut into before being further subdivided into steaks and other table-ready cuts are produced. Although different countries and cultures differ in how they divide carcasses of different species into primals, the carcass is generally divided into three primal regions – the hindquarter, middle, and the forequarter. In some cases carcasses may also be split vertically down the backbone, separating each primal region into two individual cuts.

Rail boning The practice of removing primal and whole muscle cuts from a beef side where the side is suspended from an overhead rail. Removed cuts are dropped onto an adjacent table or conveyor for subsequent further processing or trimming.

Introduction

The issues of industrialization with respect to organization, work specialization, and use of production lines, such as for slaughter line operation, apply particularly to cutting and boning technology. Indeed, such technologies are probably the area that are mostly used by the robot-assisted and computer-controlled manufacturing systems.

This article begins with a general analysis of the opportunities and challenges associated with the development of automation solutions for cutting and boning followed by a section for each of the three species covered:

- Porcine (pork) cutting and boning
- Bovine (beef) carcass cutting and boning
- Ovine (sheep and lamb) cutting and boning

The three sections related to the species include an overview of currently (2012) available automation technologies and some reviews on the historical development of the technology.

Opportunities and Challenges

The strongest incentives for the meat industry to adopt automation technology is related to labor – the drive for improved productivity through reduced labor also creates a more rewarding and safer working environment.

Cutting and in particular boning operations are very labor intensive and require skilled, hard, and hazardous work. Automation offers the potential to remove arduous work and as a result introduces more rewarding jobs in terms of planning, supervision, and control of the new technology.

Automation can also improve hygiene and product yield. In some cases, dedicated automation can further increase the production flexibility and facilitate compliance with a wide range of customer specifications without losing cost efficiency. The latter aspect is of particular benefit to export intensive companies serving a wide variety of markets.

Despite these drivers, cutting and boning operations throughout the world are still very labor intensive. Automation in the pig slaughter industry has mainly been adopted in regions with high labor costs such as Northern Europe. In New Zealand, the lamb industry has been progressive in developing and using automation technology to increase processing efficiency and overcome the challenges in recruiting, training, and retaining skilled labor for demanding and manually intensive tasks. Automation in the beef industry is limited because of the complexity associated with handling of the size and biological variation of the carcasses and cuts.

Barriers for automation include the high cost and complexity associated with the development of automation technology, combined with the limited market size, with most of the growth in production occurring in meat-producing regions that have ready access to low-cost labor.

The development of automation for cutting and boning imposes engineering challenges due to the complex structures of hard bone and softer meat and fat and the inherently variable nature of carcass geometry due to genetic variability. This requires flexible and robust machinery and tools combined with advanced measuring systems and control software.

The breakdown of carcasses for all species generally follows the same process of

- separating the carcass into primal – representing the fore – middle, and rear regions of the carcass;
- further cutting the carcass into subprimals and bone-in cuts;
- boning to produce table-ready cuts, either part-boned or bone free; and
- trimming cuts to meet customer specifications regarding shape, weight, fat cover, and presentation.

However, the inherent differences in each species have resulted in critical differences in the process for each species, by which carcasses in each species are processed and disassembled into meat cuts and related coproducts. The automation of boning and cutting processes is, therefore, addressed separately for each species in the following sections.

Pork Cutting and Boning

Concept Design for Automated Cutting

Figure 1 shows an example of a concept design for automated cutting of pig carcasses. The concept has been developed by the Danish pig meat industry, The Danish Meat Research Institute (DMRI), Denmark, and different suppliers of machinery for the meat industry.

Automatic Primal Cutting

Automatic machines for primal cutting have been available for several years, for example, from the two Danish companies, Attec and KJ Industries. The machines separate half carcasses (whole carcasses are split down the backbone as part of the slaughter process) into the three primal cuts: fore-end, middle, and hind leg by sawing after precise measurements and positioning. The two machines operate with different measuring technologies. Attec's machine applies servo-controlled mechanical sensors, whereas the machine from KJ Industries makes use of computer vision analysis.

Automatic Cutting of Pork Middles

Figure 2 shows a machine for automatic cutting of middles supplied by Attec, Denmark.

Attec also supplies a machine for automatic cutting of middles. Cuts from the middle-cutting machine are shown in Figures 3 and 4. In its basic version, the machine splits the pork middle into loin and belly and cuts off the rib-top. In an extended version, the machine further performs precutting of the ribs, without cutting in the meat. The extended version may also include removal of the feather bones. The rib precut and splitting is done based on individual recipes specifying quality parameters. Feather bone removal is also performed at this stage. Each of the different cuts are delivered on separate belts for further processing and handling.

The benefits of the middle-cutting machine are both reduced labor costs and improved yield. The yield increase is

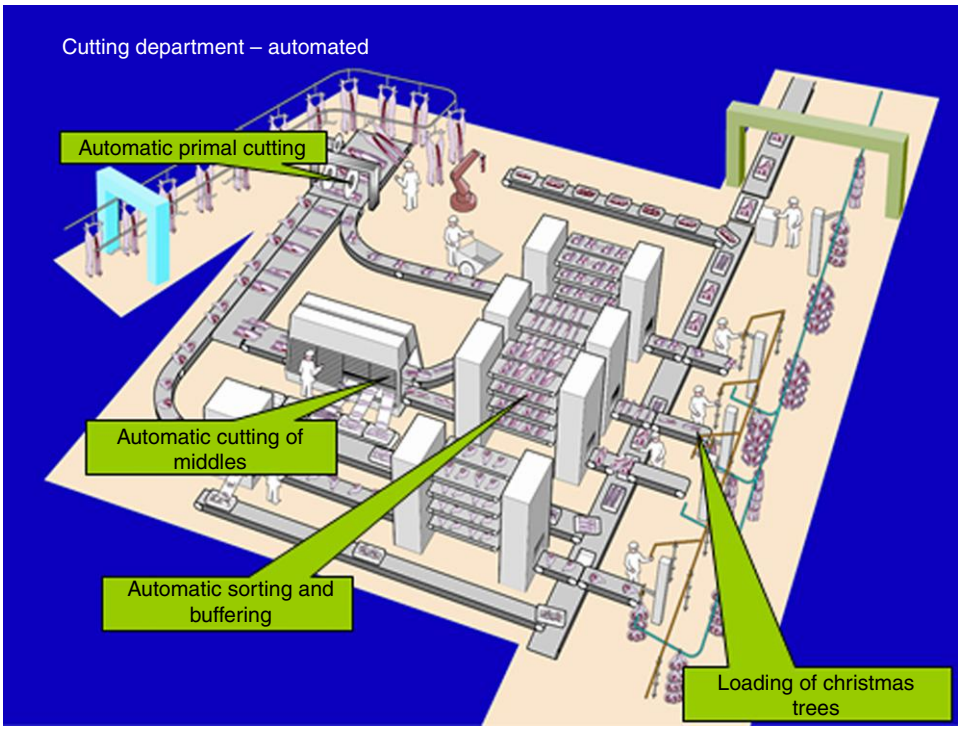

Figure 1 Concept design for automated cutting of pig carcasses. Courtesy of DMRI.

Figure 2 Automatic cutter for pork middles. Photo courtesy of Attec.

achieved because sawing of the rib-tops can be more accurate and the division of the loin and the belly can be optimized according to product specifications. Because the production recipes can be changed instantly, the machine can produce in accordance with current information of customer demands.

Automatic Sorting and Buffering

A system for automatic sorting with buffering capacity is supplied by the Danish company, KJ Industries. In the buffer storage, the different cuts are sorted according to customer specifications such as weight, meat percentage, fat thickness, pH values, and breed.

An automatic S-curved conveyor and a buffer system ensure a continuous product flow and also ensure that cuts are forwarded according to the correct sorting class. From the buffer, the cuts are automatically transported to further processing, packaging, or storage.

Semiautomatic Loading of Cuts on 'Christmas Trees'

When internal transport takes place by use of 'Christmas trees,' the semiautomatic system for loading of cuts can be applied to avoid manual heavy lifts. The cuts from the buffer storage, now arranged in quality classes, will be moved automatically to a number of loading stations and loaded on the 'Christmas trees' by the use of semiautomatic devices. A system for unloading the cuts at the destination for subsequent boning is also available.

Automation of Boning Processes

Boning is difficult to automate because of the subtleties of the process itself and the characteristics of the items to be processed. Cuts from animal carcasses are very complex, irregular, and unpredictable in terms of shape, texture, and internal structures consisting of a geometrically irregular mix of hard and soft tissue. Therefore, only a few automation solutions have been developed for boning till date.

Skinning/Derinding

One process, however, was automated – or rather mechanized – very early, namely the skinning or derinding of cuts. Ray Townsend (USA) invented the first pork skinner in 1946, and the

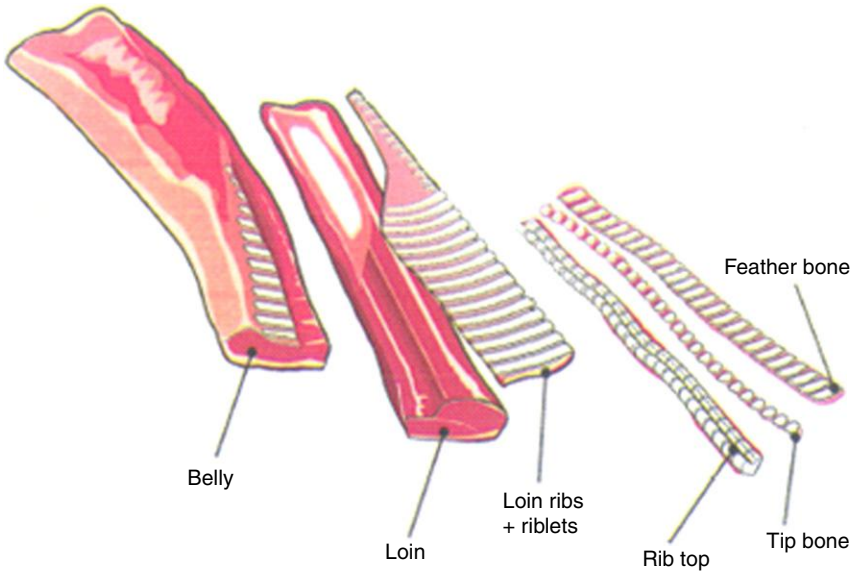

Figure 3 Processed cuts from the automatic cutter for pork middles. Image courtesy of DMRI.

Figure 4 View of splitting the middle into the loin and belly in the automatic cutter for pork middles. Photo courtesy of Attec.

Figure 5 The Attec pork ALDT. Photo courtesy of Attec.

company Townsend (now part of Marel, based in Iceland) has since been one of the leading suppliers of skinning equipment.

Today, a number of manufacturers offer this type of machine. One of the technical challenges with this process is to ensure that the skin is removed while leaving a fat layer of a specified thickness at the product. This is not easy, if possible at all, to ensure by means of conventional mechanical devices. At International Frozen Food Association 2013 in Frankfurt, however, a new development from Attec and DMRI was exhibited. The Attec pork automatic loin 3D trimmer (ALDT) is an automatic equipment using a number of individually actuated knifes controlled by a measuring unit combining ultrasound and vision measurements allows much higher precision in trimming and higher yields (Figure 5).

Industrial Robot Solutions

Although the equipment described is custom designed, dedicated machines designed as machinery equipped with PLC-control systems based on industrial robots also exist.

The German companies, Banns and e+v Technology GmbH (e+v), are examples of suppliers of such solutions based on industrial robots combined with automatic vision measurement systems (e.g., Figure 6). At present (2012), applications for primal cutting, cutting shoulders, and middles are available.

Beef Carcass Cutting and Boning

Primal Cutting and Quartering

Traditionally, most beef carcasses are fully chilled and almost equilibrated at temperature generally below 5–10 °C before further partition of the carcass sides. However, some plants in Australasia and Scandinavia conduct hot boning immediately after slaughter, or semihot boning with core muscle

Figure 6 Robot for conventional precutting (primal cutting) with four individual cuts. Robot system from Banns and e+v technology, using a Kuka robot. Photos courtesy of e+v Ltd.

temperatures of 10–20 °C. With hot boning, certain cuts may be wrapped in plastic to prevent muscle contraction, resulting in lower tenderness.

The predominant quartering process used includes cutting and sawing sides to halves or pistol/hindquarter. It is a manually operated process using powered sawing and cutting tools. Several initiatives to automate this 'scribing' by the use of standard robots mounted with saws and controlled by vision systems have been taken, for example, a joint Machinery and Robotics Pty. Ltd. (MAR, Australia), Meat and Livestock Australia (MLA)/Australian Meat Processor Corporation (AMPC) project, and a German e+v project where similar commercial systems are in place for pork. In a French-led project, robotic Z cutting into pistola and forequarter has been researched. The first commercial scribing system came in operation in 2009. Uptake of the technology so far has been limited.

Cutting and Trimming

Beef quarters are progressively broken down into individual cuts with the quarters either manually placed at tables (table-boned) or hung from the hook (rail-boned). This process requires operator skill in order to follow muscle seams and delivering presentable cuts. The work load on operators is considerable and introduction of simple force rams to aid in the pulling and separation process has been used for several decades. The systems assist the operator by pulling bone from meat or meat from bone. Likewise, systems that position the quarter in more favorable position for cutting by tilting the quarter during removal are in use. There are several similar systems are available, for example, Carne Liberator system.

More recently, a more adaptive controlled pulling device called Hook assist has been developed in an MLA/AMPC and Scott Technology Ltd (Scott, New Zealand) effort (Figure 7). The machine now being introduced in Australasia is a manual assist device developed to make boning of aitchbones and knuckles less physically demanding. The device is a mechanical arm that acts to provide the pulling force an operator requires for rail boning. Force feedback technology is used to give a boner a meat hook that can pull with four times the force of a human. The force is finely controlled by the operator using a joystick principle.

Strain on operators arises from uneasy work positions and required force for maneuvering muscles and knife trajectory. In modern plants, adjustable platforms to compensate difference in operator heights have become standard, and for rail boning, height-adjustable rams are used. Traditional layout boning room includes individual deboning table where an operator bones out quarters moved to his position.

Separating the boning process on consecutive operators allows specialization and easier design of a more ergonomically correct work position, for example, pace boning and line boning.

Automatic Loin Boning

The biological variation in beef carcasses compared with, for example, pork and poultry with respect to animal age, weight, and skeletal differences is a challenge for the development of automatic boning solutions. Flexible tools and sensors may be required to successfully deal with the biological variation. The company BLM Engineering in New Zealand developed together with MLA the Beeftech loin boning machine, where the loin cuts fixed on a moving conveyor passes a solid curved knife separating muscle from meat. This machine has a throughput of up to six carcasses per minute. The machine has been developed to a commercial version but has yet to see a widespread industry uptake.

Another recent approach for loin boning using several consecutive tools was inspired by the pork middle deboning equipment developed by Attec and DMRI. DMRI with MLA started exploring the feasibility of a loin boning concept using consecutive moving tools like sawing, a rigid knife, and several flexible knives working on a fixated strip loin piece.

Yield Management and Traceability

The increased demand for traceability, yield recording, and monitoring of operator performances have led to introduction of IT solutions with information monitors and scales at many operator positions in the boning room. An advanced example

Figure 7 An adaptive controlled pulling device called Hook assist developed in an MLA/AMPC and Scott effort. Photo courtesy of Scott Technology Australia P/L.

of this is the Marel stream line system, where cutting instructions and performance information is given on monitors. The operators are assigned cuts with specific customer specification and by weighing after trimming it is possible for management and the operator to monitor the performance of the individual operator. A built-in traceability mechanism at all levels of product handling ties the animal origin and carcass information with the individual cuts, ensuring that all product information may be used for labeling and for product recall. Although the cost of these advanced systems is significantly higher, the potential is increased yield recovery and a data-based continuous feedback to both the operator and boning room management. This enables worker pay rates to also be linked to worker performance according to their individual performance and throughput data recorded in the system.

Ovine Cutting and Boning

New Zealand and Australia are the world's largest exporters of lamb and mutton, with over 93% of all lamb and 91% of mutton slaughtered being available for export. Historically, the vast majority of this trade was in the form of frozen carcasses, primarily supplying the UK with frozen lamb in whole carcass form. Today, the vast majority of cross-border lamb exports are in a bone-in or boneless form, much of this in table-ready form and exported chilled rather than frozen. For example, in the year ended September 2010, less than 5% of New Zealand lamb and mutton was exported in whole carcass form, 20% going as boneless product and 75% going as cuts.

The trend toward producing a wide range of further processed and table-ready cuts has resulted in dramatic increase in the range and complexity of cut specifications. The typical New Zealand lamb processor will have many hundreds of individual cut specifications on file and be required to produce these regularly. Although the differences between specifications will often involve subtle differences in packaging and presentation of final trimming, this plethora of specifications will result in a typical lamb cutting and boning room being required to implement changes in processing operation to accommodate the need to produce different cuts during a single shift.

The typical lamb carcass breakdown is shown in Figure 8 and includes the most common cuts produced from each of the three primals (forequarter, middle, and hindquarter).

Lamb, unlike beef and pork, carcasses are generally not split down the backbone but instead cut into these three primals. Each of these primals is then further broken down into further processed and table-ready cuts before being packaged, boxed, and then sent to refrigerated storage before load out.

Such a wide range of complex cutting specifications offers significant opportunity for automation; however, with many variations in the cuts required, the technical complexity has represented a major hurdle to the development of automation. The constant change in the cutting operations in response to changing cut specifications has also focused automation developments on the production of higher value cuts or on operations that are common to a wide range of cuts.

Drivers for Automation

Traditionally, lamb carcasses are cut into their three primal cuts manually using band saws. This is a highly dangerous operation, with significant risk of serious hand injuries and amputations of fingers. This high risk operation has led to the development of Bladestop™, a joint development by MAR and MLA. Bladestop™ comprises an operator arm sensor attachment with a unique blade brake mechanism, all under microprocessor control. Bladestop™ mechanically stops the band saw blade when the sensor detects that a person has come into contact with the blade, stopping the blade within 10 ms and therefore significantly reducing the chance of serious injury.

Band saws also produce a significant amount of wastage, with the average band saw generating significant meat saw dust as a part of the cutting operation. There is also the risk of contamination from bone and meat dust, particularly when a

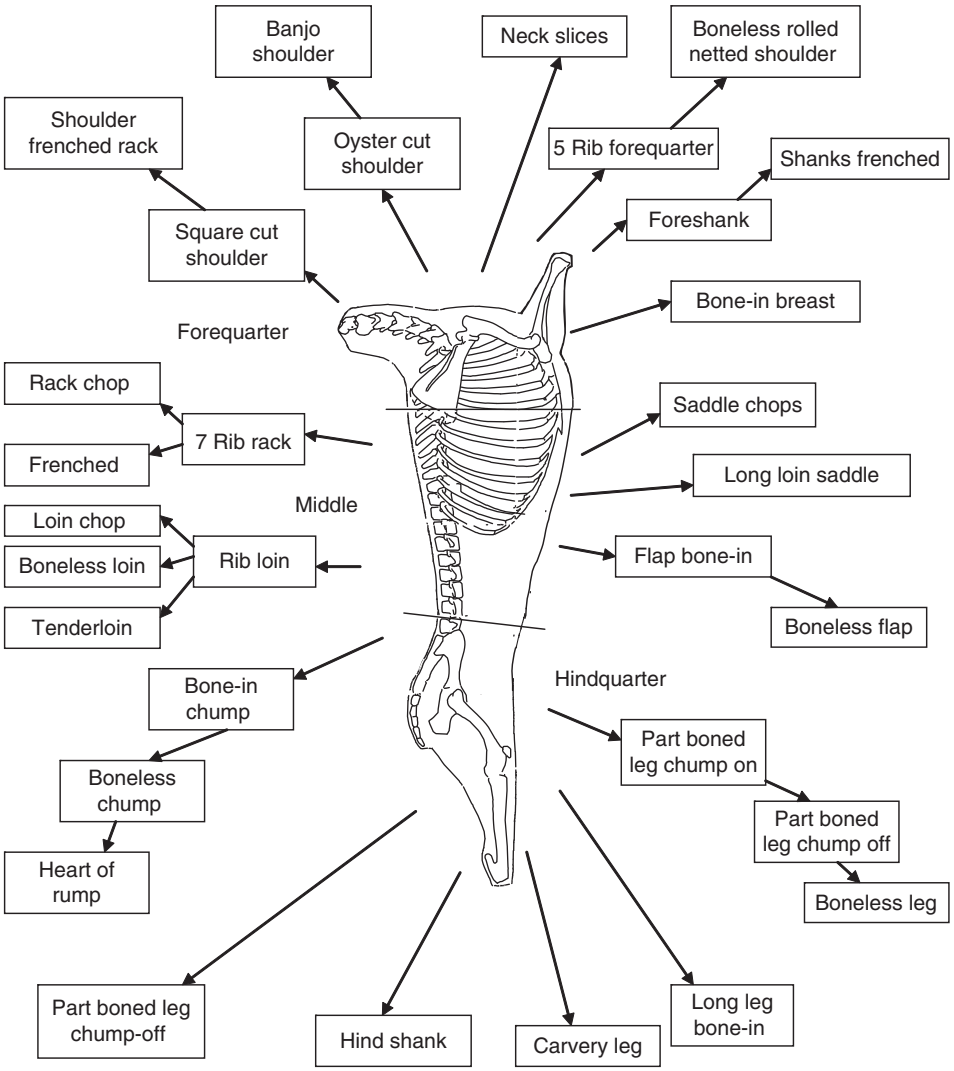

Figure 8 Typical lamb carcass break-out.

cut is made through the spinal column. Alternatives to band saws include circular cutting disks, such as those manufactured and marketed by Freund, Germany. These disks generate almost no dust, are capable of cutting through meat, fat, and bone, and offer significant advantages in terms of safety and hygiene over conventional toothed blades and band saws.

Much of the subsequent processing of primal is undertaken manually using sharp boning knives, representing a further safety risk as well as being time consuming and thus labor intensive. Automated key cutting tasks offer the potential to reduce this risk, also offering the benefits of increased hygiene through reduced cross-contamination as well as increased yield and more consistent presentation of the cut surface.

Mechanized Task Replacement

In the 1980s and 1990s, the Meat Industry Research Institute of New Zealand Inc. (MIRINZ) developed a number of mechanical systems for automating key aspects of lamb cut production. Two of these that have met with significant commercial success are the loin/saddle removal machine and the Chine bone removal machine, now manufactured and marketed by BLM Engineering in New Zealand (BLM, Figure 9). These machines perform the same repeatable task on manually loaded cuts, generating yield improvements of 10% and 8%, respectively, at throughput rates of up to 9 cuts per minute, using only a single operator. There are more than 100 of these machines currently in service within the lamb industry worldwide.

MIRINZ also developed mechanical prototypes for automating the primalling of carcasses using large, automated band saws, fleecing shoulders of the forequarter and mechanically removing the intercostals from rack saddles to produce frenched racks, but none of these developments proceeded to a commercial stage.

MACPRO abt, New Zealand, in conjunction with the MLA, also developed a number of mutton boning systems, including leg and trunk boning machines. There has been little commercial uptake of these machines by industry. The same developers, under the brand name EXOS, have recently launched

Figure 9 The loin/saddle removal and chine bone removal machines. Photos courtesy of BLM Engineering.

a new lamb loin/saddle boning machine that operates in a similar manner to the BLM machine.

Attec has developed a number of machines for lamb cutting. These include a semiautomated lamb primal cutting system that uses one or more circular disk knives to provide a cut that produces no meat or bone dust. The carcass is laid flat on a table and either aligned with the knife manually or the knives aligned by the operator positioning an optical indicator on the carcass that aligns the knives automatically. A number of installations are currently in commercial use around the world.

Attec has recently announced an automated middle cutting machine called the LMPC-200. This machine is able to perform flap trimming and chine bone removal on lamb saddles in a single operation. A lamb shoulder square cutting machine is also in development. Both of these machines require manual operators to load and unload product.

Rack frenching (the process of removing the intercostals muscles from between the ribs on a 7-rib rack) is a skilled and manually intensive task, requiring between three and six workers at typical lamb-processing rates of three to six carcasses per minute. Frenched racks are also one of the most highly valued, table-ready cuts produced from lamb carcasses, and customer specifications dictate that the intercostal tissue must be trimmed to a set distance from the eye muscle and that appearance and finish to the product be of a uniform high standard. Although a mechanical cutting solution to this manual task is yet to be commercially developed, a number of systems are currently in use applying high pressure water jets to remove the intercostal tissue from between the ribs to a consistent distance from the eye muscle. These machines require only a single operator and thus offer significant benefits in terms of labor savings and reduction in the risk of knife-based injuries. However, the disadvantages of this approach include:

- High use of water.
- Requirement to process the resulting slurry.
- Loss of the intercostals as an edible product and a loss in yield.
- The application of water limiting the shelf life of the product when stored chilled.

McLaren Engineering (New Zealand) has recently developed iFRENCH, a continuous processing French rack machine that uses water to process racks at a sustained rate of 24 racks per minute.

Robotic Automation

Before 2000, boning and cutting automation involved the mechanization of a fixed operation, with minimal, if any, modification of action to accommodate variations in carcass geometry or anatomy. More recently, a number of developments that incorporate robotics with sensor feedback have been developed, aimed at addressing the more challenging boning and cutting operations.

One such development is the Robotic Ovine Cutter (ROC), which is commercially available through MAR. This joint initiative between Midfield Meats in Australia, BMC (UK), and e+v combined an off-the-shelf robot and e+v's image vision system to automatically primal lamb carcasses. The carcass is first scanned by the vision system while still on the rail and the primal cut positions calculated. Using a custom gripper, the robot then removes it from the rail and passes it through circular disk blade before returning the hindquarter to the rail. The original system was capable of processing 200 carcasses per hour. Subsequent developments have increased the throughput to 400 carcasses per hour through the mounting of the circular disk blade on a second robot to speed up the cycle time. Higher throughput systems proposed by MAR involve additional robots to gain further reduction in cycle time. Reported results indicate that more than 90% of square shoulder cuts are made within plus or minus half a rib.

More recently, Robotic Technologies Limited (RTL), a joint venture between New Zealand's largest meat processing company Silver Fern Farms Ltd. and Scott, has revealed its vision for a fully automated lamb boning room (**Figure 10**). This development is aimed at producing an automated room for producing bone-in products at throughputs of up to 10 carcasses per minute.

The system comprises a real-time X-ray system that images each carcass from two aspects to generate the necessary information of external and internal anatomy, and in particular

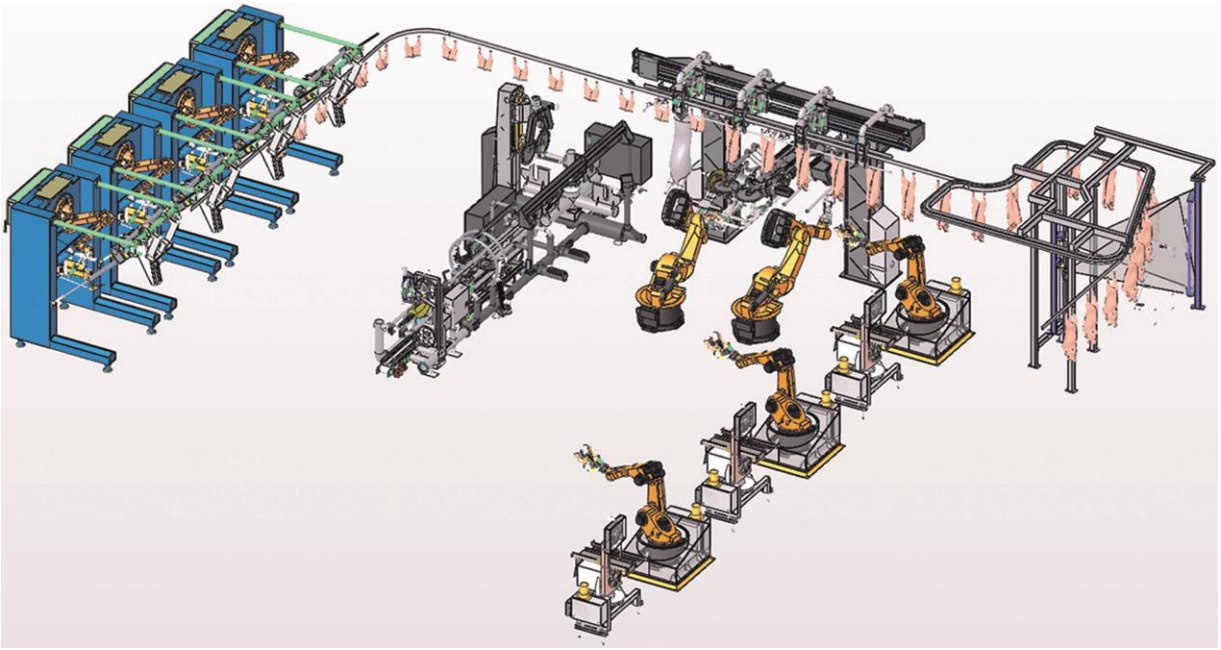

Figure 10 RTL's full automated boning room. Image courtesy of RTL Ltd.

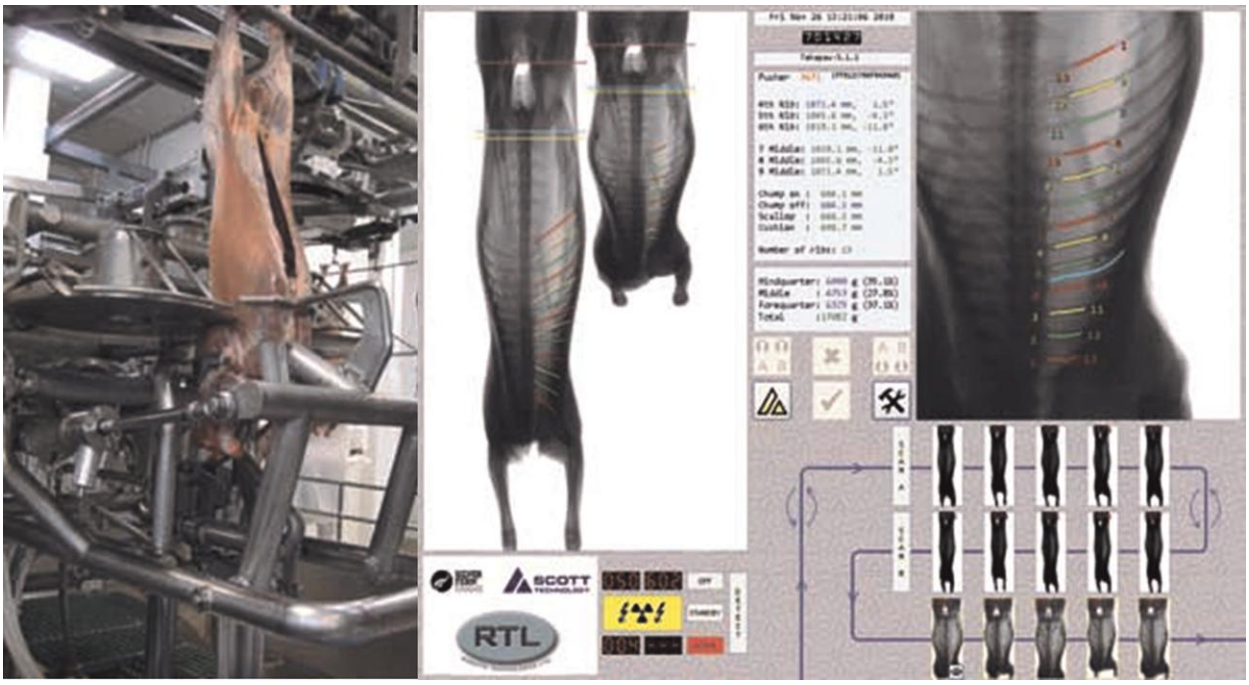

Figure 11 RTL's primal robot and the output of RTL's X-ray imaging system. Image courtesy of RTL Ltd.

the internal location of skeletal structure. It is this information that enables much of the subsequent automation.

Carcass primaling is then performed by two robotic cutting stations. The first uses circular disk knives to separate the forequarter from the carcass, with the robot being able to angle the cut in order to optimize meat yield in the higher value primal while accurately placing the cut with respect to the ribs and vertebrae. The second robot uses a blade knife to separate the hindquarter from the middle primal using a variety of cut positions (chump on, chump off) while also angling the cut to clear the pelvic bone and again optimize the meat yield in the more valuable loin area. These two robots are operational in meat plants in New Zealand and Australia.

The three primals are then handed off the three separate robotic stations. The hindquarter station uses a conventional robot, equipped with a conventional knife blade, to cut and

separate the two legs from the pelvic bone. RTL are also working on an automated knuckle tipping machine for the legs after removal form the pelvic bone.

The middle robotic station incorporates automatic spinal column material removal, saddle crosscut, flap and brisket trimming, and chine and feather bone removal. These cuts are all optional dependent on the required cut specification. This station is at the in-plant testing stage.

The forequarter robotic station uses a robot to grip and cut the forequarter using a conventional band saw. This system is able to implement cuts to the brisket, knuckle tips, and neck as well as splitting the forequarter, depending on the required cut specification. This station is installed in at least one New Zealand lamb processing plant.

Each robotic station is developed as a standalone module. In this way, they can be implemented separately or together, integrated with a carcass X-ray imaging system or independently integrated with other sensing systems installed adjacent to the robotic stations (**Figure 11**). Producing significant savings in labor and hygiene, the ability to optimize cut placement according to cut specification results in an increase in yield of higher value cuts of approximately 1%, contributing significantly to the payback of this technology, particularly in higher throughput installations.

Glossary

Bung Term used to describe an animal's rectum.
Cod Region of a beef animal in the region of the udder or scrotum.
EUROP Grid method of carcass classification implemented in 1981 by the European Economic Community to ensure the uniform classification of adult bovine animals. The EUROP grid consists of a five-point scale in which each conformation and fat class is subdivided into low, medium, and high classes resulting in 15 classes. Conformation is assigned according to the EUROP system where E is excellent, U is very good, R is good, O is fair, and P is poor. Fat class is a numerical scale where 1 is low, 2 is slight, 3 is average, 4 is high, and 5 is very high.
Flare fat Visceral fat deposit surrounding the kidneys and inside the loin of pig carcasses. It is the source of the highest grade of lard, known as leaf lard.
Paternoster lift An elevator that consists of a chain of open compartments that move slowly and vertically in a continuous loop without stopping.

Introduction

For many years slaughtering has been industrialized with respect to organization, work specialization, and use of production lines. It was from seeing the conveyor systems used by the beef slaughter industry in Chicago in the beginning of the twentieth century that Henry Ford I had the idea of implementing assembly lines that revolutionized the car industry. At present the meat industry is getting inspiration from the robot-assisted and computer-controlled manufacturing systems applied in the car industry.

This article is organized in a section with a general analysis of the opportunities and challenges associated with the development of automation solutions for slaughter houses followed by a section each for the three species covered:

- Porcine (pig) slaughter automation.
- Bovine (beef) slaughter automation.
- Ovine (sheep and lamb) slaughter automation.

The three sections related to the species include an overview of currently (2012) available automation technologies and a review of the historical development of the technology.

Opportunities and Challenges

The strongest incentive for the slaughter industry to adopt automation technology relate to labor – the drive for improved productivity through reduced labor, while also creating a more rewarding and safer working environment. Slaughtering operations are labor-intensive and require hard and repetitive work. This situation can be improved by automation, which not only removes arduous work but in addition introduces more rewarding jobs in terms of planning, supervision, and control of new technology. Automation also improves the hygiene by less manual product handling and less cross contamination between carcasses because the tools in the machines can be cleaned more effectively between each carcass. Slaughter quality and yield can also be improved by automation through more accurate, consistent, and repeatable execution of key slaughter tasks.

Despite these drivers, slaughter houses throughout the world are still very labor intensive. Automation in the pig slaughter industry has mainly been adopted in regions with high labor costs such as Northern Europe. In New Zealand, the lamb slaughter industry has been progressive in developing and using automation technology to increase processing efficiency and overcome the challenges in recruiting, training, and retaining skilled labor for demanding and manually intensive tasks. Automation in beef slaughter is limited because of the complexity associated with the handling of the biological variations of beef carcasses.

Barriers for slaughter line automation include the high cost and complexity associated with the development of slaughter automation technology, combined with the limited market size, with most of the growth in production occurring in meat producing regions that have ready access to low-cost labor.

The development of automation for slaughter houses imposes engineering challenges because the machines are to perform transformation of a material composed of complex structures of soft and hard material. Further, the machines must be able to adapt to considerable and unpredictable variations of the input material. This requires flexible but still robust machinery and tools combined with advanced measuring systems and control software.

Automation of Pig Slaughter Lines

The most common approach to developing slaughter line automation is task replacement: specialized machines dedicated to performing a specific slaughter task. More recently, specialized machines have been complemented by standard

Table 1 Overview of the pig slaughtering processes and automation

	Process	*Automation*
Unclean part		
Live animal handling	Transport to slaughterhouse	
	Unloading of pigs	Vision monitoring of animal welfare
	Veterinary antemortem inspection	
	Lairage	Semiautomatic
	Transfer to stunning	Semiautomatic
	Stunning	Semiautomatic
Sticking and bleeding	Shackling

	Carcass classification	Automatic
Downstream processes	Carcass chilling	Computer-controlled transportation systems
	Sorting into quality groups	
	Storage and temperature equilibration	

industrial robots equipped with special tools and designed specifically to survive the harsh environmental slaughter lines.

An overview of the handling of pigs for slaughter from transport of the live animals through the slaughter processes until the equilibration chilling room are shown in Table 1. The current automation possibilities are indicated.

Automation of Unclean Part of a Pig Slaughter Line

Figure 1 illustrates the unclean part of a pig slaughter line configured with available (2012) automation and mechanization technology (yellow text-boxes).

The set up shown in Figure 1 is based on gentle and animal-friendly handling of the pigs and in groups from delivery at the farm, during transportation, and until CO_2 stunning at the slaughter house. At the slaughter house, the pigs are kept in their familiar groups at the lairage and further during moving to the CO_2 stunning system by means of automatically driven gates. The pigs are stunned in groups of 5–7. The groups are led into a paternoster lift, which is lowered into the CO_2 where the pigs lose consciousness before sticking. The benefits achieved from this concept are high animal welfare, low mortality during transport, reduced drip loss, and improved meat quality.

For most of the remaining processes except shackling, sticking, gambrelling, and reading of farm identification numbers, automated mechanical solutions are available. For higher line speeds, a separate equipment for each process is used. For lower line speeds, combination systems are available, for example, systems combining scalding, dehairing, and singeing.

Automation of Clean Part of a Pig Slaughter Line

Figure 2 illustrates an automation concept for the clean part of a pig slaughter line. Automatic machines are indicated by the yellow text boxes.

In Figure 2, the shown concept has been developed in partnership between the Danish pig meat industry and a division in the Danish Technological Institute (DMRI), Denmark. The individual machines were developed in cooperation with machine suppliers, for example, Danish supplier of meat processing equipment (SFK) Systems, Denmark, that delivers a number of the shown automatic machines. The automation concept may reduce the required manning by 30–40% compared to manual operation.

Below are shown photos of selected machines for the slaughter of pigs together with a short description of the operation (Figures 3–5).

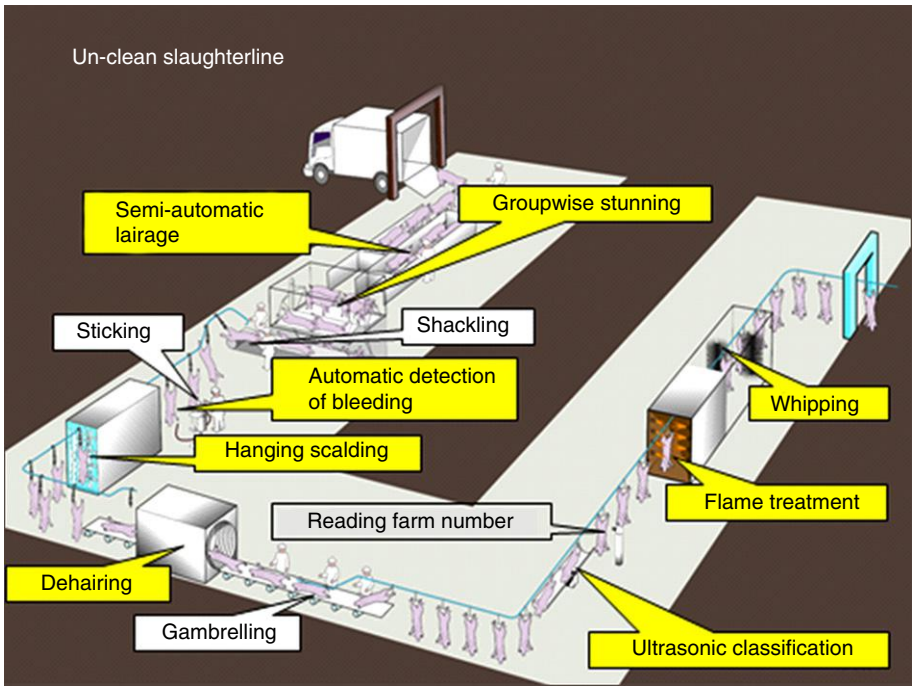

Figure 1 Unclean pig slaughter line configured with up-to-date technology.

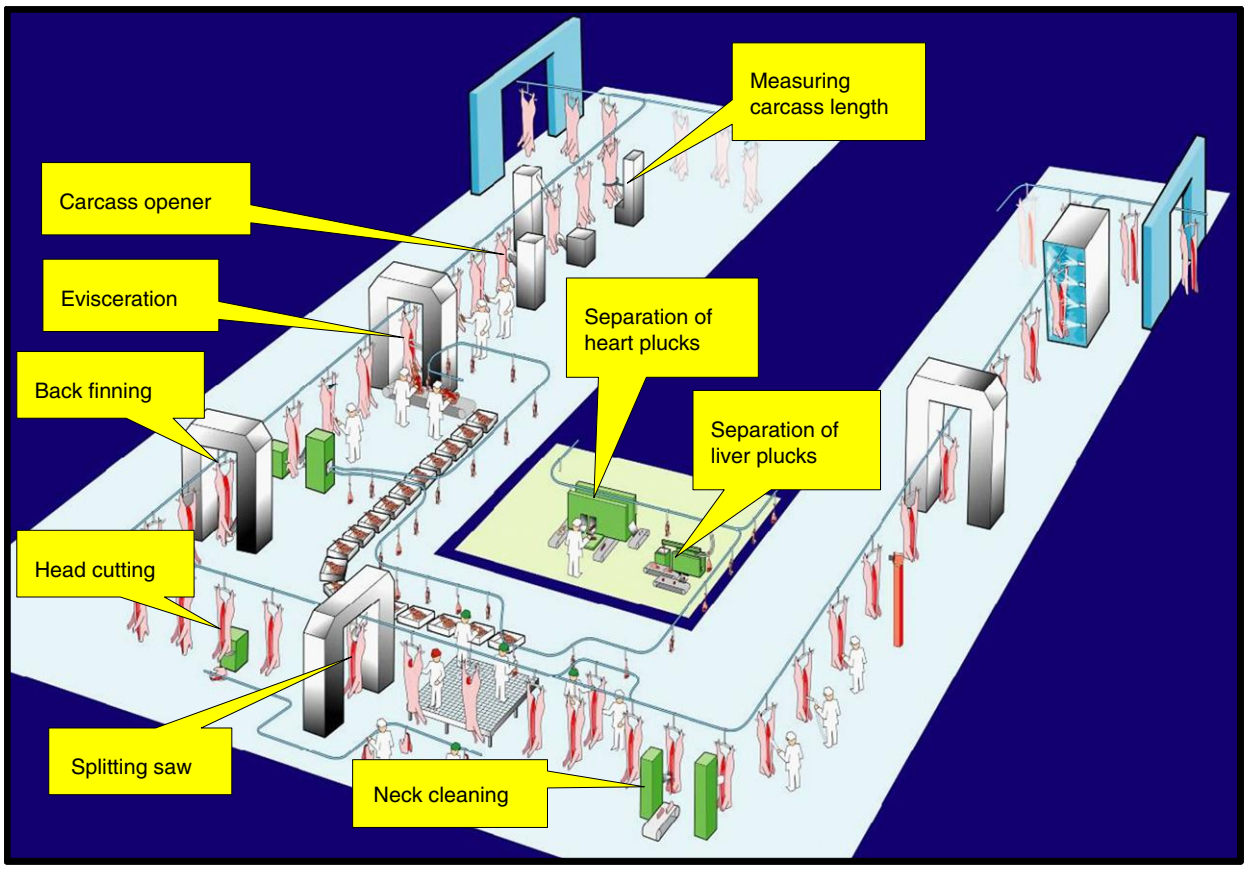

Figure 2 Clean pig slaughter line configured with state-of-the-art automation technology, 2011.

Figure 3 Automatic evisceration. The automatic evisceration machine cuts the diaphragm, tears off the flare fat, and loosens the intestinal tract such that the entire set of intestines and organs is removed from the carcass before separation (Anon, 2001a,b). Because the separation takes place outside the carcass, it can be performed consistently and reliably with lower risk of fecal contamination.

An alternative range of machines (*F*-line) for slaughter line automation is available from the Dutch company Meat processing systems (MPS). The *F*-line includes automated precutting, belly opening, rectum drilling, neck cutting, leaf lard removal, splitting, and marking.

Automation solutions based on the use of industrial robots are offered by the Germany slaughter technology company. The technology base is six-axle industrial robots in hygienic configuration, combined with high resolution visual recording systems and evaluation software as well as tools that have been designed especially for robot application. Robots are currently available for the following processes: fore-paw cutter, bung dropper, w-bone cutter, belly-and-breast opener.

Beef Slaughter Automation

Slaughter procedures for cattle are still very manual with little automation and limited technological development and application. Most of the development has been in the area of manually operated, power-assisted tools that have been improved to ease the physical work for operators or in the area of tools developed for improving the hygienic quality of slaughter.

The majority of cattle in the world are, however, still slaughtered at low line speeds. Most of the animals are slaughtered at meat plants run in single shifts at line speeds from approximately 30–75 h^{-1} and the plants are seldom specialized but are required to slaughter all types of cattle as they are delivered. This implies that new technology must be flexible and match the large biological variation in dimensions.

In the USA, larger meat plants have higher line speed up to approximately 400 carcasses per hour achieved by increasing

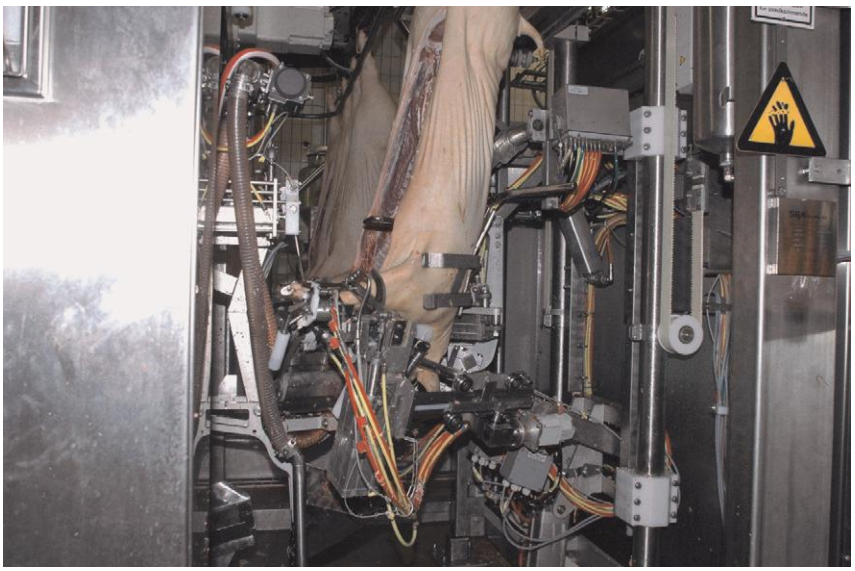

Figure 4 Automatic neck cleaning and cutting of forelegs. The machine automates some of the critical cleaning of the carcasses after carcass splitting. The machine automatically trims the neck region for glands and blood residues and from the breast part it removes the heart fat. Further, the machine cuts off the forelegs. This cut is done more precisely than by manual operation.

Figure 5 Head-cutting machine. The machine operates in two modes. It can either cut off the head entirely or leave it on a separate conveyor system or alternatively the machine can cut the neck only and leave the head hanging at the carcass by the jowls. Cutting off the head before carcass-splitting reduces the risk of contamination from the mouth and throat regions. The machine also provides better yield by leaving more neck meat on the carcass.

manning levels, sharing tasks across more operators, and by ensuring that the animals slaughtered are relatively homogenous in size, with slaughter lines tailored for steers and heifer. Often, equipment is duplicated and some tasks are progressively and sequentially performed by several machines, for example, hide pulling.

Lairage and Stunning

Moving cattle into a stunning box without electric prodders can be difficult. DMRI developed a stunning box with associated automatic drive gate, which gently pushes the animal into the stunning box; the system is used in different versions in several Scandinavian plants with a capacity of up to 60–70 animals per hour. Research has been carried out with automatic placement of the captive bolt stunner using vision and a standard industry robot, however, without any commercial uptake. In Australia, Meat and Livestock Australia (MLA) has undertaken research into automating the tracking of the head using machine vision to automate the stunning task (in conjunction with research into very high frequency stunning and alternative stunning technologies), but this has not progressed to commercial implementation. Automatic electric stunning boxes with head fixation are widely used in New Zealand and are in the market from Jarvis, New Zealand and BANSS, Germany. The box is controlled by an operator who activates the stun box for fixating the head, engages electrodes, and monitors the process. Although the electric stun with no penetration of the skull limits risk of special risk material (SRM) from the brain spreading, there are some reports of more incidences of blood splash in the muscles compared to captive bolt stunning. In the automatic electric stun box the operator has no interaction with the animal, which has been the case with captive bolt stunning without head fixation of the animal, a process that is required from 2013 in EU. Shackling is one of the most dangerous processes with reflex kicks injuring operators occasionally when putting on the chain. MLA has initiated research to automate this process by developing a prototype shackling tool, which will put on the chain by a vision-controlled industrial robot.

Hock Cutting

The first standard robot to be introduced on the beef slaughter lines is used for cutting hocks of forelegs. This solution is available from Jarvis, USA, and also trialed in Australia by MLA and Machinery and Robotics (MAR) including clipping of horns.

Dehiding

The dehiding process is one of the most mechanically assisted steps with many different versions of mechanic hide pullers in place. Guidance from an operator is crucial to achieve high hygienic quality. In the US, where line speeds are high, the process is performed in three consecutive steps. The ideal fully automatic process for this has yet to be developed. Nearly all hide-pulling equipment requires a human operator to attach the equipment to the hide, and has minimal sensing and no automated feedback to modify its action.

Bunging and Sealing

During the 1990s, a semiautomated beef bung bagging machine was developed in Australia by Australian Meat Technology Pty Ltd. (AMT) and MLA. This machine is a mechanical aid that provides a high degree of reliability in carrying out the bunging operation and delivers a significant improvement in hygiene through the reduction in the risk of contamination, see Figure 6. This machine is commercially marketed by SFK Systems A/S.

Carcass Opening

In the 1990s, Industrial Research Limited (IRL), New Zealand, developed an automated beef belly rip robot. This used a proprietary robot to perform the opening cut on beef animals. This was evaluated in North American beef plants but was unable to deliver the required performance at the throughput required, or cater for the variability in stock and stock

Figure 6 The AMT beef bunging machine. Photo courtesy of Meat Processing Systems (http://www.mps.org.au).

presentation, largely due to the limitation of the technology available at the time. With technology advancements, there is renewed interest in revisiting this and other automation challenges along the slaughter board.

Evisceration

Taking out the organs is arduous work and critical for slaughter hygiene. So far no viable automation or aid for evisceration is available to assist the operator. Some relief for the operator is gained from still more adaptive moving lift platforms that allow better positioning of the operator both in vertical and horizontal direction. Modern platforms are also being equipped with automatic cleaning of areas that may touch the carcass.

Carcass Splitting

Band saws operated manually is the predominant tool for splitting beef carcasses even at the highest line speed but with duplication of operators and saws. Circular saws mounted in a dedicated machine were used for automatic splitting in Sweden for many years. Automatic circular splitting saws are, for example, provided by MPS Meat Processing Systems, The Netherlands (MPS). However, it has been reported that the saws that are mechanically controlled require monitoring and adjustment for delivering a sufficient precise result similar to what can be achieved be a skilled operator with the ability to correct for carcass differences. MLA and MAR in Australia have researched using band saws mounted on standard industrial robot controlled by different sensing principles, for example, ultrasound and X-ray. The current technical limitation of this technology is in the sensing, which is yet to reach the level of performance and robustness required to justify commercial implementation and industry uptake. Correct placement and positioning of the carcass properly at the start of the process also adds to total automation cost, placing the technology out of reach of lower throughput plants. DMRI proposed to combine splitting and spinal cord removal in one machine to make it more cost-effective. The feasibility of this combination remains to be shown.

Cleaning of the Carcass

Slaughter hygiene is essential and steam vacuuming of contaminations, bone dust, and fragments are processes tying up several operators. Likewise, SRM removal from the carcass requires operators and equipment. Presently these operations are manual but trials with standard robots operating the steam vacuuming tools have been carried out by MLA and MAR. In the USA, carcass decontamination also involves cabinets from companies such as Birko (USA) for hide washing after sticking and different cabinets for washing, steaming, or mild acid spraying during the slaughter process.

Classification and Grading

Traditionally carcass classification was an entirely manual process. Vision systems became commercially available in the mid-1990s but commercial uptake was slow, but with the advent of more robust technology and ongoing development to improve the performance, vision-based classification and grading systems are now a mature technology. Vision systems for classifying carcasses according to EUROP conformation and fat classes, as well as rib eye cameras for automatically predicting United States Department of Agriculture (USDA) quality grades, are now in common use. In the 2000s, uptake increased as EU regulations for approval of machine grading were enforced, and likewise USDA approved rib eye camera grading. There are several suppliers of technology, some supplying local markets only, whereas some are marketing globally, for example, Cedar Creek Company, Australia, Carometec, Denmark, e+V, Germany, NORMACLASS, France, and Research Management Systems (RMS), USA.

Ovine Slaughter Automation

New Zealand and Australia are the world's largest exporters of lamb and mutton, with more than 90% of all lamb and mutton slaughtered being available for export. Over the past few decades, the New Zealand meat industry has invested heavily in the development of mechanical and automated slaughter and dressing technology for sheep and lambs, resulting in the vast majority of the annual kill being slaughtered in modern, up-to-date processing facilities. Although the main driver for automation has been to reduce the cost of labor, there has been a strong focus on maintaining stringent hygiene (critical when the vast majority of product is exported chilled to distant markets by sea) and to improve the quality of hides and related coproducts so as to extract the maximum value from each and every carcass.

Inverted Dressing

Mechanization and automation on the slaughter board had its genesis in the development of inverted dressing in the 1970s. Inverted dressing enables the hygienic processing of lamb

carcasses where the depelting procedure starts from opening cuts in the (cleaner) forequarter region, and the pelt is removed downwards toward and off the (more contaminated) hind legs. Traditionally, this process involves both manual (e.g., tunnel punching) and mechanical (e.g., shoulder and hide puller) operations that are labor- and time-intensive and can result in downgrading of the fleece if not conducted consistently.

The inverted dressing system has many benefits, including a significant reduction in manpower. However, the most significant benefit is that, with the carcass suspended simultaneously by the fore- and hind legs (called the hammock position), it is now possible to introduce automation to key tasks.

The majority of mechanization and automation has been applied to the pelting and evisceration stages, justified by the combined benefits of increased hygiene, reduced contamination and labor costs, and increased worker safety. In countries where major export customers include Muslim markets, religious requirements have impacted somewhat on the degree to which the stunning and bleeding tasks can be automated.

Mechanization for Task Replacement

Initial developments were purely focussed on creating direct mechanical alternatives to specific tasks on the slaughter chain. Mechanization was seen as a logical replacement for manual workers where the task was considered highly repetitive and routine or required significant force. Mechanical equipment was developed to replicate the key action required but still required human interaction to grip or position part of each carcass appropriately, or to perform the correct prework, to ensure correct operation. Many of these used minimal or no sensing or measurement, and were programmed simply to perform the same task repeatedly with no modification. For example, the shoulder and final pelt puller machines, originally developed by the Meat Industry Research Institute of New Zealand (MIRINZ) and commercialized by Millers Mechanical Ltd. (now Milmeq Ltd, New Zealand), once synchronized with the chain, performed their tasks without any input or feedback on the variation in size, shape, or presentation of each carcass. Additionally, the shoulder puller required an operator to clamp the foreleg pelt regions before activating the machine's operational cycle. Although the final puller automatically gripped the pelt as it hung below the carcass, additional manual workup was sometimes required to ensure satisfactory pelt removal for all variations in carcass age, size, breed, and condition. The design of these machines was in part determined by the relative immaturity of commercially available sensing and automation systems available at the time.

Where full task replacement was not deemed cost-effective, semiautomated or task-assistance machines have been developed and are now effectively deployed on the chain. These machines require manual guidance and, while making a task easier, faster, and safer, often contribute to a reduction in labor units but do not eliminate labor from the chain. Examples of these include the brisket roller machine and flanking tool, which both require manual operation and hands-on guidance but significantly reduce the effort required to do their respective tasks and thus reduce both the effort required and overall manning levels required, particularly at higher chain speeds.

A further implication of this task-replacement approach to automation has been that consideration to subsequent tasks and in particular the controlled positioning of the carcass for subsequent tasks has not been incorporated in equipment design. For example, rear hock removal is often undertaken once the pelt has been fully pulled down over the rear legs as a sock. However, pelt removal often results in overall carcass length increasing by some 10% or more due to the downward forces imparted on the carcass, therefore potentially rendering any previous carcass measurement invalid as an input to subsequent automation tasks. Although it is technically possible from an automation perspective to cut the hocks as part of the pelt pulling operation, existing hock cutting equipment has been developed as a separate piece of equipment (mostly due to commercial drivers).

One of the enablers of subsequent developments in automation has been the technological advancement in sensing, automation systems, and industrial robots. Many of the mechanical open-loop machines developed initially have been updated with more advanced sensing technology and augmented by more modern robotics to enable them to accommodate carcass-to-carcass variation as appropriate.

Table 2 gives an overview of the key tasks for a typical ovine slaughter board, along with task-replacement automation currently available.

In addition to these commercially available systems, a number of developers are working on automated solutions on a number of other tasks, including but not limited to:

- Front and hind hock tipping (clean cut).
- Tail cutting.
- Neck sanitizing.
- Bung cutting.
- Fully automated sock ringing.
- Automated gas depleting.
- Bung sealing.
- Foreleg rolling and fully automated brisket rolling.
- Sock splitting.

Robotic Automation

More recently, developments in Australia and New Zealand have seen the next generation of automation that does incorporate sensing feedback to customize each robot's operation according to specific carcass measurements. These developments have combined robots with custom end effectors and sensing technology to automate key tasks on the slaughter chain that cannot be automated by simple open-loop mechanical systems due to the complexity and degree of variation that exists between carcasses.

One of the first developments of this kind is the Y-cut robot, which automatically makes the opening cut in the pelt down the inside of each foreleg and the neck, see Figure 7. This development was a collaborative initiative by IRL, Motion Design Ltd., New Zealand, and New Zealand Meat Research and Development Council (now Beef and Lamb New Zealand). The original prototype used a proprietary robot developed specifically for this task but current commercial

versions now use third-party commercial industrial robots, with custom sensing and end effectors to measure the carcass and make the opening cuts, respectively. Systems are currently in operation on both Australian and New Zealand meat processing plants at throughput rates of up to 8 carcasses per minute, and have demonstrated significant improvements in carcass hygiene compared to manual operation.

Another example where sensing has further enhanced automation is the variable independent path (VIP) Shoulder Puller, developed by Milmeq in conjunction with Alliance Group Limited, one of New Zealand's largest ovine processors and exporters. This machine, shown in Figure 8, based on the original MIRINZ shoulder puller, uses variable force feedback and enhanced grip design to autoload, eliminating the labor unit previously required to load the machine and delivering a more uniform pull, resulting in less pelt damage.

At present there are several autoloading pelt removal machines, including the Pelt-O-Matic, developed in Australia and now marketed by Food Equipment Australia as well as SFK Systems in Europe. The Pelt-O-Matic is based on the original four-pronged puller developed by MIRINZ in the 1990s. It is an automated rotary system for pelt removal that comes

Figure 7 IRL's Y-cut robot opens the pelt inside each leg. Photo courtesy of Callaghan Innovation, formerly IRL, and Ovine Automation Limited.

in a number of configurations covering 2–10 carcasses per minute.

The combination of custom-sensing technology and standard industrial robots has also been applied to individual human task replacement on the slaughter board. In conjunction with MLA, MAR has developed fully robotic machines that can directly replace manual operators for the following tasks:

- Kidney fat removal.
- Vacuum sanitization of the neck, forelegs, brisket, and hind legs.
- Brisket cutting using a Jarvis brisket cutter (carcass inverted).
- Neck and tail tipping cut.
- Hock tipping and cutting.

Because each of these machines is designed to operate autonomously and automates only a single task, each machine is fully self-contained and incorporates the necessary sensing equipment, robotic arm, and end effector. Further, each sensing system is proprietary and has been developed specifically for the specific task. This has resulted in quite extensive development costs which, when combined with the sensing and robotic hardware costs result in a significant capital cost for each system. With the ovine processing industry looking for a payback period normally lower than 24 months (two seasons), the cost–benefit of these systems will depend significantly on the number of carcasses processed each year, throughput (carcasses per hour), number of shifts per day, and slaughter board configuration (order of tasks). Often, in smaller plants, automation does not fully replace a complete person due to the fact that, as well as the task being automated, the person is also performing other related tasks due to the chain configuration and speed. This has limited the industry uptake of these developments to date.

This limitation of focussing on automation from a direct task-replacement perspective is currently being addressed through a more integrated approach to slaughter board automation. An example of the task-integration approach is the

Figure 8 Milmeq's VIP shoulder puller.

(a) (b)

recent development of robotic brisket cutting and evisceration equipment by Ovine Automation Limited (OAL). OAL is a consortium of nine major New Zealand ovine processing companies, with support from New Zealand Ministry for Science and Innovation and MIRINZ Inc. (OAL), see Figure 9. These two items of automation have their genesis in the mechanical brisket cutter and evisceration machines originally developed by MIRINZ in the 1990s and are currently in commercial operation in one New Zealand lamb processing plant. Although these two machines automate tasks previously undertaken manually as stand-alone machines, OAL has also undertaken further development that has extended the impact of these machines beyond simply direct labor replacement. The brisket cutter is designed to open the brisket in a manner that is directly compatible with the evisceration robot. Further, the evisceration robot directly places the gut set and viscera into the gut trays and has facilitated a new approach to viscera inspection and sorting. As a result, rather than just replacing between one and two labor units, a brisket cutter robot and evisceration robot have the potential to eliminate up to five labor units on a typical 8-min lamb chain per shift. OAL is also currently pursuing an integrated approach to automating

the opening up of the pelt down the forelegs and belly of the carcass.

The benefit of this approach is that automation is able to address a suite of operations systematically rather than in isolation, with consistency and integration of process control and operating components leading to cost and development savings. More importantly, this approach enables the overall process and order of tasks from a systems perspective, enabling compound rather than incremental improvements to be achieved for a wide range of throughput operations.

Classification and Grading

As with beef and pork, carcass classification was traditionally a manual process, based on hot carcass weight, fat depth at the GR site (fat depth at the 12th rib 11 cm from the vertebrae), and sometimes combined with a subjective conformation (carcass shape) assessment, with the majority of plants still using manual grading. Although fat depth probes are widely used in the pork industry (e.g., Hennesey GP-2, Hennesey Grading systems, New Zealand, and Ultra-FOM, Carometec, Denmark), they have not seen widespread uptake for sheep. Vision systems for grading (based on one or more 2-D color images of the carcass taken at the grading station) are supplied from several companies such as Cedar Creek Company, Australia; e+V, Germany; and RMS, USA, being the most common of automated vision systems in use for ovine.

This article is a revision of the previous edition article by HJ Andersen, volume 1, pp 56–59, © 2004, Elsevier Ltd.

Introduction

There are a variety of products that fit under the bacon name, including: belly or streaky bacon, pancetta (round bacon), Wiltshire bacon, Canadian-style bacon, jowl bacon, shoulder bacon, cottage bacon, beef bacon, etc. The article on Wiltshire bacon covers basic processing and this article will focus on the production of pork belly bacon that is popular in the United States.

Belly Bacon

Belly bacon has significantly increased in popularity over the past 20 years or so. As recently as 1978, an American Can Company survey of 2000 US female heads of households found that 38% of households were consuming less bacon than previously, primarily because people were either eating breakfast less frequently, found bacon to be too expensive, were eating fewer eggs, or were on diets that restricted their bacon consumption (1978). As late as 1989, it was stated that "bacon consumption is evidently in a long-term eroding trend…".

In the early to mid-1990s, bacon shifted from being primarily a breakfast item to being added as a condiment to many quick-serve hamburgers. By this time, McDonalds had started adding round bacon to their hamburgers. Also, as a result of many quick-serve restaurants increasing the doneness of hamburgers to 'well-done,' bacon was added to improve the palatability of these hamburgers. At about the same time, precooked bacon became available, which provided a less messy, more convenient bacon for both retail and food service customers. As a result of the increased convenience, consumers started using precooked bacon on 'bacon lettuce and tomato sandwiches' (BLT's) and other sandwiches at meals other than breakfast. Belly bacon consumption has increased around the world, partially due to the introduction of precooked bacon slices and use of bacon bits on salads and other entrees, bacon as a pizza topping, and due to the introduction of Western breakfasts in international hotels. The form that bacon is sold in has expanded, to include diced, strips, and ground, in addition to the more traditional shingled, layout, bits, and stack pack.

In recent years, bacon has had nearly a cult following, with new products containing bacon or bacon flavor, such as confectionary products (doughnuts, chocolate, etc.), alcoholic beverages, sausage products, ice cream, etc. The most recent addition to this list may be bacon jerky.

History of Bacon

It is generally believed that bacon originated in the British Isles, however, there are other claims that the first bacon was

made in China. The word bacon appears to have originated from the Germanic word bakkon, which meant the 'back of the animal.' It became 'bacon' in French, and the English started using the word in the twelfth century to mean cured back bacon. Bacon in the United States refers to belly bacon. It is not clear, but belly bacon may have originated in the United States.

Precooked bacon may also have been developed in the United States. It has become popular as it is convenient for the end user, and is shelf stable, not requiring refrigeration. Rendered bacon fat resulting from this process is considered of higher quality than traditional bacon grease, as it is generated at lower cooking temperatures. This rendered bacon fat is used in other food products as a flavoring ingredient. Disadvantages of precooked bacon are reduced aroma and flavor, and a chewier texture, compared to traditional pan-fried bacon. The flavor problem has been remedied by increasing concentrations of ingredients that contribute flavor, such as salt, sweeteners, liquid smoke, etc.

The pork belly, from which belly bacon is made, has the notoriety of being the only meat cut to be traded on the Chicago Mercantile Exchange. Beginning in 1961, pork bellies were traded for 50 years in the futures market as a hedge against fluctuating pork prices.

On the other hand, pork bellies have been largely ignored in swine genetics research, as traditionally hams and loins were more valuable to processors than the bellies. As hogs have been bred to produce leaner carcasses, bellies have become leaner which results in less desirable bacon. Because of their monogastric stomachs, the diets of pigs will be reflected in the quality of the fat. Current use of distillers grains, a by-product of the ethanol industry, as a feed source, results in softer bellies, which is also not good for producing high-quality bacon.

The Raw Material Used for Bacon Production

Belly bacon is produced from pork bellies. The bellies are skinned or derined and the ribs and sternum are cut off as a sheet (spare ribs). The flank muscle is typically removed from the belly (called facing or robbing the lean) to reduce the chances of developing pickle pockets. The teat line is removed from the ventral edge of the belly to eliminate the presence of mammary glands in the final product. The complete specification for trimming pork bellies in the United States, according to the National Association of Meat Processors (NAMP, 2010) is as follows:

> The belly is prepared from the side after removal of the leg, shoulder, loin, fat back and spareribs, bones and cartilages, and practically all leaf fat, shall be excluded. The fat back shall also be excluded by a straight cut not more than 1.5 in. (3.8 cm) from the outermost dorsal curvature of scribe line. The anterior (shoulder) and posterior (leg) ends of the belly shall be reasonably straight and parallel. No side of the belly shall be more than 2.0 in. (5.0 cm) longer than its opposing side. The width of the flank muscle (rectus abdominis) shall be at least 25 percent of the width of the belly on the leg (sirloin) end. The fat on the ventral side of the belly and adjacent to the flank shall be trimmed to within 0.75 in. (19 mm) from the lean. The area ventral to the scribe line shall be free of scores and "snowballs" (exposed areas of fat) that measure 3.0 square inches (19.4 sq. cm.) or more. The belly shall be free of enlarge, soft, porous, dark, or seedy mammary tissue. The scribe line is not considered a score but shall not be more than 0.25 in. (6 mm) in depth at any point.

The weight of pork bellies after skinning and trimming is 65–85% of the skin-on weight, depending on how closely the bellies are trimmed. The amount of lean or fat that is removed during squaring up the ham end, or how far the back fat edge is trimmed from the scribe line, will determine the trimming yield (Figures 1 and 2). The amount of trimming that is done to bellies will determine the quality and cost of the final bacon.

Lighter-weight bellies are more commonly used for precooked bacon, which is sold by the slice. However, heavier bellies are more commonly used for making retail bacon, which is sold by the pound. Bellies are sorted or graded by weight, in 2 lb increments. Within weight ranges, bellies may also be sorted by thickness (Figure 3).

Belly bacon is primarily made in the United States from fresh (never frozen) bellies, however, using frozen bellies may be necessary to survive seasonal fluctuations in belly prices and availability. Obviously, frozen bellies present additional problems to processors, particularly the need to defrost the

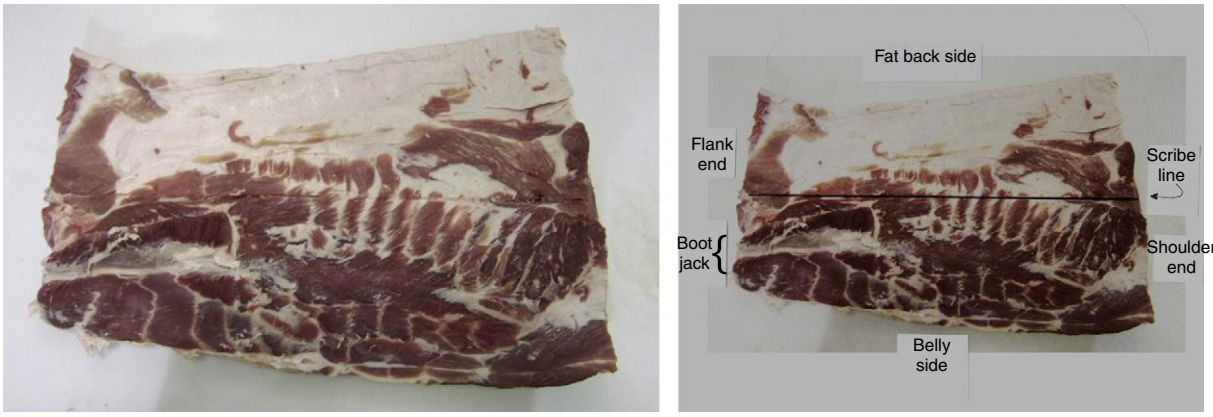

Figure 1

frozen bellies before curing. However, if done properly, using frozen bellies can be profitable for a processor. Defrosting was traditionally done by submerging the frozen bellies in water, but is currently done primarily by air tempering.

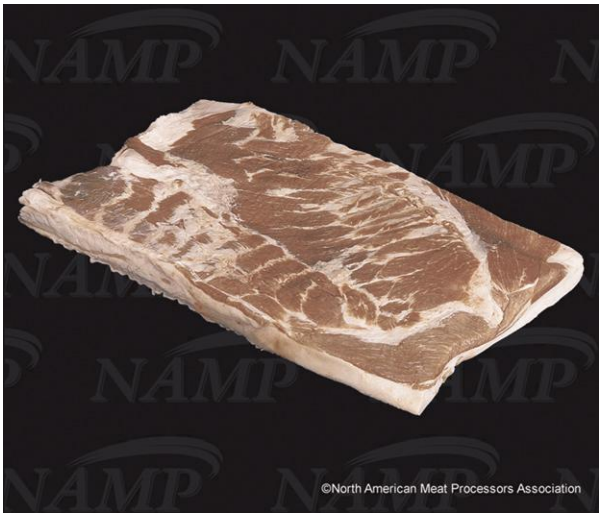

Figure 2

Fat is the most variable component of meat, and likewise, pork bellies are the most variable cut made from a pork carcass in terms of composition. Sorting bellies by thickness results in more uniform bacon, than sorting by weight.

The increase in leanness of pigs, as well as some of the ingredients that some pigs are currently fed, has resulted in a relatively higher content of unsaturated fat in the pork. Higher percentages of unsaturated fatty acids results in softer belly fat, which makes high-speed slicing difficult. Also, since fat is a major contributor to the flavor of bacon, leaner bellies may not be as desirable for making bacon as fatter bellies.

Curing Methods

Curing is the process of adding nitrite, as well as salt or sugar to meat to preserve, and enhance the color and flavor of the meat. To make bacon, pork bellies are cured with one or a combination of the following methods.

Injection

Currently, the most common method of curing is done by injecting a curing solution into the bellies, which is referred to

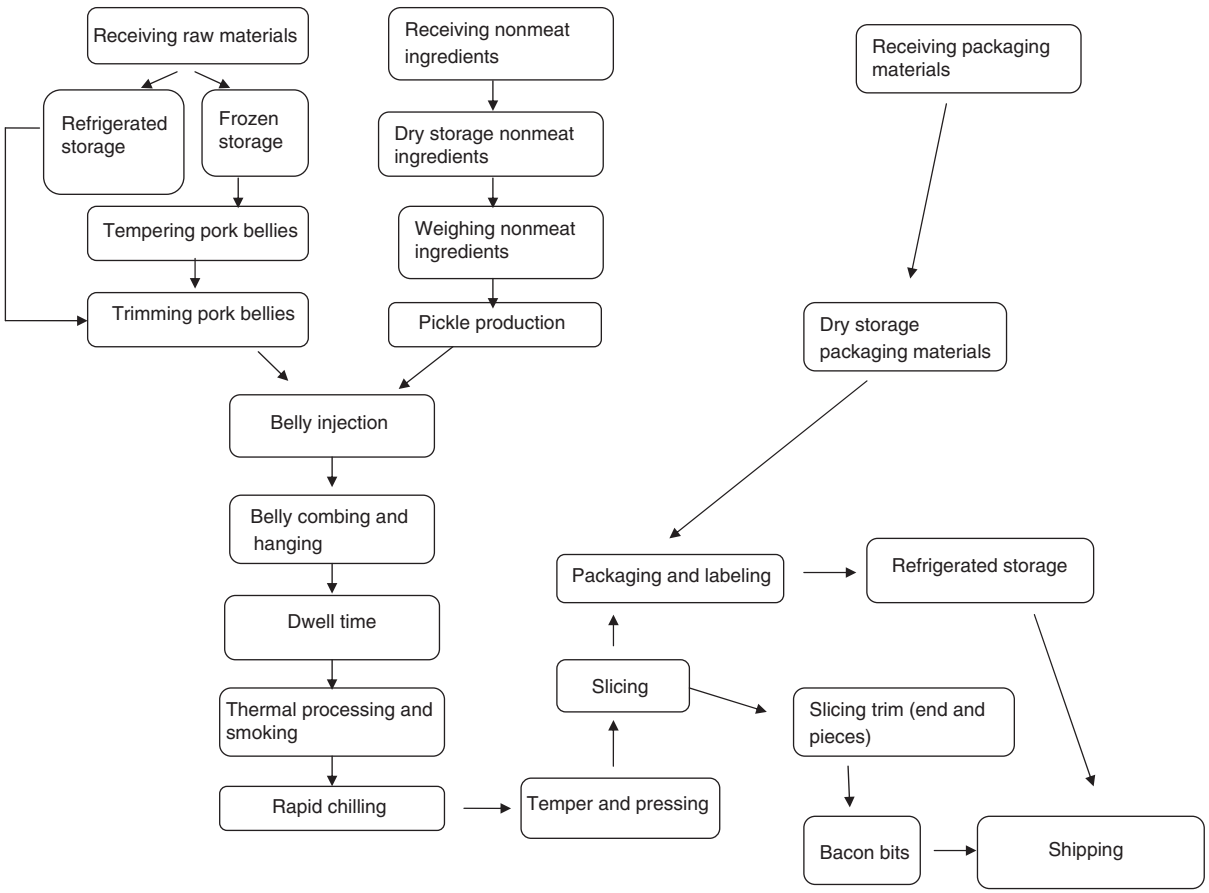

Figure 3

as stitch pumping or pickle curing. Initially, this process involved the use of a hand pump, but after World War II, more automated injectors became available.

The basic ingredients used in bacon curing solutions and their functions, include:

- Sodium chloride – flavor and preservation
- Sodium nitrite – cured color development and stability, contributes to cured meat flavor, and reduces oxidation (development of rancidity) of fat
- Ascorbate or erythorbate – curing aids that accelerate color formation and stabilize the color
- Phosphates – added to improve water-holding capacity and to reduce oxidation (development of rancidity) of fat and lean
- Sugars – for example, dextrose and glucose, counteracts salt flavor
- Spices – flavor contributors.

The order of addition of the above ingredients to water is very important. If phosphates are to be added, they need to be added to the water as the first ingredient. It is important that the phosphates are well dissolved before adding additional ingredients, particularly salt, otherwise ingredients added subsequently will precipitate out and accumulate as a white sludge on the bottom of the mixing tank.

Mixing or agitation of the curing solution is helpful in getting phosphates and other ingredients dissolved in water, however, caution should be taken to avoid over-mixing, which could whip air into the solution. Injecting foamy brine into bellies should be avoided.

In the United States, regulations require that bellies shrink back to their green (or preinjected) weight, during the smoking process, so typically bellies would be injected at an uptake level of 11–12% of the green belly weight. To calculate this level of solution uptake, a 'drip time' is typically assigned between the injection process and the final weighing process. This drip time should be kept consistent to make comparisons between batches of product. Other countries may not have the weight gain restriction, so bellies might be injected to higher percentages in those countries.

Even and consistent distribution of the curing solution is important in making bacon, and meeting injection targets for solution uptake is important to producing a consistent product. Whereas pump pressure, conveyor speed, and needle design are important in consistently meeting injection targets, consistency of belly temperatures during the injection process may influence solution uptake more than any other factor. A larger number of needles combined with warmer belly temperature will result in being able to reduce injection pressure, which will ultimately reduce incidence of pickle pockets.

After the curing process, comb hooks are placed in the flank end of the bellies, entering from the lean side, and the bellies are hung on smoke racks. It is important to catch the cutaneous trunci muscle, with the comb, to hold it in place during the smoking process. Improper combing can reduce the yield of good bacon slices by more than 8%. A drip period before smoking helps to prevent streak marks from the smoke on the smoked slabs. Some recommend a holding time of up to an hour after the last bellies are injected before the smoking process begins for improved uniformity in cured color across an entire batch of product.

Dry-Curing

Before the availability of injection systems, bellies could have been cured by either a dry-cured process, an immersion process, or a combination of the two. Dry-curing involves surface rubbing of bellies with the curing ingredients and holding the rubbed bellies for 7 days per inch of belly thickness before smoking to obtain even cure distribution. With dry-curing, sodium nitrate was used in addition to nitrite because of the additional curing time. Dry-curing is sometimes used in modern processing operations to make food service bacon, as this bacon shrinks and curls less than injected bacon during the final cooking process.

Immersion Curing

Immersion curing involved submerging the meat into a curing solution, which resulted in uniform distribution of curing ingredients throughout the meat more quickly than the dry-curing method.

Either the injected or dry-rubbed bellies may be immersed in a solution, or cover pickle, until they are smoked. Injected bellies are typically held for only 2 or 3 days in the cover pickle.

Cooking and Smoking

Traditionally, belly bacon was not fully cooked, but is only cooked sufficiently to apply a good surface smoke color and to firm up the slab to allow for efficient slicing. Typically, the endpoint temperature for bellies during smoking ranges between 52 and 53 °C (126 and 128 °F). Therefore, in the industry this process is often called smoking, rather than cooking.

Fully cooked bacon strips are cooked using conveyorized, microwave ovens, using a conveyor belt system that holds slices flat to minimize curling during the cooking process. This product is considered shelf stable, not requiring refrigeration after packaging.

Bacon bits are typically deep fried.

Post-Cook Chilling

After cooking, bellies should be rapidly chilled to 5 °C (44.6 °F), then more slowly chilled from 5 to −6.5 °C (20.3 °F) to allow the fat to set up properly. Chilling too rapidly can result in the formation of ice crystals in the cooked bacon.

Tempering

Before pressing, bellies are tempered to temperatures of −5.5 to −3.3 °C (22–26 °F) for best results. As salt content is reduced in bacon, forming temperatures can be increased to get the same sliceability. The ideal slab temperature for slicing will

vary, depending on the percent salt and injection levels of the bacon and the type of slicing equipment used. Lower salt bacon would require lower temperatures for good sliceability.

Pressing/Forming

Cooked and chilled bellies are pressed hydraulically into a rectangular shape that will result in more uniformly shaped bacon slices. Slab widths typically vary from 9.5 to 11 in., but the slab lengths may vary depending on the level of trimming done to the belly.

Slicing and Packaging of Bacon

The majority of bacon is still retailed as sliced bacon, and slicing is, therefore, a central operation in the production of many bacon products. This is the step in the process in which a processor determines how much number one product they have to sell to their customers.

Bacon slice thickness is referenced in the meat industry by the slices per pound or per kilogram. These designations include:

Thick sliced bacon	11–16 slices per pound (7–8 per kg)
Regular sliced bacon	16–22 slices per pound (8–10 per kg)
Thin sliced bacon	22 and up slices per pound (>10 per kg)

Shingle-sliced bacon is typically vacuum-packaged in 1 lb or part kilogram quantities for retail sales, using a paper L-board for the label and to support the product.

Layout bacon involves slices being placed edge-to-edge on paper for convenient loading of bacon onto oven sheets or griddles for quantity preparation of bacon. Since this product is intended for food service, it is sold by slice numbers and is packaged in a modified atmosphere to reduce the incidence of slices sticking to the paper.

Precooked, or fully cooked, bacon is typically sliced at 22–24 slices per pound (10–11 per kg), although it is sold in food service on a per slice count, rather than by weight. Precooked bacon thickness is more commonly described as slices per inch, and the most common count is 13–15 slices per inch (range: 8–16 slices per inch or 3–5 slices per kilogram).

Precooked bacon is packaged in a modified atmosphere package. Bacon jerky is an adaptation of precooked bacon made by fully cooking thick slices of bacon using the microwave process.

Canned bacon was more common in the past, and was used for US military rations, but can once again be found, particularly in camping supply stores.

Microbiology, Color, and Flavor Development

The initial microflora on bacon is that originating from the carcass, but the bacon can be contaminated via brine, especially when recirculated. Vacuum packaging results in a succession of microflora changes. While micrococci initially dominate, lactobacilli will eventually dominate. The salt content prevents putrification, but salt-tolerant bacteria (e.g., lactobacilli) will grow and result in a souring and reduction of shelf life.

The characteristic red color of bacon is formed during the curing process when the muscle pigment myoglobin forms nitrosylmyoglobin, involving reduction of nitrite. The cured flavor is a characteristic of nitrite-cured meat products and is found to be one of the most important quality attributes.

Glossary

'Live' brine An immersion brine used in the production of Wiltshire cured bacon that was continually replenished with curing salts and reused, having a characteristic salt-tolerant microflora.

Wiltshire curing A traditional method of producing bacon that originally involved the curing of whole sides of pork and included an extended period of maturation after several days of immersion in a 'live' brine.

Introduction

According to The Columbia Encyclopedia, bacon is "flesh of hogs – especially from the sides, belly or back – that has been preserved by being salted or pickled and then dried with or without wood smoke." Curing of meat is one of the most common preservation techniques that can be traced back to the ancient Greeks. Records show that Great Britain's traditional breakfast of bacon and eggs was sold as far back as 1560 by a London cheese monger. Local farmers processed bacon by rubbing the sides in salt, and the contamination of the salt with saltpeter plus bacterial action resulted in the typical red color of nitrite-cured meat.

In the middle of the eighteenth century, bacon production was simultaneously organized in the southern part of Great Britain and in Ireland. In England, pigs were transported from counties in the South West of the country to be marketed in London. On route they were rested in a town called Calne in the county of Wiltshire. Any pigs that were not fit enough to travel onwards were purchased by the Harris family for slaughter and processing into Wiltshire cured bacon. A royal warrant to supply Wiltshire cured bacon to the royal household was awarded to Thomas Harris in 1864. During the nineteenth century, bacon production went through technological developments and in 1847 the successful importation of bacon to Great Britain from Denmark was begun.

In several countries, codes of practice were established for the production of Wiltshire-type bacon to ensure the required high standards of skill and quality control in its production. Thus, from 1906 to 1989, Danish bacon was produced according to the rules given in The Danish Regulation for Bacon Production, which was administered by the Danish Ministry of Agriculture. A code of practice for the production of tank-cured Wiltshire bacon was produced in 1958 by the British Bacon Curer's Federation (which later became the British Meat Manufacturers Association and then the British Meat Processors Association). Despite the introduction of such quality schemes, bacon in most of the bacon-producing countries is now produced according to specific customer requirements.

Bacon Pigs

Bacon is one of the few processed pork products that has had a direct influence on the anatomy of modern pigs. These are referred to as 'baconers.' Particularly in Denmark, the breeding of pigs for bacon to fulfill the requirements of the British market changed the anatomy of Danish Landrace pigs from 1920 to 1970. The selection of the longest pigs for breeding resulted in an increase in length of approximately 8 cm and the introduction of two extra pairs of ribs (from 13 to 15 pairs). Simultaneously, the fore-ends of the pigs were reduced. The average thickness of backfat in Danish pigs has also reduced drastically (by more than 50%) during the past 70 years.

Feeding is known to be a critical factor for the quality of bacon. Feed with a high content of polyunsaturated fatty acids (e.g., from fish meal) is known to result in problems during processing (soft fat and off-flavor) and storage (development of rancidity). Consequently, feeding programs and optimum slaughter weight are the vital parameters for obtaining optimum bacon quality. The increase in lean meat content during the recent decades has automatically increased the ratio between polyunsaturated, monounsaturated, and saturated fats, and this has to be considered in the processing of bacon.

Wiltshire Bacon Processing

After chilling and splitting of the carcass into sides, the hind feet are sawn off (the length of the leg varies between nationalities), the tenderloin, aitch bone, cervical vertebrae, part of the sternum, and the front feet are removed; the belly is trimmed; the blade bone is removed; and the chine bones are trimmed, ending up with a traditional side as illustrated in Figure 1.

In the early days of bacon production, dry curing was the normal process. This was a slow process taking 6–8 weeks. This method has been completely replaced by systems using tank curing. The flowsheet in Figure 2 gives a schematic representation of the unit operations in the production of Wiltshire bacon.

Initially, the sides are injected with brine, often corresponding to 8–10% of the weight of the side; however, only 6–8% will be retained. In the past, this injection was done manually into the large muscles, but later multineedle injections became the normal practice, first in manually loaded machines (Figure 3) and later in continuous machines. The curing brine is typically 17°Be, which is equivalent to a sodium chloride content of 17.2% (w/v), 0.15% (w/v) potassium nitrate, and 0.08% (w/v) sodium nitrite. Subsequently, the sides are stacked in brine tanks (traditionally in large, white-tiled

 doi:10.1016/B978-0-12-384731-7.00109-4

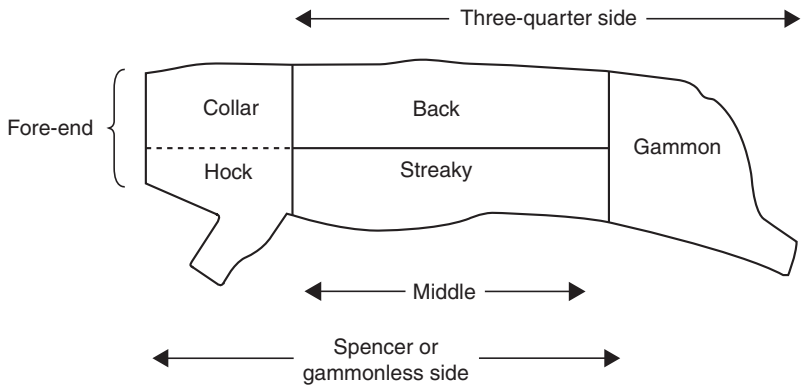

Figure 1 Bacon side with names of the typical cuts.

brick tanks; more recently in stainless-steel tanks), up to 10 sides high and with the lean face upwards and sprinkled with 300 g of salt per side to ensure curing of the areas that touch the side above or below. The cover brine is then added. The sides are kept below the surface with battens (these were originally made of timber, but have been replaced with plastic or stainless-steel battens). The cover brine is unique in traditional tank curing production, as it is based on reuse of brine from the preceding bacon production batches (some tank brines have been known to reach an age of more than 30 years), which results in the development of a specific microflora in the brine – the procedure was called 'blackslopping.' The brine itself was known as 'live brine' due to its characteristic microflora. The tank brine is typically made up to 23°Be by adding a dry salt mixture after each use. This is equivalent to a sodium chloride content of 24% (w/v), 0.20% (w/v) potassium nitrate, and 0.10% (w/v) sodium nitrite. The sides remain in the tanks for not less than 96 h and up to 120 h at a brine temperature of 5 °C. During the curing process, the sides lose weight ($\sim$2.7% of the weight before curing) and the final salt content in the meat depends on the fat content, the time in the tank, and the part of the side.

After curing, the sides are taken out of the tanks and placed in maturation rooms, where the sides are stacked on the floor or on pallets stacked up to eight high, with the rind upward at a temperature of 3–4 °C. During the drainage period and a maturation period of at least 5 days, the salt distribution equalizes in the meat. The maturation period is claimed to be essential for the production of high-quality bacon. The product is known as green sides or green bacon.

Care of the Immersion Brine

The continual reuse of the same immersion brine is a major characteristic of Wiltshire curing. Maintaining a stable brine is crucial and requires the following steps:

- Immersion brine temperature must not exceed 5 °C,
- salt, nitrate, nitrite, and pH must be measured after each use and the brine restrengthened accordingly,
- insoluble solid debris must be removed from the brine by filtration after each curing cycle,
- the pH should be between 6.3 and 6.5 and stable,
- if the brine pH is $>$6.8 it must be discarded and replaced with fresh brine,
- the total viable microbial count (on 4% salt agar at 22 °C for 5 days) should not exceed 500 000 cfu ml^{-1},
- brine should not remain unused for a lengthy period and must be aerated frequently if not in regular use, and
- a salt-tolerant microflora should prevail, which results in a predictable and controlled conversion of nitrate to nitrite.

Processing of Other Traditional Bacon Sides

In addition to the most common 'Wiltshire sides,' alternative processing methods for bacon sides also exist. Of these, Ayrshire cure is the most noteworthy. The sides have the rind removed and bones taken out before they are injected with pickle and placed in brine tanks. In the production of traditional products, such as Scottish Ayrshire rolls and Ulster rolls from Ayrshire-cured sides, the middles are defatted and tightly rolled and tied.

Brine Ingredients and Their Function in the Manufacture of Bacon Sides

The basis for curing is the brine (pickle) ingredients:

- Common salt (sodium chloride)
- Saltpeter (sodium nitrate or potassium nitrate)
- Sodium nitrite.

Common Salt

Sodium chloride is used because of its preservative quality, its physical (structural changes) and chemical interactions, and its organoleptic characteristics.

Saltpeter

Nitrate is a nitrite reservoir, as it is reduced to nitrite in the presence of nitrate-reducing bacteria. Moreover, nitrate stimulates the activity of nitrate-reducing bacteria, which can contribute to flavor development in meat.

Sodium Nitrite

Nitrite has many functions; it contributes to color development and color stability, influences the cured meat flavor

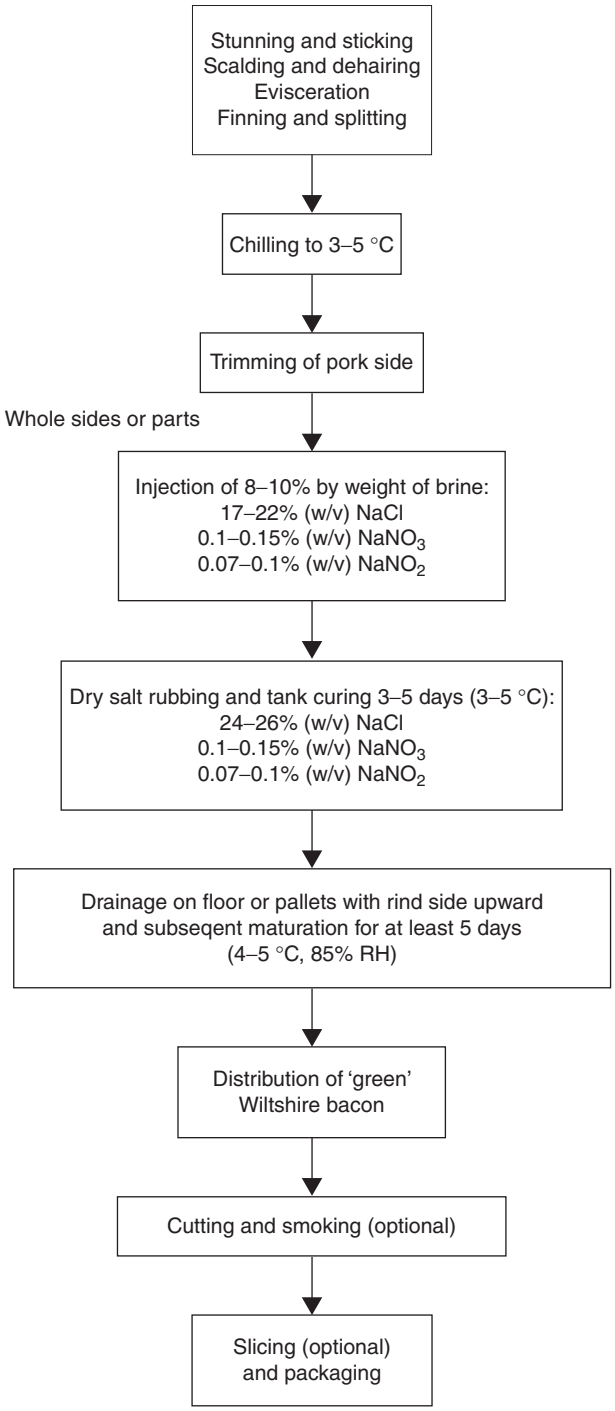

Figure 2 Flowsheet representing the general unit operations during the production of Wiltshire bacon.

(possibly owing to its antioxidant properties), and is a preservative.

Microbiology of Wiltshire Bacon

The initial microflora is that of the carcass. Salt (curing salt) used in the processing might contain spore-forming bacteria. The curing brines also contribute considerably to the microflora of bacon sides.

- Injection brines: The total colony count (in colony-forming units, CFU) of freshly prepared injection brine is normally $<10^3$ CFU ml^{-1}, but might vary considerably. Brines used in multineedle injection machines often contain a higher total colony count than registered in hand-injection brines.

This is due to the common use of recirculated surplus brine, which unavoidably transfers microorganisms to the fresh brine despite filtration. Injection brines have shown a predominance of *Micrococcus, Acinetobacter, Flavobacterium*, and coryneform bacteria, all of which are common contaminants of pork carcasses. Moreover, lactic acid bacteria, enterococci, and *Vibrio* spp. are found in recirculated brines. *Vibrio* spp. are known to cause spoilage of bacon (see below), and their presence in multineedle injection brine is due either to inadequate cleaning of the machine or to contamination with cover brine. See Table 1 for established advisory hygienic standards of injection brine.

- Cover (tank) brine: Immediately after preparation, these brines contain the same flora as injection brines. However, conventional cover brines were most often based on the 'backslopping' technique and were used repeatedly (brines could be 5–10 years old, some have even been reported to be up to 30 years old) and they, therefore, contain both microorganisms originating from the meat and some surviving in the tank brines. This results in a heterogeneous flora and a high number of bacteria (10^6–10^7 CFU ml^{-1}). In general, most saprophytic bacteria are able to survive in curing brines for varying lengths of time, and it might thus be concluded that any species found on pork to be cured can be found in brine. However, none of them can grow in brine. Organisms belonging to the genus *Vibrio* are a natural part of the flora in cover brines. The total count and the composition of the bacterial flora of cover brine is decisive for the quality of the brine, and an unfavorable count and composition gives rise to an 'unstable' cover brine resulting in unacceptable shelf life of the final product (Table 2). In contrast, cover brines with a moderate presence of *Vibrio* spp. are reported to enhance the flavor characteristics of the final product (see below).

Drainage and maturation of tank-cured bacon changes the microbial environment on the surface of the product, making growth of salt-tolerant microorganisms possible, especially if the curing brine has been unstable (Table 2). Drying of the product surface during maturation can give rise to unwanted growth of molds. Moreover, high room humidity dilutes the salt content on the surface of the product, enhancing growth conditions for salt-tolerant spoilers. Consequently, a controlled relative humidity (~85%) is most often used in the maturation/storage rooms.

When cuts or slices of Wiltshire-type bacon are placed in impermeable packages (vacuum/modified atmosphere packaging), a succession of changes in the microflora follows. Micrococci continue to dominate among the rising bacterial population, especially in the presence of nitrate. However, ultimately lactobacilli will dominate, possibly via a transitional phase in which enterococci dominate.

Figure 3 From 1970 to 1986 Danish bacon sides for Britain were injected using a special machine in which 109 needles injected the brine evenly from both the meat and rind sides into the muscles. Nowadays, it is common practice to use continuous multineedle injectors for the production of bacon cuts.

Microbial Spoilage of Wiltshire Bacon

The salt content in bacon prevents putrefactive microorganisms (e.g., pseudomonads) from multiplying. However, other salt-tolerant bacteria, such as lactobacilli, continue to grow (especially when the products are vacuum packed or packaged in a modified atmosphere), even under refrigeration, and may reach millions per gram, which results in souring and thus a reduction in the shelf life of the product. Moreover, heavy contamination with proteolytic *Vibrio* spp. may further reduce the shelf life of the product.

During processing of Wiltshire bacon products, changes in the natural meat microflora proceed toward a salt-tolerant flora. In general, a higher total colony count appears on the rind compared with the meat surface. Consequently, the microflora on sides of Wiltshire bacon varies in both number and species as a result of the heterogeneous nature of the bacon side. Surface spoilage (e.g., slime formation or discoloration) of refrigerated

bacon has been associated with growth of several species, but *Micrococcus, Vibrio, Acinetobacter,* and yeasts are the most common spoilers. Molds (e.g., *Aspergillus, Alternaria, Fusarium, Mucor, Rhizopus, Botrytis,* and *Penicillium*) can also be common in Wiltshire-type bacon spoilage if the humidity during maturation and storage is not properly controlled.

Color and Color Problems in Bacon

The characteristic red color of 'green bacon' is formed during the curing process, when the muscle pigment myoglobin binds nitric oxide and forms the bright red heme pigment nitrosylmyoglobin. Nitric oxide is formed in a series of complex reactions involving reduction of nitrite added directly or produced during bacterial breakdown of added nitrate.

Raw bacon color is quite stable if not exposed to light and oxygen simultaneously. If bacon is exposed to oxygen and light, the cured meat pigment, nitrosylmyoglobin, oxidizes rapidly to the brown metmyoglobin, giving the bacon a brown-grayish appearance. This process is accelerated if the meat surface is drying out, as seen under certain retail conditions. Oxidation of the cured meat pigment is a reversible reaction, and bacon color can, therefore, be regained if exposure of fresh discolored bacon to oxygen is prevented, for example, through vacuum or modified atmosphere packaging.

Flavor Development in Wiltshire Bacon

'Cured flavor' is a characteristic of nitrite-cured meat products and is found to be one of the most important quality parameters of these products. The nature of the 'cured flavor' is not fully understood. The high number of unit operations in the production of Wiltshire bacon causes multiple reactions that might contribute to the final flavor development. Salt in itself contributes a salty flavor of cured products. Moreover, salt is known to accelerate lipid oxidation in meat products, resulting in the formation of rancid off-flavors. Consequently, one of the most important factors in the formation of cured meat flavor is the addition of nitrite. At the levels added for curing, nitrite itself does not contribute any flavor. However, owing to its antioxidant activity it hinders the formation of rancid off-flavor. Consequently, the characteristic 'cured flavor' is probably merely the result of limitation of the formation of compounds known to give rise to rancid off-flavor and is thus due to improved human perception of the flavor characteristics of the salted meat, which would otherwise be drowned by a rancid off-flavor had the addition of nitrite not limited its formation.

Wiltshire bacon is found to have specific flavor characteristics not found in other bacon types. These flavor characteristics have been attributed to the use of the 'backslopping' technique of immersion brines, which gives rise to a characteristic microflora. This microflora has a proteolytic activity, leading to the formation of peptides and amino acids that are subsequently catabolized by the microorganisms, resulting in flavor-active compounds characteristic of Wiltshire bacon.

Packaging and Transport of Bacon Sides

In the original trade practice, bacon sides were placed in bales and wrapped for transport after drainage and maturation. At first, bales of bacon contained four green sides, with each pair of sides placed together, meat to meat, to preserve color and minimize contamination. However, trading practice has moved completely to containerization after the disappearance of small exporting factories. The introduction of refrigerated containers revolutionized bacon export because it extended the shelf life of the bacon.

Cutting of Sides and Smoking

In the early days of the bacon trade, sides were exported and further cutting and processing (boning, smoking, slicing, cooking, etc.) took place at the wholesaler's cutting plant. Subsequently, prepackaging became popular, and most bacon sides are now cut into the three traditional cuts (middle, forend, and hind leg) for easier handling. The complete side is often cut into the five cuts shown in Figure 1 and vacuum packed before retail distribution.

Smoking is a process that has always been closely associated with bacon, particularly in Scotland and Southern England. The use of smoking improves the shelf life of the bacon (it reduces both the microbial spoilage and the development of rancidity). Traditional smoking of bacon resulted in a weight loss of approximately 5%, but the introduction of alternative smoking methods (e.g., the use of liquid smoke) has minimized such losses. In addition to the preserving effect,

smoking also contributes significantly to the flavor of the bacon.

Conclusion

Curing of whole sides – traditional Wiltshire bacon – is a disappearing method of production as the costs are too high in relation to the price of bacon. The designations Wiltshire and Ayrshire bacon are still used in the branding of high-quality bacon, but these products are now made directly from cuts, as is the normal procedure in modern bacon production, and the time in immersion brine and the subsequent maturation period are drastically reduced to make the production more economical. Nowadays, immersion brines are fresh brines, and 'live' brines are limited to a few specialist producers of Wiltshire cured bacon.

Glossary

Brownian movement of bacteria A random movement of cells suspended in a fluid resulting from their collision as opposed to motility mediated by cellular appendages.

Hydrophobic Lacking an affinity for water; insoluble in water; or repelling water.

Planktonic cells Individual free-floating cells.

Quorum sensing A method of communication among bacterial cells by the release and sensing of small diffusible signal molecules.

Spore-forming bacteria Bacteria that have the ability to develop spores, a resting stage of live bacteria encased in a 'shell' that is capable of protecting the cell under adverse conditions. Under appropriate growth conditions, the spores will germinate and cells will become active.

Introduction

The concept of microorganisms attaching to surfaces to form biofilms is not new. There are several different definitions of biofilms, but common to all is that bacteria form communities that are attached to solid surfaces. There is a general tendency for microorganisms to attach to wet surfaces upon which they multiply. They produce exopolymeric substances (EPS) in which they become embedded. EPS assist bacteria to adhere to surfaces and to each other, and protect the bacteria from adverse conditions. When these processes proceed without interruption, a biofilm is formed. A biofilm consists of a biologically active matrix of cells that is embedded in EPS produced by the cells and associated with or attached to a solid surface. The formation of biofilms by prokaryotic cells is a biologically unique developmental process in which the activities of the cells are coordinated to obtain effects of mutual benefit, such as the maintenance of open water channels. Such coordination of cellular activities requires there to be inter- and intraspecies communication. Various systems of cell-to-cell signaling have been identified and are currently being investigated.

Many *in vitro* studies of biofilms have been undertaken using one or more bacterial species; however, the study of biofilms *in situ* remains challenging despite the availability of sophisticated molecular, electronic, and microscopic techniques. The application of *in vitro* findings for understanding of bacterial behavior in food processing environments is often not valid, so more study of natural biofilms is needed. Since bacteria living within biofilms can be very resistant to environmental stresses, such as drying and industrial sanitation processes, prevention of their development is an ongoing challenge for the meat industry. Of particular concern are nooks and crannies in commercial meat processing equipment that are hard to access and difficult to clean.

Formation of Biofilms

Stages of the Process

The formation and development of biofilms involves several stages. In the literature, there are different approaches to how these stages are defined and described (Table 1). Essentially, cells of microorganisms attach, first reversibly and then irreversibly, to a substratum that has been preconditioned with molecules in the environment around them. Once attached, and very early in biofilm development, the bacteria, and the microenvironment they create, become resistant to adverse or disruptive environmental conditions. If not disturbed, a mature biofilm will be formed. The formation of a mature biofilm can be achieved within a few hours but might instead take several weeks. Figures 1 and 2 are diagrammatic representations of the processes governing biofilm formation.

Surface Conditioning

When a solid material is placed in a liquid, solutes from the liquid will concentrate on the surface of the solid material and form a conditioning film. The physicochemical properties of the surface, such as surface free energy, hydrophobicity, and electrostatic charges can change. In a food processing environment, the properties of the work surfaces might change depending on the type of conditioning film. For example, if surfaces in the facility are hydrophobic, they could show a high affinity for fat and the conditioning film on all surfaces could be high in fat content. Meat juice has been shown to reduce the negative charge on stainless steel, which would be expected to change the overall properties of the stainless steel.

Transport of Planktonic Cells to Surfaces and Adhesion

Factors that cause cells to undergo the transition from planktonic mode to biofilm mode or to become attached to or detached from surfaces are associated with a variety of environmental and physiological triggers that include quorum sensing, nutrient and oxygen availability, shear stress, microbial metabolic activity, microbial gene expression, and cellular stress. Planktonic cells can move toward a conditioned surface actively, by means of flagella, or passively in response to forces such as gravity, diffusion, or fluid dynamics. Once cells are close to the surface, adhesion will be affected by factors like nutrient availability in the fluid, growth stage of the cells, and the microtopography of the contact surface. The first stage of adhesion is reversible and is the result of long-range interaction forces: electron acceptor–electron donor

interactions and hydrophobic interactions that keep cells close to the conditioned surface. At this stage, the bacteria are not firmly attached and will continue to show Brownian movement. They can still be easily removed, if the microtopography of the surface does not keep cells trapped, by processes that produce shear forces, such as rinsing, or changes in charge and hydrophobicity. Until the bacterial surface appendages become involved, the bacteria usually cannot make direct contact with the surface due to repulsive forces between the bacterial cells and the surface. Bacterial cells produce surface appendages, including flagella, fimbriae, pili, and EPS fibrils that reduce the surface area that contacts the inert surface and by which they can overcome repulsive forces such as negative charges on both cell and surface to become attached.

Flagella, composed of fine threads of flagellin protein, permit motility, which is hypothesized to overcome repulsive forces between cells and the surface so that a monolayer of cells can form on the surface. Flagella can also enable bacteria to move along the surface and allow growth and spread of the developing biofilm or form adhesive bonds between bacterial cells and surfaces.

Fine, filamentous, hair-like proteinaceous appendages, including pili, and fimbriae present in both Gram-negative and Gram-positive bacteria are involved in various processes including conjugation, adherence, and twitching motility. All of these can affect biofilm formation and the characteristics of the bacteria in the biofilm. Although bacteria with fimbriae can adhere strongly to other bacterial cells and inorganic particles, and can probably overcome the initial electrostatic repulsion barrier between the cells and the surface, fimbriae are not always involved in the biofilm attachment process. They have, however, been shown to have a critical role in the initial stable cell-to-surface attachment for *Salmonella* spp. and numerous pathogenic and nonpathogenic *Escherichia coli*. A bacterial cell might be covered in fimbriae, giving the cell a hairy appearance.

There are different types of pili, and cells can change the characteristics of the pili they produce to correspond to their environment. Cells may have one or several pili. The ends of pili are sticky and make cells adhesive so that bacteria with pili adhere strongly to other bacterial cells and inorganic particles. Pili are able to retract to bring the bacterial cell closer to the surface and Type IV pili enable cellular locomotion.

Enterobacteriaceae produce proteinaceous fibers termed curli that are implicated in cell adhesion, cell aggregation, biofilm formation, and pathogenesis. Research into these fibers is relatively limited, but there is evidence that co-expression of curli and cellulose leads to the formation of networks of tightly packed cells that are aligned in parallel and that are highly hydrophobic. EPS also has a role in stabilizing the attachment of bacteria to surfaces.

Production of Exopolymeric Substances, Irreversible Attachment, and Development of Biofilm Architecture

The production of EPS, irreversible attachment, and development of biofilm architecture are linked. An important characteristic of biofilms is that the cells are embedded in an EPS matrix. This matrix has a variety of functions, including cohesion and adhesion of cells and particulate matter; protection from biocides and other chemicals; entrapment of molecules and nutrients; binding of cations, toxic metallic ions and other substances; and resistance to dessication. The polysaccharides and proteins form the structural elements of biofilms and determine their mechanical stability. The roles of the other components are not well established. At some time after attachment of cells to a surface, this attachment becomes irreversible. The cells grow and divide to form a microcolony. The microcolony enlarges, produces EPS, and coalesces so that it becomes anchored to the surface and stabilized. Microcolonies become protected from environmental stresses, and cells can show increased resistance to antimicrobial agents within a few hours of adhesion, even before they become embedded in the EPS matrix. Over time, cellular activity continues and the biofilm matures. Biofilms can be composed of different organisms or they can contain only one species. The organization of the cells ranges from a single layer to 3-D structures with the bacteria living within a large, complex, and organized ecosystem. There might be mechanisms whereby some species are encouraged to populate a biofilm, whereas attachment of other species is inhibited. *In vitro* studies show that multispecies biofilms are thicker and more stable than single species biofilms. The distribution of bacteria within biofilms is not even. Bacteria grow within the microcolonies that are surrounded by the EPS matrix and water channels are formed among them. These channels facilitate the transport of substrates, including oxygen, metabolites, and nutrients to the biofilm and within the biofilm; and also transport products, including waste products, out of the biofilm.

The physiological state of biofilm bacteria appears to be different than that of planktonic bacteria. The combination of physiological modifications of biofilm-associated cells, including reduced growth rates and production of enzymes that can degrade antimicrobial substances, and physical protection provided by the biofilm matrix itself might be responsible for the extreme resistance to antimicrobials of biofilm bacteria.

Part of the 'life cycle' of a biofilm is that damaged individuals are eliminated from the population. Programmed cell death and lysis can be a function of spatial orientation within the biofilm. Since deoxyribonucleic acid (DNA) is a component of the EPS and is thought to be related to the stability of the biofilm, the expectation is that cell lysis has a role in maintaining the stability of the biofilm structure.

Biofilms are known to spread, but factors that control release of cells and detachment of sections of the biofilms are not well understood. They can release 'pioneer' cells or daughter cells individually, or there might be a sloughing or detachment of a relatively large part of the biofilm. When single cells or small clusters of cells detach, the effect on the biofilm is limited to the surface. When a large portion of a biofilm is sloughed off, the whole biofilm is impacted and may be lost.

Cellular Control of Biofilms – The Role of Cell-to-Cell Signaling Molecules and the Molecular Basis of Biofilm Formation

The defining characteristic of biofilms is the formation of an integrated bacterial community. This requires self-organization

and cooperation among cells, rather than the classical 'competitive' natural selection of individual microorganisms. Bacteria, which are colonial by nature, must be able to sense environmental changes and respond to them. They must also communicate with each other. Bacteria modulate gene expression and have systems of intercellular interactions and communications that are currently the focus of much study.

The molecular changes that occur in a bacterium when it changes from its planktonic form to become sessile (permanently attached to the substrate) can be very complex and are only beginning to be understood. For example, in *Listeria monocytogenes*, expression of many proteins has been shown to be upregulated, including some related to stress response, protein synthesis, carbon metabolism, and regulation. These diverse molecular shifts show that the central metabolism of *L. monocytogenes* is affected during biofilm development.

A major area of interest is the role of quorum sensing in development and maintenance of biofilms. Cell-to-cell signaling is mediated by small, diffusible molecules called auto-inducers that are produced and secreted during bacterial growth. As the bacterial population in the biofilm increases, the concentration of these small molecules increases too. When they reach a threshold or quorum level, the cells respond to them, with a variety of phenotypic responses being displayed as a result of the regulation of target genes that are quorum-sensing dependent. Quorum sensing seems to be involved in all stages of biofilm formation and maintenance. Some of the biofilm-related processes that can be controlled by quorum sensing are the establishment of bacteria in a mixed biofilm community, survival in food processing environments that are hostile to bacteria, the production of surface appendages, and motility. Since the discovery that bacterial cells communicate is relatively recent, much information is still required to fully explain the role of quorum sensing in the activities of biofilm bacteria. There is particular interest in the possibility of controlling the development of biofilms through disruption of the quorum sensing system.

Studying Biofilms

The study of biofilms *in situ* is extremely difficult for many reasons. As a result, most knowledge about biofilms has been obtained from *in vitro* studies. Such results might not be relevant to circumstances in the food industry. Many disinfection processes are designed using bacteria that are planktonic, which are more sensitive to antimicrobials than bacteria embedded in biofilms. Enumerating or determining the types of bacteria residing within biofilms can be difficult. It has been estimated that for each planktonic bacterial cell detected, another 1000 cells could be present within a biofilm. In food processing environments, surfaces are usually treated with antimicrobial chemicals during cleaning, might not provide a lot of nutrients, can be hot or cold and dry, and might be otherwise hostile environments for bacteria causing them to be stressed and/or injured and nonculturable. The types of bacteria within a biofilm and the environment in which they develop will determine its characteristics. Researchers cannot as yet wholly duplicate naturally occurring biofilms.

A variety of microscopic techniques including scanning electron microscopy, transmission electron microscopy, and laser scanning microscopy are the tools used to observe biofilms and to monitor their development under controlled conditions. One instrument being studied as a way to monitor biofilm formation online is the mechatronic surface sensor. This type of sensor is based on the analysis of the vibration response of the surface and can detect biological and chemical characteristics of a variety of surfaces such as stainless steel and polyvinyl chloride.

Biofilms in the Food Industry

The major focus of research on biofilms has been in relation to medical matters, but they are also very important in many industries, including the food industry. The bacteria in biofilms can cause food spoilage, compromise food safety and affect performance, and longevity of industrial equipment. Several pathogenic and spoilage bacteria including *L. monocytogenes*, *Salmonella* spp., *Campylobacter* spp., *E. coli*, *Pseudomonas* spp., and lactic acid bacteria have been associated with biofilm formation. In the meat and dairy industries, bacteria, including species of *Pseudomonas*, *Staphylococcus*, *Enterobacter*, *Flavobacterium*, yeasts, and *Kluyvera* were recovered from biofilms associated with clean floor materials. *L. monocytogenes* will form biofilms on floor drain surfaces, in storage tanks, on hand trucks, on conveyor belts, and on other food contact surfaces; and individual strains have been shown to persist in food plants for several years. Bacteria in biofilms can catalyze chemical and biological reactions to cause corrosion in pipelines and tanks, and if the biofilms are allowed to become thick, the heat transfer in heat exchangers and pipelines can be reduced.

Equipment and processing plant design, cleaning, and disinfection regimens are the major tools available to the food industry to control the development of biofilms. Surfaces in meat processing facilities are frequently wet and biofilms can quickly form under wet conditions. Stainless steel, the material used for many food contact surfaces, is chemically and physiologically stable over a range of temperatures, and it is easy to clean. When the microtopographies of stainless steel surfaces are examined, they are seen to have many cracks and crevices that are good locations for bacteria to become attached. All areas of food processing environments including floors, walls, pipes, drains, conveyer belts, gaskets, and dead spaces are prone to biofilm formation. Similarly, materials that are commonly used in food processing facilities such as stainless steel, aluminum, nylon, Teflon, rubber, and plastic can become colonized by biofilms.

The development and structure of biofilms depend on many factors, both intrinsic and extrinsic, including the species of bacteria in the consortium, the temperature, pH and nutrient status of the environment, and the flow conditions of fluids that contact surfaces. In the food industry, because cleaning and disinfection are frequent, mature biofilm structures or continuous bacterial films are not often observed on equipment surfaces; however, microcolony development with or without EPS is common. Whether these attached bacteria constitute a biofilm is debated. Although not showing the

typical characteristics of biofilms, these microcolonies are important to the food industry because they can exhibit increased resistance to antimicrobial treatments within only a few hours of establishment; and cleaning and disinfection regimens must be designed to remove them completely. It is hypothesized that this resistance might, in part at least, result from a reduction in surface area exposed to antimicrobial treatment as a result of the attached surfaces not being in contact with the applied chemicals. Further research is required in this area, with particular emphasis on contamination of damp surfaces in food processing areas. In hard to access areas and areas that are infrequently cleaned, mature biofilms, with microbial cluster embedded in EPS and water channels, are observed.

The best approach to control biofilm development is prevention of their establishment. Equipment should be designed so that areas that are hard to access and clean and areas that allow bacteria to accumulate, such as dead ends, corners, valves and joints, are avoided. Good water drainage should be assured and proper attention should be paid to the welding, material, and surface finishing on both exposed and nonexposed surfaces. All surfaces should be nonporous and smooth, without pits or crevices. Glass is a hard, smooth, and corrosion-resistant material but its applications are limited since it breaks easily. Stainless steel is easy to clean but the surface is easily damaged. Rubber surfaces deteriorate. Surfaces in food establishments must be cleaned, but regimens that cause corrosion and produce topographical defects should be avoided. Defects and roughness of surfaces have greater effect on the ease with which a surface can be cleaned than the type of finish. Since biofilm development occurs when moisture is present, maintenance of dry conditions will aid in prevention of their establishment.

Even with proper equipment design and attention to surface characteristics and integrity, the likelihood of preventing biofilm development is slim. Cleaning and disinfection programs necessarily remain the main strategy for controlling surface contamination. Since bacterial adhesion is initiated soon after a surface is conditioned, regular cleaning and disinfection at short intervals are required to prevent firm bacterial attachment to surfaces and the formation of mixed species biofilms. Cleaning at short intervals will help to prevent sporulation by spore-forming bacteria, which is of particular importance to the dairy industry, but might become important to the meat industry as the involvement of psychrophilic (cold-loving) and pathogenic clostridia in meat spoilage becomes more common.

One major factor militating against elimination of biofilms is that they can be reseeded with a very small number of cells. It is almost impossible to remove all cells associated with a biofilm. Pouring liquid onto a surface will erode a biofilm but a negligible number of the biofilm cells will be detached. Any cleaning and sanitation strategy must ensure that the biofilm bacteria are dead, not just dislodged. Surfaces should be cleaned prior to sanitation and cleaning processes must break up or dissolve the EPS so that sanitizers can make contact with the viable bacteria within the biofilm. Some materials used for cleaning are surfactants or alkaline products that suspend or dissolve food residues by decreasing surface tension, emulsification of fat, and denaturation of proteins. Acid products can also be used if the surfaces are coated with precipitated minerals or much food residue. If it is practicable, exposure of the biofilm to high temperature can reduce the requirements for physical cleaning. The type of cleaning process must not cause aerosols. For example, when mechanical force is applied using scrubbing and brushing, or pulsed laser beams are used, bacteria can become airborne. Such processes, including use of high pressure sprays, are being replaced by foam or gel cleaning.

Bacterial cells within biofilms are highly resistant to antimicrobials. Even after a surface is cleaned, ridding the surface of viable cells is difficult. There are several mechanisms that have either been shown or are hypothesized to cause the elevated resistance of biofilm bacteria. Penetration of antimicrobials into the biofilm can be slow or the antimicrobial can be neutralized in the outer layers of the biofilm. The rate of diffusion might be slower than the rate at which the antimicrobial is inactivated, as is observed with resistance of biofilms to chlorine. The growth rate of bacteria deep in the biofilm is decreased and cells are in a 'quasi-dormant' state in which their resistance to biocides is increased. Older biofilms are more resistant to biocides than are younger ones. Genes controlling adaptive stress responses are expressed and biofilm cells are able to sense challenges from antimicrobials. *Salmonella enteritidis* isolated from biofilms had increased resistance to heat and chemicals when compared to planktonic cells. Repeated exposure of biofilm cells to antibiotics was shown to cause an increase in EPS synthesis in the biofilm. Cells, termed persister cells, that are phenotypically variant, can develop. These cells do not grow and do not die when challenged with antimicrobials. In the medical field, such cells are considered to be largely responsible for persistent infections resulting from biofilms. Their resistance is explained by their production of cellular toxins that block cellular processes such as translation and, so, render the cells resistant.

Prevention and control of biofilms are topics of active research. At this time, there is no means known of preventing or controlling the development of biofilms without adverse side effects. Almost all materials will support the formation of biofilms. Some current efforts are focussed on the possibility of incorporating antimicrobial agents into either the construction materials themselves or surface coatings. Much work has been concerned with biomedical applications, but application in the food industry will likely follow and has been the focus of some studies. Laboratory studies in which fungicides are incorporated into flooring materials have been reported, but no results of long-term studies have been published. Covalent coupling of silicone rubber implants with quaternary ammonium coatings, coating surfaces with silver, preconditioning surfaces with surfactants and adsorption of nisin onto food contact surfaces are all in the experimental phase. In food processing, the importance of the 'house microflora' and the possibility that the presence of bacteriocin-producing bacteria and other endogenous strains might influence the establishment of biofilms are being studied. Novel approaches to prevention, removal, and inactivation of biofilm bacteria include the development of enzyme-based cleaners; various combinations of enzymes, detergents, surfactants, and phenolic antimicrobials; use of bacteriophages; interruption of quorum sensing; and manipulation of nutrient availability.

The formation of biofilms is a unique, complex, and important biological phenomenon that enables many bacteria to survive and grow in interactive communities and in environments that are hostile to them. Biofilms can be advantageous, but in many parts of the food processing industry, they are considered to be biofouling agents responsible for problems with food spoilage, food safety, deterioration of equipment, and compromised efficiency of equipment. Our knowledge of the mechanisms that contribute to the formation, development and maintenance of biofilms is limited and improved control over biofilms will depend on significant advances in the field.

BIOMETHANE PRODUCTION AND CLEANUP

J Efrén Ramírez-Bribiesca, Colegio de Postgraduados, Texcoco, Mexico

Glossary

Biodigestor A natural system that uses anaerobic digestion in a series of processes by which microorganisms break down the biodegradable material in absence of oxygen. It is used for industrial purposes in managing waste and releases energy.

Global warming Refers to an unequivocal and continuing rise in the average temperature of Earth's climate system.

Greenhouse effect A natural process that warms the Earth's surface. When the Sun's energy reaches the Earth's atmosphere, some of it is reflected back to space and the rest is absorbed and reradiated by greenhouse gases.

Methanogen Any of various archaea that is capable of producing methane from the decomposition of organic material.

Ruminal defaunation Elimination of all the protozoa (defaunation) from the rumen is a standard method of studying their overall effect.

Introduction

Global warming is the result of heat absorption by certain gases in the atmosphere and downward reradiation of some of the heat that helps to regulate the temperature of the planet. The worldwide trends of carbon dioxide have shown an increase over time, leading to an enhanced greenhouse effect and hence global warming due to its high absorption of infrared radiation. Methane is another important greenhouse gas that is produced mostly from agricultural activities and livestock. On 17 November 2003, the National Oceanic and Atmospheric Administration reported that the concentration of the potent greenhouse gas methane in the atmosphere was leveling off and it appears to have remained at this 1999 level. The Intergovernmental Panel on Climate Change (IPCC) in 2007 acknowledged that methane concentrations have plateaued, with emissions being equivalent to removals. These changes in methane atmospheric dynamics have raised questions about the relative importance of ruminant livestock in global methane.

It is a matter of concern that methane is increasing in the atmosphere at approximately 1% per year, 30% ($\sim$80 million tonnes) of which is from ruminants. This problem was a principal goal of discussion in different governments around the world, and the first assessment report of the IPCC, issued in August 1990, served as the basis for negotiation on the United Nations Convention on Climate Change. In 1995, a second report was finished and in the year 2001 approved the third IPCC report. The conclusion of the first global scientific consensus notes the importance of 'human activities' as a factor in global climate change in the past 50 years. The agreement of world political leaders was to reduce levels of greenhouse gases through the Kyoto Protocol, which entered into force on 16 February 2005. The participating countries must demonstrate that actions and progress are being made to reduce emissions of six main gases that induce the greenhouse effect, which are: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). Strategies have been established to reduce emissions of the gases in the following sectors: (1) energy, (2) transport, (3) industry, and (4) agriculture. Livestock is of interest in this article, considering aspects in the selection of animal breeds, food ingredients that produce less methane, and excreta management.

Methane Production in Livestock

Gas emission from ruminants is a direct consequence of fermentation performed by ruminal microbes due to the type of digestive process by which carbohydrates are broken down by microorganisms and methane is released as a by-product of enteric fermentation. Methane production in ruminants during the process of fermentative digestion and metabolism represents a loss of food energy, amounting to approximately 8% of gross energy at maintenance level of intake and 20% of the metabolizable energy. It is very important to know the factors associated with and the mechanisms of methane production. The methanogenic energy loss is high, particularly in low-quality roughages, such as a straw-based diet. Straw is the principal feed for vast majority of ruminants in developing countries and methane production is inversely related to propionate production, i.e., if propionate increases there is a decrease in methane production and vice versa. Evidently, the largest proportion of methane is produced from the poor-quality roughage feeds, because acetic acid is the principal fermented product of poor-quality feed. However, methane production can be changed by changing forage:concentrate ratio and the type of concentrate; moreover, forage:concentrate ratio can substantially influence methane production.

An adult bovine on an average releases between 70 and 120 kg of methane per year, and the negative effect on the climate of methane is 23 times higher than the effect of CO_2. Therefore, the release of approximately 100 kg methane per year for each bovine is equivalent to approximately 2300 kg CO_2 per year. According to the Food and Agriculture Organization (FAO), agriculture is responsible for 18% of the total release of greenhouse gases worldwide and cattle breeding is taking a major factor for these greenhouse gas emissions. Worldwide, there are approximately 1.34 billion cattle, and meat production was estimated at 275 million tons. Experts predict that by 2050 nearly twice as much meat will be produced as today, for a projected total of more than 465 million tons; a Japanese study showed that producing a kilogram of beef leads to the emission of greenhouse gases with a global warming potential equivalent to 36.4 kg of CO_2. Livestock now use 30% of the Earth's entire land surface, mostly permanent pasture but also including 33% of the global arable land used to producing feed for livestock. In 2010, at least 60% of meat was produced in developing nations, and Latin America released 11.7% of global emissions of gases that warm the atmosphere, mostly through rural activities. The Kyoto project includes the integration of many industrial countries, but the developing countries have not participated fully in the protocols of greenhouse gas emissions.

Factors Related to Methane Production in Ruminants

Animal welfare and environmental protection are increasingly important production factors. Consumers require that meat should be produced in systems that they consider animal friendly. On the environmental side, slurry-based systems for feedlots may be favoured because it is suggested that they provide lower ammonia (NH_3) and greenhouse gas (GHG) emissions than other systems. Housing systems must be found that take the animals' welfare into consideration while controlling emissions of NH_3 and GHG. Emissions from feedlots have been intensively researched, but the data are still limited and there are several differences in production systems. Feedlot systems, however, are not finely differentiated within GHG reporting; one single emission factor is given for all straw-based systems, due to limited data availability, and mitigation measures are not proposed. Figure 1 summarizes the factors associated with the animal, the dietary composition, and some modifying additives that reduce methane emissions.

Animals

There are approximately 1.34 billion large ruminants in the world; these are one of the largest methane sources, producing approximately 80 million metric tons of methane annually. Increasing the productivity of ruminants could lessen CH_4 emission per unit of meat. Specifically, in the developing countries, genetic potential of animals for production is not expressed due to under or improper nutrition; so CH_4 emissions per unit of meat produced could be decreased with proper feeding. Little information is available on opportunities to mitigate enteric CH_4 via animal genetics. Steers with a low residual feed intake (LRFI) have a higher digestibility than steers with a high residual feed intake (HRFI). LRFI cattle potentially have lower energy losses as CH4 when allowed access only to high quality pastures compared with HRFI. Residual

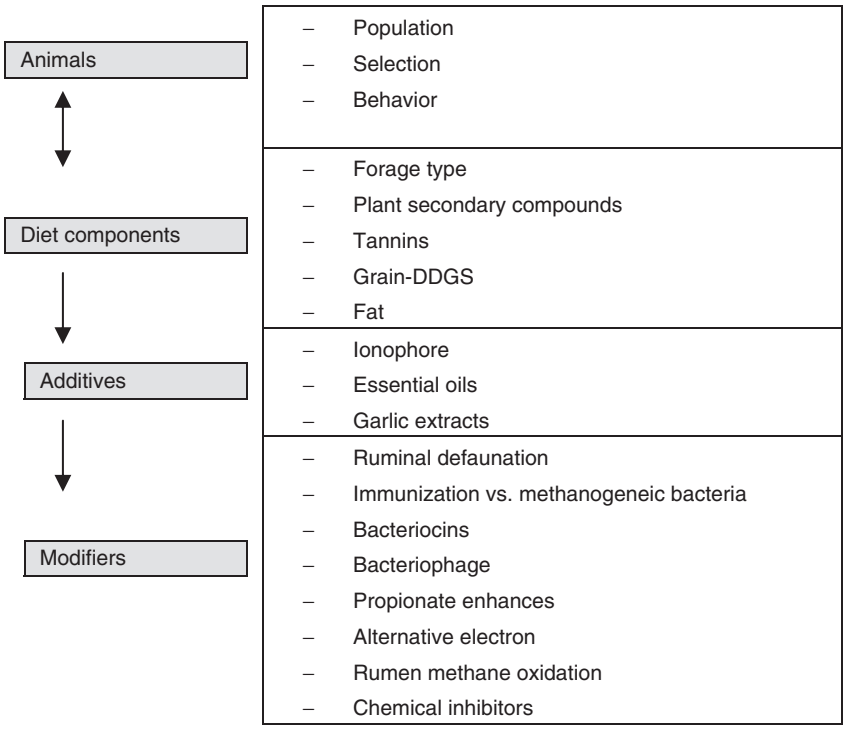

Figure 1 Schematic presentation of potential factors that reduce methane emissions in ruminants.

feed intake has been shown to be moderately heritable (0.4). An almost doubled total volatile fatty acid (VFA) concentration is also reported in rumen fluid of cow compared with HRFI steers, indicating more microbial activity fermentation and higher methane production in LRFI steers. However, improvements can be made through selection on associated trails, such as feed intake or RFI or through selection on CH_4 predicted from feed intake and diet composition. A study conducted in lactating cows found a large variation in dry matter intake (DMI) and predicted enteric CH_4 emission among first-lactation cattle; this study concludes that a classic selection program could reduce predicted methane emission by 11% and 26% in 10 years.

Diet Components

Cattle production systems have diets that are composed of forage (including grass and legumes), silage, supplements, or complete diets that provide their nutritional requirements. Cattle fattened in feedlots are fed small amounts of hay or straw supplemented with grains, silages, or other ingredients in order to increase the energy density of the diet. Decreasing the fiber content of forages has been found to reduce methane production. Particularly, some legume forages have been shown to decrease CH_4 production, which has been explained by the presence of condensed tannins, low fiber content, high DM intake, and faster passage from rumen. Saponins, such as *Sapindus saponaria* and *Sesbania sesban*, have potential to reduce CH_4 production through a direct effect on methanogen bacteria and protozoal number. Addition of 3–5% of the diet as tallow or oils has been found to decrease the methane production by 2–3%.

Additives

These are a group of feed ingredients that can cause a desired animal response through nonnutrient roles, such as pH, growth, or metabolic modifiers to reduce emissions of methane. Ionophores, such as monensin, included in diets at a dose of 24–35 mg kg^{-1} diet decreased CH_4 production by 4–10%, but the use of ionophores has been banned in the European Union. Furthermore, there are a number of reports available showing a decline of methane production as a result of garlic extracts, peppermint oil, essential oils from *Thymus* or *Origanum* plants, methanol and ethanol extracts of *Foeniculum vulgare* and *Syzygium aromaticum*, etc. The majority of the products cited have been evaluated on *in vitro* trials, but a great deal of research is still to be done *in vivo*, in order to consider the economic benefit of reducing methane production using these additives.

Modifiers

There is a wide interest in investigating the effect of rumen defaunation (elimination of protozoa) to reduce CH_4 production. Protozoa are indirectly involved in methane production due to their close symbiotic relationship with methanogens, which allows interspecies hydrogen transfer between them. Methanogen vaccines are other alternative for mitigating CH_4 emissions. Australian researchers have reported one study from immunization of sheep with whole-cell preparations of methanogens that showed a 7.7% reduction in CH_4 production; this observation suggests that vaccinating ruminants against methanogens may reduce the activity of ruminal methanogens. The use of a bacteriocin produced by *Streptococcus* sp. and therapy with bacteriophages are other alternative methods to suppress CH_4 production. Also, the addition of organic acids, such as malate and fumarate, increases propionate production, with a stoichiometric decrease in H_2 availability for CH_4 production, although other studies have concluded that supplementing diets with these acids at the levels required to decrease CH_4 emissions would be expensive.

Manure Management to Reduce Methane Emission and Using Techniques to Generate Energy

Livestock manure has been estimated to contribute 17.5 million tons of methane (CH_4) and 3.7 million tons of nitrous oxide (N_2O) to the atmosphere each year. The majority of methane emissions come from large swine and dairy farms that manage manure as a liquid. The US EPA expects that methane emissions from livestock manure will grow to 4.6 million tons in 2020 in the United States. But worldwide, the increase is expected to be particularly high in Africa (43%), Central and South America (30%), non-OECD Asia (39%), and the Middle East (10%). Interestingly, despite the rapidly increasing methane contribution from these countries, the OECD is expected to remain the top emitting region even in 2030. This increase in methane emissions is primarily due to the increasing use of liquid and slurry manure management systems that generate methane. The use of these systems is associated with the trend toward larger farms with higher, more concentrated numbers of animals. However, cost-effective technologies are available that can stem this emission growth by recovering methane and using it as an energy source; these technologies, commonly referred to as anaerobic digesters, decompose manure in a controlled environment and recover methane produced from the manure.

Anaerobic digestion that utilizes manure for biogas production is one of the most promising uses of biomass wastes, because it provides a source of energy while simultaneously resolving ecological and agrochemical issues. Anaerobic digestion involves bacterial fermentation of organic substances in the absence of free oxygen and the fermentation leads to the breakdown of complex biodegradable organics in a four-step process referred to as a three-phase process: (1) hydrolytic phase (step 1), (2) acid phase (steps 2 and 3), and (3) methane phase (step 4) (Figure 2). If the process is properly controlled in reactors so that it proceeds optimally through these stages, the principal end product, the biogas, contains 70% (by volume) of methane gas, the rest being carbon dioxide and traces of ammonia, hydrogen sulfide, and hydrogen. This biogas, which is a convenient and clean fuel, can either be used directly with or without the removal of carbon dioxide or be converted into electricity with the help of suitable generators.

The digesters are mixed mechanically to ensure uniform digestion. Each system attempts to maximize methane generation from the manure and the recovered methane can fuel engine generators to produce electricity or boilers to produce

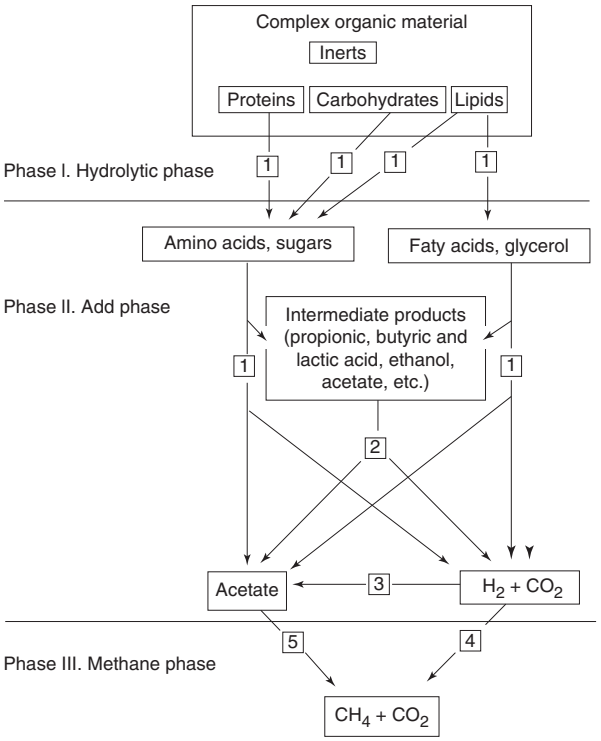

Figure 2 Steps associated with anaerobic digestion of organic materials. The bacteria involved are: (1) hydrolytic and fermentative, (2) hydrogen-producing acetogenic, (3) hydrogen-consuming acetogenic, (4) carbon dioxide reducing, and (5) aceticlastic methanogenic. Adapted from Tauseef, S.M., Premalatha, M., Abbasi, T., Abbasi, S.A., 2013. Methane capture from livestock manure. Journal of Environmental Management 117, 187–207.

heat and hot water. Electricity generation for on-farm use can be a cost-effective way to reduce farm operating costs. The economic feasibility of electricity generation usually depends on the farm's ability to use the electricity and the waste heat on-site. Digesters also reduce foul odor and can reduce the risk of groundwater and surface water pollution. Manure decomposes very rapidly when climate conditions encourage bacterial growth and so methane generation is greater in warm regions and lower in cool regions. Methane generation takes place in the volatile solids portion (VS) of the manure. The composition of the VS portion depends on livestock type and diet, so both affect the quantity of methane that can be produced per kilogram of VS in the manure. This quantity is referred to as 'Bo' and is measured in units of cubic meters of methane per kilogram of VS (m^3 CH_4 per kg VS). Methane production also depends on the type of manure management system (dry or liquid) used. Liquid/slurry systems use concrete tanks and lagoons to store flushed and scraped manure. Liquid management systems use water to facilitate manure handling. In addition, unmanaged manure from animals grazing on pasture falls into this category. Dry systems include solid storage, dry feedlots, deep pit stacks, and daily spreading of the manure. For dry systems, wet climates have higher emissions than arid climates, although emissions in either case are very low compared with wet systems.

Conclusion

Methane emissions caused by livestock and manure are high and these are the biggest contributors among the anthropogenic sources of the global warming gas methane. A number of technologies, such as animal selection, use of diet components, additives, or modifiers, are emerging to reduce methane production. The use of livestock manure is an alternative renewable source of energy and use of biodigesters can improve environmental conditions.

Glossary

Bacteriocidal A compound that is lethal to bacteria and exposure at the appropriate concentration results in cell death.

Bacteriophages Bacteria-specific viruses used to control the growth of undesirable bacteria in foods.

Bacteriostatic A compound that prevents a bacterial cell from dividing but does not kill the cell.

Diacetyl A volatile organic compound produced by certain strains of lactic acid bacteria that has a strong buttery flavor.

Lactic acid bacteria A diverse group of Gram-positive bacteria that share a common feature that they can only ferment sugars to acids and cannot obtain energy using respiration.

Modified atmosphere packaged meat (MAP) MAP is used to extend the shelf-life of fresh meat by changing the concentrations of gases in the packaged product. Gases such as CO_2 and N_2 are added to lower the concentration of O_2 in the packed product.

Starter culture A meat starter culture contains one or more strains of lactic acid bacteria that are added during a meat fermentation to ensure consistency in desirable flavor and sensory outcomes.

Introduction

Biopreservation exploits the antimicrobial activities of some microorganisms to inhibit the growth of spoilage and pathogenic microbes in foods. This biological approach seeks to minimize the addition of chemical additives to foods, such as nitrite, sodium chloride, and organic acids. Research in the field of biopreservation for meat products remains active because it is perceived that natural methods of preservation are desirable. Most research on biopreservation has focused on the antagonistic activities of lactic acid bacteria against spoilage and pathogenic bacteria. However, in the past decade, the use of bacterial viruses (bacteriophages) to eliminate pathogenic bacteria from foods has gained considerable attention.

Lactic Acid Bacteria and Their Antimicrobial Activities

The role of lactic acid bacteria in meat fermentations is well established and is grounded in centuries of traditional artisan sausage production, where the fermentation imparted desirable sensory qualities and increased the shelf life of the sausage. For example, lactic acid bacteria, such as *Lactobacillus sakei* and *Lactobacillus curvatus*, play predominant roles in the production of traditional fermented meats, such as salami and other dry-fermented sausages, by producing acids during fermentation and lowering the pH. The lower pH creates a stressful environment for pathogenic and spoilage bacteria, thereby inhibiting their growth. Owing to their importance in meat fermentations, substantial research effort has focused on the development of specific lactic acid bacteria starter cultures for the production of fermented meat products with consistent desirable sensory qualities. In addition to these traditional fermentations, lactic acid bacteria are known to be the dominant bacterial flora in vacuum-packaged or modified atmosphere-packaged fresh meat and meat products during storage. The lactic acid bacteria are a metabolically diverse group of fermentative bacteria. Some of them produce metabolites that confer off-odors and flavors on fresh meats, whereas others spoil meat products. Some do not affect the sensory qualities of meat products even when they are present in high numbers. The nonspoilage lactic acid bacteria are well suited for biopreservation of meat products, as they can be added to the products without noticeably affecting the sensory qualities of the foods. The antagonistic activities of lactic acid bacteria against other bacteria in foods have been attributed to several mechanisms that include:

- Production of organic acids, such as lactic acid and acetic acid, and reduction of meat pH.
- H_2O_2 production.
- Sequestration of nutrients required by competing organisms.
- Production of antibacterial bacteriocins.
- Production of other metabolites with antimicrobial activities, such as diacetyl and reuterin.

The various antimicrobial activities are expressed at different levels by different species and strains of lactic acid bacteria. Furthermore, the antagonistic activities can vary from bacteriostatic (growth inhibiting) to bactericidal (lethal) and

 doi:10.1016/B978-0-12-384731-7.00111-2

might affect a broad range of bacteria or only a limited, sometimes narrow, group of organisms. The acidifying effects of lactic acid bacteria are exploited for the preservation of fermented meat products, such as dry sausages. Now, rather than relying on bacteria naturally present on meat, selected strains of lactic acid bacteria are commonly used as starter cultures for fermentation. The production of bacteriocins by starter strains is currently receiving much attention because of the potentially wide use of those organisms and their products for biopreservation of meats.

Organic Acid Production

Lactic acid bacteria produce organic acids by fermentation of carbohydrates. Homofermentative lactic acid bacteria produce mainly lactic acid, whereas the heterofermentative species produce acetic as well as lactic acid and, to various extents, other acids such as formic, citric, and maleic. The antimicrobial activities of organic acids are primarily associated with the undissociated forms of the acids. For this reason, the inhibitory activities of organic acids are affected by the pH values of foods; i.e., their antimicrobial effects increase with decreasing pH. The inhibitory activities are mainly due to the following:

- Reduction of pH with an increase of the concentration of H^+ in a food. The pH can be reduced to values near or below the minima for growth of pathogens and potent spoilage organisms.
- Reduction of the intracellular pH of bacteria. The undissociated acid is relatively lipophilic and is, therefore, able to penetrate the bacterial membrane to release H^+ in the cytoplasm. Then, in order to survive, the bacteria have to use energy to transport H^+ out of cells. This causes energy depletion and cell stress.

Because the antimicrobial activities of organic acids increase as the pH decreases, their activities are greater in fermented sausages of pH 4.5 than in cooked meat products of pH 6.3. It is, however, possible to achieve some inhibitory effects by adding organic acids to products while maintaining a high pH.

Hydrogen Peroxide Production

In the presence of oxygen, some lactic acid bacteria produce H_2O_2 during fermentation of carbohydrates. To mitigate the toxic effects of H_2O_2, the bacteria produce enzymes, such as catalase, that break down the H_2O_2. The efficiencies of these enzyme systems vary among lactic acid bacteria, and the rate of production of H_2O_2 can be greater than the rate of its degradation. Then, the amount of H_2O_2 in the meat environment increases. H_2O_2 is inhibitory to bacteria because of its strong oxidative effect on cell membrane lipids and proteins. However, the production of H_2O_2 by bacteria in meats can pose sensory problems by causing green or brown discoloration of products and lipid oxidation that gives rise to rancid flavors.

Nutrient Competition

The growth of bacteria within foods depends on the amounts of nutrients available to them and various factors intrinsic and extrinsic to the food matrix, such as NaCl concentration, temperature, etc. that affect their growth. If a product is inoculated with high numbers of lactic acid bacteria capable of growth in the product, and conditions are such that the concentrations of nutrients are or become growth limiting, the growth of other bacteria using the same nutrients can be inhibited.

Bacteriocins

Bacteriocins are classified on the basis of their, often relatively narrow, range of target bacteria and their molecular compositions. Bacteriocins of relevance for biopreservation are comprised of chains of several amino acids that have undergone chemical modification. Owing to their proteinacious nature, bacteriocins can be inactivated by proteases. Bacteriocins produced by lactic acid bacteria have been known since the 1930s, when certain *Lactococcus lactis* strains (formerly known as N-streptococci) were shown to produce a compound with high antimicrobial activity. This compound is now known as nisin, which is one of the most-studied bacteriocins produced by lactic acid bacteria. The antimicrobial activities of bacteriocins are often limited to closely related lactic acid bacteria. However, some lactic acid bacteria produce bacteriocins that act against broad ranges of Gram-positive bacteria which can include the foodborne pathogens *Listeria monocytogenes* and *Staphylococcus aureus*. Nisin is effective against those organisms, and it inhibits germination of spores of *Bacillus* and *Clostridium* species. Gram-negative bacteria such as *Escherichia coli*, *Yersinia enterocolitica*, and *Salmonella* species are usually not affected by the bacteriocins produced by lactic acid bacteria. The resistance is, in part, due to the outer membrane of Gram-negative bacteria, which is not present in Gram-positive organisms. The outer membrane serves as a barrier to the entry of bacteriocins into cells of the Gram-negative bacteria and thus prevents the bacteriocins from accessing their cellular targets. However, if the bacteriocin is added together with a chemical agent that disrupts the outer membrane, for example, trisodium phosphate or a chelating agent such as ethylenediaminetetraacetic acid, the Gram-negative bacteria can become sensitive to some bacteriocins.

The bacteriocins produced by lactic acid bacteria are classified according to their primary structures and amino acid compositions. The three recognized classes are:

1. The lanthionines. These are peptides containing modified amino acids. The best-characterized bacteriocin of this group is nisin, which is produced by several *Lactococcus lactis* strains.
2. The small nonlanthionine bacteriocins. These are peptides composed of unmodified amino acids. The antilisterial bacteriocin pediocin is a member of this group.
3. The large, heat-sensitive bacteriocins. These are inactivated within 10–15 min at 60–100 °C. Only a few have been described, such as helviticin J and caseicin 80.

Bacteriocin Production

Lactic acid bacteria produce mainly Class I or Class II bacteriocins, all of which consist of between 20 and 60 amino acids. They are heat stable, hydrophobic, and cationic.

Synthesis and secretion of nisin and other lanthionines (Class I) involves the products from several genes, in addition to the structural gene. In contrast, synthesis and secretion of Class II bacteriocins generally requires just four genes. The lanthionines require genes coding for the prepeptide, transport proteins for secretion of the prepeptide, proteins involved in modification of the peptide, immunity proteins, and regulatory proteins for gene expression. The Class II bacteriocins require only genes that code for the prepeptide, two transport proteins, and one immunity protein.

The production of bacteriocins often occurs during exponential growth of the organism, although the conditions required for production can differ. For example, some strains require a specific substrate for production of a bacteriocin, whereas others produce the bacteriocin only while growing within a narrow pH range. The temperature at which a culture is incubated can affect bacteriocin production. Increasing amounts of sodium chloride can decrease and addition of glucose to a culture can increase bacteriocin production by some organisms.

Antimicrobial Activities of Bacteriocins

Bacteriocins can have either bacteriocidal or bacteriostatic effects on the sensitive bacteria. It is generally thought that bacteriocins act in two stages. In the first stage, the bacteriocin binds to a receptor on the surface of the sensitive strain. In the second stage, the bacteriocin penetrates the cell membrane, making small holes in it. Small molecular weight components leak from the attacked cell, and ultimately energy depletion causes cell death. However, recent research suggests that the antimicrobial actions of at least some bacteriocins are more complex. Thus, some bacteriocins can apparently enter the cytoplasm to interact with the cell's deoxyribonucleic acid (DNA) or essential proteins, thereby interfering with the proper functioning of the cell.

Some bacteriocins, such as the lanthionines nisin and lacticin 3147, are active against a broad range of Gram-positive bacteria. Nisin has been shown not only to be active against vegetative cells but also to prevent the outgrowth of bacterial spores. Other bacteriocins are active against only a narrow range of bacteria that are closely related to the organism that produces the bacteriocin. For example, some of the lactococcin bacteriocins are active against only strains of *Lactococcus* species. If bacteriocin-producing strains are used to increase shelf life, it is advantageous to use strains producing a bacteriocin with broad antimicrobial activity. However, if the purpose of biopreservation is to limit the growth of a specific spoilage bacterium, then use of a strain producing a bacteriocin that affects a narrow range of susceptible organisms which include the target strain might be appropriate.

The antimicrobial activities of bacteriocins can vary with food product composition. Thus, it has been shown that sodium chloride concentration, presence of fats and emulsifiers, storage temperature, and proteins in the food matrix as well as growth rate and growth phase of the target organism can affect the antimicrobial activities of bacteriocins.

Bacteriocin Resistance

Development of bacteriocin resistance by the targeted bacteria is an important issue for the effective use of bacteriocins for biopreservation. The cold-tolerant pathogen *Li. monocytogenes* is often the target for bacteriocins used for biopreservation of ready-to-eat meats. The bacteriocin resistance in *Li. monocytogenes* is well documented. When *Li. monocytogenes* is exposed to pediocin-like bacteriocins, resistance against these bacteriocins develops with a frequency between 10^{-6} and 10^{-3}. Similarly, nisin resistance in *Li. monocytogenes* has been shown to occur with a frequency between 10^{-9} and 10^{-2}.

In a few studies, a large number of strains of *Li. monocytogenes* were tested for resistance to bacteriocins. These studies showed that 1–3% of the strains were resistant to the pediocin-like bacteriocins but less than 1% were resistant to nisin. However, some strains had an enhanced tolerance to nisin, although they were not completely resistant.

Development of bacteriocin resistance can be due to various changes in the target organism. In some cases resistance develops as a result of changes to the cell membrane, in which the phosphotransferase system for uptake of sugars might be involved.

The occurrence of resistance against bacteriocins must be evaluated when practical applications of bacteriocins are considered. The risk of bacteriocin resistance is one of the reasons for not using bacteriocins as the sole preservative in a meat product. Biopreservation should be regarded as one component of a multiple hurdle approach to controlling pathogenic and/or spoilage bacteria in foods. In addition to directly enhancing control, the use of multiple barriers to bacterial growth and survival should help to minimize the risk of target organisms developing resistance to bacteriocins.

The Application of Bacteriocins to Meats

Bacteriocins can be incorporated into meats by various means. A bacteriocin-producing strain can be added to the meat, the same as a starter culture is added during meat fermentation. Alternatively, the bacteriocin can be purified from cultures of the bacteriocin-producing strains and added to meat preparations, applied directly to meat surfaces, or incorporated into packaging films that contact meat surfaces.

Traditionally, starter cultures have been used in the meat industry for production of fermented meats, with the cultures contributing to the texture, flavor, and preservation of the final products. Because bacteriocin-producing lactic acid bacteria can inhibit the growth of pathogens and spoilage organisms, there is increased interest in adding bacteriocin-producing lactic acid bacteria cultures to meat products, such as cooked, cured meat and sausages that are sliced and then packaged under vacuum or a modified atmosphere. Many patents for the use of bacteriocins and bacteriocin-producing strains of bacteria for preservation of meats have been filed. Companies selling starter cultures and other ingredients for use in foods are now marketing a variety of protective lactic acid bacteria cultures for inhibition of *Li. monotytogenes* in cooked, sliced meat products or Enterobacteriaceae that cause putrid spoilage

of fresh and processed meats. The effects of these cultures are often due to not only bacteriocins but also other antimicrobial actions of the starter cultures.

Direct addition of bacteriocins is possible because antimicrobial food ingredients containing bacteriocins, such as nisin and pediocin, are now commercially available. Examples of such products include Alta, Perlac 1911, Microgard, Chrisin, and Nisaplin. (Wesman Foods, OR, USA; Quest International, Naarden, the Netherlands; Chr. Hansen, Horsholm, Denmark; Danisco, Denmark). Manufacturers of packaging films are investigating the incorporation of active bacteriocins into edible and inedible films that can be used by the meat industry. This is an emerging technology that will require continued research to enhance the efficacies of antimicrobial films.

The intrinsic qualities of meat products can substantially affect bacteriocin activities and limit the means by which bacteriocins or bacteriocin-producing cultures can be added to meat. Fermented meats, cooked sliced meats, and fresh meats must then be considered separately with respect to the potential for use of bacteriocins in their biopreservation.

Fermented Sausages

Fermented sausages undergo rapid decreases in pH during fermentation, accompanied by development of desirable color, taste, and flavor. Lactic acid bacteria, such as pediococci and lactobacilli, are responsible for the decrease in pH and the subsequent acidic taste of the products. Micrococci, staphylococci, and yeasts are responsible for the development of desirable product color and additional flavors.

Starter cultures widely used in meat fermentation are strains of *Pediococcus acidilactici*. Use of a bacteriocin-producing strain of *P. acidilactici* was found to reduce the number of *Li. monocytogenes* by >3 log units, whereas a bacteriocin-negative variant reduced the concentration of the organism by <1 log unit. Various lactobacilli have also been shown to decrease the numbers of *Li. monocytogenes* in fermented sausages. Cultures containing one or more bacteriocin-producing starter strains for meat fermentations are available commercially.

Cooked Meats

Listeria monocytogenes can be introduced into cooked meat products after cooking and during peeling, slicing, and packaging of the product. The addition of a pediocin-producing strain of *P. acidilactici* at numbers of 10^7 colony-forming units (CFU) per gram inhibited the growth of *Li. monocytogenes* on vacuum-packed wiener and frankfurter sausages stored at 4 °C for 60 days. In the nonbiopreserved controls, *Li. monocytogenes* grew by up to 10^6 CFU g^{-1} during that time. However, this inhibition was not necessarily due to the production of a bacteriocin, as similar inhibition occurred when the products were inoculated with a bacteriocin-negative strain of *P. acidilactici*. The addition of lower numbers of the bioprotective culture (10^3–10^4 CFU g^{-1}) delayed but did not completely inhibit the growth of *Li. monocytogenes*.

Another organism suitable for inhibiting *Li. monocytogenes* in cooked, sliced meat is *Leuconostoc carnosum* 4010, cultures of which are commercially available. The effects of this organism, which produces the bateriocin leucocin, in a broad range of meat products have been documented. Cultures of the organism were applied to meat products as they were sliced, by nozzles placed next to the blade of the slicing equipment. The addition to slices of 10^7 *Le. carnosum* 4010 per gram of product completely inhibited the growth of *Li. monocytogenes* during storage at both 5 and 10 °C (Figure 1). This kind of antilisterial effect can be obtained with various bacteriocin-producing lactic acid bacteria. If meat is inoculated with high numbers of *Li. monocytogenes*, the addition of a protective culture will often cause a decrease in the number of *Li. monoctyogenes* due to the activity of the bacteriocin.

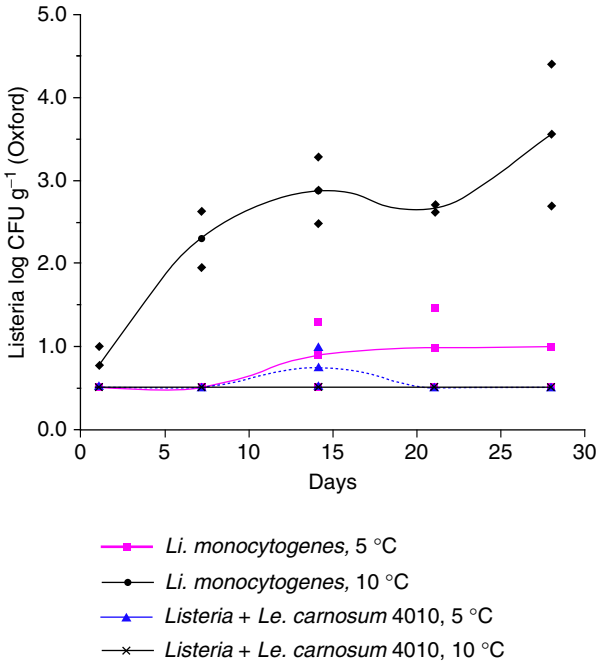

Figure 1 Inhibition of *Li. monocytogenes* in sliced ham biopreserved with *Le. carnosum* 4010. The product is sliced on a small-scale industrial slicer and the protective culture is added through two nozzles placed close to the knife. The product is packed in 20% CO_2/80% N_2 and stored at 5 °C and 10 °C. $n = 2$ for all controls only inoculated with *Li. monocytogenes*. For biopreserved series, $n = 2$ at days 1, 7, and 14 and $n = 10$ at days 21 and 28.

The use of nonbacteriocin-producing lactic acid bacteria has also shown promising effects for inhibition of *Li. monocytogenes* in sliced meat products and frankfurters. Organisms that give such effects include several strains of the species *Lactobacillus sakei*. These strains have been evaluated for antilisterial effect as well as sensory effects. The results showed that these strains are suitable for use as protective cultures in cooked, sliced meat products.

Fresh Meat

Several qualities unique to fresh meat can interfere with its biopreservation. Proteolytic and other enzymes found in the muscle tissue can remain active in raw meat. These can degrade bacteriocins and thus reduce the antimicrobial effect of the

bioprotective culture. Furthermore, other meat proteins might interact with and inactivate bacteriocins. Such proteins include glutathione, which can inactivate nisin by binding to the bacteriocin. Two other factors related to the microbial community of fresh meat can also limit bacteriocin efficacies. First, most fresh meat stored in air is spoiled by Gram-negative bacteria, and these organisms generally are not sensitive to the bacteriocins produced by lactic acid bacteria. Second, fresh meat contains a diverse bacterial community, so a bioprotective culture must be capable of competing with many different bacteria if it has to become the dominant organism throughout the entire storage period.

Biopreservation of fresh meat is potentially more effective when used in conjunction with vacuum packaging or packaging under an oxygen-depleted modified atmosphere. Vacuum-packed meat can be stored under refrigeration for several weeks. During this period, anaerobic or facultative anaerobic microorganisms proliferate on the surface of the meat. In the majority of cases, low spoilage potential flora of lactic acid bacteria will develop. However, vacuum-packed beef is sometimes spoiled due to the growth of psychotropic Enterobacteriaceae or clostridia or lactic acid bacteria of relatively high spoilage potential. Thus, some strains of *Lactobacillus sakei* are known to spoil vacuum-packed beef by producing sulfurous compounds. The growth of these organisms can be prevented by inoculating beef with *Leuconostoc gelidum* when the meat is vacuum packed. Vacuum-packaged beef can also be spoiled by psychotrophic *Clostridium* species, notably *Clostridium estertheticum*. Apparently, the growth of these strains can be inhibited by the use of biopreservative cultures. The growth of and spoilage of beef by *C. estertheticum* were prevented by addition of *Le. carnosum* 4010 to the surface of the meat before vacuum packaging. However, the use with fresh meats of additives, including biopreservative cultures, is not allowed in many countries. One possible application is the use of cultures with marinated meats because additives are permitted with this type of product.

Fresh sausages that are packaged under modified atmospheres and distributed at chilled temperature have a relatively short shelf life. Application of bioprotective cultures that have been carefully selected not to generate off-flavors can prolong the shelf life of this particular kind of sausage. Successful use of protective cultures requires trials and sensory assessment of their use with each product type, as a product might contain components that affect the culture with, ultimately, undesirable effects on the sensory quality of the product.

Bacteriophage Control of Bacteria in Meats

Bacteriophages are viruses that infect bacteria. They can be classified as lytic, if they invariably cause lysis of the infected host cell, or lysogenic, if they can integrate into the host genome and remain dormant (Figure 2). Bacteriophage host ranges are generally limited to specific bacterial species or, in some instances, to specific bacterial strains within a species. Lytic bacteriophages were recognized as potential antimicrobial agents by F. d'Herelle, in 1917. Before the discovery and subsequent use of antibiotics, bacteriophages were considered to offer a practicable means of treating bacterial infections in humans. The increase in antibiotic-resistant bacterial infections has led to a resurgence in research on the use of phages to treat bacterial infections. Several biotechnology companies are now working on the commercialization of phage therapy. Although most

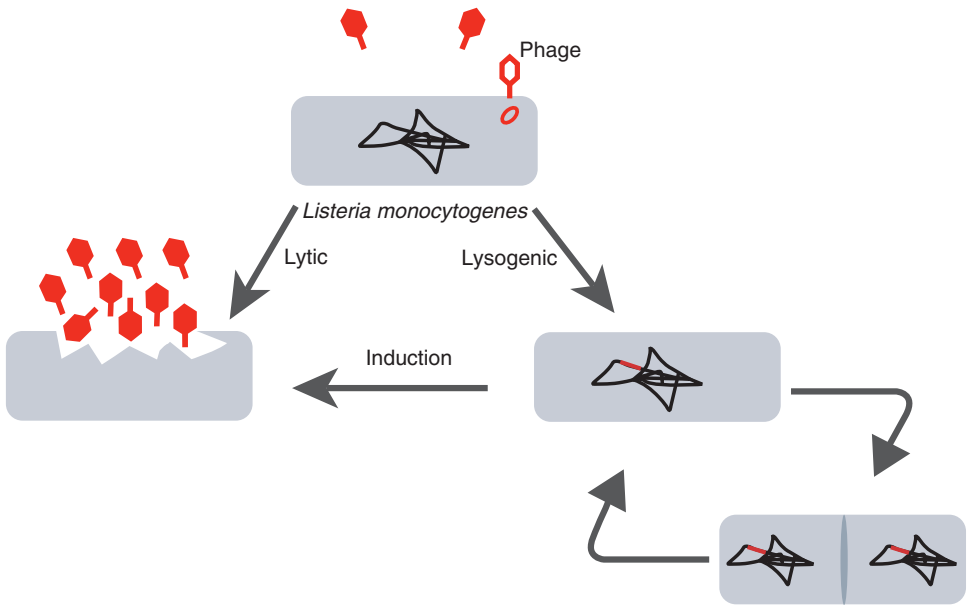

Figure 2 Bacteriophage infection begins with attachment of the phage to the host cell surface and subsequent injection of the phage nucleic acid into the host cell. The lytic life cycle results in the rapid production of progeny bacteriophage, lysis of the host cell, and phage release. The lysogenic life cycle occurs when the phage DNA integrates into the host genome, in which it is replicated and maintained in the host population during normal bacterial cell division. Induction occurs infrequently. Induced phage replicates rapidly apart from the chromosome, with consequent host cell lysis and release of progeny phage.

research on the use of bacteriophage as antimicrobials focuses on clinical applications, the use of bacteriophage as a possible means to reduce or eliminate pathogenic bacteria in foods is an emerging area of biopreservation.

The US regulatory authorities have approved the use of a phage formulation specific for *Li. monocytogenes* as an additive for ready-to-eat meats and poultry products. Consequently, commercial preparations of phages are being marketed for use in meat to control *Li. monocytogenes*. Bacteriophage preparations for use against other meatborne pathogenic bacteria, including *Salmonella* and *E. coli O157:H7*, continue to be developed with some being commercially available.

There has been only limited study of the use of bacteriophages for control of bacterial spoilage of meat. Laboratory studies have examined bacteriophage control of *Pseudomonas* spp., *Brochothrix thermosphacta*, *Le. gelidum*, and *Serratia liquefaciens*. The use of *Pseudomonas*-specific phages in trials with raw chilled beef suggested that addition of the phage extended the retail shelf life of meat by limiting bacterial growth and bacterial-associated lean tissue discoloration. However, the restricted host range of bacteriophages might limit their use for controlling spoilage, which is the result of the activities of multiple bacterial species and strains.

As with development of resistance to bacteriocins, bacteria can develop resistance to bacteriophage infection. Resistance is readily observed in controlled experiments but is seen to a lesser extent in commercial trials. To mitigate problems with resistance, bacteriophage cocktails can be used. These can contain several different bacteriophages that each use a different mechanism of cell attachment. The probability of the emergence of resistance to all components of such cocktails should be small. Ideally, the phages used as biopreservatives should be strictly lytic, because if a phage is lysogenic, development of bacteriophage resistance in the host will be promoted. Moreover, there may be other complications associated with gene exchange between host and lysogenic phage DNAs.

The interactions between bacteriophages and populations of host bacteria are complex. The efficiency of infection and cell death can be significantly influenced by the ecology of the meat. Thus, phages' concentration, threshold density of bacterial host cells, the specific meat matrix, and the storage conditions can all affect the efficacy of bacteriophage infection. Much remains to be understood about the ecology of phages in meat systems and appropriate methods for industrial application of phages before they can be routinely used as biopreservative agents for meats.

Consumer Acceptance of Biopreservation

The use of preparations containing bacteriocins or bacteriophages for meat preservation must be approved by relevant regulatory authorities. In some countries, lactic acid bacteria are considered generally recognized as safe (GRAS) organisms, which means that they can be used without any further approval, and in one instance an *Li. monocytogenes* bacteriophage has been accorded GRAS status. Bacteriocin-producing lactic acid bacteria are widely distributed and are often naturally present in fermented foods or vacuum-packaged foods, including meat products. Bacteriocin-producing lactic acid bacteria are isolated from approximately 50% of vacuum packs of sliced meat products. Such findings indicate that bacteriocin-producing lactic acid bacteria and bacteriocins are frequently consumed when vacuum-packaged meat products that have not been biopreserved are eaten. Acknowledgment of bacteriocin-producing lactic acid bacteria as usual components of meat products would likely facilitate consumer acceptance of the use of such organisms as food additives. The extent to which consumers accept the use of bacteriophage as food additives remains unclear. Consumers will probably have to be provided with appropriate information about the nature of bacteriophages and their effects on bacteria before the use of bacteriophage in foods is widely accepted.

BIOTECHNOLOGY IN MEAT ANIMAL PRODUCTION

Contents

Cloning

DN Wells, AgResearch Ltd., Hamilton, New Zealand

Glossary

Cloned animals Genetically identical animals that occur naturally in some phyla or that can be artificially produced using a variety of manipulation methods, including nuclear transfer.

Embryonic stem cells An undifferentiated cell type commonly isolated from the inner cell mass tissue of blastocyst-stage embryos. *Bona fide* embryonic stem cells can be maintained indefinitely in culture. With the appropriate induction signals, they can potentially differentiate into any somatic cell type of the body.

Nuclear (or epigenetic) reprograming Resetting deoxyribonucleic acid methylation, chromatin modification, and, ultimately, gene expression, in a differentiated somatic cell nucleus so that normal embryogenesis occurs following nuclear transfer.

Nuclear transfer The method of reconstructing a one-cell embryo from an enucleated oocyte (cytoplast) and the nucleus of a donor cell (karyoplast) to generate an embryo and ultimately a cloned animal.

Oocyte An unfertilized mammalian egg.

Pluripotent A cell that has the potential to differentiate into all three germ layers of an organism: endoderm, mesoderm, and ectoderm. However, pluripotent cells cannot develop into a fetus or adult animal themselves because they contribute poorly to the extraembryonic tissues, such as the placenta in the case of mammals.

Totipotent The ability of a single cell to divide and produce all of the differentiated cells in an organism, including the extraembryonic tissues in the case of mammals.

Introduction

A number of embryo micromanipulative techniques can be used to generate cloned livestock, the most significant of which is nuclear transfer (NT). This method involves reconstructing embryos using recipient oocyte cytoplasm and donor nuclei from individual cells. Thus, each cloned animal shares the same nuclear genetics as the original donor cell. The donor cells may be derived from embryos or somatic tissues, most notably from adults. The efficiency of NT, especially with somatic cells, is quite low, principally because of epigenetic errors in reprograming gene expression of the differentiated donor nucleus back to a totipotent state. As a consequence, aberrant patterns of gene expression during embryogenesis are believed to contribute to the cumulative losses and abnormal phenotypes observed with clones throughout development. Nevertheless, NT can produce some livestock with normal production characteristics. However, until nuclear cloning efficiency improves to levels comparable to sexual reproduction, the acceptability and utility of the technique is limited. Perhaps the best opportunity for the cloning of adults in agriculture, especially in the sheep and beef industries, is the production of teams of cloned sires from highly proven, superior progeny-tested males as an effective means of disseminating genetic gain following widespread natural mating. Cloning from embryonic cells is best combined with genomic selection, utilizing markers predictive of animal phenotype. Unique opportunities exist in both the resurrection of cloned animals following post-slaughter carcass assessment to preserve valuable genetic resources and the introduction of precise genetic modifications into the genomes of livestock via cell-mediated transgenesis.

Methods of Cloning

Animal cloning comprises a series of reproductive techniques to produce genetically identical animals. In mammals, there are four main methods:

1. blastomere separation;
2. embryo bisection;

3. embryonic stem cells combined with embryo complementation; and
4. NT.

The first two methods involve manipulating early embryos *in vitro* just a few days after fertilization (Figures 1(a) and (b)). Individual embryonic cells (blastomeres) from cleavage-stage embryos up to the four-cell stage are all undifferentiated and 'totipotent.' This means that each cell has the identical developmental potential to form offspring (following transfer back to the reproductive tract) in the same manner as the original zygote. The separated cells simply continue to divide according to their original developmental program to form a new organism. Individual blastomeres at the eight-cell stage, however, have only one-eighth the normal number of cells by the time of embryo compaction in the morula, which is insufficient for the resulting embryo to be viable. Alternatively, embryos at the morula or blastocyst stages (corresponding to days 5 and 7 postfertilization in cattle and comprising approximately 32–120 cells, respectively) can be cut into two equal halves using a microsurgical knife. The genetically identical animals produced by these manipulation methods are limited, however, to twins (or sometimes quadruplets) and mimic the processes that sometimes occur spontaneously in nature to produce monozygotic individuals. Nevertheless, embryo splitting has been integrated into multiple ovulation and embryo transfer breeding schemes to increase the number of progeny from matings between genetically superior dams and sires.

The third methodology is not currently applicable in livestock because definitive embryonic stem cells have yet to be isolated in these species. Embryonic stem cells are immortal, undifferentiated cultured cells that have been derived from embryonic blastomeres in mouse and human. Because embryonic stem cells are capable of differentiating into derivatives of all three embryonic germ lineages, but contribute poorly to placental cell types, they are defined as pluripotent. The potential of utilizing the extraordinary cellular plasticity of embryonic stem cells to produce cloned animals has been demonstrated in mice. In this species, a small group of embryonic stem cells can subsequently develop to form all of the tissues of the fetus and newborn when complemented with suitable helper cells, such as tetraploid embryonic cells, which develop into the placenta but are excluded from the fetus (Figure 1(c)).

NT is the most dramatic method of cloning because of the potential to produce extremely large numbers of clones that are genomic copies of selected individuals. Here, it is the nucleus, rather than the cell, that is totipotent. NT is essentially a replacement of nuclear deoxyribonucleic acid (DNA) between a recipient oocyte (an unfertilized egg) and a donor cell from the organism being cloned (Figure 2). The basic method was first developed in amphibians in the 1950s in order to examine the nuclear equivalence of increasingly differentiated cell types. It is noteworthy that although these pioneering studies revealed the totipotency of nuclei from larval stages, researchers were not successful in producing mature amphibians cloned from adults. In mammals, initial studies in the 1980s were restricted to undifferentiated embryonic cell types. Collectively, the data at that time suggested that cloning was more successful in those species that activated the embryonic genome later in embryogenesis, with a spectrum from mice (being most difficult), sheep and cattle (intermediate), to amphibians (relatively easy). Early mammalian experiments demonstrated the importance of coordination between the cell cycle stages of the recipient and donor cells for successful cloning. This understanding culminated in a revolution occurring in the NT field in 1996 with the birth of 'Dolly' the sheep, accomplished by Drs Keith Campbell and Ian Wilmut from the Roslin Institute in Scotland. Dolly will be forever famous as the first animal to be cloned from an adult cell. This breakthrough overturned a dogma concerning nuclear totipotency and consequently has opened new avenues of research and opportunities for agriculture and biomedicine.

Nuclear Cloning Methodology

The production of nuclear clones is a multistep process that essentially generates an entire organism with the same nuclear genetics as a selected donor cell using the technique of NT. Although there are species-specific requirements, the typical steps in the standard cloning methodology are summarized below (Figure 2):

1. Cloned animals are genomic copies of the donor cells used for NT. These can come from a variety of sources and broadly include embryonic and somatic cell types; hence the terms embryonic and somatic cell cloning, respectively. Embryonic cloning may utilize undifferentiated blastomeres or embryonic stem cells (pluripotent cultured cells derived from embryonic blastomeres; however, these have not yet been definitively isolated in livestock species). Various somatic cell types with differing degrees of differentiation derived from fetuses or biopsies obtained from selected adults can be used for NT either directly, or after variable lengths of *in vitro* culture. These primary cell cultures can be easily frozen and thawed, which provides flexibility and large numbers of cells. The optimal somatic cell type has yet to be identified. The inherent developmental plasticity of adult stem cell populations has not consistently resulted in superior cloning efficiencies, but terminally differentiated cell types typically result in very low cloning efficiency. For convenience, ill-defined dermal skin fibroblasts have commonly been used to clone adults following cell culture from an 'ear punch.' Both viable cells and intact nuclei can be obtained shortly after death (before DNA degradation), enabling suitable cell types to be isolated from carcasses (Figure 2). Furthermore, cloned animals have also been generated from tissue frozen without cryoprotectant solutions. Cultured somatic and embryonic cells can also be genetically modified *in vitro* and performing NT with these cells has many advantages in the production of transgenic animals (see Section Transgenic Animals).
2. The actual NT process begins with the enucleation of mature, unfertilized oocytes arrested at metaphase of the second cell division of meiosis. These can be obtained either by recovering oocytes from the reproductive tract a few hours following ovulation or more commonly, after *in vitro* maturation of oocytes obtained by aspirating follicles on ovaries collected from commercially slaughtered, sexually

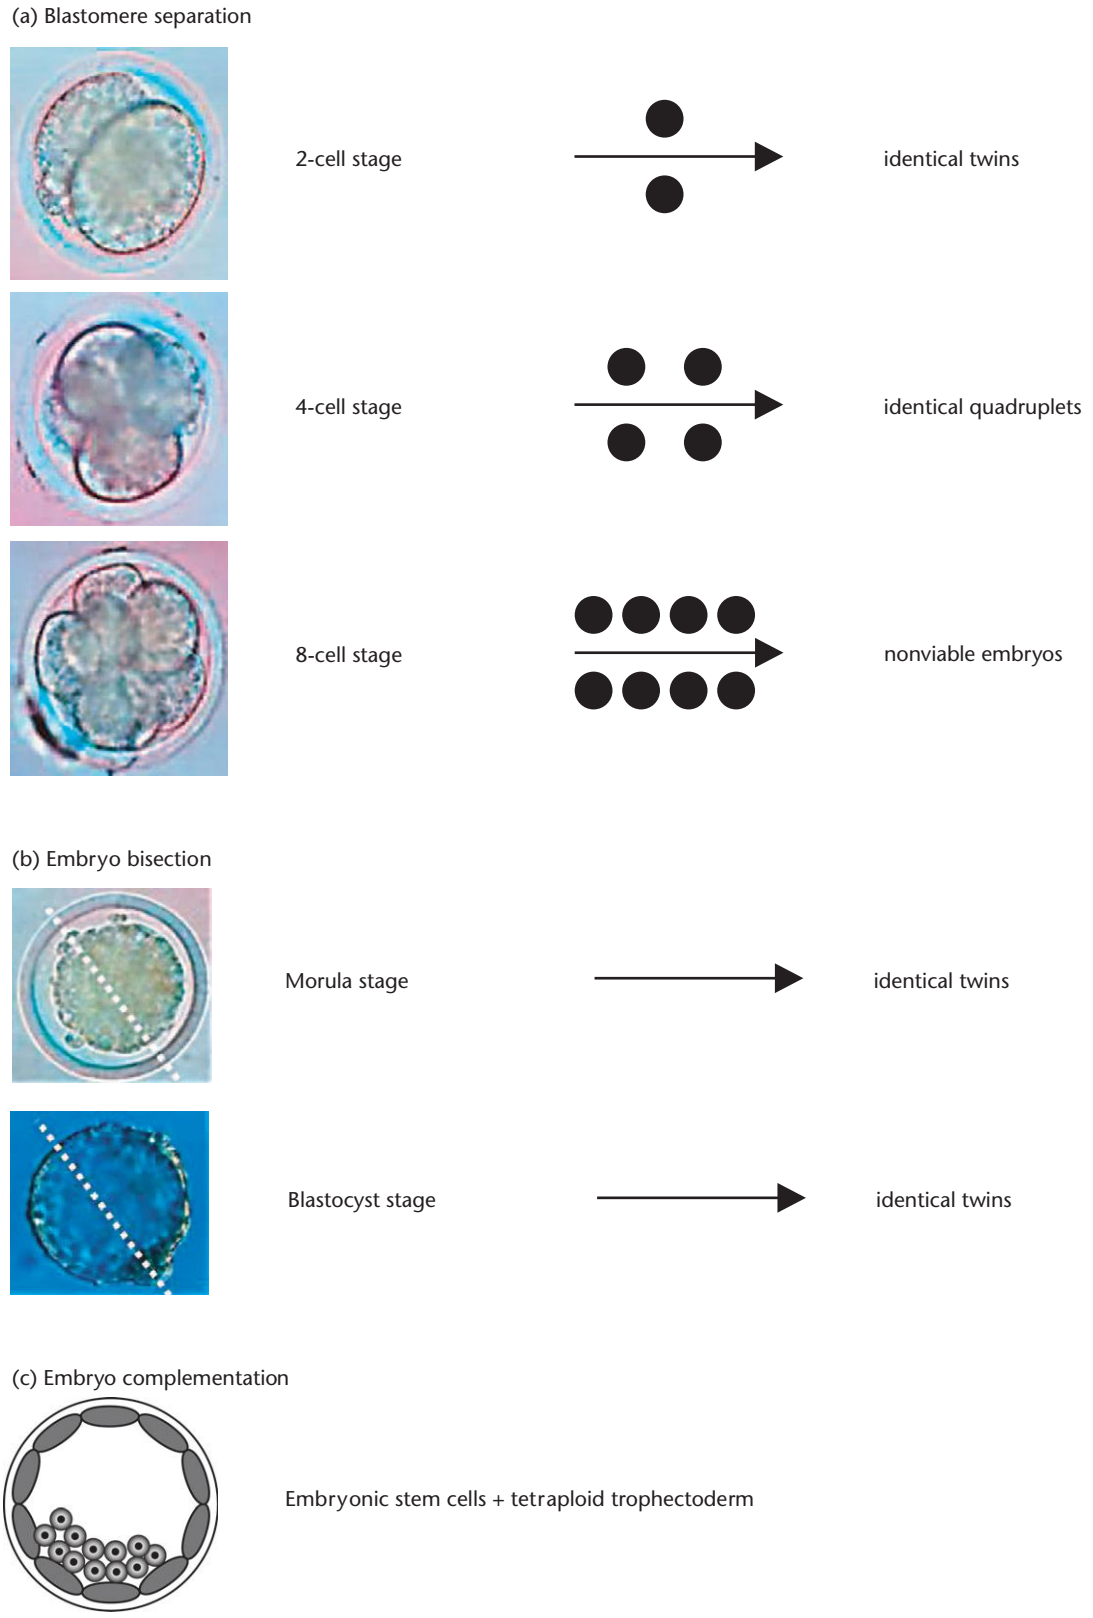

Figure 1 Cellular cloning. (a) Early cleavage-stage embryos can be separated, with each cell having the potential to produce an offspring. (b) Later preimplantation stages may be bisected, with each half possessing sufficient cells to potentially generate an animal. (c) Mouse embryonic stem cells are pluripotent (being able to contribute to differentiated derivatives of all three embryonic germ lineages) and can develop the entire fetus, but need the support of tetraploid cells in the reconstituted blastocysts to subsequently produce the placenta.

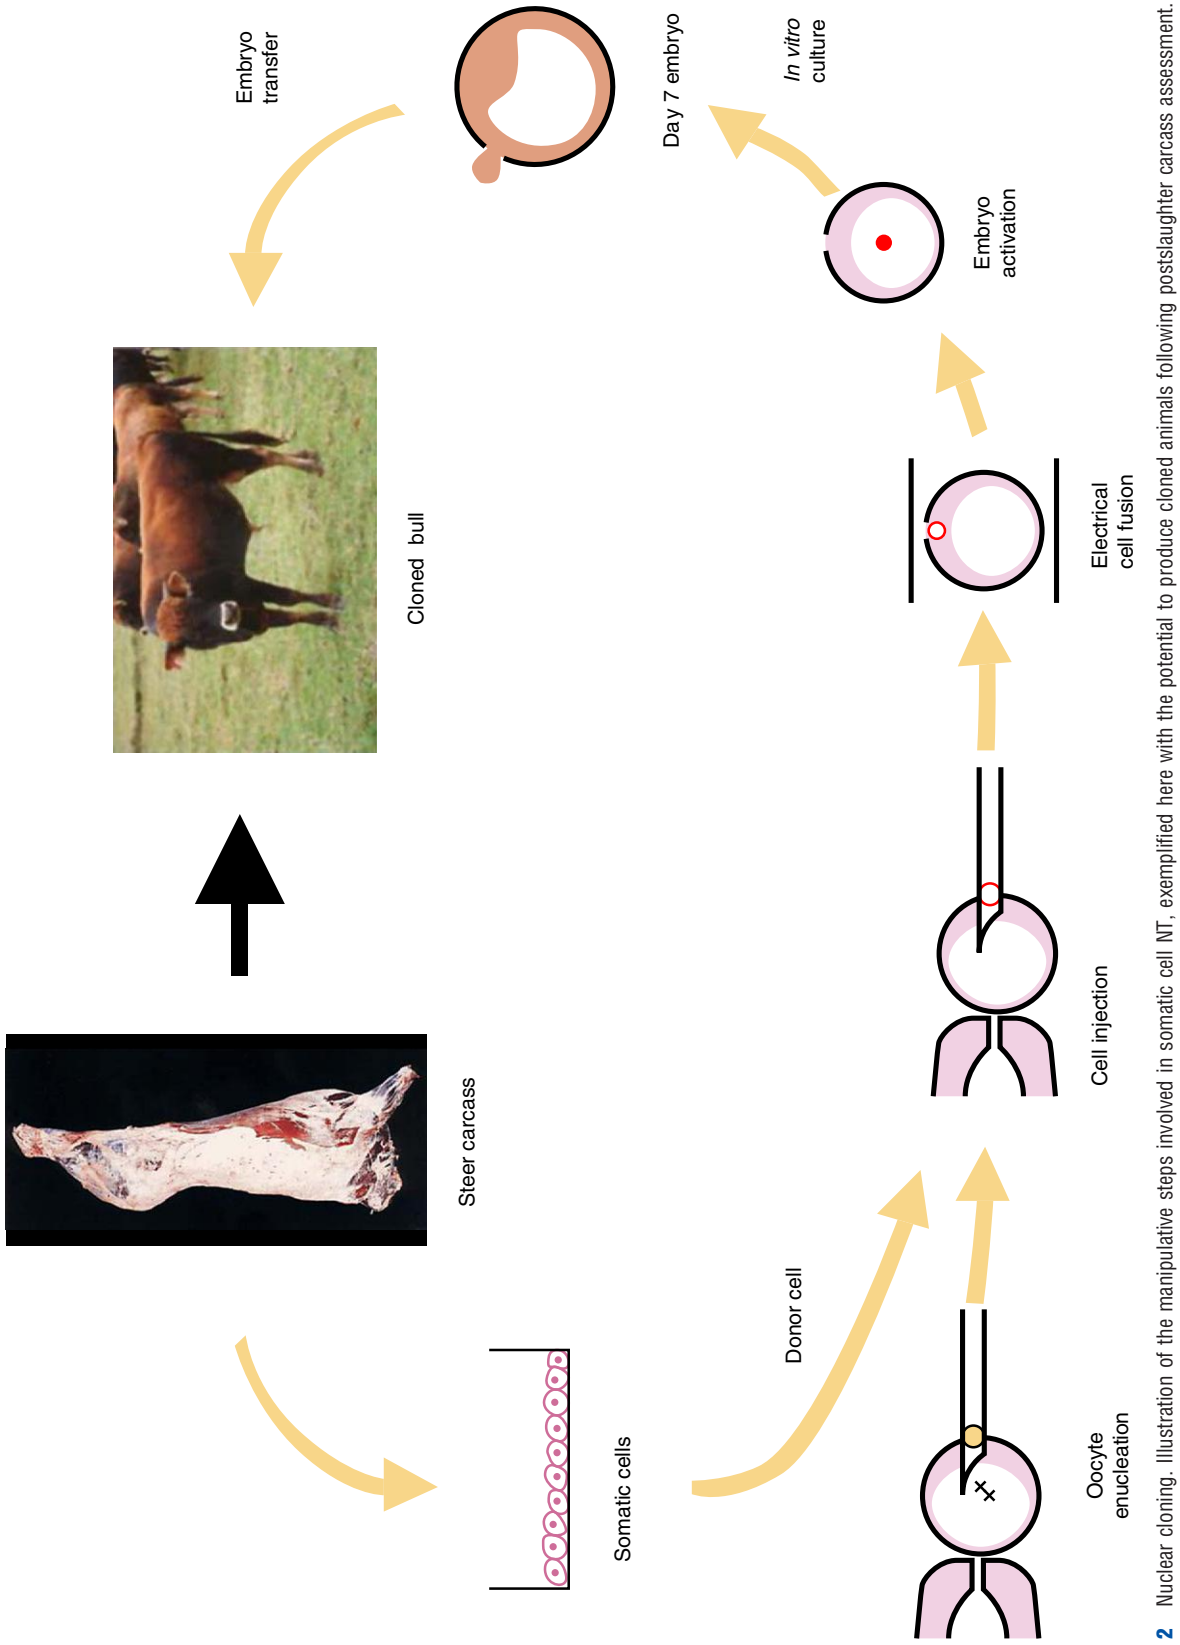

Figure 2 Nuclear cloning. Illustration of the manipulative steps involved in somatic cell NT, exemplified here with the potential to produce cloned animals following postslaughter carcass assessment. The donor cells used for NT can be obtained from a variety of somatic or embryonic types.

mature females. The enucleation process involves manipulation of each oocyte (diameter approximately 170 μm in cattle) in the microscope with finely controlled microsurgical instruments to physically aspirate the metaphase chromosomes (incorporating the oocyte's own nuclear DNA) and the extruded first polar body. Thus, the nuclear genetic material of the oocyte is removed, resulting in what is termed a cytoplast (a cell containing only cytoplasmic material). The mitochondrial DNA within the cytoplasm of the oocyte remains present (see Section Genetic and Phenotypic Identity of Clones).

3. A single donor cell is then injected underneath the outer zona pellucida (a protective membrane surrounding the oocyte and early embryo up to the blastocyst stage) and adjacent to the cytoplast membrane. Alternatively, the donor nucleus can be isolated and directly injected into the cytoplasm (circumventing fusion in step 4).
4. The cytoplast and the donor cell couplet are then correctly aligned in a fusion chamber comprising two parallel electrodes and fused together in a direct current electrical field. Thus, the genetic information contained within the nucleus of the donor cell enters the cytoplast. This is the essence of the term 'nuclear transfer,' whereby the genetic information of the oocyte is removed and replaced with that from the donor cell. Immediately following this embryo reconstruction, the donor nucleus has the opportunity to be 'reprogramed' following molecular exchanges between factors present in the oocyte cytoplasm and the donor chromatin (see Section Complete Reprograming).
5. The reconstructed one-cell embryos are then artificially activated using either chemical reagents or electrical pulses, in order to initiate embryonic development. This is *in lieu* of fertilization and ideally should mimic the repetitive intracellular calcium oscillations of the correct amplitude, frequency, and duration that simulate sperm activation.
6. Following activation, the cloned embryos are typically cultured *in vitro* in a species-specific medium to allow early development to be assessed. Culture systems that direct cloned embryos along appropriate metabolic pathways have improved development.
7. Blastocysts of suitable quality (after 7 days of culture in sheep and cattle) are then transferred to the uteri of synchronized recipient females for development to term and the eventual birth of cloned offspring that possess the same nuclear genetics as the original donor cells.

Current Efficiency of Nuclear Transfer

NT-derived clones have been produced from an ever-increasing range of species that includes laboratory mice, the major domesticated mammalian meat-producing species (including cattle, buffaloes, sheep, pigs, and goats), but not yet in poultry species. Successful cloning is influenced by many factors, one of which is the degree of differentiation of the donor cell. Expressed as the percentage of cloned embryos transferred into recipients that result in healthy offspring surviving into adulthood, the efficiency of embryonic cloning is approximately one order of magnitude higher than that of somatic cell cloning (30–40% vs. 1–15%). Specifically at AgResearch, the proportion of one-cell cattle embryos reconstructed with somatic donor cells that develop into transferable-quality blastocysts (40%) is comparable to that following *in vitro* fertilization. However, despite initial day 50 pregnancy rates being similar to those achieved with sexual reproduction (60%), the proportion of transferred cloned embryos that result in viable calves at weaning (15%) is only one-third that following *in vitro* fertilization (45%). This highlights the high rates of gestational loss that raise serious animal welfare concerns with the present cloning technology.

Complete Reprograming

One critical aspect allowing normal embryogenesis following NT is correct reprograming of the pattern of gene expression in the donor nucleus to a state comparable to that in a fertilized zygote. This involves epigenetic modifications to the organization of the donor chromatin to switch off the expression of those genes specific for the differentiated phenotype of the donor cell, and for the appropriate embryonic genes to be reactivated in the correct tissues, in the correct abundance and at the correct times to enable the cloned embryo and fetus to grow and develop normally. Our understanding of this highly orchestrated process is still evolving. Faithful expression of key embryonic genes occurs more reliably with undifferentiated embryonic cells as opposed to somatic donor cells. A functional measure of complete reprograming is evidenced by those surviving cloned animals that do display normal physiology, behavior, growth, reproduction, livestock production characteristics, and lifespans. However, even in apparently normal clones, detailed gene expression analyses indicate aberrations in up to 4% of genes implying that development is rather tolerant of subtle epigenetic differences.

Incomplete Reprograming

In the majority of reconstructed embryos, there is increasing evidence of epigenetic errors in reprograming following NT, leading to abnormal patterns of DNA methylation, chromatin modification, and X-chromosome inactivation, culminating in the misexpression of both imprinted and nonimprinted genes. The pattern of mortality and abnormalities observed following NT presumably reflects the inappropriate expression of various genes whose harmful effects are exerted at different stages of development. Moreover, sublethal aberrations that occur early in embryo or fetal development may impair subsequent health in adulthood. There is a wide spectrum of phenotypic outcomes, ranging from those that are lethal to those that are more benign and may not compromise the health and welfare of the cloned animal. As expected, the incidence and severity of the abnormalities are increased in somatic cell clones compared to embryonic clones because of the greater difficulties in reprograming a more differentiated nucleus. Understanding the molecular mechanisms involved in reprograming will ultimately improve cloning efficiencies.

The consequences of incomplete reprograming following somatic cell NT are commonly higher rates of pregnancy loss, complications during parturition, and higher postnatal losses.

Placental Abnormalities

A failure of the placenta to develop and function correctly is a common feature amongst cloned pregnancies. There are species differences in the patterns of loss during gestation but in cattle, typically 50–70% of pregnancies at day 50 are lost during the remainder of gestation compared with only 0–5% with artificial insemination. Of particular concern are the losses in the second half of gestation, especially the occurrence of hydroallantois. The accumulation of excess fluid in the allantois can be four times greater than normal. The natural occurrence of hydroallantois is rare; however, in cattle typically 25% of those cows pregnant at day 120 of gestation with clones develop the clinical syndrome. Research is underway to identify nonviable pregnancies much earlier to lessen the welfare burden. Ultimately, improved reprograming should solve this problem and increase the success.

Parturition Difficulties

Intervention is often necessary to deliver cloned offspring, as gestation length is typically prolonged and birthweight of clones can be 25% heavier than normal. Corticosteroid therapy has been used successfully to aid fetal maturation and increase the occurrence of normal vaginal delivery and subsequent rearing. Although not completely natural, this approach toward controlled parturition is feasible and acceptable on farm.

Postnatal Viability

The viability of cloned offspring at delivery and survival into adulthood depends on species, and is particularly reduced in sheep and cattle but less so in pigs and goats. The range of pathologies includes neonatal respiratory distress, defects in the cardiovascular, urogenital, neural, and skeletal systems, as well as increased incidence of chronic umbilical and lung infections. The cell cycle stage of the donor nucleus at the time of NT affects postnatal viability. Cloned calves derived from quiescent adult donor cells (in G_0 phase of the cell cycle) have significantly greater viability up to weaning compared with those derived from proliferating cells (in G_1 phase of the cell cycle; 80% vs. 50%).

Long-Term Consequences

Although clones can be physiologically normal and apparently healthy at birth, or require some time postnatally to adjust to normal homeostasis, other reports indicate abnormal clone-associated phenotypes that become apparent during juvenile and adult life. These have included obesity and shortened lifespan in mice and compromised immune systems in cattle. The incidence of these anomalies depends on the particular species, genotype, sex, cell type or specific aspects of the NT, and culture protocols used. This emphasizes the need for detailed long-term scientific studies on the health and longevity of cloned animals, especially livestock with greater biological lifespans than mice. In cattle, the current data indicate lower survival of clones between birth and 2 years of age (ranging between 47% and 80%). Although farmed livestock rarely get the opportunity to live to their biological limit, long-term viability remains an important issue with premature aging possibly affecting production characteristics, such as meat quality. The cloned offspring syndrome is a continuum, in that lethality or abnormal phenotypes might occur at any phase of development, depending on the degree of dysregulation of key genes. Even apparently normal clones can misexpress many genes without resulting in any obvious phenotype. This indicates that development is rather tolerant of some stochastic variation, at least up to a threshold, beyond which it presumably predisposes animals to some pathological condition.

Figure 3 The offspring of clones produced following sexual reproduction appear phenotypically normal, suggesting that any epigenetic errors are largely corrected during gametogenesis. This lamb resulted from the natural mating between a cloned ram (left) and a cloned ewe (center) and lacked the typical pregnancy and health complications associated with its cloned parents. Reproduced with permission from Wells, D.N., 2003. Cloning in livestock agriculture. Reproduction Supplement 61, 131–150.

Transgenerational Effects

Although there are problems in the cloned generation stemming from incomplete reprograming, the offspring of surviving clones produced following sexual reproduction appear completely normal (Figure 3). This has been most clearly demonstrated in mice; where XY male and XO female clones from the same embryonic stem cell line were mated together and produced phenotypically normal offspring, thus excluding the possibility of transmission of deleterious recessive genetic or epigenetic mutations. This indicates that the abnormal phenotypes in clones are largely epigenetic in origin and that these errors appear to be corrected during gametogenesis. This has been substantiated following the analysis of DNA methylation in the sperm of cloned bulls and provides initial confidence in those applications of NT that capture the potential of breeding from genetically elite clones.

Genetic and Phenotypic Identity of Clones

Unlike monozygotic twins, NT-derived animals are not strictly 'true clones' and there is the expectation of greater phenotypic differences among members of a clonal family (a set of NT clones derived from the same source of donor cells) than implied from the broad heritability of specific traits. There are

additional genetic, epigenetic, and environmental differences potentially contributing to variations in phenotype between clones. For instance, NT clones might possess different mitochondrial DNA derived from the recipient oocytes (if obtained from different maternal lineages). Moreover, mitochondrial DNA heteroplasmy might exist, where each cell comprises two mitochondrial genotypes, with the majority from the recipient oocyte and a minor contribution from the fused donor cell. This might have subtle but measurable effects on some livestock and meat production characteristics and could be put to advantage by combining favorable nuclear and maternal lineages. Thus, nuclear clones might at best be genomic copies of the donor cells. However, possible nonlethal point mutations or other chromosomal rearrangements in the genomic DNA of individual donor cells or which arise during embryo culture would create clones that might not even be faithful genomic copies of the donor animal. The majority of these genetic differences are likely to be inconsequential, similar to most spontaneous mutations. Epigenetic variations between clones arise from alterations in the patterns of gene expression during *in vitro* culture (of individual donor cells or embryos) and from stochastic reprograming of the donor genome following NT. Alternative patterns of mosaic X-chromosome inactivation would also be expected in cloned females. Finally, each donor nucleus/embryo/cloned animal is exposed to different environmental influences from the individual recipient oocyte cytoplasm, maternal uterus in each surrogate female, and during postnatal development. All these factors contribute to potential variations in phenotype (and genotype also in some cases) within a clonal family and deviations from the original founder animal. Despite this, the variation in livestock production traits within a clonal family would be less than the herd or population distribution, and would be dependent on the heritability of the trait. In practice, this is observed in cloned dairy cows where the composition of the milk from cloned cows is very similar to the milk of the original donor cow.

Food Safety

Despite the subtle phenotypic variability in surviving clones affecting livestock production traits, the composition of food products derived from cloned livestock is within the normal range and has been demonstrated safe to consume from animal feeding trials. It is important to note that, in most agricultural applications of cloning technology, considerably greater numbers of sexually derived progeny of clones enter the food chain, rather than the primary clones themselves.

Cloning Applications in the Meat Industry

Potential opportunities of cloning include increasing and disseminating genetic gain, the conservation of livestock genetic resources, and the production of transgenic animals. Many of these opportunities are not commercially viable until cloning efficiencies improve markedly.

Increasing Genetic Gain

Cloning might be appropriately integrated into existing breeding schemes to aid the phenotypic evaluation of selected animals, and thus contribute to additional increases in the rates of genetic progress without any increase in the rate of inbreeding. Effective breeding programs require the accurate identification of superior livestock in the nucleus population before the subsequent dissemination of their genes into the commercial population using various assisted reproductive technologies. Genomic selection strategies that allow for the identification of favorable genes or single nucleotide polymorphism markers that correlate with production will aid in selecting desirable genotypes in the future. However, actual performance might remain uncertain unless markers have exceptional predictive value for polygenic quantitative traits.

NT could be used to produce many small clonal families from selected animals. The phenotype of each family could then be determined by evaluating individual members in a variety of environmental conditions, and thus enhance genetic progress by increasing the accuracy of selection. This would also enable easier identification of genotype × environmental interactions. The evaluation of clonal families requires fewer clones per family compared with the number of offspring per parent in progeny-testing schemes to give the same accuracy of selection. This is because the clones in a family are all of the same genotype and will average out the environmental influences. However, the ideal number depends on the trait, with those of lower heritability benefiting from additional accuracy and, hence, larger family sizes. At a fixed number of animals evaluated in a breeding scheme (clones or progeny), clonal testing possibly enables greater selection pressure to be exerted by measuring more cloned families or genotypes. Another possibility is the use of lines of cloned dams in sire-proving schemes, to reduce the cost and increase the accuracy of selecting elite males for the artificial insemination industry.

The rate of genetic gain would be further enhanced by evaluating clones produced from selected embryos or embryonic cell lines to avoid the genetic lag of up to three generation intervals associated with the cloning of adults. These cell lines could be derived from embryos previously screened as superior by genomic selection following matings within nucleus breeding herds. With beef animals, for example, lines of cloned cattle could be generated and specific meat quality characteristics directly measured by harvesting some clones within each line. In those clonal lines that perform favorably, the remaining cloned animals could be used for breeding. In addition, other clones could be readily produced by thawing the appropriate frozen cells and using NT to release a larger number of the desirable animals to the industry. An extension of this is to identify carcasses with genetically superior meat characteristics shortly after harvest and to clone animals from recovered cells either for breeding or commercial meat production and, therefore, rescuing these valuable genetics (Figure 2).

Dissemination of Genetic Gain

Efficient cloning could enable the rapid dissemination of superior genotypes from nucleus breeding flocks and herds, directly to commercial producers (Figure 4). By multiplying the most superior clonal families, it has been estimated that in the dairy industry this might provide a substantial increase in

Figure 4 The application of nuclear cloning to produce multiple copies of genetically superior livestock. Somatic cells collected from the ovarian follicles of the donor cow provided the nuclear genetics to produce the 10 cloned calves.

Figure 5 The integration of cloning in the conservation of rare farm animal genetic resources. The cow in the background was the last surviving individual of the Enderby Island cattle breed, adapted to harsh sub-Antarctic conditions. Assisted reproductive technologies have been used to produce a bull calf (right), following transvaginal ovum pick-up and *in vitro* fertilization with frozen–thawed sperm available from one of nine, now dead, Enderby Island bulls, and a cloned heifer calf (left) that is a genetic duplicate of the cow. Further assisted reproduction has contributed to increasing the genetic diversity of this cattle breed. This work was supported by both AgResearch and the New Zealand Rare Breeds Conservation Society.

genetic merit for individual producers in a single generation equivalent to 15 times the annual genetic gain achieved with conventional progeny-testing schemes. The rate of genetic gain then matches that of the nucleus population until the next outstanding individuals are identified and clonally disseminated. Whole genotypes could be provided that are ideally suited for specific product characteristics or environmental conditions. Outstanding F1 crossbred animals, or composite breeds with otherwise complicated and expensive breeding strategies, could be cloned to maximize the benefits of both heterosis and greater uniformity within the clonal family without segregation of alleles following breeding. Cloned genotypes could be disseminated by the controlled release of selected lines of elite live animals for breeding or on a larger scale by the transfer of frozen/thawed cloned embryos. The embryo costs need to be relatively low, although a premium should be expected for high value known genetics of proven performance compared with semen from a progeny-tested sire that only provides half the genes and an unknown performance in the individual offspring. The marketing of cloned embryos would be an alternative to artificial insemination, but needs to be cost effective and as successful in terms of pregnancy rates, with the infrastructure and technical expertise required for extensive embryo transfer on farms, if it is to be adopted. It is noteworthy that even less complex reproductive technologies, such as *in vitro* fertilization are difficult to implement in low-cost pastoral agriculture systems and require excellent husbandry and management practices to succeed. However, if the cloned genotypes generate either novel or value-added products for which farmers receive a premium, then there might be greater economic incentive for technology adoption.

The first major commercial opportunities for cloning in agriculture will be the production of small numbers of cloned animals with superior genetics for breeding. Ideally, these would be cloned sires from highly proven, superior progeny-tested males for widespread dissemination of their elite genetics following natural breeding or, alternatively, increased semen production for artificial insemination. If cloned sires are faithful genomic copies of the original donor, this application avoids confounding issues with the transmission of mitochondrial DNA (which is only maternally inherited) and phenotypic differences arising from environmental influences, as they only need to transmit haploid copies of the donor's genome in the form of sperm. Importantly, initial results indicate that any subtle epigenetic errors in the clones are corrected via gametogenesis with resulting offspring being apparently normal. In sheep and beef industries, the use of teams of cloned sires, representing multiple copies of genetically elite males, for widespread natural mating could substitute for artificial insemination to effectively disseminate superior genes more widely throughout the population. Artificial insemination is poorly adopted in these more extensive farming systems because it is often expensive and inconvenient for farmers, quite unlike the situation in dairy industries where it has been a very successful technology to disseminate genetic gain.

Animal Conservation

Cloning can be integrated into assisted reproductive strategies to conserve rare farm animal genetic resources that should not be lost from the global gene pool (Figure 5). As most of the genetic variation in a livestock species resides in the various different breeds, the demise of indigenous or traditional breeds represents a very significant loss of biodiversity and limits any future opportunities to capture as yet unappreciated traits. More important than cloning per se, is the cryopreservation of somatic cells from rare breeds of livestock. The cryobanking of this genetic material would provide an insurance policy against further losses of diversity or possible extinction. NT could then be used to produce a clone of a deceased animal using a previously cryopreserved cell, and thus reintroduce its genetics back into the live breeding

population. Moreover, the collection and cryopreservation of somatic tissues and cells is more straightforward than the specialized and expensive protocols required for gametes and embryos. Even for conventional agriculture, it is prudent to cryopreserve cells from genetically elite animals in case of accidental death or disease.

Transgenic Animals

NT is one of several methods available to produce transgenic animals. This cell-based approach, however, has a number of distinct advantages, including: (1) the ability to introduce specific genetic enhancements to an existing genetically superior background using cells from an animal of chosen performance and sex (especially important for agricultural applications); (2) efficient production of transgenic offspring (even with current NT methods); (3) the ability to produce lines of transgenic animals rather than individual founders; (4) the potential to introduce a more extensive range of genetic modifications to the cells cultured *in vitro*; and (5) all of the transgenic animals should transmit the genetic modification through the germline rather than be sexual mosaics.

Although it is still commonplace for introduced genes (either from the same species or a different species) to be integrated at a random location within the genome, methods of site-specific integration enabling 'gene targeting' in somatic cells of livestock have been successful at some loci. Gene targeting also allows for either the functional deletion of an undesirable gene on an otherwise favorable genetic background, or to precisely alter the nucleotide sequence of a particular gene to improve a particular function in the resulting protein. However, gene targeting in primary somatic cells is considerably less efficient than with embryonic stem cells (at least, in mice). This should prompt renewed interest in attempting to isolate these pluripotent cells in livestock species with the concomitant advantage of greater NT efficiency as demonstrated in mice. The combination of NT and gene targeting has the potential to be far more precise, extensive, and rapid in terms of genetic progress than what can be achieved with traditional breeding and other available transgenic methods. For agricultural applications, cloned-transgenic males, homozygous for the trait of interest, could be used for artificial insemination or natural mating to rapidly introduce the desired genetic change into the population.

Conclusions

To develop an acceptable NT technology with wide applicability, solutions to the problem of cloning abnormalities must be found. It is recognized that the health and well-being of clones must be equal to that of conventional animals. This goal will be accomplished by improvements to the various steps of the NT process and from a greater fundamental understanding and control of reprograming. Current evidence indicates that the abnormal clone phenotypes are largely due to epigenetic errors, which are corrected during gametogenesis and are unlikely to be transmitted to sexually produced progeny. This is encouraging for the potential of cloned sires to effectively disseminate genetic gain through natural breeding or artificial insemination.

This article is a revision of the previous edition article by MB Solomon, volume 1, pp 84–91, © 2004 Elsevier Ltd.

Glossary

Chimera An animal composed of at least two different cell types. Usually these animals are made from injecting an embryonic stem cell into a blastocyst stage embryo.

Embryonic stem (ES) cell Stem cells derived from the inner cell mass of a blastocyst which are able to differentiate into all embryonic tissues.

Genetically engineered A cell or animal that has had the sequences of bases within its deoxyribonucleic acid (DNA) purposefully rearranged.

Genetically modified organism (GMO) An animal that is genetically engineered by addition of a gene (transgenic), or removal of a gene (knockout).

Lentivirus From the Retroviridae family, unique ability among retroviruses of being able to infect nondividing cells.

Pronuclear injection The use of a fine needle to inject DNA into the nucleus of an unfertilized egg.

Ribonucleic acid (RNA) interference Means of gene expression within the cell where small pieces of RNA are utilized to target degradation or translational inhibition of specific genes.

Short hairpin RNA (shRNA) A sequence of RNA that makes a tight hairpin turn that can be used to silence target gene expression via the RNA interference (RNAi) pathway in the cell.

Transgenic An animal that has a gene from another species inserted into its genome.

Zygote Earliest developmental stage of the embryo formed after fusion of male and female gametes.

Introduction

A genetically modified organism (GMO) is an organism in which genetic material is altered by genetic engineering technology. GMO may sound futuristic; however, one is already surrounded by foods derived from GMO products, as they have been present in one's food supply for decades. For example, a large portion of the various crops one consumes is GMO. In contrast, animals considered as GMO cannot enter the food supply without food and drug administration (FDA) approval. Moreover, the cost for producing transgenic animals is very expensive, thus application of transgenic animals is very limited. Dramatic advancement in the technologies used for transgenic animal production may allow one to see animal-based GMOs that can enter the food chain. A discussion of the status of GMOs in the meat food supply will be provided at the end of the article as it is still controversial and under debate.

Methods to Produce Transgenic Animal Production

The first transgenic animal was reported in 1980. Transgenic mice were born by introducing foreign deoxyribonucleic acid (DNA) into a mouse pronucleus; a procedure termed pronuclear (PN) injection. This technology permits introduction of foreign DNA into an embryo at the single cell stage. If the DNA is integrated into the zygote's genome, then it is replicated with the rest of the DNA. Thus all the cells of the embryo and hence all the cells of the resulting animal contain the genetic modification. This technology is still used to produce transgenic animals; however, there are some disadvantages of using this technology. PN injection can neither control the number of copies that are integrated nor the site of integration, thus there is less control over the expression of the transgene. In addition, founder animals often exhibit mosaicism, where the animal is made up of both modified and unmodified cells because the foreign DNA often integrates after the one-cell stage. Various transgenic animals have been produced using PN technology but the efficiency of creating a founder animal with the genetic modification represented in the germ cells is lower in other species compared to mice.

Transgenic mouse production became more practical with the development of embryonic stem (ES) cells and gene targeting. ES cells are derived from early embryos and can contribute to various cell types including germ cells when transferred into host embryos. Because of the availability of ES cells, genetic modification can be performed *in vitro* and genetically modified ES cells then introduced into host embryos. If the modified ES cells contribute to the germline, then this method can result in the production of chimeric mice. Transgenic mice with the desired genetic modification can be produced by simple mating. When gene targeting technology is combined with the ES cells, transgenic mice with specific genetic modifications can then be produced. This approach is very effective and has become the standard protocol to produce knock-out mice. However, this is unique to mice and rats because to date there have been no ES cells derived that can be used for this approach in other species.

Because of a lack of ES cells, transgenic animal production has been limited in species other than mice. This was changed when the first mammal was cloned from a somatic cell. The production of such sheep as Megan and Morag (first animals cloned from differentiated cells), the now famous Dolly (first animal cloned from an adult cell line) and Molly and Polly (first transgenic animals produced using somatic cell nuclear

 doi:10.1016/B978-0-12-384731-7.00006-4

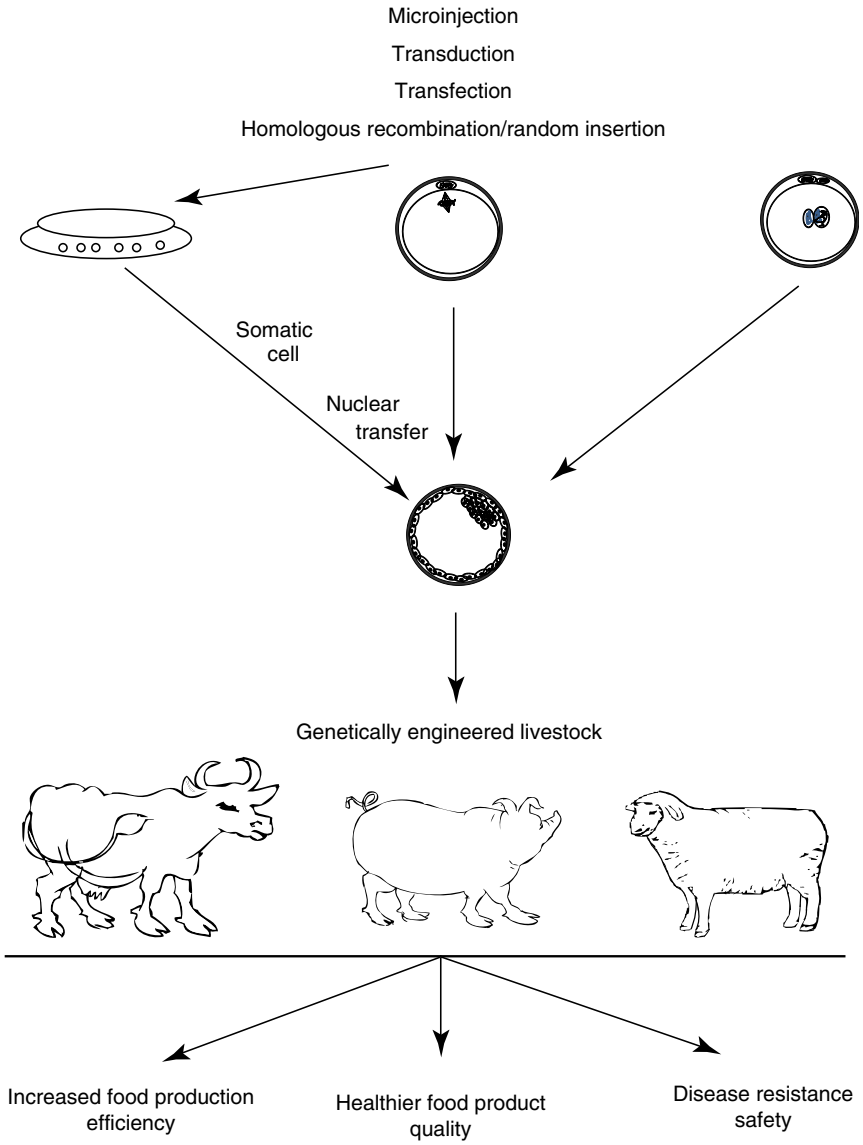

Figure 1 Schematic showing how genetic engineering can result in an early embryo that will produce an animal (cow, pig, and sheep) with the genetic modification. Such genetic modifications can increase the efficiency of meat production, make a healthier product, or result in animals that are more resistant to disease.

transfer (SCNT)) opened the door to genetic modifications that could be conducted in somatic cells *in vitro* which could then be used to produce a transgenic animal. Now SCNT technology is routinely used to produce transgenic animals in many species. However, the efficiency of genetic modification in somatic cells and cloning is extremely low, leading to the development of alternative means of transgenic livestock production.

One of these technologies is the use of a virus to deliver foreign DNA into an embryo. Certain viruses, such as retroviruses, can effectively transduce cells, oocytes and embryos when exposed to the cell surface. When oocytes were exposed to viral vectors containing foreign DNA, transgenic animals were produced in livestock animals such as cattle and pig. Advancements in this technology include the use of replication incompetent lentiviral vectors, which transduce both dividing and nondividing cells and are heritable through the germline. This method has been shown to be effective in producing transgenic cattle and swine. In addition, viral vectors have been used to generate specific genetic modifications in somatic cells that were in turn used to produce transgenic animals through SCNT. Viral vectors are certainly a way to produce transgenic animals but the viral vector can only deliver limited size of DNA fragment into the target cells (Figure 1).

Recent studies show a new possibility of producing a transgenic animal with a specific genetic modification. Zinc finger nucleases (ZFN) can be used to induce a random mutation in a specific location in zebrafish and rat embryos. ZFNs have ability to recognize specific sequences on chromosome and induce double strand break (DSB) at that location. Cells will not survive with the DSB, thus a repair mechanism is activated that results in a mutation during the repair process.

The report in the rat was a significant development because it showed that specific genetic modification could be induced in the mammalian embryonic state. It also suggested that this could be successfully utilized in other species. However, when ZFN has been introduced into pig zygotes, it showed promising results *in vitro* but there have been no viable piglets produced from the embryos. It is unknown why ZFNs are effective only in the zygotes of certain species. Application of ZFNs in transgenic animal production raises some questions on the definition of transgenic animals. In theory, ZFNs can produce transgenic animals without any trace of foreign DNA because the mutation is caused from the internal mechanism. Because of the uniqueness it will be interesting to see the future of ZFNs in transgenic animal production.

There are various methods to produce transgenic animals but there are challenges and limits in each method. Currently, production of transgenic animals on a large scale is not practical due to technological obstacles and cost. Therefore, most of transgenic animals that have been produced have been for research purposes. However, the technology provides a new avenue for improvement of livestock and specifically meat production, with the advantage of making significant genetic progress while decreasing the generation time that's normally needed with selective breeding methods.

Use of Genetically Engineered Animals in Meat Production

The ability to genetically modify food animals in order to enhance meat production provides new opportunities for livestock improvement beyond what selective breeding can achieve. Genetic modification includes not only the addition or deletion of an existing gene, but also the possibility of adding a gene from another species or utilizing already existent cellular pathways in novel ways; such as ribonucleic acid interference (RNAi). Adding a gene to improve meat quality was first investigated in 1990, when an additional copy of the growth hormone gene was introduced into swine. Earlier reports using mice demonstrated an effective increase in muscle growth using this method. However, an inability to control expression level of the gene caused researchers to halt further work with this modification. The advent of SCNT in sheep in 1997 provided a new means of modifying gene expression by allowing modification of a somatic cell line *in vitro* prior to producing embryos for transfer. This renewed interest in gene modification, paved the way for production of animal models that could someday be used to improve meat quality and production.

Current Examples of Genetic Engineering of Animals

In 2006, genetic modification was introduced to produce swine that express a gene isolated from *Caenorhabditis elegans* called *Fat-1*. The *Fat-1* gene's codons were engineered to be optimized for use in mammals prior to introduction into the pig. This gene is an *n*-3 fatty acid desaturase that converts *n*-6 fatty acids to *n*-3 fatty acids, more commonly known as omega-3 fatty acids. Omega-3 fatty acid content of red meat such as pork and beef is normally quite low because beef and swine lack an omega-3 fatty acid desaturase gene, and methods currently used to increase the omega-3 fatty acid content, such as alteration of feed ration formulations, have shown only nominal increases in content. The health benefits of consuming meat high in omega-3 fatty acids have been widely recognized. The pigs GMO produced that contain the *Fat-1* gene had elevated levels of omega-3 fatty acids in their muscle. Therefore this modification has great potential for improving the quality of the meat that is produced, and possibly the health of the animal. In 1997, the genetic modification behind the double muscling phenotype in Belgian Blue cattle was identified as a mutation in the myostatin gene, which produced an inactive protein. This mutation resulted primarily in hyperplasia (increase in number) of the muscle fibers, essentially doubling the muscle produced by one individual. Another effect of myostatin inactivation was a decrease in fat deposition, producing a leaner meat. However, this also reduced the amount of marbling in the meat; which, in many cultures, made it less desirable in taste and tenderness. Additionally, increased birth weights of the offspring contribute to dystocia in these animals, often requiring cesarean section delivery of calves. Hemizygous mutations in both mice and cattle demonstrate that the double muscling effect is dose dependent, resulting in an approximate 50% increase in muscling. This suggests that modulating the level of myostatin expression may allow us to benefit from this modification without the negative side effects seen in breeds such as Belgian Blue cattle. In 2011, researchers at Texas A&M University reported the production of calves expressing a short hairpin RNA (shRNA) targeting the myostatin gene. shRNAs work through the RNAi pathway and provide a method of decreasing the expression of a gene without eliminating its expression altogether. Other examples of increasing meat production through the use of genetic engineering include the development of transgenic trout and salmon, the latter of which will be discussed in the Section Food Safety/Approval of Genetically Engineered Animals.

Genetic modifications could also be extended to protection and improvement of the animal itself, increasing productivity and decreasing incidence of disease. One example of this is the *PrP* gene, a mutation of which results in bovine spongiform encephalopathy. Although elimination of animal-born feedstuffs such as bone and blood meal from livestock rations has dramatically reduced both the potential and the actual incidence of this disease in the US, four isolated cases in the US have still been confirmed, and spontaneous mutation of the endogenous PrP protein is still a concern. In 2006, RNAi was utilized to reduce PrP protein in goats, and then work by Richt *et al*. in 2007 produced cattle in which the *PrP* gene was ablated. Analysis of the cattle revealed that they were not only were phenotypically and immunologically normal, but that their cells also are resistant to prion propagation *in vitro*. Another example of how genetic modification can be used to improve animal health is the introduction of the lysostaphin gene into the mammary glands of cattle. This gene is used as a defense mechanism by *Staphylococcus* stimulants to guard it against other invading bacteria, including *Staphylococcus aureus*. *Staphylococcus aureus* infections in dairy cattle are extremely hard to cure, and infected animals usually end up being culled.

Expression of the lysostaphin gene in the mammary tissue of transgenic cattle effectively eliminated infection by *S. aureus* when challenged with a intramammary dose.

Another example affecting the quality of the animal product is that of people that are allergic to cow's milk. The most common immunogene is β-lactoglobulin. A transgene has been introduced into a calf that encodes a gene that produced an RNA that pairs up with the transcript for β-lactoglobulin. This pairing recruits double stranded RNA destruction pathways in the cell and destroys the RNA encoding the β-lactoglobulin. Thus β-lactoglobulin is not produced in the milk. The milk from these animals would not be immunogeneic.

Future Direction of Genetic Engineering

Genetic engineering provides a means of improving food production not only through increased muscle mass or disease resistance, but opens the door to a multitude of possibilities and allows us to decrease the time it would take to accomplish these changes through selective breeding. Consider not only increasing muscle mass, but the marbling, tenderness, or other carcass characteristics. In addition to improving disease resistance and animal health, genetic modifications could be implemented to decrease the immunogenicity of the product, increase feed efficiency and reproductive performance, increasing overall efficiency in food production and ultimately reducing food costs. The major limitation for the type of genetic modification that can be done is the imagination of the scientist. If a protein is the problem, or if a protein can solve the problem or enhance the product, then genetic engineering can probably provide a solution. The limits that exist preventing these ideas and animals from contributing to the production of quality animal products are generally not scientific, nor even economic. Although there can be considerable cost involved with the production of genetically engineered founder animals, subsequent costs are no different from any other genetically superior animal as the genes can be transmitted to subsequent generations through natural mating. The major hurdle preventing use of these genetic modifications to improve the food supply is regulatory impediments.

Food Safety/Approval of Genetically Engineered Animals

Numerous studies have reported improved growth, disease resistance, and improved qualities of carcass composition due to genetic engineering of food animals (see above examples). Unfortunately, none of these traits currently are permitted in the food supply. In contrast, genetically engineered plants have been readily accepted into and form an integral part of the food supply. Why are animals different? In 2009 the FDA issued their final guidance on regulating genetically engineered animals. They state that "the Federal Food, Drug and Cosmetic Act (FFDCA) defines 'articles (other than food) intended to affect the structure or any function of the body of man or other animals' as drugs." ….Thus "Developers of these animals must demonstrate that the construct and any new products expressed from the inserted construct are safe for the health of the genetically engineered animal and, if they are food animals, for food consumption." The final guidance was updated in 2011. Embedded in this guidance for most genetically engineered food animals is a requirement for an Investigational New Animal Drug application with the FDA. In addition, the FDA deems 'unsafe' any genetically engineered animal that has not been approved. For the new animal drug to be approved a New Animal Drug Application (NADA) must be approved.

The NADA has 14 points that must first be addressed in the text, and then there are 7 steps required to gain approval: (1) product identification, (2) molecular characterization of the construct, (3) molecular characterization of the genetically engineered animal lineage, (4) phenotypic characterization of genetically engineered animal, (5) genotypic and phenotypic durability assessment, (6) the food/feed safety and environmental safety assessments, and (7) effectiveness/claim validation. Finally there are postapproval responsibilities. So there is a clear path to approval. However, to date no genetically engineered animal has been approved for entry into the human food supply.

Since Investigational New Animal Drug Applications and NADAs are confidential information, it is not clear how many genetically engineered animals are under consideration at the FDA. One application that has become, at least partially, public information is for the Aqua Bounty salmon. These Chinook salmon have a growth hormone gene from Atlantic salmon that causes them to grow much faster and reach a marketable size in half the time as compared to wild-type salmon. While at one time it was thought that fish would be the first genetically engineered animal to navigate the approval process, there is still no approval even though Aqua Bounty appears to have provided FDA with all the information requested in 2010. There were even 2 day-long meetings (one public) evaluating the application. Unfortunately science does not always win arguments, as Congressional representatives introduced bills in Congress to ban or label AquAdvantage™ salmon. The reasons behind the opposition appear to be based on antitechnology rather than safety or economics.

Investment capital is needed for chaperoning any genetically engineered animal through the FDA regulatory process. However, if an entrepreneur evaluates the potential for approval of any of the genetically engineered animals above, he must ask himself at least two important questions. The first is "what will approval cost?", and the second is "how long will it take?" Even though these technologies have a potential to improve human health, productivity, or carcass composition, and they might make economic sense if they could be approved, an investor is not likely to take a risk on a product that may never be approved, or cost so much that the investment could not be recouped. It is not clear what will need to be done to gain approval of genetically engineered animals to enter the food supply. The longer this takes, the more likely the development of the technology will stall.

What may be needed is a product(s) that the consumer demands. One example may be pork with high levels of omega-3 fatty acids, or hypoallergenic milk, as described above. Another example may be food! The human population continues to increase and at some point the supply of food

will be limiting. When people are hungry, then they will demand increased productivity regardless if it is genetically engineered or not.

BOAR TAINT: BIOLOGICAL CAUSES AND PRACTICAL MEANS TO ALLEVIATE IT

EJ Squires, University of Guelph, Guelph, ON, Canada
M Bonneau, UMR SENAH, INRA, Saint Gilles, France

Glossary

Detection methods The methods for measuring boar taint in pig tissues.
Enterohepatic circulation The circulation of biliary acids, bilirubin, drugs, or other substances from the liver to the bile, followed by entry into the small intestine, absorption by the enterocyte, and transport back to the liver.
Genomics A discipline in genetics that applies recombinant deoxyribonucleic acid (DNA), DNA sequencing methods, and bioinformatics to sequence, assemble, and analyze the function and structure of genomes (the complete set of DNA within a single cell of an organism). The field includes efforts to determine the entire DNA sequence of organisms and fine-scale genetic mapping.
Single-nucleotide polymorphism (SNP, pronounced snip; plural snips) A DNA sequence variation occurring when a single nucleotide – A, T, C, or G – in the genome (or other shared sequence) differs between members of a biological species or paired chromosomes.

Introduction

Male meat-producing animals were traditionally castrated to increase the proportion of fat in carcasses and to reduce aggressive and sexual behavior. As consumers' preferences changed to require mainly lean meat, the lower production costs of intact males led to the elimination of castration for some species. However, young male piglets are still routinely castrated in many countries, without anesthesia or analgesia, in order to raise them to heavy market weight without the risk of boar taint, an unpleasant smell and taste from heated pork products. However, the situation is changing, at least in Europe (Australia and New Zealand adopted the no-castration policy in the 1980s); entire male production has dramatically increased in the past couple of years in countries such as the Netherlands and Germany. Moreover, anesthesia and/or analgesia are also increasingly used. Yet, the major production chains in Europe have signed a declaration where they commit themselves to stop castration by 2018.

Advantages and Disadvantages of Using Entire Males for Pork Production

Castration prevents boar taint, but intact males (entire males, boars) have better feed efficiency, nitrogen retention, and lean gain compared with castrates, which typically results in significant economic gains to producers, processors, and integrated companies. These advantages can be summarized as follows:

- Boars have up to 13% better growth rate as compared with that of castrates.
- Boars consume up to 9% less feed as compared with castrates.
- Boars have up to 14% better feed conversion (to live weight) as compared with that of castrates.
- Boars have up to 20% improvement in leanness as compared with castrates.

As a result, the overall output of nitrogen in manure is less with intact males than with castrates. Not castrating also reduces labor costs, along with reduced death losses due to castration-related infections and temporary decreases in growth performance usually seen following castration.

The lower adipose tissue content of meat cuts from entire males also makes them potentially more visually appealing to consumers. There are also some reports that the meat is redder and has increased ability to retain moisture. In addition, the higher levels of polyunsaturated fatty acids in fat and muscles and the higher protein content in carcasses from entire males might indicate nutritional advantages of this meat for consumers compared with that from castrates. However, the processing quality of fat can be worse in entire males, because it is softer and less resistant to oxidation and it might negatively affect production of bacon from pork bellies. Extreme leanness can also result in a lack of cohesiveness between backfat layers and the underlying muscles. This is important as modern commercial genotypes are lean and, therefore, feeding diets with a high content of unsaturated lipids increase the cohesiveness problem. The low intramuscular fat content, which can affect the flavor and texture of the meat, may be of some concern in intact males, if it is lower than the 2–3% level recommended for optimum sensory quality. Intact males also have a 2–2.5% lower dressing percentage than gilts and castrates and higher bone content than the other sexes.

A major driving force for using intact males is the growing animal welfare concerns associated with castration. Several EU countries have banned surgical castration (even with anesthetic) and some major retailers have decided not to sell pork from castrates. Avoiding surgical castration without anesthetic, undoubtedly, improves the welfare of the animals in the short term, although as the males approach sexual maturity, they exhibit more aggressive and sexual behavior than exhibited by castrates. The increased fighting occurring between the animals can lead to an increased incidence of DFD (dark, firm, and dry) meat, skin damage, carcass bruising, and poorer growth performance. Special care must be exercised during the preslaughter handling of intact males, for instance, avoid mixing of unfamiliar animals, optimize lairage time, and use good handling practices to reduce the amount of stress on the animals.

Avoiding castration without risking boar taint would also lower the costs of swine breeding programs because the nonselected animals could be sold for meat at a normal market price. Controlling boar taint without surgical castration would, therefore, have many potential benefits for both the pork production systems and consumers acceptance of pork products.

Boar Taint: Description and Causes

Boar taint occurs in meat from entire male pigs and makes it undesirable for sensitive consumers. Two substances are primarily responsible for boar taint: androstenone (5α-androst-16-ene-3-one) and skatole (3-methylindole). Other chemicals that might also contribute to a lesser degree to off-odor in meat include androstenols, indole, and 4-phenyl-3-buten-2-one. Aldehydes and short-chain fatty acids may also either promote the perception of skatole and androstenone or be responsible for the development of off-flavors.

Cutoff levels that define a limit between untainted and tainted samples have been proposed for androstenone and skatole from sensory assessments by trained panels. Suggested cutoff levels for skatole are 0.20 or 0.25 ppm, whereas cutoff levels for androstenone range between 0.5 and 1 ppm. A large EU study including six different countries found that 30% and 11% of carcasses from boars were above the cutoff levels for androstenone and skatole, respectively. The incidence of boar taint was quite variable, due to the different breeds, slaughter weights, and production systems used. Because of the large variation in the incidence of boar taint, and because of the variety of culinary habits between countries, the acceptability of meat from intact males can be quite inconsistent in consumer surveys. Consumers in France, Germany, Spain, and Sweden were critical of pork from entire male pigs; consumers in Denmark and Holland were negative to the odor but not to the flavor, whereas consumers in the UK were not critical at all. In all other cases outside the UK, substantially, more consumers would be dissatisfied with pork from entire male than from gilts, with the difference of 10.2% versus 6.1% for odor and 6.3% versus 2.4% for flavor.

Androstenone produces a urine-like odor, whereas skatole causes a fecal- or manure-like odor and a bitter taste. People react very differently to boar taint, depending on their sensitivity. As many as 99% of consumers are sensitive to skatole, whereas the percentage of individuals that are insensitive to androstenone ranges from 11% to 30% for women compared with 24–37% for men, depending on geographic location. Among those who are sensitive to androstenone, a small minority likes the odor, whereas the majority perceives it as very unpleasant. Some of this variation may be due to differences between individuals in the expression of the human odorant receptor, ORD7D4, which is involved in human perception of sensitivity to androstenone.

Synthesis and Metabolism of Androstenone and Skatole

Androstenone is a steroid produced in the testis as the boar nears puberty and is released into the blood stream (Figure 1). It is removed by a specific binding protein in the salivary gland and released into the saliva, where it acts as a pheromone to induce a mating response in estrous sows and regulate reproductive development in gilts. Owing to its hydrophobicity, androstenone also accumulates in adipose tissue causing an off-odor when heated. Androstenone is metabolized in the liver through both Phase I (hydroxylation) and Phase II (conjugation) reactions.

Skatole is produced by bacterial degradation of tryptophan in the hindgut, with tryptophan first converted into 3-indoleacetic acid, which is subsequently converted into skatole. It is absorbed from the gut, metabolized in the liver, and then partially excreted with the urine and partially deposited in the fatty tissue. The amount of skatole produced is primarily regulated by the availability of tryptophan and the composition and activity of the intestinal bacteria. A major source of tryptophan for skatole production is from the turnover of the gut mucosa cells. Skatole is produced in equivalent amounts in the gut of both male and female pigs but is poorly metabolized and eliminated by some males, so it accumulates in fat. High activities of cytochrome P450 2E1 (CYP2E1) and CYP2A in mature male pigs are usually associated with low skatole accumulation in fat, whereas low enzyme activities can result in both high and low skatole accumulation, depending on the intensity of skatole production.

Factors Affecting the Accumulation of Boar Taint Compounds

Androstenone biosynthesis is controlled by the same mechanism as that of other testicular steroids, namely, through the activation of the hypothalamic–pituitary–gonadal axis. Thus, during puberty, androstenone levels drastically increase simultaneously with other testicular steroids. Skatole levels also increase at puberty, possibly due to the decrease in hepatic metabolism caused by the increase in testicular steroids.

The accumulation of both androstenone and skatole in fat is affected by genetic factors, and distinct breed differences in the levels of these compounds have been identified in a number of studies. Between 5% and 8% of purebred Hampshire, Yorkshire, and Landrace boars have high concentrations of androstenone in fat, whereas 50% of Duroc intact males have high concentrations. Fat skatole levels also differ among breeds. Genetic selection for animals with low boar taint should be possible due to the relatively high heritability (range from 0.25 to 0.87) of fat androstenone. Likewise, the heritability of skatole

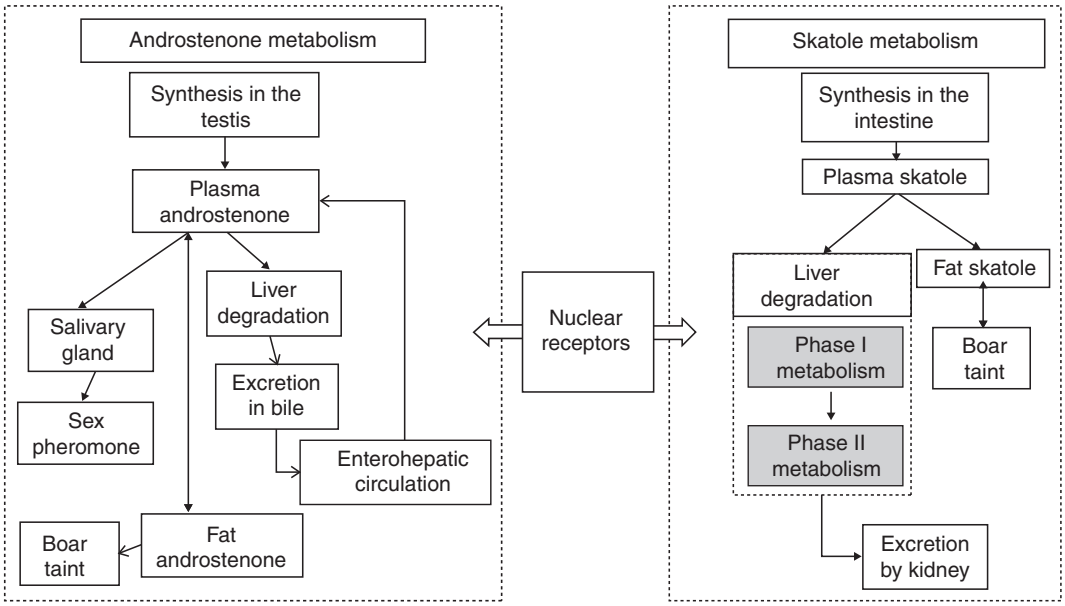

Figure 1 Summary of the metabolic pathways of androstenone and skatole. Modified from Zamaratskaia, G., Squires, E.J., 2009. Biochemical, nutritional and genetic effects on boar taint in entire male pigs. Animal: International Journal of Animal Bioscience 3, 1508–1521, with permission from Cambridge University Press.

is 0.55 for Landrace and 0.23 for Duroc and a positive genetic correlation between skatole and androstenone of 0.36 for Landrace and 0.62 for Duroc has been reported. This is likely a consequence of the interactions of androstenone and its metabolites with skatole metabolism. The accumulation of both skatole and androstenone can also be affected by dietary and management factors as described below.

Alternatives to Castration for Control of Boar Taint

Castration under anesthetic and/or analgesic is not a long-term solution. Indeed, economically viable methods (anesthesia with CO_2 or lidocaine or analgesia) are insufficient to avoid pain, whereas the combination of anesthesia during the surgical procedure and analgesia for a few days postsurgery is not economically feasible in most countries.

Given that steroids are mostly regulated by synthesis and release of the gonadotropins from the anterior pituitary gland during puberty, androstenone levels increase with age/weight. Therefore, slaughter at younger age and lower weight might minimize the risk of boar taint. However, this does not entirely eliminate boar taint, even when reducing slaughter weight to as low as 75 kg live weight, because the time of puberty can differ markedly among breeds and among individuals within the same breed. From an economic point of view, further reduction of slaughter weight is not an attractive alternative for producers or for processing companies.

Castrating pigs at 2 or 3 weeks before harvest reduces androstenone content in fat to levels similar to those in castrates and gilts, but surgical castration of older animals cannot be used in practice. Antagonists or agonists for GnRH can be used to interfere with gonadotropin production, but this is not an option in many countries including the EU. Attempts have been made to remove androstenone by active immunization against the steroid, but it was still deposited in the body tissues. However, immunization against GnRH is effective (see Section Immunoneutralization).

Sorting of semen according to sex is possible but not yet available for routine use in pigs. The use of flow cytometry is far too time consuming because it takes 10 h to produce a 150 million sperm semen dose (i.e., a typical commercial semen dose contains between 1 and 3 billion of sperm cells). There is, however, ongoing research to isolate sex-specific proteins on the sperm cell surface. The technology will produce specific molecules that bind together X-chromosome-bearing (female) sperm cells, leaving unbound Y-chromosome-bearing (male) cells free to be filtered from the sample. The bound or 'agglutinated' female cells can then be deagglutinated for immediate incorporation into a conventional diluter, resulting in a dose of sexed semen. By depositing the sperm directly into the uterus (intrauterine or deep intrauterine insemination), the necessary number of sperm cells can be reduced. This technique is more complicated than the conventional insemination technique where the sperm is deposited in the cervix, and it will require special training of personnel.

Use of Tainted Meat

Heat processing can reduce the levels of boar taint in processed meat products because both androstenone and skatole are volatile. Cooked products, such as cooked hams, luncheon meat, frankfurters, and cooked sausages, are typically acceptable unless they are prepared from very strongly tainted meat. Other ways of utilizing tainted meat include dilution with nontainted material and use of flavor-masking substances such as spices. Moreover, the actual sensory recognition of taint is much less pronounced in pork products that are consumed cold.

There is a great need for rapid online/at-line detection in abattoirs for identifying carcasses with unacceptable levels of boar taint compounds that might make them unsuitable for the fresh meat or high-quality markets. The 'boiling test' or 'soldering iron test' involves heating the fat sample, which causes volatilization of androstenone and skatole that can be detected by an operator. This is currently used at commercial level by some major operators in the Netherlands and Germany, but effective detection differs between operators and fatigue of the sensory response develops quickly. Objective methods are, therefore, needed. The most successful method used thus far is the spectrophotometric method for skatole used in some Danish slaughter plants. This is a 'skatole equivalent' method as it measures both skatole and indole. The limitation of this method is that androstenone is not measured at all and no more than 180 samples per hour can be tested. Research and development efforts are currently being devoted to finding operational and objective-automated sorting methods that will work at acceptable line speeds.

Provided that an effective sorting method can be developed, it is generally considered that producing entire males and using the tainted meat for processing would be economically viable if the proportion of tainted carcasses was less than 5%.

Strategies to Control Boar Taint

Effective Dietary and Management Methods to Control Skatole and Androstenone

There is a wide variation among different animals in fat skatole levels at slaughter depending on the rate of skatole production, intestinal transit time, intestinal absorption, and hepatic metabolism. Feeding and rearing factors affect skatole-producing bacteria in the hindgut. Including fermentable carbohydrates, such as inulin, sugar beet pulp, high-amylase barley, and raw potato starch, in swine diets decreases the production of skatole by the gut microflora and, consequently, lowers skatole levels in fat. This has been proposed to be due to decreased turnover of cells lining the gut, that act as a source of available tryptophan, or changes in the activity of the microflora in the intestinal tract. Skatole production can also be decreased by using various antibiotics to alter the gut microflora. Undigested carbohydrates increase fecal wet and dry weight and decrease intestinal transit time, which reduce the rate of skatole absorption from the large intestine. Withholding feed on the evening before slaughter has also been shown to reduce fat skatole levels. Skatole can also be absorbed from the manure, so dirty pigs of any sex can have high skatole levels in fat. Raising pigs on slatted floors decreases skatole levels compared with animals on concrete, likely because the animals are less dirty. Thus, a proper control of the environment and diet may reduce fat skatole levels to acceptable levels by decreasing the production of skatole.

Androstenone production is controlled by the sexual maturity of the boar, so diet does not affect the production of androstenone. Steroid hormones, including androstenone, are metabolized in the liver by a two-phase process involving first hydroxylation reactions and then the formation of conjugates by sulfation or glucuronidation. These conjugates can enter the bile and be delivered to the small intestine, where they can be deconjugated by the intestinal bacteria to produce the free steroids, which are absorbed into the portal venous blood from the enterocytes; this is known as the enterohepatic circulation. It is shown that including binding agents as dietary additives can reduce the accumulation of androstenone in fat (Figure 2). In these studies, boars were fed diets supplemented

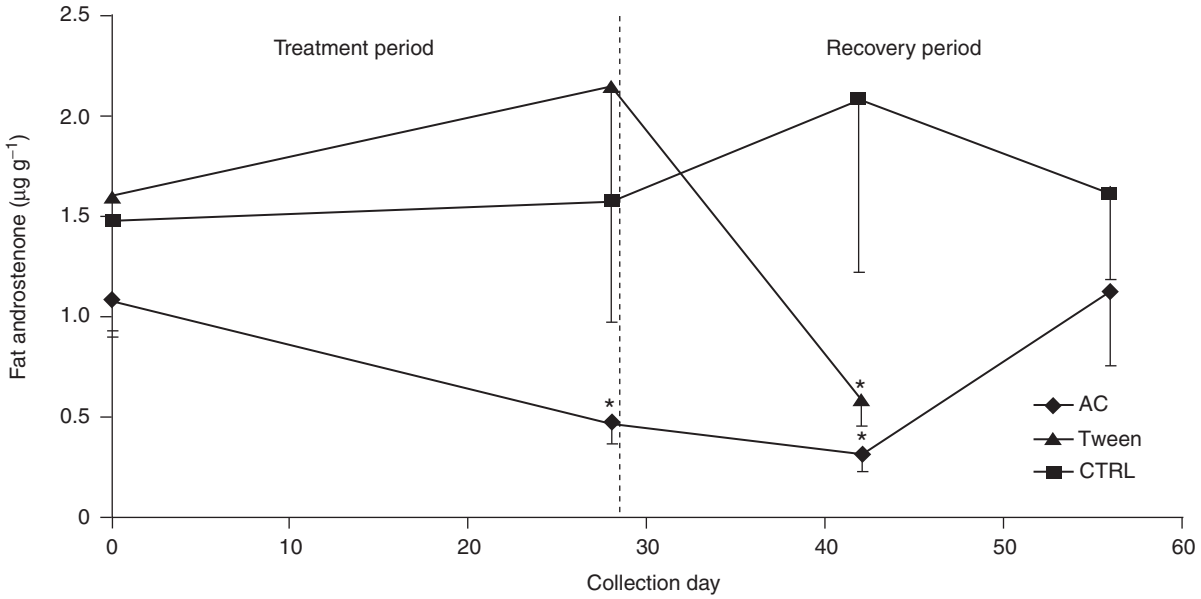

Figure 2 Profile of androstenone concentrations in fat of boars treated with activated carbon (AC, —◆—; $n=13$), (Tween, —▲—; $n=13$) and boars fed a control diet (CTRL, —■—; $n=11$). Values are plotted as means ± SE, *indicates values significantly different ($P<.05$) from values at day 0. Modified from Jen, K., Squires, E.J., 2011. Efficacy of non-nutritive sorbent materials as intestinal-binding agents for the control of boar taint. Animal: International Journal of Animal Bioscience 5, 1814–1820, with permission from Cambridge University Press.

with either 5% activated carbon or 5% tween-60 (a polysorbate that acts as a surfactant and emulsifier) for 28 days followed by either 14 or 28 days of recovery. Feeding activated carbon significantly reduced the levels of androstenone by day 42 in fat compared with day 0. Fat androstenone levels also decreased between day 28 and day 42 following treatment with tween-60. Levels of fat androstenone for control boars remained high and constant throughout the experiment. This technology is now being tested under commercial production conditions.

Immunoneutralization

Active immunization against gonadotropin-releasing hormone (GnRH), so called immunocastration or immunoneutralization, involves the administration of a modified form of GnRH to provoke the development of anti-GnRH antibodies, which bind to GnRH to prevent the stimulus for secretion of pituitary LH. Thus, a subsequent reduction of testicular steroid secretion occurs, resulting in reduced androstenone levels, size of reproductive organs, sperm numbers, and even aggressive behavior. The reduction of skatole and indole levels to low or undetectable levels in immunocastrated pigs is most likely due to enhanced metabolic clearance by the liver after suppressed steroid production, as occurs in surgically castrated pigs. IGF-1 concentrations in plasma were also reduced in immunocastrated pigs, which might affect skatole production. Therefore, immunocastration allows the production of heavy male pigs with reduced boar taint and aggressive behavior. However, the main concern about immunocastration is uncertainty about consumer acceptance of immunocastrated pork, and the adoption of Improvac™ has been slow in several EU countries and in North America. In an Australian consumer survey, consumers were positive toward the use of immunocastration, without knowing much about the background of off-odor in pork. However, the Australian pork industry has been utilizing intact males for several years and, at least to some extent, the Australian consumers are more used to potential boar taint than consumers from other regions.

To immunize pigs, two doses of Improvac™ (2 ml of 200 $\mu g\ ml^{-1}$ GnRH conjugate) are given at an interval of at least 4 weeks, with the second dose given 4–6 weeks before harvest. This allows pigs to retain the performance advantages of intact males until a few weeks before harvest, when immunologically castrated. The vaccine is administered at the base of the ear with a special vaccinator designed to prevent accidental needle sticks. Accidental self-injection of the workers performing the vaccination may, however, be a concern.

Compared with intact males, immunocastrated pigs grow faster, have a similar or slightly decreased feed efficiency, and have a higher fat content in their carcass (Table 1). This is attributable to increased feed intake, which may be due to the sharp reduction in levels of estrogen, which is known to reduce feed intake. Compared with surgically castrated pigs, immunocastrated pigs may grow faster or grow at a similar rate but consistently have improved feed efficiency and decreased fat content. This is attributable to the positive effects of androgens secreted from the testes before immunization.

An economic model to assess the costs and returns of using Improvac™ in the US market suggests an additional income of US$5.48/pig for immunocastrates compared with surgical castration. The economic implications of castration and immunocastration in the EU have also been studied.

Table 1 Effect of vaccination with Improvac™ on performance of male pigs in eight studies

Number of animals per treatment	*Growth rate*	*Feed efficiency (Gain/feed)*	*Fat content*

Development of Genetic Markers for Low Boar Taint Pigs

The use of genetic markers to produce lines of pigs that are free of boar taint but otherwise grow as normal boars is a potential long-term solution to raising entire male pigs for pork production. Although the heritability of both androstenone and skatole is moderate to high, previous attempts to select for pigs with low boar taint have resulted in reproductive problems. The development of specific genetic markers for boar taint would minimize these negative effects on reproduction. Marker-Assisted Selection programs would produce lines of pigs that have a decreased genetic capacity to accumulate androstenone and skatole in fat while maintaining the normal levels of testicular steroids and would thus grow as normal boars.

One approach to developing genetic markers for boar taint is to investigate polymorphisms, usually single nucleotide polymorphisms (SNPs), in candidate genes. Candidate genes can code for key enzymes in the metabolic pathways that regulate the synthesis and degradation of boar taint compounds and should not involve other pathways such as anabolic steroid metabolism. A number of studies have shown differences in expression of candidate genes encoding enzymes involved in the metabolism of boar taint compounds, but only a few studies have reported SNPs in these genes that are correlated with levels of boar taint. A recent report from Norway compared a large number of SNPs to boar taint in Duroc and Norwegian Landrace breeds. They found significant marker effects for fat androstenone in Duroc, but not in Landrace, and significant marker effects for fat skatole in both breeds. Individual markers explained from 2.5 to 16.3% of the total variation in the traits.

The University of Guelph studies conducted by E.J. Squires and his colleagues over the past 20 years allowed for development of genetic markers for low boar taint based on SNPs in candidate genes that were selected on the basis of functional

studies. The ultimate goal was to identify the causative mutations in the most important genes, and then use these markers in breeding programs to develop lines of pigs that were free or had reduced boar taint but otherwise grew as normal boars. These studies characterized the metabolites and enzymes of the metabolic pathways involved in the secretion and degradation of the boar taint compounds. The team developed a database of approximately 1300 animals representing eight different lines, comprising six breeds (Duroc, Hampshire, Landrace, Large white, Pietrain, and Yorkshire, $n=76–219$), which were used for the discovery and validation of SNP markers. For SNP discovery, the sequences of candidate genes from pools of DNA obtained from animals from the extremes of the boar taint phenotypes in each line were compared. All animals in the database were genotyped for each SNP and an association analysis was conducted for each SNP with the amount of boar taint from androstenone and skatole in the carcass. Approximately 80 effective SNPs in 28 candidate genes for boar taint were identified. The number of significant SNPs across lines varied from 5 to 17 and from 3 to 16 for skatole and androstenone, respectively (Tables 2 and 3). In addition, 65% of the 80 effective SNPs were associated with both skatole and androstenone, which corroborates with the reported moderate positive genetic correlation between these two boar taint compounds. It is predicted that application of the markers to produce pigs homozygous for the favorable alleles would decrease fat skatole levels by 20–53% and fat androstenone by 26–61%, depending on the genetic breed and/or line.

It was also determined that none of these markers were associated with negative effects on production traits (backfat thickness, loin muscle depth, front leg score, rear leg score, subjective live muscle/conformation score, or average daily gain).

The discovered 80 SNP marker set was also validated in six lines of pigs obtained from a different source. The number of significant SNPs across lines varied from 5 to 13 and from 2 to 10 for skatole and androstenone, respectively, with 12 SNPs associated with both skatole and androstenone. Across all lines, the SNPs explained an average of 51% (range 33–73%)

Table 2 Summary of marker effects for skatole

Breed	*Number of effective markers*	R^2	*Favorable allele frequency*	*Current geometric mean*[a]	*Mean with favorable allele*[b]	*% Change*
Duroc	13	0.59	0.05–0.95	40.9	24.0	−41.2
Hampshire	17	0.42	0.28–0.85	97.5	54.4	−44.2

Table 3 Summary of marker effects for androstenone

Breed	*Number of effective markers*	R^2	*Favorable allele frequency*	*Current geometric mean*[a]	*Mean with favorable allele*[b]	*% Change*
Duroc	11	0.41	0.03–0.96	1.38	0.67	−51.6
Hampshire	3	0.13	0.21–0.81	0.79	0.31	−60.9
LW-Duroc	16	0.35	0.06–0.78	2.14	1.23	−42.7
Landrace	14	0.32	0.05–0.79	0.52	0.29	−44.1
Large White	5	0.08	0.07–0.96	0.55	0.38	−31.3
Pietrain	12	0.51	0.10–0.94	0.35	0.18	−47.3
Sire Line	10	0.27	0.09–0.74	0.88	0.54	−38.6
Yorkshire	7	0.16	0.17–0.92	0.55	0.41	−26.0

[a]The original data was log transformed to make it normally distributed. The geometric mean is obtained by back transforming log transformed numbers.
[b]Mean with the favorable allele is the mean levels of androstenone that would be found if the animals all had the favorable allele for each marker, that is if the markers were used to select for low androstenone levels.
Note: The R^2 represents how well the markers explain the levels of androstenone.
Source: Modified from Squires, E.J., Schenkel, F.S., Mitchell, C.E., Walling, G.A., 2011. Development and validation of genetic markers for low boar taint. Plant and Animal Genomics XIX Conference Jan 2011. Available at: www.intl-pag.org/19/abstracts (accessed 07.11.13).

of the skatole variance and an average of 50% (range 24–74%) of the androstenone variance. This confirmed that the discovered markers were effective in different lines of pigs and demonstrated their potential for wide applicability in pig breeding. For instance, the effect of the discovered markers, estimated in reference populations, could be used for calculating genomic-based estimated breeding values for the boar taint compounds. Then these estimated breeding values could be incorporated into overall selection indices for selecting young animals for breeding purposes.

The specific objectives are:

Objective 1: to collect information on the attitudes of relevant stakeholders.

Objective 2: to collect information on the practice of pig castration.

Objective 3: to evaluate research work and other information, in order to examine the various alternatives to surgical castration without anesthesia and derive research priorities.

Objective 4: to integrate the collected information and evaluation in a report providing support for the EU policy.

BY-PRODUCTS

Contents

Edible, for Human Consumption

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

Introduction

The yield of edible by-products from animals varies tremendously, depending on species, sex, live weight, fatness, and methods of collection. In general, the total by-products range from 10% to 30% of the live weight for beef, pork, and lamb, and from 5% to 6% of the live weight of chickens (Table 1). The yield of edible by-products including blood and organs in cattle averages 12%, in sheep 14%, and in hogs 14% (if pork rinds are also included).

Biologically, most noncarcass material is edible if the product is cleaned, handled, and processed appropriately. What is considered edible in one geographical region though, may be considered inedible in another. Red viscera, sometimes called 'variety meat' or 'fancy meat', include the liver, heart, kidney, 'white' offal (intestines and stomach), and also blood and trimmings. Because of people's customs, religions, palatability, and reputation of products, variety meat by-products are usually limited to liver, heart, kidney, tongue, and thymus plus other sweetbreads, brain, tripe, and sausage casings. However, additional items are salvaged or used in many cultures. Although animal harvest has increased over time, the use of edible by-products for human consumption has declined.

Noncarcass material is usually separated into categories of decreasing value, such as:

1. Hides: In most cases considered nonedible.
2. Main edible ingredients: Variety meat, sausage meat, cheeks, head trimmings, and pork rinds.
3. Pet food.
4. Agricultural animal feed materials such as blood, lungs, spinal cord, breast fat, bones, and some of the stomachs. However, owing to bovine spongiform encephalopathy (BSE), tissue from ruminants in the US is no longer utilized in rumen feed and is banned as feed for farm animals in the European Union (EU).
5. Fertilizer.
6. Raw material for biogas production.

The category in which tissue is placed depends not only on potential utilization but also on market demand. Many edible by-products are downgraded in price because of a nonprofitable market. This, combined with their usually high nutritional value, makes them an economical buy, particularly in countries with low incomes; therefore, there is a large international trade in these products. If these products are not salvaged, they pose a tremendous environmental pollution problem. Fortunately, many cultural groups prepare interesting and delicious variations of variety meats and are often large consumers of these products. Variety meats are usually different from skeletal tissue in structure, proximate composition, and functional and sensory properties, and they usually have excellent nutritional value as shown by the protein, fat, mineral, and vitamin contents in Tables 2–4. In general, variety meats can be higher in cholesterol than muscle tissue (Table 5). These tissues are more perishable than muscle tissue because of their higher glycogen content and lack of fat covering. Therefore, they should be cooled quickly after slaughter, handled in a hygienic manner, and cooked as soon as possible.

Products

Liver

In market-weight animals, beef liver averages 5 kg, veal liver 1.5 kg, lamb liver 1.4 kg, and pork liver 1.4 kg (3.2 kg for a mature sow). Pork liver can be identified by the connective tissue structure, which has a 'nutmeg' (or Morocco leather) appearance. Livers are removed on the harvest floor, and the gallbladder and bile duct are removed. The liver is washed, drained under refrigeration, and quickly chilled. The liver may be sent to a retail store in this condition, or the capsula fibrosa first might be removed with a knife or with a mechanical skinner. Livers may be frozen but they become softer, and their quality decreases with increasing storage temperature. To increase storage time, vacuum-packaging can be used. Increasing

Danville, IL: Interstate.

bacterial counts (10^6 g^{-1}) and pH values below 6 often indicate spoilage.

Liver is considered one of the most nutritious parts of the animal and is often used as a source of vitamin B_{12} and vitamin A. Liver is usually thinly sliced and cooked by a variety of techniques, or it may be minced and incorporated into many dishes, loaves, spreads and sausages, such as braunschweiger (often 50% liver), liver cheese, liver loaf, liver mush, liver paste, liver paste with truffles, liver pudding, liver sausage, liver spread, and liverwurst (often a minimum of 30% liver). These sausage items frequently contain 2.5% salt, up to 3.5% nonfat dried milk, 0.3% onion powder, 0.25% sugar, sodium nitrite, sodium erythorbate, white pepper, allspice, cloves, sage, marjoram, nutmeg, and ginger. The batter mixture is stuffed into a casing and cooked in water to an internal temperature of 67 °C and then cooled in ice water.

Heart

In market-weight animals, a beef heart averages 1.4 kg, veal heart 227 g, pork heart 227 g, and lamb heart 113 g. Hearts are removed on the harvest floor and trimmed of cartilages and fat; they are slashed for inspection and to remove clotted blood. The hearts are then washed, drained under refrigeration, and chilled. Hearts are less tender than liver and require moist cooking for extended periods. They may be diced and added to stews or minced and added to other meat for added

flavor. Heart cavities may be stuffed with dressing or parsley and then roasted. Hearts may be sold fresh or frozen or used in processed luncheon meat to add high-quality protein and color.

Tongue

Beef tongue of a market-weight animal averages 1.7 kg (long cut 2.3–3.1 kg and short cut 1.6–2.3 kg) and may be white, black, or variegated and may frequently have black spots. Veal tongue averages 0.7 kg, pork tongue 0.3 kg, and lamb tongue 0.2 kg. Tongues are removed on the harvest floor, trimmed, washed, drained under refrigeration, and chilled. The tough outer membrane of the tongue can be removed easily after blanching and a short submersion in boiling water. Tongues are rather tough and require long-time moist heat cooking. In addition to fresh availability, tongues may be pickled (corned, and often requiring soaking before cooking), smoked or canned in an agar solution, or used in a perishable jellied product. This can be manufactured by curing, water cooking, mincing, adding gelatin, seasoning, stuffing or placing in molds, and chilling, or it can be potted by fine mincing, mixing with seasoning and then canned and processed. Tongue also can be used as an ingredient in luncheon meat. Tongues might be brine cured by a long-immersion cure or artery cured using the two lingual arteries at the base of the tongue. This is usually followed by placement in a cover pickle for several days. Tongues are thinly sliced and can be served hot or cold, often with garnishes or with sweet or sour sauce, horseradish, mustard sauce or other spicy sauces or dressings and might also be added to casseroles and salads.

Kidney

A pair of beef kidneys is lobed (15–25 lobes) and is contained in the kidney knob (suet and fat). An average kidney weight is 0.4–0.6 kg each. Veal kidney is similar to beef kidney, except that it is smaller (340 g) and is sometimes left as part of the

loin to produce veal kidney chops. Sheep kidney has a single lobe and averages 57 g. It is sometimes left in the carcass to produce kidney chops or English lamb chops, but most often it is sold whole. The pork kidney is single lobed, weighs 113 g in a market-weight animal, and is usually sold whole. The kidneys might remain with the carcass until it is cut. After its removal and removal of capsule membrane and fat, the kidney is soaked in water, dried and chilled. Kidneys may be used as ingredients in meat casseroles, stews, or pies. Beef kidney should be cooked in water or braised. Lamb and veal kidneys are tenderer than beef kidneys and may be broiled or wrapped in bacon and cooked on a skewer.

Sweetbreads

Sweetbreads are harvested from calves, lambs, and young cattle. Two different organs and three different tissues located in these animals are called 'sweetbreads.' A yellowish-white lobulated thymus consists of two parts: One portion (0.05–0.23 kg) is located in the cervical region in the neck adjacent to the trachea and is called 'neck bread,' 'neck sweetbread,' 'throat sweetbread,' or 'throatbread'; the other portion (0.05–0.1 kg) is in the thorax region and is called 'heart bread' or 'heart sweetbread.' The thymus tissue is large and active during animal growth (only available from young calves and lambs) but degenerates and is replaced by fibrous tissue after the animal matures. During harvest, it is separated from surrounding tissue, washed, dried under refrigeration, and then chilled. The thymus sweetbread is tender but very perishable and should be frozen, precooked (simmered in acid water), or used immediately. The membrane should be removed.

The brownish-yellow lobulated pancreas is called 'gut bread' or 'stomach sweetbread' and weighs approximately 170 g in market-weight beef animals and 85 g in sheep and pigs. It is also trimmed, washed, drained under refrigeration, and then chilled.

Sweetbreads may be scrambled (often with eggs), reheated in sauce, breaded and deep-fat fried, used in salads, or coated with butter and broiled.

Tripe

Beef tripe is produced from the first (rumen, paunch) and second (reticulum, honeycomb) stomachs of cattle. It is referred to as plain (3.2 kg) and honeycomb (680 g), respectively. Sheep stomach can be processed similar to beef stomach and will yield approximately 1 kg of tripe. Pork stomach can also be processed and will yield approximately 1.2 kg of tripe. The omasum (bible) from beef or lamb is difficult to clean, deteriorates quickly, and is not usually used for human food. Brown, almost furry, 'raw unscalded' beef tripe is the paunch that has been cold-water flushed to remove the contents. After scalding, cream-colored, denuded tripe is made from the paunch (rumen), which is then washed in running water, with hot water in a rotating machine with continuous flushing or with diluted soda water (limewater), and then soaked in tap water. The dark internal lining is scraped to remove the mucosa. The clean stomach is converted into tripe by cutting to size and pickling in salt brine, or by cooking and pickling in a weak salt and vinegar brine. Tripe may be precooked (usual form) in water, sometimes fully cooked, and may be packed in vinegar, pickled or canned.

Types of beef tripe products available include the following:

- Tripe cooked: Scalded tripe, cooled, drained, and then cooked to increase firmness.
- Tripe cooked and bleached: Cooked tripe that is bleached and neutralized.
- Mountain chain beef tripe: Dark cream-colored, muscular pillars from mature cattle that is scalded or treated with additives.

Types of pork stomach available include the following:

- Whole unscalded: Light to medium brown, inverted, cleaned, and trimmed; the lining might be removed.
- Scalded form: Cream to light brown, inverted, cleaned and trimmed, and scalded; the lining might also be removed.

Precooked tripe requires additional salt-water cooking and is often served with sauces or dressings or used in meat casseroles, stews, or pies. Because tripe is delicately flavored, it is often combined with tomato sauce, buttered and broiled, covered with dressing and baked, dipped in butter and sautéed, or combined with a thick soup.

Brains

Beef brains weigh 454–482 g, veal and pork brains 113–127 g, and lamb brains 127–142 g. They are removed on the harvest floor. Brains are less popular than in the past because of the

possible connection of nervous tissue with BSE ('mad cow' disease). Cattle brains belong to the 'specified risk material', which in the US and EU must be removed from bovine carcasses at harvest and incinerated. Other species' brains are available with the outer membrane retained or removed and usually briefly soaked in water, drained under refrigeration, and chilled. Brains are very perishable and should be used immediately, precooked (which makes removal of membrane easier and firms the tissue to make slicing easier), or frozen. Brains are tender, and are often thinly sliced, dipped in butter or flour, and deep-fat fried. They can also be broiled, sautéed, braised, cooked in liquid, or broken into pieces and scrambled (often with eggs).

Oxtail

Beef tails are removed from the carcass between the second and third coccygeal vertebrae (in some areas between the sacral and coccygeal vertebrae) and quickly chilled. It is usually available in the tipped and trimmed form, which weighs 0.8–1 kg and has the excess fat removed and three or more of the end posterior coccygeal vertebrae removed. Oxtail is usually browned and then simmered until the meat is tender, that can easily be removed from the bone, which sometimes occur before serving. It can be combined with other soup ingredients and its rich flavor adds taste and texture to soups.

Stock

Veal, lamb, pork, or cracked beef bones; cooked or uncooked and sometimes combined with meat scraps, can be converted into soup stock. Lamb and pork bones produce distinct and strong flavors and should be used in lamb and pork dishes. Stock is economical and adds nutrition and flavor to cooked products. To produce stock, bones are usually combined with vegetables, covered with hot water and placed in an oven for roasting until the bones turn brown. Fat is separated and the bones are combined with additional vegetables covered with water and simmered in the water, and then skimmed. The stock is then strained and cooled; it can be refrigerated or frozen. It is used with cooking in meat dishes, soups, vegetable dishes, sauces, or gravies.

Meat Extract

Meat extract can be produced by pressing or by cold water soaking, but the most popular procedure is rapid boiling of meat that is to be canned. The juice from these procedures is concentrated into an extract. Other edible meat products can also be used as starting ingredients. The yield and quality of the extract will be influenced by the type of raw material (sex, cut, postmortem age, type of tissue or bones, size of cut, and fat content), the length of time used in cooking, the number of times fresh product is cooked in the same soup, and treatment (open pan and holding time) during evaporation of the soup. When bones or meat are boiled, the juices are combined with meat wash water and it is often economical to boil new lots of bones or meat two or more times in the same liquid. The soup is skimmed to remove fat and filtered to remove particles and suspended solids. It is then boiled to coagulate protein, refiltered, concentrated by vacuum evaporation, and then reheated in open pans. First- and second-class extracts often contain 16% or 19.5% moisture, 44% or 40% minimum organic soluble material, 7% or 6% creatine, 1.5% maximum water-insoluble material, 25% maximum ash, 4.05% maximum salt, 0.01% maximum saltpetre, and 0.01% maximum copper.

Extracts are also produced in the solid form and are the foundation for various fluid extracts and bouillon cubes, broths, 'teas,' and soups.

Trimmings

Beef outside skirt is the thin, free portion (wing) of the diaphragm muscle with the tedious skin tissue (pleura) remaining, which is separated from the liver with a knife. In beef animals, it normally weighs 1.9–2.5 kg. After removal from the carcass, it is soaked in water, drained and chilled and then a portion of the fat and membrane material is removed. It is used in comminuted meat products.

'Hanging tender' is the thick portion (pillar) of the diaphragm muscle next to the spinal column, which is treated similarly and has similar usages to the outside skirt. In beef animals it usually weighs 0.3–1 kg.

'Beef weasand' (gullet) is the smooth-muscle lining that surrounds the oesophagus from the larynx to the first stomach (paunch). It is separated with a knife on the harvest floor. The fat and membrane, as well as the fibrous internal membrane, is removed, washed, drained, dried under refrigeration, and chilled. It is used in emulsion-type products.

Other trimmings such as 'beef cheek meat,' 'beef tongue trimmings,' 'beef meat from tongue trimmings,' 'beef head meat,' 'beef lips,' 'pork cheek meat,' 'pork snouts – lean in,' 'pork snouts – lean out,' 'pork head meat,' 'pork skirt,' and 'pork hanging tender' can be used in sausage production. The terminology for some of these products would include the following:

- Beef cheek papillae: The muscle including the lining of the mouth that is external to upper and lower jaw bones from the tip of the mouth back to the parotid salivary glands; might also include the muscle inside the lower jaw bone. It has none of the external lip remaining.
- Beef cheek papillae off ('nut' or 'kernel'): The beef cheek papillae in which the papillas' lining has been removed by trimming.

Pork Jowl

The jowl is separated from the pork carcass by a cut at the first or second cervical vertebrae and lymph nodes are removed. It is placed in water, drained under refrigeration, and chilled. Jowls are often cured like bacon.

Pig Tail

The tail of pig carcasses is removed between the fourth and fifth caudal vertebrae, washed, drained under refrigeration and chilled. Tails may be mild brine-cured or used as jelly stock for brawn (headcheese).

Pigs' Feet ('Trotters')

Feet are cleaned on the harvest floor after scalding by pulling the toenails and removing the skin and hair between the toes. The feet are then scraped free of hair, washed, and chilled. For dry-cured ham, the feet are separated at the middle of the hock joint. For other uses of hams, more part of the feet is removed. The hind foot is usually not used for human food because it contains little muscle. However, sometimes small meaty portions are removed and pickled and are called 'tid-bits.' The fore foot (0.5–0.7 kg per foot) is removed at the junction of the fore shank bone and the foot bone (vague). It is often used for food because it contains more muscle (46% raw). The fore shank or pork hocks (lower shank portion of picnic shoulder) can be sold fresh or frozen or can be used for pickled pigs' feet, boned and used for sausage, or used to produce a jelly stock for brawn-like products. Pickled pigs' feet are hot- or cold-cured with salt and nitrite, heated or reheated in water (sometimes vinegar-acidulated water), hot showered, cold-water chilled, and often boned. Large feet are usually pickled boneless or semiboneless, and smaller feet might be split ('split foot') or boneless. They are then placed in 35-grain vinegar, packed in jars that are filled with 45–55-grain vinegar (pH must be below 4.5 to be shelf-stable) containing salt, ascorbic acid, and spices or condiments. The product is then usually held for 2 weeks before selling, for continuous pickling.

Chicken or Duck Feet, and Chicken Paws

Chicken feet (4 toes, feet 30–45 g each; Fang zhao, Phonix claws, and chicken claws) and duck feet, are the shank portion of the chicken or duck leg. Poultry contains only part of the ankle bones and the industry uses the word 'hock' to describe the ankle region and 'hock joint' refers to ankle joint. Chicken paws are chicken feet cut off at the ankle. Almost all the edible portion consists of skin and tendons and many small bones (often removed before serving). The feet are mostly cartilage, which makes them very gelatinous. Chicken feet are washed and yellow skin and hard nail are removed that contain no bruises and are usually frozen. They are popular in the Orient (often selling for a higher price than the breast), and Central and South America. They have little flavor but are often deep fried or boiled or steamed, which makes them puffy before being stewed and simmered in a sauce flavored with fermented black bean paste and sugar. Marinated feet are simmered with soy sauce, sichuanse peppercorn, clove, garlic, star anise, cinnamon, and chili flakes but might also be flavored with rice vinegar and chili. They are often eaten as a beer snack, snack (like peanuts), cold dish, soup, or a main dish. The US exported approximately 500 000 metric tons in 2008. Duck feet, which are also popular are often flavored with mustard, and served with vinegar, green peppers, and crushed garlic.

Jellied Products

Jellied products such as headcheese (brawn), souse, and scrapple use high-collagen meat sources in their production. These include pork skins, head trimmings, or gelatin. Tissue often utilized in production of these products includes cured pork tongues, hearts, cheeks, ears, snouts, or pork skin gelatin; sometimes nonfat milk is also incorporated. The product is seasoned, hot-water cooked, cubed, rind minced, mixed, stuffed into natural or artificial casings, recooked in water, cold-water chilled, and placed in a cooler for a final chill. Sometimes the jellied product is cold-smoked or washed in vinegar. Because the product is very perishable, it may also be canned.

Haggis

Haggis is made from calf and sheep hearts, lungs, and livers with oatmeal added. It is heavily seasoned and cooked in a sheep's stomach.

Intestines

Pork large intestines and stomach are collected at harvest and cleaned; they are cooked, often with sauce, and are referred to as chitlings in the US and chitterlings in Europe. In some areas, a small portion of beef small intestine is also used. The intestines and other areas of the digestive track of cattle, pigs, or sheep are cleaned and some inner and outer layers are usually removed, salted, and used as sausage casings.

Testicles

Beef testicles (a bull testicle weighs 0.2–0.3 kg; calf's 'mountain oysters' are smaller) are the complete gland with the epididymis removed and chilled. Rams' testicle weight is 0.2–0.3 kg, lambs' testicles are smaller; and boar testicles weigh 127 g. They are often thinly sliced, dipped in a batter of flour (breaded), and deep-fried.

Pork Skins

Pork rind is utilized as a binding product for jellied products, for the production of gelatin, to prepare a popped snack item, or as a preemulsion for sausage production. Pigskins can also be tanned to produce leather products. Popped pork rind (bacon rind, 'skeens') are green belly skins, green backfat skins, green ham skins, or cured and smoked bacon skin removed from the respective cuts, usually producing a skin with as little as 6 mm of fat. The rind is then cut into 1.3–21.5 cm squares. Next, it can be cooked and allowed to cool and drain and then placed in a wholesale package. It is later taken out and processed in hot oil so that it puffs up or expands to a much larger volume with a crisp texture. The puffed product can receive salt and several types of seasoning to give a variety of flavors. These puffed skins are less hygroscopic than most puffed snack items. Rinds that are to be used in sausage emulsion are cooked, minced and combined with pork fat, water, and emulsifying or stabilizing agents such as soy protein isolate or sodium caseinate to produce the preemulsion, which is used as is or sometimes dried (in granular form). Either type can be used hot or chilled and incorporated in the chopping stage of sausage manufacturing.

Blood

Blood is the first product obtained at harvest. Beef will yield 10–12 l and sheep 1.5 l. In some countries, blood is utilized as human food, usually in sausage. To extend the shelf-life for a

few days in areas without adequate refrigeration, high levels of salt might also be added. Typically, blood from healthy animals is free from microorganisms, but it is necessary to obtain it in as sanitary a fashion as possible. The product is mixed with other meat ingredients, stuffed into natural or artificial casings or moulds and water-cooked, chilled and normally cold-smoked, and then rechilled. Blood is usually limited to 0.5–2% in a sausage product. Above this level, it has a negative effect on color and flavor. In Europe, blood is often stabilized with citrate and collected. It is sequentially separated and the plasma fraction is used in processed meat products as a high-protein ingredient. The red corpuscles are often frozen and used as mink feed. Blood can be separated into corpuscles (dense blood, primarily red blood cells) and plasma (yellowish liquid) by centrifugation. Plasma can be incorporated at the rate of 10% to replace some of the meat and water in sausage. Anticoagulated or defibrillated beef blood might be cured and strained, and used to form an emulsion when it is mixed with chopped, cooked, ground, defatted pork skins and subsequently added to the sausage mixture. Some products have a high proportion of whole blood, such as black pudding and blood (black) sausage. Blood not collected in a sanitary manner is used to make feed for young pigs.

Spleen

Beef spleen will weigh 0.9–1.4 kg, pig spleen 170 g, and sheep spleen 57–85 g. After removal and trimming, the spleens are soaked in water, drained, dried, and then chilled. Before use, the connective tissue covering is removed. Spleen can be fried, used in a pie as melt or used for flavoring or in blood sausage. To remove the gristle-like texture, it is sometimes processed through a mechanical deboner with a desinewing head. The use of spleen in sausages is often limited to less than 10%.

Poultry Giblets

The heart, liver, and gizzard (split, emptied, washed, and lining removed) and sometimes the neck are cleaned and wrapped in paper, bags or film and inserted into the bird's body cavity. They might be washed, salted and wrapped in aluminum foil, and cooked with poultry. Giblets can also be simmered in salted water until tender. They can then be ground and added to crumbled bread or cornbread, or cooked with rice, to produce stuffing. Milk and cooking broth might be added to minced giblets to form gravy. Livers can be fried with bacon or onions to produce a flavorful product. Owing to reduce the risk of *Salmonella* cross contamination, most poultry in Europe is sold without giblets. Poultry livers, hearts, and gizzards are packed in consumer packs (150–300 g) and sold frozen in retail stores.

Mechanically Separated Meat

Mechanically separated meat (MSM) (species) is obtained by forcing bone and attached meat through a sieve using high pressure to separate the soft tissue (meat and some calcium dust) from hard tissue (bone and connective tissue). The soft tissue was declared (1996) to be safe for human consumption by United States Department of Agriculture/Food Safety and Inspection Service. It can be labelled trimmings or ground (species) and must be in the ingredient list as mechanically separated (species).

MSM is the most widely used system in the US and the product where it is used most commonly is in hot dogs, which can contain no more than 20% of mechanically deboned pork. Compared to hand deboned tissue, protein is lower, and fat content is higher than hand deboned, because of the higher content of bone marrow (increases red color) and lower content of connective tissue (improves tenderness), and with a calcium content that is higher (the US diets are low in calcium), and fluoride is higher but most of the fluoride is discarded with the bone.

MSM (species), mechanically recovered/reclaimed meat (MRM), and mechanically deboned meat (MDM) are all processed by the same system and the only difference is the starting material. MSM (species) gives information on the species used, whereas MRM and MDM do not give information on species.

MDM (could contain beef), owing to concerns (2004) with BSE, it is considered inedible (the US, the UK, and the EU).

In chicken or turkey (MSM species) franks, the quantity of mechanically deboned poultry is unlimited and may contain chicken or turkey skin and fat in proportion to a turkey or chicken carcass. These techniques salvage a lot of soft, edible, highly nutritious meat that does not contain connective tissue that would otherwise essentially be wasted. As the world population grows we cannot afford discarding nutritious products that can be salvaged.

Hides and Skins

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

Introduction

Humans have utilized animal skins throughout recorded history, and nomadic people still utilize them for shelter, clothing, weapons, and food containers. In spite of competition from synthetic materials, many quality items still demand the wearing ability, moisture–vapor transfer, and insulating properties of leather.

Animal hide is a very significant proportion (4–12%) of the live weight of an animal (Table 1) and is one of the most valuable by-products that can be converted into a variety of items. A few examples are shown in Table 2. Other uses of animal skin include food, cosmetics, and medical prosthetics.

Trade in Hides and Leather

A significant percentage of US cattle hides enter the export market. Many types of pigskin have other uses and often are not salvaged for leather; this market, therefore, has a large potential for growth. Tanning of fish skins has also made fish leather available. Developing countries account for the manufacture of approximately 45% of the world's leather products. For example, China now has 10 000 tanning enterprises employing 1 million workers. Table 3 indicates that 88% of US footwear is derived from other countries. Table 4 illustrates leather movement and Table 5 shows its origins and destinations, showing that leather indeed is a global product.

Classification

Hides are classified according to weight, whether or not the hide is branded and location of the brand, sex, fatness, defects, and skill of removal (Tables 6 and 7). Sheep pelts are graded according to wool length. The leather industry has its own terminology, and glossaries can be found on the Internet at sites listed under Further Reading.

Hide Composition

The skin of living animals forms a physical protective barrier. The thickness of the skin varies with species, age, sex, and body region. It is is composed of three major layers: the surface pigmented epidermis, the underlying connective tissue corium, and the deep subcutis (Table 8).

The chemical composition of the skin (Table 9) varies with the type and age of animal, sex, fat level, and hide treatment. In general, the hide is low in fat and minerals and high in

Table 2 Examples of some cured and tanned uses of hides, skins, or pelts and their by-products

Portion of hide, skin, or pelt	*Examples of finished products*
Cattle hide by-products	
Cured and tanned hides	Sole, upper, linings and heels for leather shoes, rawhide, bags, athletic equipment, belting, upholstery, harness, saddles, etc.
Corium layer	Picking bands, textile shuttle holders and passers, reconstituted collagen sausage, casings, cosmetics products, and collagen products
Tail hair	Paint brushes and upholstery padding (no longer used much)
Body hair	Felting, plaster retardant, etc.
Inside of ear hair	Imitation camel hair brushes
Hide trimmings	Tankage, fertilizer, glue, and inedible gelatin
Hide fat	Tallow
Calf skin	Light-weight leather, fabric trimmings, drumheads, gloves, etc.
Hog skin by-products	
Pig skin	Gloves, belts, razor straps, shoe uppers, inner-soles, upholstery, shoe counters, sausage, pork rinds, edible gelatin, glue, etc.
Trimmings	Dog chews
Hair	Upholstery padding (not used much anymore), felting, and plaster retardant
Bristles	Brushes
Sheep pelt, by-products	
Wool	Blankets, gloves, clothing, carpets, upholstery fabric, lanolin, etc.
Slats (skin after wool or fleece is removed)	Shoe and slipper uppers and lining, hat sweat bands, fancy shoes, gloves, garments, sporting goods, chamois, book bindings, diplomas, etc.
Hair sheep	Small pneumatics, diaphragms, and bellows
Pelts (wool or fleece left on) and trimmings	Heavy coat material, moutons, shearlings, glue, and tankage
Horse hide by-products	
Cured and tanned hides	Shoe sole and uppers, gloves, sporting goods, luggage, belts, harness, saddles, etc.
Domesticated land and water buffalo hide by-products	
Cured and tanned hides	Shoe sole and uppers, fancy leather goods, luggage, handbags, and buffing wheels
Goat and kid	
Cured and tanned hides	Shoe uppers and linings, gloves, fancy leather, handbags, and book bindings
Deer and elk hide by-products	
Cured and tanned hides	Shoe uppers, clothing, gloves, moccasins, and mukluks
Kangaroo hide by-products	
Cured and tanned hides	Shoe uppers, diaphragms, and bellows
Exotic and fancy leathers	
Aquatic group	Frog, seal, shark, walrus, and turtle leather
Land group	Camel, elephant, ostrich, emu, rabbit, and pangolin leather
Reptile group	Alligator, crocodile, lizard, and snake leather

protein (collagen), which increases as the hides are converted to leather. Hair is composed almost entirely of the protein keratin (6–10% of total hide protein).

Hide Harvesting

The quality of leather depends on techniques used for hide removal (flaying) and the processing that takes place in the harvest facility. The operations performed there are hide removal, preservation, fleshing, trimming, selection and grading, storage, and shipping.

Hide removal from cattle, sheep, and goats is accomplished by two basic techniques: the knife-skinning technique, using either conventional skinning knives or air-driven reciprocating knives, or the hide-puller technique. Another technique used in some countries pumps compressed air between the hide and the carcass to cause hide separation. Today in most modern plants, hides are pulled, because they can be removed by less-skilled labors, and the pulling technique results in less hide damage, lower manpower requirements per animal, less carcass contamination, and an increase of 2% in carcass yield because the stripper (or puller) pulls the hide from the fell rather than from the carcass itself, and this reduces shrinkage of the hide.

Pigs are often scalded in hot water (57–71 °C) containing chemicals to aid in hair and scurf removal until the hair slips, and dehairing occurs mechanically in a dehairing machine ('polisher') for 10–15 s. This machine scraping action, along with hot (60 °C) water spray, removes the hair. Difficult to remove hair is hand-scraped with bell scrapers and shaved, and the remaining hair is often singed with a gas flame. However, the skin (rind) is then not generally used for leather production because it has been denatured by heat, which causes the protein in the hair follicles to denature and result in 50% of pigskin being unsuitable for upper shoe leather. Therefore, the skin (rind) often stays on the carcass and is cooked as part of the meat joint (crackling), is used as filler in meat processing, or converted into gelatin. Pigskin that has been dehaired at a temperature less than 58 °C can be removed from the carcasses or a portion of the carcasses (e.g., belly) and used for production of leather (e.g., Puppy leather). In some countries, a covering during scalding protects the skin that is to be pulled. The Wolverine skinner pulls this portion of the carcass through a knife that separates the pigskin from the carcass. The pigskin goes through a fleshing machine, which removes all but approximately 3% of the fat. The skin is then refrigerated and shipped to a tanner.

A Townsend skinner separates the skin and some of the fat from other tissues and is often used to remove the skin from dehaired ham, loin, or belly, and the skin and some adhering fat is used for pork rinds, cracklings, or gelatin production. The gelatin industry in the United States uses approximately 50% of pork skins. Some undenatured pork skins are used in human burn/grafting after the hair has been removed by a laser. In some countries, pigskin is eaten, whereas in others pigskin is used as filler in sausages and meat pies.

Mechanical pulling of pork hides (dehiding) is gaining popularity (96% of all pigs are, e.g., dehided in Japan) because of the energy and labor savings and the fact that the carcasses chill more quickly, which reduces the risk of producing pale, soft, and exudative pork. This technique produces hides that are useful for leather production and for medical use (burn treatment). The mechanically pulled pig hides are fleshed, salted, and shipped to tanners.

Hide Curing

The hide after removal is quickly cooled or treated with a bactericidal spray or acidic or caustic treatment. Then, it is cured to remove excess water and to arrest bacterial and enzymatic decomposition. With pigskin, traditional salt curing does not work well; solvent dehydration may be used, or the uncured hide may go directly to the tanning operation (usually chrome).

Drying in areas with low relative humidity may be used to preserve hides or, more commonly, salt may be used as the curing ingredient. There are four basic techniques for curing: air-drying, salt-pack, mixer, and raceway curing.

The oldest salt curing method is the salt-pack technique (**Table 10**). Salt-pack curing is simply a flesh side-up stack (1–1.3 m) of hides with approximately a unit of salt per unit of hide spread evenly over the flesh side of each hide. This salt level controls bacterial growth and draws moisture out of the hides. Preservatives are often used with salt-pack curing; 1% sodium fluoride (NaF – should not be inhaled) or 1% naphthalene ($C_{l0}H_8$) plus 1% boric acid (H_3BO_3), based on the weight of salt, have been used successfully. Other salt additives might be zinc oxide (ZnO) or sodium metabisulfite ($Na_2S_5O_2$) in various combinations. Cattle hides in the stack are usually allowed to cure for 20–30 days.

Brine curing reduces curing time from 30 days (salt-pack curing) to 24 h. It is desirable to flesh hides first because fat retards salt penetration and moisture removal. The mixer curing method (hide processor) is often used, particularly in smaller plants. The mixer looks and operates much like the familiar cement mixer. It utilizes a saturated salt solution, or

Lancaster, PA: Technomic Publishing Co.

fresh salt may be added at 20–24% of the weight of hides. A chlorinated lime or similar bacterial or mold deterrent is also often utilized. The hides are rotated in the mixer for 6–12 h. When hides are removed from the mixer they are wet. They pass through a wringing machine to squeeze out the excess liquid or are hung to drain by dripping.

Raceway curing is the most common method of curing hides (Tables 11 and 12). The raceway-shaped tank ('raceway vat') is agitated by two overhead paddle wheels that circulate the brine and keep the hides moving. The raceway is filled with saturated brine together with other additives (Table 13), for example, 0.3% (of hide weight) of sodium fluoride (NaF). This method requires approximately four units of saturated brine for each unit of green hide. Hides are cured in the raceway for 16 h. When hides are removed from the curing raceway, moisture is removed as with brine curing. A proper brine-cured hide should contain $<40\%$ moisture with a salt saturation of $>85\%$. Pit curing or vat curing is a modification of raceway curing and salt-packing. The hides are salted and the pit is flooded with saturated brine (Table 14). This curing technique requires 24–33 h. Owing to the environmental impact of sodium chloride, potassium chloride (KCl) can be used instead. Nonsalt methods of cattle hide curing are also available. These include sodium sulfite/acetic acid; solvent processing (acetone at pH 4.5–5.0, ether–alcohol, or ether–alcohol and ether–ester); biocide curing, which has been utilized in South Africa due to restrictions on salt; electron beam radiation; refrigeration (but freezing is not an alternative); and chrome tanning, at least to the blue stock stage immediately after harvest.

Fleshing

Fleshing is necessary to produce quality hides. The fleshing machine removes 9–12 kg fat, flesh, hair, and manure per cattle hide. The fleshing operation may be done before or after curing. Fleshing residue and hide trimmings are also utilized by the by-products industry.

Trimming

Trimming can be accomplished before or after fleshing and therefore before or after curing. Hides are trimmed to remove parts that have no value as leather. A knife is used to remove ears, ear butts, snouts, lips, scrotal sac, udders, tail, head skin, fat, and muscle tissue from the side of the head and ragged ventral edges.

Sorting

Sorting of hides after curing is done on the basis of sex, weight, and branding. Basic categories of hides include steer hides, both native (unbranded) and branded; heifer; and cow and bull hides. Bulls produce the thickest hides, which are used for production of shoe sole leather. Steer and heifer hides tend to be thicker than cow hides but thinner than bull hides and are often used for shoes and boots. Cow hides are usually the thinnest. Mature bovine hides are used to produce garments, purses, and gloves. Hides are also graded for quality into categories 1, 2, or 3. The difference in grade is based on number and type of defects, which include scratches, cuts, branding, mange, insects, and animal diseases. Further Reading includes sources for more complete listings of hide damage and defects during storage and shipment.

Graded hides are next sprinkled with approximately 450 g of 'safety salt' to avoid deterioration during storage and shipment. Hides are folded, flesh side out, and tied to form a bundle. The bundles are then stacked to a maximum height of 1 m to squeeze out excess moisture and stored to await shipment. Under cool conditions, the hides can be stored for 1 year, but under hot and humid conditions, hides can be stored only for a few months.

In some countries, unsalted hides are chrome tanned at the slaughter plant to produce a 'wet blue' moist product. These hides can be stored for months. Another possibility for eliminating salt curing is treating with sodium sulfite (Na_2SO_3) and acetic acid (CH_3COOH) and holding them in a closed system. Hide-shipping containers are usually sprayed with an insecticide before loading.

Quality of Cure

Hides and skins are normally evaluated for quality of cure by determining the moisture (volatile material) and salt (or ash)

Table 6 Packer cattle hide selection (North America)[a]

Selection	*Description*	*Range of net weight (lbs)*[b]	
		Conventional	*Trimmed and fleshed*
Slunk	Unborn calf		
Light calfskin		Less than 9	
Heavy calfskin		9–15	
Kidskin		15–25	
Overweight kidskin		25–30	
Heavy native steer	Steer hide free of brands	58 and above	47 and above
Light native steer	Steer hide free of brands	48–58	39–47
X-light native steer	Steer hide free of brands	30–48	23–39
Heavy butt-branded steer	Steer hide branded one or more times behind the break in flank	58 and above	47 and above
Butt-branded steer	Steer hide branded one or more times behind the break in flank	30 and above	23 and above
Heavy Colorado or side-branded steer	Steer hide branded one or more times forward of the break in flank	58 and above	47 and above
Colorado or side-branded steer	Steer hide branded one or more times forward of the break in flank	30 and above	23 and above
Light-branded steer	Steer hide branded one or more times	30–58	23–47
Heavy Texas steer or branded steer	Steer hide branded one or more times	58 and above	47 and above
Texas steer or branded steer	Steer hide branded one or more times	30 and above	23 and above
Heavy native cow and heifer (plump)	Hide from female bovine free of brands	53 and above	43 and above
Light native cow and heifer (plump)	Hide from female bovine free of brands	30–53	23–43
Heavy native cow and heifer (thin or spready)	Hide from female bovine free of brands	53 and above	43 and above
Light native cow and heifer (thin or spready)	Hide from female bovine free of brands	30–53	23–43
Branded cow and heifer	Hide from female bovine branded one or more times	53 and above	43 and above
Light branded cow and heifer (plump)	Hide from female bovine branded one or more times	30–53	23–43
Heavy native bull	Hide from bull free of brands	58 and above	
Heavy branded bull	Hide from bull branded one or more times	58 and above

content. Hide moisture of less than 40% indicates excessive drying and protein denaturation and that of more than 48% indicates an inadequate cure.

Tanning

When cured hides arrive at the tannery, they are retrimmed and split along the backbone. Hides are graded and sorted into uniform size, weight, and type so that the tanning operation can be adjusted.

Soaking

'Soaking' is utilized to restore moisture that was removed for control of bacterial growth. Soaking flexes and softens hides and is accomplished with water, wetting agents (detergents), and disinfectants. The soaking process usually requires 8–20 h for reabsorption of needed water. The last step of soaking is washing the hides free of dirt, manure, salt, and blood.

Dehairing

The dehairing process is chemical in nature; however, mechanical dehairing equipment is sometimes used after hair has been chemically loosened. The most common chemical depilatory agents are a saturated solution of calcium hydroxide ($Ca(OH)_2$; hydrated lime) and sodium sulfide (Na_2S) or sodium bisulfide (NaHS) at a pH of 12.5. Other mixtures used to remove hair might include milk of lime (CaO) fortified with sodium sulfide (NaS), sodium bisulfide (NaHS), arsenic sulfide (As_2S_2), or dimethylamine ($(CH_3)_2NH$). Another formulation uses 30% water, 6–12% sodium sulfide, 2–3% sodium

bisulfide, and 4% hydrated lime. Dimethylamine sulfate is also often used and allows reduction of lime and sulfide concentrations. If hair is to be saved, a weak solution and a low temperature is used, and only the hair roots are loosened. In 2–4 days, hair is collected, washed with water, rewashed in water (100 parts) with acetic acid (1 part), and dried. More concentrated solutions that have a higher pH (>11.5) and are applied at higher temperatures can be used. Hair can be totally dissolved in a few hours. Pigskin requires higher concentrations (4–5%) of sulfide than cattle hides. If all of the hair is not removed by the chemical reaction, the dehairing machine removes the remainder. Enzymes can also accomplish dehairing and dewooling. This technique has the advantage that the hair comes out by the roots, and it yields more hair and a cleaner hide grain.

Table 8 Skin layers and two methods of splitting hides (USA)

Side	*Skin*	*Leather*	
		Five layers	*Four layers*

Some leather is tanned with the hair or wool remaining on the hide (e.g., shearling leather) that is produced from sheepskins (uniformly clipped to short lengths). Either chrome or the vegetable process can tan this type of product, but the wool must be cleaned and degreased. Weaker tanning solutions for longer lengths of time are used.

Some hides such as kidskins, sheepskins, and pigskin contain a large quantity of fat (Table 9). Degreasing is done by warming hides in water and pressing them in a hydraulic press, followed by washing and rinsing. In some cases, hides are washed with surface-active or emulsifying agents (i.e., quaternary ammonium salts of higher fatty alcohols).

Deliming

The deliming process consists of a washing step in which ammonium sulfate ($(NH_4)_2SO_4$)) or ammonium chloride (NH_4Cl) and sometimes trisodium phosphate (Na_3PO_4) or sulfuric acid (H_2SO_4) are added to convert the remaining lime into water-soluble compounds. Ammonium chloride penetrates faster than sulfate and results in softer leather. Ammonium sulfate is used for most shoe upper leather because it produces firmer leather with more temper. These deliming operations lower the pH to 8–9, which reduces the alkaline swelling of the hide appropriate for enzymatic bates.

Table 12 Agitated brine-curing of fleshed cattle hides, requiring a minimum of 2 days and yielding 62–68% of green hide weight

Weight of hides (kg)	*Operation or activity*	*Composition or change*
Green		
100	Receive hides from slaughter	65–70% water, 30–35% of weight is hides
100	Trim ears, snout and tail	3% loss; 3 kg trim to rendering
97	Wash hides	2% loss; 2 kg blood and manure
95	Flesh and demanure with machine	12–18% loss; 12–15 kg fleshing to rendering; 1–3 kg manure
80	Trim pattern	3–4% loss, 3 kg trimming to rendering
77	Move hides to raceway	4 kg of brine per kg of hide, maintain brine at 94–97° salimeter
77	Cure in moving brine for 24 h	15–17% net loss in weight; 20–25 kg loss in water; 7–10 kg uptake of salt; 10–15 kg loss of salt to sewer[a]
Cured wet		
	Remove from brine and pass through wringer	Loss of excess brine
65	Inspect, add 1 kg fine salt, bundle	1 kg uptake of salt
65	Move hides to storage or load for shipment	12–15% salt; 40–50% water; 35–45% hide substance

[a]Most modern processors recycle excess brine and do not discharge it. Also the use of evaporation ponds decreases discharge to sewers.

Bating

Bating removes the alkaline dehairing chemicals and other nonleather substances. Bates digest and dissolve the noncollagenous protein constituent of skin and are inactive on collagen. Bates are enzymes of bacterial, fungal and plant, or animal origin. Bating makes the hide softer, less harsh, and cleaner. Bates also remove the glue-like material between the collagen fibers that would result in hard and 'tinny' leather. The bating operation may last from a few hours to 16 h. A strong bating action is used when making soft leather and a light bating action is used in making less flexible leather. Antiseptics, such as sodium fluoride, sodium pentachlorophenol (C_6HCl_5ONa), or β-naphthol ($C_{10}H_8O$), are sometimes added. Many bates are a mixture of deliming materials and various enzymes, so that deliming and bating can be conducted simultaneously. After bating, the pelts are rewashed to remove undesirable, digested nonleather material.

Pickling

Pickling (which can be skipped if hides are to be tanned immediately after bating) places the hides in acid (pH < 3). The hides require a pH reduction in order to accept the tanning materials (e.g., chrome), which are not soluble in an alkaline environment. Sulfuric acid (H_2SO_4) is the most common acid employed, but other acids can also be used. The pickling procedure starts with the addition of salt. This prevents swelling (acid swelling) by tying up excess moisture. The pickling takes only a few hours.

Tanning

Tanning converts the collagen fibers of skin into stable, nonputrescible leather. Chrome tanning is the most popular (90%) method of tanning because it can be accomplished quickly and produces leather with desirable physical and chemical properties (long wearing and heat resistant). Chrome plays a role in hide preservation, acts as a hide stabilizer to temperature extremes, and is a well-fixed, nonleaching tanning material. Disposal of chrome is something of a problem, even though chromium in leather is Cr(III) and not the toxic Cr(VI). Accordingly, the Environmental Protection Agency does not consider the waste as toxic. A chromium salt (e.g., sodium bichromate, $Na_2Cr_2O_7$) reacts with a reducing sugar (maltose, $C_{12}H_{22}O_{11}$) and sulfuric acid (H_2SO_4), which reduces the chromium salt to basic chromic sulfate ($Cr(OH)SO_4$, called 'chrome'), which is then added to the hide at 1.5–3%. A sodium salt of a chlorinated phenol preservative (0.02–0.1%) is sometimes added. The pH of the drum contents is increased ('basification') to 3.4–3.6 by adding sodium bicarbonate ($NaHCO_3$, baking soda) or other alkalis, which increase the affinity of the collagen to the chrome. The theory of chrome tanning is that cross-linkage is accomplished by bonding the various chrome ions with free carboxyl groups in the collagen side chains. The liming helps in exposing additional carboxyl groups by chemical hydrolysis of amine side chains. The tanning operation requires 4–6 h and the resultant bluestock is now called leather. It is preserved against putrefaction and its thermal stability has been raised. Hides are now 'in the blue.'

Table 14 Pit-curing of fleshed cattle hides, requiring a minimum of 3 days and yielding 62–68% of green hides weight

Weight of hides (kg)	*Operation or activity*	*Composition or change*
Green		
100	Receive hides from slaughter	65–70% water and 30–35% of weight is hides
100	Trim ears, snout and tail	3% loss; 3 kg trim to rendering
97	Wash hides	Wash – hides and manure
95	Flesh and demanure with machine	12–18% loss; 12–15 kg fleshing to rendering; 1–3 kg manure
80	Trim pattern	3–4% loss; 3 kg trimming to rendering
77	Salt hides down into pit 1.2–1.5 m (4–5 feet) deep; flood with saturated brine	0.5 kg of salt (no. 1 rock salt) per 1 kg of hide
77	Cure in pit (still brine) for 48–55 h; drain pit for 24–33 h	15–17% net loss in weight; 20–25 kg loss in water; 7–11 kg uptake of salt; and 10–15 kg loss of salt to sewer[a]
Cured		
65	Remove from pit, inspect, and bundle	Reclaim excess salt
65	Move hides to storage or load for shipment	12–16% salt; 35–45% water; and 40–50% hide substance

[a]Most modern processors recycle excess brine and do not discharge it. Also the use of evaporation ponds decreases discharge to sewers.

Source: Adapted from Biedermann, K., Neck, H., Neher, M.B., Wilhelmy Jr., V., 1962. A technical–economic evaluation of four hide curing methods. Agricultural Economic Report No. 16. Washington, DC: Marketing Economics Division, Economic Research Service, USDA; Minnoch, J.K., Minnoch, R.M., 1979. Hides and Skins. Ithaca, NY: National Hide Association; and Ockerman, H.W., Hansen, C.L., 2000. Animal By-Product Processing and Utilization. Lancaster, PA: Technomic Publishing Co.

Vegetable tanning (see Retanning below) is a slower process that takes several months and produces firmer leather with more water resistance. Zirconium (Zr) can be processed into ZrO_2 and, along with silica and under acidic conditions (pH <2), can tan skin rapidly.

A small percentage of skins are tanned by the alum (aluminum potassium sulfate, $AlK(SO_4)_2$) process, sometimes called 'tawing' process, to obtain pure white or sole-grey leather. The oil method using 'fish' oil (cod, whale, seal, or shark) is used to produce soft leather for moccasin or chamois leather. Other tanning methods include the formaldehyde procedure (formalin solution for white and washable leather), the glutaraldehyde method (for producing light-tan washable shearling bed pads), the calgon method (5% sodium hexametaphosphate at pH 2.8), the quinone technique, tungsten tanning, the aluminum method, the iron technique, and the silica procedure.

Wringing/Setting

The purpose of wringing or setting, sometimes called 'sammy,' is to remove excess moisture, smooth the grain, and remove wrinkles from the hide. The machine that accomplishes this is similar to the previously described wringing machine.

Splitting and Shaving

The purpose of splitting and shaving is to adjust leather thickness. Hide thickness (sometimes 8 mm or more) can vary from animal to animal as a result of age and can also vary between different areas of the skin on the same animal. The major portion of the thickness adjustment is accomplished by splitting with a horizontal band saw that contains a sharp flexible knife instead of saw teeth. The hide is fed through the machine with the grain (outer) portion up and this is the portion that is sized. Adjustable feed rolls above and below the knife control the ultimate thickness of the grain side of the hide to 0.25 mm. The underside (flesh layer) is called a 'split' (it does not contain any grain) and is often thick enough to be used for suede.

The two most popular methods of splitting hides can be found in Table 8.

Retanning

Hides are often 'retanned' using the combined desirable properties of more than one tanning agent. Retanning stabilizes chrome from leaching, imparts softness and body, and, in some cases, bleaches the chrome blue color. The more popular retanning agents are vegetable extracts and syntans. Vegetable extracts are some of the originally used tanning agents extracted from trees and shrubs with water and heat. Tannin (tannic acid, $C_{76}H_{52}O_{46}$) is the active agent in vegetable extracts and is found in more than 300 species of plants. Vegetable tanning results from hydrogen bonding between the tannin phenolic groups and the peptide bonds of protein chains. Frequently, 50% (by weight) of tannin is incorporated into hides.

Vegetable retanning results in solidity, body, and more uniformity in chrome-tanned leather. This is important in pigskin to modify the difference in temper of various parts of the skin.

Syntans are synthetic chemicals generally produced by condensing aromatic sulfonic acids or phenols with formaldehyde. They can also be of the acrylic resin type. Syntans are used to produce softer leather and to produce white or pastel shades because the syntan has a bleaching effect on the blue-green chrome-tanned leather.

For retanning, hides are washed and neutralized with a mild alkali to adjust the pH for the retanning material selected (e.g., pH 5 for vegetable tanning). After the retanning agent is added, the process usually takes 1–2 h.

Dyeing/Coloring

Dyeing (coloring) of leather is often preformed. There are hundreds of different dyestuffs and auxiliary products, and leather is usually dyed with blends to achieve the desired color. The tanner uses pH control to affect the affinity of the dyestuff for the fibers.

Useful properties of dyes can be classified into various categories:

- Acid dyes: penetrate readily, bright colors.
- Aniline types: combine with skin fibers.
- Basic dyes: surface dyeing, brilliant shades.
- Direct dyes: surface dyeing, deep shades.
- Metallized dyes: level dyeing, subdued colors.

The aim of coloring is not only to produce the right strength (contraction) and shade (hue or dullness) but also to produce a color that will resist fading, will not bleed, and can be dry-cleaned or washed.

Fatliquoring

Fatliquoring is used to adjust the firmness or softness of leather by lubricating the internal fibers and to increase the tensile strength of leather. The basic ingredients ('sponging' compounds) are vegetable, fish, mineral, or animal oils, such as neatsfoot oil; glycerin and related fatty substances; soaps; egg yolk; and sometimes waxes or clay and chemical reagents to improve water solubility or emulsifiers that disperse the nonpolar oils. Some fatliquoring materials are highly sulfated oil blends (e.g., sulfated castor oil). Fatliquoring increases softness by breaking down thick fibers into smaller ones. Anionic fatliquoring substances are prepared from mixtures of sulfated or sulfonated oil; cationic fatliquors are blends of alkylated long-chain amines mixed with raw oils. By selection of the type and amount of fatliquor, various degrees of softness can be achieved. Pigskin usually requires more fatliquor than cattle skins.

Setting Out

The 'setting out' process smoothes and stretches the leather and compresses and squeezes out the excess moisture and grease. This is accomplished on a machine, like a fleshing machine with a blade designed to exert pressure and to smooth the grain. This compresses the leather and results in a product with 60% moisture.

Drying

Drying removes all but the equilibrium moisture. There are four different drying methods that influence the characteristics of leather. The simplest drying method is 'hanging,' in which the leather is hung and often passed through a large drying oven. Another method is called 'toggling,' in which the skins are stretched and attached to a perforated metal frame by fastening hooks called toggles. An additional skin is then fastened to the other side of the frame. These frames are then placed in a drying oven.

A popular drying technique is called 'pasting,' in which hides are actually pasted to large stainless-steel, porcelainized steel, or glass plates and are placed in a drying oven (60–66 °C, 40% relative humidity) for 4–6 h. Another drying technique uses 'vacuum dryers.' After drying, the skins contain 10–12% moisture.

Conditioning

Conditioning or 'wetting back' involves introducing controlled amounts of moisture. The moisture is applied by shower-like nozzles, and the hides are then stacked and covered with a moisture-proof material to 'mull' for approximately 16 h. The moisture level is raised to 25%.

Staking

'Staking' (mechanical massaging) is done to soften the leather and to make leather more pliable, in combination with fatliquoring. This primarily governs the final temper. The combination of pulling and rolling by the staking machine applies a great deal of mechanical stress and flexes the fibers.

Buffing

Buffing involves smoothing the grain surface by light mechanical sanding to improve the appearance. Brushes, jets of air, or vacuuming removes leather dust.

Table 15 Physical properties of shoe-upper leather

Property	*Value*
Tensile strength (MPa)	15.3–37.5
Elongation at break (%)	29.5–73.0
Stitch tear strength (N cm^{-1})	1280–2275
Thickness (mm)	1.5–2.4
Bursting strength (kN cm^{-1})	1.1–24.5
Apparent density (g cm^{-3})	0.6–0.9
Real density (g cm^{-3})	1.4–1.6
Heat resistance	Shrinks depending on moisture; anhydrous decomposition at 160–165 °C

Journal of the American Leather Association 46, 34; Kirk-Othmer, 1981. In: Martin, G. (ed.), Kirk-Othmer Encyclopedia of Chemical Technology, third ed. vol. 14, pp. 200–230. New York: Wiley; and Ockerman, H.W., Hansen, C.L., 2000. Animal By-Product Processing and Utilization. Lancaster, PA: Technomic Publishing Co.

Finishing

Finishing is the application of film-forming materials (polymeric impregnates) that provide abrasion and stain resistance, enhance color (finishing material; transparent to opaque), add body, alter tactile properties, and make an easy care leather. The type of finish is determined by the type of skin and its ultimate use.

Coating materials include the following:

- Acrylate polymers (basic structure acrylic acid, $C_3H_4O_2$).
- Albumin, blood (see 'albumin, egg').
- Albumin, egg (egg white: 53% C, 7% H, 16% N, 2% S).
- Butadiene polymers (basic structure butadiene, C_4H_6).
- Casein (cow's milk protein, 54% C, 7% H, 16% N, 22% O, 1% P, and 1% S).
- Isinglass (fish glue).
- Linseed oil (glycerides of linolenic, linoleic, oleic, stearic, palmitic, and myristic acids).
- Nitrocellulose ($Cl_2Hl_6N_4O_{18}$).
- Polyurethane (basic structure is urethane, $NH_2COOC_2H_5$).
- Acrylic-urethane copolymer.
- Shellac (resinous excretion of an insect).
- Vinyl polymers (basic structure is vinyl acetate, $C_4H_6O_2$).
- Wax (vegetable fat expressed from fruit).

After the finishing material is applied, it is dried in a tunnel that is heated with steam or infrared units. Maximum results are obtained when several finish coats are applied with intermittent drying.

Planning

'Planning' smooths the grain surface or produces a varied grain texture and is conducted on presses. The leather can also be embossed in which pressure is applied by engraved plates that produce a permanent pattern.

Area Measurement

Because leather is sold by area, it is measured with a planimeter. This employs fingers that sense the leather as it passes through a machine and sums the total area. The final step is grading for uniformity of thickness, color, and defects.

Physical Properties of Leather

Leather has many unique and valuable physical properties (Table 15), most of which can be attributed to its internal

Table 16 Tanning steps and what occurs at each stage

Tanning step	*Explanation*
Flaying	Hide removal: Knife, puller, and air pressure used
Hide curing	Temporary protective (from bacteria and enzymes) treatment for hides, traditionally by NaCl, sometimes drying
Fleshing	Removes attached adipose tissue (can also be done prior to curing, soaking or liming)
Trimming	Removes odd-shaped, unworkable areas of the hide
Sorting	According to sex, weight, branding, and defects
Storage/shipment	Safety salt and insecticides are often used
Soaking	Removes salt, blood; restoration of moisture
Liming/dehairing	Removes hair, epidermis, some soluble proteins; traditionally uses $Ca(OH)_2$, and Na_2S or sulfides, NH_3; enzymes can also be used
Splitting	Diverts bottom layer into food use (e.g., sausage casings)
Deliming	Removes alkali (traditionally using $(NH_4)_2SO_4$)
Bating	Removes noncollagenous materials enzymatically
Pickling	Lowers pH (using salt, then H_2SO_4) for reception of tanning chemicals
Tanning	Preserves from putrescence; imparts thermal stability; 90% of hides tanned with salts of Cr(III)
Wringing/setting	Removes excess moisture
Trimming	Removes unusable perimeters; generates Cr-containing waste
Splitting	Lower layer destined to suede, top layer to grain leather
Shaving	Adjusts thickness, generates Cr(III)-containing waste
Retanning	(Minerals, vegtans, and syntans) Adds body, softness, bleaches colour, and stabilizes Cr from leaching
Coloring	Dyeing (with acid, metallized, direct, and basic dyes)
Fat-liquoring	Lubricates for flexibility, softness (lipid derivatives; emulsifiers)
Setting out	Removes excess moisture, stretches, smoothing of grain surface
Drying	Removes all but equilibrium moisture
Conditioning	Introduces controlled amounts of moisture for softness
Staking	Mechanical flexing for softness
Buffing	Sanding of grain surface; generates Cr(III)-containing waste
Finishing	Impregnates and coats with polymeric materials for abrasion and stain resistance, adds body, colour effects, gloss and handling properties and makes the leather easier to care for
Planning	Smooths grain and produces varied grain texture
Area measurement	Leather is sold by area

structure. Leather has high tensile strength, which makes it one of the strongest flexible sheet materials. Leather also has very high tear strength, because the fibers are random in orientation and do not have a fixed tear path. Pigskin, however, is much weaker in tear resistance and cannot be used in some products. The elongation (maximum stretching without breaking) of leather can be controlled (15–73%) by selecting the tanning and fatliquoring processes. Leather also has excellent flexibility over a wide temperature and moisture range, making the product suitable for harsh environments. Leather also provides a safety feature through its puncture resistance, which contributes to its long wearing. Leather can absorb and transmit moisture (breathability; pigskin is very good at this), has the ability to cool in hot weather and insulate in cold weather, and can block wind, all of which make it an ideal material for garments and shoes. Leather can also be molded; it retains its other desirable properties even after being permanently deformed into new shapes, which is one of its most significant properties for making shoes. This combination of properties makes leather a unique and very useful material.

Tanning Effluent and Waste

Information on these topics can be located in the Further Reading.

Summary

A summary of the tanning process and what each step accomplishes is given in **Table 16**.

Inedible

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

This article is a revision of the previous edition article by G.G. Pearl, volume 1, pp. 112–125, © 2004, Elsevier Ltd.

Introduction

Inedible meat by-products have a prehistoric significance that was established long before the advent of the meat industry. As animal protein (meat) was acquired primarily by hunting and fishing for food purposes, the inedible portions were left for nature's disposal or used for clothing, housing, fuel, and other life-support functions. In the early days of the modern meat industry, the inedible meat and fat remaining after hide removal were likewise disposed of by, most often, dumping into trenches or rivers. The earliest nonedible usage of animal by-products (ABPs) was probably as fertilizer. American-Indians placed fish with seeds when planting corn. Also, the protein and mineral fraction that remained following the removal of a portion of fat was generally disposed of by spreading over crops. The modern world is more environmentally sensitive and dense population centers made this practice unacceptable. This evolution began in the nineteenth and early twentieth centuries, and it was during this period that rendering was adopted as a means of processing animal raw materials via cooking and fat extracting. Fat was then used in soap making and candle making in this era. The protein fraction was not used extensively until the early 1900s. A recorded benefit of the use of digester tankage animal protein was documented in 1901 by Professor C.S. Plumb of Purdue and later of The Ohio State University (OSU). He published research conducted with swine showing dramatically increased growth rate by including animal protein ingredients as a supplement to ear corn. This research was so important that a university building was named after him at OSU. Since that important discovery, the literature has rapidly indicated the benefits of animal protein and fat ingredients for all livestock, poultry, domestic animals, and aquaculture species.

In recent years, bovine spongiform encephalopathy (BSE) – mad cow disease – and other transmissible spongiform encephalopathies (TSEs) have become endemic throughout regions of the world. The infectious agent in BSE is believed to be a specific type of misfolded protein called prion. Prions are not destroyed even if the beef containing prion is cooked. This ruminant disease is transferable to humans by consumption of contaminated tissue. Current regulations have mandated modifications in processes and precautionary principles to prevent animal and human diseases. Currently, regulations for the utilization of ABPs in North America differ from those in Europe as well as in other parts of the world. The United States has prohibited use of mammalian-derived proteins in any feed for cattle or other ruminant animals, with specific exemptions (21CFR589.2000), since 1997. Downer cattle are also no longer permitted in the food chain.

The European Union (EU) has issued Regulation (EC) No. 1774/2002 on the use of ABPs. Detailed requirements for the processing and use of ABPs are currently divided into three categories. Meat and bone meal (MBM) is at present not allowed as feed for farm animals. MBM produced from category 3 ABP materials can be used for pets (companion animals). The conditions for rendering ABPs are also specified in the EU regulation, including maximum particle size, temperature, time, and pressure for heat treatment. All category 1 ABPs must be incinerated, whereas category 2 ABPs can be used, for example, as fertilizer or for landfill. The categories according to the EU regulation are defined in Table 1. Regulations and directives that govern the processing and utilization/disposal of animal coproducts are under constant review with regard to possible changes as dictated by current issues affecting individual countries; thus, changes can be expected.

Table 1 Basic categories of animal by-products (ABPs)

Category 1 ABPs	*Category 2 ABPs*	*Category 3 ABPs*
Animals suspected of transmissible spongiform encephalopathy	Manure or digestive tract content from mammals	Animal waste fit for human consumption
Specified bovine spongiform encephalopathy (BSE) risk material (including dead ruminants)	Material from treatment of wastewater (category 2 and 3 plants)	Nonruminant blood, hides, and skins, which have passed antemortem inspection
Material from treatment of wastewater (category 1 plants)	Products containing veterinary drug residues	Shells, hatchery by-products, and cracked eggs with no sign of clinical disease
Pet, zoo, and circus animals	Farmed animals that have died or been killed on the farm	Raw milk from healthy animals
Experimental animals	Fish with clinical signs of disease	Food destined for animal consumption
Products from animals with residues of prohibited substances or environmental contaminants		Fish and fish offal
International catering waste		Blood, hides, hooves, feathers, and hair from animals with no sign of disease
		Catering waste, including used cooking oils

The Office International des Epizooties is structured to evaluate science, to assess risk and, to develop policies that affect animal health on a global basis. Future direction and policy will, undoubtedly, be supplied by this organization, which currently represents 175 members. It is considered by most authorities as the 'World Organization for Animal Health.' The incidences of TSEs as well as all emerging diseases and ethnic and ethical issues will continue to dictate specific geographical policies.

Processed ABPs are generally classified as either animal proteins or fats. This article discusses the products within these major classifications.

Inedible By-Products

Production and processing of edible meat and poultry result in an inedible fraction. Edibility is a relative term and is determined by a number of factors, including consumer acceptance, demographics, regulatory requirements, economics, tradition, hygiene, and religious beliefs. The inedible raw materials from animal production consist of hides, skin, hair, feathers, hooves, horn, feet, heads, bone, toe nails, blood, organs, glands, intestines, muscle, fat, egg shells, and whole diseased carcasses. Using approximations, these tissues comprise 50% of the live weight of cattle, 40% of the live weight of pigs, and 30% of the live weight of broilers. As further processed, prepackaged, and table-ready meat products are being brought to the marketplace, the inedible portions have increased in relation to the original weight of the animal. In recent years, global regulations and directives have arisen as precautionary principles for adding specific animal tissues categorized as inedible fractions. These trends are expected to continue and to contribute even more inedible tissue to the by-product pool. The only exception to this trend is mechanical deboning, which converts soft tissue (attached to the bone and bone marrow) and extracted gelatin from bones into the edible category.

World production of ABPs is not known in exact quantities due to the inconsistency of terminology, specifications, processing, and end usage.

Processing

Several processes are utilized to handle or dispose of inedible raw animal tissues. The most frequently referenced are burial, landfill, and composting as well as burning (on pyres), incineration, or rendering. Rendering, composting, and biogas production are the only processing methods that recycle and provide value to the by-product tissues, as the other processes are disposal procedures. Rendering and incineration are the only processes in which temperature-, time-, and pressure-controlled procedures and other controlled process procedures are used in treating raw animal tissue. The rendering process separates fat from the proteinacious and mineral components, removes most of the moisture, and inactivates microorganisms and parasitic organisms. The rendering process completely decharacterizes the muscle, connective, structural, organ, and adipose tissues. The resulting tissue is a rich granular-type substrate and fats with specific nutritional components that have no resemblance to the original raw material. Biosecurity questions arise with all disposal procedures that do not incorporate sterilization principles provided by the controlled application of heat or other treatments. The UK Department of Health provides a summary of potential health risks for various methods of handling ABPs (Table 2). This summary associates a risk factor with the most common methods of handling ABPs. Rendering remains the primary method for processing ABPs in most countries.

In 2009, the United States produced and harvested approximately 9 billion head of livestock as well as 8.9 billion poultry and a growing number of fish for the aquaculture industry. This makes animal food production one of the largest economic industries within the United States. Animal production is similarly important in most other countries. Animal protein and fat are important components of human diets.

Table 2 Summary of potential health risks for various methods of handling animal by-products

Disease/hazardous agent	*Exposure of humans to hazards from each option*				
	Rendering	*Incineration*	*Landfill*	*Pyre*	*Burial*
Campylobacter, *Escherichia coli*, and *Listeria*	Low	Low	Moderate	Low	High
Salmonella and *Bacillus anthracis*	Low	Low	Moderate	Low	High
Clostridium botulinum and *Leptospira*	Low	Low	Moderate	Low	High
Mycobacterium tuberculosis var. *bovis* and *Yersinia*	Low	Low	Moderate	Low	High
Cryptosporidium and *Giardia*	Low	Low	Moderate	Low	High
Clostridium tetani	Low	Low	Moderate	Low	High
Prions for BSE and Scrapie	Moderate	Low	Moderate	Moderate	High
Methane and CO_2	Low	Low	Moderate	Low	High
Fuel-specific chemicals and metal salts	Low	Low	Low	High	Low
Particulates, SO_2, NO_2, and nitrous particles	Low	Moderate	Low	High	Low
PAHs and dioxins	Low	Moderate	Low	High	Low
Disinfectants and detergents	Low	Low	Moderate	Moderate	High
Hydrogen sulfide	Low	Low	Moderate	Low	High
Radiation	Low	Moderate	Low	Moderate	Moderate

Abbreviations: BSE, bovine spongiform encephalopathy; PAH, polyaromatic hydrocarbons.

The pig population in China in 2007 was 462 million, nearly seven times that of the United States. China is also the largest producer of aquaculture foods. Projection for the next 30 years suggests that the world will need to produce 250% more meat, milk, and eggs than it currently produces. This production challenge requires adapting new technology and production practices.

On a global scale, modern efficient rendering facilities are concentrated in countries and regions possessing strong and well-established animal production industries. In the United States, the current annual quantity of inedible raw material generated from animal processing is approximately 23.4–24.3 billion kg. World or country data for individual countries are not readily available. An estimate of EU production is 16.1 million tonnes of animal by-products annually, of which 14.3 million tonnes are sourced from fit-for-human-consumption sources and 1.8 million tonnes from unfit-for-human-consumption sources. Argentina, Australia, Brazil, and New Zealand collectively process another 11 million tonnes of ABPs per year. In China, the rendering process is virtually nonexistent, and the inedible portion derived from each animal species is considerably lower than in other parts of the world. The protein, mineral matter, fat, and water derived from specific ABP materials are outlined in Table 3.

The Rendering Process

The rendering process uses ABPs from meat production. All ABPs are the direct result of animal food production and originate from the animal food production chain, for example, slaughterhouses (abattoirs), meat processing plants, butcher's shops, supermarkets, and livestock rearing.

The rendering process comprises a number of processing stages as depicted in Figure 1. The raw material is received at the installation in regulated, closed transportation units. Processing is usually initiated within a short time following receipt. Preparation for rendering involves prebreaking to reduce the particle size, which is important to provide proper heat penetration during the cooking process. The material is then heated under controlled conditions for specific monitored times.

EU regulations require that mammalian by-product materials are processed to 133°C for at least 20 min without interruption at a pressure (absolute) of at least 300 kPa produced by saturated steam. Sterilization by pressure cooking is not required for nonmammalian (poultry) material. Pressure cooking is not a standard practice in the United States and some other countries. Thus, processing specifications and the equipment used vary between installations and facilities.

Table 3 Reference data for animal carcasses and slaughterhouse by-product use. The sum of protein, mineral matter, fat, and water portions need not be 100%, as there are other ingredients in the substances mentioned, for example, starch, nucleic acid, and raw fibers. The figures serve only as a guide, as they depend on the actual composition of the raw material

Raw material and finished wastewater (condensed vapor)	*Quantity*	*Protein matter*		*Minerals*		*Fat*		*Water products*	
	(kg)	*(%)*	*(kg)*	*(%)*	*(kg)*	*(%)*	*(kg)*	*(%)*	*(kg)*

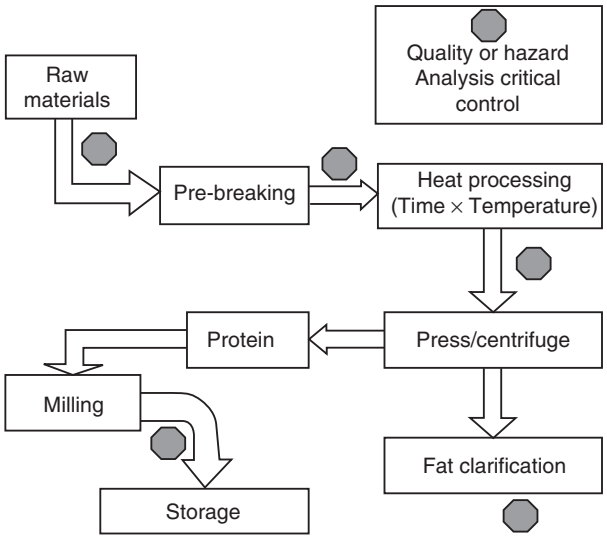

Figure 1 The basic rendering process.

Although the heat-processing vessels vary between batch and continuous systems, the process provides the sterilization function and also separates the fat from the nonfat material. Batch systems (dry rendering cookers) use vats of varying sizes that are surrounded by a steamheated jacket in the pressure cooking process. The newest installations use continuous cylindrical containers in which material is preheated and conveyed through the heating vessel in a continuous flow calibrated to meet the required temperature and time. In facilities requiring pressure treatment, the material is held in a pressure chamber at 300 kPa at the end of the cooking phase.

In either case, systems rely on heat to release fat from the cells of the fatty tissues, either in the absence (dry rendering) or the presence (wet rendering) of added water/steam. In dry rendering, the prebroken fatty tissues are heated in a steam-jacketed vessel to disintegrate the fat cells, release the melted fat, and drive off moisture. Most batch cookers for dry rendering are equipped with rotating agitators, which may be steam heated. Agitation aids in heat transfer in both batch and continuous systems while also serving as part of the conveyor action for the continuous systems. Dry rendering can be achieved at atmospheric pressure, under vacuum, or most commonly, at elevated pressure.

Cooking times vary but average approximately 2.5 h, during which the content is heated and sterilized and water is evaporated. After discharge from the cooking vessel into a percolator, which allows free fat to drain, the material passes to an expeller or centrifuge for further defatting. For efficient fat removal, a solvent extraction plant is sometimes used. This can reduce the fat content in the residue to 10–5%, but it is not often used today because of the explosive potential of the solvent. The cooked proteinaceous residue, most often referred to as cracklings or crax, is then cooled and milled to produce MBM.

Processing of Feathers and Pig Hair

Processing of feathers and pig hair first releases keratin, an indigestible protein, by hydrolysis. The hydrolyzed protein is then dried to produce a digestible, high-protein meal, which could be sold separately before the European ban on the use of certain animal proteins in animal feed, but today it is normally mixed with other types of meal and used as a protein concentrate.

Pig hair and feathers are treated separately, as the conditions (temperature and time) for a suitable hydrolysis of the two products are different. A more powerful heat treatment is required to 'open' pig hair.

The processing can be done in batches in dry rendering cookers, where the keratin-containing material is exposed to high temperature (135–145 °C) and pressure for 30–60 min. The pressure is then released and the product is dried and milled. This can eliminate the requirement for mechanical dewatering.

Special rendering equipment is also available for the continuous hydrolysis of feathers and hair. The material is transported in small batches to a compression chamber, where it is preheated, and then to the hydrolysis unit, where it is treated with direct steam under suitable pressure conditions for a shorter period (normally 10–15 min). The hydrolyzed material leaves the reactor at the bottom. Part of the water is then removed in a decanter. An evaporative unit is used for concentrating the liquid phase. The dewatered product is dried separately or with other rendering products.

Feather processing produces high sulfide emissions in the waste water. Removing hydrogen sulfide is important, because sulfide can impair the activity of the activated sludge and thus the biological treatment process.

Statutory Requirements for Rendering

Regulatory practices concerning ABPs are not consistent between countries. The EU has very severe restrictions. Regulations are altered frequently as a result of geographical incidences of specific animal and human diseases. Permitted disposal methods also differ between countries. Even the process of rendering is interpreted and regulated differently. As an example, an EU directive requires mammalian-derived raw material to be processed at 133 °C, 300 kPa pressure for 20 min. Processing conditions incorporating pressure treatment generally lower the nutritional value of resulting protein meals, except for those tissues with high keratin content. The rendering processes are consistent as a time–temperature treatment for the inactivation of microbiological organisms (bacterial, viral, protozoan, and parasitic).

Raw materials processed by the rendering industry are known to contain significant numbers of microorganisms. Many are potential foodborne pathogens, including a large number of *Salmonella* serovars. Clinically normal animals presented for slaughter and processing harbor microbial organisms, especially within their digestive systems. The presence of digestive tissue and intestinal content, other contaminated tissue from processing, and fallen stock contribute to raw materials with a high microbiological content. This is illustrated by the data for isolation from raw material representing multiple species of food animals as shown in Table 4.

Table 5 illustrates the efficacy of properly managed time–temperature processes for rendering. Temperatures exceeding the thermal death values for specific microorganisms and exposure to excessive temperature are correlated with lowered nutritional values, especially of protein and amino acids. Although research has shown that rendering lowers the infectivity of the prion, the agent most commonly believed to be the cause of the TSEs, it is not inactivated by any of the currently available rendering processess (see section Introduction for more information on BSE). Thus, rendering methods have never been capable of completely inactivating TSEs, nor has any other industrially described operational process.

Table 4 Microbiological isolations of foodborne pathogens from raw material at 17 US/Midwestern rendering establishments during two periods of sampling: winter and summer[a]

Organism	*Number of isolates/number of samples including replicates*			
	Winter	*Summer*	*Total*	*Percentage*
Clostridium perfringens[b]	30/42	30/42	60/84	71.4
Listeria spp.	33/42	31/42	64/84	76.2
Listeria monocytogenes	4/42	3/42	7/84	8.3
Campylobacter spp.	19/42	6/42	25/84	29.8
Campylobacter jejuni	15/42	2/42	17/84	20.0
Salmonella spp.	37/42	34/42	71/84	84/5
Coliforms[b]	42/42	42/42	84/84	100

[a]Some establishments operated more than one rendering line. Sampling occurred twice at each visit for each line, hence the denominator is based on 21 lines sampled twice each visit = 42.
[b]Characterization of the bacterial organisms and aerobic plate counts were not possible owing to the nature of the material.
Note: Fats and Proteins Research Foundation, Inc., Directors Digest no. 312.

Table 5 Microbiological isolations of foodborne pathogens from crax at 17 US/Midwestern rendering establishments during winter and summer[a]

Organism	*Number of isolates/number of samples, including replicates*			
	Winter	*Summer*	*Total*	*Percentage*
Clostridium perfringens[b]	0/42	0/42	0/84	0
Listeria spp.	0/42	0/42	0/84	0
Listeria monocytogenes	0/42	0/42	0/84	0

[a]Some establishments operated more than one rendering line. Sampling occurred twice at each visit for each line, hence the denominator is based on 21 lines sampled twice each visit = 42.
[b]Other organisms were isolated and recorded as laboratory observations but not identified within the scope of this pilot study.
Note: Fats and Proteins Research Foundation, Inc., Directors Digest no. 312.

Industrial Uses of Animal By-Products

Although the significant historical utilization of ABPs has been for feed ingredients, they have also been used in a variety of industrial applications. Rendered animal fat has been used to provide fuel sources and to make soap for more than 2000 years. These uses have declined in nearly all countries with the increased use of petroleum-based and synthetic ingredients. To illustrate this point, during the 1950–60s, more than 75% of all tallow production was directed to the soap-making industry. Today, the figure is approximately 6–7%. Nevertheless, usage has expanded into other areas, such as hand and body lotions, creams, and other cosmetic and bath products. Several hundred categories of chemical processes and formulations use animal-derived fatty acids. These include rubber and plastic polymerization, heavy metal salts, fabric softeners, lubricants and plasticizers, and oleochemical compounds. Gelatin, collagen, and glycerin have been basic ingredients for surfactants, paints, varnishes, adhesives, antifreeze, cleaners, polishes, and numerous pharmaceuticals. During the past few years, animal fats have proven to be a potentially valuable resource as an alternative fuel. Their use as a biofuel (biodiesel or burner fuel) has significantly lowered pollutant emission compared with the combustion of petroleum-based products. Thus, the industrial applications for nonfood, nonfeed by-products have provided an important market for utilizing inedible ABPs. It is projected that the conversion of unused animal tissues into value products will become increasingly important to the world's huge meat and poultry industry.

Animal By-Product Feed Ingredients

Animal protein supplements and fats have long been utilized by the feed compounding industry, primarily for their protein (amino acid) content, mineral content (calcium and phosphorus), and energy contributions. More than 125 individual ABPs are listed in the Association of American Feed Control Officials 2002 Ingredient Manual, but only 11 are major high-volume ingredients. This listing includes 46 different animal protein ingredients. The major protein ingredients are MBM (meat meal (MM)), poultry meal, hydrolyzed feather meal (HFM), blood meal, blood and plasma meal, and fish meal. Similarly, five primary categories comprise the major quantity of animal fats, which are tallow, choice white grease (CWG) (lard), yellow grease, poultry fat, and fish oil. All of these ingredients have different nutrient and product specifications. They all have specific contributions when used as components of livestock, poultry, companion animal, and aquaculture diets. The term nutrient is applied to any food constituent or group of constituents of the same general chemical composition that aids in the support of life. Protein, carbohydrates, fat, minerals, and vitamins are the generally recognized classes of nutrients. ABP ingredients not only contribute most to protein, fat, and mineral nutritional requirements of animals but also provide several sources of fat-soluble and B vitamins. The nutrient qualities complement other feed ingredients and particularly the feed grains, which are primary carbohydrate sources. During early development of the modern nutrient requirement and nutrient allowance data, MBM provided unidentified growth factors

(UGFs) that contributed to unexplained improvements in growth, feed utilization, reproduction, and disease prevention. Most of the UGFs have now been identified as specific vitamins, amino acids, or microminerals that can be included in diets from synthetic or refined sources. However, both modern commercial and experimental diets exhibit improved performance when animal by-products are included in the diets under a variety of management and production practices. Several antinutritional compounds and contaminants associated with other ingredient classes are not problematic with ABPs. Specifically, these include trypsin inhibitors, goitrogenic compounds, gossypol, mycotoxin/aflatoxins, glucosinolates, tannis, lectins, phytates, lathyrism, oxalates, alkaloids, and cyanogens. In addition, animal proteins do not contain oligosaccharides and other nonstarch polysaccharides that have been shown to alter gut viscosity and to reduce the digestibility of fats and proteins.

The animal feed and ingredient industries are major users of rendered animal fats and proteins. The subsequent text addresses the specific characteristics and specifications for each of the basic animal fats and protein ingredients.

Major Animal-Derived Fats

Inedible Tallow

Tallow is primarily derived from rendered beef tissue but can contain other animal fat as well. In terms of total volume and economic value, tallow is one of the most important animal fats. The term 'inedible' does not define any specific grade or specification other than that the rendering or processing was not conducted under food regulatory supervision. Edible animal fat in the United States can be rendered only in food-grade plants under inspection of the US Department of Agriculture. Most countries have similar requirements. Tallow is accompanied by many grades, specifications, and criteria depending on its end use. Titer is a basic specification requiring solidification above 40 °C (104 °F) after saponification. In contrast, greases solidify below this temperature. Fat quality is determined by hardness, color, moisture, impurities, stability, and free fatty acid (FFA) content. For reference, the commodity trading standards for tallow and greases are included in Table 6. These specifications place an emphasis on titer and FFA content in determining grade and value. For soap production, 'hard fats' or fats of high titer make soap of hard textures, whereas lower titer fats make softer textured soap. Fats with higher FFA contents have a greater glycerin loss in the soap-making process, which lowers their value.

These specifications, however, do not have the same influence on the value of fat utilization when used as feed ingredients. The primary benefit of using fats in animal diets is their energy contribution. Fats provide the most concentrated energy of all food/feed materials, containing approximately 37 kJ of energy per gram. As a general rule, fat provides at least 2.25 times the energy content supplied from the same weight of corn. In some formulations, management conditions, and species, the difference may be as high as 3.8 times the energy of feed grains.

Tallow is used extensively as a feed ingredient. Chemically, animal feeding fats are triacylglycerols, whose structure consists of 1 unit of glycerol and 3 units of fatty acids. The fatty acids are actually the components that give the respective fats their individual characteristics. Table 7 provides fatty acid profiles for the respective mammalian-derived fats. Most fatty acids found in natural fats vary in chain length between 8 and 24 carbon atoms. Feeding fats are predominantly of chain lengths between 14 and 18 carbon atoms. Fatty acids that contain double bonds are termed 'unsaturated' (the number of double bonds is indicated after the number of carbon atoms; thus, $C_{16:3}$ is a 16-carbon fatty acid with 3 double bonds). Conversely, structures without double bonds are termed 'saturated' fatty acids. As the carbon chain length increases in saturated fatty acids, the melting point increases. In other words, they possess higher titer and are thus 'harder.' A comparison of various animal fats, marine oils, and vegetable oils is provided in Table 8.

Tallow can be categorized as a saturated fat with its primary fatty acid profile that consists of palmitic (16:0), stearic (18:0), and oleic (18:1) acids. These qualities position tallow as the most appropriate feed ingredient for use in ruminant diets. When dairy cattle diets are fortified with tallow at 0.45–0.90 kg per cow per day, a routine positive milk production response is achieved. Studies have demonstrated a 6% improvement in feed efficiency incorporating tallow in feedlot cattle rations. Tallow has been utilized most recently in finishing diets for swine and in sow diets to improve pork quality. Scientists continue to explore the benefits of tallow as a feed supplement for improving feed efficiency; reducing feed dust; preventing segregation of ingredients; improving meat quality; and slightly modifying fatty acid profiles in meat, milk, and egg products as well as numerous expanded uses in both the industrial and feed ingredient industries.

Choice White Grease

CWG is commonly the inedible fat derived from swine. As described for tallow, an inedible designation for fats derived from swine is determined by a similar procedure. Edible fat from swine

is most commonly labeled lard, although edible lard may likewise be used as a feeding fat. The composition, characteristics, and consistency of lard vary greatly according to the part of the animal or tissue from which it is extracted (Tables 7 and 8) and the composition of the fat consumed. Both lard and CWG possess titers of less than 40. CWG contains less saturated fatty acids than tallow does and a more even distribution among the respective C16 and C18 chain length fatty acids.

CWG and lard are quite similar in composition. Their use has been primarily for feed or food, although several important industrial applications utilize these fat sources. Industrial dependence or applications are not as extensive as for tallow. CWG as feeding fat is generally directed to swine, poultry, and companion animal diets, although it is not restricted to these species. Piglet diets routinely contain from 5–8% fat, with animal fat being a primary source and CWG most often being the preferred source. A substantial database exists to predict a 2% improvement in feed efficiency for each 1% supplemental fat incorporated into swine growing-finishing diets. The most common formulation level is 2–5% supplemental fat. The use of fat in late gestation and lactation is a very common feeding strategy. Feeding fat to sows before and during lactation increases both milk fat percentage and total milk yield, thus increasing the survival potential of the litter. Enhanced energy intake during lactation provides reproductive benefits that include shorter return to oestrus and increased sow longevity. The beneficial effects of fats may be more pronounced in environments of elevated temperatures.

[a]IFN, International Feed Number.

[b]Dash indicates that measurements were taken but no values were detected.

The literature abounds with examples of the utilization of CWG, lard, or pork fat for various applications in feed formulation and production. Similarly, the importance of pork to the global supply of animal protein foods indicates that lard and CWG will remain a source of these fats for both feed and food purposes.

Poultry Fat

Poultry fat is derived from the slaughter and processing of chickens, turkeys, ducks, and other avian species. The majority of poultry fat is derived from broiler chickens. The available quantity has increased, and continues to rise, as further processing increases. As with further processing of other major categories of meat, this practice leaves more tissues for rendering at the processing sites and less as table waste. The fats rendered from poultry are of the lowest titer and have the highest ratio of unsaturated fatty acids compared with the saturated fatty acid components of the fats of any other species. A fatty acid profile is included in Table 7.

Poultry fat is used in domestic pet diets. Fat extracted from feathers has a high content of cholesterol and is a resource for the pharmaceutical industry.

Yellow Grease

Yellow grease is a very misunderstood product with respect to its source and utilization. It is a category of fat that evolved from the practice of renderers assuming their responsibility to collect, process, and utilize used cooking oils and restaurant greases as part of their raw material resources. Traditionally, fat/grease acquired from restaurants was of animal origin (tallow and lard), but with the controversy surrounding health effects of saturated and unsaturated fatty acids, the major components of frying media are now plant oils. These changes were made despite a lack of sound empirical data and the fact that most taste panels preferred foods prepared in animal fats. These major changes had drastic effects on the tallow and lard markets and brought about a new category of fats: feed-grade animal fat or yellow grease.

Yellow grease is best defined as a fat product that does not meet the definitions for animal fat, vegetable fat or oil, hydrolyzed fat, or fat ester. Like any other grade of fat, it must be sold on its specifications, which include the minimum percentage of total fatty acids, the maximum percentage of unsaponifiable matter, the maximum percentage of insoluble impurities, the maximum percentage of FFAs, and the amount of moisture. Most importantly, it must meet the Food and Drug Administration's established criteria for pesticides or other toxic chemicals.

The basic specifications for yellow grease are:

Total fatty acids (min)	90%
FFA (max)	15.0%
Moisture (max)	1%
Impurities (max)	0.5%
Unsaponifiable (max)	1%
Total MIU (max)	2%

Abbreviation: MIU, moisture, impurities, and unsaponifiables.

Although these are basic specifications, they are subject to negotiation between buyer and seller on a contract-by-contract basis. The presence of FFA in fats or ABPs was once considered an indication of rancidity. Questions are still raised regarding the utilization of fat sources with high FFA content as a feeding fat ingredient. A very reliable research database exists to indicate that FFA per se is not, on its own, a qualitative monitor for fat quality. Dr. Park Waldroup and coworkers at the University of Arkansas reported no difference in performance in broilers fed diets supplemented with fats with low or high (44.7%) FFA content. Dr. Richard Zinn of the University of California has likewise reported similar findings in feedlot cattle. In the studies (of growth performance) comparing 10% FFA yellow to 50% FFA, no differences were detected. Thus, a higher FFA content without the indicators of rancidity (rancid odor, palatability influences, or high peroxide values) does not affect the feeding value of yellow grease. There are specific industrial uses for which high FFA levels may become a factor, such as in the esterification process associated with biodiesel.

Yellow grease has many uses. It is a primary contributor to the total fats and oils used as feeding fats. It has several industrial end uses, including as a biofuel either in biodiesel or perhaps as a burner fuel. Its properties and its recyclable benefits make it anything but waste grease.

Fish Oils

Fish oils are produced during the processing of fish meal in a manner similar to the processing of other rendered products. The raw materials are derived from fishing specifically for species of fish for fish meal and fish oil production, such as menhaden, sand eel, and Norway pout. The increase in aquaculture production has resulted in an increase in use of both the fish oil and the meal derived as a by-product from seafood production and processing. Fish oil is used extensively in aquaculture diets for all species, providing specific fatty acids not available in other fats and oils. It is likewise a common ingredient in companion animal diets, especially for the feline species. Industrial, pharmaceutical, and nutraceutical uses have been replaced by other fats and oils, synthetic vitamins, and other products that in the past relied on fish oil.

Fish oils derived from different species vary considerably in their characteristics, so quoting specifications is difficult. Tables 8 and 9 detail the fatty acid content of various fish oils. Fatty acids designated as 'omega-3' and 'omega-6' (symbolized as n – 3 and n – 6 in Table 8) have received considerable support for their beneficial effects on human health.

Summary: Animal Fats

The inedible raw materials derived from producing and processing food animals provide high-energy products that are available for feed ingredient, industrial, and bioenergy uses. The available resources correlate with the numbers of animals processed for food and the recycling efficiency of used cooking and restaurant greases. These energy by-products are the direct result of livestock, poultry, and marine animal production. They are highly regarded as economically and socially beneficial adjuncts to the primary meat products.

Major Animal-Derived Proteins

The primary animal products derived from processing inedible animal tissues are MBM, MM, blood meal, poultry meal, feather meal, hair meal, and fish meal. Tissues subjected to the rendering process are treated to remove the fat, then dried and milled to produce the respective animal protein products. The ingredients, or product specifications and definitions, are distinct for each product.

Meat and Bone Meal

The regulatory definition of MBM in the United States is the rendered product from mammalian tissues, including bone but exclusive of blood, hair, hoof, horn, hide trimmings, manure, and stomach and rumen contents. The definition describes materials that are used in the manufacture of MBM and, more importantly, what cannot be included. MBM, as defined, must contain a minimum of 4% phosphorus with a calcium level not exceeding 2.2 times the actual phosphorus level. Ingredients containing the same tissues but less bone content, and thus a lower phosphorus content, are defined as MM. Although regulations and directives vary worldwide and from country to country, MBM can be used nutritionally in all nonruminant species of livestock and poultry and as an aquaculture rations to provide protein, amino acids, phosphorus, calcium, energy, and other nutrients. Sourced (nonruminant) and processed raw material must be used in ruminant rations in the United States. The EU has suspended the feeding of MBM to all farm animals. It is important to consult the current regulations in each country of use.

Both MBM and MM have protein levels that generally meet or exceed 50%. The 1998 Nutrient Requirements of Swine (National Research Council) references MBM as containing 51.5% protein and MM as containing 54.0% protein. Standards for product specifications vary according to country of origin and must be referenced using peer-reviewed databases. Although no standard is required for MBM and MM products, guarantees for protein as well as minimum calcium and fat contents must be stated on the identifying label. Unfortunately, MBM and MM are often combined into common databases. This is illustrated in Table 10, showing data from 29 samples of MBM assembled by the Fats and Protein Research Foundation and analyzed at the University of Illinois. Although all of the products were identified as MBM, more than 50% were below the phosphorus minimum. Supplier guarantees are often much more reliable indicators of nutrient content than product names.

Blood Meal

Approximately 4–5% of the live weight of animals is collectable blood. Dried blood is high in protein and rich in the amino acid lysine; moreover, the amino acids are highly digestible. Procedures for processing blood into blood meal have been much improved during the past decade. Flash drying techniques provide digestibility of the essential amino acids that exceeds 90% and generally approaches 95%. Newer processes are available to separate the plasma (serum) from the red cell portion. Both products, when dried properly, are value-added ingredients utilized extensively in animal nursery diets. Measured in value per unit, blood meal comprises the highest of all of the commodity terrestrial animal meals. Measured in total quantities or final dried meal (total tonnes), blood meal comprises a relatively small amount compared with other ABP protein sources.

Poultry Meal

Poultry meal consists of the milled, rendered, and cleaned parts of the carcasses of slaughtered poultry. Inedible tissues comprising the raw materials include the heads, necks, feet, undeveloped eggs, intestines, and skeletal frames from which muscles have been removed. The completeness of muscle removal for boneless chicken meat varies somewhat. Similarly, several of the tissues listed above also have edible markets. Poultry meal is to be exclusive of feathers, with the exception of such amounts as might occur unavoidably with the use of good processing practices. A considerably higher quantity of inedible tissue from poultry processing is acquired from each carcass as trends advance for further processing and more table-ready foods.

Poultry meal is an excellent source of protein. It is a product used extensively in companion animal diets. Processing improvements have resulted in better poultry meal, as with most by-product ingredients. Improvements in digestibility have enhanced its usage in other animal species, such as in aquaculture and starting pig diets. Specifications vary slightly depending on source. Broiler chickens, laying hens, and turkeys comprise the major sources of poultry raw

materials. However, they all yield similar final rendered products. Ducks and other less dominant avian species may show some variations.

Feather and Hair Meal

Feather meal is often referred to as HFM. Feathers contain a protein level averaging 87%, but the protein is in an undigestible keratin helix and special processing is necessary to break the disulfide-bonded helices. Pressure cooking is the most common processing procedure, although enzymes under experimental conditions have also been effective.

Although HFM is high in protein, the availability of essential amino acids, lysine, methionine, and histadine, is limited. However, the product is an excellent source of the sulfur-containing amino acid cystine as well as elemental sulfur and selenium. Its protein has limited degradation in the rumen of ruminant species, which allows its passage and digestion in the intestinal tract. HFM has emerged as an important ingredient for ruminant animals. Recognizing the contribution of bioavailable amino acids, HFM can be supplemented via synthetic sources or combined with other by-product ingredients to supply its deficiencies and thus can be a very useful feed ingredient. Hair meal derived from pig hair is a similar product, but it is produced in much lower quantities and requires even higher pressure and temperature for its production.

Fish Meal

Fish meal is acquired from the specialized industry that maintains fleets that harvest entire fish exclusively for processing into fish meal. Fish meal is also produced from the inedible portions of food fish. The protein derived from both sources is highly valuable to the feed and ingredient industry. Historically, fish meal has commanded premium prices compared with other animal protein sources and most plant sources. It has an excellent amino acid composition that is highly bioavailable. Fish meal is appreciated as a feed ingredient for its palatability-enhancing properties, especially in feline diets. Properties of fish meals vary with respect to the species of fish that comprise the raw material; there are species differentiation of respective and fish meals that are often included in the ingredient name. Some countries prohibit the use of fish meal for finishing pigs due to the risk of 'fishy' off-flavor.

There has been concern recently about the depletion of free harvested fish and thus over the future availability of fish meal.

Each year a higher proportion of seafood and shellfish produced by aquaculture replaces seafood and shellfish traditionally sourced from commercial fishing and the aquaculture industry is projected to continue its growth.

The processing of fish by-products from aquaculture production represents a supplementary income to producers and processors of fish for human consumption.

Summary

Inedible by-products resulting from the production and processing of meat for edible use comprise approximately 50% of total livestock, poultry, and aquaculture production. This article described the basic alternatives for maintaining a symbiotic utilization of both the edible and inedible fractions. Alternatives as well as challenges surrounding the utilization or disposal of raw inedible by-products are controversial. Requirements that this highly perishable material must be collected, processed, and utilized in a manner that satisfies ecological, economic, environmental, and biosecure methodology are paramount. These criteria must be scientifically validated. Rendering has provided a time–temperature process that has met these criteria for bacterial, viral, fungal, and parasitic organisms. The etiology of TSE has presented an enigmatic assessment yet to be resolved in terms of animal by-product processing and disposal. Realistically, the world is still trying to understand the biology of this complex group of diseases, which are unlike any other. This complicated group of diseases deserves the utmost scientific scrutiny.

All the protein, fat, minerals, and other compounds currently derived from the inedible fraction of food animals are the direct result of livestock and poultry production. Technologically advanced meat production does not produce meat, milk, eggs, and animal fibers without the associated production of inedible tissues. Changes in technology will inevitably alter the amount and nature of by-products. Response to these changes will be influenced by consumers, legislators, and myths/biases as well as scientific guidance and will, undoubtedly, bring many unpredictable developments and opportunities. It is easier to analyze the history than to predict the future. Historically, the performance of livestock agriculture would predict a strong future for animal-derived products to be utilized by both humans and animals.

Glossary

Anaerobes The microorganisms that are able to grow and proliferate in the absence of oxygen.
A_w The amount of water available in a food for enzymatic reactions or microbial growth.
Emulsion A two-phase system formed by a disperse phase (or droplets) in a continuous phase.
Gel A physical system in which water is trapped in a lattice, usually formed by proteins or carbohydrates.
Heat capacity The amount of heat necessary to increase the temperature of a given material.
Mesophiles The microorganisms that are able to grow and proliferate at moderate temperatures (usually between 15 and 30 °C).
Microaerophiles The microorganisms that are able to grow and proliferate in low oxygen concentrations.
Oxygen tension The pressure of oxygen on a surface.
Redox potential The positive or negative net charges in a system.
Thermal conductivity The ability of a given material to transfer heat.
Thermophiles The microorganisms that are able to grow and proliferate at high temperatures (usually above 40 °C).
Transport phenomena The physical mechanisms involved in heat and mass transfer.

Introduction

Heating is probably the most efficient preservation method for foods. The main objective of heating for preservation is to ensure the destruction of microbial populations; both vegetative cells and spores of pathogens are prevented from growing and, in relevant cases, from producing toxins. Depending on the expected shelf life, a specific food is subjected to a specific set of conditions. The severity and length of the heat treatment are the key factors to ensure sanitation. However, when thermal processing is too severe, it might impair product quality; so a compromise must be reached between sanitation and quality. If a food is cooked, only partial elimination of viable cells and enzymes might take place and additional means of preservation would be necessary. In the other extreme of heating, canning allows the destruction of virtually all viable cells. The result of the canning process is the production of self-stable foods with a considerably long shelf life without the need of applying any further preservation method. In addition, canning of meat allows its storage and transportation, otherwise a highly perishable food commodity in conditions under which no other preservation method could succeed. This is particularly true in high-temperature and high-humidity environments such as tropical zones. However, although this process may preserve chemical characteristics of food, canning is also likely to alter sensory and physical characteristics; in some cases this process changes the physical structure of meat products. In some cases, physical modifications are highly desirable, even in part of some processes, such as luncheon meat preparation, where an emulsion changes to a gel.

Microbial Population and Process Severity

From a microecological point of view, the events determining food sanitation and quality are contamination, colonization,

and metabolite production, either harmful to humans or able to change food characteristics. Once undesirable microorganisms are reduced as much as possible by any preservation method, particularly thermal technologies, it is necessary to avoid nullifying the effects of processing by preventing recontamination. This is achieved by packaging in hermetic containers or by the use of aseptic containers such as cans or flexible pouches; in both cases, measures must be taken to avoid recontamination. Finally, food distribution must be carried out by delaying the growth of surviving microorganisms. Thus, in addition to sufficient thermal processing to ensure food sanitation, other precautions must also be taken.

Canning is based on a heat gradient from a heating medium to the food inside the container. Thermal processing for canned meats focuses on reducing counts of *Clostridium botulinum*, the most dangerous agent, which produces a fairly heat-stable toxin. Reduction of spoilage populations is the second task of heat treatment. Any commercially sterile canned food is free of spoilage microorganisms such as *Bacillus stearothermophilus*, *Clostridium perfringens*, or spore-forming thermophiles such as *Clostridium sporogenes* if the storage temperature is approximately 40 °C. Heat treatment is severe enough to destroy *C. botulinum* or *C. perfringens* and gives a stable food without the need to apply special storage conditions.

Microbial communities in foods are dynamic; heterotrophic populations changing with time, depending on the presence of specific chemicals. Preliminary processing before canning modifies intrinsic food characteristics, particularly in rich substrates such as meats containing almost all necessary nutrients to support a wide variety of microbial populations. In raw meats (pork, lamb, or beef), the native microflora is dominated by *Acinetobacter*, *Aeromonas*, *Enterococcus*, *Moraxella*, *Pseudomonas*, and *Psychrobacter*. If raw meat is refrigerated before canning, the specific microbial associations are nonfermenting psychrotrophs such as *Pseudomonas*, *Alcaligens*, *Flavobacterium*, *Shewella*, and *Moraxella*. Cured meats represent an ecological niche for Gram-positives, such as *Micrococcus*, *Lactobacillus*, *Carnobacterium*, and *Brochothrix*. The main spoilage microorganisms in canned meats are *Clostridium thermosacarolyticum*, surviving at a very high temperature; *Pseudomonas* sp.; *Achromobacter*; mesophile *E. coli*; *Bacillus subtilis*; *Streptococcus thermophilus*; *C. perfringens*; and *Bacillus stearothermophilus*. Certain specific microorganisms are also likely to colonize a given meat species, such as *C. perfringens*, *Salmonella* spp., *Staphylococcus* spp., and *Campylobacter* spp. in raw poultry meat and poultry products. As heat treatments depend on a time–temperature relationship, process severity will be calculated on the basis of the degree of destruction necessary for an indicative microorganism. Therefore, the specific dominant microflora of a meat or meat product implies different processing parameters.

Thermal Resistance of Microorganisms

Although meat sanitation depends on destruction of specific microorganisms, particularly pathogens, shelf life extension depends on intrinsic food characteristics (mainly chemical composition) and external conditions (mainly temperature and nutrient availability). While vegetative cells are destroyed at 50–70 °C, spores can survive at much higher temperatures. Heat treatment conditions destroying *C. botulinum* and *C. sporogenes* result in a thermostable food with considerably long shelf life. However, for tropically preserved products expected to have a minimum shelf life of 1 year at 40 °C, destruction of sporulated thermophiles are of consideration. The destruction of food enzymes involved in spoilage reactions is also a criterion for theoretical considerations; usually process calculations for microbial destruction are also valid for enzyme inactivation. Because process calculations are specific for a given food product, some basic information is necessary, in addition to knowing the type of dominant or indicative microflora.

Meat Physicochemical Characteristics

Meat physicochemical characteristics are closely related to the types of microorganisms present. Resistance to heat processing and process efficiency depend on physicochemical characteristics, such as pH, water activity, food composition, and structure. Low-acid foods (pH > 4.5), such as most meats and meat products, need more intense heat treatment due to the possible presence of *C. botulinum* and production of toxins in canned meats. This pathogen, however, needs A_w 0.95–0.97 or higher to grow; therefore, reducing water activity which can also reduce process severity. Canned meat is a system totally void of oxygen. Because oxygen tension is decisive for certain strict anaerobes, such as *Clostridium* spp. or microaerophiles, these microorganisms can proliferate. Other pathogens, such as *Staphylococcus* spp., can grow in low oxygen concentrations. Finally, food composition drastically influences process severity extension. Carbohydrates, fats, and proteins are bad thermal conductors. Because meat contains protein and some fat, meat products need more severe treatments.

Expected Shelf Life

There are mainly four thermal processes applied to food materials, based on the severity of heat application and the expected wholesomeness duration of the food.

(1) Blanching, in which the process temperature is 65 °C, is applied to food materials to eliminate gas from tissues and to provide initial cleaning. It is used to inactivate enzymes in products receiving further heat treatment; (2) cooking, at approximately 85 °C, is applied to improve sensory characteristics, to moderately reduce microbial populations present in the food material, and to inactivate some enzymes. These two treatments are mostly related to cleaning and to improving food quality; (3) pasteurization is a thermal process per se; it destroys vegetative pathogen cells, but certain heat-resistant microorganisms and spores can survive. Typical pasteurization time–temperature regimens are 140–150 °C for 1–45 s or 70–73 °C for 15–20 s. Pasteurized foods have short shelf life even at refrigeration temperatures; (4) sterilization, to destroy vegetative cells as well as spores, sterilization processes must be applied. The shelf life of sterilized foods is considerably extended even without the application of additional preservation methods. Time–temperature regimes depend on the thermal

resistance of a given microorganism taken as an indicator, such as *C. botulinum* and *C. sporogenes* for meat products.

Heat and Mass Transfer during Canning

Thermal processing is basically an operation in which heat flows from a hot element (the heating medium of water or steam) through a barrier (a can) to a cold element (the food). Canning includes two transport phenomena: (1) heat transfer, where heat flows in direct proportion to the driving force and in inverse proportion to the resistance to flow; (2) mass transfer within the food material and brine and also as a result of reactions between food components (lipids, proteins, minerals, etc.). In products such as soups containing meat pieces, or sausages in brine, a combined heat and mass transfer mechanism takes place. Heat is transferred from fluid to and within the meat, and between the product and the heating medium, and mass transfer as water and nutrients diffuse within the can. Knowing the type and extent of the driving forces involved allows estimation of transport parameters in the system. Heat transfer obeys one of the following mechanisms: conduction, convection, or radiation.

The mechanisms involved in heat transfer during canning are conduction and convection. Radiation has no practical application in food canning; it only occurs in heating systems such as microwaves and infrared heating. Conduction occurs within a solid as a result of vibrations of adjacent molecules. In meat canning, conduction takes place in brines containing solid chunks, such as soups containing meat pieces, canned sausage in brine, and in gelled canned pastes, as in the case of luncheon meat. Conduction also varies among meat cuts within the same animal depending on the particular chemical composition.

Convection heating is mostly related to fluids; it takes place in foods such as soups, brine, milk, etc., as a result of movement of fluid of different densities when the fluid is heated or cooled. Convection can be accelerated if stirring is applied, thereby reducing the temperature difference. Therefore, to obtain the maximum heating rate during canning, condensed steam is the most efficient heating medium through a barrier (the can) to the cold fluid inside the can.

Thermal Properties of Meat Systems

Thermal properties establish the heat distribution within the product. These properties include transference properties (thermal conductivity and specific heat) and physical properties (density and product geometry). In addition, meat thermal properties are altered during heating as fat melts, proteins denature, and water evaporates. Cooking time decreases with increasing thermal conductivity, but increases with increasing product size and specific heat capacity. This is the case of thermal conductivity of meat emulsions, such as sausage, that increases with temperature and moisture content.

Average thermal conductivity of meats is 1.89 kJ h^{-1} mol^{-1} K^{-1}, but it also dependent on the direction in which heat is transferred. Thermal conductivity in lean beef at 78.5% water content and 0 °C, when thermal flow is perpendicular to the meat fibers is 1.75 kJ h^{-1} mol^{-1} K^{-1} whereas under the same conditions, if the flow is parallel to muscle fibers, conductivity is 1.79 kJ h^{-1} mol^{-1} K^{-1}.

Heating mechanisms might change in products that modify their physical characteristics during processing. In canned emulsions, such as luncheon meats and pâtés, where the product changes from semifluid to solid, the heating mechanisms change from convection to conduction. In a meat emulsion, the continuous phase is made of muscle fibers, connective tissue fractions, carbohydrates, and other additives; the disperse phase is made of fat droplets; the high fat content allows the spreadability of the product. It turns from an emulsion to a gel by protein unfolding and interlinking during heating. Convection occurs in fluids, whereas conduction is a heat mechanism for solids, which results in convection changing to conduction. As the transfer mechanism changes from convection to conduction during gelling of a meat emulsion, heating rate also varies. Thermal conductivity increases with process temperature and moisture content, whereas thermal properties change as fat melts, proteins denature, and water evaporates. The heat process is, therefore, a combination of convection and conduction.

Meat Canning Operations

Canned meat products include whole muscles, meat stews, luncheon meat, sausages, sauces with meat pieces, and paste products. Meat canning essentially includes three main operations: can filling, exhaustion, and heat treatment. Heat penetration is affected by the solid:liquid ratio as well as the distribution of solid within the can. Solid materials packed loosely are heated faster than closely packed material. In general, 30% of the can volume must be a liquid (brine or sauce) in order to allow good heat transfer. When pastes are filled in the can, it is important to ensure the absence of air bubbles, as heat transfer is less efficient in air and may create sterilization problems. Headspace, approximately 0.5% of the total can volume, must also be taken into consideration in thermal calculations.

Exhaustion is carried out by evacuation of air from the headspace and the bulk of the food. Exhaustion is necessary to achieve good heat penetration and the desired sterilization temperature. Air exhaustion also reduces the risk of promoting the growth of aerobes, particularly if the product is pasteurized, as are some luncheon meats. Exhaustion is generally carried out by vapor injection or by conveying the cans on a belt into an exhaustion chamber or tunnel in which they are heated at 85–95 °C, removing 90% or more of the air in the headspace; in both cases, the cans are then immediately closed. When the cans are cooled, partial vacuum is produced by condensation of the water vapor.

Heat Treatment

Heat treatment includes two cycles: heating and cooling. Heating is involved in microbial and enzyme inactivation, whereas cooling is applied for several reasons, such as ease of handling and reduction of the deterioration of sensory

characteristics. These two cycles are the core of canning operations. Process severity and length are calculated on the basis of several considerations, such as composition of the food material (i.e., heat sensitivity of the microbial population depending on the food composition); specific microbial population; and factors necessary to achieve a given shelf life, depending on transport and storage conditions, initial microbial load, and desired final microbial load; among other things.

Inactivation Parameters

To model a thermal process at an industrial level, several inactivation parameters have been developed as mathematical tools to obtain a time–temperature relationship, which is necessary to achieve a successful treatment.

D- and z-values

If a microbial population is subjected to temperatures slightly above the optimum for vegetative cell or spore growth, destruction occurs with cell concentration (c) decreasing with time (t) in direct proportion to instantaneous cell concentration (c) (equation 1).

$$\frac{dc}{dt} = kc \qquad [1]$$

That is, 90% of the microorganisms are destroyed in a given characteristic time interval if constant temperature is applied. The time interval is different for each microorganism, and is called the decimal reduction time (D). D-values are expressed at a given temperature (e.g., D_{120} for treatment 120 °C). This parameter enables the processor to compare the severity of various processes. The z-value is the temperature increase necessary to reduce D-values in 1/10.

F-value

Several events occur during thermal processing. First, temperature is increased from the ambient to the process temperature specific for the destruction of a microorganism chosen as the process indicator. This temperature is then held for a fixed time to achieve the desired lethality rate. At the end, the temperature is decreased. Each of these events has an effect on the entire process. F-values represent the severity of the whole process, summing the individual effects. To consider process severity in detail, it would be necessary to calculate the effect of temperature increase at every point of the container – an impracticable task. For this reason, the $F=1$ concept is applied; this is the lethality effect of heating at 120 °C for 1 min. Heat treatments are also calculated taking into consideration spore survival from two of the most damaging bacteria in meat products: *C. botulinum* and *C. sporogenes.* While heating at 120 °C for 1 min, the D-value for *C. sporogenes* is taken as a calculation basis. Finally, F_s is the sum of all F-values in each part of the container.

As heating is not homogenous throughout the can geometry, calculations are always performed considering the temperature rise where heating is slowest, that is, in the cold point when the sum of all lethal effects is F_c. The position of the cold point is determined by the dominant heat transfer mechanism, which, in turn, is related to the type of food material. When convection heating is the main mechanism involved, the cold point is on the vertical axis, close to the bottom end of the can. In conduction heating, the cold point is located in the geometric center of the container. Viscous meat materials cooked inside the can, such as luncheon meats, show the cold point close to the geometric center. The position of the cold point is also affected by can rotation in the retort. In static heating of liquid or semisolid products, such as meat pieces in brine, where the leading heat transference mechanism is convection, the cold point is one-third from the can bottom end. F_c is always lower than F_s as the heat effect in the center is always lower than in the rest of the container. Thus, F-values are related to the shelf life required for a given food and to the severity of the thermal process. Process lethality, or destruction rate per minute of a given microorganism at temperature T, is given by eqn [2]:

$$\log\left(\frac{t}{F}\right) = \frac{250-T}{z} \qquad [2]$$

where t=processing time and z=z-value as described before. Therefore, lethality can be calculated at a given temperature throughout the process.

Implications for Meat Quality

Process severity and length affect the quality of canned meats. Sometimes these changes are desirable, such as protein denaturation and development of aroma- and flavor-related compounds. In other cases, deleterious changes might occur. Changes due to microbial growth can take place before heat treatment if a delay between filling and sealing following heat processing occurs. Processing must not be delayed more than 20 min after closing the cans. When thermal processing is insufficient, microbial metabolism can promote can blowing, acidification, or the development of off-odors and flavors. Process conditions (time–temperature relationship) and the microbial quality of raw materials must be checked, as well as sanitation of the equipment, water supply, etc.

Microbial contamination can occur through leaks in can seams from cooling water lacking adequate sanitary characteristics. Changes can also be due to insufficient heating caused by formation of air packs within the retort. If the cans are tightly loaded in the retort, there is no free access of vapor or water to all parts of the container, resulting in irregular heating.

When cooling is not carried out at a suitably fast rate, growth of thermophiles occur. Canned meat products must be cooled to 35 °C, or lower if large can blocks are stocked. Recontamination after heat treatment is one of the commonest problems and a cause of can blowing. In addition to being due to gas production by microbial metabolism, can blowing may occur owing to reactions between meat components and tin if the can has defects in the covering enamel or minute failures (pinholes). The reaction produces hydrogen or stannous sulfide. Severe heating can also alter sensory characteristics, such as by fiber disruption, which promotes excessive tenderness or production of flavor-related compounds by Maillard reactions and oxidation of acids to aldehydes.

Physical alterations in the can itself are due to inadequate operation of the heating equipment, such as rapid increase in retort pressure, insufficient vacuum conditions, or excessive can filling. The presence of air in the can produces excessive internal pressure during heating as a result of expansion of the gas. Conversely, excessive exhaustion promotes can collapse.

Conclusion

Caning ensures the destruction of pathogens and spoilage microorganisms and allows foods to be handled and transported in an easy way. Canned products processing is calculated according to the expected shelf life: from semipreserves requiring further preservation methods, to full and tropical preserves, with a shelf life of 4 years at 25 °C and up to 1 year at 40 °C, respectively. Heat treatments are also applied to develop specific sensory characteristics or physical properties, as well as to improve the nutritional availability of several food components.

CARCASS CHILLING AND BONING

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

Glossary

Aging Holding the carcass under refrigeration to improve tenderness.
Cold shortening The effect, on muscle and tissue, of chilling the carcass quickly after harvesting.
Electrical stimulation Passing electrical current through the carcass after harvesting.
Hot boning Removal of muscle from bone prior to chilling.
Scalding Placing the carcass in hot water to aid in hair removal from the pig or feather removal from birds.

Introduction

There are varying procedures for converting animal carcasses into meat items for consumers. A few of the more popular systems will be discussed, together with their effect on meat quality. Some of the factors that have a major influence on final meat quality are electrical stimulation, carcass chilling, salt addition, and carcass boning (*see* Tables 1–3). This article harmonizes many of the processing, boning, and chilling technologies.

Carcass Boning and Hot Boning

Carcass boning, or production of retail cuts containing bones, can be performed in the traditional manner on a chilled carcass for products designated for the retail steak and roast trade and for sausage manufacture, and ground meat (Table 2). Another boning technique is to utilize the prerigor hot carcass, from which the tissue is primarily used for meat or sausage manufacturing (Table 2). A third technique is carcass boning after some chilling of the warm product; this technique, which is used mainly for pig carcasses, economically produces a quality chop or roast product in a more cost-effective manner (Table 3). Because conventional boning is simple (Table 1) and covered elsewhere, this article will concentrate on the newer and less-understood hot-boning and rapid-chilling techniques. Equipment is now available that will hold the carcass stationary and will pull muscles downward to assist in hot boning.

Hot boning has potential advantages over cold boning of higher meat yields (1.4%), labor saving (20%, faster, 4 min/carcass), less weight loss during chilling (1.5% less), less drip loss in vacuum packages (0.1–0.6%), more uniform products, a darker color, reduced refrigerator space (50–55%), lower refrigeration costs (40–50%), shorter processing time (40–50%), lower transport costs (primals vs. carcasses), and superior water-holding capacity and emulsifying capacity. However, there are some problems associated with hot boning, such as shape distortion of cuts because the muscle is not attached to the bone, reduced flexibility in production, stricter hygiene requirements, increased temperature control, new cutting procedures, retrofitting of conventional cold-boning areas, retraining or hiring of new boning personnel, quality changes in cuts such as reduced tenderness often caused by cold and rigor shortening, alteration of color, and accelerated microbial growth. The major quality problem with hot boning is that substantial cold shortening may result in tougher (a major quality factor) meat with higher drip loss. Carcass chilling systems that maintain a meat temperature of 15–16 °C during rigor minimize tenderness reduction due to cold

Table 1 Extreme variation in chilling of beef carcasses

Traditional chilling	*Rapid chilling*
• 2–4 °C including aging for 5–21 days	• Electrical stimulation
• Tenderness increases with aging up to about 21 days	• –20 °C or –35 °C, air velocity 3.2 m s^{-1}, 10 h
• Shrinkage continues during aging	• 24 h postmortem at 2 °C
• Exposed muscles become darker on aging	• Aged for 6 days
• Mold growth can occur during prolonged aging	• Increased tenderness at 6 days, shorter time to obtain acceptable tenderness
	• 21 days no difference in tenderization
	• Reduced cooler time and shrink, slower rate of pH drop, increased perception of marbling, darker color, increased drip at retail, good meat quality

Table 3 Dutch 'semihot' boned fresh pork

	Nonexported fresh pork	*Exported fresh pork*
Preboning	Blast chill –25 °C for 80 min or 45 min	Blast chill –25 °C for 80 min or 45 min
Equilibration	At 2 °C for 100 min or 135 min	At 2 °C for 100 min or 135 min
Semihot boned	Semihot boned	Semihot boned
Packaging	Vacuum	Vacuum
Temperature	1 °C	1 °C
Storage	12 days at 1 °C	Storage would occur during transport
Results	Similar appearance, sensory and bacteriological qualities as for conventional procedure	

Source: Reproduced from Van Laack, R.L.J.M., Smulders, F.J.M., 1989. Quality of 'semi-hot' and cold boned, vacuum-packaged fresh pork as affected by delayed or immediate chilling. Journal of Food Protection 52 (9), 650–654.

shortening. Hot boning is particularly susceptible to cold shortening and increased toughness when applied to small carcasses and carcasses with low fat cover, because under these conditions the deep areas can be chilled much faster. This increased toughness can be reduced by introducing a conditioning period (e.g., semihot boning, Table 3) of 4 h more until rigor has occurred (in beef sometimes as much as 24 h or more) before chilling. This procedure will still allow improvement in production economy and productivity and an increase in carcass throughput. To reduce the time for rigor mortis to occur, electrical stimulation immediately after slaughter is utilized for carcasses that are going to be hot boned. Electrical stimulation was first applied to lamb carcasses that were to be rapidly frozen.

Other Options of Hot Boning

Carcasses boned directly off the slaughter floor and placed in typical cartons and conventionally air blast frozen often cannot meet the required chilling rate requirements; therefore, modified hot boning is often utilized.

1. A modified hot-process system for beef carcasses involves removal of the lower-value cuts along with associated bone and fat. This product is preblended with salt and chilled for emulsion-type products or immediately processed by rendering or directly processed into fresh hot-boned meat. The remaining high-value cuts are chilled in the usual manner. The time required to chill the deep tissue of the hindquarter is not significantly different from that for conventional chilling, but this technique can be cost-effective for less-valuable cuts.
2. 'Australia' carcasses above 20 °C deep but temperature must be processed using a deep boning program. Usually, the carcasses are chilled several hours before boning (warm boning, boning on the curve, same day boning) until deep butt temperature is 30–36 °C. In the US, approximately 25% of pork is sold fresh, and the remainder is either sold as cured meat or sausage products. With leaner pork carcasses and with rapid chilling, cold shortening might become a problem. However, because normal postmortem metabolism in pork occurs rapidly, cold shortening and increased toughness are not likely to be a major problem. Whole-hog fresh sausage processors can utilize hot boning and rapid salting. This process almost doubles the sausage microbiological shelf life, because surface bacteria have not had time to grow in this favorable environment before the antimicrobial salt addition. Also, as the product is comminuted, toughness is not a problem. This technique results in a higher ultimate pH and consequentially increased water-holding and emulsifying capacities, which result in better eating quality.
3. Electrical stimulation of carcasses will lower the pH and speed up rigor mortis and enhance tenderness, which will reduce some of the disadvantages of hot boning.

Chilling

Chilling is critical for meat hygiene, safety, product shelf life, appearance, and eating quality. Chilling in air reduces carcass surface temperature, enhances carcass drying, and reduces the growth of bacteria.

Refrigeration equipment in large plants often consists of ammonia units. Medium to small plants often have a range of hydrochlorofluorocarbons (HCFCs, R-22, R-123, R-408A) and hydrofluorocarbon (HFCs, R-134a), because chlorofluorocarbons (CFCs, R-11, R-12, R-502, R-113, R-500) are now being phased out. All systems have three basic components: the compressor, the condenser, and the evaporators. The evaporators are most critical in relation to meat quality. They consist of finned tubes (coils) through which the refrigerant flows. Air is forced over the fins and through the cooler. Rapid chilling can be accomplished by utilizing low refrigerated temperatures. However, this will result in increased shrinkage of the carcass and condensation and freezing on the coils, which will require frequent defrost cycles. Minimum weight loss, higher humidity, and fewer defrost cycles can be accomplished by keeping the temperature differential as low as possible (or practicable) between the temperature of the air entering and exiting the coils. A practical air return temperature would be 10 °C as the cooler is being loaded with hot-boned meat or carcasses, and this should be reduced to 0 °C after 1–2 h. Air velocity has less effect on chilling rate than temperature and should be low (0.5 m s^{-1}) during loading of the cooler, higher (1–2 m s^{-1}) during maximum chilling, and low (<0.5 m s^{-1}) during holding.

An increase in air velocity and/or a decrease in temperature (both controllable) decrease chilling time. A limiting factor, however, is difficulty in removing heat quickly from the deeper tissues of carcasses. For traditional chilling of beef carcasses, a temperature of 5 °C or less (air velocity of less than 1 m s^{-1} and a relative humidity greater than 80%) is recommended, because the growth of both spoilage and pathogenic bacteria is greatly reduced at these temperatures. Aging (>5 °C) is a major factor for improving tenderness, and this is most often accomplished with the traditional (Tables 1 and 2) procedure. However, early consumption after slaughter of double-muscled

breeds is often recommended, but a longer aging time is necessary for most carcasses to obtain optimum tenderness. It is recommended that chilling regimes should always be optimized for the carcass types utilized.

Chilling of high-quality beef carcasses (young, grain-fed animals) is traditionally accomplished at a temperature slightly above freezing for a long period of time to produce the highest quality product. In areas where refrigeration is not available, hot boning is required before the tissue spoils microbiologically. For most hot-boned products, when electricity is available, electrical stimulation is used to accelerate rigor and to compensate for the reduced tenderness caused by muscle shortening during onset of rigor when the muscles are detached from the bones and chilled.

Rapid carcass chilling increases yield due to lower evaporation from the surface, and rapid drying of the carcass surface helps to reduce bacterial growth. Also, less shrinkage results in financial savings. If meat is removed from the carcass while the tissue is still hot and then cooled in vacuum packages, the chilling time is normally reduced by 50%. Commercial chilling equipment is capable of reducing the temperature of an 8 cm thick piece of meat from 40 to 2 °C in less than 8 h. It is often recommended that beef should be at a high temperature for as short a time as possible and muscles should enter rigor at 10–15 °C for optimum tenderness. Prerigor chilling has been conducted at −15 °C for 1 h and postrigor chilling at −5 °C for 10 h; however, this does result in some muscle freezing. Optimum rapid chilling of beef carcasses has been recommended at −15 °C (air velocity 0.5 m s^{-1} and a RH of 90%) for 1 h and then chilling up to 10 h postmortem at 0 °C. It has also been suggested that carcass quality can be improved by appropriately positioning evaporators and fans, room loading, and air-mixing devices.

Pale, soft, and exudative meat (PSE) in pork is a major problem that is genetically linked, but it can also be influenced by the chilling rate. Rapid anaerobic glycolysis produces lactic acid, which results in a rapid lowering of pH, and if this is combined with a high carcass temperature it often results in a denaturation of proteins followed by high moisture loss and increased shrinkage. An increase in the rate of chilling will lower the temperature rapidly and thus reduce the rate of glycolysis and pH fall, resulting in a reduced incidence of PSE. Scalding and singeing of the carcasses can also contribute to the PSE problem. Dehided carcasses, compared to scalded/dehaired carcasses, have an improved muscle color and water-holding capacity and often have lower bacterial counts. Electrical stimulation is not often used in the pork industry owing to the natural rapid onset of rigor mortis and the risk of producing PSE meat. Rapid chilling after slaughter is often employed in the pork industry to improve pork quality, produce a darker color, increase firmness, decrease the chilling loss, and increase the shelf life without altering tenderness. Chilling is often used as a critical control point (CCP) in pork slaughter hazard analysis and critical control point (HACCP) plans.

PSE is also becoming a problem for poultry pectoralis muscles for the same reason as in pork, which is an accelerated postmortem glycolysis while carcass temperature is still high, which results in protein denaturation and poor meat quality. PSE in poultry is often blamed on slow chilling rates.

Control of air temperature to ensure that carcass surface temperature requirements are met is the most important aspect of carcass chilling. This will vary according to the size of the carcass, glycolytic rate, fatness, and species. Achieving an even air flow at optimum velocity over all carcasses is also important to provide adequate and uniform heat transfer and minimum weight loss.

European Union regulations (95) stipulate that carcasses of cattle and horses must be cooled to a temperature less than 7 °C within 36 h and smaller slaughter animals within 24 h to decrease bacterial growth. There is some concern that this rapid chilling in some cases could result in cold shortening and increased toughness of beef.

Beef

Hot boning beef from the skeleton may reduce contamination with the central nervous system (CNS) tissue compared to splitting the spinal column. Beef carcass chilling time can be decreased by an increase in air velocity and decrease in temperature. Recommendations are often that the air velocity should be less than 1 m s^{-1} and the relative humidity should be greater than 80%. Besides the avoidance of cold shortening, aging is the main factor influencing beef tenderness. Some reports suggest that beef should be at a high temperature for as short a time as possible, and muscles should enter rigor at 10–15 °C for tenderness to be optimized.

Research has also shown that rapid chilling of beef carcasses at −5 to −10 °C (air speed 1–2 m/s, RH of 90–100%, chilling time 115–212 min followed by holding in a cooler at 0–4 °C) resulted in a significant decrease in meat tenderness as a result of cold shortening although weight loss and bacterial counts were lower. However, other reports suggest that beef carcass meat quality superiority can be gained by prerigor chilling at −15 °C (air velocity of 0.5 m/s and 90% relative humidity) for 1 h and further chilling at 10 h postmortem at 0 °C.

Delayed chilling ('tenderay process' – for meat held at 16 °C for 3 days at 2 °C for up to 15 days) can improve beef quality compared to conventional chilling and conditioning for all carcass grades. Because microorganisms grow rapidly at this temperature, ultraviolet lights are used to inhibit growth. Preventing the muscles from shortening by wrapping can prevent toughness.

Electrical stimulation can enhance the tenderness of beef, accelerate the rate and extent of tenderization, and reduce the difference between British and tropical breeds and produce a more consistently tender beef product. Recent work has shown that electrical stimulation produces beef carcasses that are more tender than nonstimulated carcasses, and the sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) band pattern of myofibrils show a more rapid breakdown of troponin T and troponin I bands than for nonstimulated carcasses. In chilled beef carcasses, the relationship between pH and color is primarily influenced by the chilling temperature. Recent studies have shown drip as a consequence of tenderization (from denaturation of cytoskeletal proteins rather than myosin as in PSE); there is initially more drip with electrical stimulation but the total amount of drip does not increase for the same tenderness.

It has been reported that very fast chilling (−20 to −35 °C) of beef carcasses immediately after slaughter improves tenderness at 6 days but this improvement disappeared after 21 days of aging. The advantages of this extreme chilling regime are a significant reduction in chilling loss, a slower rate of pH fall, and an increased perception of marbling but it also resulted in a darker meat color and increased drip losses. An increased toughness and shorter sarcomere lengths have also been found with ultrarapid chilling (−30 °C for 30 min with an air velocity of 4 m s^{-1}) of beef carcasses, suggesting an increased risk of cold shortening.

Spray chilling of beef carcasses with an intermittent water mist (1 °C, intermittent for 4–16 h) reduces carcass shrinkage (reduced by 0.08 g per 100 g per hour of spraying) without compromising quality or increasing spoilage losses. However, there should be sufficient time after the end of spray chilling to prevent the carcass from having an undesirable pale color and a wet surface, which would increase bacterial growth and make boning more difficult.

Stretching prerigor muscles during postmortem chilling tends to increase the tenderness of the stretched beef muscles and is particularly helpful in conditions that might produce cold shortening. In the method an S-shaped hook is placed in the obturator foramen, and the carcass is hung from this hook, which causes the pelvic limb to hang in a horizontal position. 'Tender cut' involves severing the bones, connective tissue, and some muscles at the 10–11 vertebrae leaving only the thoracis lumborum intact, and a second cut in the round/sirloin junction behind the 5th sacral vertebra causes gaps after hanging of 12 cm and 3 cm, respectively, in those two cut areas. Both of these carcasses suspension methods have been reported to be useful for improving tenderness for rapidly chilled (susceptible to cold shortening) cattle carcasses.

Organic acid (lactic or acetic) sprays for both hot and chilled carcasses results in pathogen reduction. Decontamination processes, such as steam vacuuming, preevisceration carcass washing and organic acid rinsing, and hot water carcass washing are techniques that could be useful for improving the microbial quality of beef carcasses.

Lamb

Owing to lamb size, temperature falls during chilling can be rapid, particularly if there is little fat covering, and this means the carcasses are subject to cold shortening with such rapid chilling. Because of the propensity of lamb to cold shorten and toughen prerigor, the acceleration of rigor mortis through electrical stimulation has been incorporated into lamb processing, especially in New Zealand and Australia and, additionally, the long aging period during shipping ensures a reproducible tender product.

Pork

Approximately 25% of US pork is processed fresh and the remainder is either sold as cured meat or sausage products. Hot boning was first applied by Oscar Mayer to packer sows hams that were to be used for sausage manufacturing. With leaner pork carcasses and with rapid chilling, cold shortening could also be a problem with pork. However, because normal postmortem metabolism in pork occurs rapidly, cold shortening and increased toughness should not be major problems. Whole-hog fresh sausage processors can utilize hot boning and rapid salting, which can almost double the sausage microbiological shelf life because surface tissue bacterial numbers have not had time to grow in this favorable environment before the antimicrobial salt addition, and because the product is ground, toughness is not a problem. This technique results in a higher pH and, consequentially, increased water-holding and emulsifying capacities.

Comparison of dehided and scalded/dehaired pig carcasses indicates that 24 h after chilling, the dehaired carcasses had higher weight loss than the skinned carcasses. Skinned carcasses should have improved muscle color and water-holding capacity and normally have lower bacterial counts. The higher counts of dehaired carcasses are thought to be caused by high temperature and humidity around the scalding process, which would encourage bacterial growth. During the first 2 h of chilling, internal temperature reduction was more rapid for the skinned pork carcasses, but no difference was obtained in subsequent chilling. Additionally, pH or surface bacterial counts were not affected by subsequent chilling. Pork quality did not differ between the two procedures. The pH values of accelerated chilling (−32 °C for 100 min) of pork carcasses resulted in 0.15 higher pH value from 4.5 to 24 h postmortem. Fat trimming of the hot carcass can accelerate the chilling rate, reduce PSE, and can improve the hind leg muscle color, water-holding capacity, and firmness scores.

PSE (pale in color, soft in texture, and exudative or watery) in pork is a major problem that has been genetically linked, but the incidence of PSE also can be influenced by the chilling rate. A rapid accelerated anaerobic glycolysis produces excess lactic acid, which results in a rapid decline in pH, and if this is combined with a high carcass temperature, particularly at approximately 45 min postmortem, approximately 20% of the sarcoplasmic and myofibrillar proteins will be denatured, resulting in free moisture loss and increase shrinkage of the tissue. An increase in the rate of chilling will lower the temperature and reduce the rate (which is temperature dependent) of glycolysis and pH decline, resulting in less denaturation and reduced incidence of PSE. Scalding (60 °C) to aid in hair removal (used by 69% of US processors due to the speed of the operation) and singeing can also contribute to the PSE problem because both increase carcass temperature, which accelerates glycolysis and pH decline. This combined with high carcass temperature can also increase protein denaturation and the incidence of PSE. Rapid chilling after slaughter is often employed in the pork industry to improve pork quality, produce a darker color, increase firmness, decrease muscle separation, decrease shrinkage during chilling, and increase shelf life without altering tenderness. This accelerated chilling also slows the rate of glycolysis, which lowers temperature and thus reduces denaturation and PSE. Chilling is often used as a CCP in pork slaughter HACCP plans.

Electrical simulation is not normally used in the pork industry due to the natural rapid onset of rigor mortis in this species; however this may change as pork carcasses become leaner and more susceptible to cold shortening and increased

toughness. In some UK studies with electrical stimulation, the pork was more tender with a nonsignificant early appearance of drip (due to early tenderization) – stimulation is not currently used with pork in the UK, however.

To reduce incidence of PSE, it is recommended that pigs are rested 2 h before slaughter, that accelerated chilled be used, and that hot fat trimming of the carcasses be employed. Washing of live pigs and subsequently pork carcasses with cold water has been reported not to be an effective microbiological control measure. Rapid chilling is often used as a CCP. Rapid chilling of pork carcasses can reduce the combination of purge loss and cooking loss without affecting tenderness. Ultrarapid chilling (−30 °C, air velocity 4 m s^{-1}) can result in increased sheer force values, indicating an increased risk of cold shortening.

Spray chilling of pork carcasses results in no significance difference in muscle color values after 20 h of chilling; however, the surface of the skin does become lighter. Pork carcasses can be chilled in brine or slush ice and the temperature can control the degree of shell freezing. However, this technique is not commercially practical, but this procedure would require less time and possibly less energy if cold water or ice was used instead of traditional air chilling.

Injection of calcium chloride for in-plant marinating 24 h postmortem has been reported to enhance tenderness. Use of sodium bicarbonate has also been shown to increase pH, water-holding capacity, decrease tenderness, and to produce a darker muscle color. However, these are not common practices in the pork industry to date.

Poultry

Factors, such as delayed chilling, that lead to a rapid postmortem pH fall will reduce the quality of turkey breast meat. Improper slow chilling of turkey pectoral muscle causes accelerated postmortem glycolysis while the carcass temperature is still high, resulting in protein denaturation and poor meat quality (PSE-like). Evaporative chilling reduces total bacterial count on the external surface of the poultry carcass by approximately 0.5 log total viable count, but air chilling has shown little effect on total bacterial count. Total count of the visceral cavity is unaffected by the chilling method. However, some new plants are using air chilling to reduce bacterial counts.

Chicken breast muscle tenderness increases with aging time, but when sodium tripolyphosphate (STPP) was applied to plant-marinated chicken breast immediately after carcass chilling, the tissue was tougher than the controls. However, this increase in toughness can be avoided by aging for 2 h before treatment with STPP. Electrical stimulation has been successfully used in poultry.

Fish

Fish are also processed by a variety of procedures. Saltwater fish usually follow one of these routes: caught, filleted, frozen or iced on board the ship; caught, iced or frozen, and filleted on the shore; caught, frozen, shipped to destination, thawed, filleted; caught, eviscerated, iced or frozen, filleted on the shore or at the destination. Freshwater fish usually follow one of these routes: caught, filleted, iced or frozen; caught, iced or frozen, shipped to destination, filleted. Even though fish go into rigor quickly, the fish that are caught and then filleted, or small fish that are caught and quickly frozen usually are in a prerigor state when boned. Fish that are iced and filleted later are usually in a postrigor state when boned. Because fish are very susceptible to bacterial growth, quality is usually determined by handling hygiene and low temperature and much less by the order of processing.

Glossary

Motor unit A motor unit is made up of a single motor neuron as well as all the muscle fibers that neuron activates. A single motor neuron can control several hundred muscle fibers at a time, depending on the size and function of the muscle.

Muscle fiber Cylindrical, multinucleate cell composed of numerous myofibrils that contracts when stimulated. Also called muscle cell.

Myofibril Slender striated strand within skeletal muscle fibers, composed of bundles of myofilaments. Myofibrils occur in groups of branching threads running parallel to the cellular long axis of the fiber.

Sarcolemma Plasma membrane of the muscle cells.

Sarcoplasmic reticulum Special type of smooth endoplasmic reticulum found in smooth and striated muscle fibers whose function is to store and release calcium ions.

T-tubule Deep invagination of the sarcolemma which appears as a small tubule that runs transversely from the sarcolemma across the myofibril of striated muscle.

Introduction

In nature, the edible parts of an animal killed for food are not organized according to the requirements of consumers. Even after up to twelve centuries of domestication, the structure of animals used by humans as meat is still dependent on the strict requirements of the living animal to successfully seek food, overcome environmental hazards, and compete for the right to reproduce.

It is, therefore, unrealistic to separate an account of carcass structure and function from the function of the living animal. This is especially true because, following the death of animals, chemical processes that are essential for the survival of the whole organism continue by a process of anaerobic glycolysis for hours, and sometimes days. This article emphasizes that a meat carcass consists of structural elements, formed according to the requirements of the living animal. Structure is highly relevant to meat production, not only because the art of butchery is an anatomical process but also because most of the material making up a carcass has a mechanical role, forming an essential part of a living machine.

This article is, therefore, a description and an explanation of meat carcass anatomy, ranging in scale from grossly dissectible components to microscopic and molecular elements. Inspection of any comprehensive textbook of anatomy will show that the subject is burdened with considerable detail. It is hoped that by restricting this account to topics relevant to meat production, the information presented is no more than is needed to introduce, describe, and explain the carcass features that will be addressed in other articles.

Meat Carcasses

Following the slaughter of an animal for meat, certain parts of the whole animal are separated from the carcass (1). The procedure varies for different species and countries. For instance, a pig carcass usually includes the skin and head, and the cannon bones are left with the sheep carcass in some countries. With the exception of the skin in pigs (Figure 1c), a carcass contains only three tissues present in amounts significant for meat production. Although these are designated as 'tissues,' muscle, fat, and bone each consist of a variety of different cell types and extracellular material. The process of separation of carcass muscle, fat, and bone, whether by the butcher's knife or by consumer's knives and forks, is an anatomical one. The three carcass tissues are, therefore, defined as those that can be separated grossly with a knife. Fat in the total carcass, or in a particular part of it, can also be measured by solvent extraction. The proportions of each tissue in carcasses of cattle, sheep, and pigs, and typical ranges, are given in Table 1. Interestingly, the muscle:bone ratio is higher in fat sheep carcasses than in lean carcasses, which is not the case for beef and pork carcasses. The remaining structures, such as blood vessels, lymph nodes, nerves, tendons, ligaments, joint capsules, and fibrous sheets, such as the linings of the body cavities, seldom total more than 2% of the weight of a carcass.

Although the functions, and hence the carcass proportions, of the three major tissues are closely interrelated, it is convenient to divide this account into a discussion of each of them. Their growth characteristics are discussed in other sections.

Table 1 The composition of meat carcasses. Muscle, fat, and bone weights as percentages of total carcass weight for animals of 'lean' (L), 'average' (A), or 'fat' (F) condition. All carcasses are without head, feet, and skin. The carcasses of pigs have the highest muscle to bone ratio. Because muscle and fat content of pig carcasses is similar to that for cattle and sheep, the higher muscle to bone ratio appears to be due to a lower bone content

Carcass Muscle

In living animals, muscles are essential for maintaining the shape of the body in a particular position and to provide physical movement. Even standing still requires muscular activity. Without normal muscle tone, such as during sleep or anesthesia, maintenance of posture is not possible. Muscles also enable the body of animals to bend and systematically move and change the support of their limbs, and thereby altering their relation to their environment. Such movement, when suitably coordinated, results in specific actions such as locomotion. Both posture and movement are basic to the survival of animals.

Carcass muscles are separated by loose connective-tissue sheets that might contain intermuscular fat. Each of these named muscles is free to act as a separate entity, contracting or resisting stretch between its unique attachments to the skeleton or other structures. Many muscles, especially those related to the vertebral column and ribs, act over many joints and have complex structures because of the number of attachments (Figures 2 and 3). The distribution of carcass muscle in cattle is shown in Figure 4: 55% of the muscle mass is involved in attaching the limbs to the trunk and moving the shoulder and hip joints (muscle groups 3, 4, and 9). The next largest group (14%) supports and moves the vertebral column (muscle groups 5 and 7). This accounts for the large masses of lean meat, relative to bone, obtained from the shoulder, loin, rump, and thigh regions.

Muscle Connective Tissue

Each muscle consists of a highly ordered arrangement of connective tissue in which muscle fibers are embedded. Muscle connective tissue shares similar features with the connective tissue of other organs.

Connective tissue contains fixed cells, free cells, and protein fibers, all embedded in a matrix. The fixed cells include the fibroblasts that produce both the fibrous component and the matrix of connective tissue. These remain subsequently in a less active secretory phase as fibrocytes. Also fixed within the tissue are the fat cells, which contain the major intramuscular fat of the carcass.

The two major types of protein fibers identifiable in the connective tissue of muscle are collagen and elastin. Collagen fibers contain a regularly oriented array of polypeptide chains, resulting in a highly fibrillar structure (Figure 5). Collagenous tendons can be stretched approximately 4% of their length

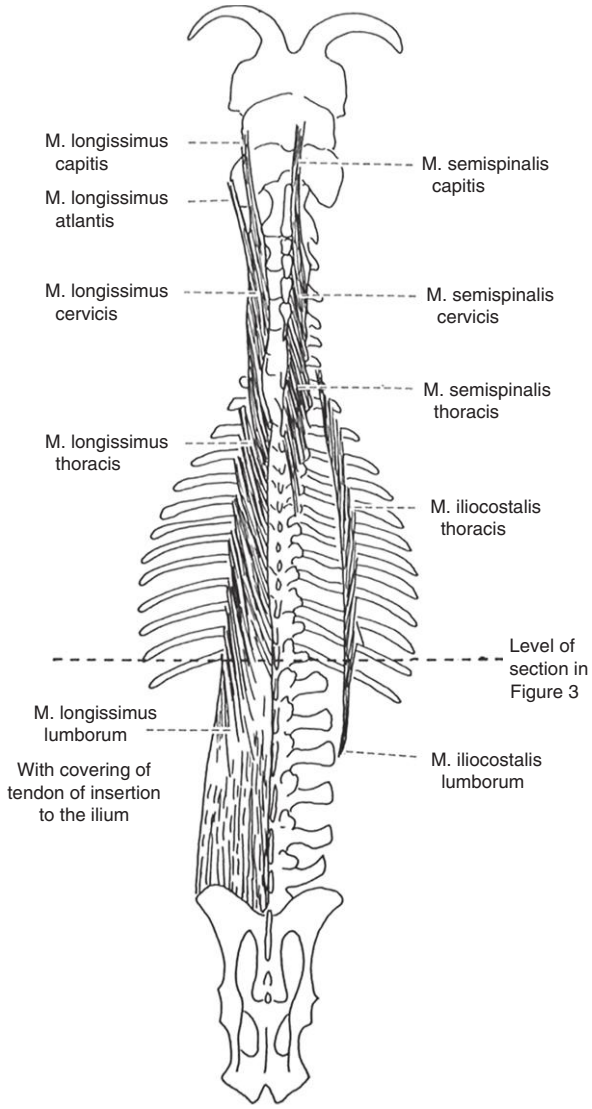

Figure 2 Some long and segmented muscles of meat carcasses. Selected muscles of the trunk of the goat are shown schematically, from a dorsal aspect. Although the longissimus muscle is a single segmented muscle reaching from the thorax to the hip bone, a series of names are given, depending on the region. The whole muscle was formerly called 'longissimus dorsi.' It is shown in transverse section for the sheep, at the level indicated by the dotted line in **Figure 3**. Adapted from Getty, R., 1975. Ruminant myology. In: Getty, R. (Ed.), Sisson and Grossman's The Anatomy of the Domestic Animals, fifth ed. Philadelphia, PA: WB Saunders, pp. 791–860.

elastically, i.e., they return to their original length without permanent deformation. Elastin in which polypeptide chains are arranged randomly provides the elasticity to the connective tissue. The fibers appear amorphous except for fine microfibrils embedded in them. Their elastic performance matches that of rubber, because they can be stretched 250% without permanent deformation. This can be demonstrated on the large elastic ligament in the neck of ruminants, easily seen on a half-carcass. This nuchal ligament, by stretching when the head is lowered, enables raising of the head again with little muscular effort. In tendons external and internal to muscles (Figure 6), collagen fibers are packed densely and have high tensile strength. The epimysium (Figure 7(b)), the connective tissue on the outside of a single muscle, is thick and strong when it forms part of the tendinous apparatus of the muscle. It is continuous with the grossly visible internal muscle connective tissue, the perimysium, which branches within the muscle to enclose bundles of muscle fibers (Figures 7(b), (c)). As for epimysium, perimysium can also, in some parts of a muscle, be thick and tendinous. In other locations within the muscle, the collagen fibers of the perimysium are arranged in a loose but well-ordered criss-cross lattice at an angle to the long axis of the muscle fibers. Elastin is also present in perimysium. Fat cells may accumulate. Vessels and nerves servicing the muscle are supported and protected within the perimysium. The 'grain' of a muscle, grossly visible, especially when cooked meat is broken apart, consists of perimysially enclosed bundles of muscle fibers. In the process of marinating or cooking, the integrity of the collagen fibers of the perimysium is partially lost and the muscle fiber bundles are easily separable.

The layer of connective tissue surrounding individual muscle fibers is endomysium (Figures 7(c), (d)). This contains only a light network of collagen fibrils, not bundled into fibers as in epimysium and perimysium. These collagen fibrils are the reticular fibers that form a continuous network around each muscle fiber. Reticular fibers are demonstrated by silver stains, apparently because of their thinness (0.5–2.0 μm) and their relationship to the interfibrillar matrix. The basal lamina is a relatively thin layer (1 nm), closely applied to the membrane of the muscle fiber. Endomysial collagen fibrils enter it. The basal lamina contains a nonfibrillar variant of collagen. Endomysium contains the capillary network from which muscle fibers obtain nutrition and respiratory gases, and to which waste products are passed. Also found here are the terminal ends of the nerves supplying each muscle fiber.

The matrix of muscle connective tissue is amorphous. It is composed predominantly of various types of large proteoglycan molecules, which have a protein core with multiple polysaccharide side chains.

The relevance of muscle collagen to meat production is due to the peculiar properties of the collagen molecule. To construct a tendon from polypeptide chains, these chains must first be woven together to form collagen molecules, then linked to form collagen fibrils, which in turn form collagen fibers, as shown in Figure 5. The binding of collagen molecules to form a collagen fibril that is visible electron microscopically is due to cross-linking (Figure 8). In newly formed collagen fibrils, these are solely intermolecular head-to-tail cross-links. However, the properties of collagen change with age. In mature animals, collagen fibers are much more stable owing to the cross-linking of several molecules, thereby linking fibrils in register (Figure 8(b)). Such fibers are more rigid, and less susceptible to enzyme degradation. Most significantly, their thermal properties are affected. At approximately 65 °C and above, collagen molecules are denatured. They lose their highly organized structure and become gelatin. The cross-linkages in mature collagen are heat stable, however, and some strength is progressively maintained with increasing animal age. The effect also results in more tension being generated under isometric conditions as the fibers shrink with

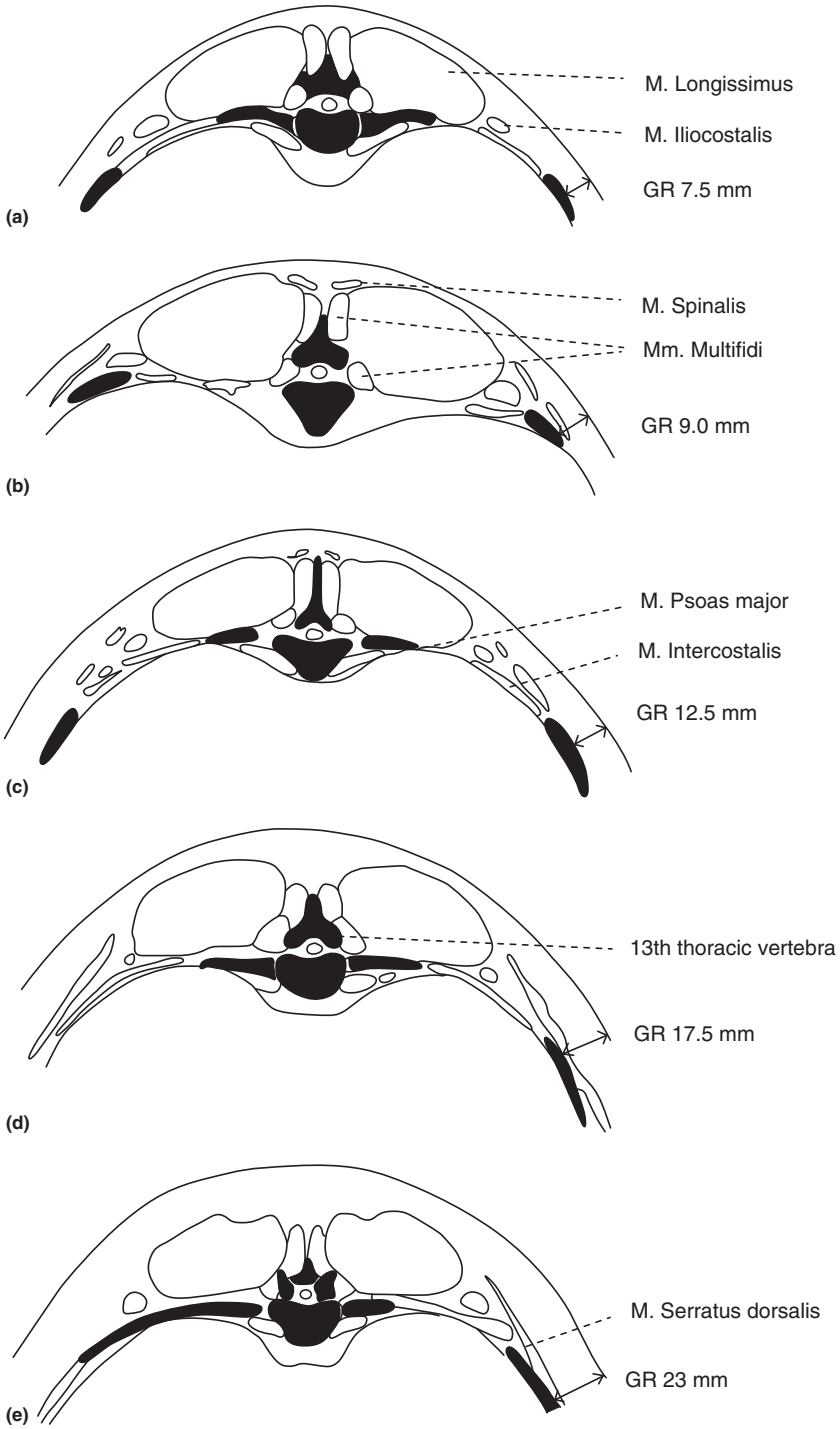

Figure 3 Anatomical features of a lamb chop. Transverse sections of the dorsal part at the level of the 13th thoracic vertebra of 5 lamb carcasses with increasing fatness (a, b, c, d, and e respectively), as indicated in **Figure 2**. The sections of the longissimus muscle ('eye muscle') have frequently been used to predict muscle mass in carcasses of cattle, sheep, and pigs. The series here shows sections from five lambs of the same carcass weight (22.7 kg), but increasing fatness as indicated by the increasing thickness of subcutaneous fat directly over the 13th rib ('GR' measurement). Adapted from photographs supplied by J.M. Thompson.

heat. The relevance of these properties to meat tenderness is discussed in another part of this encyclopedia.

Thus, even though muscle collagen content does not increase over the postnatal lifetime of animals, meat from older animals is tougher. It is the quality, not the quantity, of the collagen that is relevant. It is considered that collagen quality is a major determinant of texture in cooked meat.

The highest collagen content is found in muscles with much internal tendon, where strength is important rather than range of movement and where the muscle functions to some

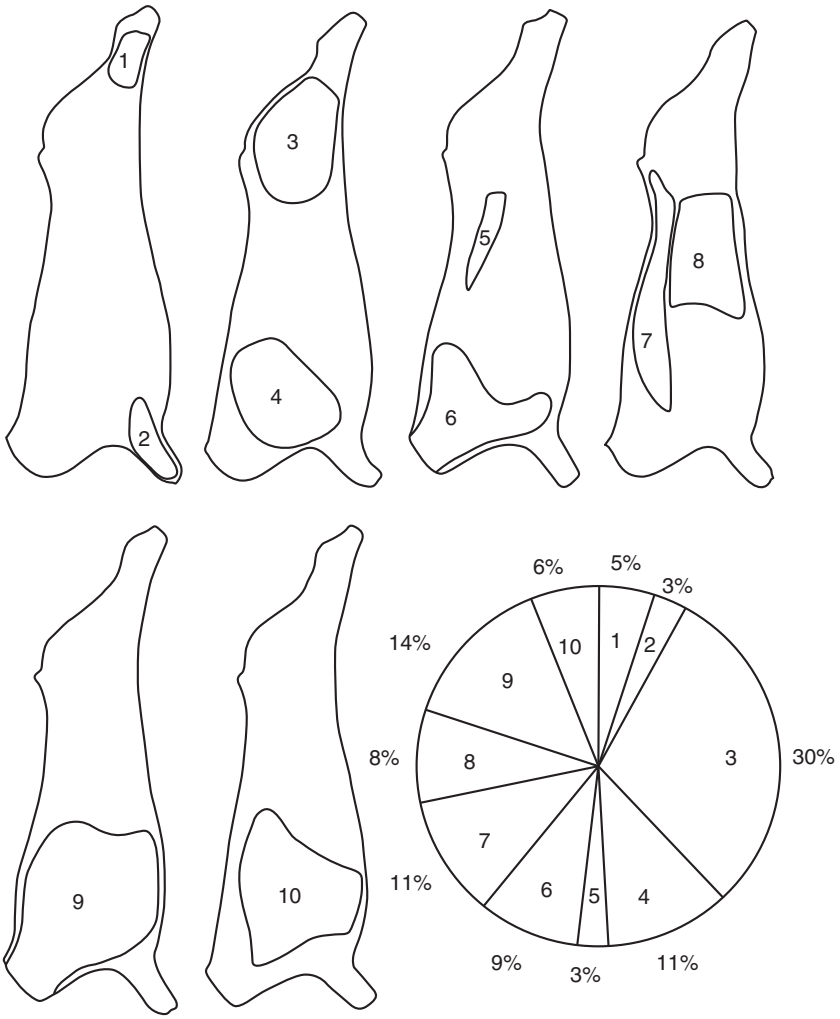

Figure 4 The distribution of muscles in carcasses. Muscle groups shown have weights appropriate to a Jersey cow of live weight 381 kg, carcass weight 178 kg, and total carcass muscle weight of 100 kg. The pie graph shows the weight of each muscle group as a proportion of total muscle. The muscle groups shown are: 1, muscles surrounding the tibia; 2, muscles surrounding the radius and ulna; 3, muscles surrounding the hip bone and femur; 4, muscles surrounding the scapula and humerus; 5, deep muscles ventral to the vertebral column; 6, deep muscles of the neck; 7, muscles dorsal to the vertebral column; 8, abdominal muscles, 9, muscles attaching the fore limb to the trunk; 10, deep muscles of the thorax. Data reproduced from Tan, G.Y., 1981. Carcass development and cellular growth of muscle and fat in male and female cattle. PhD Thesis, Massey University, Palmerston North, New Zealand.

extent as an adjustable ligament in the fixation of joints. A complete range of muscles, from those with a wide range of movement, to tendons, where only passive elastic movement occurs, is found in meat animals (Figure 6).

Muscles of the distal parts of limbs are especially high in collagen (Figure 9(a)). Collagen content is lowest in muscles of the back and abdomen and in muscles connecting limbs to the trunk (Figure 9(a)). These muscles have the widest range of movement.

The elastin content in the connective tissues of muscle varies considerably among individual muscles, but not in a pattern similar to that for collagen. It is especially high in the perimysium of the bovine semitendinosus and biceps femoris muscles, where it is approximately 20 times that for the surrounding thigh muscles. This may explain the strikingly mosaic appearance of the freshly cut transverse surface of these muscles.

The presence of intramuscular fat cells in the perimysium depends on overall carcass fatness. When this is high enough, the cut surface of a muscle has a 'marbled' appearance due to fat located between the muscle fiber bundles in the perimysium. Intramuscular fat also varies among muscles. In pigs, and presumably other species, the fattest muscles are those adjacent to the subcutaneous layer, especially in the neck, thorax, and abdomen (Figures 9(b) and 10). A certain amount of intramuscular fat is valuable for increasing palatability and adding flavor to meat.

Muscle Fiber Structure and Physiology

There are many millions of muscle fibers in a meat carcass. For a medium-sized hind limb muscle of a beef carcass, there

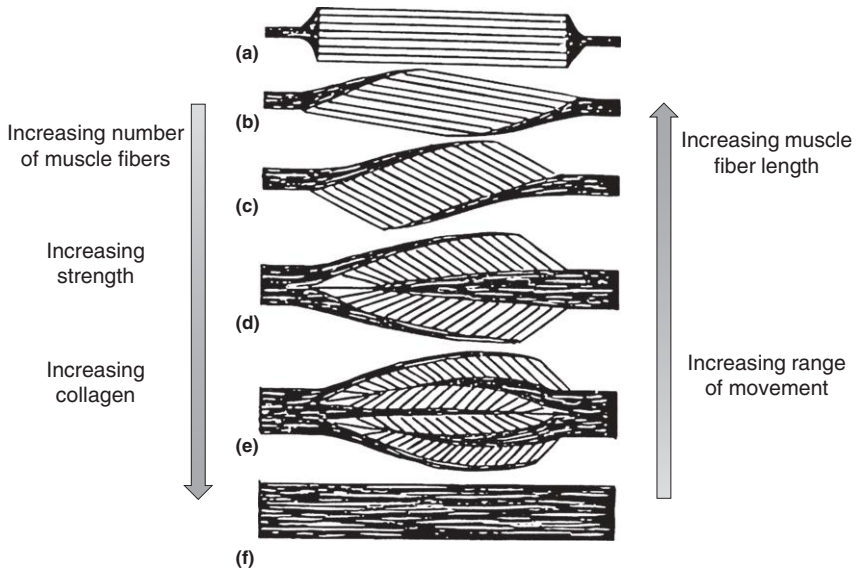

Figure 6 Fibrous architecture of muscle. Diagrammatic representation of possible arrangements of the muscle and collagen fibers within muscles. The extreme stages, from a strap muscle (a) to a ligament (f) are separated by a series of progressively more pennate muscles (b, c, d, e).

are approximately one million fibers in a transverse section (Table 2). Individual fibers are too small in diameter (50–100 µm) to be seen with the naked eye, but they span the length of small muscles, being several centimeters long.

The special property of muscle fibers is their ability to contract, or to resist stretching by an external force. Each fiber is an electrical unit, with its own triggering system. The apparatus involved in the electrical excitation of muscle fiber will be described first, followed by an account of the contractile apparatus itself.

Each muscle fiber of a carcass, together with from 5 to 200 other fibers that form a single motor unit, is linked to a large nerve cell in the spinal cord or the brain (Figure 11). Because the whole substance of the muscle fiber contracts simultaneously, there is an elaborate mechanism to ensure that the electrical impulse reaching the muscle is transmitted rapidly

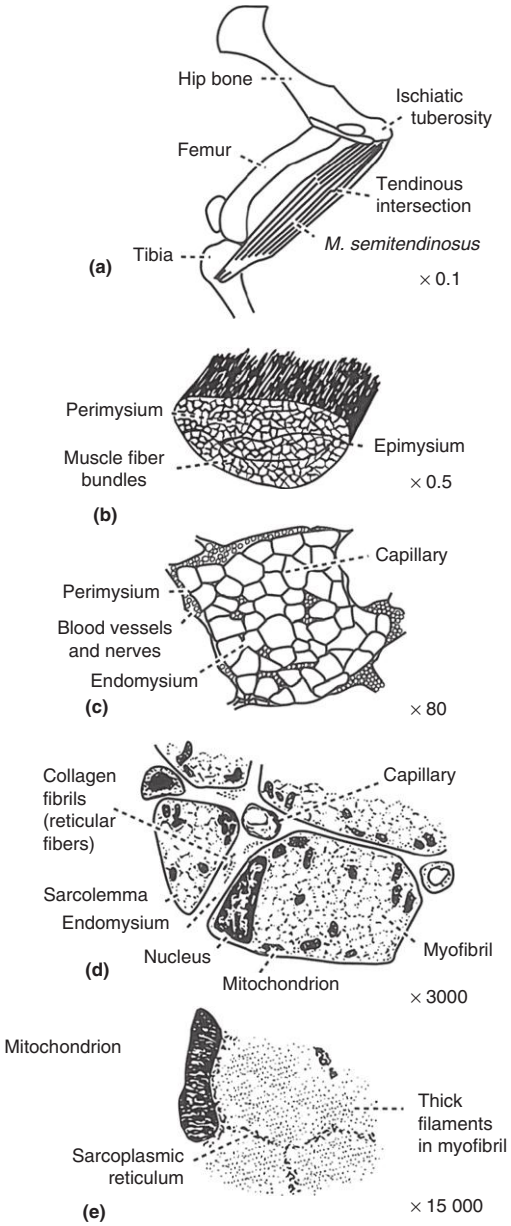

Figure 7 Gross and ultrastructural anatomy of the sheep semitendinosus muscle. The semitendinosus muscle lies caudally in the thigh region (a). Seen grossly in transverse section, perimysial strands course through the muscle and enclose muscle fiber bundles (b). Within a bundle, an endomysial connective tissue network is revealed by light microscopy to surround individual muscle fibers (c). Electron microscopic examination shows a network of sarcoplasmic reticulum enclosing myofibrils within the fibers (d). The two complete fibers drawn sectioned here are smaller than actual fibers in the sheep semitendinosus muscle (Table 2). At a still higher magnification, a pattern of thick filaments is visible within each myofibril (e).

throughout it, and that the contractile apparatus can react accordingly. The time taken for a muscle to produce peak tension is approximately 20 ms from stimulation. The components of the muscle fiber necessary to achieve this are summarized in Figure 11 and Box 1.

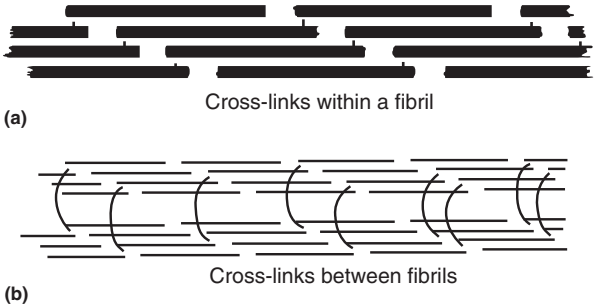

Figure 8 Cross-linking in collagen. The cross-links in immature connective tissue pass between collagen molecules within a fibril (a). The molecules are linked head to tail to form an infinite polymer. In a mature collagen fiber (b), the cross-links pass between the fibrils to link them in register. PhD Thesis, Massey University, Palmerston North, New Zealand and Data for sheep from Sivachelvan, N., 1980. An anatomical study of adaptive processes in muscle. PhD Thesis, Massey University, Palmerston North, New Zealand.

Following the harvest of an animal for meat, muscle remains excitable for some time. The chemical changes necessary to convert muscle into meat are associated closely with the excitation apparatus.

Within the muscle fiber, and parallel to its length, are cylindrical myofibrils 0.5–1.0 μm in diameter (Figures 7(d), (e), and 12). Each myofibril consists of two types of protein filaments called 'thick' filaments and 'thin' filaments (Figure 13 and Box 3). Thick filaments are formed from myosin molecules that are grouped in bundles. Thin filaments are formed of actin, troponin, and tropomyosin molecules. More details about the myofibrils structure are available in another part of this encyclopedia. Myofibrils are isolated from each other mainly by sarcoplasmic reticulum but also by other structures in the nonmyofibrillar part of the fiber (sarcoplasm). These are listed in Box 2. Because contraction depends on the diffusion of calcium ions into and out of the myofibrils and the sarcoplasmic reticulum, myofibrils are the same diameter regardless of the size or the stage of development of the muscle fiber.

The filaments within a myofibril are aligned to the T-tubular system (Box 1). A T-tubule is associated with each A-I junction in mammalian muscles (Figure 12). The filaments in all myofibrils are, therefore, in register, right across the fiber. It is for this reason that a fiber in skeletal muscle appears striated. Early light microscopists recognized various elements of the striations that have been shown to be significant by electron microscopy and X-ray crystallography (Figure 13). The particular components of the contractile apparatus that are considered currently to be relevant to contraction in the living animal, as well as to processes occurring after slaughter, are listed in Box 3. The functional component of muscle is, therefore, intracellular. Muscle cells result from the fusion of many precursor cells that do not contain contractile proteins. The contractile apparatus is elaborated only after the fusion of myoblasts to form a multinucleated syncytium, the muscle fiber.

Muscle Fiber Metabolism

The energy for the interaction between the thick and the thin filaments is provided by the 'splitting' of the metabolic intermediary adenosine triphosphate (ATP). The site for the catalysis of this fundamental reaction is in the heads of the myosin molecule (Figure 13(d), Box 3). The enzyme is therefore known as myosin ATPase and is rate limiting for the speed of muscle contraction. The higher the level of activity, the faster is the speed of ATP splitting and the more energy that is available for mechanical work. Fast-contracting fibers, with a time to peak tension of approximately 10 ms, have a high level of myosin ATPase activity. Slow-contracting fibers (approximately 80 ms to peak tension) have a demonstrably lower myosin ATPase activity. This difference can be shown histochemically (Figure 14(a)).

Because all fibers within a motor unit are stimulated by the firing of their common motor neuron, they must contract together and have the same speed of contraction and the same level of myosin ATPase activity (Figure 15). In the living animal, fast-contracting fibers are used to accelerate parts of the body, whereas slow fibers are more economical for deceleration such as the maintenance of posture. In the latter case, chemical energy is not converted into mechanical energy but into heat. Muscles vary in their proportion of fast and slow fibers, according to their function in the body. There is also much variation in the proportion of these fiber types within and between muscles (Figure 16(b)).

The contraction speed is usually linked with the means by which ATP is regenerated after splitting. Figure 17 shows that when there is an adequate blood supply, this can be achieved aerobically. In this case, oxygen and nutrients diffuse into the fiber from surrounding capillaries, and waste products can diffuse back. Muscles must also often function without a

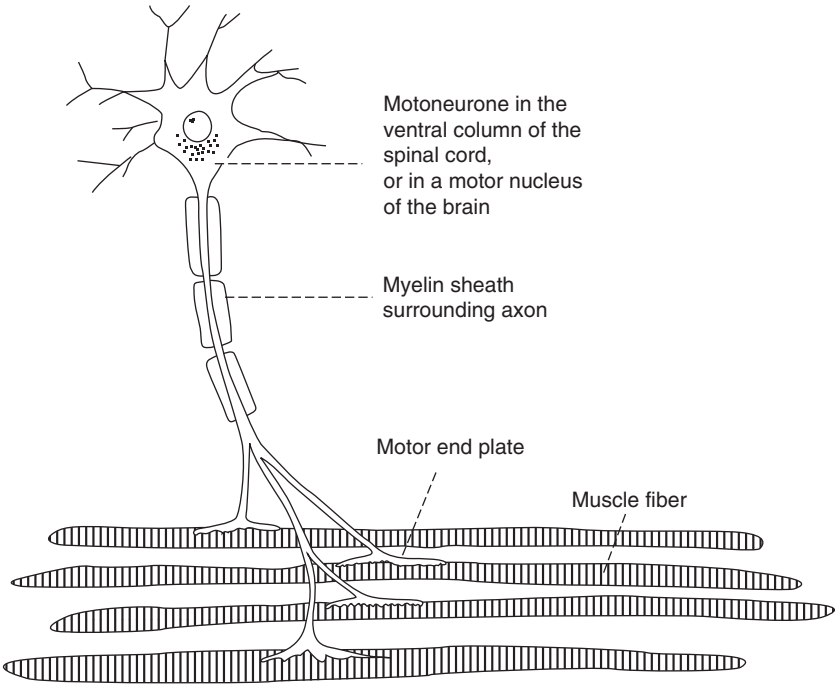

Figure 11 The motor unit. Several muscle fibers share the same motor neuron and are therefore stimulated simultaneously.

Box 1 The control of contraction in muscle

Motor end plate (**Figure 11**)
- Located at about midlength of the fiber.
- Transfers the electrical impulse from the nerve ending to the muscle fiber membrane.

Muscle fiber membrane (sarcolemma) (**Figure 7(d)**)
- 7 nm thick.
- Envelops the muscle fiber.
- Electrically excitable; on stimulation there is rapid depolarization over the whole fiber.

Transverse tubular (T-) system (**Figure 12**)
- Fine tubules with membranes continuous with the sarcolemma, 20 nm in diameter.
- By branching, the tubular system surrounds each myofibril at every A–I junction.
- Transfers the sarcolemma depolarization to the entire contractile apparatus within the fiber.

Sarcoplasmic reticulum (**Figure 12**)
- Forms a network of branching membranous sacs around each myofibril.
- Parts of it approach a T-tubule on each side to form a 'triad' in a section transverse to the T-tubule.
- On stimulation, releases and then actively reabsorbs calcium ions, which stimulate the chemical processes necessary for contraction within the myofibrils.

blood supply: this might be a temporary diversion or, if the muscle is seldom used, the capillary density around the fibers may be low. In this case, an intrinsic energy store (glycogen) must be used, and waste products cannot be removed from the muscle. The situation is essentially the same when muscles go on living after the death of animals. The anaerobic process is less efficient than the aerobic one, but wholly aerobic metabolism is possible only in continuously active muscles (such as the heart), which are very well irrigated. Slow fibers usually use aerobic metabolism because of their more continuous use, for which efficiency is desirable and, because in their deceleration function, they release heat that is only safely dissipated by a rich blood supply. Slow fibers are, therefore, found closest to the blood supply to a muscle (**Figure 16(b)**) and are surrounded by a dense network of capillaries. They contain more myoglobin in their cytoplasm for the transfer of oxygen and possess a high density of mitochondria with their enzymes of aerobic metabolism (**Box 2**, **Figures, 14**, **16(c)**, **17**).

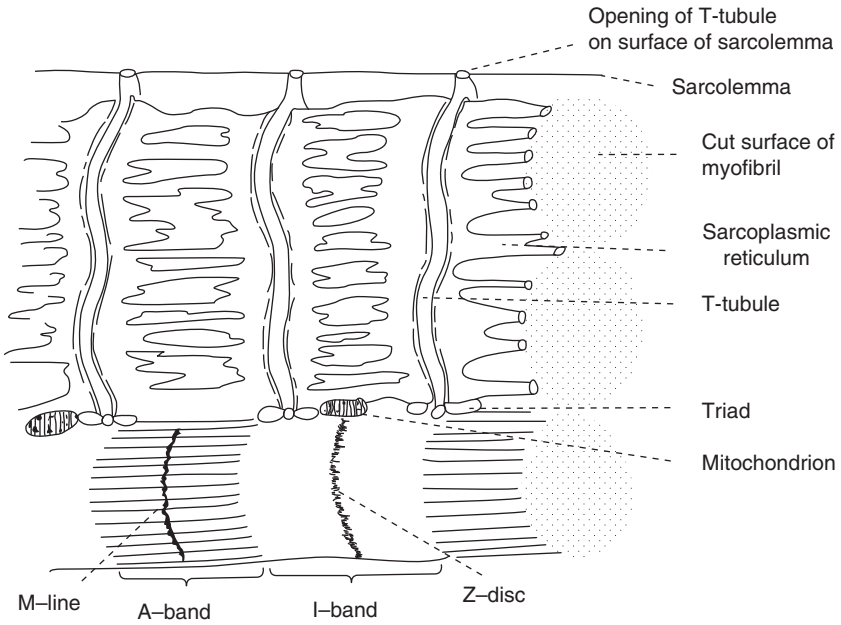

Figure 12 The sarcoplasmic reticulum and the T-system. This diagrammatic representation of three myofibrils extends **Figure 7(e)** three-dimensionally. The lower myofibril has been stripped of its surrounding T-tubular system and sarcoplasmic reticulum to show the relationship of these to the array of myofilaments within the myofibril. A 'triad' of one T-tubule and two parts of sarcoplasmic reticulum is sectioned at the level of each junction of A- and I-bands.

This association between slow fibers and aerobic metabolism does not imply, however, that slow fibers have no store of glycogen and cannot use anaerobic metabolism. Neither does it imply that fast fibers are exclusively anaerobic. Most muscles contain a high proportion of fast fibers with both aerobic and anaerobic metabolism. In fact, all metabolic combinations are possible and can be altered by a changing frequency of muscle use, such as prolonged aerobic training. **Box 4** shows some of the terms that have been used to describe the different fiber types in muscle. The supposed color distinction of 'red' and 'white' has largely been abandoned. It is especially inappropriate for the muscles of animals producing red meat. The terms 'type I' and 'type II' fibers, and their subsets, are still favored by pathologists.

Muscle Contraction

Muscle, a valuable nutritional source for humans, is nevertheless fundamentally a chemical machine driven by isothermal combustion. The contraction of voluntary muscles in all animals takes place by the mutual sliding of two sets of interdigitating filaments: thick, containing the protein myosin, and thin, containing the protein actin, organized in sarcomeres (**Figure 13**). The relative sliding of thick and thin filaments is brought about by the movement of cross-bridges, parts of the myosin molecules protruding from the thick filaments and acting cyclically with the thin filaments, transporting them by a kind of rowing action (**Figure 18**). It is the hydrolysis of ATP that provides the local energy for this linear motor. ATP is also a relaxing factor, in that it dissociates actin and myosin. Without ATP, the thick and thin filaments are bound together at the cross-bridges (**Figure 19**). The energy for the replenishment of ATP comes from the metabolic processes shown in **Figure 17**. A part of the ATP regeneration comes from phosphocreatine, which can donate a phosphate group to adenosine diphosphate (ADP) to form ATP. Moreover, adenylate kinase, also known as myokinase, catalyzes the formation of 1 molecule of ATP from 2 molecules of ADP.

The globular heads of myosin catalyze the hydrolysis of ATP. The rest of the myosin molecule forms a long helical coil. The myosin head is the structure forming a cross-bridge between filaments, as seen by electron microscopy. This cross-bridge binds to actin and changes its angle as one molecule of ATP is hydrolyzed in each cycle. Thin filaments are helical polymers of globular actin. Actin-binding sites have been identified in X-ray crystallographic models.

The chemical process by which animal movement takes place has long intrigued investigators. They have developed special technology to tackle the problem of three-dimensional chemical reactions at the atomic level taking place at high speed. Experiments using high-energy X-ray sources have confirmed a swinging cross-bridge hypothesis, although interpretations are ambiguous. Isomerism between an extended and a flexed state results in large changes of angle of the lever arm at the distal end of the myosin head. This accounts for a 12 nm power stroke (**Figure 19**). A burst of approximately 100 such cycles powers the sliding filaments so that peak tension in muscle can be reached in 10 ms.

Once an animal dies, the intrinsic metabolic processes that restore ATP eventually fail. The actin and myosin association becomes permanently fixed at the stage in **Figure 19(a)**. This rigor mortis state, an important consideration in how muscle becomes meat, is detailed in another part of this encyclopedia.

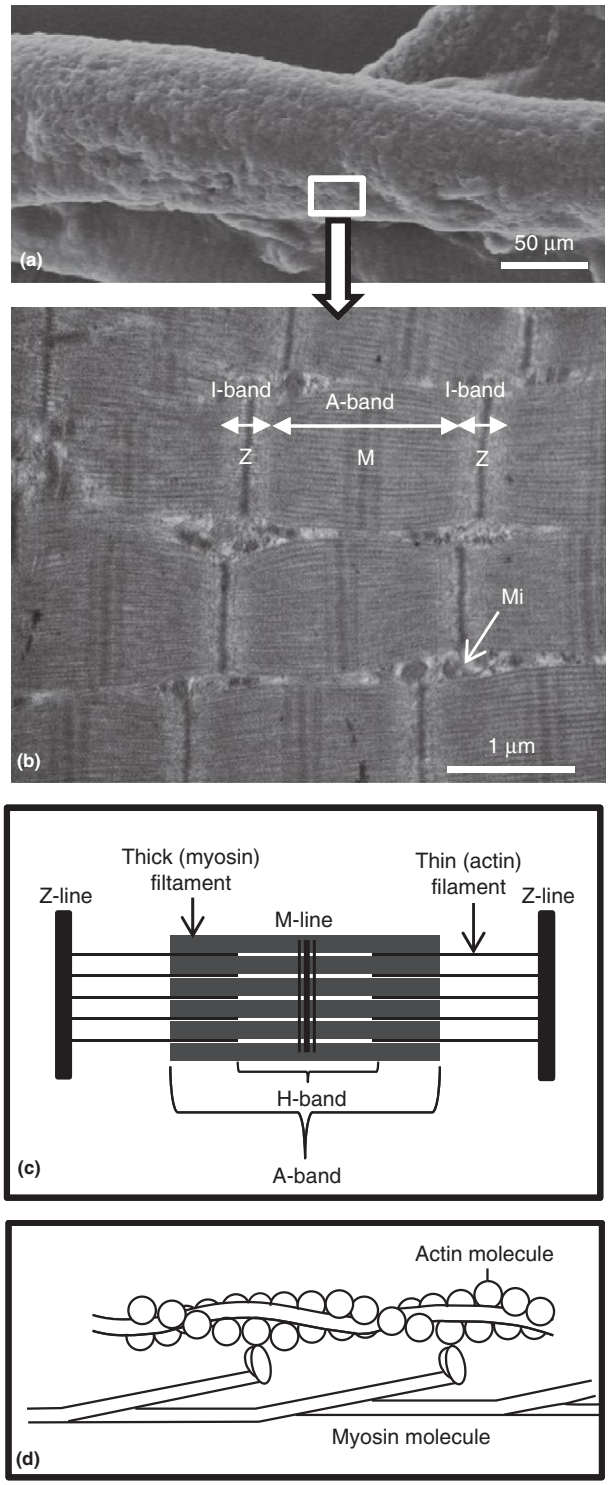

Figure 13 Fibrillar and molecular structure of the contractile elements of muscle. (a) Skeletal muscle fiber visualized by scanning electron microscopy. (b) Longitudinal section of a muscle fiber observed by transmission electron microscopy showing the myofibrils with a series of anisotrope (A-band) and Isotrope (I-band) areas, the sarcomere located between two Z lines with the M line in the middle part of the sarcomere. Mi, mitochondria. (c) Scheme of the sarcomere showing its organization. (d) Structure of thick (myosin) and thin (primarily composed of actin) myofilaments.

Carcass Fat

In living animals, fat insulates against cold and provides a store of energy. A large store is not essential for meat animals continuously supplied with enough food for optimal growth. The increased fat content that has almost invariably occurred with the domestication of meat animals must be contrary to natural selection and survival in the wild. Fat storage is,

Box 2 The contents of the sarcoplasm

Nuclei (**Figures 7(d)**)
- Located directly beneath the sarcolemma.
- Several thousand per fiber.
- Once a muscle fiber nucleus is involved in the synthesis of myofibrils, it is no longer capable of further division. A supply of nuclei in undifferentiated 'satellite cells', for growth and renewal, is located outside the muscle fiber.
- The function of the nuclei in mature muscle is to provide the DNA code for renewal protein following wear and tear of the myofibrils.

Lysosomes
- Small particles involved in intracellular digestion.
- May be significant in converting muscle to meat.

Mitochondria (**Figures 17**, **7(d)**, (e) and **13(b)**)
- Organelles containing the enzymes of aerobic metabolism.
- A high mitochondrial density results in dark, red meat. This is because some of these enzymes are pigments, and because aerobic metabolism in muscle is also associated with the red-pigmented iron-containing protein, myoglobin, in the sarcoplasm.

Glycogen
- These particles are usually numerous.
- They contain a carbohydrate nutritional store and associated enzymes.
- The preslaughter depletion of muscle glycogen is important in meat quality.

Box 3 Features of a myofibril

Bands (**Figures 12**, **13(b)**, **(c)**, and **18**)
- A-band: The region of thick (myosin) filaments.
- I-band: The region containing only thin filaments.
- Z-disk: A dark thin line in the middle of the I-band. It contains zig-zag elements that anchor the ends of the thin filaments.
- M-disk: A darker line in the middle of the A-band. Contains the protein myomesin. Connects the centers of the thick filaments together.

Sarcomere (**Figures 13(c)** and **18**)
- An assembly of thick and thin filaments between adjacent Z-disks forming the fundamental contractile units of muscle. The sarcomere length is greatest in stretched muscle (4.5 μ) and least in contracted muscle (less than 1.5 μ). These lengths are closely related to the toughness of meat. The length change is made without change in the length of the filaments. The fundamental interconversion of chemical to mechanical energy in muscle takes place between the thick and the thin filaments. This results in the sliding of interdigitating filaments (**Figure 19**).

Thick filaments (**Figure 13(c), (d)**)
- Each is an assembly of myosin molecules.
- Each filament is 12 nm in diameter and 1500 nm long.
- Each molecule has two heads, associated with the sliding of thick and thin filaments by forming cross-bridges between them. The enzyme catalyzing the splitting of ATP to achieve this is located in the heads.

Thin filaments (**Figure 13(c), (d)**)
- Each is an assembly of several proteins, predominantly globular actin, supported by troponin and tropomyosin.
- Each filament is 8 nm in diameter and 1000 nm long.

Cytoskeletal framework
- A distinct lateral component links adjacent myofibrils at the Z-disks. This remains after the removal of the thick and thin filaments. The most prevalent proteins present here are titin (connectin) and nebulin.
- T-filaments remain after the thick and thin filaments have been stretched beyond their overlap. Their diameter is 2 nm. They possibly contribute to the toughness of meat.

however, useful even under farm conditions in the case of red deer stags (**Table 3**), and in breeding females with pregnancy or lactation occurring at a time when grazing conditions are poor.

Joint fat and the epicardial fat surrounding the vessels in the grooves of the heart are present even in starved animals, and also presumably have a mechanical role. Because of their size or location, none of these fat depots are significant for meat production.

Fat is a particularly valuable component of meat because of its influence on the flavor of cooked meat and its ability to improve palatability.

Fat is distributed in meat carcasses in three anatomically distinct locations. The subcutaneous depot (panniculus adiposus) lies on both sides of the superficial fascia and the cutaneous muscle layer (panniculus carnosus) (**Figure 20**). The intermuscular depot lies especially thickly in certain regions. The fat immediately beneath the thin shiny membrane lining

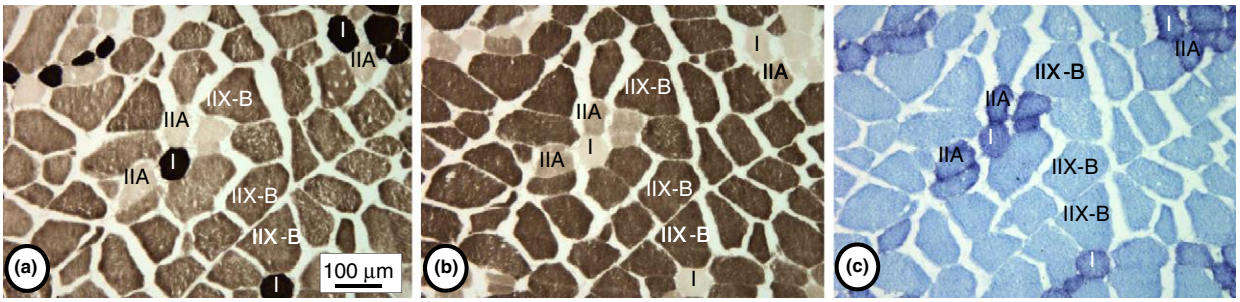

Figure 14 Intrinsic speed and metabolism in muscle fibers. Transverse serial sections of the pig longissimus dorsi muscle stained for myosin ATPase activity after section preincubation (a) at pH 4.45, (b) at pH 10.4, and (c) for succinate dehydrogenase. Type I fibers show a strong reaction after pH 4.45 preincubation (a), and a low reaction after pH 10.4 preincubation (b). IIX and IIB fibers not separable by this method and identified IIX–B are stained in dark grey while IIA fibers have an intermediate response (a and b). For succinate dehydrogenase staining (c), a dense reaction indicates a high mitochondrial density and therefore a high level of aerobic metabolism. Type I fibers are aerobic slow-twitch fibers, type IIA fibers are aerobic fast-twitch fibers, and IIX-B fibers are anaerobic fast-twitch fibers. Adapted from Davies, A.S., Gunn, H.M., 1972. Histochemical fibre types in the mammalian diaphragm. Journal of Anatomy 112, 41–60.

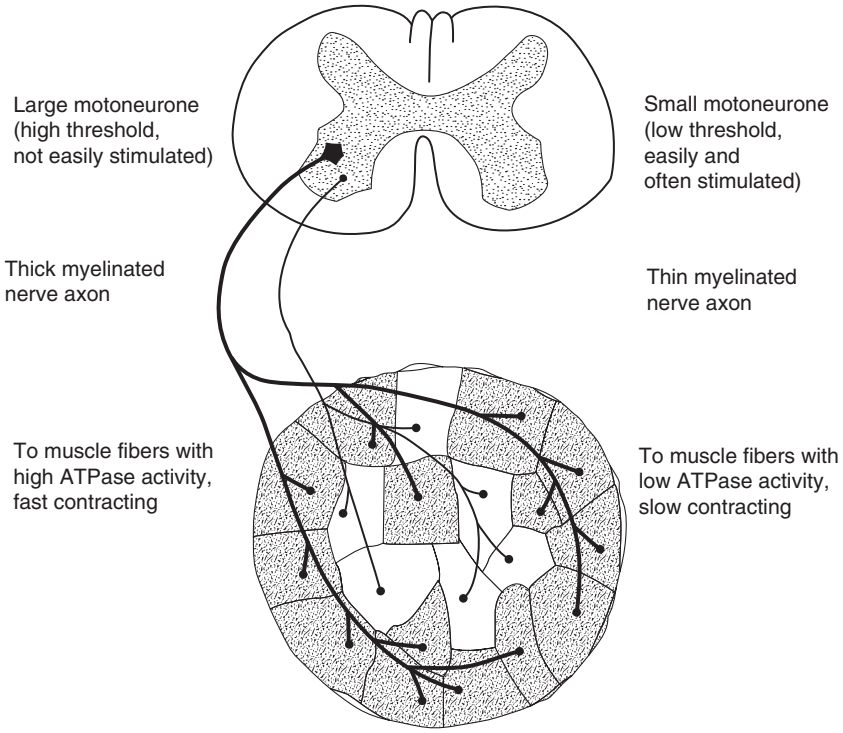

Figure 15 Innervation of fast and slow fibers. The speed of contraction of muscle fibers is related to motor neuron size. Small motor neurons are more readily, and hence more frequently, stimulated. They innervate slow fibers, which have a greater economy of energy use.

the body cavities (peritoneum and pleura) is called cavity fat and is especially thick around the kidneys and caudally into the pelvic cavity.

The subcutaneous fat depot is better developed in pigs than it is in ruminants (Table 4). In ruminants, it is possible to locate the sites in which it first develops perinatally, before they coalesce as the deposits grow (Figure 21). Each fat depot is composed predominantly of fat cells (adipocytes), which are spherical cells containing large amounts of lipid. Fat cell size varies between depots. When the cells are large, such as in the cavity fat surrounding the kidneys, the lipid content of the depot is higher (Table 5).

Subcutaneous, intermuscular, and cavity fat can be separated, with varying degrees of difficulty, from the other carcass tissues by dissection. Significant fat depots are also found within the perimysial connective tissue of muscles, as described above, as well as within the medullary cavity of bones. For this reason, and because fat has much less of a mechanical role than

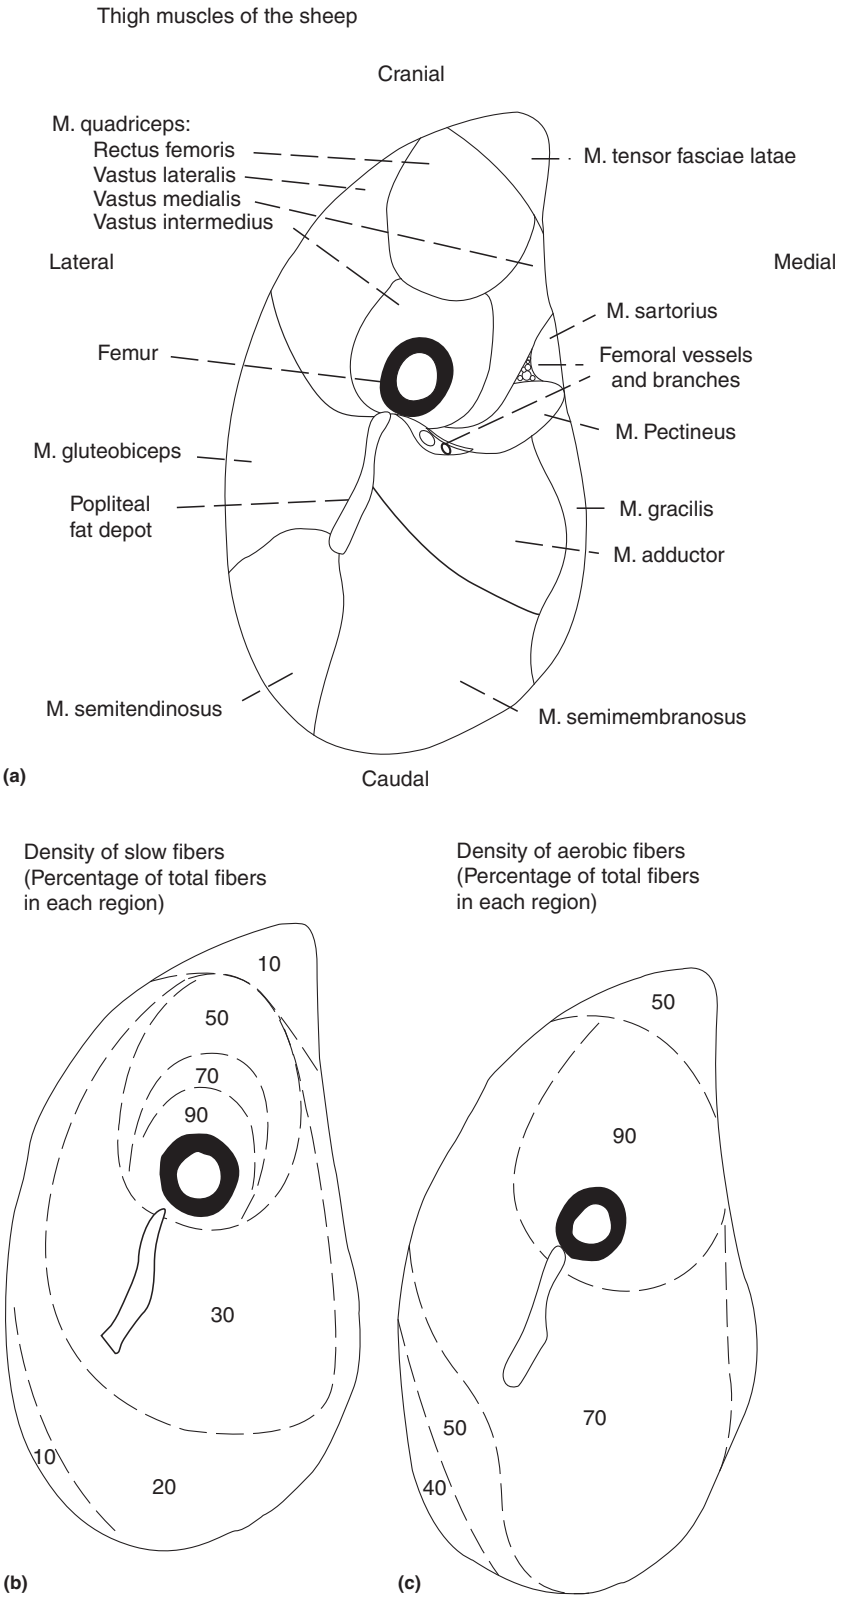

Figure 16 Heterogeneous distribution of fiber types in muscle. (a)Transverse section of the hind limb of the sheep. The density of slow-contracting fibers is shown in (b), and the density of fibers with a high level of aerobic enzyme activity is shown in (c). The muscles closest to the femur and the main blood supply to the limb have the highest density of slow, aerobic fibers. Adapted from Suzuki, A., Tamate, H., 1988. Distribution of myofiber types in the hip and thigh musculature of sheep. Anatomical Record 221, 494–502.

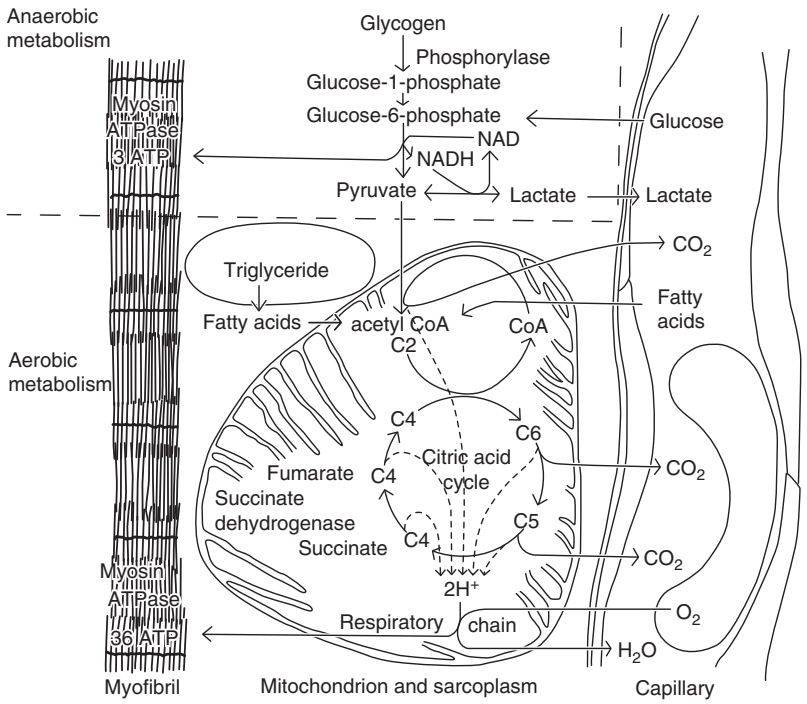

Figure 17 Aerobic and anaerobic metabolism in muscle. The metabolic processes enclosed by the dotted line in the upper left corner are those that required neither the availability of an extrinsic source of energy and oxygen nor the removal of metabolites from the muscle fiber. Under these circumstances, 3 mol of ATP are regenerated per mole of glucose-1-phosphate consumed. In contrast, 37 mol are regenerated per mole of glucose-1-phosphate metabolized through the citric acid cycle. The latter process is, however, effective only if an adequate blood supply is available. This cannot occur for all muscles during all periods of activity. This rationing of aerobic metabolism during life is curtailed following slaughter, when, without circulating blood, only anaerobic metabolism is possible. The length of carbon chains (between C2 and C6) is changed during the coenzyme A and citric acid cycles by the release of CO_2 as waste from aerobic metabolism. Lactate is the waste product from the anaerobic breakdown of glycogen.

Box 4 Mammalian muscle fiber types

An outline of chronological development of a classification system, showing the confused symbols used during the 1960s and the functional interpretation that became possible in the early 1970s. For most muscles of meat-producing animals, a functional classification of three types of fibers has been adequate in a variety of subsequent studies.

Date	*Species*	*Method*	*Classification*		
1873	Rabbit	Histology and physiology	Slow red		Fast white
1960	Rat, man	Histochemistry	I		II
1962	Rat	Mitochondrial distribution and histochemistry	B	C	A
1964	Rat	Histochemistry	III	II	I
1970	Pig	Histochemistry	Red	Intermediate	White
1970	Rat, man	Histochemistry	I	IIA	IIB
1970	Rat, cat	Histochemistry			
1971	Sheep	Histochemistry	C	A	B
1971	4 species (including ox, pig)	Histochemistry	β-red	α-red	α-white
1971	Cat	Physiology and histochemistry	Slow	Fast fatigue resistant	Fast fatiguable
1972	9 species (incl. ox, sheep, pig)	Histochemistry	Slow aerobic (fast aerobic and slow aerobic and anaerobic fibers were also identified)	Fast aerobic and anaerobic	Fast anaerobic
1972	Guinea pig, rabbit	Physiology, histochemistry, and biochemistry	Slow oxidative	Fast oxidative glycolytic	Fast glycolytic

muscle and bone and, hence, a less significant internal structure, chemical studies of total carcass fat are useful. However, these do not usually recognize the existence of anatomically definable fat depots and the morphological differences between them.

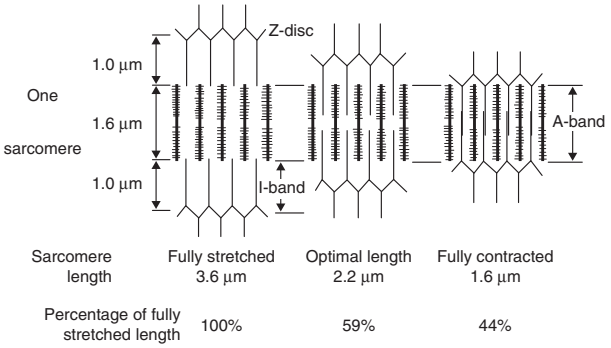

Figure 18 Sliding filaments in muscle. The sarcomere can normally contract to 44% of its fully stretched length. A sarcomere length of 2.2 μm is optimal for force generation, because the thin filaments are then maximally in apposition with the cross-bridges of the thick filaments. In some circumstances, if the fibers penetrate the Z-disk, sarcomere length can be as low as 1.3 μm.

The lipid within each fat depot is stored within the fat cells or adipocytes. Growth of a fat depot results from the degree of multiplication of adipocytes, depending on the depot (Table 5), but mainly in an accumulation of lipid droplets within the cytoplasm of cells.

Carcass Bone

Bone forms the passive part of the musculoskeletal system, in contrast to the active role of muscle. Whether functioning to support the animal or to make it move, muscles use energy. The main use of energy in bone is for growth and repair, processes that are remarkable in that they take place without loss of function. A bone is formed in a fetus as a cartilaginous template of its adult form and maintains an essential supporting role before and after birth while its tissues are replaced many times over (Figure 22).

Unlike muscle and fat, the structural components of bone tissue are formed outside the bone cells or osteocytes. Layered and sculpted formations of collagen and mineral remain in close contact with osteocytes so that they can direct growth and repair. Bones are remodeled extensively during growth,

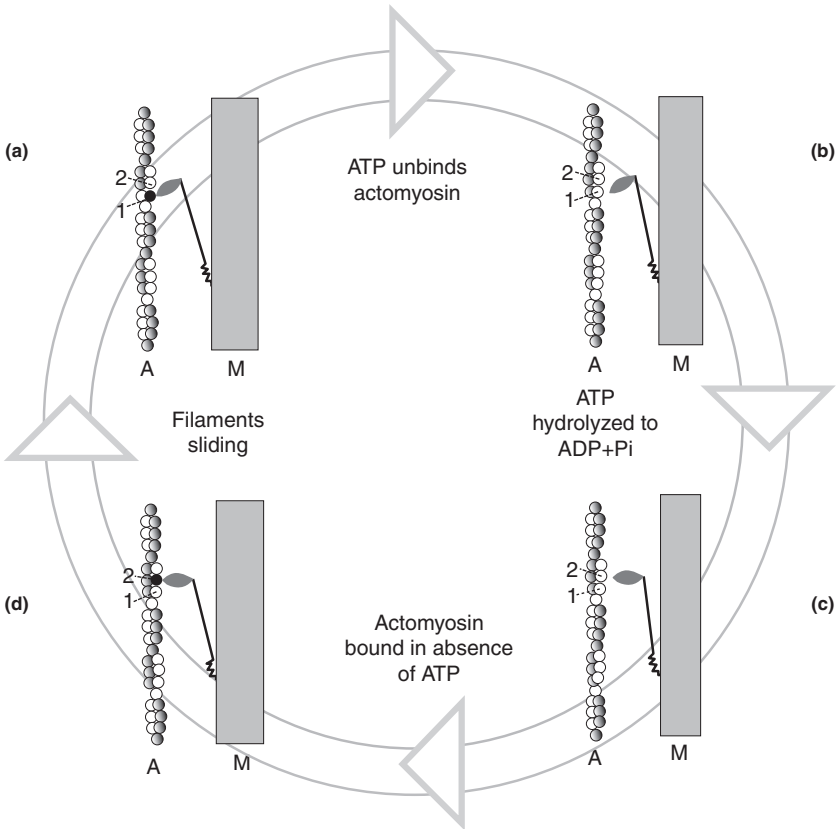

Figure 19 The actomyosin cycle. Reversible changes in myosin and actin association are due to the action of ATP and its products of hydrolysis. In the step (d) to (a), the actin filament A is 'rowed' past the thicker myosin filament M by an association of an adjacent globular actin molecule with the myosin cross-bridge. Adapted from Holmes, K.C., 1996. Muscle proteins – their actions and interactions. Current Opinion in Structural Biology 6, 781–789.

enabling regular complete replacement of collagen and mineral.

A bone is designed so that it performs a specific role with the lightest architectural structure possible. Such weight budgeting is essential because mineralized bones form the densest structures of the body and are therefore heavy to carry around. Of the tissues forming bone, fat is the least dense, followed by collagen and the blood-forming tissues, and then mineralized bone. The fat store within the bone is, therefore, located where there are no applied forces, whereas the mineralized cortex is thickest and densest where compression forces, in particular, are greatest.

Bones form a nutritional store, both of minerals and fat, but the bones of meat animals have no general value in human food production. The amount and distribution of carcass bone is, therefore, interesting mainly from a negative point of view because the amount of bone in any particular part of a carcass reflects how much of the part is to be considered as waste (Table 6). There are some breed differences in bone density that occur, and genetic gains in meat animal production can be made by selecting for lighter bone structure. Charolais cattle have distinctly less dense bone than Jerseys, for example, and the bone structures of wild and domesticated pigs appear quite different. The statement often made on mechanical grounds that larger animals must contain a higher

Table 3 Live weight and carcass changes in red deer stags. During the breeding season (rut), the single or combined effects of hormonal activity, physical activity, and/or the failure to graze result in a decrease in fat content but not apparently in the muscle and bone content of the carcass

Mean weight (kg)	*Prerut (n = 3)*	*Postrut (n = 3)*
Live weight	171	145
Carcass weight	100	85
Carcass muscle	70	68
Carcass bone	12.4	12.6
Carcass fat	19.4	4.6

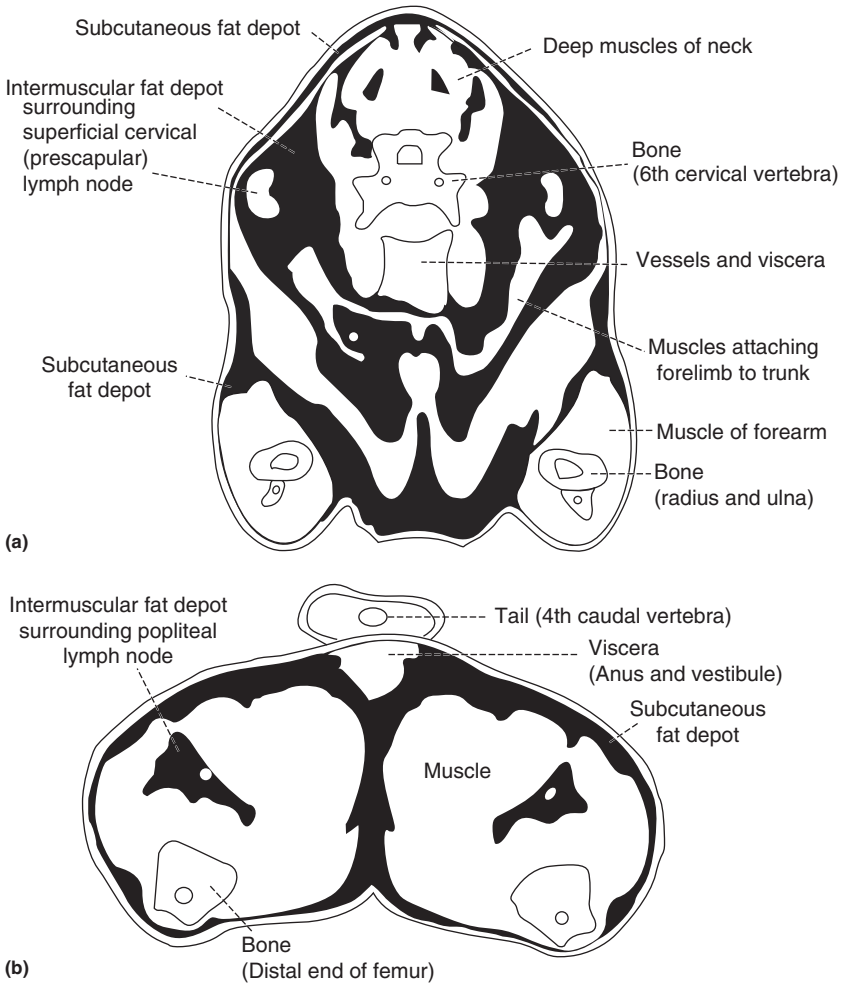

Figure 20 Distribution of fat in sheep carcasses. In these sections of the caudal neck region (a) and both thighs (b), the deposits of subcutaneous and intermuscular fat are shown in black. The drawings are adaptations of computed X-ray tomograms on a living sheep. Adapted with permission from Davies, A.S., Garden, K.L., Young, M.J., Reid, C.S.W., 1987. An Atlas of X-ray Tomo-graphical Anatomy of the Sheep. Wellington, New Zealand: DSIR-Science Information Publishing Centre.

proportion of bone is not shown in the tissue proportions of meat animals (Table 6). The ratio of muscle to bone in a carcass does, however, depend on the level of maturity of an animal. The proportion of the most desirable tissue, muscle, is higher in animals at a time when the fat proportion is higher than optimal and the collagen in their muscles breaks down less readily with cooking and the meat generally is, therefore, tougher. The age at which meat animals are slaughtered is decided by a trade-off of economic factors as well as the quality of the carcass based on muscle tenderness, fat development, and the muscle/bone ratio.

Table 4 The relative development of subcutaneous fat in lean, average, and fat pigs, sheep, and cattle. The values given are typical ranges for British livestock. With increasing fatness, the proportion of subcutaneous fat is higher, but the values for pigs are always much higher than in ruminants

Range of fatness	*Subcutaneous/intermuscular fat ratios*		
	Lean	*Average*	*Fat*
Pigs	3.0	3.7	4.0
Sheep	0.7	1.1	1.5
Cattle	0.3	0.6	0.9

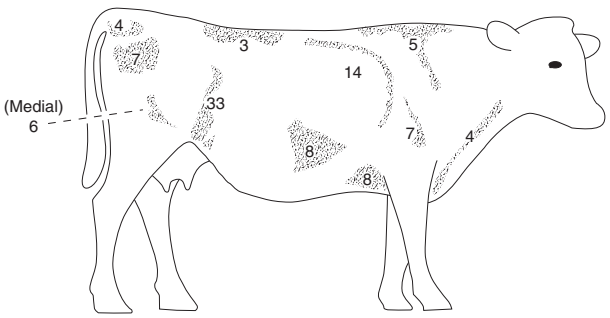

Figure 21 Subcutaneous fat distribution in cattle. The centers of subcutaneous fat development that become apparent around birth are shown here on an immature animal of 200 kg live weight. The proportions by weight of each area is shown as a percentage of the total subcutaneous fat weight of 1.5 kg. Data reproduced from Tan, G.Y., 1981. Carcass development and cellular growth of muscle and fat in male and female cattle. PhD Thesis, Massey University, Palmerston North, New Zealand.

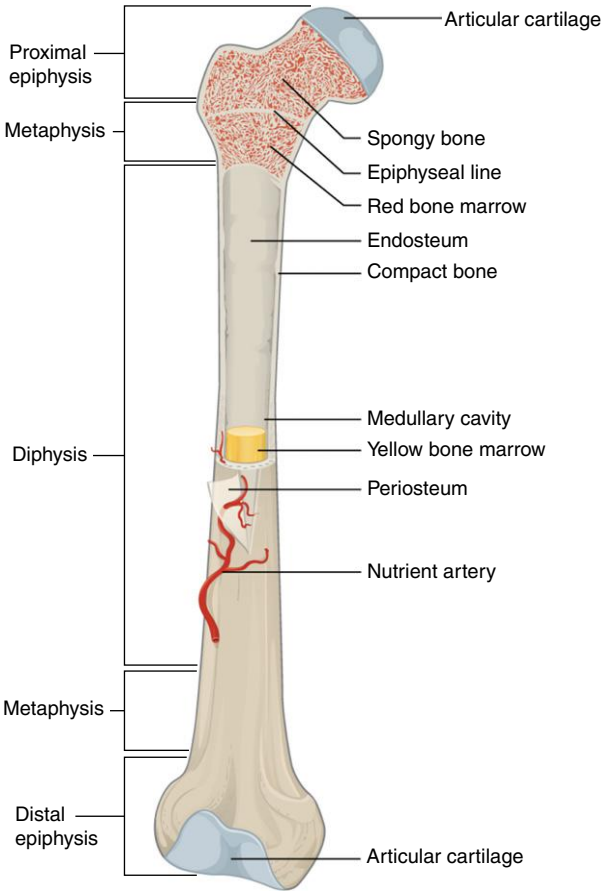

Figure 22 Tissues forming a bone. Reproduced from OpenStax College, 2013. Bone Structure. Connexions. Available at: http://cnx.org/content/m46281/1.3/ (accessed 24.09.13).

Table 5 The cellularity of fat deposits in cattle and sheep. The results are for the mature rams, and for bulls at 65% of mature live weight. Values for 'cavity fat' are for kidney fat in rams and for all the internal fat deposits in bulls. The lipid content of cavity fat (CAV) is higher than that for the subcutaneous (SC) and intermuscular (IM) depots. This corresponds to the larger fat cells of cavity fat and suggests that the better mechanically protected fat depots of the body can have larger fat cells with less supporting connective tissue between them

	Bulls			*Rams*		
	SC	*IM*	*CAV*	*SC*	*IM*	*CAV*
Lipid as a percentage of fresh depot weight	62.4	55.6	79.4	88.5	80.3	93.7
Fat cell volume ($\mu m^3 \times 10^5$)	0.40	0.67	1.03	0.55	0.63	1.18

Analysis of Final Product Composition for Labeling

TJ Braggins, Analytica Laboratories Ltd., Ruakura Research Center, Hamilton, New Zealand

This article is a revision of the previous edition article by TJ Braggins, volume 1, pp 179–185, © 2004, Elsevier Ltd.

Introduction

Labeling refers to the compilation of nutritional and nutrient content information printed on the packaging of retail-ready food products. Many countries have legislation that stipulates that nutritional labels must be printed on most, if not all, retail-ready foods. What nutritional or nutrient component qualifies to be included on a label varies to some degree from country to country. On a global scale, greater harmonization of food labeling standards is being developed through the Codex Alimentarius Commission. The overall purpose of labeling the nutritional content of food is to allow the purchaser of the food product to make an informed decision about the nutritional and nutrient value of the food, to protect the consumer from false and misleading claims, and to promote healthy diets. Nutritional and nutrient labeling requires product sampling and analytical methods that reliably measure nutritionally relevant processed food product components. Standard analytical methods, such as those of the International Organization for Standardization (ISO) and Association of Analytical Communities (formally Association of Official Agricultural Chemists) International, should be used, so that analyte values reported on food labels are consistent between countries. Values for analytes of many foods and food components already exist in numerous databases that can be sourced by food manufacturers to compile nutritional labels for final product composition without having to chemically test new formulations. However, chemical testing is still required to determine values of nutrients in new processed food product, when nutritional requirements change or for compliance verification.

Current Labeling Requirements

Most food manufacturing countries have legislation covering labeling requirements for retail foods. However, details may vary between countries. For example, in the US the Food and Drug Administration (FDA) Nutritional Labeling Education Act (NLEA) of 1990 amends the Food, Drug, and Cosmetic Act (FD&CA), and addresses serving size, health claims, and nutrient content labeling to help increase the consumer's ability to make healthy dietary choices. Currently, under the NLEA, full nutritional labeling is mandatory for 14 nutrients and voluntary for 36 additional nutrients. In 2003, the FDA amended the food labeling regulations to require *trans*-fatty acid declaration. The Food Allergen Labeling and Consumer Protection Act of 2004 further amends the FD&CA. It requires food labels to state the presence of the eight major food allergens identified by the act: milk, eggs, fish, shellfish, tree nuts, wheat, peanuts, and soybeans.

The European Union (EU) Regulation No 1169/2011 for Nutritional Labeling for Foodstuffs states that a nutrition declaration is mandatory. The nutrition label should include:

1. Energy value; or
2. Energy value and one or more of the following nutrients only:
   a. fat (unsaturates, monosaturates, and polysaturates),
   b. carbohydrate (sugars, polyols, and starch),
   c. salt,
   d. fiber,
   e. protein, and
   f. any of the vitamins or minerals listed in Annex XIII of the Regulation.

Figure 1 shows the Regulation's requirements for the expression and presentation of the nutritional declaration.

An increasing number of foods labeled and advertised bear nutrition and health claims. To ensure a high level of protection for consumers and to facilitate their choice, the European Community (EC) has issued a Regulation (No. 1924/2006) on Nutrition and Health Claims Made on Foods so that

Energy	kJ/kcal
Fat	g
of which

Table 1 Maximum fat and connective tissue content for ingredients designated by the term 'meat'

Species	*Fat content (%)*	*Collagen/meat protein ratio (%)*[a]
Mammals (other than rabbits and porcines) and mixtures of species with mammals predominating	25	25
Porcines	30	25
Birds and rabbits	15	10

[a]The collagen/meat protein ratio is expressed as the percentage of collagen in meat protein. The collagen contentis the hydroxyproline content multiplied by a factor of 8.

products put on the market are safe and adequately labeled. Article 4 of Regulation (No. 1924/2006) proposed the establishment of specific nutrient profiles that foods or certain groups of foods must respect to bear nutrition and health claims. The use of nutrient profiles aims to avoid a situation where nutrition or health claims could mislead consumers as to the overall nutritional quality of a food product when trying to make healthy choices in the context of a balanced diet. The Regulation requires that the setting of nutrient profiles should take into account the dietary role and importance of food groups and their contribution of nutrients to the overall diet of the population. Meat and meat products is one of the food groups with important dietary roles. However, to date the rule to require nutrient profiles has not been implemented because of disagreement with setting nutrient thresholds for some foods.

What constitutes a meat product? Excluding the obvious – meat cuts and anatomical parts that are sold without further processing – products that contain meat as an ingredient are usually defined in legislation. The Commission of the European Communities (Annex I to Directive 2000/13/EC) defines a meat product as containing skeletal muscle including naturally occurring attached fat and connective tissue subject to maximum limits (see Table 1). If these maximum limits are exceeded in formulations, the labeled 'meat' content must be downgraded accordingly and the list of ingredients must mention the presence of fat and/or connective tissue. Other animal parts, such as offal (including the heart, intestine, and liver) or fat, have to be labeled as such and not as 'meat.' Mechanically recovered meat (MRM) differs significantly from 'meat' as perceived by consumers and is excluded from the scope of the 'meat' definition. MRM, designated by the name of the species, has to be labeled separately and cannot form part of the meat content of any products in which it occurs. Mechanically recovered beef is banned entirely because of bovine spongiform encephalopathy (BSE). The BSE outbreak in Europe motivated the introduction of the compulsory (EC No. 1760/2000) beef labeling system requiring operators and organizations marketing beef to indicate its origin, in particular where the animal or animals from which the beef was derived were born, fattened, and slaughtered. A complimentary voluntary system covers labeling information on breed, type of production, and animal age, as well as information on the way the animals are reared and fed and their general welfare. This additional information is considered to help differentiate their products by identifying particular characteristics and thereby gain a commercial advantage, and to provide a more precise legislative framework than that created by the general principles of the labeling directive (Directive 2000/13/EC).

In addition to the 'meat' content defined by the Commission of the European Communities, the following particulars are compulsory in the labeling of foodstuffs:

- The name under which the foodstuff is sold.
- The list of ingredients, in descending order of weight. Important additions include compound ingredients, added water/concentrated foods, and cheese. The following ingredients require a specific statement on the label: genetically modified organisms, packaging gases, sweeteners, aspartame and polyols, quinine, and caffeine.

- The quantity of certain ingredients or categories of ingredients (Quantitative Ingredient Declaration).
- The net quantity of prepackaged foodstuffs expressed in metric units (liter, centiliter, milliliter, kilogram, or gram).
- The date of minimum durability in a specific format or the 'use by' date for highly perishable foodstuffs.
- Any special storage conditions or conditions of use.
- The name or business name and address of the manufacturer, packager, or vendor established within the Community.
- Particulars of the place of origin or provenance in cases where absence of such information might mislead the consumer.
- Instructions for use.
- The actual alcoholic strength for beverages containing more than 1.2% alcohol by volume.
- A mark to identify the lot to which a foodstuff belongs.
- Treatments undergone, with specific indications for irradiated foods or deep-frozen foods.

Global food trading requires greater harmonization of food labeling standards. This harmonization is being developed through the Codex Alimentarius Commission (CAC). The Codex Alimentarius (CAC) is a series of food standards and related texts that aim to provide a high level of consumer protection and fair practice in the international trade of food and agricultural products. The CAC, which administers the Codex standards and related texts, is an intergovernmental body jointly sponsored by the Food and Agriculture Organization and the World Health Organization.

Nutritional Databases

Compilations of nutrient data for various food components and products constitute nutritional labeling databases. Most of these databases are derived from published or proprietary chemical composition tables (e.g., United States Department of Agriculture (USDA), National Nutrient Database for Standard Reference). Some information contained within the databases is derived from ingredient databases that comprise components of a product's recipe. Software is used to assist food retailers and manufacturers in deriving average nutrient quantities for calculating information for a nutritional label. For example, the Food Standards Australia New Zealand website provides a Nutrition Panel Calculator to help food manufacturers calculate the average nutrient content of their food products and prepare a nutrition information panel. When nutritional information is unavailable in nutritional databases, when new food products are developed, or when food products require compliance testing, reliable and accurate analytical test methods are required to ensure that robust nutrient values are obtained for food products requiring labeling.

Chemical Analysis

Product Sampling

Meat and meat products are generally not as homogeneous as other animal-derived foods such as milk. The composition of meat can vary significantly within a carcass apart from the variation resulting from differences of species, breed, age, and nutritional status of the supply animals. This natural variation, along with other food components added during meat processing, warrants careful attention to a well-designed sampling plan to ensure that whatever nutritional claims are made on a food label are as representative as possible of the average composition of the final food product. Because most analytical methods are invasive and destroy part of the product tested, it is impractical to test every unit of a particular product. Instead, a sampling plan designed to take a representative sub-set of the total population of production units is needed. It is important to recognize that the samples being analyzed must be representative of the product that will be labeled with the results of the chemical analysis. If current production is not representative of future production, it is inappropriate to use current batches for sampling for representative testing.

The sampling plan must take into consideration any factors that will impact on the nutrient and composition content of the product. These could include changes in raw materials, processing procedures, storage conditions, and packaging and retail display conditions. The last three factors are important, and sometimes overlooked, when considering vitamin content of some food products, for example.

The FDA in the US recommends that at least 12 individual consumer units be selected randomly from a lot and then combined to make three composite samples of a minimum of four consumer units each. The three composite samples are then analyzed, and the mean value provides an estimate of the lot nutrient content.

Test Sample Preparation

Meat and meat products contain protein, fat, water, and ingredients from other food sources such as cereal-based material, stabilizers, and flavorings. Composite samples must be rendered homogenous, so that no biases in test results are encountered during analysis. Meat, fat, and connective tissue are particularly prone to causing problems during sample preparation. Excessive mixing or blending can result in the temperature of the sample rising excessively, causing fat to separate from the lean meat component and adhere to the surface of a mincer or food processor. Blunt mincing blades are ineffective in cutting connective tissue, resulting in the tissue collecting around the mincing auger.

An effective method of preparing homogeneous meat product samples is to soft-freeze the meat, dice it into chunks of approximately 2 cm with a knife, and pass it twice through a 3 mm mincing plate that has been precooled to approximately 4 °C. Alternatively, the diced chunks can be blended in a domestic or commercial food processor. Mincers or food processors should be of adequate size to accommodate all the composite samples to be mixed at one time. Once blended, samples are stored in an airtight container with minimum airspace to prevent the sample drying out. Samples stored in a refrigerator or freezer should be remixed thoroughly before analysis.

Test Procedures

Standard analytical methods, for example, those of the ISO and AOAC International, which have undergone peer review

Table 2 Association of Analytical Communities (formally Association of Official Agricultural Chemists, AOAC) methods[a] recommended for nutritional analysis

Component	*AOAC method numbers*
Protein	976.05, 981.10, 928.08, 977.14, 992.15, 960.39, 976.21, and 985.15
Fat	996.06 (Sum of fatty acids expressed as triglycerides)
Ash	920.153
Moisture	950.46 B (a) or (b)
Unsaturated/saturated fats	996.06
Trans-fatty acids	996.06 (Revised with 100 m column)
Cholesterol	994.10 and 976.26
Vitamins A	974.29
Vitamin C	984.26
Fiber	992.16, 985.29, 991.42, and 991.43
Sodium	968.08
Iron	985.01
Calcium	968.08 and 983.19
Sugars	Not available

[a]AOAC International (2000).

and collaborative laboratory comparison, should be used, so that analyte values reported on food labels are consistent between countries. The US Food Safety and Inspection Service specifies for nutritional analysis the methods of the USDA Analytical Chemistry Laboratory Guidebook; otherwise the Official Methods of Analysis of the AOAC International are to be used. Common methods of analysis for components listed on nutritional labels are given in Table 2.

Some vitamins and minerals in processed foods can undergo changes when exposed to heat, air, or light. Minerals such as copper, iron, and zinc can be affected by moisture, and may react with other food components such as proteins and carbohydrates. Vitamins and minerals can also be lost through leaching into cooking/processing water. It is important to take into account possible nutrient changes during processing and storage of meat products before consumption. One area that possibly needs more attention is the effect of storage on nutrients in meat products. Final product testing is usually done on freshly processed product, with little attention given to changes that might occur during cold chain transportation and storage.

Calculations

Meat Content

Many countries require statements of minimum meat content of meat products. Meat content can be calculated after the determination of the product's nitrogen, fat, carbohydrate, and collagen content. The Nitrogen Factor Method, adopted by the UK Food Standards Agency, is a method used for calculating the amount of meat, allowable fat and connective tissue, and excess fat and connective tissue in a meat product. The percentage of nitrogen, on a fat-free basis, is known as the nitrogen factor.

1. Meat protein% (P_M) (excluding contributions from non-meat nitrogenous sources) = meat nitrogen%×6.25.
2. Carbohydrate% (C) = 100−(water%+fat%+protein%+ash%).

Table 3 Some nitrogen factors for meat

Type of meat	*Nitrogen factor*	*References*
Beef	3.65	[a]
Pork	3.50	[b]
Lamb	3.50	[c]
Mutton	3.47	[d]
Chicken	3.70	[e]
Turkey	3.65	[f]

3. Connective tissue% (CT%) = (collagen%/P_M)×100 where collagen = (8×%hydroxyproline).

Added Water

Added water is subject to maximum limits and must be declared in the labeling of meat products. In general, for 'pure meat' the percentage of fat-free meat plus percentage of fat is taken as the meat content; if this does not add up to 100% then the discrepancy is considered 'added water.' Calculated apparent added water is dependent on the meat nitrogen factor (N_{ff}). Nitrogen factors (the percentage of nitrogen, on a fat-free basis) for a variety of meats are published by the Nitrogen Factors Subcommittee of The Royal Society of Chemistry (Table 3). In Europe, the three most common methods of calculating added water are the German Method, the Danish

Table 4 Some energy factors derived from Atwater tables

Class of food	Energy factor					
	Protein		Fat		Carbohydrate	
	(kJ g^{-1})	(kcal g^{-1})	(kJ g^{-1})	(kcal g^{-1})	(kJ g^{-1})	(kcal g^{-1})
Poultry	17.9	4.3	37.7	9.0	16.2	3.9
Beef	17.9	4.3	37.7	9.0	NA	NA
Beef, processed	17.9	4.3	37.7	9.0	15.4–16.9	3.7–4.0
Food of animal origin	17.9	4.3	37.5	9.0	16.2	3.9
Food of plant origin	15.0	3.6	36.6	8.7	16.7	4.0
Total food	16.7	4.0	37.3	8.9	16.6	4.0

Abbreviation: NA, not available.

Method, and a modification of the Stubbs and More Method. The Danish Method is probably the most used method for the calculation of added water and initially needs only the prior analysis of total water and nitrogen content of the meat product. If the resultant calculated 'apparent' added water value is excessive, then a more rigorous chemical analysis including fat, nitrogen, ash, and water is required for calculation of the added water content.

Danish Method I (initial)

%Added water = %total water − [(%nitrogen × 100/N_{ff}) − %protein]

Danish Method II (confirmatory calculation)

%Added water = 100 − [(%nitrogen × 100/N_{ff}) + %fat + (%Ash − 1)]

where (%nitrogen × 100/N_{ff}) is referred to as the %fat-free meat (%FFM).

Energy Values

The energy factor is the metabolizable energy (ME) of the food component calculated according to eqn [1], expressed in kilojoules (or kilocalories) per gram of food component, rounded to the nearest whole number.

$$ME = GE - FE - UE - GaE - SE \quad [1]$$

where ME, metabolizable energy; GE, gross energy (as measured by bomb calorimetry); FE, energy lost in feces; UE, energy lost in urine; GaE, energy lost in gases produced by fermentation in the large intestine; and SE, energy content of waste products lost from surface areas.

Energy factors have been derived by bomb calorimetry for a number of food types (see Table 4). Using the values in the table, the energy value of specific foods can be calculated. The number of grams of each of the macronutrients (protein, fat, alcohol, and carbohydrate) per 100 g of product is derived analytically. The energy value for each component is then calculated as in eqn [2] using an appropriate energy factor.

$$\begin{aligned}\text{Energy (kJ)} = {} & (\text{kJ g}^{-1}\ \text{protein} \times \text{g protein}) \\ & + (\text{kJ g}^{-1}\ \text{fat} \times \text{g fat}) \\ & + (\text{kJ g}^{-1}\ \text{carbohydrate} \times \text{g carbohydrate}) \\ & + (\text{kJ g}^{-1}\ \text{alcohol} \times \text{g alcohol}) \end{aligned} \quad [2]$$

The original work to determine energy factors for a range of foods was done by Atwater and others between 1899 and 1912 and was extensively reviewed in 1973, resulting in minor modifications. Generalized factors of 17/37/17 (kJ g^{-1}) or 4/9/4 (kcal g^{-1}) for carbohydrate, fat, and protein, respectively, are in common use. Average energy value for fiber should be 8 kJ g^{-1} (2 kcal g^{-1}).

Energy values can be expressed for nutritional labeling purposes either as kilocalories (kcal) or kilojoules (kJ) using the conversions factor in eqn [3]

$$1\ \text{kcal} = 4.184\ \text{kJ} \quad [3]$$

This article is a revision of the previous edition article by JR Andersen, volume 1, pp 160–167, © 2004, Elsevier Ltd.

Introduction

Analytical chemistry is concerned with identifying and determining a compound (the analyte) in a sample (the matrix). Occasionally, only the presence or absence of an analyte is determined; this is called qualitative analysis – in contrast to quantitative analysis where the actual concentration of the analyte is established. Qualitative analysis is seldom of use in meat science, and consequently this article is concerned solely with quantitative analysis, i.e., with verifying amounts (concentrations) of analytes. Concentrations can be estimated by a number of direct or indirect techniques, and here a number of examples of particular interest to meat science will be given.

Chemical analysis, or more correctly physicochemical analysis, is of interest in this context because it is intimately involved one way or another in almost all areas of meat science. Breeding programs, feed conversion studies, monitoring of residues of unwanted chemicals, nutritional studies, curing processes, fermentation processes, etc., all need chemical analysis data either as support or as a primary source of information in making decisions or achieving progress.

Consequently, the nature of the analytes and their abundances span the full spectrum: from elements to complicated organic molecules and concentrations expressed in percentage to parts per trillion. This, of course, impacts heavily on the number of methods needed and their complexities.

The most widely used instrumental techniques in current meat and meat product analysis are discussed. However, owing to space limitations, the treatment must be selective rather than comprehensive, and it is chosen to emphasize the traditional 'chemical' techniques. Enzymatic and immunological methods are, among others, not covered. For the same reason, the methods mentioned are not treated in any great detail; for some, though, more particulars are included when this appears justified.

Methods that are considered obsolete, although they are still being used in some laboratories, are omitted. Instead, their more modern counterparts are included.

Finally, the text is broken down into subsections in a natural manner, starting with pretreatment methods followed by classical methods such as gravimetry and volumetry and moving upward in complexity to end with sophisticated mass spectrometry (MS).

Sample Pretreatment

Samples taken from carcasses, i.e., different kind of tissue samples such as muscle, organs, fat, blood, etc., and samples of meat products are all rather complicated matrices. In contrast to some liquid samples, they need to be homogenized before analysis is attempted to secure representative samples and valid, meaningful results. The aspects of sampling are dealt with elsewhere, but it seems appropriate to list here some of the most common pretreatment methods currently being used.

Homogenization

Most samples encountered in a meat science laboratory are inhomogeneous and must therefore be homogenized to obtain representative samples. Mincing or blending of the samples usually achieves this. Connective tissue is sometimes an obstacle for adequate homogenization, and consequently several passages through the mincer are needed. In such circumstances, treatment in a blender appears to perform less satisfactorily.

Ashing/Mineralization/Hydrolysis

For elemental analysis, or the determination of ash content, a convenient way of separating the analyte from most of the matrix is by total oxidation of the organic constituents in the sample. This is referred to as ashing or mineralization, and it may be done in a wide variety of ways.

The simplest is probably complete combustion of the sample in a muffle furnace; this is used for determination of ash content, and as a first step in the analysis of many elements. However, the method must not be used uncritically in elemental analysis, as many elements, for example, mercury, arsenic, selenium, lead, or tin, will be (partly) lost owing to their high volatility.

Wet oxidation with oxidizing acids at elevated temperatures is often used, sometimes with the addition of a catalyst as in the Kjeldahl destruction. Often wet oxidation at elevated pressure as well as elevated temperature is called for, either in the so-called bombs (metal containers with quartz or Teflon inner beakers) or in heavy-walled Teflon or Kel-F containers. In the latter case microwave-assisted heating is often used.

For some analyses only partial breakdown is necessary, for example, when degradation of protein into individual amino acids is the target. This is the case in the predominant method for determination of collagen, which rests on a quantification of the amino acid hydroxyproline.

Extraction

Many analytical methods comprise one or more extraction steps in order to separate analyte from matrix.

Simple extraction

Simple extraction of a (finely divided) matrix with a (hot) solvent is in some cases sufficient, whereas multiple extractions in a Soxhlet apparatus under other circumstances are necessary. A variation on the theme of simple extractions is found in the accelerated solvent extraction method, which utilizes a solvent or mixture of solvents at elevated pressure and temperature. Supercritical fluid extraction works in a similar manner, but in this case a supercritical fluid is the extractant; CO_2 is the most commonly used compound for achieving the supercritical state and, as it evaporates rapidly under ambient conditions, the technique has the advantage of leaving the analyte solvent-free.

Liquid–liquid extraction

Liquid–liquid extraction (partitioning) between a polar and a nonpolar solvent is another versatile method. Often several extractions are carried out with pH changes in the polar solvent, facilitating a more complete separation of the analyte.

Solid-phase extraction

Solid-phase extraction (SPE) is a method similar to simple extraction; the main difference is that the extractant is a solid. The method is often used as a clean-up step after an initial simple or liquid–liquid extraction, where the analyte plus residual matrix elements are in a solution. The solution is treated with the solid extractant, which extracts either the analyte or matrix elements. In the former case, the analyte is subsequently liberated from the solid by another liquid extractant. Prefabricated cartridges filled with the solid extractant are commonly used. Immunoaffinity columns may be considered a subclass of SPEs.

Solid-phase microextraction

Solid-phase microextraction utilizes a thin coated fiber to extract analyte molecules from a gaseous or liquid phase. The fiber is subsequently introduced directly into a gas chromatographic column, where the extracted molecules are evaporated and separated.

Matrix solid-phase dispersion

Matrix solid-phase dispersion is a method that sometimes can be used successfully to extract residues, in particular residues of veterinary drugs, directly from a homogenized tissue. A solid extractant, for example, a C_{18} reversed-phase liquid chromatography (LC) column material, is mixed thoroughly (dispersed) directly with the tissue, using mortar and pestle. The large surface area of the column material and mechanical treatment of the mixture secure an efficient extraction.

Chromatographic Separation

Methods such as open-column- and thin-layer chromatography (TLC) are sometimes used as separation steps before the actual analysis takes place.

Derivatization

It often happens that the analyte has to be modified for it to be analyzed by a suitable method; in some instances because the analyte is 'difficult,' alternatively because the analyst would like to use a method to which the analyte is not suited per se.

Examples of the first case are encountered when the analyte does not have an 'analytical handle,' i.e., when it does not possess any highly absorbing chromophores, it does not fluoresce, it is neither oxidizable nor reductable, etc., and when the equipment at hand calls for such a 'handle.' As part of the pretreatment it is then obligatory to introduce such a suitable 'handle' by a chemical modification of the analyte.

The second situation often arises because there is a desire to use a certain method; then a modification of the analyte is necessary to make it amenable for analysis by this method. Trimethylsilylation of polar compounds to make them analyzable by gas chromatography (GC) is a well-known example.

Classical Methods

Gravimetric Analysis

In gravimetric analysis, the analyte is separated completely from the matrix and its concentration is subsequently determined by weighing. Gravimetric analyses are often used in meat science laboratories, for example, for the determination of ash content after a complete combustion of the sample in a muffle furnace, or for determination of water and dry matter content after drying to constant weight at 105 °C.

Volumetric Analysis

In volumetric analysis, a solution of the analyte is treated with a solution of known concentration of a reagent. The reagent solution is added to the analyte solution in small aliquots (titration), and a suitable detector monitors the subsequent immediate reaction between analyte and reagent to find the titration endpoint. The latter is the point where equivalent stoichiometric amounts of analyte and reagent are present. Suitable detectors depend on the chemical reaction taking place during the analysis; common examples are acid–base indicators that change color with changes in pH, or ion-selective electrodes that change potential as a function of analyte or reagent concentration.

Examples from meat and meat product analysis are the final back-titration step in the Kjeldahl determination of nitrogen (protein) content, where an acid–base indicator is used to find the endpoint, and the potentiometric determination of chloride in cured meat products utilizing an ion-selective chloride electrode for the same purpose.

It should be mentioned that at present most volumetric analyses are carried out by means of automated burets, and endpoints are registered automatically; this makes titrations less laborious than in the past.

Electrochemical Methods

Potentiometric Methods

Potentiometry is commonly used in the meat science laboratory, and its use may be divided into two major areas. In direct

potentiometry, the measurement of an electrode potential is used in finding the concentration (more correctly the activity) of an ionic species; in potentiometric titrations change in electrode potential on addition of a reagent is used to find the titration endpoint.

In both cases an ion-selective electrode and a reference electrode are used. The most common ion-selective electrode is the glass membrane electrode used in measurements of pH; however, solid-state electrodes and liquid–liquid membrane electrodes are also frequently used for measurements of activities of a wide variety of ions, most notably halides, sulfides, and some heavy-metal ions.

Voltammetric and Polarographic Methods

These are scarcely used in meat analysis. Both methods rely on the current–voltage relationships arising at a (micro) electrode when diffusion is the rate-determining step in the electrochemical reaction. The gross distinction between the two methods is that in voltammetry a stationary working electrode is used, for example, manufacture of glassy carbon, whereas in polarography the dropping mercury electrode does the job.

Some commercially available high-pressure (or high-performance) LC (HPLC) detectors use voltammetry as the working principle, and in some meat science laboratories voltammetry/polarography is used in the determination of heavy metals, for example, lead and cadmium. In such cases, the modified techniques of anodic stripping voltammetry or differential pulse polarography are normally employed.

Spectrophotometric Methods

Spectrophotometry is the name for a variety of instrumental methods that all have a common feature – the interaction of molecular species or elements with electromagnetic radiation (light). In the present context, the molecules or elements are analytes, and spectrophotometry is a method used in determining their concentration. Depending on the energy of the electromagnetic radiation, different processes take place in the analytes, but it is beyond the scope of this article to go into detail. A pragmatic approach without much theory will be followed and a look at spectrophotometry as a workhorse in the meat science laboratory will be presented.

UV–Vis Spectrometry

This method harnesses the properties of electromagnetic radiation at wavelengths from approximately 200–800 nm. As this embraces the ultraviolet (UV) and the visible (Vis) range in the electromagnetic spectrum, it is referred to as UV–Vis spectrometry. Measurements carried out in the 'Vis' range are sometimes referred to as colorimetry, i.e., the measurement of color. UV–Vis spectrometry measures absorption of radiation (energy).

Examples of meat and meat product analyses in which UV–Vis spectrometry has a role are numerous. It may be the single analytical principle apart from pretreatment procedures, as in the determinations of collagen/hydroxyproline and pigment/heme, or UV–Vis spectrometry may be used as a detector system, for example, in LC or flow injection analysis (FIA) in the form of diode array detectors (DADs).

Single- or variable-wavelength detectors are also used as endpoint monitors in pH titrations employing traditional color changing acid–base indicators as well as in LC and FIA.

Luminescence Spectrometry

Like UV–Vis spectrometry, luminescence spectrometry is mostly of interest in the wavelength range from approximately 200–800 nm; the distinction between the methods is that, whereas UV–Vis is concerned with absorption of radiation, luminescence has to do with emission of radiation. This emission can originate from two sources: either from excess energy imparted by radiation, fluorescence, or by a chemical reaction, phosphorescence.

Phosphorescence spectrometry is hardly ever used in meat analysis, whereas fluorescence spectrometry is more frequently of assistance, mostly as an LC detection principle.

Near Infrared Spectrometry

The wavelength area immediately neighboring the visible range is referred to as the near infrared (NIR). The total spectral area is normally considered to be from 800 to 2500 nm, but sometimes distinction is made between the near, NIR (N^2IR; 800–1050 nm), and the full range (NIR). In the N^2IR range, silicon photodiodes may be used as detectors; above 1050 nm, the more expensive or less sensitive detectors based on PbS, PbSe, InAs, InGaAs, etc., must be resorted to.

Another feature of the near, NIR is that transmission spectrometry is possible for most samples of interest, and commercially available spectrometers take advantage of this fact. At higher wavelengths, reflection spectrometry must be used owing to high absorbance from water in the samples.

NIR spectroscopy is an indirect technique measuring overtones and combination tones of fundamental absorptions taking place in the infrared region. This means that the technique must be calibrated with samples of known composition. Previously, this constituted a major task, involving many test samples with known composition and a good knowledge of statistics, a fact that was obstructive to the popularity of the technique for many years. This has changed recently, mostly as a result of new mathematical methods known as chemometrics, based on multivariate calibrations and artificial neural nets. This has made the calibration process less cumbersome and the resulting calibration models more robust. At present, some vendors of NIR instrumentation supply calibrations with purchase of their equipment.

NIR is currently used in many meat science laboratories for the simultaneous and nondestructive determination of protein, fat, and moisture in meat and meat products. Connective tissue content is sometimes determined in the same run, but so far it appears to be a less satisfactory method in terms of accuracy and precision.

Nuclear Magnetic Resonance Spectrometry

From 2500 nm and above, little interest to the meat science laboratory takes place until the megahertz (MHz) range is

reached. Here, nuclear magnetic resonance (NMR) spectrometry experiments are possible, in which interactions between nuclear spins in a magnetic field and high-frequency electromagnetic radiation may be harnessed for analytical purposes.

The only nucleus of immediate interest is the proton, ^{1}H, but as protons are highly abundant in meat and meat products, this does not constitute an obstacle (^{13}C, ^{19}F, and ^{31}P are other examples of NMR-active nuclei).

For a number of years total fat determinations in water-free matrices have been possible by 'low frequency' NMR, i.e., at frequencies in the range 10–30 MHz. The protons from water, if they were present, would be measured as well and would thus constitute a severe interference, hence drying of the samples is mandatory for this method. The actual measurement is carried out at 45–60 °C, where the fat is liquid and fat protons are mobile; only mobile protons give a response and the rest of the matrix protons, for example, from the protein part of the sample, are still in the 'solid state,' and are not measured.

Recently, a new generation of low-frequency NMR spectrometers has been introduced; they bring the possibility of applying strong pulses of electromagnetic radiation in discrete time domains, and such a pulse will completely swamp the signal from protons in that domain. As water and fat protons have slightly different properties, it is possible to pulse one kind out while measuring the other, and vice versa. With such an instrument it is thus within the realm of reality to measure both water and fat contents in the same (non-dried) sample.

Atomic Absorption and Emission Spectrometry

Elemental analysis is conveniently carried out by spectroscopic methods in which the elements are brought into a gaseous state before the interaction with electromagnetic radiation takes place. Two slightly different techniques are available.

The first technique vaporizes the analyte atoms without ionization, and subsequently the amount of energy at an element-specific wavelength absorbed by the analyte atoms to excite them to a higher energy state is measured. The more energy absorbed, the higher the concentration of analyte. Vaporization is facilitated by means of a flame or graphite furnace in this method, called atomic absorption spectrometry (AAS).

The second method also vaporizes the analyte atoms but ionization also takes place. The energy, again at an element-specific wavelength, that is emitted when the ionized atoms return to a lower energy state is measured. The more energy emitted, the higher the concentration of analyte. Vaporization is by means of a flame or an inductively coupled plasma (ICP) of argon; the method is known as atomic emission spectrometry (AES).

Both AAS and AES normally operate in the UV–Vis range, thus silicon photodiodes or photomultiplier tubes are common means of detection. However, when utilizing ICP as the energy source for the vaporization of the analyte atoms, it is also common practice to detect them using quadrupole MS, in which case the method is called ICP–MS.

Chromatographic Methods

It is a matter of temperament whether one regards chromatography a sample pretreatment technique or an analytical method in its own right. Strictly, because chromatography does not achieve the actual detection of analytes, but only their separation from interfering substances, it is a sample pretreatment. However, in common language and most contexts, chromatography is considered an analytical method, and it will be treated as such here.

In chromatography, two immiscible phases are brought into contact; one is the stationary (nonmoving) phase and the other is the mobile (moving) phase. A sample mixture is introduced into the mobile phase and interacts (partitions) with both mobile and stationary phase many times as it moves through the system carried by the mobile phase. Differences in chemical and physical properties in the sample components influence the rate of migration of each individual component to different degrees, i.e., some components move faster than others. The result is a separation of the components.

A column is an integral part of contemporary chromatography, and this may be packed or coated with stationary phases from a wide variety of different materials, solids or liquids. The mobile phase is a gas or liquid, again with many different choices of characteristics. The vast number of different combinations of stationary and mobile phases makes possible the separation of even closely related molecules.

Gas Chromatography

Analysis of contaminants in meat and meat products probably constitutes most of the work carried out by GC. Examples of analytes are trace amounts of organophosphorus and organochlorine pesticides, polychlorinated biphenyls, and residues of certain veterinary drugs, the last in rare cases in their native state but often after derivatization to make the drug residues more volatile.

Another use of GC analysis has more to do with meat and meat products themselves. Good examples are fatty acid composition analysis after saponification and derivatization of the individual fatty acids (the fatty acid methyl ester method) and headspace analysis in monitoring fermentation processes of meat products; the latter sometimes referred to as aroma analysis.

Capillary columns are invariably used in the modern laboratory, and a great variety of stationary phases is commercially available, both liquids (gas liquid chromatography) and solids (gas solid chromatography). The mobile phases normally encountered are nitrogen or helium, and sometimes also hydrogen.

A number of different detectors are available depending on the nature of the analyte. The most versatile and frequently used is likely to be the flame ionization detector, which although versatile is also very indiscriminate. Anything that will burn in a mixed atmosphere of oxygen and hydrogen will be detected with greater or lesser sensitivity.

For chlorinated or fluorinated species, and for molecules containing other highly electron-attracting substituents, the electron capture detector is often used because of high

sensitivity for such compounds while being blind to many matrix interferents.

Other detectors are suited particularly for molecules containing nitrogen and phosphorous (thermoionic emission detector) and sulfur and phosphorus (flame photometric detector).

In recent years the mass-specific detector (MSD) has become increasingly popular because of its versatility, high sensitivity, specificity, and its ability to identify unknown components. The MSD is a low-resolution mass spectrometer, either with a quadrupole or an ion-trap mass filter. When full electron impact (EI) mass spectra of unknowns can be obtained, comparisons with known spectra from a database will often be able to identify the unknown (EI is the most common ionization method for GC–MS experiments. The ionization is caused by collision with 70 eV electrons, and in most cases this leads to substantial fragmentation of the analyte molecular ion. EI is called a 'hard' ionization technique because of the surplus of energy transferred to the eluting components; hard implies substantial fragmentation).

Liquid Chromatography

A number of related methods come under this head. These include open-column chromatography, paper chromatography, TLC, and HPLC; but only the last will be included here. The reason is that open-column and paper chromatographic methods are almost totally absent from contemporary analytical science, and although TLC is sometimes used in screening for particular analytes, its use is limited, and confirmatory analyses of suspected analytes are always necessary.

However, HPLC is widely used for a variety of different analyses; examples include the determination of nitrite and nitrate in meat products by ion-exchange HPLC, and the numerous analyses harnessing reversed-phase HPLC such as vitamin determinations, boar taint component determination, and determination of veterinary drug residues.

In ion-exchange HPLC, the stationary phase is an ion exchanger and the mobile phase is an aqueous buffer; reverse-phase HPLC utilizes a hydrophobic stationary phase and polar solvent (mixture) as the mobile phase.

A number of detectors are used in HPLC; most common are spectrophotometric detectors in the UV–Vis range, either operating at single or variable wavelengths or as DADs covering a range of wavelengths. In addition, fluorescence detectors and electrochemical detectors are used; the former more often than the latter.

Recently, MS detection in combination with HPLC separation of analytes has come to a stage where routine analysis is possible. The predominant form is by single-stage MS, where soft ionization (see Section MS-MS and MS^n Methods) with little fragmentation takes place and only the ion originating from the analyte plus adduct ions between buffer constituents from the mobile phase and the analyte are detected. More sophisticated MS detection principles are mentioned in Section MS-MS and MS^n Methods.

Finally, it should be mentioned that other types of detectors are available, but they are not often used for analysis of meat and meat products.

Electronic Sensing; 'Noses' and 'Tongues'

Single chemical components or mixtures of components may be assessed by these methods; gaseous compounds by the electronic nose ('odor/flavor analysis') and compounds in solution by the electronic tongue ('taste analysis'). Electronic sensing is an often used term for attempting to mimic human sensory perception by such noses or tongues.

The principle of the measurements is normally adsorption of analyte molecules to an array of related, but not identical, sensors, thereby causing a physical change of the sensor. In quartz crystal microbalance sensors, for example, a measurable change of the crystal resonating frequency will occur upon adsorption (other sensor principles are also common). Many different signals from the sensor array are then treated mathematically (e.g., by chemometric methods) to yield outputs, which after calibration may be used in assessing intensity and/or identity of odors or tastes.

Known, but not very successful, uses of electronic sensing in meat science have been in boar taint intensity determination and monitoring progress of fermentation processes.

Flow Injection Analysis

FIA is a comparatively new form of automated analysis that is becoming increasingly popular in meat science laboratories. Previously, automation of analyses was carried out with the help of laboratory robots able to perform a wide variety of steps in an analytical method such as addition of reagents, mixing, timing, etc. However, this form of automation involves many moving parts that are likely to become worn and quite often involve a lot of cumbersome programing.

FIA, in contrast, is a continuous flow analysis method where all such manipulations take place in a continuous, nonsegmented stream of liquid. Samples pass through the same length of tubing, one after the other, with reagents being added at appropriate positions and other handling steps being performed while the sample is moving toward a flow-through detector (the auto-analyzer system, used for decades in many clinical laboratories, also utilizes a flow system that in many respects is like the FIA; however, the auto analyzer has bubbles of air segmenting the flow. The advantages of FIA are that the method has a higher sample throughput, requires smaller samples, and consequently uses less reagent).

The determination of nitrite and nitrate in meat products and brines by the Cd-column reduction method is an example of a newly introduced commercially available FIA method in meat analysis.

Mass Spectrometric Techniques

MS–MS and MS^n Methods

In the preceding sections, MS detection was mentioned in conjunction with chromatographic separation. In most cases the mass spectrometers are comparatively simple devices with low resolution (unit resolution meaning that mass X is distinguishable from mass $X+1$ over the available mass range)

based on single quadrupole or ion trap mass filters. In GC–MS, full mass spectra consisting of the molecular ion and fragments thereof may often be obtained as explained in the section 'Gas Chromatography', whereas only molecular ions and adduct ions normally are recorded from LC–MS experiments.

Such data are not always sufficient to give valid analytical results, and consequently more refined techniques such as MS–MS or MS^n can be helpful. The principle in both is the addition of more, normally low-resolution, mass filters; two in total for MS–MS and several for MS^n. The mass filters may be real or virtual as described in the last paragraph of this section.

Between the actual mass filtrations, further fragmentation of individual ions is often desirable; this is often the case in LC–MS–MS. As 'soft' ionization (soft implying no or little fragmentation) techniques such as electrospray or atmospheric pressure ionization are normally employed, only a few ions are generated in the ion source. Hence one of the ions can be selected with the first mass filter, and be fragmented by collision with an inert gas before being analyzed by the second mass filter. In this fashion a mass spectrum of the selected ion giving additional information of its identity may be achieved.

A similar procedure may, of course, be carried out on one or more of the multitude of ions normally generated by EI ionization.

More mass filters, and more fragmentation steps (MS^n), are sometimes needed, but very seldom for analytical reasons. This may be achieved either by a series of mass filters or by running a sequential series of experiments on an ion trap mass filter.

High-Resolution Methods

Most mass spectrometers used for routine analytical purposes have low-resolution mass filter with little or no focusing of the molecular beam. As there is always a spread in ionic energies between otherwise identical ions depending on where in the ion source the ion is formed, the result is peak broadening and hence low resolution.

For certain applications, high-resolution MS is necessary, and then double focusing mass spectrometers are employed. They have two different mass filters, a magnetic analyzer and an electrostatic analyzer, the combination of which may result in very high resolutions. For dioxin analysis, for example, the resolution must be better than 10 000 to distinguish the different dioxin congeners from overlapping interferents.

Miscellaneous Techniques

The pretreatments and instrumental techniques mentioned in this article are not restricted to meat science laboratories; they may be found in any analytical chemistry laboratory. There are, however, a number of methods that are more or less restricted in use to meat science.

Sarcomere length determinations by laser diffraction, meat tenderness determinations according to Warner–Bratzler or Volodkevich, and meat color determinations by reflection spectrometry (e.g., in Hunter Lab or Commission Internationale de l'Eclairage values) are examples of the methods. Such special methods are mentioned only for the sake of completeness; more information about them may be found in the literature.

Quality Assurance

Finally, some words concerning quality assurance and control of the analytical methods seem to be appropriate. It is, of course, of utmost importance that analytical results are valid in terms of accuracy and precision. Even the most expensive equipment will not guarantee valid results. Results obtained from the methods may be used for documentation of product composition and compliance with legal requirements. Consequently, analytical results are normally only trusted if they are produced in laboratories with implemented quality systems according to international standards for example, ISO/IEC 17025. The laboratories should ideally be accredited by an approved accreditation body, which is a member of the International Laboratory Accreditation Cooperation, an international cooperation of laboratory and inspection accreditation bodies formed more than 30 years ago to help remove technical barriers to trade.

Before analytical methods can be accredited, they must be validated or at least verified. A number of standards exist that describe how to validate analytical methods. Validation should always be done on matrices relevant for the use of the method. Validation should include a variety of matrices; the following properties of a method should be included in the validation: specificity, range, linearity, sensitivity, trueness, precision, and robustness.

Both for validation and for periodic control of a method, the laboratories can use certified reference materials (CRM's). A CRM is a material produced and certified by acknowledged institutes (e.g., National Institute of Standards and Technology (NIST) (USA) or Institute for Reference Materials and Measurements (IRMM) (EU)) and companies. A CRM contains certified amounts of compounds and substances. Comparing results from the analysis of CRM with the certified values can determine a bias (=systematic error) of the method, thereby making adjustments possible.

Participation in proficiency testing (PT) is also a must for laboratories. A number of providers of PT exist; as their quality varies, accredited suppliers should be preferred. When participating, a laboratory can compare its own results with those of other laboratories. Normally a z-score is calculated and this parameter should be > -2 and < 2. Interpretation of results may be difficult if participants use different methods and if the number of participants is too low for proper statistics.

On a daily basis methods should be controlled using stable and homogenous control materials. A material representative for the matrices analyzed should be used. Preferably two samples should be employed with low and high content compared to the measuring range. Some labs use CRM for daily control, however, this is expensive and not necessary. The results of the control analysis is followed on a Shewhart Control Chart, a system introduced for statistical process control introduced by Walter A. Shewhart in 1924. A system can easily be prepared in Excel. A number of commercial systems are also available.

Raw Material Composition Analysis

JG Sebranek, Iowa State University, Ames, IA, USA

Glossary

Artificial neural networks A nonlinear statistical data modeling tool that is used to find patterns in the data presented.

Dielectric constant The relative permittivity of a material to an electric field that is a measure of the polarity of a substance. Water, for example, has a dielectric constant of 80.1 whereas air has a dielectric constant of slightly more than 1.0.

Guided microwave spectrometry Measurement of the selective absorption and emission of microwaves of various frequencies.

Near infrared Spectroscopic method that uses light from the near infrared region (800–2500 nm) to determine selective absorption of infrared light by different substances.

Nuclear magnetic resonance Spectroscopic method that utilizes magnetic properties of atomic nuclei to determine properties of the molecules in which the atoms are contained.

Proximate composition The determination by prescribed methods of the composition of food in terms of the principal components. For meat, these components consist of moisture, fat, protein, and ash.

Introduction

Meat is composed of water, protein, fat, and ash, the total of which is commonly referred to as proximate composition. However, meat as a raw material is, for all practical purposes, a three-component mixture of water, protein, and fat. Consequently, composition analysis in the meat industry focuses on these three components in studies of proximate composition as it relates to fresh meat quality attributes or when attempting to achieve formulation targets during manufacturing of processed meat products. In the case of processed meats, precise control of product composition is essential to satisfying regulatory and labeling requirements, and to maximizing eating quality, shelf-life, and appearance. Further, control of composition is essential for the production of consistent finished products that have the same properties regardless of the raw meat materials used. Many different analytical methods have evolved over the years and have been generally categorized as 'official' or 'rapid' methods. The official methods have been critically evaluated for performance by an analytical methods organization such as AOAC International (AOAC), and are considered to be the most dependable. The rapid methods have been developed to be fast and easy but may be less accurate and/or less precise. More recently, new technology has resulted in methods that are both fast and reliable. In fact, some of these formerly 'rapid' methods have demonstrated a degree of accuracy and precision that is comparable with the official methods, and have been reclassified as official methods by the methods organizations.

Composition of Meat as a Raw Material

The average composition of muscle without external fat cover is, in general, composed of approximately 70% water, 20% protein, and 9% fat. The remaining 1% is ash or mineral content. The total water, protein, and fat contents will vary in different muscles and different animal species but the above values represent a typical average composition for raw muscle with the external fat cover removed. However, it is important to remember that meat as a raw material for further processed products includes much more than well-trimmed muscle. Subcutaneous and intermuscular fat deposits are usually included with trimmings from carcass fabrication and will dramatically alter the overall composition of raw materials used for processed meats. In addition, differences between species such as beef and poultry, and the effects of animal age will add even more variation to meat composition. Finally, some processed meat products may utilize hearts, livers, skin, or other nonmuscle animal protein sources, all of which add additional variation to product formulations. It should be no surprise that composition analysis of raw meat materials is critical to success in the processed meat industry.

Fat is the single most variable component in meat, and in raw materials it is likely to range from as low as 1–2% to as high as 80–90% or even more. As water and protein make up the remainder, the combination of water and protein together is inversely related to the fat content, and this is a consistent relationship. Water and protein in meat are also closely related to each other, and in raw meat will most often exist in a 3.6:1–3.8:1 ratio of water to protein. The relatively constant water: protein ratio is sometimes utilized for a quick approximation of composition when only one of the two components is actually measured. As fat is closely correlated with protein and water but in an inverse relationship, fat content of meat can also be estimated if either the water or protein content is known.

The extreme range in composition of meat raw materials means that an accurate and precise analysis is absolutely essential to the manufacture of consistent finished products that provide the eating quality desired by consumers. In the past, the official methods used to analyze raw materials were often too slow to provide useful information for high-speed, high-volume processing operations. Consequently, a large number of rapid methods have been developed for day-to-day

 doi:10.1016/B978-0-12-384731-7.00053-2

compositional analysis of meat raw materials. The rapid methods can vary widely in performance capabilities and processors must evaluate methods carefully to choose those best suited to their needs. Rapid methods can provide practical, useful results without the same degree of performance as the official methods. Some of the methods first developed as rapid methods have since been improved to a level of performance that has resulted in their qualifying as official methods.

Performance of Analytical Methods

Regardless of the methods chosen for analysis, method performance should be measured on a routine basis to assure that the method used is performing as expected. Performance can be monitored by calculating variance such as the standard deviation of the mean of a series of measurements. Periodic analysis of a known standard for comparison of results with another laboratory provides additional measures of performance.

Performance of a method is usually evaluated as repeatability, reproducibility, and bias. Repeatability is defined as the standard deviation of repeated measures by the same laboratory; reproducibility is the standard deviation of repeated measures by different laboratories; and bias is the consistently high or low mean values produced by a method relative to known, authenticated values.

One example of performance criteria has been those used by the US Department of Agriculture (USDA) – Food Safety Inspection Service for USDA-accredited laboratories. These criteria include repeatability and reproducibility measures of 0.63% and 0.66%, respectively, for fat; 0.46% and 0.65%, respectively, for water; and 0.24% and 0.32%, respectively, for protein. These performance criteria provide a good basis for comparison of method performance. Rapid methods may result in larger performance variation values and, even so, can be very useful but, clearly, values close to the standards for performance are desirable. It should be noted that reproducibility will usually be larger than repeatability for a given method because it includes both intralaboratory and interlaboratory variation whereas repeatability includes only intralaboratory variation. It is possible, in rare instances, for these two measures to have the same value but, by the same token, repeatability can never be larger than reproducibility.

The standards for comparison of all methods are those methods approved as official methods and published by one or more of the several methods organizations. AOAC International, the American Oil Chemists Society, and the American Society for Testing and Materials are the organizations most widely recognized in the US, whereas the International Organization for Standardization, the Comité European de Normalization, and the Nordic Committee on Food Analysis are examples of international and European organizations that also publish standard methods for food analyses. A critical prerequisite for official or standardized methods is a performance evaluation, normally done by a collaborative study. AOAC International, for example, utilizes collaborative studies involving several laboratories (usually eight or more) to evaluate analytical methods in terms of repeatability and reproducibility. This evaluation, and subsequent publication of the method as 'official.' provides analysts with standardized methods that can be expected to provide accurate, precise, and dependable measurements.

After performance is evaluated, a second concern for analytical methods is often the disposal of waste reagents and byproducts of chemical reactions involved in the method. Many high-performance methods generate toxic and hazardous wastes that create significant disposal problems for laboratories. A considerable effort has been devoted to the development of analytical methods that minimize or eliminate laboratory waste disposal problems. Traditional wet chemistry is being replaced by new technologies made possible by the computer and electronics industries.

Another frequent question concerning methods is cost. The initial capital investment for an analytical method can range from less than US$1 000 to much more than US$100 000. Each laboratory needs to calculate a per-sample cost to determine which method will best serve its needs. The methods most commonly used in the US meat industry for the analyses of raw meat materials' composition are listed in Table 1.

Methods of Fat Analysis

Official Methods

As the fat content of meat raw materials is so variable and because fat is critical to finished product palatability and production economics, there have probably been more methods developed for fat measurement than for any other proximate component. The method of choice for 'official' fat analyses has long been a solvent-based extraction. AOAC International currently lists three solvent-based methods as approved methods for the measurement of total fat content of meat. These methods (Table 1) include ether extraction followed by gravimetric measurement (AOAC Method 991.36), which has been widely used by many laboratories; tetrachloroethylene extraction followed by specific gravity measurement (AOAC Method 976.21); and methylene chloride extraction followed by gravimetric measurement (AOAC Method 985.15). Conventional extraction with ether typically requires several hours whereas tetrachloroethylene and methylene chloride methods require only approximately 15 min. However, the latter two require specialized equipment that is no longer available because of concerns for the toxicity of the solvents used and because of the development of alternative methods such as near infrared (NIR) and nuclear magnetic resonance (NMR) spectroscopy (Table 1).

Additional Methods for Fat Analysis

The solvent extraction method with ether is commonly utilized to obtain a measure of total fat as triglycerides. However, other lipid components such as phospholipids and free fatty acids are not included in the extraction. These lipid components are relatively low in quantity in raw meat (1% or less), but in some cases, it may be important to include them for a true total fat measurement. To include phospholipids and other minor lipids in extraction procedures, a modified solvent

Table 1 Some of the more common methods available to the meat industry for the measurement of fat, moisture, and/or protein in meat raw materials used for further processing

Component	*Method*	*Method status/performance*
Fat	Ether extraction	Official (AOAC Method 991.36)
	Specific gravity	Official (AOAC Method 976.21)
	Microwave/solvent extraction	Official (AOAC Method 985.15)
	Nuclear magnetic resonance (NMR) (CEM SMART Trac II)	Official (AOAC Method 2008.06)
	Near infrared (FOSS Food Scan™)	Official (AOAC Method 2007.04)
	Caviezel (total fatty acids)	Correlation of 0.99 with ether extraction
	Accelerated solvent extraction	Rapid method; repeatability ±0.4–0.8%
	Supercritical fluid extraction	Rapid method; repeatability ±0.5–1.3%
	Modified Babcock	Rapid method; repeatability ±0.75%
	X-ray (KartridgPak Anyl-Ray; FOSS Meat Master™, EAGLE™ FA)	Rapid method; repeatability ±0.60–10%
	Database extrapolation (CEM SMART Profat)	Rapid method: fat determined from database following moisture measurement by microwave drying
Protein	Kjeldahl	Official (AOAC Method 928.08)
	Combustion	Official (AOAC Method 992.15)
	Protein tagging (CEM Sprint™)	Official (AOAC Method 2011.04) – direct protein measure
	NIR (FOSS Food Scan™)	Official (AOAC Method 2007.04)
Moisture	Oven drying	Official (AOAC Method 950.46)
	Microwave (CEM SMART Turbo)	Official (AOAC Method 2008.06)
	NIR (FOSS Food Scan™)	Official (AOAC Method 2007.04)
	Infrared, halogen lamp drying	Rapid method; can be variable
Multicomponent	NIR (FOSS Food Scan™) (fat, protein, moisture)	Official (AOAC Method 2007.04)
	Microwave, NMR (CEM SMART Trac II) (fat, moisture)	Official (AOAC Method 2008.06)
	Microwave, database extrapolation (CEM Profat Meat Analyzer) (fat, protein, moisture, ash)	Rapid method: fat, protein, and ash determined from database following moisture measurement by microwave drying
	NIR	Rapid method: repeatability ±0.42–0.51% (fat) ±0.32–0.36% (moisture) ±0.53–0.54% (protein)
	NMR	Rapid method: correlation of 0.967 with known fat values
	Guided microwave spectrometry	Rapid method: repeatability ±0.3% for all components (fat, moisture, protein)

(chloroform–methanol) or a pre-extraction acid hydrolysis treatment (Schmid–Bondzynski–Ratzlaff or Weibull–Stoldt method) must be used.

As the traditional extraction methods with ether measure primarily triglycerides, another extraction method, the Caviezel method (Table 1), has been developed for the measurement of total fatty acids in fat. This procedure is used to meet the US Food and Drug Administration (FDA) definition of total fat as lipids including all fatty acids for labeling of food products. The FDA definition includes fatty acids from triglycerides, phospholipids, and sterols as well as free fatty acids. The procedure uses *n*-butyl alcohol for fat extraction followed by saponification and isolation of fatty acids, which are then quantified by gas chromatography. A comparison of the Caviezel method with the conventional extraction methods have shown correlations of 0.99 or greater with values reported for the Caviezel method being slightly higher than that for conventional extractions because all fatty acids are included. Automated equipment is available that permits sample preparation and analysis in less than 2 h.

Accelerated solvent extraction (ASE) is another approach to solvent extraction that is based on the traditional solvents but uses elevated pressure and temperature to increase the rate and efficiency of the extraction process. Generally, less solvent is required for a quantitative extraction by ASE and the time required is considerably less, typically approximately 15 min. Equipment is available that can provide for continuous operation and recovery of extracts for further analysis. The ASE technique has been reported to be very effective for unbound lipids and is often used in environmental testing laboratories for recovery and analysis of lipid components.

Supercritical fluid extraction (SFE) is a method that uses carbon dioxide at elevated pressures and temperatures. Under the conditions used for SFE, carbon dioxide is a good nonpolar solvent and can quantitatively extract lipids. The procedure requires approximately 20 min and, most importantly, results in no waste solvent when samples are returned to normal pressure and temperature because carbon dioxide returns to its normal gaseous form. Performance has been reported to be close to that of traditional methods but the SFE method is easily affected by the presence of water. Water absorbers such as diatomaceous earth may have to be included with meat samples even after the samples have been dried.

One of the limitations of many of the solvent extraction methods is that they are matrix-dependent and require use of a specific solvent, depending on the objective of the extraction. Samples also usually require preparatory treatment such as drying and sometime use of water absorbers to prevent interference by water. Initial sample size should be relatively large for these methods because of the difficulties in collecting and preparing a representative sample of the original meat block.

Improved extraction procedures, which utilize microwave heating to accelerate the process and microsolvent extractors to reduce solvent volume, have been developed. However, the recent trends in methods for fat analysis have been away from extraction methods toward multicomponent analyses such as NIR and NMR that include fat as one of the components measured.

Rapid Methods for Fat Analysis

A simple and inexpensive method for fat measurement that is used by some laboratories in the meat industry is the Modified Babcock (Table 1). This approach utilizes an acid digestion to release fat from a sample, followed by centrifugation to bring all of the fat to the top of the fluid, digested mixture. A calibrated bottle is used to measure the percentage of fat present based on the height of the fat layer. Bottles are calibrated for sample weights of 9 g or 18 g, and for low (up to 10%) or high (up to 50%) fat content. Standard deviations for this method have been reported to be approximately 0.75%. Although performance can be quite good in some laboratories, this method is generally considered to be too variable for more than preliminary formulation decisions.

A more sophisticated approach to rapid methods for fat is the use of X-rays such as the Anyl-Ray instrument (KatridgPak, Tegetec, Frederikssune, Denmark), the MeatMaster™(FOSS, Hilleroed, Denmark), and the EAGLE™ FA (EAGLE Product Inspection, Tampa, Florida, USA). This approach utilizes an X-ray machine that measures the differential in X-ray absorption between fat and lean. The X-ray method is nondestructive so the sample is not damaged or lost. Calibration of the machine with a standard allows determination of the fat content in unknown samples. A unique aspect to the Anyl-Ray instrument is that it requires a 5.9 kg sample. The relatively large sample size is an advantage because it is easily representative of the larger amount being sampled. The MeatMaster™, on the contrary, is designed to scan and measure meat materials in-line at up to 20 t per hour. The measurement requires less than 1 min and standard deviations have been reported to be 0.60–0.80%. The EAGLE™ FA is designed to scan as many as 30 cartons (up to 28 kg) per minute or bulk products at up to 120 t per hour with results that are within 1.0% of actual fat content. This system includes a 45 s automatic calibration, is effective for fresh or frozen products, and will also detect contaminants such as metal, glass, and bone. All of these methods utilizing X-ray technology have been well accepted in the industry for formulation estimates but have not shown the performance required of official methods.

An indirect approach to fat measurement in meat developed by Least Cost Formulations Ltd (Virginia Beach, Virginia, USA) and called 'QC Assistant' is based on a software package coupled with a moisture measurement. This approach is dependent on a consistent moisture/protein/fat relationship in raw meat and draws from a database of values to estimate fat based on the measured moisture content. This system is combined with CEM Corporation's (Mathews, North Carolina, USA) microwave drying oven which has received official methods status (AOAC Method 2008.06) for moisture. The combined system is called SMART Profat and can provide moisture, protein, and fat values for a sample in approximately 3 min. It is important to keep in mind that the measurement of fat (and protein) by this method are indirect and dependent upon both the analysis for moisture and the assumption of a consistent moisture/fat relationship in the samples analyzed with the database of values. As moisture:protein, moisture:fat, and protein:fat relationships in raw meat are consistent, one component can be effectively estimated if one or two of the others are known.

Despite the development of several different rapid methods for fat analysis, some of which perform very well, the trend in methods for fat analysis has been toward the measurement of fat as part of multicomponent methods such as NIR and NMR.

Methods for Protein Analysis

Official Methods

The long-time standard for protein analysis has been the Kjeldahl method (AOAC Method 928.08) (Table 1). The longevity of this method is obvious when considering that the method was first published in 1883. In the past, the need to develop faster methods for protein analysis has probably not been perceived to be as important as the need for rapid fat and moisture methods. However, more recently, processed meat product definitions and labeling requirements have placed increased emphasis on protein content and the need for rapid, dependable protein measurements is now as great as for methods for fat and moisture. In addition, the heavy metal catalysts used in the Kjeldahl method plus the concentrated acid and alkali waste generated by conventional Kjeldahl procedures have been a disposal concern for laboratories. Some of the past method developments for protein have included approaches such as dye-binding procedures but none of these early efforts achieved major advances in methodology. Improvements in instruments that provide automated, relatively rapid Kjeldahl analysis have included accelerated acid digestion units and automated rapid distillation units to achieve an easier, more rapid analysis than the traditional Kjeldahl method.

A significant step forward in protein methods occurred in the 1990's when the combustion method received AOAC approval (AOAC Method 992.15). The combustion method is based on sample combustion (~850 °C) followed by quantitation of the released nitrogen. The method concept itself is even older than the Kjeldahl method, and was first published by Dumas in 1831, but only since about 1980 have instruments that utilize thermal conductivity to achieve accurate measurement of the released nitrogen been available. A major advantage to the combustion method is that no toxic or hazardous wastes are produced. The procedure is also relatively

fast requiring approximately 5 min or less per sample. Repeatability has been reported to be 0.12–0.41%. One concern for the combustion method has been that a relatively small sample size is required for combustion efficiency, making sample preparation critical to method success. Recent instrument developments have increased the sample size but it is still quite limited compared with most other methods.

A significant potential limitation to keep in mind for both the Kjeldahl and the combustion methods is that both of these methods measure sample nitrogen content from which protein content is then calculated. In the case of meat products, the nitrogen content is multiplied by a conversion factor of 6.25 because meat protein typically contains 16% nitrogen. However, nonmeat proteins will have different nitrogen contents and different conversion factors must be used. Further, recent fraudulent cases of nonprotein nitrogen addition to animal feeds to falsely increase the apparent protein content by Kjeldahl analysis has resulted in the development of improved methods that provide a direct measurement of the protein content.

Rapid Methods for Protein

Rapid methods for protein alone have not been developed as extensively as those for moisture and fat in terms of available commercial instruments. However, the developments of multicomponent methods that include protein measurement have fulfilled the need for rapid protein analysis. These methods for protein, as for fat, will be described in the discussion on multicomponent measurement. In addition, because of the limitation of the Kjeldahl and combustion methods for direct protein measurement, methods that utilize direct dye-tagging of proteins have been refined and improved to allow direct measurement of proteins. CEM Corporation, for example, provides an instrument (Sprint) that uses protein tagging technology to provide for rapid (approximately 3 min) and direct protein measurement. This method has also very recently qualified as an AOAC official method (AOAC Method 2011.04) (Table 1).

Methods of Analysis for Moisture

Official Methods

The standard reference method (Table 1) for the measurement of moisture in meat has been oven drying (AOAC Method 950.46). Weighed samples may be dried in a conventional oven (air drying) at 100–102 °C for 16–18 h or in a convection oven at ~125 °C for 2–4 h, and reweighed to determine the amount of moisture lost during drying. Use of higher temperature ovens and/or use of vacuum ovens can serve to shorten drying time but may not be suitable for samples with a high fat content. In all cases, it is necessary after drying to hold the dried samples in desiccators during cooling to prevent water absorption from the air before reweighing. It is also sometimes necessary, even at lower oven temperatures, to take precautions with samples that are high in fat content. If high-fat samples are dried in cellulose thimbles for subsequent fat extraction, for example, some melted fat may soak through the thimble and be lost, resulting in erroneously high values for moisture. The use of aluminum weighing dishes alleviates this potential problem. To be consistent, these methods should follow prescribed conditions and procedures carefully in order to achieve the expected results. It is also useful to keep in mind that oven drying does not determine moisture exclusively but also includes a mixture of volatile compounds that are volatilized at the temperature used. The volatiles released in addition to moisture is an extremely small quantity in terms of weight and does not significantly alter the quantitative measure of moisture but represents a change in some of the chemical components of the sample.

As the air-drying methods are relatively time-consuming, the use of microwave ovens has been investigated as a means of rapid drying. The most successful approach has been that of CEM Corporation, who designed a microwave analyzer (SMART Turbo), specifically for the measurement of moisture and solids content of food products. The procedure requires less than 3 min. As noted earlier, this CEM method and an early version of the microwave instrument has received AOAC International approval as an official method for moisture measurement of meat (AOAC Method 2008.06).

Rapid Methods for Moisture

A wide variety of rapid methods for the measurement of moisture content have been studied. Most of these have involved some form of accelerated drying such as infrared or halogen lamp heating sources (Table 1). These approaches give relatively rapid results (usually 15–30 min) but are typically highly variable. Heating rates, sample dispersion, and sample moisture content can each contribute to case hardening of the sample if conditions are less than ideal, and will result in highly variable measurement of moisture content. An exception to these limitations of rapid drying methods is the specially designed microwave instrument described earlier, which is even faster than the instruments using infrared or halogen heat sources. Other methods for the measurement of moisture content of meat that have been studied with somewhat mixed results include electrical conductance, toluene distillation, and Karl Fischer titration. However, the advances of multicomponent methods that include moisture measurement have shown these alternatives to be very successful and provide a good means of quickly measuring the moisture content of meat products.

Multicomponent Methods

The development of methods that will measure fat, protein, and moisture in meat simultaneously and almost instantaneously has been a monumental advance in practical analytical methods. There are three multicomponent concepts currently in use (Table 1). NIR has been used for many years for a variety of applications but new instruments have made this technology available for meat applications in the laboratory and for in-line analysis of products on the production line. Guided microwave spectrometry (GMS) has also been developed as a multicomponent measurement and has been

available as a component of meat processing equipment. NMR is a very effective method for rapid measurement of lipids and protein but functions best with dried samples, consequently a combination of NMR with rapid drying procedures has resulted in effective multicomponent measurement systems.

Near-Infrared Method

NIR methods have been used for more than 40 years for a variety of products, most notably moisture measurement of harvested grain. However, improvements in the method and especially in instruments have opened a very broad range of applications including analysis of the composition of meat products. NIR scans are unique to the measured sample, and for pure chemical compounds, essentially provide a 'fingerprint' that can be used for compound identification. Meat, however, is a complex mixture of chemical compounds and the infrared response to a meat sample is also a mixture reflecting the compounds present. Consequently, quantitative measurement of meat components requires measurement of several known samples for instrument calibration. Unknown samples of similar type can then be scanned and the components determined by comparing the response data with the calibration data. Once calibration is complete, the method provides a simultaneous measure of fat, moisture, and protein that is extremely fast and nondestructive.

The availability of economical microprocessors and electronic systems that provide for easy calibration using artificial neural networks has made NIR instruments commonly available for meat analysis. Examples of available instruments include those from NDC Infrared Engineering, Inc. (Irwindale, California, USA) called InfraLab™, and from FOSS (Hilleroed, Denmark) called Food Scan™. Currently, infrared analysis is finding a wide variety of meat applications in addition to proximate composition measurements. These include estimates of fat softness, determination of prior temperature history of meat, and identification of species of meat origin among other things. It is important to remember that NIR analysis is highly dependent on proper calibration of instruments with samples similar to the unknowns to be measured. Recalibration is necessary for any change in sample material that is outside the range of properties of the samples used for calibration. The need for careful and proper calibration is viewed by some analysts as a disadvantage of this method.

In the case of meat samples, water and fat have particularly high NIR absorption, whereas protein absorption is somewhat weaker, but all three components can easily be measured with proper calibration. Several instruments are available as tabletop analyzers for laboratories or as in-line analyzers on meat processing equipment. Changes in method technology have resulted in changes of most instruments from NIR reflectance measurement to NIR transmission (NIT). The transmission measurements utilize greater sample volume, which improves consistency of results. Although correlations between NIR and AOAC methods for fat, moisture, and protein have been very good (0.93–0.99), correlations between NIT measurements and AOAC methods have been reported to be 0.984–0.995, 0.987–0.992, and 0.949–0.957 for fat, moisture, and protein, respectively, in meat. Repeatability ranges from 0.42% to 0.51%, from 0.32% to 0.36%, and from 0.53% to 0.54%, respectively, for fat, moisture, and protein in meat have also been reported.

In addition to simultaneous, nondestructive measurement, NIT is typically very fast, and frequently repeated measurements are an attractive option with this method. The high frequency of measurements has facilitated the design of NIT systems as part of meat processing equipments such as grinders and mixers to provide continuous, on-the-spot monitoring of fat, moisture, and protein during grinding, mixing, and blending. In most cases, the NIT systems are built into the meat processing equipment to provide continuous formulation information and control. Wolfking (GEA Food Solutions, Dusseldorf, Germany), for example, has offered an NIT system called the GEA MultiTrack™ for use on mixers and grinders. This system utilizes an 850–1050 nm wavelength range to continuously monitor fat moisture and protein content during mixing of meat batches, and composition can be adjusted on the spot. Standard deviations of 0.3% for the measurements have been reported.

In addition to fat, moisture, and protein, NIR measurements have been studied extensively for the determination of collagen content in meat. Although this would be a very useful measurement for meat processors, correlations between NIR and other methods for collagen have been relatively low.

Guided Microwave Spectrometry

GMS has not been studied as extensively as NIR and NIT systems but this technology has been developed to the point of being offered commercially as part of meat processing equipment, similar to NIR and NIT. The GMS measurement is based on microwave energy absorption which is used to measure differences in conductivity and dielectric constants of water. The conductivity and dielectric constants are then used for the determination of sample fat, moisture, and protein content. Protein and fat are indirect measures with this method. Calibration with known samples is necessary for GMS measurements.

Although there is less information available on GMS systems than for most other analytical methods, one of the limitations to this method appears to be matrix sensitivity. For example, the presence of air bubbles or ice crystals in a meat mixture has been reported to have a significant effect on results.

Nuclear Magnetic Resonance

One of the most recent developments in commercial instruments for fat analysis of meat has been use of NMR. NMR data can distinguish between protons from different molecular sources, and can provide sharp contrasts between meat components such as fat and lean. Correlation between NMR measurements and known fat content in meat samples has been reported to be 0.967.

Studies of NMR applications for food products have suggested many potential uses, including identification of contaminants, specific composition of fats and oils, and changes in lipids as an indicator of product freshness. Although NMR

has been studied as a means of measuring water and protein as well as fat, the method appears to be most effective when used for the measurement of lipid components.

For meat samples, NMR applications for fat measurements are often limited by interference from water protons. Interference from water can be overcome by utilizing a dried sample but drying is ordinarily a time-consuming preparation step which has, in the past, reduced the practical usefulness of NMR as a rapid method. However, CEM Corporation has combined NMR technology with the CEM microwave oven-drying procedure to create a multicomponent moisture/fat method for meat that can be completed in 4–5 min. The CEM instrument, called SMART Trac II, has been approved by AOAC International as an official method for determination of both moisture and fat in meat (AOAC Method 2008.06). This combined methods approach offers significant advantages in terms of speed, no organic solvents or waste are formed, and there is no need for calibration.

Summary

A wide variety of methods are available for measuring the proximate composition (fat, moisture, and protein) of meat raw materials used for the manufacture of processed meat products. These methods range from traditional wet chemistry methods that have been in use for decades to extremely rapid, in-line multicomponent analyses that have evolved recently. A critical consideration for comparison of methods is performance measurement. Repeatability, reproducibility, and bias must be determined in order to permit selection of a method that will meet expectations. These performance measures must also be monitored while a method is in use to ensure continued acceptable method performance.

Glossary

Figures of merit Measurements, including limit of detection, sensitivity, R-square, and linear range that indicate how accurate and precise a standard curve will be at determining unknown concentrations.
Limit of detection The lowest value for an analytical assay that is reportable for an unknown sample.
Relative standard deviation This value is the standard deviation divided by the average and multiplied by 100.
Sensitivity The magnitude of change for a measuring device or analytical assay as compound concentration changes.
Significant figures The number of reportable digits for a result obtained in a chemical analysis.
Standard curve A linear regression analysis that is used to determine unknown concentrations. The regression analysis is based on known standard concentrations of a chemical analyte as the X-variable and an analytical parameter, such as absorbance units for ultraviolet-visible spectroscopy and peak area for gas or high performance liquid chromatography.
Standard deviation A measurement of analytical precision that indicates how close values are together. It is a measure of how much variability or spread is around the mean.

Introduction

Chemical analyses result in values that indicate compound concentration. However, even the most experienced person will not be able to repeat an analysis and obtain exactly the same value each time. For practical reasons, other people should also be able to do the analysis, at another time and perhaps in another place, and these factors will cause some deviation from the true (unknown) value and imply that the true value is present only within an observed interval.

Statistical analysis is used to determine confidence intervals (CIs) and account for variability. If the preconditions (environment, performance, etc.) have limited influence on the chemical analysis, only a few samples are necessary to obtain reliable results as compared with the use of techniques with low robustness or techniques with poor ability to give similar results under varying conditions. For example, a food processing plant might only take two measurements for protein, fat, and moisture percentage of a bologna meat batter because it is part of the daily production process and the variability in the process has been established. However, more than one measurement still needs to be taken to ensure repeatability and reliability. In research, >30 samples per diet may be necessary to determine the moisture, protein, and fat percentage of the resulting meat when feeding broilers diets with varying concentrations of lysine and methionine.

This article deals with the statistical methods related to the reliability of measurements and different aspects of the sampling problem. The subjects are discussed in relation to chemical analyses, but similar considerations should be made for all types of measurement.

Statistical Requirements of Analysis Techniques

Measurement of Central Tendency

A minimum of three measurements are commonly taken to determine the mean and standard deviation in a chemical analysis. Occasionally, two measurements can be taken if it is a robust measurement and a consistent industrial process. However, more than three measurements are commonly needed when there is a large standard deviation in the analysis, either due to the analytical measurement or due to heterogeneity of the process or product. This is often necessary in research and when setting specifications for a process. From these observations, a mean is calculated as an estimate of the true value. The equation for the mean is as follows:

$$\bar{x} = \frac{x_1 + x_2 + x_3 + x_4 + x_5 + \cdots + x_n}{n} = \frac{\sum x_i}{n}$$

Example: Three samples are randomly taken from a production batch to measure the protein percentage of a meat batter using near-infrared spectroscopy that is used to make frankfurters and values of 18.34, 18.73, and 18.92 are recorded. The calculated mean is 18.663 33. The value should be reported with 3 significant digits, 18.7, because it is clear that the first 2 values of the number are 18, but it is not clear that the value in the tenths place is 7. A measurement of the variability is needed so that the standard deviation and the relative standard deviation (RSD) (also called the coefficient of variability) are calculated. The standard deviation is a measure of how much variability or spread is around the mean and is calculated as s because the true mean is not known:

$$\text{Standard deviation} = s = \sqrt{\frac{\left(\sum(\bar{x}_i - x)^2\right)}{n}} \text{ if } n \geq 30 \text{ and}$$

$$s = \sqrt{\frac{\left(\sum(x_i - x)^2\right)}{n-1}} \text{ if } n < 30$$

For the example above, the standard deviation is the square root of $((18.34–18.66)^2 + (18.73 - 18.66)^2 + (18.92 - 18.66)^2)/(n-1) = \sqrt{0.0874} = 0.296$.

This mean should be reported as 18.7 ± 0.296 or 18.7 with a standard deviation of 0.296.

The RSD is calculated using the following equation:

$$\text{RSD} = \frac{s}{\bar{x}} \times 100$$

For the value 18.7, RSD = 0.296/18.7 × 100 = 1.58%.

An RSD ≤5% is generally considered acceptable for analytical measurements.

Confidence Intervals

The most CI used is the 95% CI, but 90% and 99% CIs are also commonly reported. If this is a repeated measurement in which >30 total measurements have been taken, and it has been proven that these values follow a normal distribution, then *z*-values can be used to determine the CI. The *z*-values for 90%, 95%, and 99% CIs are 1.645, 1.96, and 2.58, respectively. Therefore, a 90% CI for the example taken in this article would be $\text{x} \pm \text{Z value} \times s/n = \sqrt{18.66} \pm 1.645 \times (0.296/3) = \sqrt{18.66} \pm 0.28 = (18.38, 18.94)$. For a 95% and 99% CI, the values would be (18.32, 19.0) and (18.22, 19.10), respectively. Note here that even though one reports the mean as 18.7 due to significant digits, the mean is reported as 18.66 within the CI so that the CI is as accurate as possible.

If three measurements were taken and these samples were not part of a larger dataset with a normal distribution, the *t*-distribution would be used because $n < 30$, and a 95% CI with three measurements would yield $n - 1 = 2$ degrees of freedom. Table 1 contains the *t*-statistics that should be used for 90%, 95%, and 99% CIs. In this example, the 95% CI is $\text{x} \pm \text{t value}_{n-1} \times s/n - 1 = \sqrt{18.66} \pm 4.303 \times (0.296/2) = \sqrt{18.66} \pm 0.90 = (17.76, 19.56)$. The same mean and standard deviation with 10 measurements has a $\text{CI} = \sqrt{18.66} \pm 2.262 \times (0.296/9) = (18.43, 18.89)$. This demonstrates the effect of sample size on statistical confidence.

Example

Three protein measurements were taken for frankfurter batter as an example. However, the values for protein are 17.7, 18.7, and 19.7. The mean, standard deviation, and RSD are 18.7, 1.0, and 5.3%, respectively. Because these three measurements are taken for every batch on every day, the normal distribution is assumed and the 95% CI is $\sqrt{18.7} \pm 1.96 \times (1.0/3)$ (resulting in values of 17.56 and 19.84). It is assumed that a minimum of 18% protein is needed to emulsify the meat product and meet quality and sensory standards. This indicates that the lower number in 95% or 99% CI needs to be greater than 18% and, if it is not, an adjustment needs to be made to the formulation. This also demonstrates the importance of controlling variability in production, instrumental analysis, and sampling because a standard deviation such as this would not be acceptable in sausage production as the mean and lower CI need to be close to 18.0 to minimize costs.

Table 1 *t*-Statistics for two-sided 90%, 95%, and 99% confidence intervals (CI) and one-sided 95% CI within the *t*-distribution

Degrees of freedom (n − 1)	t-*statistic (two-sided 90% CI and one-sided 95% CI)*	t-*statistic (two-sided 95% CI)*	t-*statistic (two-sided 99% CI)*
1	6.314	12.701	63.66
2	2.920	4.303	9.925
3	2.353	3.182	5.841
4	2.132	2.776	4.604
5	2.015	2.571	4.032
6	1.943	2.447	3.707
7	1.895	2.365	3.499
8	1.860	2.306	3.355
9	1.833	2.262	3.250
10	1.812	2.228	3.169
30	1.697	2.042	2.750
∞	1.645	1.960	2.576

Standard Curves

Instrumental analyses, such as spectroscopy, gas chromatography (GC), and high-performance liquid chromatography (HPLC), require the use of a standard curve to determine unknown concentrations. Simple linear regression with concentration as the *x*-variable and either absorbance or peak area as the *y*-variable are used to determine $y = mx + b$. The slope, or sensitivity, is m, x is the concentration, and b is the *y*-intercept.

Example: A laboratory measures protein solubility as an indicator of protein functionality in processed meat products. The laboratory has been asked to determine total protein solubility for breast meat from broilers that are stressed before harvest by lengthy transport times in the summer (35–40 °C). A standard curve for the biuret assay is used to determine the concentration of solubilized protein with bovine serum albumin (BSA) as the standard. For this assay, the absorbance is determined using an ultraviolet–visible spectrometer at 540 nm.

The standard curve concentrations and absorbances are reported in Figures 1 and 2. The initial range of the protein standards was 0–14 mg ml^{-1} BSA. Simple linear regression was run on the samples with x as the concentration (explanatory variable) and y as the absorbance (response variable). Figures of merit were determined and include R^2 (coefficient of determination), limit of detection (LOD), linear range, and sensitivity. It is a general rule that a standard curve should have a minimum R^2 of 0.99. If $R^2 = 0.99$, this indicates that 99% of the variability in the absorbance (y) is explained by the concentration (x) and the remaining 1.0% is random variability. For the example in Figure 1, the excel output indicates an R^2 of 0.988. At first glance, this appears to be a sufficient standard curve because it is very close to the standard of 0.99. However, the line graph indicates that the data were only linear up to 12 mg ml^{-1} (Figure 2). Removal of the 14 mg ml^{-1} point improved the standard curve substantially and an $R^2 > 0.999$ was achieved. Therefore, the data from 0–12 mg ml^{-1} should be used because the R^2 is acceptable based on the requirement of 0.99 and the linearity of the curve. The LOD can be calculated for analytical instruments and an assay. For instruments, the LOD is 3 times the noise of the sample when a blank is run in the spectrometer, GC, HPLC, etc. The LOD for the assay is dependent on the random variability of the regression line and the slope and is calculated as either 3 × standard error (s.e.)/slope (m) or 3.3 × s.e./m. For the examples taken in this article, 3 × s.e./m is used to calculate LOD because this is what is done in a lab, but some literature reports using 3.3 × s.e./m to calculate LOD. Therefore, for the two

BSA (mg ml^{-1})	Absorbance (AU)
0	0
2	0.106
4	0.208
6	0.31
8	0.418
10	0.519

Figure 1 Standard curve data and simple linear regression output from Microsoft Excel for the biuret analysis to determine protein solubility of turkey breast protein for use in further processed meat products. The output with eight observations is for 0–14 mg ml^{-1} BSA and with seven observations is for 0–12 mg ml^{-1} BSA.

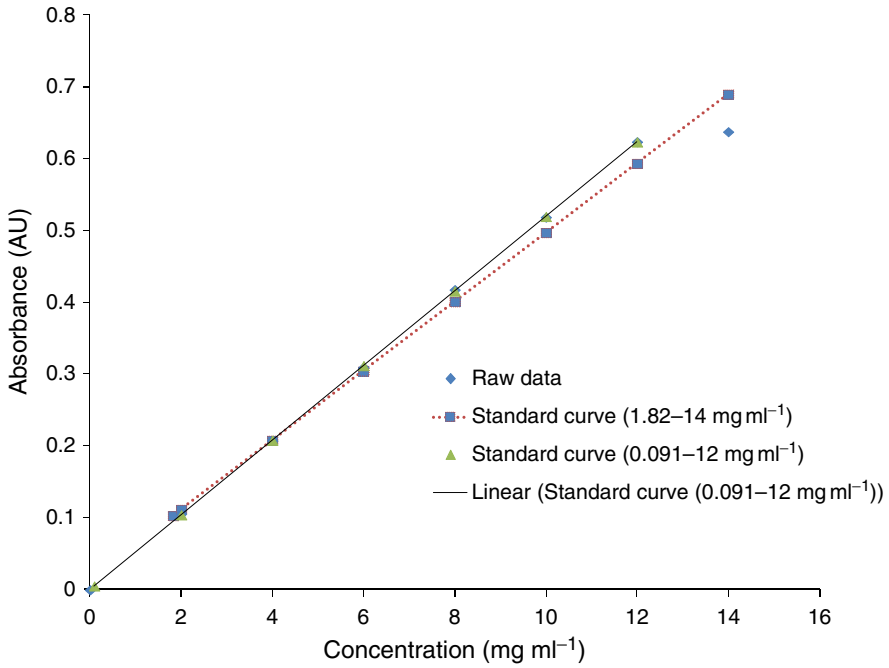

Figure 2 Standard curve graph for raw data and the standard curve lines 1.82–14 mg ml^{-1} BSA and 0.091–12 mg ml^{-1} BSA to determine protein solubility using the biuret assay.

regression assays, the LODs were calculated as $(3 \times .0280$ AU)/0.0482 AU (mg ml^{-1})$^{-1}$ and $(3 \times 0.00157$ AU)/0.0519 AU (mg ml^{-1})$^{-1}$, respectively (Figure 1). These LODs are 1.82 and 0.091 mg ml^{-1}. This large difference demonstrates the impact of a small increase in R^2 on the LOD when part of the curve is not linear. Any unknown sample that has a concentration below the LOD based on the standard curve should be reported as not detectable.

The limit of quantitation (LOQ) has been previously reported as either equal to the LOD or as $9 \times$ s.e./m. In addition, different organizations have varying definitions for LOD and LOQ. For clarification on LOD and LOQ, the Association of Official Analytical Chemists is the authority on analytical measurements of meat products. The third figure of merit is sensitivity or the slope and is defined as the change in response (absorbance) due to a 1-unit increase in concentration. A high-sensitivity assay should be used to determine small differences between samples, and a low-sensitivity assay, such as the biuret analysis, is sufficient for samples with higher concentrations or treatment samples that have large differences in concentration. The sensitivity for the two examples (Figure 1) are 0.0482 AU (mg ml^{-1})$^{-1}$ and 0.0519 AU (mg ml^{-1})$^{-1}$, respectively. This indicates that removing 14 mg ml^{-1} from the standard curve slightly increases the sensitivity of the test. The fourth and final figure of merit is the linear range. The linear range starts at either the LOD or LOQ and ends at the highest concentration that is used in the final regression analysis. The linear ranges of these two examples are 1.8–14 mg ml^{-1}

and 0.091–12 mg ml^{-1}. It is important to note that unknown samples can have concentrations only within the linear range for the assay to be valid for that sample. If a sample has a value outside of the linear range, it either needs to be concentrated or diluted for it to be readable using the assay.

Determining Unknowns

Example: Triplicate samples are run for each of the two treatments (stressed vs. nonstressed broilers) for the example above. To make sure that the values were representative of the treatments, eight whole breasts were ground and homogenized for each of the triplicate samples. The stressed broilers yielded breast meat with absorbance values of 0.431, 0.443, and 0.449 AU, and the nonstressed broilers yielded breast meat with absorbance values of 0.591, 0.587, and 0.573. To understand this data, the following protocol was followed: (1) verification that the concentration was within the linear range, (2) means, standard deviations, RSD, and CIs were calculated, and (3) data were reported as significant digits. To determine the unknown concentrations, the $y = mx + b$ equation was used to solve for x, in which $x = (y - b)/m$. For the regression with a linear range of 0.091–12 mg ml^{-1} $x = (0.431\ \text{AU} - 0.000\ 571\ \text{AU})/0.0519\ \text{AU}\ (\text{mg ml}^{-1})^{-1}$; $(0.443\ \text{AU} - 0.000\ 571\ \text{AU})/0.0519\ \text{AU}\ (\text{mg ml}^{-1})^{-1}$; and $(0.449\ \text{AU} - 0.000\ 571\ \text{AU})/0.0519\ \text{AU}\ (\text{mg ml}^{-1})^{-1}$, which are 8.29 mg ml^{-1}, 8.52 mg ml^{-1}, and 8.64 mg ml^{-1}, respectively. The mean, standard deviation, and RSD were determined for the concentrations and are 8.5 mg g^{-1}, 0.178, and 2.1%, respectively. The final concentration was reported as two significant digits because there was confidence that the eight was correct, slight confidence that the five was correct, but no confidence that the number in the hundredths place was correct. In addition, the concentration of the unknown samples was within the linear range, and the 95% CI was 8.28–8.69 for the normal distribution and 7.94–9.03 for the *t*-distribution. Even though two significant digits is correct based on the precision for the test, it is reported as three digits to make the CI as accurate as possible. Following the same calculations, the average, standard deviation, and RSD for the breast meat from nonstressed broilers was 11.2 mg ml^{-1}, 0.184 mg ml^{-1}, and 1.64%, respectively. The 95% CI was 11.02–11.43 g ml^{-1} and 10.68–11.77 mg ml^{-1} for the normal and *t*-distributions, respectively. Because the 95% CI for the nonstressed broilers does not overlap with the 95% CI for the stressed broilers, the breast meat from the nonstressed broilers had greater protein solubility, which indicates that it would have better water-holding capacity and texture than the breast meat from the stressed broilers in both fresh and processed meats.

Significant Figures

Determination of significant figures is reported in most freshman-level chemistry books. A few examples related to meat science are included to demonstrate the importance of accounting for both analytical and biological variability when determining how to report significant digits. For example, *CIE* L*(lightness/darkness) values are measured for porcine semimembranosus muscles from animals from two different genetic strains, in which one strain is more resistant to stress. In the summer time, 64 hogs were harvested from each genetic strain and the *CIE* L* values ranged from 48.00 to 54.00 for the resistant strain and from 54.00 to 60.00 for the nonresistant strain. The biological variability for the treatments is fairly large, even though the chroma meter is accurate to 0.01. In addition, the means are 50.432 13 and 56.243 12. There are three possibilities for reporting these data. Because the accuracy of the instrument is to 0.01, many researchers would report these values with four significant digits as 50.43 and 56.24. This would not be incorrect from an instrumental standpoint. However, if the biological variability in the sample is taken into account, you can assume that the average is being approached as sample size increases ($n > 30$), so there is confidence that 50 and 56 are correct digits for the averages, but it is unlikely that the 4 and 3 are correct in the tenths place. Therefore, it is logical to report the data as 50.4 and 56.2 because one can be confident of the numbers in the tens and ones place but not the tenths place. Even though there is a large biological variability that could infer that there should only be two significant digits, using two significant digits would make the results less accurate and therefore it would not be the best practice to report the data that way.

For the standard curve example above, averages of 8.5 and 11.2 mg ml^{-1} are used for the assay. However, 2.00 g of sample were initially homogenized to a total volume of 35.0 ml buffer. Therefore, the final concentrations are 8.5 mg ml^{-1} × (35.0 ml/2.00 g) and 11.2 mg ml^{-1} × (35.0 ml/2.00 g) = 148.75 and 196.00 mg g^{-1}, respectively. Because 8.5 has only two significant digits, the rule of thumb is to report this as 150 mg g^{-1}. However, 149 mg g^{-1} would also be appropriate because it is more accurate. The 196.00 mg g^{-1} sample should be written as 196 because 11.2, 35.0, and 2.00 all have three significant digits based on the standard curve, the scale, and the volumetric flask that was used. In a laboratory, these values would be reported as 149 and 196, even though 150 and 196 are more technically correct based on the following rule of thumb: A result cannot have more significant digits than the value in the multiplication, subtraction, or addition with the least number of significant digits. There are a few items to remember with respect to reporting data: (1) Be able to explain why you reported the data with the number of significant figures that were chosen. (2) Take into account the number of significant digits in all values going into a calculation. (3) Consider the biological variability in the meat tissue when research is conducted. (4) Consider the accuracy and precision of the analytical instrument. (5) Increase the number of figures by 1 if it increases the accuracy of the value. For example, if two significant figures are correct, but it decreases the accuracy of the value, use three significant figures. (6) Do not let significant figures be a stumbling block. There is usually more than one answer that is acceptable with respect to reporting the data. There are usually two and sometimes three values that are logical. However, there are many wrong ways to report the data.

Selecting the Test Samples

When analyzing meat, it is very important to know the objective of the sampling, i.e., what the test sample is supposed to represent. Should the test sample represent a muscle or the

meat ready for cooking? If a muscle, should it be a muscle in live animals, in the carcass just after the harvest, or after the postmortem process has ended? A muscle is not completely homogeneous because the muscle cells vary from the periphery to the middle and from one end to the other. From live animals, only biopsy samples will be possible; consequently, the test sample will represent only a very specific part of the body. After harvest or conversion to meat, representative test samples could be taken from the muscle after it has been homogenized in a mincing machine, but if only 50 g or less is needed for analysis, the experiment would be very expensive. In any case, the method might be intended not for minced meat but for a piece or slice of meat of a certain size. There is no single, and simple, solution to the sampling problem. An experiment has to be carried out to study the variation within the muscle. If the variation along the loin muscle, for instance, varies depending on different uncontrolled factors, several test samples from each muscle are needed to represent the whole muscle.

Survey Sampling

Representative Test Samples for Experiments

In meat science, exploratory sampling to gain information about the effect of different treatment of animals or subpopulations is the most common example of survey sampling. The first step will be to identify the objective of the problem and the next to clarify the experimental unit. Again, the lack of identical test units is a general problem. If examination of the effect on meat quality due to different treatments of the animals, such as feeding, stabling, or transport, is required, identical groups of animals treated differently are needed. If, say, pigs are studied, it is an obvious tactic to distribute pigs of the same sex from the same litter into groups. The pigs in a litter are not identical, but they will be more nearly identical than pigs from different litters. This is the best way to get replicates, but, because of the kinship, the observations (replicates) will be correlated. This is not a problem as long as the statistical model takes this fact into account and the sample size is large enough.

If one wished to obtain knowledge about a certain population, the first problem would be to choose pigs that represent the population in question. Ideally, pigs should be chosen at random. However, for this to happen, each pig should have the same probability of being selected for the sample; in practice, this could never be the case. There is no simple answer to this problem, but one must try to consider which factors could influence the results – the producer, the season, the time, or the place and so on. Once the sample is selected, investigations can be carried out if the sample is similar to the population with respect to certain key characteristics.

Sample Size

When determining the sample size, two problems must be addressed: How to compare treatments and the statistical power of the test to be carried out. Imagine an investigation for the effect of different treatments (e.g., different types of feed) on ordinary pigs with respect to the fat content in their meat. The statistical assumptions for making an analysis of variance (ANOVA) are present and the analysis shows that the fat content seems to vary because of the type of feed. This is probably not fully satisfactory as an additional question arises: Which type of feed implies the lowest or highest fat content? Consequently, comparison needs to be made of the results from the different treatments. When this is the objective, an ANOVA table should be used to determine overall significance of the model and a mean separation technique, such as Duncan's multiple range test or Tukey's honestly significant difference test, should be used to separate treatment means. When conducting these types of experiments, it is general practice to conduct at least three separate replications of treatments with enough animals/subsamples to have a sufficiently low alpha (0.05) and beta (<0.10). Beta is not often calculated when conducting analyses or reporting data, but it should always be considered when statistical analysis is utilized to determine differences between treatments.

To investigate the equality of two subpopulations, an experiment must be designed by selecting two representative samples of equal size, one from each population; the question is how large the sample size should be. In answering this question, small differences between the populations must be accepted and the size of the true difference must be detected with some probability. In the example above, a true difference of 0.5 units of fat content might be considered as not significant, whereas a difference of two units might be considered significant. It might be considered acceptable to have a probability of, say, 80% for detecting a difference of two units. Consequently, the experiment is designed to have the power of 80% for detecting two units of true difference. Finally, if the two (conceptually infinite) populations are expected to vary as normal (Gauss) distributions having the same variance and an estimate of the size of the variance, σ^2, is also available, the number of test samples in each sample can be estimated using the formula

$$Z_\beta = (-\sqrt{n})\frac{\delta}{\sqrt{2}\sigma} + Z_\alpha$$

where Z_β denotes the $(1-\beta)$ quantile and Z_α denotes the α quantile in the normal (Gauss) distribution. δ denotes the true difference to be detected at a power level $(1-\beta)$ (type II) and α denotes the risk (type I) of rejecting the null hypothesis wrongly. In the example above, $Z_\beta = -0.842$, $Z_\alpha = 1.96$, and $\delta = 2$; the only information missing before estimating n is an estimate of σ^2. The best estimate can often be obtained from the previous observations. Alternatively, a small pretest for this purpose can be performed. If the problem involves several comparisons or characteristics, the α level must be reduced accordingly. A best practice is to calculate β and power after each statistical analysis based on the data that are obtained.

To sum up, the following steps have to be considered before carrying out the sampling:

- Clarify the objective and the characteristics to be measured.
- Identify how test samples should be prepared.
- Estimate the level of type I and type II risks together with the number of replicates.

Acceptance Sampling

In the production of meat products, the process must be checked to insure that the requirements attached to the product can be met. On the one hand, the requirements can be set by the authorities to insure specific levels of compounds or microorganisms for health reasons. On the other hand, the producer is to ensure a defined level of quality. For this purpose, a Guide on Sampling for Analysis of Foods has been prepared by a working group established by the Nordic Committee on Food Analysis. The idea is to set up a sampling plan that describes how inspection should be carried out. Typically, the inspection consists of three levels: normal inspection, tightened, and reduced inspection. The inspections focus on the produced lots (or batches) of products; a 'lot' is a quantity of products produced under uniform conditions. From each lot, a number of sample items are selected, analyzed, and evaluated. The evaluation results in acceptance or rejection of the lot. If the inspection results in acceptance of consecutive lots, the inspection can be reduced, that is, fewer sample items need to be selected. However, if the inspection rejects consecutive lots, the inspection will be tightened.

A number of estimates are necessary to specify the sampling plan. First, the method for deciding on acceptance or rejection has to be determined; in principle, only two methods are included. In an attribute sampling plan, each selected test sample is classified according to the quality characteristics (i.e., acceptable or defective). In a variable sampling plan, the acceptance evaluation is based on the average and variability of the measurements, which must be considered as observations from a normal distribution. Besides this, the lot size has to be known and the acceptable quality level, which is an index corresponding to a maximum rate of defective items in the lots, has to be determined. With this information, it will be possible to determine a standard sampling plan (according to ISO 2859) that can be understood by all interested parties and that is known to be optimal as it includes an appropriate sample size.

Determination of Specifications

When determining processing capability or if a product meets specification, it is important to have statistical data during both the product development and the production phases to set specification limits and then have a sampling plan to verify that data for samples are within the specification limit. For example, a meat processor receives a request from a food service establishment for meatballs and will randomly sample 5 kg bags that are shipped to them for salt concentration and meatball diameter. Once the production process for the meatballs is set up and running correctly, sampling ($n > 30$) should be conducted on the initial production runs for 5–6 days. After setting the preliminary specifications, samples ($n > 30$) should be conducted for approximately 6 reps (processing days) to verify or change the specifications. Based on the data that are acquired, either a 95% or a 99% CI (if possible) should be used as the specification limits. Sampling should still be conducted for each lot of production (possibly a day's production, morning, afternoon, evening, etc.). If the sample fails to meet specifications, the lot should not be shipped without appropriate rework. These specification limits may need to be changed based on changes to the process or production process. This is not a five time and finished process. Data should continue to be added to the body of knowledge to adjust specifications and hopefully improve accuracy and precision.

Glossary

Applicability The method's ability to identify and measure the physical and chemical forms of the analyte that are likely to be present in the material, with regard to matrix effects.

Interferences The effects of any other components that are likely to be present at appreciable concentrations in matrices of interest and which may interfere in the determination.

Limit of detection The amount of an analyte corresponding to the lowest measurement signal which with a closely defined confidence may be interpreted as indicating that the analyte is present in the sample but without allowing exact quantification.

Precision The closeness of agreement between independent test results obtained under stipulated conditions.

Recovery The difference between the measuring results for a sample without the analyte and a sample to which a known amount of the analyte has been added, divided by the added amount.

Repeatability The precision under conditions where independent test results are obtained with the same method on identical test items in the same laboratory by the same operator using the same equipment within short intervals of time.

Reproducibility The precision under conditions where test results are obtained with the same method on identical test items in different laboratories with different operators using different equipment.

Standard developing organizations The organizations elaborating methods; in this context, within food analysis.

Trueness The degree of agreement between a sample's true content of a specific analyte and the result of the analysis. Trueness is not the same as accuracy. Accuracy is the sum of trueness and precision. Trueness is the systematic error, precision is the random error, and accuracy is the total error (systematic+random error).

Use of Standard Methods

Reliable analytical methods are required to achieve 'true' analytical results and compliance with national and international regulation. In some sectors, it is prescribed by law to use standard methods or fully validated methods. Most chemical standard methods are fully validated, i.e., the methods' performance characteristics have been studied in interlaboratory studies (also known as collaborative studies or collaborative trials). Conducting collaborative studies requires a lot of work, but if a method is required by a large number of laboratories, the cost of collaboratively validating a method is justified. When using a collaboratively studied method, the measures a laboratory needs to carry out before taking the method into routine use are reduced considerably. Using a collaboratively validated method gives an advantage when trying to get the method accredited, because the laboratories need only to demonstrate that they can achieve the performance characteristics stated in the method.

Standard Developing Organizations

There are several Standard Developing Organizations (SDOs), elaborating chemical methods for food analysis. Some of these SDOs provide standards for specific products, for example, the International Dairy Federation (IDF) elaborating standards in the field of dairy products and the American Oil Chemists' Society (AOCS) developing standards within the field of fats and oils. Other SDOs such as The Scientific Association Dedicated to Analytical Excellence® (AOAC International), the European Standardization Organization (CEN), International Standardization Organization (ISO), and Nordic Committee on Food Analysis (NMKL) are all developing methods for different food products. The structures of the different organizations vary. Some organizations consist of national committees or national standardization bodies. The SDOs depend on submission of method proposals from experts within these committees or national standardization bodies. Further, the national bodies forward method comments and give or withhold their approval of the method. The AFNOR (Association Francaise de Normalisation, France), DIN (Deutsches Institute für Normung, Germany), DS (Danish Standard, Denmark), BSI (British Standards Institution, UK), and NS (Norwegian Standard, Norway) are such national standardization bodies of ISO and CEN in Europe and the ANSI is the American National Standardization Institute.

The Food and Agriculture Organization of the United Nations and World Health Organization are both elaborating food standards (Codes) in the Codex Alimentarius – more than 180 countries representing 97% of the world's population are members. In these food standards, analytical methods are often referenced. These methods are primarily intended as international analytical methods for the verification of provisions in the Codex standards. They should be used for reference, in calibration of methods in the use, or introduced for routine examination and control purposes. To date, Codex has endorsed specific methods for analysis of the

provision of interest. Recently, Codex has adopted the Criteria Approach for the method performance. Instead of adopting specific methods, any methods fulfilling the given criteria might be used. In the Codex Alimentarius Commission Procedural Manual, twenty-first edition, Codex gives guideline for establishing numeric criteria for the method performance characteristics which corresponds to the characteristics listed below.

How a Method Becomes a Standard

Initially, the need for a standard is put forward by laboratories, government, or industry. A suitable method for the purpose has to be drafted and tested by experts within the specific topic. Most of the standardization work is voluntary; a number of experts and their institutions support standardization work by providing their valuable knowledge, effort, and time. Collaborative studies involve considerable effort and should, therefore, be conducted only on methods that have undergone prior testing in a laboratory. The collaborative studies should be conducted according to international acceptable rules. Several organizations have adopted the International Union of Pure and Applied Chemistry (IUPAC) protocol for the design, conduct, and interpretation of method performance studies of 1994. This protocol gives guidance on how to design, conduct, and interpret the results of a collaborative study.

Performance Characteristics Examined

In a collaborative study, the following characteristics are determined:

- Applicability: The method's ability to identify and measure the physical and chemical forms of the analyte that are likely to be present in the material, with regard to matrix effects.
- Interferences: The effects of any other components that are likely to be present at appreciable concentrations in matrices of interest and which may interfere in the determination.
- Limit of detection: The amount of an analyte corresponding to the lowest measurement signal which with a closely defined confidence may be interpreted as indicating that the analyte is present in the sample but without allowing exact quantification.
- Precision: The closeness of agreement between independent test results obtained under stipulated conditions.
- Repeatability: The precision under conditions where independent test results are obtained with the same method on identical test items in the same laboratory by the same operator using the same equipment within short intervals of time.
- Reproducibility: The precision under conditions where test results are obtained with the same method on identical test items in different laboratories with different operators using different equipment.
- Trueness: The degree of agreement between a sample's true content of a specific analyte and the result of the analysis.
- Recovery: The difference between the measuring results for a sample without the analyte and a sample to which a known amount of the analyte has been added, divided by the added amount.

Determination of Performance Characteristics

Testing Materials Used in Collaborative Studies

A material is a given combination of an analyte (substance), its concentration, and a given matrix. For a single type of substance, at least five materials should be used. The number of materials used can be reduced to three if the method studied is applicable only for a single-level specification for a single matrix. The two or more test samples of blind or open replicates are considered as a single material. The concentrations of the analyte in the materials used should be of low, middle, and high level.

The main objective with the collaborative study is to generate data to form the basis of a reliable estimate of the repeatability and reproducibility. Repeated analysis of one single sample is not an acceptable basis. An estimate of the repeatability is best accomplished by using one of the following models (in prioritized order).

1. For each level, measurement is carried out on a single determination on two materials with the same or almost the same concentration of the parameter (split-level pair).
2. For each level, measurement is carried out on materials where some are split-level pair and some are disguised parallel test samples (combined uniform-level pairs).
3. For each level, measurement is carried out on disguised/hidden parallel test samples (uniform-level pair).

The Material Quality

Materials used in a study are subject to strict requirements. The samples should as far as possible be natural foodstuffs. It is of vital importance that the materials are properly homogenized, tested for homogeneity, and stored and shipped under the correct conditions. The conductor of the study must prepare enough samples to ensure homogeneity and stability and should also be prepared to provide additional samples to laboratories that for some reason might need them. It is important that the conductor keeps an open dialog with the participating laboratories about when the materials are to be analyzed.

The Number of Laboratories

In a collaborative study, results from at least eight laboratories should be obtained. To obtain this number of results, 12–15 laboratories should be appointed. If it is impossible to obtain this number of participating laboratories, for instance, if the study requires very expensive instrumentation or specialized laboratories, the study may be conducted with an absolute minimum of five laboratories. Usually, the laboratories do not receive any funding for their efforts in such study; they receive only honor of participating (in terms of good name and reputation).

Analysis of the Samples

The conductor of the study forwards the test samples to the participating laboratories. The laboratories must perform the analysis according to the method draft in question. Sometimes a prestudy is conducted in order to ensure that everyone has understood the procedure correctly and to eliminate any problems. If a laboratory modifies the method, the results from this laboratory must be excluded from the study.

Statistical Analysis of the Results

As an example, the 'statistical analysis' of the results conducted within the NMKL consists of the following six steps.

1. Recognition of valid data. Valid data are results that are not to be rejected. Results to be rejected are, for instance, results achieved from analyses in which the method was not followed precisely; a nonlinear calibration curve was used when a linear one was expected; the analytical equipment did not work satisfactorily and test samples were lost; the separation of peaks (in chromatography) was not satisfactory; or analyses in which unexpected reaction (chemical or microbiological) or any atypical phenomenon occurred. Quite often, the review of valid data is based on comments from the participating laboratories, which are attached to the study form distributed along with the study samples.
2. Variance analysis of the valid data. As described in the section "Testing Materials Used in Collaborative Studies" the samples in the studies are paired. The statistical analysis should be conducted on each pair. One-way analysis of variance is performed on all valid data for each sample pair and is the statistical procedure for obtaining the estimates of within-laboratory (intralaboratory) and between-laboratory (interlaboratory) variability on a material-by-material basis. Examples of calculations can be found in the NMKL Report No. 11 and ISO 5725–2, 1994.
3. Outlier tests by Cochran and Grubbs. The Cochran outlier test is used for testing the figures for significant differences in obtained results from a single laboratory compared with those obtained from other laboratories. The Grubbs outlier test is used for testing the figures for extreme mean values obtained at single laboratories compared with those obtained at the other laboratories. (For the testing, see IUPAC Harmonized Protocol.)
4. Recalculation of the variance, mean, the repeatability, and reproducibility. This is done after results have been removed in accordance with the outlier tests. According to the IUPAC Harmonized Protocol, no more than 22.2% (two of nine laboratories) should be removed.
5. Estimation of Horrat values. Based on several hundred method performance studies, including a huge number of analytes, materials, and techniques, Dr. William Horwitz established an equation describing the relation between the concentration ratio and the expected relative standard deviation. This is expressed as eqn [1], where C is the concentration ratio.

$$\text{Theoretical RSD} = (\text{PRSD}_R) = 2C^{(-0.1505)} \qquad (1)$$

C is the concentration ratio. For concentration of 10 mg kg^{-1}, C is $10\times10^{-6} = 10^{-5}$.

The Horrat value is the ratio of the estimated relative standard deviation (RSD_R) and the theoretical RSD_R ($PRSD_R$):

$$\text{Horrat value} = \text{RSD}_R/\text{PRSD}_R \qquad (2)$$

6. Evaluation of the method: A method can be approved as acceptable when:
   a. the study is performed according to the IUPAC-1994 recommendations.
   b. all the relevant (valid) results are examined for outliers, and fewer than one out of five samples contain less than 20% inexplicable outliers (no more than two out of ten laboratories or two out of ten samples can contain more than two outliers).
   c. the Horrat value is no more than 2 (in some occasions, less than 1.5 is recommended).

   The study reports are reviewed by experts within the relevant field of interest.

The collaboratively validated methods are reviewed after a given period. In the NMKL, the collaboratively validated methods are reviewed after 10 years, or sooner if necessary.

The Codex Alimentarius' Guidelines for Numeric Values for Method Performance Criteria

Only the analyte (provision) in the specific commodity of interest along with its maximum level, minimum level, normative level, or concentration range of interest (here noted as ML) is needed when establishing numeric values for method criteria. In the Codex, the numeric values are guidelines for the Codex purposes and hence relevant for the SDOs and laboratories when elaborating and selecting methods **Table 1**.

How Methods Come into Being

Establishing a collaboratively validated method is a demanding task. A lot of effort from different experts and laboratories is laid down in a method. Usually, it takes between 2 and 5 years to establish a method. Exactly how methods come into being in the different organizations varies quite a bit. However, to illustrate the process, the practice of the NMKL, is described in the flowchart in **Figure 1**. The NMKL is a Nordic organization consisting of microbiologists, chemists, and sensory analysts from Denmark, Finland, Iceland, Norway, and Sweden, with the primary objective of selecting, collaboratively validating, and publishing methods on analysis of foods.

Chemical Standards and Official Methods on Meat and Meat Products

In recent years, the organizations have been working toward making horizontal standards, methods applicable to all kind of foodstuffs, rather than vertical ones. References to Chemical standards and official methods applicable to meat and meat

Table 1 Guidelines for establishing numeric values for the criteria

Applicability:	The method has to be applicable for the specified provision, commodity, and level(s) (maximum and/or minimum) (ML). The minimum applicable range of the method depends on the specified level (ML) to be assessed and can be expressed either in terms of the reproducibility standard deviation (S_R) or in terms of Limit of Detection (LOD) and Limit of Quantification (LOQ).	
Minimum applicable range:	For ML≥0.1 mg kg^{-1}, [ML−3 S_R, ML+3 S_R]	
	For ML < 0.1 mg kg^{-1}, [ML−2 s_R, ML+2 s_R]	
	s_R = standard deviation of reproducibility	
LOD:	For ML≥0.1 mg kg^{-1}, LOD≤ML 1/10	
	For ML < 0.1 mg kg^{-1}, LOD≤ML 1/5	
LOQ:	For ML≥0.1 mg kg^{-1}, LOQ≤ML 1/5	
	For ML < 0.1 mg kg^{-1}, LOQ≤ML 2/5	
Precision:	For ML≥0.1 mg kg^{-1}, HorRat value≤2	
	For ML < 0.1 mg kg^{-1}, the RSD_{TR} < 22%	
	RSD_R = relative standard deviation of reproducibility	
Recovery (R):	Concentration (unit)	Recovery (%)
	≥10% (10 g 100 g^{-1})	98–102
	1% (1 g 100 g^{-1})	97–103
	0.1% (1 mg g^{-1})	95–105
	100 mg kg^{-1}	90–107
	10 mg kg^{-1}	80–110
	1 mg kg^{-1}	80–110

Curing Agents

KO Honikel[†]

This article is a revision of the previous edition article by KO Honikel, volume 1, pp 195–201, © 2004, Elsevier Ltd.

Glossary

Ingoing and residual amouts Nitrite and nitrate are toxic substances that react with meat batter constituents changing their concentration. Thus, for food safety reasons, some countries limit the ingoing (added) amounts at the time of production; other countries define the residual (remaining) amounts or both in the ready-to-eat meat products.

Introduction

This article describes the chemical reactions of nitrite and nitrate in meat products leading to their antimicrobial and antioxidative activity, as well as cured color and flavor. The formation of nitrosamines is also discussed. The analytical procedures for the determination of nitrate and nitrite are described.

Definitions

Curing of meat means the addition of nitrite and/or nitrate together with salt (NaCl) to meat in various degrees of comminution and at different processing steps.

The most basic method of curing is the covering of meat cuts (e.g., part of the hind legs of pigs) in a mixture of salt and curing agent. The salt and curing agents penetrate slowly into the muscular tissue. This dry-curing process lasts up to several weeks. The process can be accelerated by wet curing, in which the meat cuts are either inserted into brine and curing agents and/or brine is injected into the meat with needles.

In small pieces of meat, in minced or comminuted meat as in sausages, salt and the curing agent are mixed in or comminuted in a bowl chopper. This way of curing is fast and within a short time (less than 1 day), depending on the processing, leads to the characteristics and appearance of a cured product.

Legal Requirements

Various concentrations of curing agents are permitted to be added into the product or are required in the ready-for-sale product. In the European Union, the concentrations shown in Table 1 are permitted basically for addition and as maximum residual amounts in products for sale. But there exist quite a number of exemptions from the basic rules for defining not-heat treated meat products of the various EU member states.

Other countries differ somewhat in these legal requirements. In Russia, for example, nitrate is not allowed in meat products; in the USA, approximately 150 mg kg^{-1} nitrite is permitted as an ingoing amount in most products.

Reasons for Addition

The primary reason for the use of nitrate and nitrite is the preserving action of these compounds. They prevent growth of some microorganisms early in the processing and retard the oxidation of fats during storage.

Other effects are of secondary importance but are nevertheless regarded as positive actions of the curing agents. Cured

[†]Deceased.

 doi:10.1016/B978-0-12-384731-7.00059-3

Table 1 Amounts of permitted curing agents in meat products in the European Union (Directive 2006/52/EC). There exist a number of traditionally produced mostly dry-cured nonheat treated (raw) ham products with other ingoing amounts and some with other residual amounts at the point of sale (residual amounts are presented in the range permitted for all meat products)

Additive	*EEC number*	*Foods*	*Ingoing amounts (mg kg^{-1})*	*Residual amounts[b] (m kg^{-1})*
Potassium nitrite	E 249	All meat products	150[a]	50–175
Sodium nitrite	E 250			
Potassium nitrate	E 251	Nonheat treated meat	150[a]	10–250
Sodium nitrate	E 252	Products		

[a]Expressed as $NaNO_2$.
[b]Residual amount at point of sale to the final consumer expressed as $NaNO_2$.

$$NaNO_2 \longrightarrow Na^+ + NO_2^- \quad [I]$$

$$4\ NO_2^- + 4\ H^+ \rightleftharpoons 4\ HNO_2 \quad pK_a = 3.35\ (K_a = 4.47 \times 10^{-4}\ mol\ l^{-1}) \quad [II]$$

$$4\ HNO_2 \rightleftharpoons 2\ N_2O_3 + 2\ H_2O \quad [III]$$

$$2\ N_2O_3 \rightleftharpoons 2\ NO + 2\ NO_2 \quad [IV]$$

$$2\ NO_2 + H_2O \longrightarrow HNO_3 + HNO_2 \quad [V]$$

$$\text{Sum [III] to [V]: } 3\ HNO_2 \longrightarrow 2\ NO + HNO_3\ \text{(oxidation/reduction)} + H_2O \quad [VI]$$

$$HNO_3 \longrightarrow H^+ + NO_3^-\ \text{(strong acid; completely dissociated)} \quad [VII]$$

$$NO + \text{Myoglobin} \longrightarrow \text{NO-Myoglobin (red colour)} \quad [VIII]$$

Oxygen sequestration:

$$2\ NO + O_2 \longrightarrow 2\ NO_2 \quad [IX]$$

Figure 1 Sequence of reactions of nitrite in aqueous solutions of pH approximately 5.5–6.0.

color, a heat-stable red color, results from the formation of nitrosyl myoglobin, and a so-called cured flavor, which can be detected by sensory assessment, is also produced by curing. However, it is not clear whether the flavor is caused by direct reactions of curing agents with meat constituents or whether oxidative processes like fat rancidity development, which result in a negative sensory reaction, are retarded.

Thus, curing agents are believed to have four effects within the permitted concentrations:

- Antimicrobial activity
- Antioxidative activity
- Formation of a red cured color
- Expression of cured flavor.

Chemistry of Curing Agents

Nitrate

Nitrate itself has no direct curing potential. Nitrate is only effective if it is reduced to nitrite. This is done primarily by microorganisms. Thus, nitrate as a curing agent is only relevant in raw meat products that are cured and fermented around ambient temperature for longer periods of time. In all meat products that are heated within hours after adding the curing agent, nitrate is useless and superfluous. Accordingly, nitrate is used mainly in raw hams and raw sausages that are fermented.

Nitrite

Nitrite is the basis for the real curing agent. Sodium or potassium nitrite is added to the meat with the salt. In many countries, nitrite must be premixed with common salt (NaCl) to prevent an overdose of nitrite, which is toxic in higher concentrations; 0.4–1.0% of nitrite in a salt mixture is common.

Nitrite salts dissociate almost completely in water to yield Na^+ (K^+) and NO_2^- ions (Figure 1, eqn [I]). The nitrite anion (NO_2^-) itself is not active as a curing agent. In a meat cut or meat batter, the pH value is approximately 5.5–6.0. In this slightly acidic environment a small proportion of NO_2^- anions react with H^+ ions to form nitrous acid (HNO_2); Figure 1, eqn [II]. HNO_2 is a medium-strong acid with a pK_a value of 3.35.

HNO_2 is in equilibrium with its anhydride N_2O_3 (Figure 1, eqn [III]). N_2O_3 breaks down into NO+NO_2 (Figure 1, eqn [IV]). NO is the effective curing agent that binds to myoglobin (Figure 1, eqn [VIII]).

The NO_2 reacts with water to yield HNO_2+HNO_3 (nitric acid) (Figure 1, eqn [V]). HNO_2 reenters the sequence of events (Figure 1, eqn [III]). HNO_3, as a strong acid, is completely dissociated into H^++NO_3^- (Figure 1, eqn [VII]). This means (Figure 1, eqn [VI]) that 1/3 of the HNO_2 (oxidation state +3) is oxidized to HNO_3 (oxidation state +5) and 2/3 are reduced to NO (oxidation status +2).

Table 2 Formation of HNO_2 in batters

Assumptions:

1. pH of raw batter 5.7 ($c_{H^+} = 2 \times 10^{-6}$ mol l^{-1})
2. 80 ppm of nitrite added $c_{NO_2^-} = 1.75 \times 10^{-3}$ mol l^{-1}

$HNO_2 \rightleftarrows H^+ + NO_2^-$ ($pK_a = 3.35$; $K_a = 4.47 \times 10^{-4}$ mol l^{-1})

$K_a = 4.47 \times 10^{-4}$ mol $l^{-1} = c_{H^+} \times c_{NO_2^-} / c_{HNO_2}$

Hence,

$c_{HNO_2} = (2 \times 10^{-6})(1.75 \times 10^{-3})/(4.47 \times 10^{-4})$

$c_{HNO_2} = 0.78 \times 10^{-5}$ mol l^{-1}

$c_{HNO_2} = 1.65 \times 10^{-4}$ mg kg^{-1}

$= 0.165$ ppm HNO_2

NO is easily oxidized by oxygen to NO_2 (Figure 1, eqn [IX]). In a comminuted meat batter, oxygen is present and reactions [IX] and [V] occur. This means that another part of the created NO is finally oxidized to HNO_3. This latter oxidation can be reduced by vacuum chopping or by antioxidants such as ascorbate, isoascorbate, or tocoferols. However, as a result of this series of reactions, a considerable part (1/3 or more) of the nitrite is oxidized to nitrate during curing of meat products. Thus, even if only nitrite has been added, nitrate will always be found in cured meat products.

As indicated above, the equilibrium of $HNO_2 \rightleftarrows NO_2^- + H^+$ is on the left side of the reaction. In a raw batter with a pH of 5.7 and a concentration of 80 ppm (80 mg kg^{-1}) nitrite added to the batter, a theoretical concentration of 0.165 ppm HNO_2 is formed (Table 2). This is approximately 1/500 of the nitrite concentration added.

In batters of higher pH (e.g., liver or blood sausages with pH 6.2–6.8) the concentration of HNO_2 is even lower (by as much as a factor of 10). Nevertheless nitrite is oxidized to nitrate as shown in Figures 2 and 3. In the more acid environment of a raw sausage or an emulsion-type batter with lower pH (e.g., due to the use of glucono-δ-lactone), the HNO_2 concentration is higher: more NO is formed and a more intense red color may be formed, as it will be in the presence of antioxidants that inhibit Figure 1, eqn [IX] and subsequently Figure 1, eqn [V] of Figure 1.

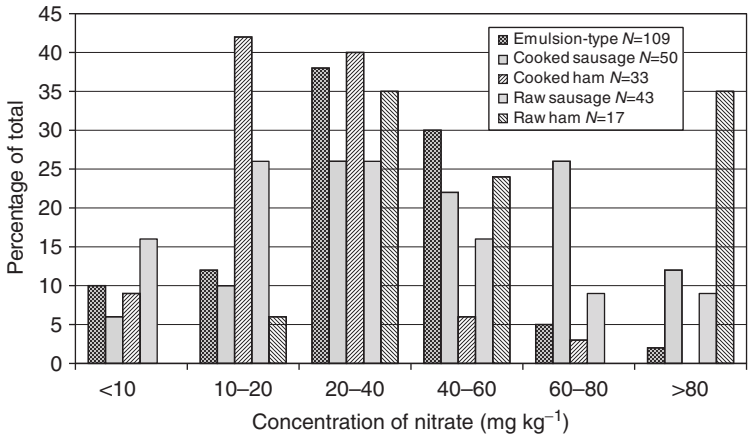

Figure 2 Nitrite concentrations in ready-to-eat meat products from Germany. Data from Dederer, I., 2001, personal communication.

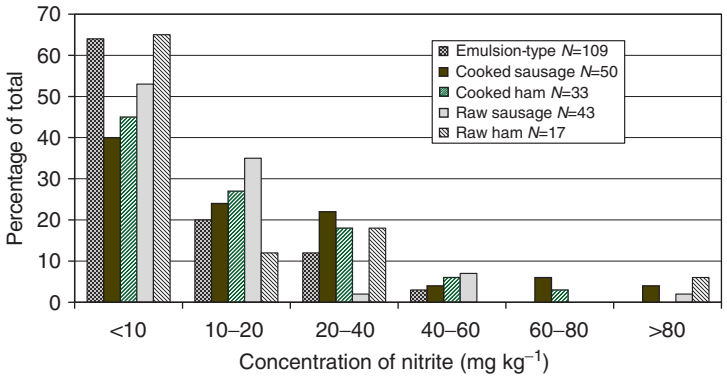

Figure 3 Nitrate concentration in ready-to-eat meat products from Germany. Data from Dederer, I., 2001, personal communication.

Concentrations of Nitrite and Nitrate in Meat Products

The concentration of nitrite in 252 samples of all groups of meat products is presented in Figure 2. For these German meat products it can be assumed that for emulsion-type, cooked sausages 80–100 ppm and for cooked hams 100–150 ppm of nitrite were added during preparation. The pointless use of nitrate can be discounted. Nitrate up to 150 ppm may have been used additionally in raw meat products.

Despite the addition of nitrite with 80–150 ppm, the concentration in the heated products ready for sale was below 20 ppm in more than 80% of all products at the time of measurement, which was 1–2 weeks after manufacturing.

In raw hams and raw sausages, the situation is similar. In these products nitrate (up to 250 ppm) has often been added as well as nitrite (up to 150 ppm). A total of 300 ppm, however, was not exceeded. Some products had concentrations of nitrite above 20 ppm on measurement, which took place 3 weeks to 3 months after manufacturing. The cooked sausages (liver and blood sausages) with pH > 6.2 cannot make much use of the nitrite, as the HNO_2 is formed only in very small concentrations. But nevertheless it is sufficient that a cured color is formed.

Figure 3 shows the nitrate concentrations for the same products as in Figure 2 for nitrite. The concentrations of nitrate are in general considerably higher than those of nitrite in Figure 2 with a maximum between 20 and 40 ppm.

Changes of Nitrite during Storage

The process of nitrite degradation happens not only during the manufacturing step, but it also occurs during storage. The results of Russian researchers are shown in Table 3. At concentrations of nitrite even beyond those permitted in Russia (75 ppm), the concentrations of nitrite are reduced to rather low concentrations during storage for 60 days. Thus, it is evident that reactions of nitrite occur even under storage conditions.

Analysis of Nitrite and Nitrate

There are a number of methods for determining the concentrations of curing agents. Nitrite and nitrate anions can be detected with high-performance liquid chromatography (HPLC) as an ion-exchange chromatography method and by isotachophoresis. Nitrite can also be determined titrimetrically with permanganate, but the most common method for determining the curing agents in meat products is to measure nitrite after a colorimetric reaction and nitrate after reduction to nitrite.

Table 3 Remaining nitrite (ppm; mg kg^{-1}) during storage at 2 °C of an emulsion-type sausage

Storage	*Concentration of nitrite added (ppm)*			
	75	*100*	*150*	*200*
After heating	21.9	30.5	59.5	53.7
20 days	7.5	9.3	10.2	15.4
40 days	3.6	6.4	7.6	7.7
60 days	0.5	0.9	4.0	5.8

Source: Data based on work of Kudryashow, L., 2003, Personal communication.

The colorimetric assay is based on the reaction of nitrite, sulfanilamide, and *N*-1-naphthylethylenediamine under acidic conditions to form a red azo dye that has an absorbance maximum at 540 nm. This method is described in many national standards (e.g., British Standard 1976; AOAC 1980; Germany L 08.0014 §64 LFBG (2006)).

The same method can be applied to nitrate after its reduction to nitrite. In older standards, nitrate is reduced with metallic cadmium, with the nitrate running through a column filled with cadmium particles. Cadmium is oxidized to Cd^{2+} and nitrate is reduced to nitrite. Newer standards use the enzyme nitrate reductase, which reduces nitrate to nitrite whereas the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) is oxidized to $NADP^+$. The reaction is carried out in one batch and followed by the color reaction.

Two colorimetric measurements must be made to determine nitrite and nitrate, one before and one after the reduction process. The result of the second analysis minus the first gives the nitrate concentration.

Reduction/colorimetry assays are potentially prone to interference from a number of sources, including incomplete reduction of nitrate to nitrite and also overreduction of nitrate, via nitrite, to lower oxides. High concentrations of inert salts may adversely affect the accuracy of the method, and the buffering effects of organic acids may affect the pH-dependent absorbance of the azo dye.

In principle, any component of the sample that is able to compete with the sulfanilamide reagent for nitrite during the color development reaction will cause a negative interference. The close comparability of the results obtained for the nitrite content of cured meats by colorimetry and by HPLC, where such an interference is not anticipated, suggests that this is not a widespread problem. Cured meats containing high levels of ascorbate are, however, known to give low results for nitrite owing to significant competition with the coupling reagent. In addition to chemical effects, the colorimetric assay may also be adversely affected by physical interferences arising from turbidity in the measuring solution. This is likely to occur if the postextraction precipitation and filtration steps are ineffective. Detection limits for nitrate and nitrite in cured meats are generally approximately 1–3 mg kg^{-1}. However, for samples that contain appreciable quantities of ascorbate or other interferents, the effective limit of detection may be an order of higher magnitude. The ascorbate interference is minimized or excluded by heating in alkaline solutions before the colorimetric reaction. Numerous standards recommend this step.

Effects of Nitrite in Meat Products

As nitrate is effective only after the reduction to nitrite, only the effects of nitrite in meat products are considered. Nitrite has antimicrobial effects in its form as HNO_2 or NO. Owing to its small concentrations in many meat products after manufacturing (pH range 5.0–6.8), the antimicrobial action of HNO_2 or NO is possible only in raw meat products and in the raw batter of emulsion-type sausages before heating.

Pathogenic microorganisms like *Salmonella* spp. and *Clostridium botulinum* are inhibited. Other microorganisms are not inhibited by nitrite or HNO_2. Spores, especially those of *C. botulinum*, are seen to be damaged or retarded by HNO_2/NO during the heating process. Nitrite alone does not protect against spoilage. Other microbiological hurdles such as salt, water activity (a_w), pH, redox potential, and temperature of heating are required to be crossed for stability.

Nitrite and its metabolites also act as antioxidants by sequestering oxygen and by binding to iron ions in the myoglobin cofactor heme. It is thus responsible for the heat-stable red cured color. Nitrite or its metabolites also play a part in the 'cured' flavor either be enhancing the meat flavor or by retarding its degradation. The latter may be an antioxidative effect.

Nitrosamine Formation

Some nitrosamines/amides are carcinogenic, and are formed by the reaction of amines or amides with nitrite under acidic conditions. Only secondary amines form stable nitrosamines (Figure 4). Furthermore, the pH must be low (<5.5). For these reasons, the formation of nitrosamines is small or negligible in emulsion-type and cooked sausages because of their pH values (>5.7) and the use of fresh meat (or early postmortem frozen meat) in which secondary amines are present only in very small amounts. The most convincing sequence of events is shown in Figure 4.

In low-pH raw sausages or raw hams (pH<5.5 for a longer period of time), with long fermentation and presence of secondary amines, the formation of nitrosamines is possible (Table 4). Nevertheless, the concentrations are mainly in the range 1–2 μg kg^{-1}. Reducing agents such as ascorbate prevent the formation of nitrosamines (see Table 4).

The problem of nitrosamines becomes larger with cooking, for example, in the frying of bacon, where the same conditions are present as in raw hams (low pH and possible formation of amines over the long storage time). In the frying of bacon, these conditions are combined with high temperatures (>130 °C), particularly in the case of frying to crispness.

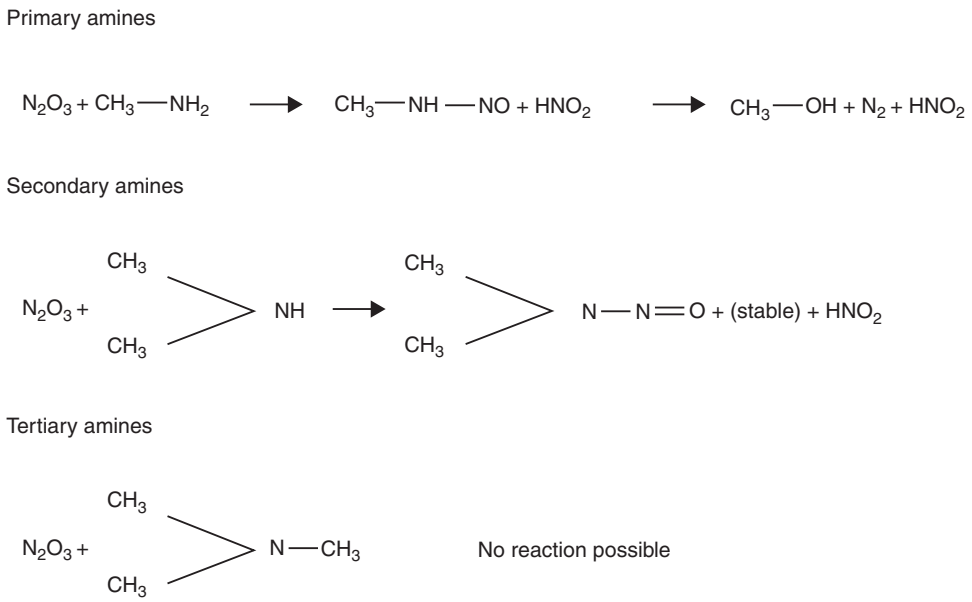

Figure 4 Nitrosamine formation.

Table 4 Frequency of various levels of nitrosamine concentration in raw sausages and ham

	Nitrosamine species[a]	*Number of samples with nitrosamine concentrations of μg kg^{-1}*					*Percentage of samples with <1 μg kg^{-1}*
		0–05	*<1*	*<2*	*<5*	*>5*

Table 5 Toxicity (lethal dose) of nitrate and nitrite

Nitrate	80~800 mg nitrate per kg bodyweight per day
Nitrite	33~250 mg nitrite per kg bodyweight per day

Source: Data from Schuddeboom, L.J., 1993. Nitrates and Nitrites in Foodstuffs. Strasbourg: Council of Europe Press.

Owing to the high temperatures, some of the volatile nitrosamines, which are the main carcinogenic ones, evaporate from the fried product, but fried bacon nevertheless has potential for higher concentrations of nitrosamines than any other meat products.

Toxicological Aspects

The acute toxicity of nitrite and nitrate is reported to cover a wide range (Table 5). A person of 60 kg who consumes 100 g of meat products with 20 mg nitrite per kg consumes 0.033 mg nitrite per day per kg body weight. This is 1/1000 of the lower limit of toxicity. With nitrate the intake is in a similar range. Thus, both curing salts *per se* can be regarded as posing no health hazard with normal use.

Glossary

Amino acids Organic compounds, with relevant biological functions, made from amine and carboxylic acid groups. They have a side chain specific to each amino acid.
Carbohydrates Present in minor amounts in meat, mainly composed of glycogen and small amount of glucose.
Fat A major component in meat consisting of triacylglycerols and phospholipids as well as some free fatty acids and minor amounts of cholesterol and fat-soluble vitamins.
Fatty acid A carboxylic acid with a long aliphatic tail which is either saturated, monounsaturated, or polyunsaturated.
Gas chromatography (GC) Separation technique carried out in a column having gas as the mobile phase.
Internal Standard (IS) A substance not contained in the sample with physical–chemical properties as similar as possible to those of the analyte that has to be identified and which is added to each sample at a known concentration.
Liquid chromatography (HPLC) Separation technique carried out in a column packaged with small particles having liquid at a relatively high pressure as the mobile phase.
Meat proteins There are three major classes consisting of sarcoplasmic (soluble in water), myofibrillar (soluble in high ionic strength solutions), and connective tissue proteins (insoluble).

Introduction

Fat and protein are major components of meat. Fat, composed mainly of triacylglycerols and phospholipids, can make up as much as 50% of some meat products, whereas protein, composed of amino acids, can represent more than 20% of lean meat. The analysis of these major components is the subject of this article.

Carbohydrate, in the form of glycogen, is present in very low amounts in meat (approximately 0.5 g per 100 g in meat and 1.5–5 g per 100 g in liver (this higher value applies to beef liver; calf liver may go up to 10 g per 100 g liver) and is considered only briefly in this article.

The term fat is not clearly defined and can be subdivided in many ways. The analysis of the different lipid classes – such as tri-, di-, and monoacylglycerols, phospholipids, and free fatty acids – is very complex and falls outside the scope of this article. The analysis of specific proteins and peptides also falls outside the scope of this article.

Fat and protein can be analyzed using a wide range of methods, from traditional wet chemical analysis, which can be automated to some extent, to advanced gas chromatography (GC), high-pressure liquid chromatography (HPLC), and ion-exchange chromatography (IEC). Indirect methods such as nuclear magnetic resonance (NMR) and near-infrared transmission (NIT) and near-infrared reflectance (NIR) spectroscopy are also used.

Fat

The terms fat, total fat, crude fat, and total lipids are all terms covering more or less the same components. Triacylglycerol is the form in which fat chiefly occurs in the intermuscular and subcutaneous fat, or depot. Phospholipids are mainly contained in the structural fat. Fat also consists of minor amounts of other components, for example, free fatty acids, waxes, mono- and diacylglycerols, sterols, and fat-soluble vitamins. The extraction techniques can be classified into three different types, depending on the solubility of lipids in organic solvents or their physical characteristics (Figure 1).

The property of lipids, being soluble in organic solvents but insoluble in water, provides methods to separate lipid components in foods from water-soluble components, such as proteins, carbohydrates, and minerals. However, several new efficient methods have been developed during recent years. In solvent extraction methods, samples should be prepared by drying the samples to facilitate the organic solvent to penetrate. Particle size of samples should be reduced to produce a homogeneous sample and increase surface area. Before solvent extraction, it is necessary to submit the sample to acid hydrolysis in order to release bound lipids. Finally, the selection of the solvent depends on the polarity of lipids present in the samples. Polar lipids (e.g., phospholipids) are more soluble in polar solvents (alcohols) than in nonpolar solvents (hexane), whereas the opposite occurs for nonpolar lipids (triacylglycerols). Therefore, the total lipid content determined will be different depending on the nature of organic solvent used.

The first solvent extraction methods were discontinuous as they were based on the mixture of sample and solvent in a container, such as the Folch and Bligh and Dyer extraction methods, (Figure 1) where the lipid is extracted with a 3:1 mixture of chloroform:methanol. This very polar mixture of solvents extracts all the lipids, including structural lipids, and also extracts other components. Results for total lipid with this method, therefore, tend to be high. This method has fallen out

 doi:10.1016/B978-0-12-384731-7.00057-X

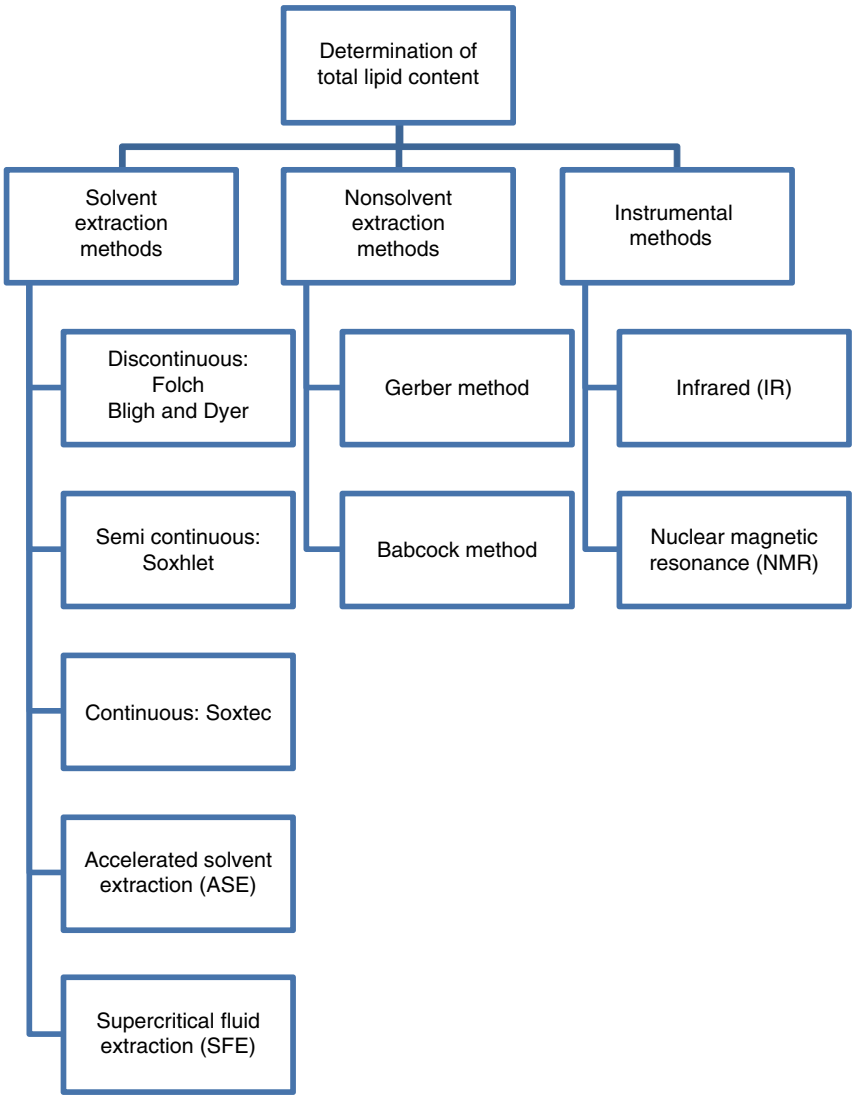

Figure 1 Scheme of methods to determine total lipid content.

of use for routine fat determination as chlorated solvents are banned for health reasons from many laboratories.

In semicontinuous classical Soxhlet extraction, the sample is extracted many times with a nonpolar solvent like hexane or petroleum ether, the solvent is evaporated, and the extracted fat is weighed. With this method, the major part of the triacylglycerol fraction and most of the cholesterol in meat will be extracted, but only a fraction of the phospholipids and lipoproteins. If extraction is carried out with diethylether, a more polar solvent, the yield will be higher. Modified versions of the Soxhlet method has been designed to reduce the use of solvents and time (e.g., Soxtec). The Soxhlet extraction method is the most used one, as it is the officially recognized method.

The Folch and Bligh and Dyer methods and Soxhlet method to determine fat content are tedious and time consuming, and high solvent consumption is a disadvantage from a health point of view. The newest extraction technique is the accelerated solvent extraction, which reduces extraction times down to minutes using very small amounts of solvent. The efficiency of extraction is increased by doing it at higher temperature and pressure than in normal process as well as by the availability of special instruments.

In addition, fat can be extracted using supercritical fluid extraction, with carbon dioxide as the solvent. Because this solvent is nonpolar like petroleum ether, only the triacylglycerols will be extracted, unless it is modified with other solvents, such as ethyl alcohol. The equipment is expensive, and it can be difficult to adjust the solvents to give comparable results to the classical reference methods; however, they are beneficial from a cost and environmental point of view by not using organic solvents.

Other liquid extraction methods do not use organic solvents but use other chemicals to separate lipids. The classical Gerber method, known for milk analysis, can also be used for meat. It is then known as the modified Babcock method. The sample is hydrolyzed with sulfuric acid in a special Gerber tube, a little amyl alcohol is added to aid the separation, and the mixture is centrifuged. The amount of fat can then be read

directly from the calibrated scale on the Gerber tube. It is necessary to adjust the temperature carefully at all times to secure correct calibration. The precision is not as high as for the other methods as it depends on the scale on the tubes, and a special centrifuge is necessary. However, this method is still in use in some laboratories.

There is a wide variety of instrumental methods for fat determination (Figure 1) and each one has its own advantages and disadvantages. In general, the advantages are nondestructive, require little or no sample preparation, and measurements are fast, precise, and simple, whereas the main disadvantage is the necessity to prepare a calibration curve specific to the type of food matrix used. NIT and NIR are instrumental methods based on absorption of light in the sample in the near-infrared range from 800 to 2500 nm.

NMR is another instrumental method based on the measurement of a spin echo of protons in a magnetic field. The samples must be heated to ensure that the entire fat phase is liquid. It is also necessary to dry the samples, as protons from water will give a signal. A linear regression with results from a reference method must be used for calibration, so the NMR technique has the same limitations as mentioned above for NIR/NIT. A newer NMR technique with pulsed field gradients allows measurement on nondried samples, and it is possible to measure both water and fat. However, a higher precision can be obtained from dried samples. Equipment needed for instrumental methods is expensive but allows very rapid measurements of fat on a large number of samples. In addition, the measurements are nondestructive, which makes it possible to use such techniques in process control.

Thus, the choice of method for fat determination depends on how much of the lipids should be included in 'total fat,' and also on both the sample load, which decides the degree of automation and the sample mix. Many different matrices are well suited to automated classical methods, but only a few are suited to instrumental methods. For meat and meat products, it is necessary to use acid hydrolysis to release all the fatty acids. A simple Soxhlet extraction is only sufficient for determination of added fat as triacylglycerols.

Fatty Acids

Methods for fatty acid analysis are much simpler to review as almost all rely on GC on capillary columns of fatty acid methyl esters (FAME), although there are many variations. The fatty acids are isolated either as total fat or as free fatty acids and are then converted into FAMEs, which are extracted with a nonpolar solvent, and a small proportion is injected into the GC. Results are calculated either per 100 g sample or per 100 g fat or fatty acids.

Isolation of Fat or Free Fatty Acids

Fat obtained from Soxhlet extraction or fatty acids extracted after acid hydrolysis can be used to determine fatty acids. Instead of evaporating the solvent, the extract is diluted to a known volume, an aliquot corresponding to approximately 100 mg fat is taken, and then the solvent is evaporated.

Methylation

The quantification of fatty acids by GC requires previous methylation consisting of the transformation of the analytes to methyl esters in order to make them volatile enough for GC. This conversion of the fat or fatty acids to methyl esters can be achieved by boiling in methanol for 2 h with strong acids like hydrochloric acid or sulfuric acid. The free fatty acids are methylated rapidly but the transesterification of triacylglycerols takes a little longer. Basic catalyzed transesterification is even more rapid. When using sodium methoxide in methanol as catalyst, the methylation takes only a few minutes. The presence of water must be avoided; if water is present, then free fatty acids will be formed instead of the methyl esters. The most commonly used catalyst is boron trifluoride. The sample is boiled for a few minutes in methanol and potassium hydroxide, cooled, boron trifluoride in methanol is added, and the mixture is boiled again for a few minutes in a stoppered glass tube. Care must be taken that the tube is tightly stoppered, otherwise the unsaturated fatty acids might be destroyed and the more volatile short-chain fatty acids might escape. After cooling the mixture, the FAMEs are extracted with n-hexane or isooctane, and they are now ready for the GC.

Gas Chromatography of Fatty Acids

The FAMEs are injected on a capillary column, usually 50–100 m long, with an internal diameter of 0.25–0.32 μm. The capillary column is coated with a highly polar material to achieve the necessary separation of FAMEs (100% biscyanopropyl polysiloxane or 90% biscyanopropyl/10% cyanopropylphenyl polysiloxane). Initial separation is according to chain length and then according to the number of double bonds. For instance, oleic acid will elute later than stearic acid and linoleic acid will elute later than oleic acid. *Trans* fatty acids (TFA) will elute before their corresponding *cis* fatty acids. For positional isomers, the elution time will increase with the nearness of the double bond to the methyl end of the molecule. Oleic acid ($C_{18:1\ n-9}$) will thus elute before $C_{18:1\ n-7}$.

Recent technologies for fatty acid analysis are based on 100-m capillary columns coated with high polarity cyanosilicone stationary phases. The most widely reported are CP Sil 88 (100 m×0.25 mm×0.2 μm, Varian Inc.) and SP 2560 (100 m×0.25 mm×0.2 μm, Supelco) capillary columns, both containing similar makeups (biscyanopropyl polysiloxane), and HP 88 (100 m×0.25 mm×0.2 μm, Agilent Tech.) with a different stationary phase (88%-cyanopropyl-methyl aryl polysiloxane) that shows a slightly different FAME profile. The elution of the fatty acids depends on their own characteristics: chain length, double bonds, position, geometry, and branches. In addition, temperature program affects the elution order of fatty acids.

The most used official method for fatty acid analysis is Association of Official Analytical Chemists (AOAC) method 996.06, which determines total, saturated, and unsaturated lipid in food. The major limitation of this method is the incomplete separation of TFA and the absence of validation data for their quantification.

A flame ionization detector (FID) is usually used to detect the eluted peaks. An internal standard is often used for

quantification of the fatty acids. The quantification is based on the assumption that the FID detector gives a linear response for each fatty acid over the entire range of concentrations present in the sample. The odd-numbered fatty acids, most commonly C_{17} but also C_{13}, C_{21}, and C_{23}, can be used as an internal standard, because they occur in nature in very small amounts. By adding an amount of internal standard to the sample before the extraction of fat, the amount of fatty acids can be determined per 100 g sample or expressed as a percentage of total fatty acids.

Detection can also be achieved using mass spectrometry (MS) with electron impact ionization. For FAMEs, only the molecular weight can be ascertained. Other structural information cannot be obtained because the double bonds shift back and forth during ionization. However, if the fatty acids are esterified with nitrogen-containing heterocyclic compounds, like picolinyl esters or dimethyloxazoline (DMOX) esters, the double bonds will be stabilized, and their position in the molecule can be seen, although the difference between *cis* and *trans* mass spectra is not visible.

Special Procedures for *Trans* Fatty Acids

The new regulations on labeling and limitation of TFA has introduced new or updated methods to be able to improve the separation of TFA from other fatty acids. The main limitation is the limited availability of reference materials to confirm the identifications. The latest AOAC methods for the determination of *cis*-, *trans*-, saturated, monounsaturated, and polyunsaturated fatty acids (official method Ce 1h-05 and recommended practice Ce 1j-07) are based on the separation through CP Sil 88 and Supelco 2650 capillary columns and provide the identification of FAME based on available reference materials. However, other fatty acids may be present and not indicated in the reference materials. In those cases, the identification is achieved by available literature and GC/MS/MS analysis. In addition, the elution order of fatty acids with different unsaturation can be affected by column polarity, column age, or oven temperature.

To solve problems associated with the direct analysis of TFA by GC, the use of fatty acids fractionation, such as liquid chromatography (silver ion chromatography), solvent phase extraction cartridge (Ag-ion cartridge), reverse-phase HPLC, or high-speed counter current chromatography, has been proposed. The elution pattern of *trans* monounsaturated fatty acids has been characterized; however, the quantification of polyunsaturated TFA is limited due to the lack of reference materials and confirmed identifications. The identification of fatty acids has been based on GC/MS/MS of DMOX derivatives, but they do not provide information about *cis*–*trans* configuration, and the identification needs to be confirmed by other techniques. Recently, a new technique based on covalent adduct chemical ionization MS/MS (CACI-MS/MS) was able to identify position and geometry of FAME double bonds.

Protein

Total protein or crude protein is usually determined by measuring the content of nitrogen and multiplying by a conversion factor that depends on the specific proteins in the different foods. Thus, a value for the meat protein content is obtained by multiplying nitrogen content by the factor 6.25. Only two methods, the Kjeldahl and the combustion methods (based on Dumas method), are of interest. Another option is to determine and add all the amino acids after hydrolyzing the sample to derive a value for the protein content as will be described in the next section. Some indirect methods will also be mentioned. Figure 2 illustrates the main methodologies for protein determination.

In the Kjeldahl method, the material is digested in a Kjeldahl digestion flask with concentrated sulfuric acid and several catalysts. After cooling, the mixture is made alkaline with sodium hydroxide and the released ammonia is distilled and trapped in a boric acid solution, which is then titrated back with hydrochloric acid. The method determines protein-bound nitrogen from protein, peptides, or amino acid origin and from ammonium salts if present in the sample as well as determines nitrogen from a very large number of other organic nitrogen compounds. In addition, nitrogen in nitrate and nitrite will be determined to some extent, with a very large variation of approximately 60%. The distillation and titration step can be automated to obtain high throughput and safe handling of samples. Even so, the method takes approximately 2–3 h to complete an analysis.

In the combustion method, the sample is placed in a combustion chamber, having temperature between 950 and 1300 °C, where all covalently bound nitrogen is converted into nitrogen gas, which is quantified by passing through a conductivity cell. The method can be automated, but special and rather expensive equipment is necessary, demanding a high sample load to be profitable. The combustion method tends to give slightly higher results than the Kjeldahl method, as nitrogen-containing salts, like nitrate and nitrite, will also be converted into nitrogen with higher recoveries. For meat products, where nitrate and nitrite salts have been used to cure the meat, this could be of importance. The major benefit of this combustion method is the very rapid turnaround time, usually 5 min at a rate of approximately 100 samples per day, and that hazardous and toxic chemicals are not utilized.

The NIR/NIT indirect method described for fat determination can also be used to determine protein. Again a calibration is needed, which means that the indirect method will inherit the precision and all the limitations of the reference method.

When the sum of amino acids is determined, called the net protein value, and compared with total protein calculated from the content of nitrogen, the net protein value will be significantly lower than the crude protein value that might be due to the Kjeldahl, and combustion methods determine more nitrogen than that from amino acids. The difference for meat is that net protein values are approximately 20% lower than crude protein values.

There are two general ways to calculate the total amount of amino acids. The simplest consists in the analysis of the global amino acids amount without discriminating each other, which would include free amino acids and small peptides. These methods are based on the reaction of the α-amino group with reagents like *o*-phthaldialdehyde (OPA), fluorescamine, cadmium-ninhydrin, or trinitro-benzene-sulphonic acid.

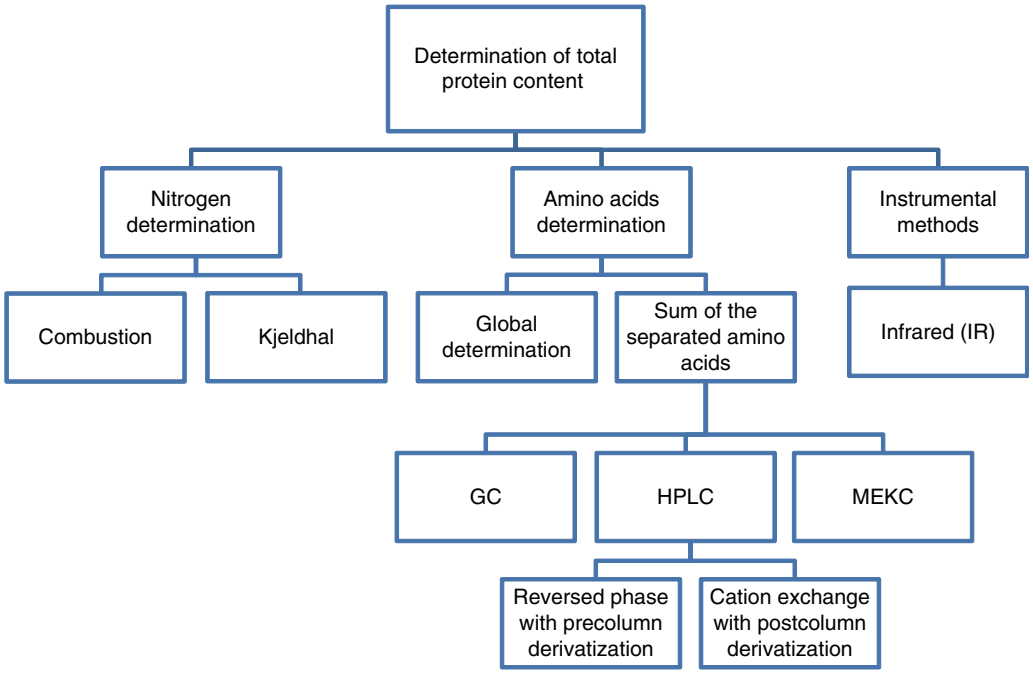

Figure 2 Scheme of methods to determine protein content.

Amino Acids

Amino acids constitute a very diverse group of chemical compounds that have in common an amine and carboxylic groups linked to the same carbon that support a wide variety of side chains, including sulfur-containing side chains like methionine and cysteine, benzene rings like phenylalanine and tyrosine, *N*-containing rings like tryptophan and histidine, or carbon chains like lysine and alanine that differentiate each other. This diversity gives them very different behavior in terms of oxidative stability, hydrolysis, reactiveness, charge as a function of the pH medium, and solubility in water. Thus, the simultaneous analysis of all naturally occurring amino acids is very complicated – far more so than the analysis of fatty acids. Here it is only possible to touch briefly on the most important factors in amino acid analysis.

Hydrolysis

Hydrolysis is the first step in the analysis of total amino acids. Hydrolysis is carried out by boiling samples in strong (6 mol l^{-1}) hydrochloric acid for approximately 24 h, either with reflux condenser or in sealed ampoules. Other possibilities are microwave systems with the use of special vessels, which can withstand high pressures. This allows the use of temperatures as high as 180 °C and reduces the hydrolysis time to 10 min. Not all the amino acids can be recovered after hydrolysis. Tryptophan is totally destroyed in the hydrolysis process, and so a special procedure with basic hydrolysis using sodium, barium, or lithium hydroxide and prolonged heating for approximately 16 h at 110 °C is used. However, tryptophan is also somewhat unstable by basic hydrolysis, which can be compensated by adding an internal standard – for instance, 5-methyltryptophan or α-methyltryptophan – before hydrolysis. Cysteine and methionine are not stable to the acid hydrolysis either and form diverse products of oxidation. This problem can be overcome by driving the oxidation to completion with phenol-containing performic acid to cysteic acid and methionine sulfone. However, this process destroys tyrosine, which then must be determined in an unoxidized sample. Bonds among serine, threonine, valine, leucine, and isoleucine amino acids are quite heat resistant and thus recoveries tend to be a bit low (85–95%), which is usually considered tolerable or can be rectified with the use of a correction factor. Glutamine and glutamic acid are determined together, as are asparagine and aspartic acid. Thus, the hydrolysis procedure is a series of compromises with many parameter sets described in the literature to obtain reasonable results for most of the amino acids. It is necessary to hydrolyze both an oxidized and an unoxidized sample and to carry out a special procedure for tryptophan, when analysis for total amino acids is the goal.

Chromatographic Separation

Separation of amino acids can be achieved by chromatographic techniques, like GC or HPLC, by either IEC or reversed-phase HPLC. Also, electrophoretic techniques like micellar electrokinetic capillary chromatography (MEKC) are used. Ion-exchange HPLC techniques are now gradually being replaced by reversed-phase HPLC carried out on standard equipment but with commercially available kits for the derivatization of the amino acids for a better detection.

Cation-exchange chromatography separates amino acids in their free form by gradient elution with a row of sodium-based buffers, giving a typical run time of approximately 1.5 h.

Detection of the amino acids is typically performed by light absorption after postcolumn reaction with ninhydrin, which forms a purple complex with all primary amino acids with a maximum at 570 nm. The secondary amino acid proline forms an intermediate reaction product with a maximum at 440 nm. Fluorescamine or OPA may also be used for the respective visible or fluorescent amino acid detection.

Reversed-phase HPLC is usually carried out on C_{18} columns with particle size of 5 μm or 3 μm, and gradient elution is common with a mixture of acetonitrile, methanol, and acetate or phosphate buffers. Precolumn derivatization to separate and detect the amino acids is necessary. Reagents like phenylisothiocyanate, OPA, 9-fluorenylmethylchloroformate (FMOC), 6aminoquinolyl-N-Hydroxysuccinimidyl carbamate, and dansyl and dabsyl chlorides are typically used, making ultraviolet or fluorimetric detection possible.

Hydroxyproline is an amino acid occurring predominantly in collagenous connective tissue, which contains 12.5% hydroxyproline. Therefore, a determination of hydroxyproline can be used to determine the amount of collagenous connective tissue in meat and meat products. Hydroxyproline can be determined in the analysis for total amino acids, but a much easier colorimetric procedure has been developed. The sample is hydrolyzed in sulfuric acid at 103 °C, filtered, and diluted. Hydroxyproline is oxidized with chloramine-T. After addition of 4-dimethylaminobenzaldehyde, a red-purple color is developed that is measured photometrically at 558 nm.

Because the free tryptophan is obtained after basic hydrolysis, it can be determined independently of the others amino acids, directly by reversed-phase HPLC and using its native fluorescence.

Amino acids to be analyzed by GC must be derivatized in order to increase their volatility and thermal stability. The application of *N*-methyl-*N*-tert-butyldimethylsilyl trifluoroacetamide as derivative reagent facilitates the GC analysis of amino acids. This reagent requires mild conditions to react, is stable, and has a very good behavior in MS detection together with the high efficiency of the GC technique, which makes this method a very good alternative to HPLC for free amino acid analysis.

The technique of capillary zone electrophoresis (CZE) is an extremely efficient technique for separations of charged solutes. Amino acids constitute a mix of basic, neutral, and acidic constituents and thus proper separation of all of them is not possible by this technique. MEKC is a modified version of CZE where surfactant-formed micelles are included in the running buffer to provide a two-phase chromatographic system for separating neutral compounds together with charged ones in a capillary electrophoresis system.

Glycogen

Glycogen is a starch-like molecule with a high molecular weight and is built of glucose units. The amount of glycogen depends on the conditions of the animal before harvest (resting, exercise, or fasting). Early postmortem, the reserve of glycogen is rapidly depleted and the generated glucose is rapidly converted into lactic acid. So, the amount of glycogen in meat is too small to be determined with the traditional method of subtracting fat, total protein, and ash from the dry matter. The glycogen can be broken down only partly with amylase but fully with amyloglucosidase or phosphorylases, releasing glucose phosphate. Glycogen can also be broken down by acid hydrolysis to glucose units, which then can be determined by an enzymatic method using commercially available kits or by reversed-phase or ion-exchange HPLC.

Micronutrients and Other Minor Meat Components

A Cilla, A Alegría, R Barberá, and GL Guadalupe, University of Valencia, Valencia, Spain
F Toldrá, Instituto de Agroquímica y Tecnología de Alimentos (CSIC), Valencia, Spain

This article is a revision of the previous edition article by T Leth and P Ertbjerg, volume 1, pp 190–195, © 2004, Elsevier Ltd.

Glossary

Cholesterol Principal sterol synthesized by animals which is an essential structural component of cell membranes required to establish proper membrane permeability and fluidity, and for bile and steroid hormones synthesis.
Micronutrients Nutrients required throughout life in small quantities to orchestrate a range of physiological functions, including trace elements and vitamins.
Proteases Enzymes that catalyze the release of an amino acid from the amino terminus of a peptide (exopeptidases) or able to hydrolyze myofibrillar proteins to polypeptides (cathepsins and calpains).
Proteolysis Enzymatic breakdown of proteins with the formation of peptides and free amino acids.
Vitamins Essential organic compounds needed in low amounts for the control of metabolic processes which must be supplied through diet since the organism cannot synthesize them.

Introduction

The chemical analysis of the many micronutrients contained in meat and meat products will be addressed in this article. Vitamin content in meat derives from naturally available vitamins – meat being a good source of B vitamins: thiamine, riboflavin, and niacin are probably the most important in the group. Vitamins E and C are added to processed meat due to their reducing properties as antioxidants. Losses during processing can modify the vitamin content in processed meat. In many cases, the fortified levels of vitamins are high in comparison to the natural levels. Therefore, the availability of methodologies of use in monitoring the quality (technological indicators) of the product and for evaluating their nutritional value is of interest. Meat constitutes a major dietary source of iron, zinc, phosphorus, and magnesium. It is relatively poor in sodium and calcium. Nevertheless, the nutritional importance of foods of animal origin lies in their essential trace element contents. Of note in this sense is their iron content in the form of heme (hemoglobin and muscle myoglobin), offering high bioavailability in red meats. No other food contributes such high iron bioavailability. Moreover, heme iron contributes to the improvement of the organoleptic properties of meat as a result of its color. Meat contributes 50–70% of ingested zinc, and the latter (particularly in beef) is more bioavailable than zinc from vegetables. Despite the low selenium content of meat, its bioavailability is high – because the element is present in the form of selenomethionine and selenocysteine. Meat and meat products are also sources of cholesterol, considered by some relevant for health, which makes the analysis of cholesterol a part of this article.

Fat-Soluble Vitamins

Extraction and Purification

Analysis of fat-soluble vitamins in meat requires a complex sample preparation (extraction and purification) before vitamin determination via liquid chromatography (LC). Hot saponification with ethanolic potassium hydroxide solution containing an antioxidant is one of the most widely used procedures for extracting vitamins A, E, D, and carotenoids to disrupt the matrix, to release the free form from esters, hydrolyze triacylglycerols to glycerol, remove fats and other interfering substances, and produce soaps of free fatty acids. Vitamin K cannot be extracted by saponification because of its instability in alkaline media. The unsaponifiable fraction has been extracted with organic solvents such as hexane, isooctane, and petroleum-diisopropylether.

Liquid–liquid direct extraction using solvents such as hexane, ethanol, acetone, methanol, tetrahydrofurane, and petroleum ether is a more simple method of sample preparation. In meat products (liver, bacon, and sausage), extraction with 2-propanol (as protein denaturing solvent) and hexane as organic solvent to extract the vitamin was recommended for routine analysis of vitamin K in meat products. The main disadvantages are high consumption of organic solvents and the long time required for analysis.

As an alternative to these classical methods, saponification after supercritical fluid extraction (SFE) has been applied to fat-soluble vitamin determination in meat products (meat and liver paste). The advantages of SFE comprise minimal consumption of organic solvent (environmental protection), the exclusion of oxygen, reduction of thermal treatment, lesser economical cost, shorter extraction times, and less laborious processing, because these procedures can be automated.

In general, purification has only been applied to extracts of vitamins K and D from previously saponified samples to remove nonpolar components such as triacylglycerols. Samples with low fat contents ($<10\%$) are most effectively and easily purified with solid-phase extraction and the semipreparative high-performance liquid chromatography (HPLC).

Determination

HPLC became widely used for fat-soluble vitamin analysis, mainly because of its ability to effect rapid separation,

 doi:10.1016/B978-0-12-384731-7.00058-1

nondestruction of the sample, and, more importantly, the good resolution achieved. Normal-phase HPLC on silica columns is by far the preferred technique for the analysis of vitamin A, which is eluted with small amounts of a polar organic solvent, often 2-propanol in *n*-heptane or isooctane, and often with gradient elution. Reverse-phase HPLC can also be used on C18 columns, but it is very difficult to achieve sufficient separation between all-*trans*-retinol and other vitamin A isomers, especially 13-*cis*-retinol. This is important, because other isomers do not have the same biological activity as all-*trans*-retinol. Fluorescence detection offers greater selectivity and sensitivity for all-*trans*-retinol and especially for tocopherols compared with ultraviolet (UV) detection, but usually the separation power of the column and the vitamin contents are high enough to permit UV detection to be used.

Capillary gas chromatography (GC)-flame ionization detection (FID) has been described for the determination of retinol (vitamin A) and α-tocopherol (vitamin E) in meat.

Water-Soluble Vitamins

Microbiological methods have been used for many years and are still employed for some of the water-soluble vitamins, including the determination of some B vitamins. This is based on the fact that certain microorganisms can only grow with a specific vitamin B in the growth medium. The vitamins are released by hydrolysis, growth medium is added, and the solution is inoculated with the microorganism. After incubation, the growth of the microorganism is measured using turbidimetry. The hydrolytic process is not always sufficient to release the vitamins in a form the microorganisms can use; enzymes therefore have to be added (papain, taka-diastase, and a phosphorylase) for thiamin and riboflavin. Folate is found in food in the form of polyglutamates, but the microorganisms can only use mono-, di-, or tri-glutamates; the bonds therefore have to be cleaved by enzymatic treatment. In vitamin B_{12} analysis, it is necessary to add potassium cyanide to transform naturally occurring hydroxycobalamin to more stable cyanocobalamin. In modernized versions of the microbiological assays, an enzyme-linked immunosorbent assay reader is used. This saves a lot of hard work for the laboratory staff and improves the precision of the assays.

Microbiological assays/methods are tedious and time-consuming; HPLC is therefore the most widely used technique for determining natural and fortified levels of water-soluble vitamins in meat products.

Thiamine (Vitamin B_1) and Riboflavin (Vitamin B_2)

Thiamine (the sum of thiamine, thiamine monophosphate, thiamine pyrophosphate, and thiamine triphosphate) and riboflavin (flavin mononucleotide-FMN and flavin adenine dinucleotide-FAD) are present in all animal tissues, and therefore in all natural unprocessed animal foods/meats.

HPLC is the method of choice for the simultaneous determination of B1 and B2, though excellent analytical data can be obtained using microbiological or fluorimetric procedures applied to thiamin (AOAC Official Method 942.23) and riboflavin (AOAC Official Method 970.65).

The extraction procedures generally applied in the determination of total thiamine and riboflavin by HPLC involve acid hydrolysis by boiling or autoclaving to release free thiamine and riboflavin and their phosphate esters from the food matrix (their association to proteins), followed by enzymatic hydrolysis (similar for the microbiological assay) of the phosphate esters to complete release. Generally, the acid hydrolysis step is carried out by heating the foodstuff with 0.1 M HCl, and using commercial enzymes (takadiastase, papain, pepsin, clara-diastase, acid phosphatase, and amylases).

Owing to the lability of flavins to light and to alkaline or extremely acidic pH values, special nonhydrolytic extraction conditions are required to quantify riboflavin and its coenzymes (FMN and FAD). This requires carrying out the extraction and analysis of the individual vitamers (compounds with similar molecular structure that show vitamin-activity in a vitamin-deficient biological system) between pH 5.0 and 7.0, and under subdued light in brown glassware.

The individual and simultaneous vitamin (B_1 and/or B_2) determinations are made by ion-pair reverse-phase HPLC using C18 columns. Elution with methanol or acetonitrile and phosphate buffer containing sodium heptane sulfonate, and fluorimetric detection, are the conditions normally used. Riboflavin has its own fluorescence, but the thiamine and phosphate esters must be oxidized to their fluorescent thiochromes. Simultaneous HPLC with UV detection determination of thiamine and riboflavin does not require the pre- or postcolumn derivatization needed in thiamine determination with fluorescence detection. However, higher levels of thiamine and riboflavin are needed (e.g., liver).

Capillary electrophoresis constitutes an interesting alternative to the HPLC method for determining thiamine, and is economical and ecologically sound.

Vitamin B_6

Vitamin B_6 comprises pyridoxine or pyridoxol (PN), pyridoxal (PL), and pyridoxamine (PM). Pyridoxamine phosphate and pyridoxal phosphate are the main vitamin B_6 vitamers in meat. HPLC techniques are the most widely used options for analyzing the various vitamers of B_6 (fluorescence detection). Determination of total B_6 requires hydrolysis: acid hydrolysis with HCl or H_2SO_4 and/or enzymatic hydrolysis (phosphatase or diastase, or an enzyme mixture of α-amylase, papain, and acid phosphatase). The official microbiological method (AOAC 961.15) allows the determination of PN, PL, and PM by using an anion-exchange resin and *Saccharomyces uvarum*.

Possible interconversion among vitamers due to the extraction and/or analytical procedure used, resulting in apparent losses and changes in B_6 vitamer composition, cannot be ruled out. This is the reason why identification of the vitamin B_6 vitamers by HPLC has been shown to be a source of error.

Vitamin B_{12} (Cyanocobalamin)

The predominant forms of cobalamin present in animal tissues include hydroxycobalamin and the two coenzyme forms, methylcobalamin and adenosylcobalamin.

The release of vitamin B_{12} from proteins is generally obtained by heat or protease treatment (pepsin). The addition of sodium cyanide during sample treatment before quantification converts the native vitamin forms into dicyanocobalamin. Vitamin B_{12} compounds are extracted in phosphate buffer containing a reducing agent (metabisulfite or ascorbic acid) to protect the cobalamins throughout extraction.

Generally, for the routine analysis of vitamin B_{12}, a microbiological method (AOAC Official method 952.20) has been used. HPLC methods for the determination of B_{12} have been reported but are less sensitive than the microbiological methods. Other techniques such as radioisotope dilution assay and chemiluminescence analysis have also been used.

Folates

HPLC methods for folate are not yet fully standardized. Poor stability of folates during extraction and the variability in deconjugation are the main problems. HPLC has been applied to the quantification of the main folate forms: tetrahydrofolate and 5-methyltetrahydroflate, using purification by ion-exchange chromatography before HPLC on a C18 column with gradient elution with acetonitrile–phosphate buffer and fluorimetric detection.

Minerals

Wet or dry decomposition procedures are the first step in the method of mineral analysis in meats. Wet digestion with concentrated acids (nitric, perchloric, and sulfuric acid alone or in combination) is the most common sample pretreatment technique, carried out at atmospheric pressure in open systems or at higher pressures in a closed vessel by conductive or microwave heating. Microwave energy has allowed a reduction of digestion time. The main limitations of these procedures are matrix interferences due to the use of concentrated acid in atomic absorption spectrometry (AAS); the formation of highly carcinogenic nitrous vapors; high blank values; the possibility of sample contamination; and long cooling times required before opening the low or high pressure pumps, etc. New sample pretreatment methods such as acid leaching assisted by microwave or ultrasonic bath have been developed. The procedure involves the solubilization of minerals in the leaching solvent (an acid and/or oxidant agent) without sample matrix decomposition. This type of procedure minimizes the main limitations of the wet digestion methods.

Other pretreatments such as enzymatic hydrolysis, consisting of the hydrolysis of proteins or lipids in the sample by using enzymes such as protease, trypsin, pronase, and lipase, and the determination of free mineral after a centrifugation step or the use of slurries represents an alternative to sample digestion before mineral determination. Slurry sampling offers the advantages of the direct solid and liquid sampling methods.

The methods for the determination of minerals are almost all atomic spectrometric techniques, AAS and inductively coupled plasma atomic emission (ICP-AES) or mass spectrometry (ICP-MS) – these being the most reliable options for multielement analyses. The extensive annual literature reviews in the section entitled Atomic Spectrometry Update-Clinical and Biological Materials, Food and Beverages, of the *Journal of Analytical Atomic Spectroscopy*, reflect the major role atomic spectroscopy has played in the development of the current databases on minerals in foods.

In general, iron and zinc may be determined by AAS using flame atomization and deuterium background correction with vaporization in an air-acetylene flame. Flame AAS and ICP-AES provide sufficient detection capability for the quantitation of elements of interest in meat (Fe, Zn, and Mg), and provide good precision over their entire calibration range. The dynamic range for ICP-AES is clearly larger, making the need for sample dilution less likely, and it is less prone to chemical matrix interference due to molecule formation than flame AAS – though there can be problems with spectral line overlaps. Selenium, present in much smaller quantities, is determined by the more sensitive graphite furnace AAS (GF-AAS) technique with Zeeman background correction, or by hydride-generation flameless AAS. ICP-MS is a fast and multielement technique with a wide dynamic range and excellent detection limits for element analysis in meats. The major drawback is that it suffers from spectral and nonspectral interferences.

The determination of phosphorous is the only gravimetric method proposed by the AOAC (969.31). Phosphorous can be precipitated as $Mg_2P_2O_7$. The precipitate is first dried and then ashed in a furnace at 550 °C. The spectrophotometric techniques remain valid for the determination of P and Fe. Fluorimetric methods for determining selenium involve wet digestion, where Se is converted to Se (IV) and determined by measuring the fluorescence of the piazselenol formed on reacting with 2,33-diaminonaphthalene or 3,3′-diaminobenzidine.

Other available techniques such as near infrared spectrometry, neutron activation analysis, and X-ray fluorescence are sufficiently sensitive (with detection limits of $1\,\mu g\,g^{-1}$ for Fe and Zn and $2\,\mu g\,g^{-1}$ for Se), and only very simple sample treatment is needed (drying and grinding to homogenize size, or dried and pelletized meat sample without dissolution). This simplifies the analysis and minimizes the risk of contamination.

Elements can be present in ionic form and/or complexed to various binding proteins. It is of special interest to be able to distinguish or speciate between heme and nonheme iron, because heme iron bound in myoglobin and hemoglobin is more bioavailable than nonheme iron. Several colorimetric methods are able to determine nonheme iron based on reaction with ferrozine or bathophenantroline. Heme iron can be determined by isolation of hematin with acetone-hydrochloric acid and colorimetric measurement. The hyphenated techniques such as size exclusion chromatography (SEC) coupled with ICP-MS have been successfully applied to Cu, Zn, Fe, Mg, among other elements, in liver. A magnetic sector mass spectrometer eliminates polyatomic ion interferences for Fe, S, and P, and provides high sensitivity. Sample preconcentration is not needed. This method generates information on the approximate molecular weight of proteins containing particular elements, without using a standard sample of the same protein. This is one of the advantages of SEC compared to RP-HPLC or ion-exchange chromatography. SEC and reverse phase (RP) chromatography coupled online to ICP-MS to investigate metallothioneins and superoxide

dismutase, Fe, Cu, Zn, and Mn species, has been applied to porcine liver and meats. Speciation of selenium (determination of selenomethionine and selenocysteine) in meats is feasible using SEC and/or ion exchange (IE) coupled to ICP-MS.

Cholesterol

Cholesterol in meat ranges from 50 to 70 mg per 100 g, partly independent of the fat content. Cholesterol can be analyzed routinely by GC-FID without derivatization. However, other methods, especially HPLC coupled to an UV/visible/photodiode array detector, can also be used when nondestructiveness is preferred, especially when cholesterol must be separated from other compounds such as tocopherols. More advanced methods, such as gas chromatography/HPLC-isotope dilution/mass spectrometry, are primarily used for quality control purposes.

Direct saponification with ethanolic KOH solutions at high temperatures has been preferred for hydrolyzing samples because of cost and time effectiveness, and has been shown to be effective in recovering cholesterol and in eliminating fatty acid interference. Nonsaponifiable matter is extracted with different solvents, but toluene seems to provide sufficient recovery in a single extraction – though the formation of an emulsion associated with this solvent is possible, and careful postsaponification manipulation is required. Derivatization with silylating reagents such as hexamethyldisilane has been used to form trimethylsilyl ethers (TMS), and has been applied by several methods, including the AOAC Official Method (994.10). TMS ethers, although allowing for greater sensitivity and a sharper peak shape, potentially cause deposits of silicon dioxide ion in FID, thereby affecting linearity of the FID response. In addition, methods involving derivatization are sensitive to moisture, which can facilitate hydrolysis of the ether derivative and reduce recovery. 5α-Cholestanol behaves like cholesterol during the analysis and is used as an internal standard, which can be added before saponification.

Methods involving direct saponification, smaller sample size, and lesser amounts of toluene for extraction compared with the AOAC method, and analysis of free cholesterol, without derivatization, have been applied. In this case, emulsification may occur during the purification process. The addition of ethanol, KOH, and water in subsequent steps of the cleanup is usually required.

Total sterols can be determined by an enzymatic method after saponification. Sterols are oxidized with cholesterol oxidase to stenones, with the release of hydrogen peroxide, which oxidizes methanol to formaldehyde in the presence of catalase. Formaldehyde reacts with acetyl acetone to form a yellow compound, which can be measured colorimetrically at a wavelength of 405 nm. The reagents can be acquired as a kit. The method works well if only cholesterol is present, as is the case for meat; however, if both plant sterols and cholesterol are present, the results will be difficult to interpret.

Enzymes

This section is only focused on muscle proteolytic enzymes, which constitute a group of enzymes involved in protein metabolism and thus affecting muscle growth processes in the living animals as well as the proteolysis phenomena during conversion of muscle to meat. These enzymes are also deeply involved in changes in quality during postmortem storage and further processing, especially in those related to fermented and dry-cured meat products. The most studied enzymes are the endopeptidases mainly consisting of the calpain system and cathepsins. The assays for their respective activities are briefly described below.

Calpain is an intracellular calcium-dependent cysteine endopeptidase. The two most commonly analyzed isoforms in meat are μ-calpain and m-calpain, which have been found in the range 10–100 μg g^{-1} of muscle. The calpain inhibitor calpastatin is also present in the muscle and extracted together with calpains making necessary its further purification previous to the assay. Usually either phenyl-Sepharose or butyl-Sepharose chromatography is used to remove calpastatin, followed by anion-exchange chromatography (diethylaminoethyl-Sepharose, or Mono Q fast protein LC) to separate μ- and m-calpain. A faster one-step procedure using only anion-exchange chromatography is also used, but incomplete separation of the μ-calpain fraction from calpastatin is often a problem. Casein is the classical substrate used for *in vitro* assays of calpain. Casein is cleaved by calpain during incubation at 25 °C and pH 7.5 in the presence of $CaCl_2$, and the remaining intact protein is precipitated by adding trichloroacetic acid. Subsequent to centrifugation, the absorbance of the supernatant containing the released peptides is measured at 278 nm. More sensitive assays are based on the use of fluorescent substrates like casein-fluorescein isothiocyanate at pH 7.5. The enzyme reaction is started by the addition of $CaCl_2$ and incubation at 25 °C for 20 min. Again, the remaining intact protein is precipitated by adding trichloroacetic acid and, subsequent to centrifugation, the fluorescence is measured at 485 nm and 538 nm of excitation and emission wavelengths, respectively. One unit of activity is defined as the amount of enzyme capable of hydrolyzing 1 mmol of substrate per hour at 25 °C.

Alternatively, calpain activity can be determined by casein zymography. Casein is incorporated in separating gels, and calpain extracts are loaded onto the gels that are run under denaturing conditions. After electrophoresis, calcium and a reducing agent are added to activate calpain, and the casein-gels are incubated for 16 h at 25 °C. After staining with Coomassie blue, the calpain activity will appear as a clear band in the dark blue gel corresponding to casein depletion (digested into peptides that have diffused out of the gel). Quantification can be done by expressing the density of the bands relative to the density of reference standards within each gel.

Muscle also contains other endopeptidases like cathepsins that are located in the lysosomes with a high hydrolytic potential. Main cathepsins are B, H, and L (cysteine) and D (aspartic) and are active in acid conditions. In meat, cathepsin activity is controlled by several factors including release from lysosomes, pH, extent of precursor activation, and specific endogenous inhibitors (cystatins). The activity of these enzymes can be assayed after a gentle homogenization procedure. Total lysosomal enzyme activities in meat extracts can be determined by extraction and homogenization at pH 5.0 in the presence of Triton X-100. The activity of cathepsin D can

be typically determined at pH 4.5 and 45 °C, using 10% w/v hemoglobin as substrate. The activity of cathepsins B, B+L, and H has been determined following isolation from their physiological inhibitors, cystatins, by affinity chromatography. The activity of cathepsins B, B+L, and H is usually determined at 37 °C and pH 6.0 for cathepsins B and B+L, and pH 6.8 for cathepsin H. Specific fluorescent substrates are used, *Z*-arginine–arginine-7-amido-4-methylcoumarin for cathepsin B, *Z*-phenylalanine–arginine-7-amido-4-methylcoumarin for cathepsin B+L, and *Z*-arginine-7-amido-4-methylcoumarin for cathepsin H. Once the reaction is stopped, the released fluorescence is measured at 380 nm and 440 nm of excitation and emission wavelengths, respectively. One unit of activity is defined as the amount of enzyme capable of hydrolyzing 1 μmol of substrate per minute at 37 °C.

The 20S proteasome is a muscle enzyme exerting endo- and exopeptidase activity and has been associated with the degradation of damaged oxidized proteins. This enzyme shows five main catalytic activities: trypsin-like, chymotrypsin-like, peptidyl–glutamyl peptide hydrolase, branched-chain amino acid-preferring, and small neutral amino acid-preferring, which hydrolyze synthetic peptides at the carboxyl group of alkaline, hydrophobic, acid, branched-chain, and neutral amino acids, respectively. The activity can be assayed with fluorescent substrates after extraction and homogenization at pH 8 in the presence of glycerol, ethylenediaminetetraacetic acid (EDTA), ethylene glycol tetraacetic acid (EGTA), and inhibitors E64 and pepstatin A. The activity can be determined with leucine–serine–threonine–arginine-4-methyl-coumarin-7 amide, *N*-Suc-leucine–leucine–valine–tyrosine-4-methyl-coumarin-7 amide, or 100 mmol l^{-1} benzyloxycarbonyl-leusine–leusine–glutamic acid-2-naphthylamide to measure trypsin-like, chymotrypsin-like, and peptidyl–glutamyl peptide hydrolase activities, respectively.

Glossary

Calibration standard A device for measurements that represents the quantity of substance of interest in a way that ties its value to a reference base.
Confirmatory method A method that provides full or complementary information enabling the substance to be unequivocally identified and quantified at the level of interest.
Decision limit (CCα) The limit at and above which it can be concluded with an error probability of α that a sample is non compliant.
Detection capability (CCβ) The smallest content of the substance that may be detected, identified, and/or quantified in a sample with an error probability of β. In the case of substances for which no permitted limit has been established, the detection capability is the lowest concentration at which a method is able to detect truly contaminated samples with a statistical certainty of $1 - \beta$. In the case of substances with an established permitted limit, this means that the detection capability is the concentration at which the method is able to detect permitted limit concentrations with a statistical certainty of $1 - \beta$.
Fortified sample material A sample enriched with a known amount of the analyte to be detected.
Interlaboratory study Evaluation of tests on the same sample by two or more laboratories in accordance with predetermined conditions to determine testing performance.
Internal Standard (IS) A substance not contained in the sample with physical-chemical properties as similar as possible to those of the analyte that has to be identified and which is added to each sample at a known concentration.
Laboratory sample A sample prepared for sending to a laboratory and intended for inspection or testing.
Level of interest The concentration of a substance or an analyte in a sample that is significant to determine its compliance with legislation.
Recovery True concentration of a substance recovered during the analytical procedure and expressed as a percentage.
Ruggedness Susceptibility of an analytical method to changes in experimental conditions.
Screening methods Methods that are used to detect the presence of a substance or class of substances at the level of interest. Generally are high throughput methods.
Specificity The ability of a method to distinguish between the analyte of interest being measured and other substances that may have similar physicochemical properties.

Introduction

There are many veterinary drugs that may be used in farm animals either for prophylactic purposes or to promote growth, to improve the distribution of fat and protein, and to increase feed-to-muscle conversion rate. After the administration of these veterinary drugs some residues may remain in the tissues at toxicologically unacceptable concentrations.

International and national legal bodies agreed for the so-called maximum residue limits (MRLs) for substances allowed for veterinary use. So, MRLs for specific veterinary drugs are derived from acceptable respective daily intakes from foods of animal origin. The MRLs should ensure that even in extreme consumption patterns, consumers are at an acceptable or nil health risk toward the intake of residues of certain veterinary drugs. There are no MRLs for banned drugs, including carcinogenic substances, because their residues are not tolerated at any concentration in food products. The national MRLs may be different from country to country probably due to differences in the level of risk that individual governments are prepared to accept and the methodologies for establishing MRLs.

Recent multiple outbreaks of residue-contaminated food products have scared consumers and increased the public's awareness of the use of veterinary drugs in the food chain. Furthermore, some of these residues may also exert carcinogenic, genotoxic, or other undesirable effects on health. So, the potential presence of residues in meat and poultry must be controlled to assure consumers' safety. This article is reporting the analytical procedure for the detection of residues in farm animals and meat.

Sample Preparation

Sampling

The concentrations of residues in foods of animal origin may be quite variable depending on the type of drug used, the type of administration, and the washout time left before slaughtering. Larger concentrations may be found near the injection site but also some substances may concentrate in certain organs. It is very important to select the appropriate target tissue or matrix where the analyte is expected to accumulate (e.g., liver, kidney, urine) because the concentrations are low and need very sensitive techniques for their detection. This is even worse when certain types of cocktails, prepared as a

mixture of low amounts of different growth-promoting substances with synergistic effect, are used. The same biological effect is obtained but making it rather difficult for the detection of the individual components because of their low individual concentrations. The sample must be chosen so that the result reflects the residue status of the laboratory sample and thus that of the sampled tissue or body fluid. Portioning of the laboratory sample, either at the sample collection site or in the laboratory, should always be considered to prevent unnecessary freeze–thaw cycles affecting residue integrity and allowing the possibility of further analysis in case of doubtful results or any other analytical problem.

Sample Storage and Sample Pretreatment

Sample storage is very important because sometimes the time elapsed between sample collection and analysis may be long. Depending on the postmortem processing of the sample and its storage, some reactions may convert the original residue into (unknown) derivatives. The residue may be object of physicochemical reactions like oxidation, proteolysis, or precipitation, even being covalently linked to proteins, making necessary the cleavage of such links for an adequate extraction. Residues may also be degraded by microbiological or enzymatic reactions. For instance, carbadox and chloramphenicol are susceptible to cytochrome P-450 degradation in liver and kidney samples, even during storage at −20 °C, but this degradation may be inhibited by adding piperonyl butoxide.

Sample Extraction

The target analyte is usually the parent residue molecule but its metabolites should also be considered. In all the cases, residues may be extracted with aqueous buffers or organic solvents. It must be taken into account that many veterinary drugs, including oestradiol, chloramphenicol, levamisole, and phenolic-type β-agonists like salbutamol, are present as conjugate forms (glucuronide or sulfate), as a way of detoxification, usually excreted through the urine. When analyzing such types of residues and before residue determination, it is necessary to hydrolyze the sample under mild conditions, usually achieved by incubating with *Helix pomatia* juice, which is a mixture of arylsulfatases and β-glucuronidases or any other hydrolysis procedure. Residues bound to proteins through weak interactions can be extracted after heat or acid treatments.

Solid matrices, including fat, kidney, liver, retina, and skin, are usually extracted by homogenization of the sample in the presence of solvents. Waring blenders, Ultra-Turrax, glass grinders, and stomachers can be used for homogenization; of course, heating of the sample must be avoided to preserve the integrity of the analyte. Sometimes, the sample can be grounded in liquid nitrogen. A cleanup of the sample is necessary to remove any matrix components that might be coextracted. The solid–phase extraction (SPE) is extensively used because the analyte can be concentrated in a single step with minimal sample and solvent consumption compared with the classic liquid–liquid extraction. There are many available stationary phases in SPE that facilitate the choice of the better phase for each particular analyte. SPE cartridges have evolved into miniaturized columns integrated in microwell assay plates and into disks consisting of membranes with high, reversed-, and ion exchange phase capacity.

An advanced extraction procedure can be obtained with immunoaffinity cartridges (IACs) that contain a support with linked antibodies for the specific target analyte that facilitates the affinity extraction with a high degree of specificity. An enormous concentration can be reached in a single step. The sensitivity is significantly increased even though these cartridges are expensive. IACs are commercially available for a number of residues, particularly of banned substances. Molecularly imprinted polymers (MIPs) are another alternative. MIPs can be synthesized from highly cross-linked polymers in the presence of the print molecule (a variant of the analyte). Removal of the print molecule leaves an imprinted sorbent for highly selective extraction of the analyte.

The so-called matrix solid-phase dispersion approach consists of simultaneous homogenization and extraction, which is accomplished by mixing the sorbent material in the homogenate and thus omitting liquid extraction of the homogenate as a separate step. The bonded reversed phase may act in this case as a surfactant and may help in unfolding and disrupting cellular structures to release contained residues. Columns prepared from the sample/sorbent mixture are eluted in a similar way to SPE cartridges.

Microwave-assisted extraction allows the rapid heating of the solvent, which accelerates the extraction by reducing the needed time and consuming less solvent. It also facilitates a high throughput. Supercritical fluid extraction has also been used as a suitable alternative to solvent extraction for lipophilic substances such as androgens, gestagens, and oestrogens, from a variety of matrices. Carbon dioxide is the most used fluid because it acquires physical properties intermediate between those of the liquid and gas phases at a certain combination of temperature and pressure. More recently, pressured liquid extraction is being used because a fast and efficient extraction of the analyte from the solid matrix is obtained. The solvent is kept in the liquid phase at temperatures above the boiling point by applying high pressure.

Following extraction, the analyte-containing solution is concentrated by removing the excess of solvent either by evaporation or sublimation. This can be achieved either by applying a vacuum or by using a flow of an inert gas (nitrogen), sometimes in combination with mild heating.

Analytical Methodologies

Analysis strategies are very important considering the wide variety of residues to be analyzed and the large number of samples, usually with results requested in a short period of time. Consequently, the initial phase consists of using low-cost screening methods with high throughput, acceptable false positive incidence and a very low false negative rate, are used. For those samples suspected to be noncompliant, the next phase consists of the use of confirmatory methods usually involving expensive instrumental techniques, almost exclusively based on mass spectrometry detection, and requiring highly skilled operators.

The samples that contain a residue at a concentration above the detection limit (CCα) (see section validation) within the EU, are considered as noncompliant (positive). A sample containing a substance with an MRL will be considered as noncompliant when the concentration of the target residue is found to be in excess of its MRL.

Screening Methods

There are different types of screening methods depending on the type of residues. The main types of screening techniques are listed in Table 1. So, residues of antimicrobial drugs can be screened with microbiological growth-inhibition assays like the European Union (EU) Four Plate Test, the New Dutch Kidney Test, and the Delvotest SP, which use antibiotic-sensitive bacterial reporter strains such as *Bacillus subtilis* and *Bacillus stearothermophilus* var. *calidolactis*. These bacteria are inoculated under optimal conditions with and without sample. After culturing, results are read from visible inhibition zones or color change of the bacterial suspension in agar gels.

The availability of relatively large amounts of immunoglobulins, for example, polyclonal antibodies or monoclonal antibodies, recombinant antibodies, or antiidiotype antibodies, of which the production is assured, has enabled the development of a range of immunoassays for many types of growth promoters and antimicrobials. These methods include radioimmunoassays, enzyme immunoassays, enzyme-linked immunosorbent assays, strip- and dip stick-based immunoassays. These methodologies have been expanded in the range of residues to detect and the sensitivity and have also developed for high throughput. Some commercial instruments include the CHARM Test II and Penzyme III.

Other types of screening methods are based on the detection of an interaction between biomolecule and analyte, not requiring any labeling. These biosensors allow realtime monitoring of the analyte immunoglobulin–receptor interaction. Commercial instruments include the surface plasmon resonance biosensors.

Finally, liquid chromatography (HPLC) and more recently ultra performance liquid chromatography (UPLC) are also used for the screening of multiple residues in a sample in a relatively short time, especially with the advent of new types of columns. Analytes that are not detected by light absorption or fluorescence at the level they are expected to occur in samples may require derivatization to render them active as fluorescents, chromophores, or UV-light absorbing compounds.

Confirmatory Methods

When samples are suspected to be noncompliant, the next phase consists of the use of confirmatory methods. It should be noted here that the use of an internal standard should be considered, to allow continuous assessment of the performance of the designed assay, and to facilitate calibration in quantitative determinations. Mass spectrometry is the most reliable for such confirmatory purposes especially when coupled to gas chromatography (GC) or liquid chromatography (LC). The main techniques are listed in Table 1 and major advantages and disadvantages of confirmatory methods are summarized in Table 2.

In GC analysis, the universality and discriminative power of the mass spectrometer (MS) in combination with electron-impact ionization have led to this being the method of choice for some residues like steroids.

In LC analysis, the evolution of mass selectors, ionization techniques and the available interfaces between them, have made mass spectrometry the standard equipment in a residue analysis laboratory. Mass selectors comprise triple quadropole,

Table 1 List of main analytical techniques available for screening and confirmatory purposes

Screening methods	*Confirmatory methods*
Microbiological plates bioassays	Gas chromatography coupled to MS, MS–MS, or MS^n
Dipsticks or enzyme-linked immunosorbent assays test kits	Liquid chromatography (HPLC) coupled to MS, MS–MS, or MS^n
Radioimmunoassay	Ultra performance liquid chromatography (UPLC) coupled to MS, MS–MS, or MS^n
Multiarray biosensors	HPLC or UPLC coupled to time-of-flight
High performance thin layer chromatography with full scan UV/Vis	HPLC or Gas chromatography coupled to Infrared (IR) spectrometric detector
Gas chromatography coupled to electron capture detector	
HPLC coupled to ultraviolet/visible (UV/Vis), diode array detector (DAD) or fluorescence detector	
UPLC coupled to UV/Vis, DAD or fluorescence detector	

Table 2 Major advantages and disadvantages of current confirmatory methods

Advantages	*Disadvantages*
High sensitivity	Need of sample preparation (extraction and purification)
High specificity	
Lot of information about the analyte	High initial investment (equipment)
Short time (few min/sample) to obtain the results	High maintenance costs
Screening and confirmation in one injection	Expertise required

Table 3 Some examples of the number of identification points earned for different analytical techniques

Technique	*Number of ions*	*Identification points*[a]
GC–MS Electron impact (EI) and Chemical ionization (CI)	2 EI and 2 CI	4
GC–MS EI or CI	N	n
LC–MS	N	n
GC–MS–MS	1 Precursor and 2 daughters	4
LC–MS–MS	1 Precursor and 2 daughters	4
GC–MS–MS	2 Precursor ions each with 1 daughter	5
LC–MS–MS–MS	1 Precursor, 1 daughter, and 2 granddaughters	5.5

[a]1 point per precursor and 1.5 points per daughter or granddaughter.

Source: Commission Decision of 12 August 2002 implementing Council Directive 96/23/EC concerning the performance of analytical methods and the interpretation of results. Official Journal of the European Communities of 17/8/2002, L221, 8–36.

ion trap, time-of-flight instruments and combinations thereof. In particular, the mild ionization techniques of atmospheric pressure chemical and electrospray ionization, combined with their suitability for interfacing with HPLC, have enabled MS analysis of both hydrophobic and hydrophilic molecules ranging from relatively small to large. In addition, MS-induced molecular fragmentation allows elucidation of the chemical structure of the residue. A major drawback is matrix-caused interference of the ionization process, which may reduce analyte signals dramatically.

Validation

Regulatory action can be taken only after unequivocal identification of the residue. The European Commission, for example, released the Decision 2002/657/EC, which describes the required quality performance criteria and guidelines for the interpretation of analytical results as well as validation of the methods. Other international organizations like International Organization for Standardization (ISO), International Union of Pure and Applied Chemistry (IUPAC), Association of Official Analytical Chemists (AOAC) International have issued similar criteria and recommendations. This Decision also includes the CCα, which is defined as the limit at and above which it can be concluded with an error probability of α that a sample is noncompliant and the detection capability (CCβ), which is defined as the smallest content of the substance that may be detected, identified, and/or quantified in a sample with an error probability of β.

Topics that have to be assessed are trueness and precision of the result, and specificity and selectivity of the method. Variables that may influence the measurement, such as minor changes in pH, evaporation conditions, temperatures, SPE flow rate, time intervals, and the use of different SPE batches or of different producers, have to be evaluated to establish the ruggedness of the method. The validation of analytical methods is largely based on the fortification of control samples with a known quantity of the analyte. Although fortification is a well-established procedure, it has to be recognized that the added analyte may be more available for extraction than its incurred counterparts. In addition, fortification and incubation time following the addition will most likely not imitate metabolic processes, including conjugation and formation of bound residues. Finally, the Decision 2002/657/EC also establishes the need to accomplish a number of the so-called identification points (IPs) for the correct identification of the residue substance. Examples of the number of IPs earned when using different techniques are shown in **Table 3**. At least three IPs should be obtained for a satisfactory detection of a substance with an MRL, whereas four IPs are needed for positive identification of banned substances.

Future Trends in Residue Analysis

Sensitivity and selectivity will continue to improve thanks to the rapid developments in analytical instrumentation, especially in computerization and miniaturization so that levels of detection will drop to very low ultratrace levels.

The time required per analysis will be reduced thanks to new columns, packing materials, elution conditions, and instrumental devices. The trends toward high throughput techniques will continue so that more multiresidue methods will be developed with more analytes per sample to be analyzed per unit of time.

Biosensor systems, with microchips containing antibodies against many different analytes in one single chip that requires only a few microliters of sample, are attracting particular attention for such applications.

Glossary

Conjugated linoleic acid (CLA) Fatty acids containing two double bonds, typically as 1,3-dienes with one double bond in the *cis*-configuration and one double bond in the *trans*-configuration, although some CLA isomers contain two *trans*-double bonds.

Monounsaturated fatty acids (MUFAs) Fatty acids, typically with the double bond in the delta-9 position in the *cis*-configuration.

Polyunsaturated fatty acids (PUFAs) Fatty acids containing at least two double bonds as 1,4-dienes with all double bonds in the *cis*-configuration.

Saturated fatty acids (SFAs) Fatty acids containing no double bonds, with relatively high melting points.

Stearoyl-CoA desaturase Delta-9 fatty acid desaturase that converts saturated fatty acids to monounsaturated fatty acids.

Thiazolidinediones A synthetic compounds that stimulate the differentiation and lipid filling of adipocytes.

Introduction

Fat (or lipid) contributes substantially to the caloric content of meat. This is especially true in the US, where total fat content can be as high as 30% in ground beef and 40% in some sausages. However, recent studies have indicated that ground beef produced from grain-fed cattle in the US is high in monounsaturated fatty acids (MUFAs) and actually may have important health benefits. It also has marked effects on mouthfeel and flavor of meat, which are primary components of palatability. For beef, the level of lipid in meat necessary to achieve consumer acceptance is between 3% and 7.5% (uncooked basis; Figure 1). The amount of fat and fatty acid composition both influence palatability. Additionally, the kinds of fatty acids present in meat and its cholesterol content influence the perceived healthfulness of meat. The location and composition of lipids within meat will be discussed, with particular emphasis on the adipose tissues associated with meat.

The composition of lipids in adipose tissues of meat varies in response to diet and the time at which the lipids are deposited. The fatty acid composition of pork is especially sensitive to dietary manipulation, whereas that of beef and lamb is affected primarily by the age of the animal and is modified by dietary means, particularly by feeding pastures as compared to grains. The cholesterol content of meat generally is resistant to dietary modification, except that any means of increasing the amount of intramuscular neutral lipids will ultimately cause small, incremental increases in cholesterol concentration.

Sources of Lipid in Meat

Although abdominal adipose tissues (kidney, pelvic, and heart fat; and omental fat) represent a large percentage of total body fat in livestock and poultry, they will not be included in this discussion because they are not associated with typical meat cuts. Furthermore, kidney, pelvic, and heart fat clearly originate as brown adipose tissue in sheep and cattle and, therefore, may represent a metabolically distinct adipose tissue depot.

 doi:10.1016/B978-0-12-384731-7.00089-1

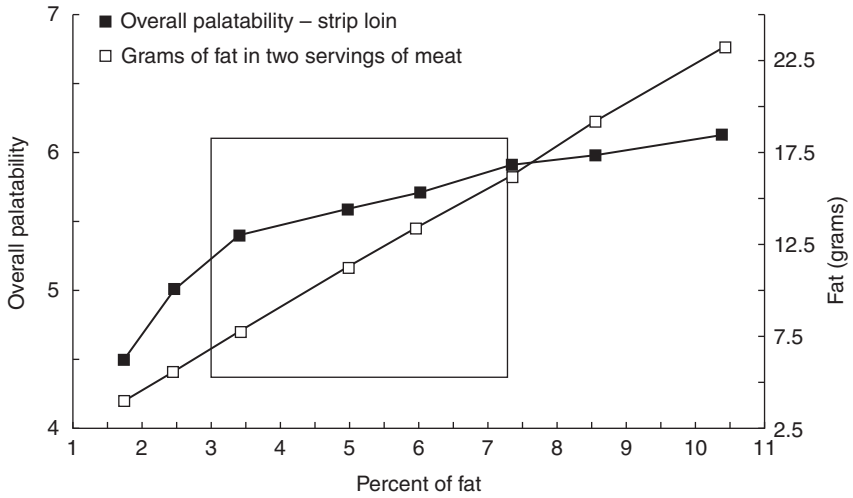

Figure 1 Window of acceptability for fat content of meat (palatability vs. grams of fat, two servings. The window is based on a fat content range of 3.0–7.5%, which is equivalent to the range for beef from the M. longissimus dorsi (12th–13th rib) that grades in the lower range of United States Department of Agriculture (USDA). Select (3.0–4.27% fat content) and that which grades in the high range of USDA Choice (4.28–8.0% fat content). Reproduced from Savell, J.W., Cross, H.R., 1988. The role of fat in the palatability of beef, pork, and lamb. Designing Foods: Animal Product Options in the Marketplace. Washington, DC: National Research Council, pp. 345–355.

There are thus four sources of lipid in meat: the muscle fibers, subcutaneous adipose tissue, intermuscular (seam) adipose tissue between muscle groups, and intramuscular (interfascicular, marbling, and i.m.) adipose tissue (Figure 2; intermuscular adipose tissue is not indicated). Most whole cuts of beef in the marketplace now are closely trimmed of subcutaneous and intermuscular adipose tissue, but processed meat products such as ground beef and sausage can contain significant amounts of fat trim. Several countries, such as Japan and Korea, place a premium on soft beef fat, as do countries like Australia that export to these countries. In these countries, softness of the fat has a substantial impact on the value of beef. Fat softness in beef produced in Japan and Korea is achieved by an unusually high enrichment with MUFAs, whereas fat hardness in pasture-fed beef is the result of elevated levels of saturated fatty acids (SFAs). These issues will be addressed later.

Once subcutaneous and intermuscular fat have been removed, the primary contributor to the lipid content of meat is i.m. adipose tissue. Very lean beef, pork, or lamb, in which all subcutaneous and intermuscular adipose tissues have been removed, contain approximately 1% extractable lipid. At the other extreme, closely trimmed beef from Japanese Black (or Wagyu) cattle can contain more than 35% extractable lipid. This extraordinary concentration of lipid can be attributed solely to lipid in i.m. adipose tissue.

Intramuscular adipose tissue has several metabolic features that distinguish it from other depots. Intramuscular adipocytes typically display rates of fatty acid biosynthesis that are 5–10% of the rates observed in subcutaneous (s.c.) adipose tissue, and i.m. adipocytes are smaller (25–50 μm diameter) than s.c. adipocytes (100 μm to as much as 500 μm diameter) in beef and pork. Triacylglycerol biosynthesis from most fatty acids also occurs at lower rates in i.m. than in s.c. adipose tissue. However,

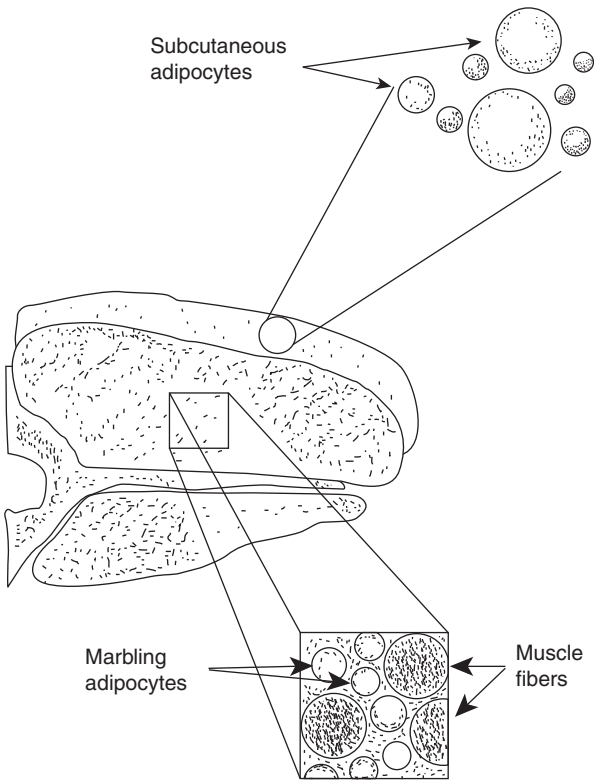

Figure 2 Sources of lipid in meat. Subcutaneous adipose tissue and intermuscular (seam) adipose tissue (not shown) contribute as much as 30% to the total lipid content of meat. Lipid associated with muscle fibers contributes approximately 1%, whereas intramuscular adipose tissue (marbling) can contribute from less than 1% to more than 35% of the lipid in meat in certain breeds of cattle.

i.m. adipose tissue incorporates palmitic acid into triacylglycerols at rates that exceed those in s.c. adipose tissue. Finally, glucose contributes a greater proportion of carbon to *de novo* fatty acid biosynthesis in intramuscular than in subcutaneous adipose tissue. Thus, the metabolic evidence indicates that intramuscular and subcutaneous adipose tissues are distinct.

Lipid Accumulation in Adipose Tissue

The accumulation of specific fatty acids in adipose tissue is regulated by the stage of differentiation of adipocytes. Preadipocytes first proliferate, followed by induction of the genes responsible for lipid filling. Thus, both the apparent number of adipocytes and the size of adipocytes increase with animal growth. In the case of intramuscular adipose tissue, adipocytes initially are visible as linear strings of small, lipid-filled cells embedded in perimyseal adipose tissue (Figure 3(a)). Adipocytes from cattle after 4 months of grazing on pasture do not enlarge measurably, nor does their apparent number increase (Figure 3(b)). In cattle after being fed a grain-based finishing diet, both the size and apparent number of adipocytes increase substantially (Figures 3(c) and (d)).

Initial lipid filling is characterized by the appearance of small lipid droplets (Figure 4). Although quite apparent in preadipocyte cell culture, this multilocular stage is difficult to detect *in situ* in growing animals. Lipid droplets coalesce as adipocytes enlarge, leading to the unilocular adipocytes characteristic of mature adipose tissue. There is evidence to indicate that preadipocytes within tissue beds of livestock species can proliferate even after accumulation of some lipid. The result is that in meat-bearing animals both processes – proliferation and lipid filling – are occurring concurrently.

Fatty Acid Composition of Subcutaneous, Intramuscular, and Muscle Lipids

Differentiation of preadipocytes is characterized by the expression of genes, such as those encoding stearoyl-coenzyme A desaturase (SCD, a delta 9 desaturase), and enzymes that support *de novo* fatty acid biosynthesis. Early in their differentiation, lipid-filling preadipocytes typically contain high concentrations of SFAs such as palmitic acid (16:0) and stearic acid (18:0), and concomitantly low concentrations of their delta 9 desaturase products, palmitoleic acid (16:1n-7) and oleic acid (18:1n-9). Treatment of bovine preadipocytes with insulin and thiazolidenediones, such as pioglitizone, markedly stimulate SCD differentiation (Figure 5(a)), which promotes lipid filling and increases the concentration of MUFAs in the cells. This can be depressed by concurrently treating the preadipocytes with *trans*-10, *cis*-12 CLA, which strongly inhibits SCD gene expression (Figure 5(b)).

Palmitic acid is produced by the combined activities of acetyl-coenzyme A carboxylase and fatty acid synthase, whereas stearic acid is produced by the addition of two carbons to palmitic acid via fatty acid elongase. Palmitoleic and

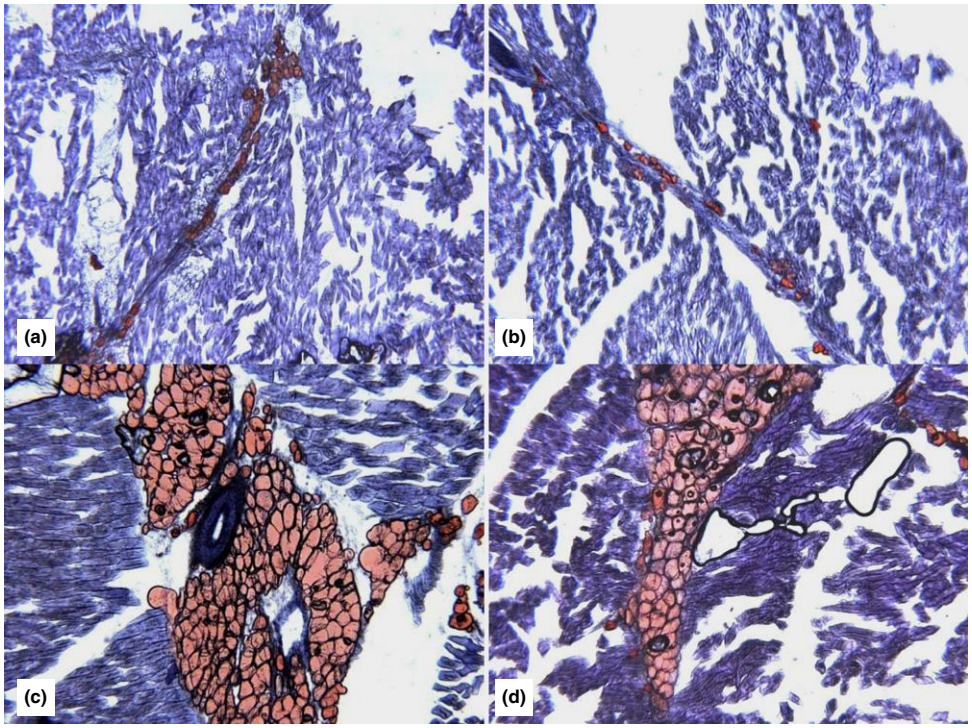

Figure 3 Intramuscular adipocyte development in M. longissimus thoracis of Angus steers. Cells were stained with Oil Red O to stain adipocytes and hematoxylin solution to stain for nuclei. (a) Sample taken at weaning (8 mo of age). (b) Sample taken after 4 mo on native Texas pasture (12 mo of age). (c) Sample taken in steers fed a corn-based, grain finishing diet for 4 mo after weaning (12 mo of age). (d) Sample taken in steers fed a corn-based, grain finishing diet for 4 mo after grazing native pasture for 4 mo (16 mo of age). Intramuscular adipocytes are visible as thin threads of adipocytes (a and b) or as clusters of roughly spherical adipocytes (c and d). Magnification approximately ×100.

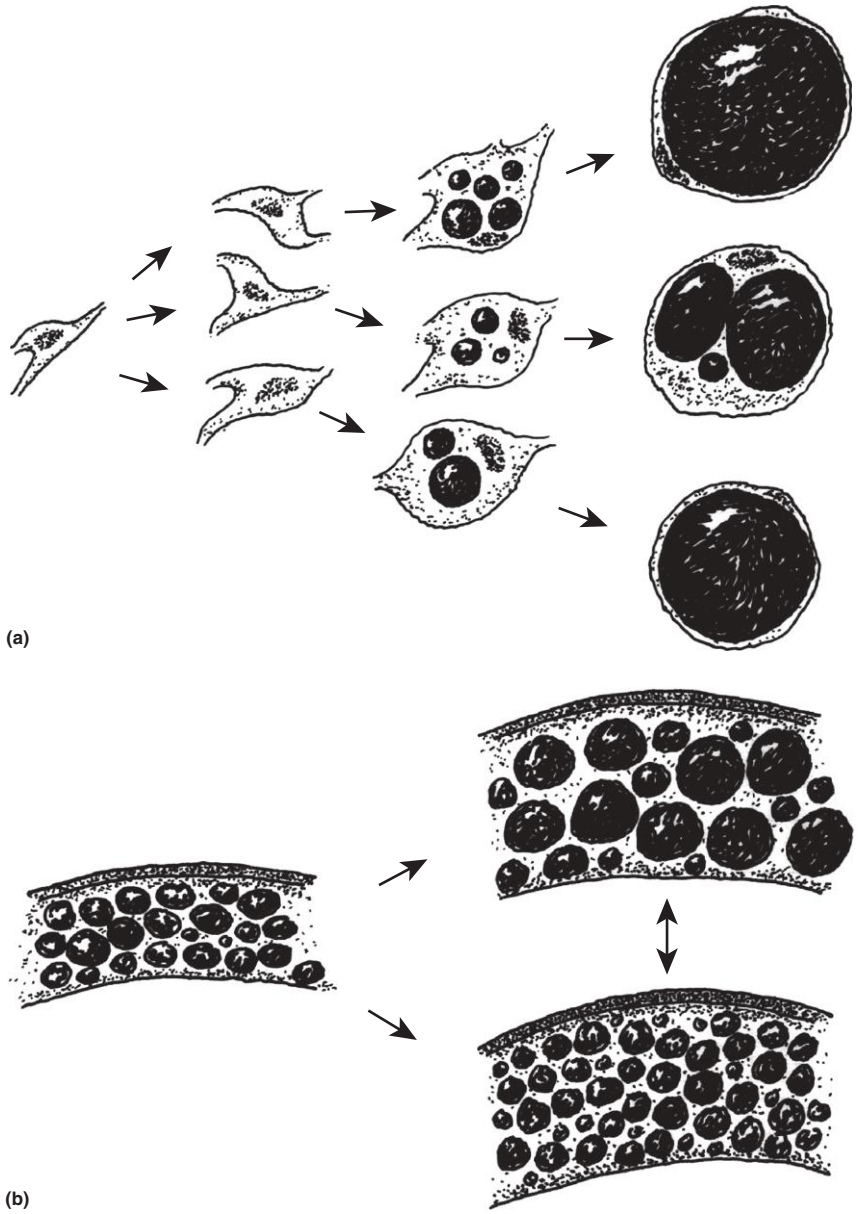

Figure 4 (a) Accumulation of lipid during preadipocyte differentiation and postnatal growth. After a series of proliferative divisions, preadipocytes begin to accumulate lipid (i.e., differentiate). In most species, this lipid arises primarily from *de novo* fatty acid biosynthesis, so it is composed primarily of palmitic, palmitoleic, stearic, and oleic fatty acids. (b) Postnatally, depots such as subcutaneous adipose tissue accumulate lipid in response to hypertrophy of adipocytes (upper right portion of figure), or by preadipocyte proliferation (lower right portion of figure), or by a combination of both processes (indicated by the double-headed arrow). The fatty acid composition of these adipocytes will be determined by *de novo* synthesis and by the composition of dietary lipids. This is especially true for monogastrics such as pigs.

oleic acid are the products of the delta 9 desaturation of palmitic acid and stearic acid, respectively, catalyzed by SCD. The activities of acetyl-coenzyme A carboxylase, fatty acid synthase, fatty acid elongase, and SCD persist at varying levels in adipose tissues throughout the life of the animal. For this reason, palmitic, palmitoleic, stearic, and oleic acids are always present in adipose tissues of animals. Relative concentrations of each are dictated primarily by the activity of SCD and availability of unsaturated fatty acids in the diet. The unsaturated fatty acids typically consumed by livestock species include oleic acid and the polyunsaturated fatty acids linoleic acid (18:2n-6) and α-linolenic acid (18:2n-3).

The MUFA:SFA ratio increases with time on a grain-based finishing diet in subcutaneous adipose tissue of postweaning calves (Figure 6). The MUFA:SFA ratio does not increase in calves grazing pasture, although there is a sharp increase in the concentration of MUFA in subcutaneous adipose tissue once the cattle are adapted to a grain-based diet. The net

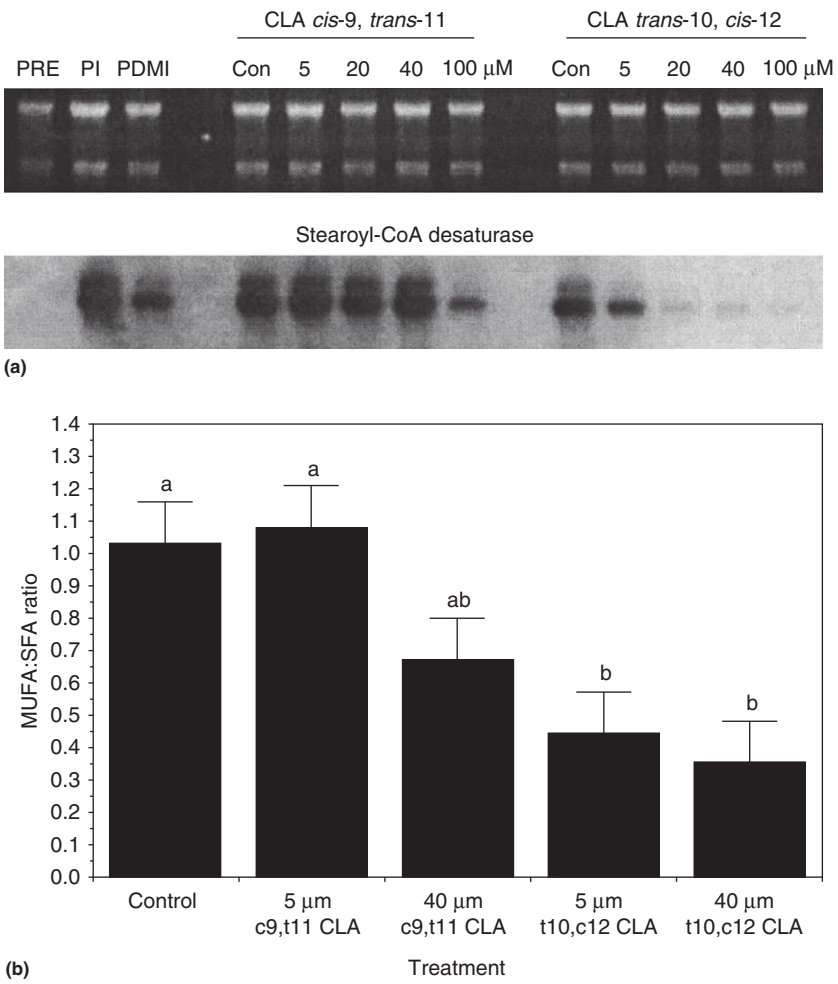

Figure 5 SCD gene expression and MUFA in bovine preadipocytes. (a) SCD gene expression in preconfluent bovine preadipocytes (PRE); in preadipocytes incubated with pioglitizone, insulin and holo-transferrin (PIM); in preadipocytes incubated with PIM plus dexamethasone (PDMI). Preadipocytes were cultured for 7 days PIM or PDMI, followed by 3 days of treatment with *cis*-9, *trans*-11 CLA or with *trans*-10, *cis*-12 CLA. (b) MUFA:SFA ratio of lipids from control preadipocytes and preadipocytes treated with 5 or 40 μM *cis*-9, *trans*-11 CLA or 5 or 40 μM *trans*-10, *cis*-12 CLA, MUFA = 16:1+18:1n-9+*cis*-9, *trans*-11 CLA; SFA = 14:0+16:0+18:0+18:1*trans*-11. Lipids were extracted from 7-day differentiated preadipocytes, followed by 3 days of treatment with the CLA isomers. [ab]Means with common superscripts are not different ($P > .05$).

accumulation of MUFAs apparently persists throughout the lifetime of livestock species in the US.

As seen for i.m. adipose tissue development, the MUFA:SFA ratio does not increase in pasture-fed cattle (Figure 6) and may actually be depressed by pasture feeding. Saturated fatty acids, especially stearic acid, accumulate in adipose tissues of pasture-fed cattle. Once the cattle begin consuming a grain-based diet, the MUFA:SFA ratio increases, although i.m. adipose tissue remains relatively higher in saturated fatty acids than s.c. adipose tissue. This may indicate that i.m. adipose tissue remains less differentiated than s.c. adipose tissue throughout production.

Lipid Accumulation in Meat

Fatty acids in adipose tissue are stored primarily as triacylglycerols (Figure 7), which coalesce in the large lipid vacuoles that are the central feature of adipocytes. The longissimus muscle of cattle produced in the US can accumulate at most approximately 11% i.m. lipid, primarily as triacylglycerols. For the US grading system, this represents carcasses that grade Prime, with Moderately Abundant marbling scores (Figure 8). Thus, i.m. adipocytes would provide the greatest amount of fatty acids in meat.

The most abundant fatty acids in i.m. adipose tissue of beef and pork are palmitic, stearic, oleic, and linoleic acids (Figures 9 and 10). As indicated previously, the first three of these fatty acids are derived from endogenous synthesis of fatty acids, whereas linoleic acid is derived from plant materials included in the diet.

The contribution of both *de novo* fatty acid synthesis and fatty acid desaturation to the fatty acid composition of adipose tissues is especially apparent in bovine adipose tissues (Figure 9). Stearic acid constitutes more than 80% of the fatty acids available for absorption from the duodenum in

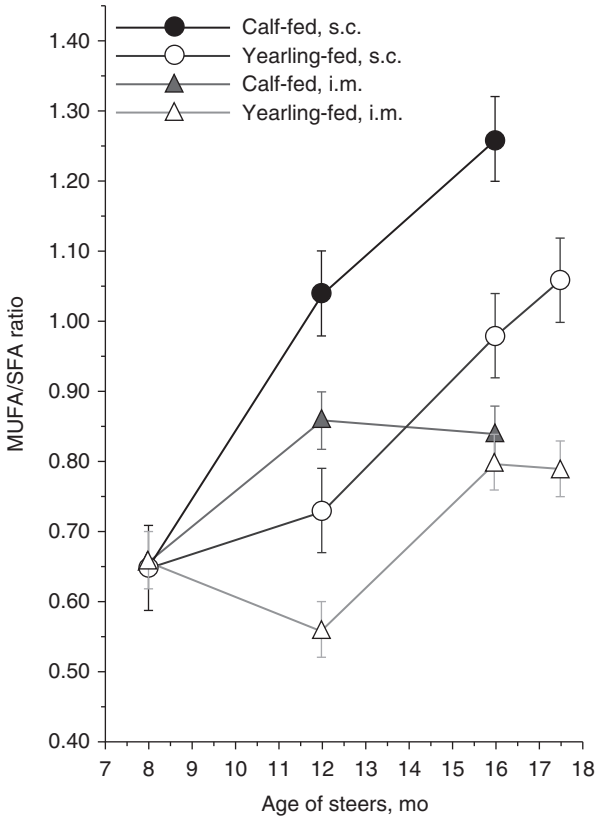

Figure 6 Changes in the MUFA:SFA ratio over time in calf-fed (closed symbols) and yearling-fed (open symbols) Angus steers. Steers were weaned at 8 mo of age. The CF steers were fed a corn-based, grain finishing diet for 4- or 8 mo after weaning. The YF steers grazed pasture until 12 mo of age, and then were fed the same corn-based, grain finishing diet for 4- or 5.5 mo of age, until they reached the same body weight as the calf-fed steers. At each sampling time (including 8 mo of age, immediately postweaning), fatty acids were measured in samples of intramuscular (i.m., triangles) and subcutaneous (s.c., circles) adipose tissue, at taken at the 5th–8th thoracic rib. Reproduced from Smith, S.B., Kawachi, H., Choi, C.B., *et al.*, 2009. Cellular regulation of bovine intramuscular adipose tissue development and composition. Journal of Animal Science 87(E. supplement), E72–E82, doi:10.2537/jas2008-1340.

beef cattle, yet the most abundant fatty acids in bovine adipose tissues are palmitic acid (the product of *de novo* synthesis) and oleic acid (from desaturation of stearic acid).

Typically, abdominal adipose tissue is more highly saturated than s.c. or i.m. adipose tissue. Perirenal adipose tissue develops very early in fetal life, and by the time cattle reach slaughter weight the perirenal adipose tissue is quite low in metabolic activity. In beef, i.m. lipid is also higher in stearic acid than is s.c. adipose tissue (Figure 9). In this respect, the smaller, less mature adipocytes of i.m. adipose tissue resemble preadipocytes of secondary cell lines. Unlike the situation for beef, i.m. lipid from pork contains less stearic acid than does subcutaneous adipose tissue (Figure 10).

As monogastrics, swine have adipose tissues with fatty acid composition that more closely resembles that of dietary fatty acids. Thus, diets enriched with oleic or linoleic acid will cause

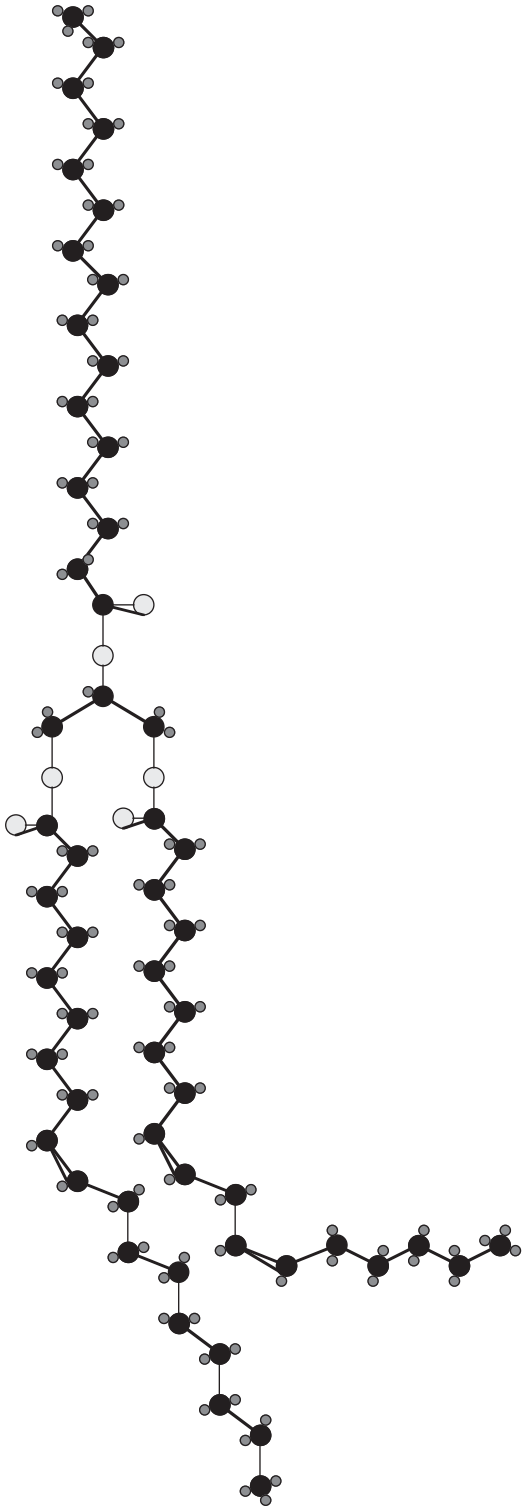

Figure 7 Typical structure of a triacylglycerol: *sn*-1 fatty acid (on left), oleic acid; *sn*-2 fatty acid, palmitic acid; *sn*-3 fatty acid, linoleic acid. This triacylglycerol would be common in porcine adipose tissue. In bovine and ovine adipose tissue, palmitic acid would occupy the *sn*-1 position and stearic or oleic acid would occupy the *sn*-2 position. the lipids associated with pork to become similarly enriched with these fatty acids. Elevated unsaturated fatty acids do not have a major effect on the sensory properties of fresh pork. However, polyunsaturated fatty acids are especially susceptible to oxidation during long-term storage of pork or pork products. This results in the formation of undesirable aldehydes and ketones, rendering the meat less acceptable. Furthermore, feeding pigs diets enriched with polyunsaturated fatty acids causes the carcasses to be oily and may lead to production problems such as soft bellies. Enrichment of carcass lean and

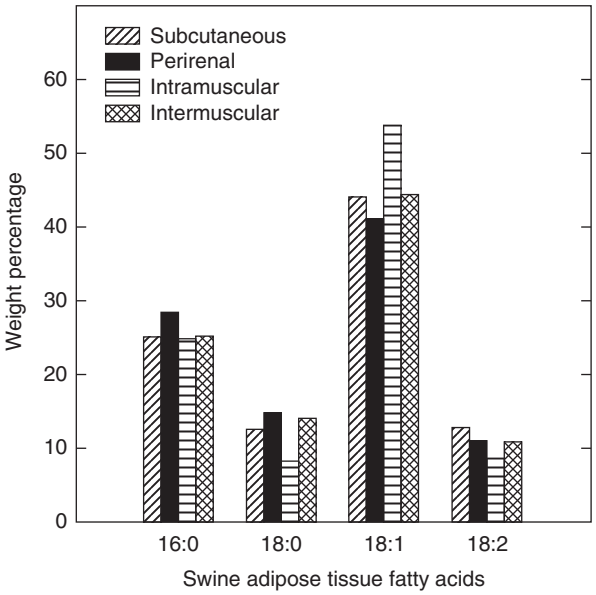

Figure 10 Fatty acid composition of porcine adipose tissues. Reproduced from Rule, D.C., Smith, S.B., Romans, J.R., 1995. Fatty acid composition of muscle and adipose tissue of meat animals. In: Smith, S.B., Smith, D.R. (Eds.), Biology of Fat in Meat Animals: Current Advances. Savoy, IL: American Society of Animal Science, pp. 144–165.

adipose tissues with oleic acid, which is a solid at typical freezer temperatures, does not appear to accelerate lipid oxidation or cause excessively soft bellies.

In contrast to pork, the fatty acid composition of beef is relatively resistant to dietary modification. Small increases in oleic acid have been demonstrated for cattle fed high-oleic acid sunflower seed. Similarly, adipose tissues and muscles of grass-fed cattle typically contain elevated concentrations of linoleic and α-linolenic acid. These increases are modest; even in grass-fed cattle, linoleic and α-linolenic acid concentrations rarely exceed 4% and 2%, respectively, of total fatty acids. Interestingly, the meat of range-fed bison has been reported to contain nearly 8% linoleic acid and nearly 3% α-linolenic acid. Also, beef from cattle fed in Australia can contain unusually high concentrations of stearic acid, although the biochemical basis for this is unknown.

Conjugated Linoleic Acid

Tissues of ruminants fed pasture grasses also are relatively enriched in by-products of ruminal biohydrogenation of linoleic and α-linolenic acid, vaccenic acid (*trans*-11), elaidic acid (*trans*-9), and a group of conjugated dienes collectively known as CLA. The most abundant of these are *cis*-9, *trans*-11 CLA (18:2*c*9,*t*11) and *trans*-10, *cis*-12 CLA (18:2*t*10,*c*12).

In addition to ruminal synthesis, 18:2*c*9,*t*11 may also be derived from desaturation of vaccenic acid in intestinal mucosa or within the muscle fibers or adipocytes. Similar to the synthesis of oleic acid from stearic acid, a *cis* double bond is inserted between carbons 9 and 10 of vaccenic acid by SCD. This

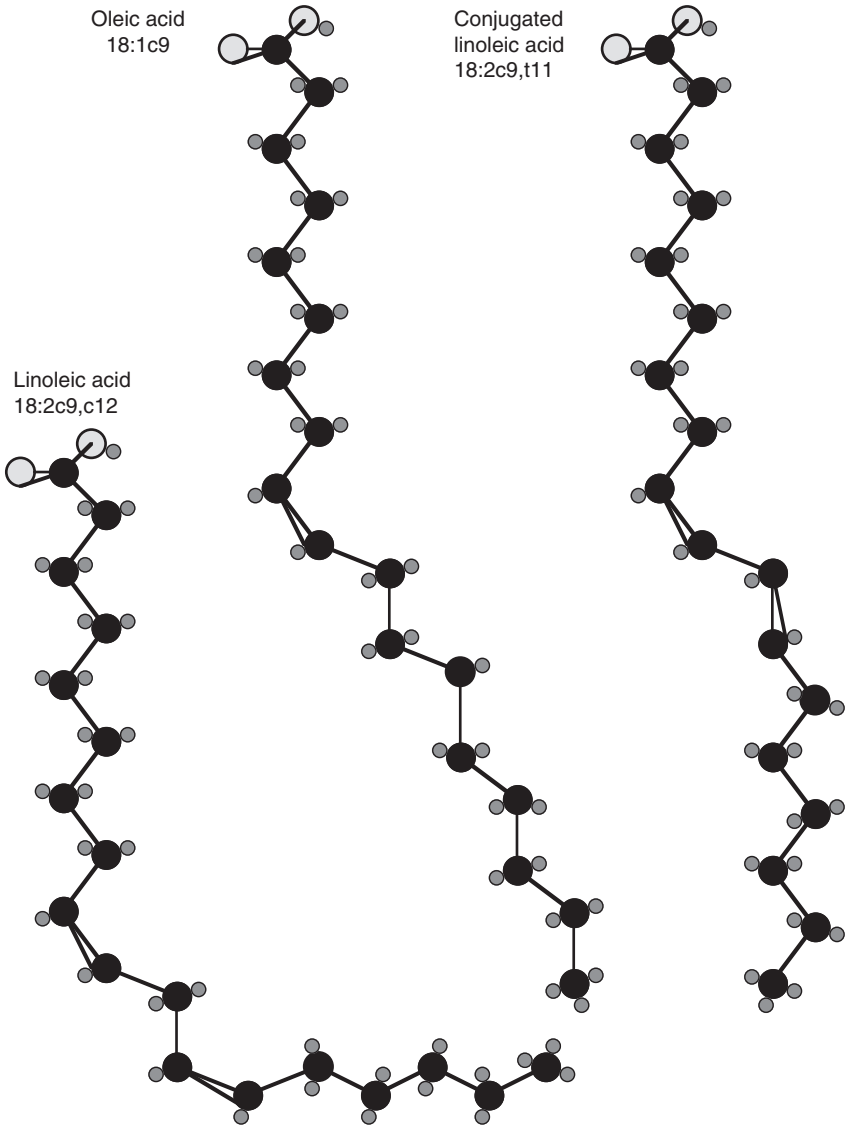

Figure 11 Structures of linoleic acid, oleic acid, and the *cis*-9, *trans*-11 isomer of CLA. Large filled circles represent carbon; large shaded circles represent oxygen; small shaded circles represent hydrogen.

results in a conjugated diene (Figure 11). Because of the *trans*-double bond between carbons 11 and 12, 18:2*c*9,*t*11 has a more linear configuration than linoleic acid. For this reason, free fatty acids or triacylglycerols of CLA have melting points that are similar to that of oleic acid and well above that of linoleic acid.

Although ruminant species produce and deposit CLA isomers in their tissues, the concentration of total CLA isomers rarely exceeds 2% of the total lipid. Attempts to increase CLA by dietary means (by feeding pasture grasses or flax seed) have caused the accumulation of vaccenic acid (produced from linoleic acid), with very little effect on the concentration of 18:2*c*9,*t*11. This indicates that SCD activity, either in the intestinal mucosal cells or muscle or adipose tissue, limits the rate of conversion of vaccenic acid to 18:2*c*9,*t*11.

Several investigators have demonstrated that porcine tissues can be enriched substantially by feeding mixtures of CLA isomers. Total concentrations of CLA isomers in pigs fed diets containing up to 3% CLA (as free fatty acids) are approximately 6% of the total lipid in the tissues. There appears to be no preference for the CLA isomers in porcine muscle or adipose tissue. Thus, 18:2*c*9,*t*11 and 18:2*t*10,*c*12 are enriched to the same degree in neutral lipids and cell membranes. However, porcine muscle and adipose tissue endoplasmic reticulum are enriched to less than 50% of the levels seen in other subcellular compartments. This indicates that there is greater specificity for the fatty acids that make up the endoplasmic reticulum, or that the fatty acids in this compartment turn over more slowly and thus are more difficult to modify by dietary means.

A primary effect of feeding CLA to pigs is to raise the melting point of the lipids of pork muscle and adipose tissue. This effect appears to be caused by the higher concentration of stearic acid typically observed in tissues of CLA-fed pigs. The amount of SCD mRNA is depressed in preadipocyte cell lines treated with CLA, and SCD enzyme activity is reduced in adipose tissue of pigs fed CLA. This has the beneficial effect of

producing pig carcasses with relatively hard bellies, which should improve ease of fabrication. However, the reduction in SCD activity caused by CLA concomitantly decreases the concentration of oleic acid, which is considered a healthful fatty acid.

Desaturation of Fatty Acids

Although ruminal hydrogenation of unsaturated fatty acids makes it difficult to enrich beef with unsaturated fatty acids, desaturation of fatty acids available for digestion in the duodenum ensures that plasma, muscle, and adipose tissue are not overly enriched with saturated fatty acids, especially stearic acid. The activity of SCD has been demonstrated in liver, muscle, s.c. adipose tissue, and intestinal mucosa of pigs and cattle (Figure 12). By far, the greatest SCD activity is located within adipose tissue, indicating its importance in the overall process of determining the fatty acid composition (and hence fluidity) of adipose tissue. However, substantial activity is also observed in intestinal mucosal cells, where it may function to modify the composition of chylomicrons and very-low-density lipoproteins produced within the mucosal cells. In this manner, SCD activity within mucosal cells would largely influence the composition of fatty acids available for deposition in other tissues.

Contribution of Intramuscular Adipose Tissue to the Concentration of Cholesterol in Meat

Cholesterol in meat exists in two forms: as free cholesterol and cholesterol ester. Free cholesterol is associated primarily with cellular and subcellular membranes of muscle and i.m. adipocytes. Because i.m. adipocytes are essentially lipid-filled spheres with very little membrane content (Figure 13), the amount of cholesterol associated with membranes is small (approximately 25% of total cholesterol in i.m. adipose tissue). Cholesterol ester, located within the triacylglycerol-rich central lipid vacuole, comprises approximately 75% of the total cholesterol in adipose tissue. Muscle fibers, which are rich in membranes but contain comparatively little lipid, have approximately 75% of their total cholesterol associated with membranes and the other 25% associated with their neutral lipids.

The concentration of cholesterol in lean, closely trimmed beef has been reported to be 45–65 mg per 100 g of muscle (wet weight). The variation may be due to methodology but is probably caused by varying amounts of neutral lipids contained within the muscle fibers themselves. Intramuscular adipose tissues contain approximately 115 mg of cholesterol per 100 g of i.m. adipose tissue or 1.15 mg cholesterol for every 1 g increase in total i.m. lipid content of meat. Several investigators have reported that increasing the amount of i.m. adipose tissue had no significant effect on the cholesterol content of meat. One study indicated that USDA Prime steaks (11% total lipid) contained 64 mg cholesterol per serving (100 g; approximately 3.5 ounces of uncooked beef). USDA Select steaks (2% total lipid) contained 61 mg cholesterol per serving. These values were not significantly different.

It seems inconsistent that increasing the amount of a relatively cholesterol-enriched source (i.m. adipose tissue) fails to increase total cholesterol in meat. There are two reasons for the minimal effect of i.m. adipose tissue on the concentration of cholesterol in beef. (1) Each gram of i.m.

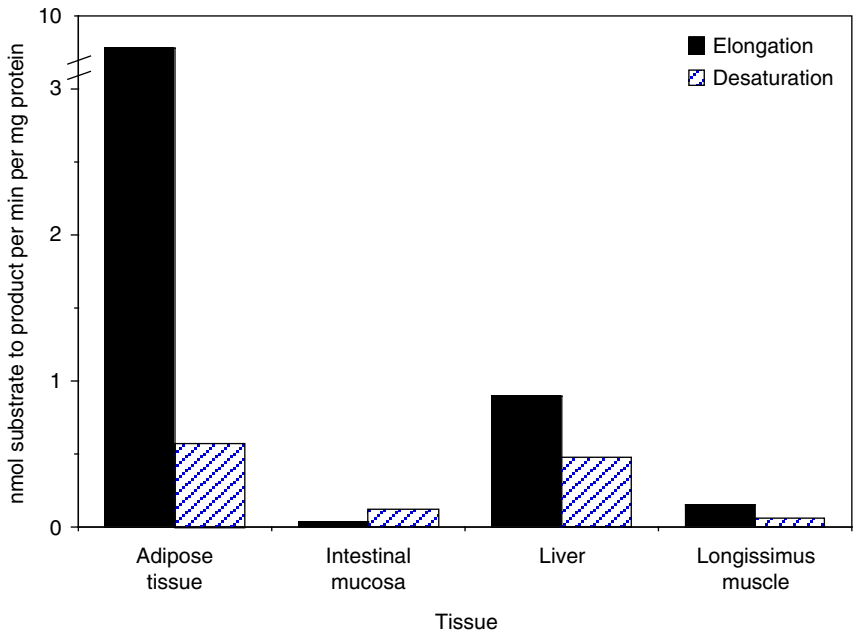

Figure 12 Fatty acid elongation and desaturation (SCD) enzyme activities in bovine tissues. Similar activities for SCD in adipose tissue, intestinal mucosa, liver and longissimus muscle have been demonstrated in porcine tissues. Reproduced from Smith, S.B., 1995. Substrate utilization in ruminant adipose tissues. In: Smith, S.B., Smith, D.R. (Eds.), Biology of Fat in Meat Animals: Current Advances. Savoy, IL: American Society of Animal Science, pp. 166–188.

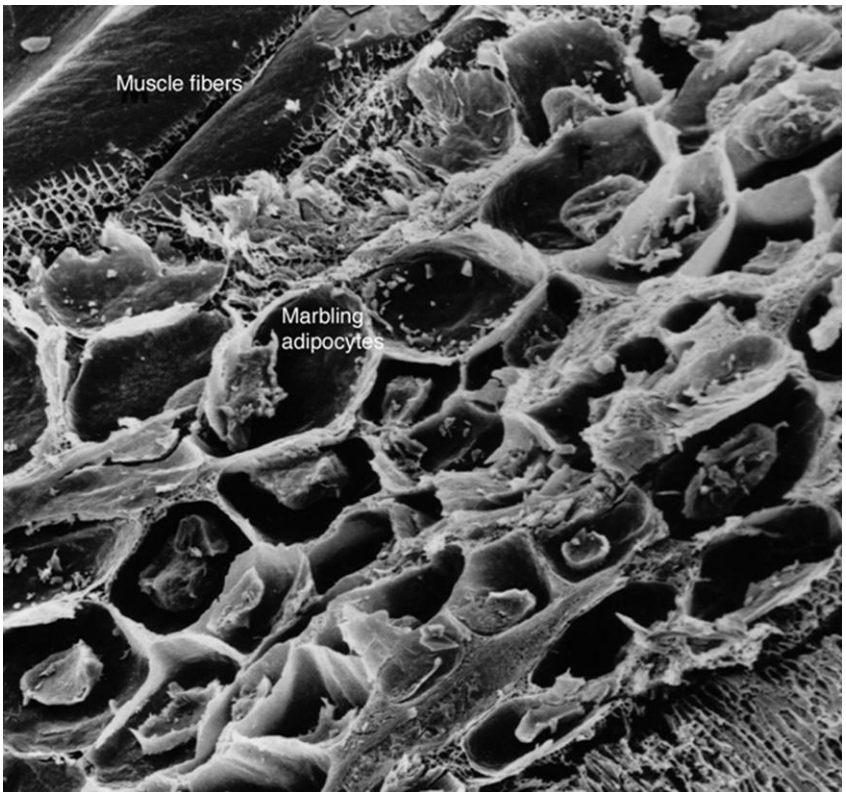

Figure 13 Distribution of marbling adipocytes within bovine longissimus muscle. Muscle fibers are oriented diagonally in this scanning electron micrograph. Reticular connective-tissue fibers connect the muscle fibers to the seam of marbling adipose tissue. Marbling adipocytes were dilapidated during the fixation process, and their upper surfaces were removed during sectioning. Diameters of the adipocytes are 10–50 μm.

adipose tissue contributes only 1.15 mg of cholesterol, which is below the level of sensitivity for some methods of cholesterol analysis. (2) Any increase in i.m. adipose tissue replaces an equal volume of muscle, which contributes approximately 0.65 mg of cholesterol per gram. Thus, any contribution of i.m. adipose tissue to total cholesterol is diluted by the amount of muscle it displaces. For this reason, Prime and Select cuts of meat may vary substantially in the number of calories from fat but will differ only slightly in their cholesterol content.

Fatty Acid Composition and Melting Point of Lipids

Several studies have described differences in fatty acid composition of adipose tissue and muscle across breed types of pigs, sheep, and cattle. In general, those breed types with larger adipocytes (s.c. or i.m.) have more saturated fatty acids in their tissues than those with smaller adipocytes. For example, s.c. adipose tissue from mature Hereford cows contained more lipid and saturated fatty acids than that from mature Brahman cows.

Another example of the relationship between adipocyte size and saturated fatty acid content is the Japanese Black. Japanese Black cattle were derived from Korean Hanwoo cattle but, unlike the Korean Hanwoo cattle, Japanese Black cattle were crossbred with Continental Europe and British dairy and beef breeds during the nineteenth century. Japanese Black cattle and the closely related American Wagyu cattle exhibit an unusual ability to accumulate i.m. adipose tissue. On the Japanese grading system, cattle raised in the US cannot achieve a Beef Marbling Standard (BMS) score greater than 5, whereas the best Japanese Black cattle achieve BMS scores of 12. The

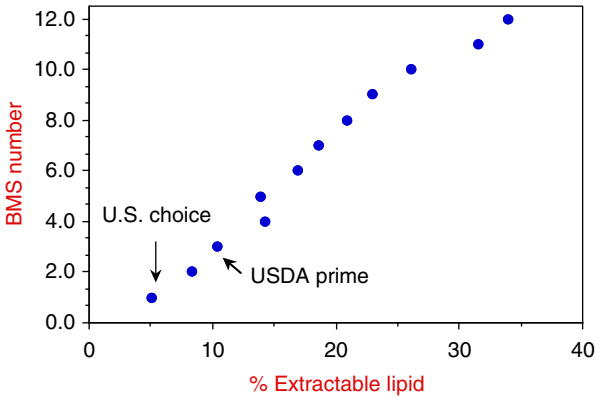

Figure 14 Japanese BMS as a function of extractable lipid in the 6th–7th ribs of the M. longissimus thoracis of purebred Japanese Black and American Wagyu cattle. Relative locations are indicated for USDA Choice and USDA Prime, adjusted for lipid concentrations at the 6th rib. Adapted from Cameron, P.J., Zembayashi, M., Lunt, D.K., *et al.*, 1994. Relationship between Japanese BMS and intramuscular lipid in the M. longissimus thoracis of Japanese Black and American Wagyu Cattle. Meat Science 38, 361–364. © Elsevier Science.

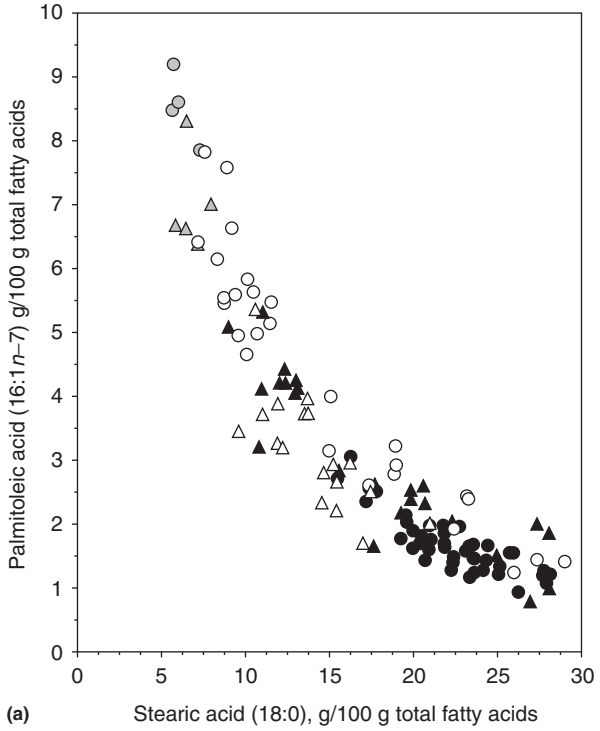
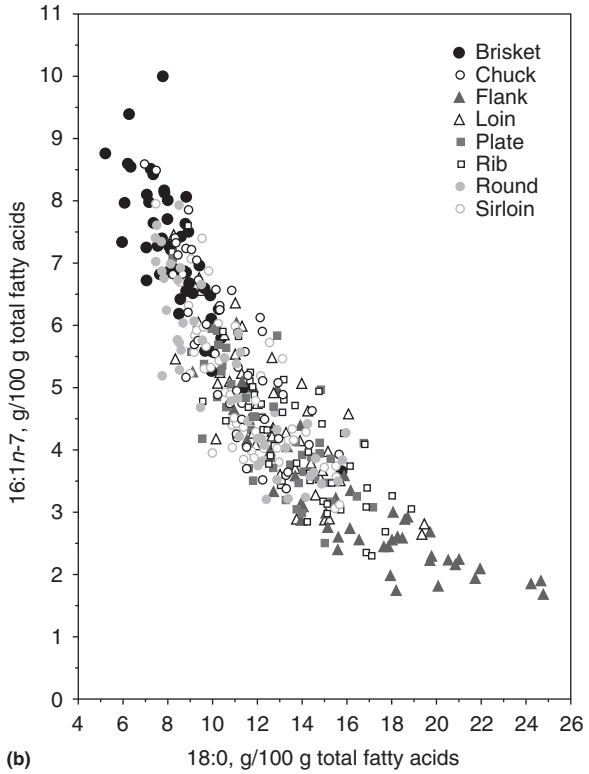
relationship of BMS number to extractable (primarily i.m.) lipid is illustrated in Figure 14. USDA Choice cattle occupy the very lowest portion of this curve, whereas the highest-grading Japanese Black cattle (with A5 carcasses) occupy the upper portion.





In spite of the great amount of i.m. lipid in beef from Japanese Black cattle, the i.m. adipocytes of Japanese Black steers are smaller (53 μm) than Angus i.m. adipocytes (61 μm). Intramuscular adipose tissue from Japanese Black cattle also contains more MUFA (57% of total fatty acids) than i.m. adipose tissue of Angus steers (50% of total fatty acids), even when raised under identical conditions. There is greater SCD activity in adipose tissues from Japanese Black cattle than in other breed types raised in the US, which would account for the greater concentration of MUFA in adipose tissues of Japanese Black cattle.

Studies that have included direct comparisons of American Wagyu cattle and other breed types have provided strong evidence for the genetic regulation of i.m. development and composition. Even when raised to the same physiological maturity under identical production conditions, American Wagyu steers accumulate more i.m. adipose tissue that is higher in MUFA than even those breed types that marble well (such as Angus cattle). Additionally, certain strains of Japanese Black cattle, such as those from the Hyogo Prefecture in Japan, can achieve BMS scores of 12 and their i.m. adipose tissue can contain more than 70% MUFA.

The contrast in fatty acid desaturation between Japanese cattle and cattle produced in other developed countries is best illustrated by comparing the concentrations of palmitoleic and stearic acid, as first proposed by Dr. Ron Tume, Commonwealth Scientific and Industrial Research Organization (CSIRO) Australia. Subcutaneous adipose tissue lipids from Japanese Black or American Wagyu cattle typically contain more than 6% palmitoleic acid and less than 7% stearic acid, indicating elevated SCD activity (Figure 15(a)). Conversely, s.c. adipose tissue lipids from young, Angus steers contain 1–2% palmitoleic acid and 20–30% stearic acid.

Interestingly, similar differences are observed across adipose tissues within the same carcasses (Figure 15(b)). Thus, brisket adipose tissue contains more than 6% palmitoleic acid and less than 10% stearic acid, whereas s.c. adipose tissue overlying the flank contains less than 3% palmitoleic acid and more than 15% stearic acid. The highly consistent, negative relationship between palmitoleic acid and stearic acid demonstrated in several studies indicates that the concentrations of these fatty acids are coordinately controlled by SCD.

Figure 15 Palmitoleic acid (16:1*n*-7) plotted as a function of stearic acid (18:0) in subcutaneous adipose tissue lipids. (a) Lipids from American Wagyu steers (shaded circles), Japanese Black steers (shaded triangles), mature Angus steers (open circles), young Angus steers (filled circles), Brangus steers (open triangles), and cattle raised in Australia (filled triangles). Subcutaneous adipose tissue lipids from American Wagyu and Japanese Black cattle contained the most palmitoleic acid and least stearic acid. Reproduced from Smith, S.B., Lunt, D.K., Chung, K.Y., *et al.*, 2006. Adiposity, fatty acid composition, and delta 9 desaturase activity during growth in beef cattle. Animal Science Journal 77, 478–486. (b) Lipids from eight subcutaneous adipose tissue depots, taken from 50 carcasses of unknown background. Lipids from brisket adipose tissue contained the greatest concentration of palmitoleic acid and least stearic acid, whereas lipids from the flank contained the least palmitoleic acid and the most stearic acid. Reproduced from Turk, S. N., Smith, S.B., 2009 Carcass fatty acid mapping. Meat Science 81, 658–663.

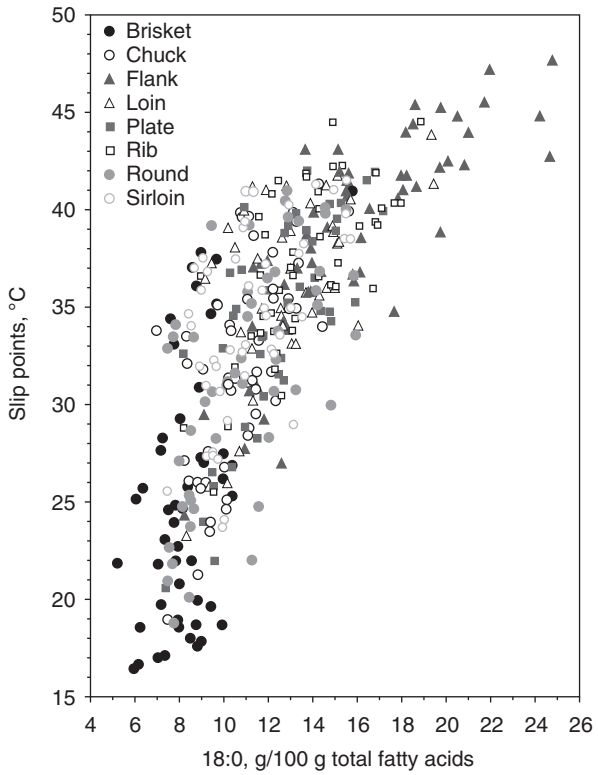


Figure 16 Lipid melting point (slip point) plotted as a function of stearic acid (18:0) in lipids from eight subcutaneous adipose tissue depots. Lipids from brisket adipose tissue had melting points less than 17 °C, whereas lipids from the flank had melting points greater than 45 °C. Reproduced from Turk, S.N., Smith, S.B., 2009. Carcass fatty acid mapping. Meat Science 81, 658–663.

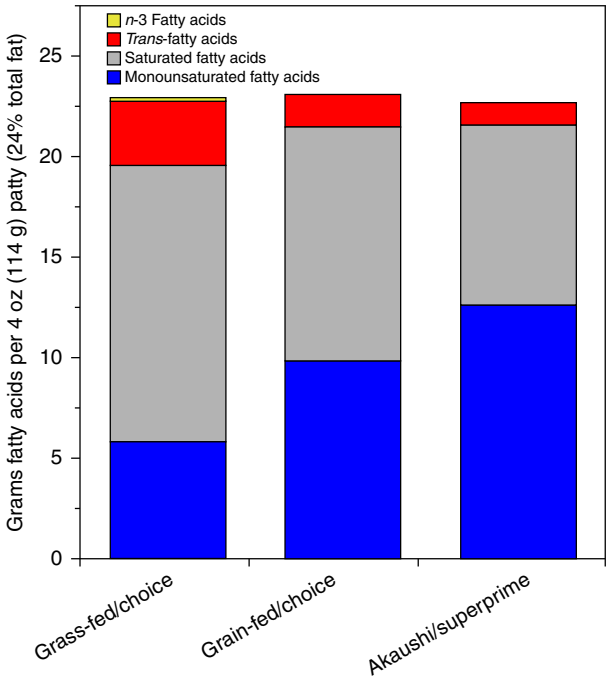

Figure 17 Total grams of fatty acids in one 4 oz (114 g) ground beef patty containing 24% total fat. Grass-fed/Choice, ground beef from Angus steers fed to USDA Choice on native Texas pastures, with no access to grains; Grain-fed/Choice, conventional ground beef purchased from a local retail outlet; Akaushi/Superprime, ground beef from Akaushi (red Japanese cattle) raised by Japanese production methods. *trans*-fatty acids include all 18:1 *trans*-isomers; saturated fatty acids include 14:0, 16:0, 18:0 and 20:0; monounsaturated fatty acids include 14:1n-5, 16:1n-7, 18:1n-7 and 18:1n-9. The only n-3 fatty acid that was quantifiable in the ground beef was α-linolenic acid.

The concentration of stearic acid in adipose tissue lipids is the primary determinant of lipid melting points (Figure 16), and even lipids extracted from adipose tissues of the same carcasses can exhibit a remarkable range of melting points. These differences in lipid melting point can have major practical importance. Pork carcasses enriched with unsaturated fatty acids may suffer from undue oiliness and belly softness, because the melting point of their tissue lipids is below 30 °C. Conversely, for those countries where carcasses are boned by hand, excessive fat hardness increases time and effort required for carcass fabrication. Perception of juiciness and mouthfeel also may be influenced by the melting point of lipids within meat, and depressing the concentration of MUFA in meat may reduce its healthfulness.

It is clear that breed type, production diet, stage of adipose tissue development, and adipose tissue depot all profoundly affect adipose tissue composition. Each one of these factors could have a significant impact on the healthfulness of beef, particularly ground beef. At least 40% of the 30 kg per year per capita beef consumption in the US is consumed as ground beef, and more than 31% of ground beef consumed in the US contains 22–30% fat, whereas the next 35% consumed contains 16–22% fat. Approximately 100 g of fat is consumed daily in the US, and ground beef, therefore, makes a significant contribution to total fat intake. Because pasture feeding of cattle depresses adipose tissue development and, concomitantly, SCD activity, a 4 oz (114 g, 24% total fat) ground beef patty from pasture-fed cattle can contain 2 g more *trans*-fatty acids and 2 g more saturated fatty acids, but only 60 mg more n-3 fatty acids, than conventionally produced ground beef (typically from grain-fed cattle in the US; Figure 17). The melting point of s.c. adipose tissue lipids of pasture-fed cattle can exceed 45 °C. Ground beef from cattle with a high genetic capacity to accumulate i.m. adipose tissue that is high in MUFA has 0.5-g less *trans*-fatty acids and 2.5-g less saturated fatty acids than conventional ground beef. These differences in fatty acid composition, due to differences in adipose tissue development among pasture-fed, conventional grain-fed, and highly marbled cattle, would have profound impacts on the eating quality and nutritional value of beef.

Glossary

***Bos indicus* (or *Bos taurus indicus*)** Also called Zebu, are typified as herbivorous, humped domestic cattle and adapted to hot climates.
***Bos taurus* (or *Bos taurus taurus*)** Typical herbivorous domestic cattle descended from Europe, north-eastern Asia, and parts of Africa. They are referred to as 'taurine' cattle and many are adapted to cooler climates.
Bovine A diverse group of 10 genera of medium- to large-sized ungulates, including domestic cattle, bison, African buffalo, the water buffalo, the yak, and the four-horned and spiral-horned antelopes. Breeds of cattle fall into two main types *Bos taurus* and *Bos indicus*.
Ovine (*Ovis aries*) A genus of ruminant even-toed ungulate mammals that are herbivorous and typified as domestic sheep.
Porcine (*Sus domesticus*) A genus of domestic swine or pork that are omnivorous and classified as even-toed ungulates.
Poultry (*Gallus domesticus*) A domesticated fowl commonly referred to as poultry or chicken that has been adapted to commercial meat and egg production.
Turkey Fowl (*Meleagris gallopavo*) A domesticated version of wild turkey fowl adapted to commercial meat production.

Introduction

The material in this article includes the major and minor chemical constituents of meat tissues of bovine (*Bos taurus* or *Bos indicus*, humped cattle), ovine (*Ovis aries*), porcine (*Sus domesticus*), turkey fowl (*Meleagris gallopavo*), poultry (*Gallus domesticus*), and aquatic species. The primary components of meat tissues are moisture, proteins, lipids (fats), carbohydrates, and inorganic matter (ash or minerals). Alterations in the composition of meat tissues as they affect meat quality are briefly discussed.

Major Chemical Components of Meat Tissues

Edible animal tissues from carcasses are designated as 'meat' and consist of variable amounts of muscle, adipose tissue, connective tissue, blood, blood vessels, lymphatic tissues, nerve tissue, tendons, cartilage, and bone (the last three are typically removed before consumption). Meat tissues are composed of five primary chemical constituents: moisture (water), proteins, lipids (fat), carbohydrates, and inorganic matter (ash or minerals). Other components include nonprotein nitrogen compounds (e.g., nucleotides, peptides, creatine, creatine phosphate, urea, inosine monophosphate, nicotinamide-adenine dinucleotide and nonnitrogenous substances (e.g., vitamins, glycolytic intermediates, organic acids). Skeletal muscle tissue is composed of approximately 75% water, 19% protein, 2.5% lipid, 1.5% nonprotein nitrogenous compounds, 1% carbohydrate and nonnitrogenous components, and 1% inorganic matter.

The primary chemical components (water, protein, and fat) vary in meat tissues and meat products with species, maturity, anatomical location, amount of skin and bone, and the inclusion of added nonmeat ingredients such as salt, alkaline phosphates, sodium nitrite/nitrate, sugars, spices, or seasonings. In tissues, the percentages of water, protein, and ash are inversely related to the percentage of fat; in other words, the percentages of moisture, protein, and ash decrease with increasing amounts of fat (Figure 1). The percentage of carbohydrate, however, remains rather constant as the fat content of meat increases.

Eleven primary chemical elements make up over 99% of an animal's body composition whereas 25 essential and nonessential microelements are also present in the tissues. The major elements by weight include oxygen (65%), carbon (18%), hydrogen (10%), nitrogen (3%), calcium (1.5%), phosphorus (1.0%), potassium (0.35%), sulfur (0.25%), sodium (0.15%), chlorine (0.15%), and magnesium (0.05%). Essential elements that are required for normal metabolical function are cobalt, copper, iodine, iron, manganese, molybdenum, selenium, and zinc, whereas barium, bromine, cadmium, chromium, fluorine, and strontium are considered nonessential. For a more detailed listing of specific nutrient components of meat, the reader is referred to the United States Department of Agriculture National Nutrient Database for Standard Reference, Release 25 (2012).

Factors Influencing the Chemical Composition of Meat

Meat tissue composition varies according to differences in species, chronological and physiological maturity at harvest, plane of nutrition, genetic predisposition (e.g., pale, soft, and exudative (PSE) tissue vs. dark, firm, and dry tissue), and anatomical location of cuts within a carcass. Primarily, the composition of an animal carcass and the corresponding meat

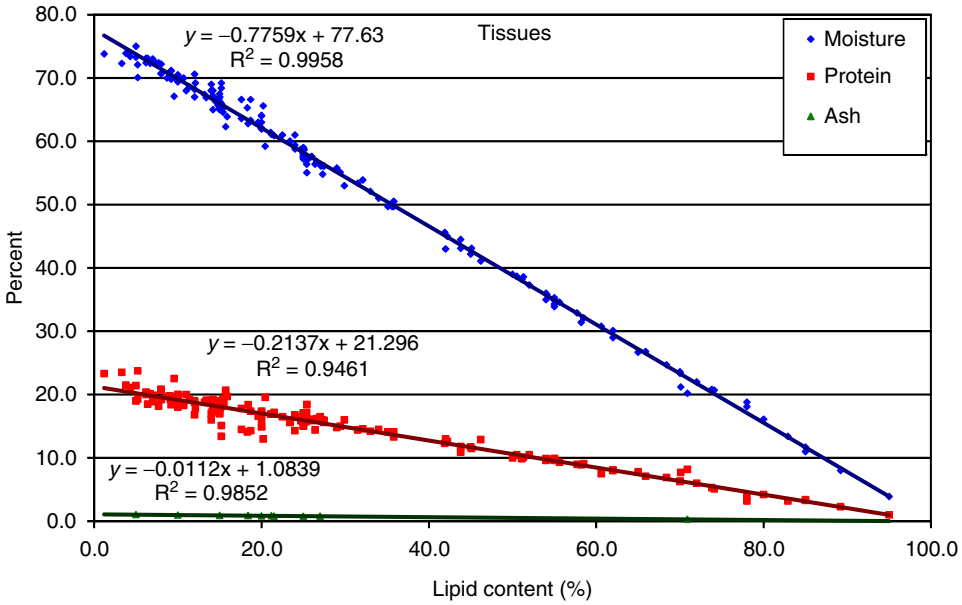

Figure 1 The inverse relationship of moisture, protein, and ash levels with increasing percentages of fat in boneless meat tissues.

tissues varies most depending on the stage of growth, the plane of nutrition, and the maturity level at which the animal is harvested.

Muscle, fat, and bone are the major carcass components that change in their proportions from birth to maturity. At birth, muscle (~67%) is the predominant component of a beef carcass, followed by bone (~25%), and lastly fat (~8%). At maturity, muscle may represent ~55% of a carcass whereas fat amounts to ~28% and bone ~15%. Thus, with growth and maturity, the percentages of separable muscle and bone decrease whereas the percentage of fat increases. The percentage of bone decreases only slightly once an animal's body or carcass weight is near that of an adult. Table 1 illustrates the decline in the percentage of moisture, crude protein, and ash with a corresponding increase in the fat content from birth to maturity. As noted in Table 1, the chemical composition changes when components are compared on the basis of a whole animal or a carcass (bone-in or boneless).

Chemical differences are also evident among species when carcass composites and selected skeletal muscles are compared (Table 2). Carcasses are chemically more diverse, whereas individual muscles from each species are more similar in gross composition (moisture, protein, and fat). However, muscles vary in the proportions of specific chemical components (e.g., collagen content, myoglobin concentration, and sarcoplasmic proteins) or nutrients (e.g., saturated, monounsaturated, and polyunsaturated fatty acids; iron).

organ metabolism, as a transport medium for metabolites and waste products, as a thermoregulator, as a solvent, and as a lubricant. In postmortem muscle tissue, water is the primary component of individual cells and comprises 75–80% of the cell mass. Thus, water comprises a major part of the sarcoplasm of muscle as well as surrounding the myofibrillar proteins. The myofibrils make up 75–92% of the volume of lean muscle and play a dominant role in the water-holding capacity (WHC) of the tissue. For the meat industry, the WHC of fresh meat is known to affect its economic value, such as processing yield and product quality. Poor WHC may reduce water retention, alter color, reduce sensory quality, and decrease acceptable appearance due to the presence of 'purge' ('drip') in a package.

The ionic environment (pH), availability of specific cations and anions, and the degree of contraction of myofibrillar proteins are the primary factors affecting the retention or loss of moisture from muscle tissues. As the postmortem pH is reduced by the accumulation of lactic acid, acidification of the muscle tissue reduces the pH from 5.6 to 5.8. The myofibrillar protein's ability to retain water is diminished and this may result in a corresponding increase in the percentage of protein. Table 3 illustrates the compositional changes and loss of WHC in porcine Longissimus muscle due to a decline in pH. The ionic environment of contractile protein side-groups and capillary entrapment of water within the myofibrillar matrices affect a muscle's WHC. At ~pH 5.1, myofibrillar proteins of postmortem tissue are near their isoelectric point (pI) and WHC is lowest at that point.

Moisture sorption isotherms of proteins estimate that $<0.1\%$ of the total water surrounding the protein is tightly bound or absorbed into the accessible polar sites of a protein's native structure. This water, designated as constitutional (bound or monolayer) water, is tightly bound within a protein and does not freeze at −40 °C. Additional 'layers' of water (~5%) interact with charged and polar protein surface groups to form a hydration shell around the protein. These water molecules participate in hydrogen-bonding, are slightly mobile, remain mostly unfrozen at −40 °C, and begin to have a plasticizing effect on solutes. When the hydration shell reaches a concentration of 0.38 g water per gram dry protein, a monolayer of water covers the surface of the protein. Additional water outside a protein's hydration shell is known as bulk-phase water, which constitutes ~95% of the water in a cellular system. Bulk-phase water consists of entrapped and free water, portions of which are susceptible to loss as 'purge' ('drip') or loss during thermal processing. This water is freezable and allows for a large degree of molecular mobility.

Table 3 Compositional differences in porcine *Longissimus* muscle exhibiting pale, soft, and exudative (PSE) characteristics

Component (%)	*Normal pork loin*	*PSE pork loin*

Proteins and Nonprotein Nitrogen Compounds

Proteins constitute 16–22% of skeletal muscle tissue and are composed of 20+ amino acids connected via a peptide linkage as shown in Figure 2. Proteins are generally categorized according to function: myofibrillar (contractile), sarcoplasmic (metabolic), or stromal (connective or support). The metabolic turn-over or replacement rates for each of these tissues are intermediate, rapid, and very slow, respectively. Meat proteins as a whole contain ~16% nitrogen (including nonprotein nitrogen compounds) that can be converted into

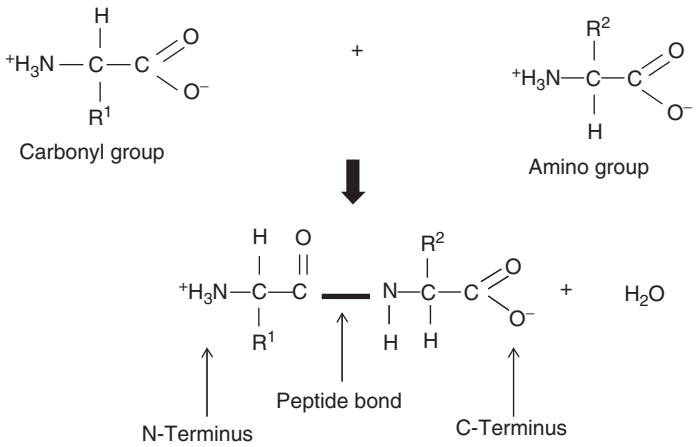

Figure 2 The peptide linkage between amino acids is formed by the condensation reaction of the carboxyl group of an amino acid reacting with an amino group of another amino acid.

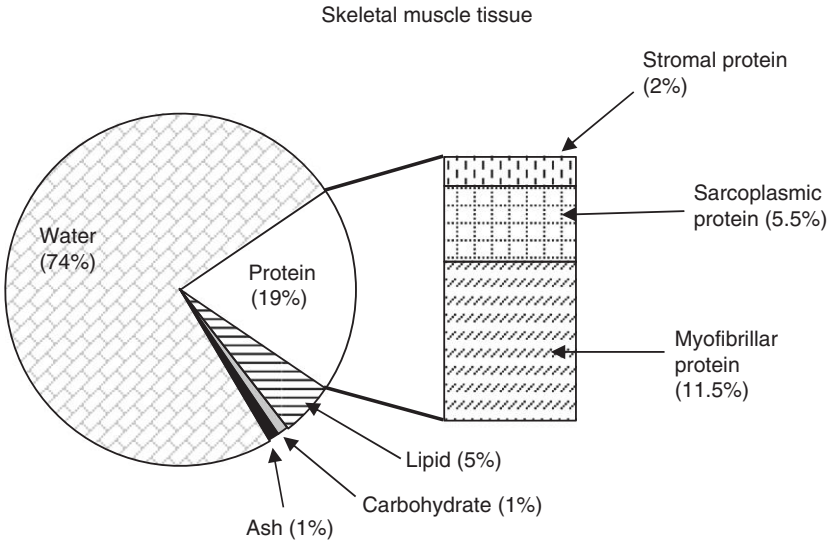

Figure 3 Composition of skeletal muscle tissue.

percent crude protein by multiplying percent nitrogen by 6.25 (100/16 = 6.25).

Myofibrillar, or salt-soluble, proteins comprise approximately 11.5% of the 19% total (Figure 3) and are extracted with a KCl solution of >0.3 mol l^{-1}. Myosin (43%), actin (22%), titin (8%), tropomyosin (5%), troponin (%), nebulin (3%), C-protein (2%), α-actinin (2%), M protein (2%), and desmin (<1%) account for ~93% of the 20+ different contractile proteins making up the myofibril. Actin and myosin constitute approximately 22% and 43%, respectively, or 65% of the total amount of myofibrillar proteins. Myosin (520 kDa; 2 subunits of 220 kDa, 4 of 20 kDa) and actin (42 kDa) complex during rigor mortis to form actomyosin and are the most important proteins influencing WHC (swelling) of muscle tissue, intermolecular binding in a meat gel matrix (gelation), and mechanical stability of a meat emulsion (encapsulation of fat globules).

Sarcoplasmic, or water-soluble, proteins account for approximately 5.5% of the 19% protein total and are extracted with low-ionic strength KCl solutions of ~0.06 mol l^{-1}. These proteins are found in the sarcoplasm or fluid surrounding the myofibrils and are made up of predominantly oxidative enzymes (cytochromes, the flavin nucleotides), various heme pigments (myoglobin), the mitochrondrial oxidative enzymes, lysosomal enzymes, and nucleoproteins. The glycolytic enzymes that make up most of the sarcoplasmic proteins are also bound to the myofibrillar protein actin. The concentration of sarcoplasmic proteins is ~55 mg ml^{-1}, with the most abundant proteins (mg g^{-1} tissue) in decreasing order of abundance being glyceraldehyde phosphate dehydrogenase (12), aldolase (6), enolase (5), creatine kinase (5), lactate dehydrogenase (4), pyruvate kinase (3), phosphorylase (2.5), and myoglobin (0.1–20+). Concentrations of these enzymes/proteins vary with species, muscle fiber type, maturity, and sex of the animal. Sarcoplasmic proteins are more effective emulsifiers in sausages or restructured meat products than are stromal proteins (collagen), but not as effective as myofibrillar proteins.

Myoglobin (Mb, 16 kDa) is the primary pigment giving color to muscle tissues, which is dependent on the concentration of myoglobin, the oxidation state of the iron atom in the planar porphyrin ring, and the molecule attached to the sixth site on the iron molecule. Examples of the iron oxidation state, the pigment form, the attached molecule, and the color of the tissue are as follows: Fe^{2+}, myoglobin–H_2O (purplish red); Fe^{2+}, oxymyoglobin–O_2 (bright red); Fe^{3+}, metmyoglobin–H_2O (brown); and Fe^{2+}, nitrosylhemeochromogen–NO (pink). Some uncertainty exists with regard to the specific molecule attached to some pigment forms. Concentrations of myoglobin in raw muscle tissue are shown in Table 4.

Stromal or connective tissue proteins normally comprise approximately 2% of the 19% total protein in skeletal muscle and are rather insoluble. Connective tissue consists of a viscous solution of soluble glycoproteins (proteoglycans) with extracellular fibers of collagen and elastin embedded in the glycoprotein matrix. Collagen is a unique triple-helical molecule and is the most abundant single protein in an animal. It can comprise 20–25% of the total body protein with the inclusion of skin, ligaments, tendons, cartilage, and bone. Collagen is extracted only with strong acid or alkaline solutions, or it can be digested with pepsin and collagenase. It has an unusual amino acid composition of approximately 33% glycine, 11% alanine, 9–10% proline, and 13–14% hydroxyproline. Because hydroxyproline is unique to collagen (and to a lesser extent elastin) and is present at a consistent concentration in collagen, chemical determination of the collagen content of meat tissues is performed via hydroxyproline analysis.

When heated (60–70 °C) slowly under moist conditions, collagen will unfold owing to the breakage of noncovalent bonds, some covalent (disulfide) intermolecular and intramolecular bonds, and a few peptide bonds, resulting in the collapse of the triple-helical polypeptide units. This conversion of helical collagen to an amorphous form (gelatin) is known as gelatinization. When it is chilled to refrigeration temperatures (~4 °C), partial renaturation occurs, resulting in a solidified, jelly-like gel or solidified gelatin. Reheating above 43–49 °C reliquefies the gelatin.

Elastin is a rubbery protein in a β-pleated sheet arrangement that is present in ligaments, in arterial walls and in the support structure for organs. The cervical ligament (*ligamentum nuchae*) in ruminants is primarily composed of elastin, which contains 1–2% hydroxyproline and two unique amino acids, desmosine and isodesmosine. It is very resistant to solubilization, cooking, or enzymatic digestion because of its high content (~90%) of nonpolar amino acids and desmosine cross-links.

Table 4 Myoglobin concentration in muscle tissues of various species

Species/maturity/color	*Myoglobin concentration (mg g^{-1} tissue)*
Mature beef (dark, red)	16–20
Young beef (bright, cherry red)	4–10
Veal (brownish pink)	1–3
Pork (grayish pink)	0.3–3
Mature pork (red)	8–12
Lamb (light red)	2.5–8
Mutton (brick red)	12–18
Horse (dark red)	7–8
Turkey (dull red)	0.4–1.5
Poultry (gray–white, dull red)	0.5–1.5
Fish (white to red)	0.3–1
Fish (dark red)	5–25
Whale (very dark red to black)	>25

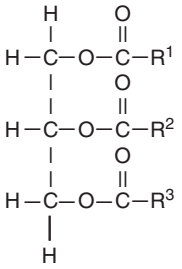
Lipids/Fat/Triacylglycerols

Animal adipose tissue (fat) is composed primarily of neutral lipids known as triacylglycerols and phospholipids that collectively range from 1.5% to 13% in muscle tissue. Lipids also exist as sterols and sterol esters (cholesterol and cholesterol components) and cerebrosides. Various lipid forms serve as an energy source for the cell, as a structural and functional component of the cell wall, as insulation or protection for vital organs, and as solubilizing agents for certain hormones and vitamins (A, D, E, and K). Fats can be metabolized to yield 2.25 times more energy than carbohydrates or proteins and thus are an energy-dense nutrient.

Neutral lipids (triacylglycerols) are glycerol esters composed of one glycerol molecule and three even-numbered long-chain fatty acids. Except in milk, the presence of fatty acids having a chain length of 10 or fewer carbon atoms in animals is rare. Triacylglycerols may be simple (all attached fatty acids are identical) or mixed (two or more attached fatty acids are different). A generalized structure of a triacylglycerol is shown in Figure 4.

Most fatty acids in animal fats contain an even number of carbon atoms, but a few odd-numbered carbon fatty acids are also known. Fatty acids are characterized as saturated (containing no double bonds between carbon atoms); monounsaturated (containing one double bond between two carbon atoms); and polyunsaturated (containing two or more double bonds in the carbon chain). The combined chemical



{Glycerol} + {Fatty acid} = Triacylglycerol

Figure 4 General structure of a triacylglycerol; R^1, R^2, and R^3 represent fatty acid chains.

Table 5 Melting point characteristics of fatty acids and triacylglycerols commonly found in animal tissues

Fatty acid	*Chemical designation*	*Melting point (°C)*
Saturated		
Butyric	C_4	−8.0
Caproic	C_6	−3.4
Caprylic	C_8	16.7

Dubuque, IA: Kendall/Hunt, pp. 9–43.

characteristics (carbon chain length, number of double bonds, melting point, fluidity, hardness, and susceptibility to lipid oxidation) of the fatty acids attached to a triacylglycerol give a fat its own particular set of physical characteristics. Melting point characteristics of fatty acids and triacylglycerols commonly found in animal tissues are presented in Tables 5 and 6. Palmitodiolein and oleopalmitostearin are the two most prevalent triacylglycerols in beef, lamb, and pork.

The melting point of fats is determined by the carbon chain length and the number of double bonds (degree of saturation) within the fatty acid carbon chain. As the carbon length of a fatty acid becomes longer, the melting point increases, whereas, as the number of double bonds increases, the melting point decreases. Table 7 illustrates the effect of chain length and double bonds on melting points of common fatty acids in animal tissues.

Internal fats surrounding the organs are generally more saturated and have higher melting points than external subcutaneous fats. Saturated fatty acids having more than 12 carbon atoms are solids at body temperature as shown in Table 5.

Table 6 Melting points of lipids in meat cuts and tissues commonly used in sausage processing

Source species	*Melting Point (°C)*
Lamb	32.2–46.1
Beef	31.7–43.3

Fatty acid nomenclature is derived from numbering the carbon atoms from the carboxyl (COOH) or methyl (CH_3) ends of the molecule. Using the carboxyl numbering method, oleic acid ($C_{18:1,\ 9C}$) is named *cis*-9-octadecenoic acid. In the methyl numbering scheme the double bond is located on the third carbon from the methyl end (*n*-3). Fatty acids designated in this manner are called 'omega-3' fatty acids and are primarily found in cold-water fish. Most unsaturated fatty acids in meat are of the *n*-6 variety (sixth carbon from the methyl end).

The degree of unsaturation of a fat is typically determined by measuring the number of grams of iodine reacting with 100 g of fat, to produce an iodine number. Unsaturated fatty acids may be made more saturated by hydrogenation of the unsaturated carbons with the use of a catalyst such as nickel or sodium methoxide. A *trans* fatty acid conformation can result from this process and is more stable having less mobility and fluidity. The *trans* fatty acids have been implicated in contributing to coronary heart disease and increasing low-density lipoprotein cholesterol while decreasing high density lipoprotein cholesterol. Most fatty acids in foods are in the *cis* conformation, which is less stable than the *trans* form, and are also more fluid. Isomers of linoleic acid that have double bonds on the C9 and C11 sites rather than the C9 and C12 sites are designated conjugated linolenic acid and may have

unique and beneficial properties for processing and dietary purposes.

The proportions of fatty acids making up a specific fat depot vary with species and diet. In general, oleic acid ($C_{18:1}$) (20–47%) is the most abundant fatty acid in the animal body of lamb, cattle, and pigs, whereas palmitic (C_{16}) (26%) is the most abundant in poultry. The fatty acid composition, ranking from most saturated (harder fat) to least saturated (more oily) by species is as follows: lamb > cattle > pigs > poultry > fish. For cattle, lamb, pigs, and poultry, palmitic (C_{16}) (25–30%) and stearic (C_{18}) (7–27%) saturated fatty acids predominate, with lesser quantities of lauric (C_{12}) (trace), myristic (C_{14}) (0.1–5%), and arachidic (C_{20}) (trace to 3%). Linoleic ($C_{18:2}$) (2–20%), palmitoleic ($C_{16:1}$) (1–7%), linolenic ($C_{18:3}$) (0.2–0.6%), and arachidonic ($C_{20:4}$) (0.2–2%) unsaturated fatty acids are also present in the amounts indicated. Linoleic and linolenic are considered essential fatty acids in humans.

Phospholipids are the structural and functional components of cell membranes comprising 0.5–1% of the lipid in skeletal muscle. The most common phospholipids in muscle tissue are: phosphatidylethanolamine (cephalin) (33%), phosphatidylserine (6%), phosphatidylcholine (lecithin) (58%), and sphingomyelin (3%). These lipids are more readily oxidized by oxygen than are triacylglycerols, resulting in the development of specific off-aromas and flavors in meat products known as warmed-over flavor. Phospholipids are very similar to triacylglycerols with a phosphoric acid inserted between the glycerol ester bond and the R^3 fatty acid shown in Figure 4. Saturated fatty acids are the least susceptible to lipid oxidation, followed by monounsaturated fatty acids, and lastly polyunsaturated fatty acids, which are the most susceptible to free radical lipid oxidation. Free-radical oxidation produces a variety of undesirable breakdown products, especially short chain acids, aldehydes, and ketones.

Sterols are minor constituents present in the fat of the human diet. Cholesterol is the main animal sterol and is the precursor of bile acids, provitamin B, and the steroid hormones. Cholesterol can be present in the free form or esterified at the hydroxyl group with fatty acids of various chain length and saturation. Cholesterol is a component of meat lipids, and high blood levels in humans have been shown to increase the risk of cardiovascular disease. Cholesterol intake has been recommended not to exceed 300 mg per day. The content of cholesterol in meat and meat products is influenced by diverse factors, such as type of meat, anatomical location, and preparation conditions. The average cholesterol content of domestic meat species and their by-products are summarized in Table 8.

Fat content varies with species, maturity (Tables 1 and 2), and diet. From birth to maturity, fat is deposited in the following order: around vital organs, subcutaneously, intermuscularly (between muscles), and lastly intramuscularly (between muscle bundles as 'marbling'). Adipose tissue is dynamic and is constantly being stored or mobilized. All meat animals synthesize fatty acids in the liver and/or in adipose tissue from carbohydrates and proteins. Fats in the diet of monogastric animals are broken down to their parent fatty acids and may be assimilated and deposited in relatively unchanged form; thus carcasses have characteristics related to the fatty acid composition of the dietary fat. Without careful management of the diet, problems can arise during processing or at the time of consumption. For example, the carcass fat of pigs fed a diet containing lower melting point fats such as flax seed, highly unsaturated vegetable oils, fish meal, or peanuts takes on the characteristics of the dietary fat. In this case, pigs would have more oily, softer carcasses resulting in meat cuts with poor appearance, poor slicing characteristics (bacon), painty/fishy off-flavors (especially when heated), or raw oyster-like fat in the center of a ham slice. Ruminants, however, deposit more saturated fats that have higher melting points (harder fat) due to the degradation and resynthesis of dietary fats by rumen bacteria before assimilation and deposition in the tissues.

Limiting fat and cholesterol intake are considered to be important measures to prevent obesity and hypercholesterolemia, conditions that are thought to predispose humans to various chronic diseases of the circulatory system. Epidemiological and clinical studies have suggested that high-fat diets, regardless of their fatty acid distribution, increase the concentration of cholesterol in the blood. Therefore, several strategies have been applied to reduce the fat content of carcasses due to consumer demand for leaner meats. These strategies to reduce fat include selection of leaner genetic lines within breeds, and changes in animal rations to include feed supplements such as probiotics, antibiotics, β-agonists, and growth hormones. These practices have allowed for a substantial reduction of intramuscular, intermuscular, and subcutaneous fat. However, reduction of intramuscular fat ('marbling') should be carefully controlled to maintain meat quality attributes such as tenderness, juiciness, and flavor.

Table 8 Average cholesterol content of meat species and by-products

Type of meat/by-products	*Cholesterol (mg per 100 g edible portion)*
Type of meat

Carbohydrates

Glycogen is a branched polysaccharide consisting of α-D-glucose units linked by α-1, 6 glucosidic and α-1, 4 glucosidic bonds. It is the most abundant carbohydrate in animal tissues and is present in the liver at 2–8%, but ranges from 0.5% to 1.5% in living skeletal muscle tissue. The initial amount of glycogen in the muscle tissues at slaughter affects ultimate muscle color, texture, firmness, WHC, emulsifying capacity, and shelf life.

Glycogen can have a molecular weight in the millions and is stored in the muscle cell for subsequent conversion to glucose. The amounts of initial pre-slaughter glycogen depend on preslaughter stress conditions and in particular the levels of adrenaline (epinephrine) and/or preslaughter exercise that play a significant part in its conversion to lactate with potentially adverse effects on meat quality. Postslaughter anaerobic glycolysis essentially results in the glucose moiety being metabolized to two moles of lactate. The final lactate concentration dictates the end-point muscle pH and is proportional to the initial glycogen concentration. Glucose in a living muscle cannot leave but will be used up by muscular exercise (glucose can be transported in but not out of the muscle). Lactate leaves muscle, is transported to the liver, and eventually over time (a long time in ruminants) recycles in living animals. Ordinarily, fatty acids are the low-level energy source and glycogen is used only in intensive bursts of muscle activity or is used only preferentially when adrenaline is available. Even then exercise (e.g., trembling, shivering) is needed to use up the glycogen over time. The glycogen replenishment rate depends on species and is higher in pork than ruminants.

Typical resting muscle glycogen and lactate levels vary depending on species (Table 9). At 24 h post mortem, the lactate concentration can range from 77 to 130 mmol kg^{-1} of tissue whereas the glycogen drops to less than 10 mmol kg^{-1} of tissue. Variations of postmortem glycogen and lactate concentrations among species are presented in Table 9. As a consequence of the build-up of lactate, the pH drops from 7.1–7.3 to 5.5–5.7. The pH decline of a muscle or carcass is temperature dependent, with the pH of warm muscle declining at a faster rate than that of muscles or carcasses that have been chilled quickly.

Other carbohydrates that are found in animal tissues include the glycosaminoglycans and proteoglycans that are associated with the extracellular matrix of connective tissues, as well as the glycoproteins found in plasma and blood, and some hormones, glycolytic intermediates, nucleotides, nucleosides, and the glycolipids. Of all these carbohydrates, D-glucose is the most abundant. Glycosaminoglycans are covalently linked to core proteins to form complex proteoglycans. Hyaluronic acid, the chondroitin sulfates, dermatan sulfate, keratan sulfate, and heparin-like polysaccharides are components of the glycosaminoglycans.

Some genetic strains of swine are susceptible to stress and as a consequence, exhibit a PSE condition in some major muscle groups due to a rapid decline in pH to an endpoint of 5.2–5.4 (in comparison to a 'normal' post mortem pH of 5.5–5.7). The accelerated pH decline results in denaturation of muscle protein with changes in muscle chemical composition and damaging consequences to the quality of the tissue. PSE muscle (ham and loin) typically exhibits poor WHC, pale color, soft texture, excessive cooking losses (lower processing yields), poor cured color, and a dry, 'mealy' mouthfeel.

Inorganic Matter (Minerals)

Approximately 3.5% of total body weight consists of inorganic matter (bones and teeth) that is typically analyzed as percent ash. Minerals in ash are in the form of oxides, sulfates, phosphates, nitrates, chlorides, and other halides. In meat tissues, the percent ash is an estimate of the total mineral content that makes up cellular constituents (myoglobin, hemoglobin, and enzymes), bone (bone fragments, mechanically separated tissue, and advanced meat recovery systems), or ingredients (sodium chloride, potassium chloride, alkaline phosphates, lactate salts, spices, seasonings, batters, and breading) used in processing. Bone is a major component of carcasses and contributes primarily calcium and phosphorous. Muscle tissue is low in calcium (3–6 mg g^{-1}), but abundant in potassium (250–400 mg g^{-1}), phosphorus (167–216 mg g^{-1}), sodium (55–94 mg g^{-1}), magnesium (22–29 mg g^{-1}), zinc (1–5 mg g^{-1}), iron (1–3 mg g^{-1}), and copper (0.5–0.13 mg g^{-1}). The heme iron from meat is more readily absorbed as a nutrient, and heme iron accounts for 40–60% of the total iron. Calcium, magnesium, sodium, and potassium are directly involved in contraction in living muscle, whereas magnesium and calcium contribute to muscle fiber contraction post mortem. Sulfur (2.5 mg g^{-1}) is present in sulfur-containing amino acids that compose proteins, whereas chlorine (0.65 mg g^{-1}) is principally an anion for salts in soft tissues and intracellular fluids.

Iron, copper, zinc, iodine, manganese, molybdenum, cobalt, and selenium are essential microelements in the diet, whereas barium, bromine, cadmium, chromium, and fluorine are microelements within meat tissues with defined functions. Aluminum, arsenic, boron, lead, lithium, nickel, rubidium, silicon, silver, strontium, titanium, and vanadium are present,

Table 9 Resting and postmortem muscle glycogen and lactate concentrations

Species	*Resting*		*Postmortem*	
	Glycogen (mmol g^{-1})	*Lactate (mmol g^{-1})*	*Glycogen (mmol g^{-1})*	*Lactate (mmol g^{-1})*
Bovine	60–100	10–16	16–37	72–100
Porcine (normal)	52–85	16–28	1–10	79–97
Avian	37–56	10–40	0–7	89–120

Color and Pigment

SP Suman, University of Kentucky, Lexington, KY, USA
P Joseph, Kalsec, Inc., Kalamazoo, MI, USA

This article is a revision of the previous edition article by DP Cornforth, P Jayasingh, volume 1, pp 249–256, © 2004, Elsevier Ltd.

Introduction

The color of meat is the most important attribute influencing consumers' purchase decisions at the point of sale. Consumers often correlate cherry-red color of fresh meats with wholesomeness. However, at the point of consumption, a dull-brown color of cooked meats is used as an indicator of doneness. Cured meat products have a characteristic pink color. Myoglobin is the sarcoplasmic heme protein primarily responsible for the color of meat harvested from well-bled carcasses. Nonetheless, hemoglobin, cytochrome, and other pigments may also be present in meats at low levels and contribute to color to a lesser extent. Although exsanguination of food animals removes significant amount of blood, residual blood/hemoglobin can be found in blood vessels within the skeletal muscles and can contribute to meat color. In general, pigments other than myoglobin are more relevant to color in poultry and game meats than in red meats.

Myoglobin

The pigment myoglobin is composed of a protein moiety (globin) and a heme prosthetic group. In live muscles, myoglobin is responsible for oxygen binding and delivery functions. The globin polypeptide chain consists of eight helical segments – A through H, which forms a coil around the heme moiety (Figure 1). The hydrophobic heme group is arranged such that the vinyl groups are oriented toward the hydrophobic interior and the propionic acid groups toward the outer surface of the molecule (Figure 2). The heme group of myoglobin contains an iron atom that can exist in a reduced (ferrous/Fe^{2+}) or oxidized (ferric/Fe^{3+}) form. The globin portion of the molecule confers water solubility upon the hydrophobic heme group and, more importantly, protects the heme iron from oxidation. The resonant nature of the conjugated double bonds of heme is responsible for the ability of myoglobin to absorb visible light.

The ferrous iron within the heme group can accept six electrons in its outer orbital and can thus form six coordinate bonds, four with pyrrole groups of the porphyrin ring of heme and one with histidine (F8 position in globin), which connects heme to the globin chain. The sixth position is available for binding oxygen or other small ligands such as carbon monoxide (CO) or nitric oxide (NO).

Amino Acid Sequence of Myoglobin

In the postgenomic era, the amino acid sequences of myoglobins from several hundred species are available in the protein databases. Mammalian and avian myoglobin molecules consist of a single polypeptide of 153 amino acids. The molecular masses of beef, water buffalo, pork, sheep, goat, and horse myoglobins are 16 946, 17 034, 16 953, 16 923, 16 896, and 16 952 Dalton (Da), respectively. However, avian myoglobins are approximately 300–400 Da heavier than their mammalian counterparts, and the molecular masses of myoglobins of turkey, chicken, ostrich, and emu are 17 291, 17 291, 17 297, and 17 380 Da, respectively. Several low-molecular weight amino acids in red-meat myoglobins are replaced by heavier ones in avian myoglobins leading to the mass increment. In addition, these substitutions provide improved protection to the heme group in avian myoglobins. Tuna myoglobin has only 146 amino acid residues and a lower molecular weight (15 529 Da) than avian and mammalian myoglobins. Livestock and poultry myoglobins are among the few proteins in biological systems that do not contain cysteine residues. In contrast, highly oxidizable cysteine residues are present in the myoglobins of humans, great apes, rodents, and tuna. The presence of cysteine contributes to the rapid oxidation in tuna myoglobin.

In mammalian and avian myoglobin molecules, the heme is attached to the globin moiety at histidine F8, which is

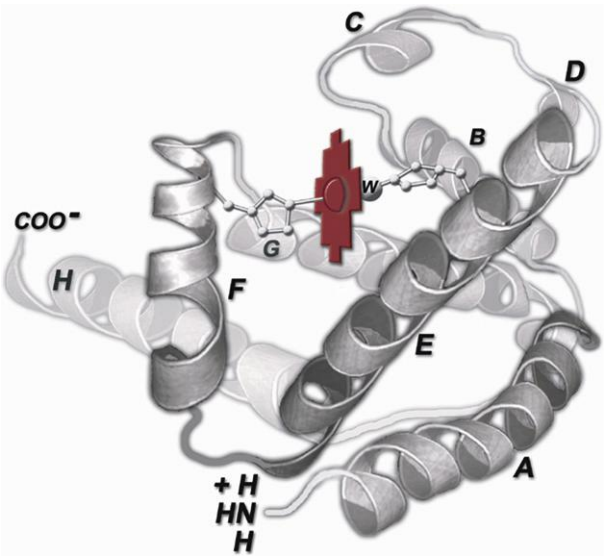

Figure 1 The myoglobin molecule consists of heme attached to globin. A to H indicate the eight helical segments of the globin moiety. The heme group is located in a hydrophobic cleft, where only small ligands such as oxygen and carbon monoxide have ready access. Owing to the hydrophobic environment, even water (W) has limited access to the heme group.

 doi:10.1016/B978-0-12-384731-7.00084-2

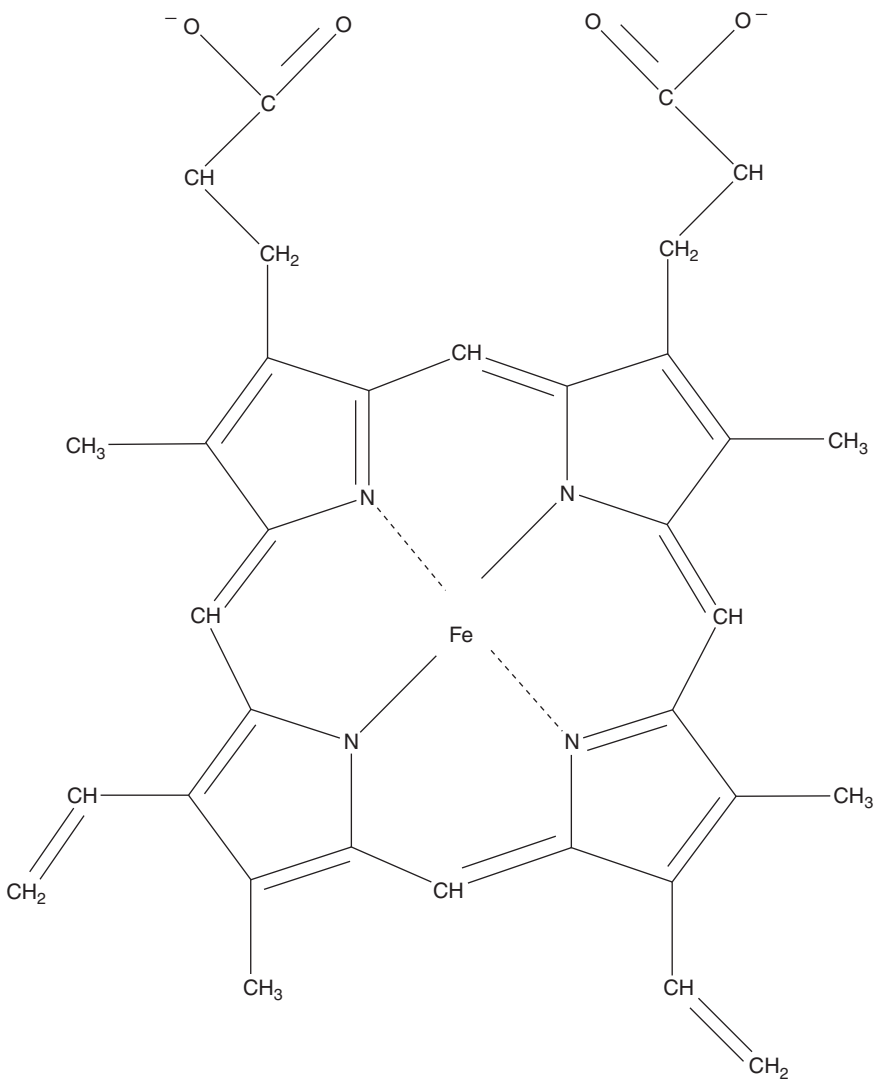

Figure 2 Planar view of the heme group of myoglobin. The iron can be in a ferrous (Fe^{2+}) or ferric (Fe^{3+}) form.

residue 93 from the amino terminal. Histidine 93 is termed the proximal histidine. The heme group is also stabilized in the heme pocket by coordination with histidine 64, the distal histidine, which is located in the E segment of globin. Whereas distal and proximal histidines are conserved in livestock myoglobins, in elephant myoglobin distal histidine is substituted by glutamine, and this substitution contributes to the absence of proton-catalyzed autoxidation. Despite the differences in amino acid sequences, several biological, structural, and functional properties of myoglobin are conserved across mammalian and avian species. Nevertheless, the primary structure of myoglobin influences biochemical attributes such as autoxidation, heme retention, structural stability, thermostability, and oxygen affinity, which are critical to meat color stability as well as the protein's function in live animals.

Several phylogenetically closely related mammalian and avian species have identical or nearly identical myoglobins. The myoglobins of European cattle, American bison, and yak have the same amino sequence. Zebra myoglobin is identical to horse myoglobin; myoglobin of European red deer is identical to that of the North American white-tailed deer. Among poultry species, chicken and turkey myoglobins share the same primary structure. Furthermore, myoglobins of several meat-producing ruminant livestock demonstrate high homology, albeit differences at key amino acid positions (e.g., European cattle and water buffalo; sheep, and goat). Histidine residues in myoglobin are susceptible to nucleophilic attack by reactive lipid oxidation products. The number of histidines in livestock myoglobins is 13 in beef and water buffalo; 12 each in horse, sheep, and goat; and 9 in pork (Figure 3). However, turkey and chicken myoglobins contain 9 histidines.

Myoglobins of meat-producing livestock share 85–100% homology in primary structure. The amino acid sequences of pig, cattle, sheep, goat, water buffalo, and horse myoglobins differ at 29 positions. Five mutations are required to obtain pig myoglobin from ancestral mammalian myoglobin, whereas 24, 19, and 13 mutations are necessary to obtain cattle, sheep, and horse myoglobin, respectively. Thus, pig myoglobin can be considered the most primitive among the domestic mammals.

Pigments in Fresh Meats

Myoglobin Redox Forms in Packaged Fresh Meats

In packaged fresh meats, myoglobin can exist in any of the four redox states – deoxymyoglobin, oxymyoglobin, carboxymyoglobin, and metmyoglobin (Figure 4). Deoxymyoglobin, oxymyoglobin, and carboxymyoglobin are in the ferrous state. Deoxymyoglobin is purplish-red, whereas oxymyoglobin and carboxymyoglobin provide bright cherry-red color critical to consumer acceptance. Deoxymyoglobin does not have any ligand bound with the heme iron, whereas the sixth coordinate of heme iron is occupied by oxygen in oxymyoglobin and CO in carboxymyoglobin. Formation of brown metmyoglobin results from oxidation of the ferrous forms to a ferric state and is associated with meat discoloration. Metmyoglobin has a water molecule bound at the sixth coordinate of the ferric heme. It is incapable of binding oxygen and thus is physiologically inactive. All the four forms of myoglobin are soluble in cold water, and the best extraction can be achieved by 0.04 M phosphate buffer at pH 6.8. The visible light absorption maxima and chemistry of fresh meat pigments are presented in Table 1.

The porphyrin ring of heme pigments absorbs visible light in the Soret region (400–440 nm). The interactions between heme iron and ligands are responsible for the alpha and beta absorption peaks. Whereas deoxymyoglobin exhibits a strong absorption maximum at 555 nm, oxymyoglobin absorbs at 420 nm in the Soret region and has large twin maxima at 544 and 582 nm. Very similar to oxymyoglobin, carboxymyoglobin also has two absorbance maxima at 543 and 581 nm. Metmyoglobin exhibits peaks at 409 and 500 nm, with a small peak at 630 nm. The absorption spectra of the four redox forms intersect (isobestic point) at 525 nm. Thus, spectrophotometric absorbance at 525 nm is used to estimate total myoglobin concentration in fresh meats. Treatment of meat samples with potassium ferricyanide converts all myoglobin forms into cyanometmyoglobin, allowing quantitation by spectrophotometric measurement of absorbance at 540 nm.

Carbon monoxide has a greater affinity to hemoglobin than oxygen, leading to the displacement of oxygen from blood resulting in carbon monoxide poisoning. Similarly,

myoglobin also has a high affinity for CO, forming bright cherry-red carboxymyoglobin. The visible light absorption spectra of carboxymyoglobin and oxymyoglobin are nearly identical, and the red color of these two proteins is similar and indistinguishable to the naked eye. Nevertheless, there are distinguishable differences between the absorbance spectra of these two cherry-red redox forms in the alpha and beta peaks. The differences in the relative intensities of the two peaks can be used to differentiate these redox forms in aqueous solutions.

Carboxymyoglobin is more resistant to oxidation than is oxymyoglobin, owing to the strong binding of CO to the iron-porphyrin site on the myoglobin molecule. Therefore, low levels of carbon monoxide are beneficial in modified atmosphere packaging (MAP) of fresh meat to maintain a stable cherry-red color. Between 1985 and 2004, the Norwegian meat industry had safely and effectively used low levels of carbon monoxide in fresh meat MAP. The MAP system consisted of 0.4% CO and variable combinations of nitrogen and carbon dioxide. In 2004, Norway discontinued the use of CO MAP in compliance with the regulations in European Economic Area. A similar MAP system was approved for retailing fresh red meats in the US in 2004. Although myoglobin of fresh meat strongly binds CO, the CO is released

upon exposure to light and heat. Interestingly, carboxymyoglobin is one of the pigments responsible for the pinking of irradiated chicken breast meat, as a result of CO production during the irradiation process.

Cytochrome c

Cytochrome c is a low-molecular weight (13 000 Da; 104 amino acids) hemoprotein, which participates in the redox reactions involving the synthesis of ATP (adenosine tri phosphate) in the mitochondria. Cytochrome c, associated with electron transport chain and inner mitochondrial membrane, can be spectrophotometrically distinguished from myoglobin by its absorption peaks at 521 and 550 nm (Table 1). Relative to the myoglobin content, cytochrome c is found at low levels in red meats than in poultry. However, cytochrome c possesses greater heat stability than myoglobin. Thus it can contribute to the persistent pink color in cooked turkey rolls after other heme pigments have undergone denaturation-induced browning.

Sulfmyoglobin

Reaction of hydrogen sulfide with ferrous heme iron of myoglobin yields the green pigment sulfmyoglobin, with a characteristic absorption peak at 617 nm (Table 1). Greening is associated with the growth of sulfhydryl-producing bacteria *Pseudomonas mephitica*. This organism requires low oxygen tension (less than 1%) and a pH greater than 6.0 for the production of hydrogen sulfide from sulfur-containing amino acids. To avoid the green discoloration, meat with high ultimate pH (such as dark cutting beef) should not be packaged under low oxygen tensions (vacuum packaging or low oxygen-modified atmosphere packaging systems). Oxidation of sulfmyoglobin by oxygen or ferricyanide yields the red pigment metsulfmyoglobin (Table 1), leading to the disappearance of the absorption peak at 617 nm.

Acid Ferrimyoglobin Peroxide

This green pigment is the product of hydrogen peroxide-induced oxidation of myoglobin under acidic conditions, along with oxidation of the distal histidine. It is also known as hydroperoxymetmyoglobin. Lactic acid-producing microbes such as *Lactobacillus viridescens*, *Leuconostoc*, and *Pediococcus* generate hydrogen peroxide under aerobic conditions. These facultative bacteria are salt-tolerant, catalase-negative, and are capable of growing at low temperatures.

Ferrimyoglobin Peroxide

This red pigment is also a product of hydrogen peroxide-induced oxidation of myoglobin. The action of peroxide on myoglobin first generates the red intermediate ferrimyoglobin peroxide. The red pigment accumulates under alkaline conditions (pH 8.0) and is subsequently converted into the green pigment (acid ferrimyoglobin peroxide) under mild acidic conditions of meat.

Ferrocholemyoglobin

The green pigment ferrocholemyoglobin is formed when myoglobin oxidation proceeds extensively leading to cleavage of the porphyrin ring. The degree of myoglobin oxidation can be determined by the addition of a dilute solution of sodium dithionite (sodium hydrosulfite), which is a strong reducing agent. The green pigments sulfmyoglobin and hydroperoxymetmyoglobin are only mildly oxidized and therefore can be converted back to myoglobin by the addition of a reducing solution. However, the green ferrocholemyoglobin is almost completely oxidized and cannot be converted into myoglobin by dithionite.

Lipid Oxidation-Induced Myoglobin Oxidation

Lipid oxidation generates secondary reactive products, such as aldehydes and ketones, which are responsible for the off-odors. Aldehyde products of lipid oxidation covalently bind to myoglobin and accelerate heme oxidation and metmyoglobin formation, leading to meat discoloration. Lipid oxidation-induced meat discoloration has been studied using oxymyoglobin and 4-hydroxynonenal (a highly reactive aldehyde generated by the oxidation of lipids containing polyunsaturated fatty acids). Hydroxynonenal forms adducts with the histidine residues in myoglobin, including distal and proximal histidines, and compromises the protein's redox stability. Lipid oxidation-induced meat discoloration is species-specific; beef oxymyoglobin is more susceptible to a nucleophilic attack by lipid oxidation products than its pork counterpart. The differences in the primary structure of myoglobins, along with the number and location of histidines within the globin chain, are responsible for this observation. Greater oxidation rates are observed in oxymyoglobins with greater number of histidine residues, such as beef and sheep (12 histidines) than in pork and chicken (9 histidines). Comparative kinetic studies using mass spectrometry observed 4-hydroxynonenal adduction at distal histidine (93) in beef myoglobin, but not in pork myoglobin, indicating that lipid oxidation is more critical to beef color than to pork color. Furthermore, 4-hydroxynonenal preferentially adducted 2 histidines (at positions 88 and 81) in the close vicinity of heme pocket in beef myoglobin compared to only one histidine residue (at position 36) far away from the heme pocket in pork myoglobin.

Within a meat species, carboxymyoglobin shares same amino acid sequence with oxymyoglobin, and therefore can theoretically interact with lipid oxidation products in a way similar to oxymyoglobin. Although horse carboxymyoglobin demonstrated greater resistance to browning than horse oxymyoglobin on exposure to 4-hydroxynonenal, the amino acid residues adducted by 4-hydroxynonenal were the same (histidines at 24, 36, 48, 81, and 93) in both the redox forms suggesting possible similar mechanistic interactions.

Pigments in Cooked Meats

Exposure to heat during cooking of meat causes denaturation (unfolding) of the globin protein. The exposed heme is more

prone to oxidation than the one in its native state. Denaturation of globin in metmyoglobin results in the formation of denatured globin hemichrome (also called as ferrihemochrome), which is the pigment responsible for the dull-brown color of cooked meats. This dull-brown pigment is also formed when meat is cooked in the presence of air. Globin denaturation in ferrous myoglobin forms leads to the formation of pink/red ferrohemochrome (denatured globin hemochrome), which subsequently and readily is oxidized to brown ferrihemochrome. Cooking of meat under anaerobic conditions (canned meats and in vacuum bag in hot water) also generates the pink ferrohemochrome. Owing to heat denaturation of the globin protein, these pigments coagulate and therefore are insoluble in water or buffers. Thus, reflectance measurements are used to study cooked meat pigments. The pink denatured globin hemochromes are characterized by the reflectance minima at 530 and 558 nm (Table 2). The minimum at 558 nm is much more pronounced. However, brown hemichromes are characterized by the reflectance minima at 495 and 545 nm. Heat-induced denaturation of carboxymyoglobin (cooking of CO-treated meats) leads to the formation of pink-red denatured globin CO hemochrome.

A variety of pink hemochromes are possible if the heme iron is maintained in the reduced ferrous state (Table 2). All such hemochromes have reflectance minima near 530 and 560 nm. After heat-induced denaturation, nicotinamide or other nitrogen-containing ligands can bind with the heme group at the coordinate previously occupied by globin. Alternatively, the denatured globin may remain associated with heme, but nicotinamide or nitrogen-containing ligands (such as the histidine side chains of other denatured proteins) may associate with the sixth coordinate of heme. Nicotinamide hemochrome and related pyridine hemochromes have been investigated as a replacement for nitrite as additives to generate pink color in cooked meats.

Premature Browning

Premature browning (PMB) is the phenomenon observed in cooked ground beef wherein myoglobin denaturation occurs at a temperature lower than that is required to destroy foodborne pathogens. Because the dull-brown color of cooked beef is often considered as an indicator of doneness, PMB can lead to food safety concerns. The thermal denaturation temperatures are different for myoglobin redox forms, and therefore the incidence of PMB is influenced by the predominant redox form of myoglobin in beef before cooking. The resistance of myoglobin redox forms to thermal denaturation is in the order: deoxymyoglobin > oxymyoglobin > metmyoglobin. Processing strategies that increase the proportion of oxymyoglobin and metmyoglobin in beef, such as oxygen-rich packaging (high-oxygen MAP and aerobic packaging), thawing frozen beef, and bulk packaging, increase the incidence of PMB. In these cases, meat pigments are exposed to oxidative conditions before cooking, causing accelerated pigment denaturation during cooking. However, antioxidants and vacuum packaging increase the relative proportion of deoxymyoglobin and thus minimize PMB. Ground beef packaged in CO MAP demonstrates a low incidence of PMB, presumably due to the increased resistance of carboxymyoglobin pigment to oxidative environments and/or due to the pink-red denatured globin CO hemochrome resulting from the cooking of CO-treated beef.

Pink Color Defect

Pink color defect (PCD) is another color quality problem in cooked meats (primarily observed in poultry), which results in an uncooked pink appearance in fully cooked, uncured products. Consumers often correlate the pink appearance to an uncooked product, although the microbiological safety is

assured, and reject such products. Nondenatured myoglobin can be present at significant levels in meats cooked to internal temperatures as high as 80 °C. Meat pH above 6.0 (typical in poultry) also stabilizes myoglobin against heat-induced denaturation, resulting in the pink color after cooking. Although various preharvest and postharvest factors contribute to the occurrence of PCD, the interactions of myoglobin with ligands and small biomolecules are considered as a major endogenous factor contributing to PCD. Pink color may result if meat is exposed to nitrite in ingredients and water used in the processing plants, or to nitrogen dioxide and carbon monoxide in combustion gases from gas-fired ovens. Furthermore, the interiors of large roasts may appear brown immediately after cooking but turn pink during refrigerated storage due to slow conversion of the brown cooked pigment (denatured globin hemichrome) to its reduced form (denatured globin hemochrome). Molecular studies indicated that the unique biochemistry of poultry myoglobins, along with the protective pH of poultry meat (pH 6.2), contributes significantly to the increased thermostability of poultry myoglobins leading to the incidence of PCD.

Pigments in Cured Meats

Cured meat products have a stable pink color, which is generated through the reaction of meat pigments with nitrates/nitrites in curing mixture or with nitrogen dioxide in smoke. Sodium nitrite, applied either onto the surface or injected into the meat, is the ingredient responsible for the pink color of conventionally cured meat. In Roman times and before, meat was preserved using salt. Sea salt contains sodium or potassium nitrates, which are reduced to nitrites by bacteria leading to pink color development. In 1925, the US Department of Agriculture approved the direct addition of sodium nitrite to cured meats, accelerating the curing process. Smoked meats also have a desirable surface pinking, and nitrogen dioxide is the compound in smoke responsible for the cure reaction.

In all three curing pathways (nitrate, nitrite, and nitrogen dioxide), it is nitrous acid that reacts with myoglobin. On contact with water, nitrite forms nitrous acid, which reacts with myoglobin. Myoglobin is oxidized to metmyoglobin by nitrous acid, and subsequently the nitrous acid is reduced to heme-bound NO. Nitric oxide metmyoglobin is brown in color and is reduced to nitrosyl myoglobin (red pigment) under anaerobic conditions (brine equilibration). When subjected to cooking, nitrosyl myoglobin is denatured and converted into nitrosyl hemochrome, which is the final cured pink pigment (Table 3).

Nitrosyl hemochrome levels in meats are determined after extraction in 80% acetone, and the absorbance of the extracted NO–hematin is measured at 540 nm. If the extraction solution is acidified with concentrated HCl, total heme (as hematin) can be determined by absorbance at 640 nm. Cured meats with desirable pink color have 60–80% total pigment existing in the nitrosylated form. Very low levels of nitrite are needed for pinking; as little as 4–6 ppm of sodium nitrite is sufficient for pink color development. Addition of excess nitrite (>1000 ppm) causes excessive myoglobin oxidation to green nitrimetmyoglobin (nitrite burn).

Although nitrosyl hemochrome is stable, it is sensitive to the presence of oxygen, temperature, and light. Exposure to oxygen and light leads to the fading of cured color. Under these conditions, the bound NO dissociates and the heme iron is oxidized to the ferric form. Pink color dissipates as the concentration of gray–tan cooked meat pigment (denatured globin hemichrome) increases. Therefore, cured products are vacuum packaged in opaque protective films for retailing.

Palatability

RK Miller, Texas A&M University, College Station, TX, USA

Glossary

Cold shortening A physiological occurrence that results from rapid temperature decline during the onset of rigor mortis; this process results in muscle fibers that are contracted to a greater extent than muscle fibers from muscles that were not subjected to very cold temperatures during the onset of rigor mortis.

Endomysium The connective tissue that surrounds muscle fibers.

Myofibrillar component The portion of muscle cells that contains the muscle proteins responsible for muscle contraction.

Perimysium The connective tissue that surrounds muscle bundles.

Phospholipid A lipid that contains phosphoric acid and fatty acids esterified to glycerol; found in all living cells and in the bilayers of the plasma membrane.

Protease A protein that is involved in breaking down or degrading other proteins.

Protein denaturation The process of modifying the molecular structure of a protein; alteration of the protein from its original state.

Sarcomere length A measurement of the distance between the two Z lines (outer boundaries) of one sarcomere.

Triglycerides Esters of glycerol that contain three ester groups and either one, two, or three fatty acids attached to the ester group.

Volatiles Compounds that are vaporized from a product.

Introduction

Meat palatability is important as it relates to the eating quality and consumer acceptance of meat as a protein source. Meat palatability relates to how meat tastes and is defined as juiciness, tenderness, and flavor. These three attributes have been related to consumers' perception of overall acceptability and preference. Juiciness is the amount of perceived juices in the meat during chewing or mastication. Tenderness is how easily meat breaks down during chewing. Toughness would be the opposite of tenderness or it is the resistance of meat to breakdown during chewing. Flavor is a combination of smell from the olfactory senses; aromatics perceived during consumption of meat from the olfactory senses; the basic tastes of salt, sour, sweet, and bitter are perceived from the tongue; and feeling factors in the mouth during the consumption of meat. Also, flavor consists of aftertastes perceived after consuming the product. Although these three palatability components have been shown to individually impact consumer preferences, they are also interrelated and changes in one component might affect another component. For example, trained sensory panelists can measure whether a meat sample is dry or juicy and if the same sample is tough or tender. However, when serving the same sample to consumers, they might not differentiate between juiciness and tenderness. Additionally, consumers may perceive a dry product as tougher, even if the samples are similar in mechanical measurements of tenderness.

There are many factors, both antemortem and postmortem, that affect meat palatability. These factors influence meat palatability by affecting the underlying chemical and physical components within meat. Therefore, it is important to understand how chemical and physical components of meat impact meat palatability before understanding how meat palatability can be managed, altered, or impacted by live animal management, harvesting, or processing. Meat is comprised of lean tissue or muscle fiber cells (also called the myofibrillar component of meat), fat, and connective tissue. Fat or adipose cells are found intramuscularly as marbling, contained between muscles as seam fat, or fat that is deposited externally as subcutaneous fat. The three major components of meat – fat, lean or the myofibrillar component, and connective tissue – impact meat palatability in different ways.

Fat or Lipids: Effects on Meat Palatability

Intramuscular fat content or marbling affects flavor, juiciness, and tenderness of meat. The 'Window of Acceptability' presented in Figure 1 illustrates the role of increased intramuscular fat on pork, lamb, and beef palatability. In general, as fat content increases, palatability increases, but the rate of improvement in palatability with each incremental increase in fat is not constant. When meat contains less than 3% fat, meat palatability is lowest and is outside the acceptability window. As fat increases from less than 1% to 3%, palatability increases at the highest rate. In fact, this is the steepest slope on the curve or where the greatest improvements in meat palatability occur. As fat increases from 3% to approximately 6%, meat palatability improves, but not as dramatically as reported at the lower levels. As fat content exceeds 7.3%, meat fat content is again outside the Window of Acceptability as the fat is plainly visible and might be perceived by health-conscious consumers as too high in fat content. High fat content in foods has been related to increased incidence of coronary heart disease, obesity, or some forms of cancer in humans. Diet/health-conscious consumers may be willing to sacrifice palatability for lower fat content meat in order to reduce their risk of the aforementioned dietary-related diseases. Therefore, meat with fat content between 3% and 7.3% is generally considered acceptable.

As meat fat content increases, juiciness increases. During initial chewing of high fat content meat, fat is released. Humans

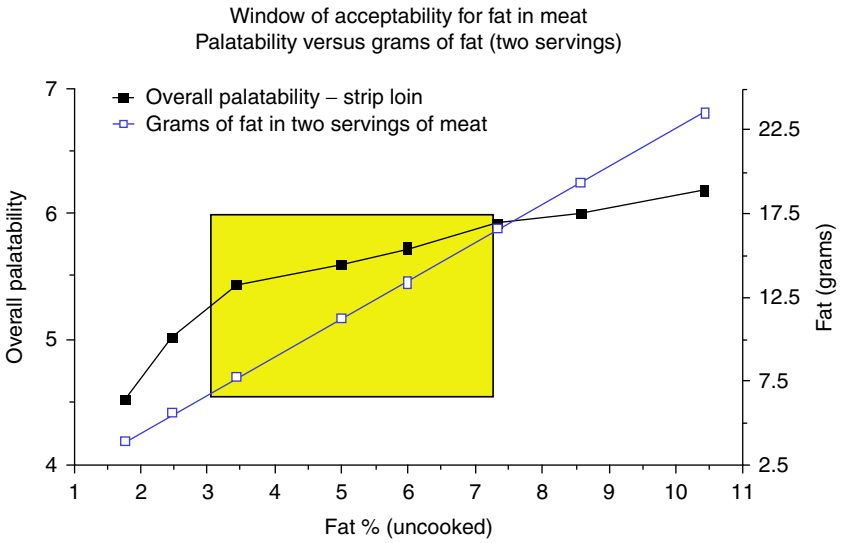

Figure 1 The window of acceptability to demonstrate the relationship between grams of fat and meat palatability. Adapted from Savell, J.W., Cross, H.R., 1988. The role of fat in the palatability of beef, pork, and lamb. Designing Foods: Animal Product Options in the Marketplace. Washington, DC: National Academy Press.

perceive this fat as juice. Additionally, when fat is released early in the chewing process, the salivary glands are stimulated. With increased salivation, the meat is perceived as juicier. Meat with higher fat content will have longer sustained perception of juiciness. Also, fat affects juiciness by lubricating the muscle fibers during cooking and by increasing tenderness of meat.

Four Theories of Marbling or Lipid Contribution to Meat Tenderness

Intramuscular fat content affects meat tenderness, even though this relationship is not always strong. There is conflicting information on the relationship between meat fat content and tenderness. Four theories are proposed on why meat with higher fat content is tender. The 'bulk density theory' says that as fat is not as dense as heat-denatured meat proteins, meat with higher amounts of fat or soft tissue is more tender. Another way to express the relationship is that in high fat meat, a higher percentage of the bulk of meat is soft, the meat is more tender.

The second theory is the 'lubrication effect.' The majority of fat in meat is stored as triglycerides that are found in adipose cells. Adipose cells make up marbling or intramuscular fat and these cells are embedded in connective tissue surrounding muscle fiber bundles called perimysium. When meat is chewed, these lipids are released and they provide lubrication between muscle fibers. With higher lubrication, muscle fibers can give more during chewing or provide less resistance. If there is less resistance during chewing and the meat is perceived as more tender.

The third theory is the 'insurance theory.' This theory proposes that fat slows or provides insurance against severe heat-induced toughening of muscle fibers during cooking. Muscle cells are approximately 17% protein and approximately 75% water. Meat proteins help to hold water within the muscle. When meat proteins are heated, they denature and lose some of their abilities to hold water. The more severe the denaturation or the higher proportion of muscle fibers that are severely denatured, the greater the amount of water that is released from meat during cooking. This phenomena is called cooking loss. The weight of meat lost during cooking is mainly water, even though small amounts of water-soluble proteins and lipid also are lost. The goal is to limit the amount of water lost during cooking so that the muscle fiber proteins are not concentrated; the more concentrated the muscle fiber proteins are, the tougher the meat is. As fat is an insulator, or heat does not easily transfer through fat, meat with a higher fat content will slow down heat transfer during cooking. When heat transfer is not as rapid or severe, meat proteins do not denature to a great extent and less moisture is lost during cooking and the resulting meat is more tender.

The last theory is called the 'strain theory.' Adipose cells or marbling are imbedded in connective tissue perimysium. As marbling increases, perimysial connective tissue is weakened and does not play a large role in meat toughness. Therefore, the connective tissue is strained and the meat is more tender.

The four theories are difficult to prove and they are most likely not independent. Each theory could be contributing to fat's relationship with meat tenderness. Although some studies show a low to no relationship between meat fat content and tenderness, in general, whether palatability is measured using trained sensory panels or by consumers, meat with a higher fat content tends to be more tender, juicier, and flavorful. Meat with higher marbling provides some insurance against toughening and drying when cooked to higher degrees of doneness.

Use of Marbling or Intramuscular Fat to Segment Meat for Expected Palatability Differences

An example of marbling as an indicator of meat palatability is found in the United States Department of Agriculture (USDA), Agricultural Marketing Service (AMS) Beef Quality Grading System. The purpose of the USDA, AMS Beef Quality Grading

System is to segment beef carcasses into classes based on expected meat palatability. Beef cuts that qualify for higher beef quality grades are expected to be more tender, juicier, and flavorful and the value of this beef is greater. For carcasses from young cattle, the most common USDA, AMS Beef quality grades are from highest to lowest: prime, choice, select, and standard. To classify for a quality grade, the beef carcass is assessed for physiological age and the marbling in the Longissimus muscle at the 12th and 13th rib interface is assessed. The greater the marbling score, the higher the quality grade assigned and the higher the expected meat palatability. Figure 2 shows the relationship between the four major USDA quality grades for young beef and overall palatability rated by a trained sensory panel for beef top loin steaks. The figure shows the sensory attribute overall palatability score that was a combination of juiciness, muscle fiber tenderness, connective tissue amount, overall tenderness, and flavor intensity using eight-point descriptive scales. Marbling predicted beef palatability attributes with 30–38% accuracy and as quality grade increased, beef top loin steaks were more palatable. As the quality grade increased, the range of variation in palatability decreased as exemplified by the reduction in the size of the box for each higher quality grade. The size of boxes in Figure 2 represents the range of sensory scores for top loin steaks in that quality grade. Using a five on the bottom scale as the lowest level of acceptability (a five on this scale represents a verbal score slightly desirable for juiciness, tenderness, and flavor), the percentage of ratings less than five decreased as the quality grade increased. Note that the greatest improvements in reducing the number of steaks with ratings less than five occurred when quality grade changed from standard (traces and practically devoid marbling or less than 2% chemical lipid) to select (slight marbling or ~3% chemical lipid). As beef quality grade moved from select to choice, the percentage of samples with ratings below five decreased from 26.4% to 10.8%, respectively. Steaks from Prime carcasses only had 5.6% of the steaks with ratings less than five for overall palatability. This figure shows that marbling, or quality grades, are positively related to overall palatability. However, sensory ratings across quality grades overlap or there were standard steaks that were as palatable as prime steaks (Figure 3).

Consumers also can detect differences in meat palatability as marbling score changes. In the United States, consumers tended to rate top loin steaks with the highest amount of marbling (Top Choice that includes USDA, AMS marbling scores of modest and moderate) higher for palatability traits than those with low slight marbling (Table 1). Trained sensory panelists found that as marbling score increased, cooked beef top loin steaks from top choice were juicier, more tender, had more intense flavor, and they had higher levels of beef flavor and beef fat flavor than those with the lower marbling score of slight. Warner–Bratzler shear force values (a mechanical measure of meat tenderness) decreased, or steaks were more tender, for marbling scores of moderate, modest, and small (Top and Low Choice grades) than those with slight marbling (Select grade). The marbling to meat palatability relationship is not always strong for cuts from different muscles within an animal. When top round and top sirloin steaks were evaluated in the same study, marbling did not affect consumer ratings. Steaks derived from lower fat beef muscles tend not to be affected by the marbling to meat palatability relationship. As there is not as much fat and the fat content is less variable in other muscles, it would stand to reason that marbling would not impact palatability to the same extent. In muscles used for locomotion that have higher amounts of connective tissue, the higher amount of connective tissue plays a greater role in the palatability or tenderness than marbling or fat content.

The marbling or lipid to meat palatability relationship may not be as strong in meat from animals of other species as reported for beef. In a US pork consumer study, consumers rated pork loin chops the same regardless of lipid content (Table 2). pH of the meat had a greater impact on consumer

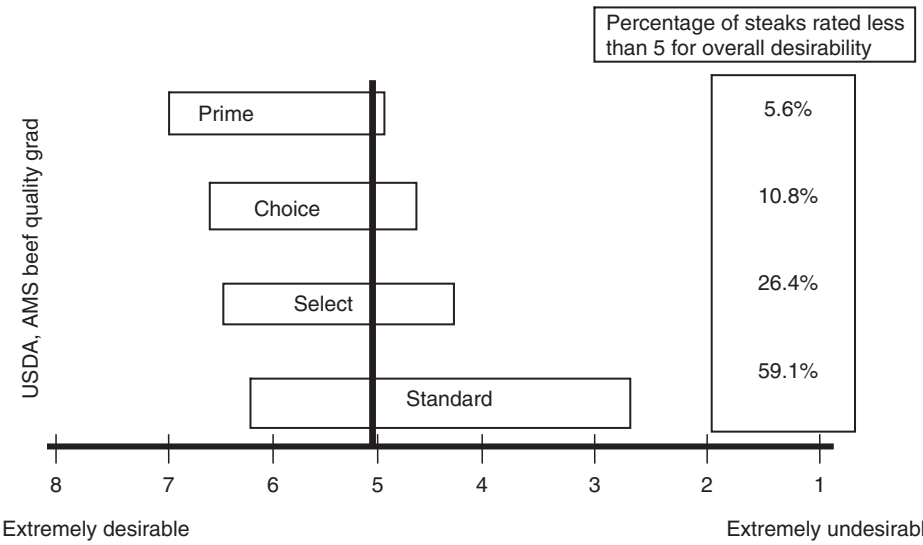

Figure 2 Percentage of loin steaks receiving desireable and undesirable overall palatability ratings, where 8 = extremely desirable palatability and 1 = extremely undesirable palatability. Adapted from Smith, G.C., Savell, J.W., Cross, H.R., *et al.*, 1987. Relationship of USDA quality grades to palatability of cooked beef. Journal of Food Quality 10, 269–286.

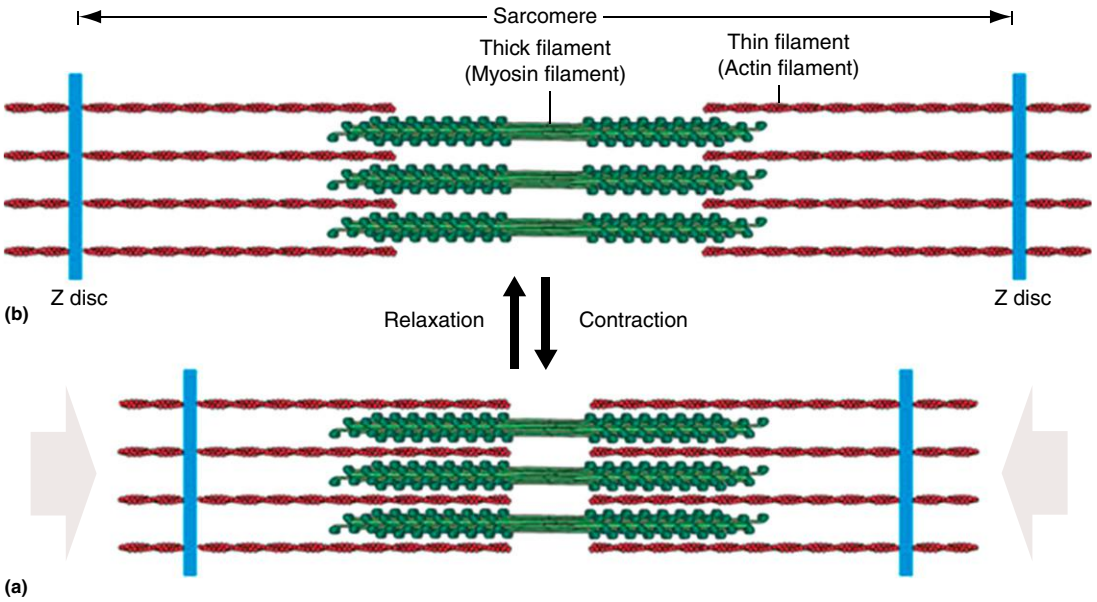

Figure 3 Illustrations of muscle fiber contractile state of postrigor muscle, where (a) shows a muscle fiber with a shorter sarcomere length than (b). The sarcomere length in (a) would be considered cold shortened and the sacromere length in (b) would be normal. The subsequent cooked meat from sample (a) would be tougher than the cooked meat from sample (b).

marbling to meat palatability relationship is also affected by cultural and geographic influences on consumer preferences.

Marbling or Intramuscular Fat as an Indirect Measure of Meat Tenderness

Intramuscular fat also has an indirect relationship to meat tenderness. As animals grow and develop, fat is deposited sequentially into five different fat depots – mesenteric fat; kidney, pelvic, and heart fat; subcutaneous fat; seam fat; and marbling or intramuscular fat. As marbing is the last fat depot to be deposited, it can be used as an indication of growth and nutritional status of animals. If animals are fed high energy-based diets, they grow rapidly or they have high rates of protein and lipid accretion. Therefore, these animals are heavier with higher levels of subcutaneous, seam, and intramuscular fat and greater muscle mass. These heavier, fatter, and more muscular carcasses chill slower and are less susceptible to cold-induced toughening. Meat from early postmortem muscle subjected to cold shortening or cold-induced toughening has shorter muscle contractile state that results in tougher meat. Additionally, animals fed energy-based diets that grow rapidly have higher collagen solubility. Meat that has greater collagen solubility will be more tender because, during cooking, more of the collagen matrix (the main component of connective tissue) will melt. As more collagen melts, the connective tissue within the muscle will not contribute toward meat toughness or the meat is more tender.

Marbling or intramuscular fat positively affects meat flavor (Tables 1–3). As fat level increases, consumers tend to like the flavor of beef and pork. Fat has a characteristic flavor and is one of the major components of meat flavor. Many times it is not the predominant flavor in meat, but it does provide a balance with lean meat flavors. When meat contains very low levels of fat, the predominant flavors are associated with the

lean, such as cooked beef lean, serumy, bloody, grainy, metallic, livery/organy, and brothy flavor aromatics. As the level of fat or marbling increases, the cooked fat aromatic or flavor increases in meat and this aromatic can assist in decreasing or masking flavor attributes associated with lean, thus providing a balance of meat flavors. The chemical basis of how adipose tissue and lipids contribute toward meat flavor will be discussed in the Section Lipids and Off-Flavor Development.

Muscle Fiber or Lean Components Contribution to Meat Palatability

Muscle fibers, or the cellular structure of meat, are the main components of lean meat. The unique aspect of muscle fibers is that they contain a very organized array of proteins that perform various functions. Muscle fiber proteins are classified either as contractile proteins, structural proteins, or regulatory proteins. The contractile proteins are the most abundant proteins and they perform work within the muscle fiber as well as function to bind water within the muscle cell. Structural proteins provide the lattice work or structural support for the muscle fiber and assist in organizing components of the fiber. The structural integrity, the ability of the muscle proteins to bind water, and the contractile state of the muscle fiber affects meat tenderness and juiciness.

In living tissue, muscle fibers are elastic and have the ability to contract and relax. During the conversion of muscle into meat, muscle undergoes a stiffening process called rigor mortis. In this process, muscle fibers lose their ability to relax. They stiffen and become inelastic. Sarcomere length is the distance between the two Z lines within a sarcomere. Z lines are rigid structures that compose the exterior of a sarcomere. They are very strong structures that have to withstand the forces applied during contraction. As Z line concentration increases within a given quantity of meat, meat is tougher as there is a higher concentration of rigid structures to bite or chew through. Conditions that result in shorter sarcomere lengths produce meat that is tougher; whereas conditions that result in muscles with longer sarcomere lengths produce more tender meat.

As sarcomere length shortens, there is less physical space for water to bind to the contractile proteins of actin and myosin. As a result, there is less physical water bound in the meat and juiciness decreases.

Strength of the structural components within the muscle fiber impacts meat tenderness. As the structural apparatus of muscle is degraded and weakened, meat tenderness improves. The structural apparatus of muscle fibers consist of Z lines and multiple structural proteins that hold the myofilaments in an organized array and help to strap the protein structures together and to the sarcolemma. With timely postmortem, degradative enzymes work to break apart the muscle fiber structural apparatus. As the structural component of the muscle fiber degrades, meat is more tender. This phenomena is called meat aging. Meat that is inherently tender immediately postrigor tends to not undergo substantial meat aging or tenderization with storage. Meat aging is also impacted by sarcomere length. Muscle fibers that are shorter do not degrade as rapidly postmortem as there is not sufficient room for degradative enzymes to work within the crowded sarcomere.

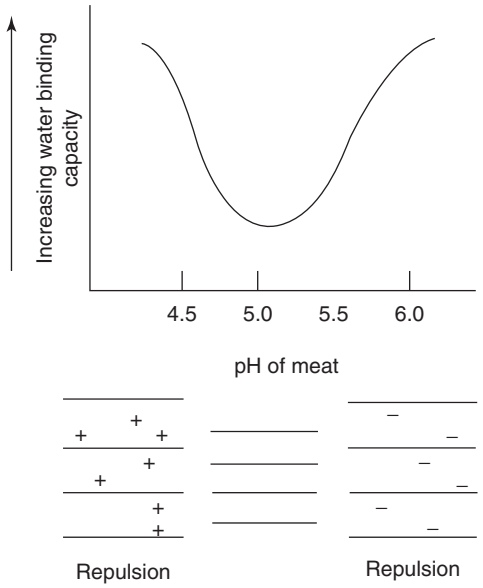

Figure 4 An illustration of the relationship between pH and water-holding capacity of muscle, where the isoelecric point is the pH where water-holding capacity is lowest. Adapted from Aberle, E.D., Forrest, J.C., Gerrard, D.E., Mills, E.W., 2001. Principles of Meat Science, fourth ed. Debuque, IA: Kendall/Hunt Publishing Company.

The ability of myofibrillar proteins to bind water within the muscle fiber also is related to meat tenderness and juiciness. Myofibrillar proteins have charged side-groups that contain ionic charges and these ionic charges bind water. Actin and myosin, the most abundant proteins in the muscle fiber, bind the majority of water within the muscle fiber. The charge on proteins can be either positive or negative. Charges on proteins can be altered by changing the pH. As pH increases, there is a net increase of negative charges and as pH decreases, protein side-groups become more positively charged (Figure 4). As the net charge of proteins become either more positively or negatively charged, ionic forces increase and water is bound or held more tightly to the proteins. An increase or decrease in meat pH will change the ratio of positive and negative charges on protein side-chains and will alter the ability of muscle proteins to bind water. The isoelectric point of a protein is the pH where there is a balance of positive and negative charges on the protein side-groups. The isoelectric point is where muscle proteins have the lowest ability to bind water. As meat pH reaches the isoelectric point, meat loses more water as drip loss during storage or water loss during cooking. As meat loses more water either during storage or during cooking, the meat becomes drier and tougher. Therefore, meat pH is an important component of meat quality as it relates to the ability of muscle proteins to bind water and the subsequent juiciness and tenderness of the meat.

Connective Tissue Influences on Meat Palatability

Muscles used for work or major movements have higher connective tissue content than muscles that provide structural support. Muscles with higher connective tissue are tougher. In

general, muscles from the hindquarter of animals used for locomotion, such as the Biceps femoris and Semimebranosus are inherently tougher than structural support muscles, such as the Longissiumus lumborum. Table 4 shows the relationship between collagen content and tenderness as measured by Warner–Bratzler shear force for 37 different beef muscles. As collagen content increases, muscles tend to be tougher.

Connective tissue is composed of proteins bound in a lattice-type structure. The major protein in connective tissue is collagen, even though elastin, reticulin, proteoglycans, and glycoproteins are also components of the connective tissue matrix. Collagen crosslinks within the connective tissue matrix and the type of crosslinks impacts meat tenderness. Crosslinks are either heat soluble or heat insoluble. In raw meat, collagen is elastic; however, with cooking, collagen undergoes thermal shrinkage and it can shrink to one quarter of its length. If collagen is bound by heat-soluble crosslinks, the protein can solubilize from the meat and not contribute to meat tenderness. However, if the collagen is crosslinked into stable linkages, the collagen matrix will shrink and develop force. The end result is tougher meat. Therefore, solubilized crosslinks are more tender and, on solubilization, collagen does not contribute negatively to meat tenderness. As animals age, the percentage of heat-stable or insoluble crosslinks increases. As the percentage of heat-stable crosslinks increase, meat is tougher. Meat from older animals is usually tougher than meat from younger animals and this phenomena is mainly due to increased proportion or percentage of collagen crosslinks in the heat-stable form.

Chemical Development and Reactions of Meat Flavor

Cooked meat flavor is the result of chemical reactions that occur within and between the lipid and lean portions of meat during cooking. Raw meat contains very little aroma. Raw meat aroma can be described as bloodlike or one that has a serumy taste, but precursors to cooked meat flavor are contained within raw meat even though in the raw state these precursors are nonvolatile or nondetectable. In general, cooked meat flavor develops as a result of interactions between amino acids, peptides, reducing sugars, vitamins, and nucleotides or their breakdown products during cooking from the lean component. Lipids also play a role in meat flavor and much of the species-specific flavor of meat is derived from adipose tissue. Lipid degradation and oxidation both contribute to meat flavor, usually negatively by contributing off-flavors.

Sulfurous- and carbonyl-containing volatile compounds are thought to be mainly responsible for flavor aromatics in meat. These chemical reactions are complex and intermediate reaction products can interreact with multiple products.

From a sensory standpoint, meat flavor is segmented into aroma or smell before consumption by the olfactory senses, the flavor aromatic perceived by the olfactory senses during chewing, basic tastes of sweet, sour, bitter, and salty sensed from taste receptors on the tongue; mouthfeels identified from the trigeminal receptors in the mouth that provide astringent and metallic sensory attributes; and aftertastes that are perceived after swallowing that are almost always flavor attributes perceived by the olfactory senses. The underlying chemical components that contribute to these sensory attributes have been extensively studied.

Cooked Meat Flavor Development

Cooked meat aroma or flavor aromatics are mainly derived from volatile compounds that develop during heating. In beef, 880 volatile components have been identified, but only 25 have meaty odors. Poultry has more than 450 volatile components with 16 primary odor compounds having been identified. Most of these compounds are the result of the effect of heat on sugars or amino acids. These reactions are defined

as Strecker degradations and Maillard reactions, and the secondary products of these reactions also can react and contribute to cooked meat aroma and flavor aromatics. Strecker degradation is the reaction of α-amino acids that results in the formation of alkylpyrazines. These Strecker aldehydes have meat aroma. Maillard reactions are the interaction of a free amino group, such as an amino acid, amines, peptides, proteins, or ammonia with a carbonyl compound. Examples of carbonyl compounds are aldehydes, ketones, and reducing sugars. Numerous volatile compounds or products result from this reaction as a wide array of precursors and reactive substances are available for reaction.

Maillard reactions are a series of reactions involving the reaction of aldehydes with amines and the ultimate development of meat flavor and dark pigments. In meat, the first reactions involve the reaction of an α-amino with an aldose or ketose. This results in the formation of Amadori or Heyns nonvolatile compounds. These compounds are heat labile, and with heat they decompose in the second-stage reactions. The result of the second stage is the formation of highly reactive compounds that decompose and further interreact. Also dehydration of cyclic forms of Amadori compounds contribute to the formation of volatile compounds. Maillard reactions with cysteine or cystine, sulfur-containing amino acids, have been extensively studied as these reactions and the subsequent products are major contributors to meat flavor.

Thermal degradation of thiamine is also an important meat flavor reaction. During heating, thiamine decomposition can result in the formation of carbonyls, furanoids, thiophenoids, thiazoles, and aliphatic sulfur compounds. These compounds contribute toward flavor and can also react with Maillard reactions products to form meat volatile compounds.

Basic Tastes in Meat

Compounds in muscle foods that contribute to the basic tastes of sweet, sour, bitter, and salty have been identified. Sweet basic tastes in muscle foods are related to the presence of carbohydrate and L-amino acid compounds. Levels of carbohydrates, such as glucose, fructose, ribose, and many L-amino, such as glycine, alanine, serine, threonine, lysine, cysteine, methionine, asparagines, glutamine, proline, and hydroxyproline contribute toward the sweet taste in muscle foods. Sour basic taste is derived from acid components in meat, such as aspartic acid, glutamic acid, histidine, asparagines, succinic, lactic, inosinic, orthophosphoric, and pyrrolidone carboxylic acids. Inorganic salts and the sodium salts of glutamate and aspartate contribute toward the salty basic tastes in muscle foods. Bitter basic taste comes from the presence of hypoxanthine, anserine, carnosine and other peptides, and the L-amino acids of histidine, arginine, lysine, methionine, valine, leucine, isoleucine, phenylalanine, tryptophan, tyrosine, asparagines, and glutamine. Umami tastes or the savory characteristic of meat is mainly derived from glutamic acid, but the presence of monosodium glutamate, 5′-inosine monophosphate, 5′-guanosine monophosphate, and other specific peptides also can contribute to umami tastes in muscle foods.

Species-Specific Flavor of Meat

Lipids not only contribute fat flavor to meat, but species-specific flavors are also found in the fat component. Lipid derived from the phospholipid component in meat (phospholipids are mainly found in muscle fiber membranes and make up $\sim$1% of the lipid in meat) contributes chemically to the development of meaty flavor aromatics, and the lipid stored as triglycerides are not essential to the development of meat flavor, but contribute to cooked fat-specific flavors. It is thought that heating of lipids results in volitilization of compounds contained in adipose cells that are species-specific. Therefore, the flavors that are specific to beef, lamb, pork, poultry, or fish are derived from adipose tissue. Additionally, adipose cells serve as reservoirs for storage of aroma compounds derived from external sources, such as the environment, feedstuffs, or for compounds that contribute toward flavor-forming reactions. The seasonal development of off-flavor in catfish is associated with the concentration of aromatic compounds in plants found at the bottom of lakes where catfish reside. For example, flavor aromatics of 2-methylisoborneol/lagoon/bluegreen, geosmin/musty/woody, rotten plants, and grainy/corn/green vegetable can be found in catfish. These aromatic flavors are associated with blue-green algae growth in pond water, decaying wet wood, decaying vegetation and feed grains, and corn husks, respectively. As catfish consume what is in their environment, off-flavors associated with increasing concentrations of these materials will be reflected in the harvested catfish meat. Similarly, cattle grazing on plants high in selenium will have off-flavors associated with the flavor of selenium and its by-products.

Lipids and Off-Flavor Development

Lipids also contribute to meat flavor through their contribution to the development of off-flavors, mainly through autooxidation or oxidation of lipids. Autooxidation is a three-step chemical process. The first step, or the initiation step, involves the attack of oxygen on unsaturated fatty acid double bonds to form highly reactive free-radical compounds and hydroperoxide. Phospholipds in muscle fibers have been shown to be the lipids most susceptible to lipid oxidation due to their high concentration of polyunsaturated fatty acids. Initiation reactions can be catalyzed by heme compounds but the predominant thought is that nonheme compounds most likely act as catalysts in meat systems. However, heme-containing compounds found in meat, such as hemoglobin, myoglobin, and cytochromes, also have been shown to contribute toward catalyzing the initiation of lipid oxidation. These highly reactive free-radicals then react in multiple potential reactions during the second step, or propagation. In propagation, multiple new peroxy radicals, hydroperoxides, and new hydrocarbon radicals are formed. Products of propagation interreact to form stable end-products in the third step, or termination. Some products from propagation and termination are volatile and contribute to off-flavor. These flavors have been described as rancid or the flavor in general has been called warmed-over flavor in cooked meats. More

specifically these off-flavor aromatics have been described as cardboardy, painty, fishy, and livery.

Other off-flavors in meat are also associated with species-specific issues such as mutton flavor in lamb that is a result of concentration of 4-methyloctanoic and 4-methylnonanoic acids or boar-odor in intact swine that is due to the presence of 5α androst-16ene-3one, a metabolite of testoterone.

Measuring Meat Flavor

Meat flavor can be detected either chemically or by using humans, defined as 'sensory evaluation.' Sensory evaluation may include either trained or consumer methods. Chemical detection of meat flavor identifies the volatile compounds from meat using gas chromatography. The compounds are separated, usually by molecular weight, and can be identified using mass spectroscopy. Ideally, as compounds come from the gas chromatography to the mass spectrometer, a portion of the compounds are directed to a sniff port. A trained evaluator can smell the compounds as they are eluded and identify the odor characteristics and intensity of volatile compounds. Because all volatile compounds not are detectable by humans, this information can be used to identify compounds that contribute to the flavor of meat. Multivariate techniques, mainly principal component analyses, can be used to identify compounds that contribute toward flavor attributes in the meat.

Flavor attributes in meat are commonly defined by trained sensory panels. Trained sensory panels can use flavor attributes defined in a flavor lexicon. The beef lexicon was developed after an expert panel evaluated beef under a multitude of conditions. The panelist determined descriptors of beef flavor and developed standardized references that could be used to uniformly and consistently identify and quantitate beef flavor attributes. The beef lexicon provides a list of attributes, definition of the attributes, and references to maintain a standard of identify across sensory panelists. Flavor attributes defined by trained, descriptive sensory panelists can then be used in principle component analyses to understand the relationship between chemical volatile compounds and human perception of flavor.

pH Measurement

KO Honikel[†]

This article is a revision of the previous edition article by KO Honikel, volume 1, pp 238–242, © 2004, Elsevier Ltd.

Glossary

pH buffer There exist strong, medium, and weak acids, and their counterparts strong, medium, and weak bases. The acids dissociate in aqueous solutions into H^+ (proton) and A^- (anion). Strong acids such as HCl dissociate to more than 99%, medium acids such as lactic acid to 1–5%, and weak acids to lesser than 0.1%. In water, the undissociated molecules of medium and weak acids will further dissociate with increasing pH. With declining pH, more undissociated molecules will be formed. In this way they provide more or take up protons and the increase or decrease of pH will slow down. These compounds buffer the pH change. The counteractive bases will perform in a similar way but the other way around.

Introduction

The pH of meat influences its color, water-holding capacity, flavor, tenderness, and shelf life. Its measurement at different times postmortem provides information about the forthcoming quality characteristics. The pH value at the full development of rigor mortis is termed as the ultimate pH. To monitor ultimate pH in a meaningful way, a proper measurement is necessary. However, because of the inherent characteristics of such measurements, it is not always easy to achieve accuracy and reliability.

What is pH?

The pH of a solution is defined as the negative base 10 logarithm ($\log_{10}$) of the concentration of hydrogen (H^+) ions or, to be more precise, the concentration of the reaction of H^+ with a water molecule to produce a hydroxonium ion (H_3O^+). For example, a concentration of 10^{-5} mol l^{-1} H_3O^+ in an aqueous solution has a pH of 5. The pH scale in aqueous solutions ranges between 0 and 14. Pure water has a pH of 7.0. In animal bodies most of the organs have similar neutral pH values, for example, blood has a pH value of approximately 7.3–7.4, muscles are in the pH range of 6.9–7.0.

Hydrogen ions are formed when acids such as lactic acid (CH_3–CHOH–COOH) dissociate in water according to eqn [1].

$$CH_3\text{–}CHOH\text{–}COOH + H_2O \leftrightarrows CH_3\text{–}CHOH\text{–}COO^- + H_3O^+ \quad [1]$$

The dissociation of acids can be more or less complete in strong acids such as hydrogen chloride, or it can be in equilibrium in medium strong acids such as lactic acid. Similar to pH, the degree of dissociation is defined as the pK of an acid (HA), where K is the dissociation constant of the reaction. The relationship between pK, concentration of hydrogen ions (C_{H+}), concentration of anion (C_{A-}), and concentration of acid (C_{HA}) is shown in eqn [2].

$$pK = -\log\left(\frac{C_{H+} \times C_{A-}}{C_{HA}}\right) \quad [2]$$

pK values are found in published tables. For example, for a 0.1 mol l^{-1} solution at 20–25 °C, the given pK value for lactic acid is 3.1. Using the pK value, the pH value of a solution of a weak or medium strong acid can be easily calculated. Using lactic acid as an example, the pH of a pure 0.1 mol l^{-1} lactic acid solution in water can be calculated using eqn [2], where it can be assumed that the concentration of H^+ is equal to the concentration of A^- (anion CH_3–CHOH-COO^-). Thus $C_{H+} = C_{A-}$, substituting the published pK value into eqn [2], results in eqn [3], which can be solved to give a pH value of 2.04.

$$\begin{aligned} 3.1 &= -\log\left(C_{H+} \times C_{H+}/10^{-1}\right) \\ 8.4 \times 10^{-4} &= (C_{H+})^2/10^{-1} \\ 8.4 \times 10^{-5} &= (C_{H+})^2 \\ C_{H+} &= \left(8.4 \times 10^{-5}\right)^{1/2} \\ C_{H+} &= 9.16 \times 10^{-3} \\ \text{pH} &= 2.04 \end{aligned} \quad [3]$$

The pH of an aqueous solution of 0.1 mol l^{-1} lactic acid is therefore approximately 2.0.

pH Changes from Muscle to Meat

During the early postmortem changes in muscles of slaughtered animals, the pH declines from approximately 7.0 in the muscle of a live animal to 5.3–5.8 as its final value, termed as ultimate pH (pH_u). The reason for the pH decline is the formation of approximately 0.1 mol l^{-1} lactic acid from glycogen in the anaerobic glycogenolytic pathway.

Buffering Capacity

The discrepancy between the pH of an aqueous 0.1 mol l^{-1} lactic acid solution of approximately pH 2 (see above) and the pH of approximately 0.1 mol l^{-1} lactic acid in meat (5.3–5.8) is due to the buffering capacity of other constituents in meat

[†]Deceased.

 doi:10.1016/B978-0-12-384731-7.00086-6

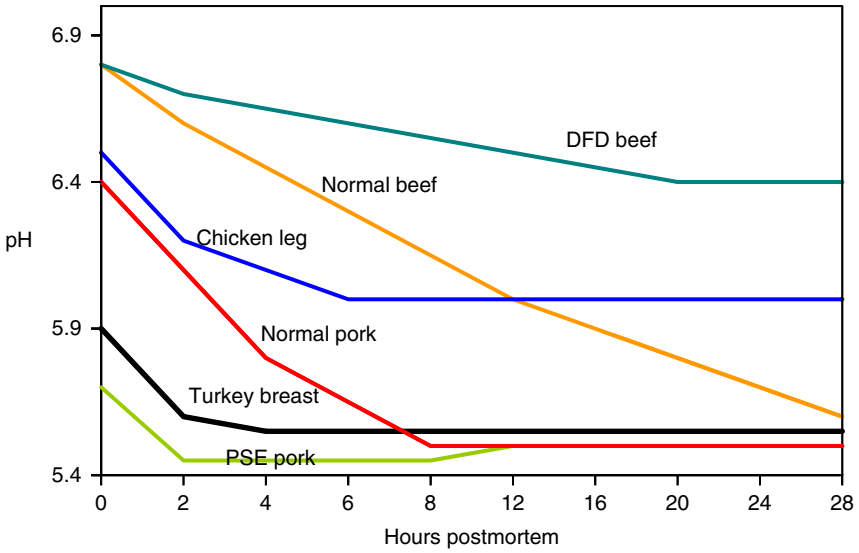

Figure 1 pH changes of individual muscles of different species. Muscles of different animals and species can differ from those shown here.

that modify the ultimate pH. Buffers are composed of either moderately strong or weak acids or bases (p*K* values between 3 and 9) and their soluble salts. These buffering substances in meat bind H^+ ions from the lactic acid formed and lactate anions prevail. It has been calculated, expressed in formed lactate units, by the breakdown of glycogen, that the buffering capacity in meat is between 35 and 50 mmol lactate/pH unit × kg of meat in the range of pH 7–5.

In a simple buffer of an acid and its corresponding salt, eqn [2] also applies. Owing to the addition of the soluble salt to the acid solution, the concentration of A^- is increased. This means that for the equilibrium to be maintained, C_{H+} must become smaller. This means in practice that both lactic acid and lactate mixtures have a greater pH than lactic acid solution alone. This happens with meat in a similar way, as expressed above in 'lactate terms' but it is much more complicated because there are many other constituents involved. Side chains of amino acids, peptides such as carnosine and anserine, phosphate ions, etc. serve as buffering substances and lead to ultimate pH values of 5.3–5.8 – more than 3 pH units greater than that of a pure lactic acid solution. In other words, less than 0.1% of the lactic acid formed is present in its dissociated form.

Importance of pH Changes and Ultimate pH in Meat

The ultimate pH of meat is reached at different times postmortem depending on species, muscle type, and stress over the preslaughter period and immediately preslaughter and can range from 5.3–7.0. The elevation of ultimate pH through stress affects tenderness and keeping quality. In pork muscles, a condition arises where the ultimate pH (5.3–5.5) is reached within 1–2 h postmortem termed pale, soft, exudative (PSE).

In normal pork muscles, pH values of 5.5–5.8 are reached approximately 6–8 h postmortem. In beef muscles, the ultimate pH of 5.5–5.6 occurs at 18–36 h postmortem. In chicken, ultimate pH values are usually greater, ending at pH 6.0 or more at 2–4 h postmortem under commercial chilling conditions (Figure 1). The rate of pH decline can be reduced by increasing the rate of carcass chilling; however, the extent of pH decline is dictated specifically by the glycogen content in the muscle at the time of exsanguination.

Quite often in bovine muscles, as a result of preslaughter stress, the pH decline stops at pH values above 6.0 owing to the lack of glycogen. The reduced glycogen content will result in less lactic acid. The so-called dark, firm, dry (DFD) beef or dark-cutting beef is the result (Figure 1). In such cases the pH values affect many meat properties including color and drip loss.

A low ultimate pH of approximately 5.5 has two effects on meat. The low pH prevents or retards microbial growth and the lactic acid/lactate gives the meat a positive flavor component. Also, at this pH the aging process results in tender meat. The rate of pH change postmortem also influences meat quality. Proteins in muscles before death are 'native' due to the prevailing salt concentration, pH value, and temperature. Falling pH values at prevailing high temperatures like those in PSE-prone muscles lead to the denaturation of proteins. These changes are counterbalanced by the rate of chilling of meat. If chilling and normal pH decline take place in a controlled way, as is achieved in many slaughterhouses, then the denaturation of proteins is limited and there is limited inactivation or activation of enzymes (e.g., calpains).

In PSE muscles of pork, the chilling of a carcass cannot keep pace with the fast pH decline. The final pH value can be reached at temperatures in the muscle well above 30 °C. Consequently many proteins denature – the meat becomes pale due to the denaturation of dissolved sarcoplasmic proteins including the meat-color-producing myoglobin. Also, proteins in membranes denature and intramuscular fluid can leak out into the extracellular space. The exudate (also termed drip loss) increases rapidly and the muscles become soft.

Time of pH Measurement

pH measurements early postmortem, at the end of the slaughterline at 30–45 min, are very helpful. A pH value of 5.8

and lower at 45 min postmortem indicates that pork muscles will very likely become PSE meat. An ultimate pH value above 6.0, as in DFD meat, indicates that an early microbial spoilage of the meat can be anticipated. Thus pH measurements are important for detecting meat quality characteristics.

Measurement of pH in Meat

Principal Methods

Until the end of the 1950s, the measurement of pH was carried out using a wide range of coloring substances (pH indicators) in a solution or bound to paper strips that changed color at various pH values. Although this was very helpful in an otherwise colorless solution, in meat or meat extracts, with their red color, colored solutions could not be used. Paper strips with pH indicators bound to the paper could be used, but they were still rather inaccurate with an error of approximately ±0.2 pH units. Indicator strips with a range of different indicator substances later enhanced the accuracy to ±0.05 pH units.

Glass electrodes were developed in parallel to metal electrodes in the 1950s. Glass electrodes are based on the principle that if a glass surface is immersed in a solution, the electrical potential developed depends on the hydrogen ion concentration. This potential can then be compared with that of another (a reference e.g., a metal) electrode so that, for example, the pH of a meat slurry can be measured with a good reproducibility. A glass electrode is a proton (H^+)-sensitive electrode. The proton sensor is a glass surface (membrane) that consists of a swollen surface layer (depth 5–500 nm) on both sides of the glass body of the membrane (Figure 2). On the outside surface of the membrane, hydrogen ions are replaced with sodium ions (Na^+). On the inside, a buffer solution with a constant pH is used. An electrical potential is built up, which is compared with a pH-insensitive reference electrode, usually a silver–silver chloride or calomel electrode, which is connected with a wick or diaphragm to the solution to be measured. This means that two electrodes need to be inserted into the same solution.

As this design was rather complicated, the so-called combination electrode was designed with glass and reference electrode combined in one shaft. The connection between the outside (the solution where the pH is measured) and the reference electrode inside is achieved via a porous ceramic membrane (Figure 3).

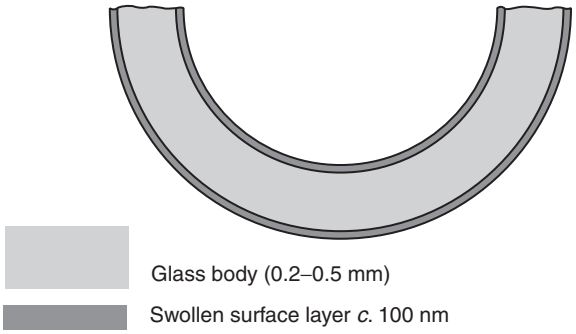

Figure 2 Structure of the glass membrane of a pH electrode.

The early glass electrodes were very fragile and could not be inserted into a piece of meat. The membrane and the diaphragm became rapidly contaminated with fat and protein particles and had to be cleaned rather frequently. Later a noble metal wire like platinum was fused in the glass shaft instead of a porous diaphragm to provide more reproducible results.

Between the outside and inside of the glass membrane, there is a high resistance of approximately $10^{10}\,\Omega$. The electrical potential between the inside and outside, measured through the diaphragm or another reference junction, must remain undisturbed. Fat or protein particles must not plug the junction. Furthermore, all parts (measuring solution or meat (carcass)) must be earthed to avoid false readings. As the glass membrane exchanges H^+ against Na^+ ions, pH measurements are influenced by a number of ions. Measuring in pure (distilled) water or in a high-salt solution (e.g., in brine with approximately 5% salt or more or in a salted batter) gives misreadings. Likewise concentrated protein solutions have a similar effect. In meat, the misreadings are not significant but an accuracy below 0.05 pH units is not possible. Temperature also has a greater influence on readings for the solution or meat.

In the 1990s, the so-called ion-sensitive field effect transistor electrodes appeared in the market. With these electrodes, the surface of a solid-state silicon chip binds H^+ ions and changes its conductivity. However, these surfaces also bind other charged particles such as proteins and have to be cleaned very frequently.

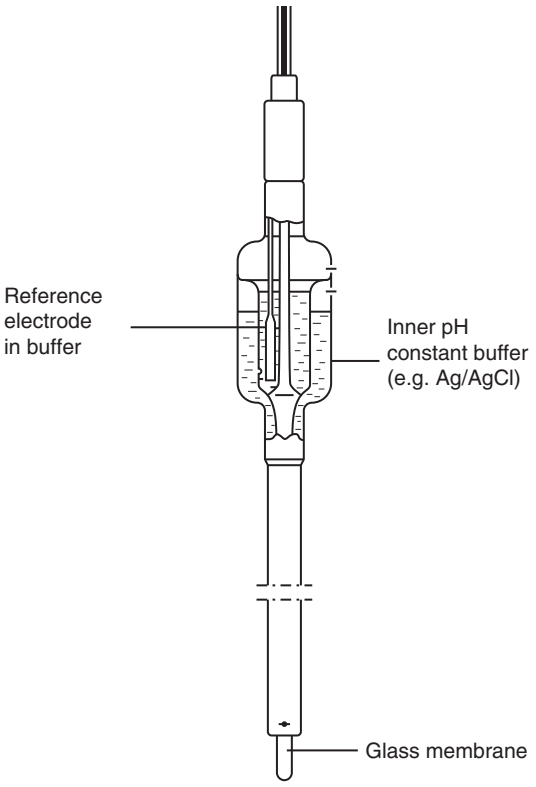

Figure 3 A modern combination of glass electrode. The connecting porous membrane or the noble metal wire is indicated by the black spot just above the glass membrane.

Today, glass electrodes are mechanically robust and stable enough to be inserted into meat. They measure pH in meat in a reproducible manner, if calibration and cleaning is done properly.

Conditions for Measurement

Most chemical reactions are temperature dependent, including the dissociation of acids and bases. Internationally, pH is recommended to be measured at ambient temperature of 20–25 °C. However, in meat, temperatures between 0 and 43 °C are common, so this must be kept in mind in interpreting pH measurements in meat, as in most cases calibration is done at approximately 20 °C, yet the meat may be at a considerably different temperature. Even a temperature adjustment at the glass electrode equipment itself corrects only the temperature dependence of the glass electrode and not the changes within the meat matrix or meat product, which may follow a different temperature dependence. Therefore, it is recommended to accept pH readings of meat to no more than one decimal place, if the calibration temperature and the temperature of the meat differ by more than 10 °C. Greater accuracy demands a calibration at the temperature of the meat. In these cases the temperature drift of calibration buffers must also be taken into account (Figure 4).

Calibration

Calibration and associated maintenance are the keys to meaningful pH measurements. A glass electrode has to be kept wet during storage. A dry glass electrode has to be conditioned (hydrated) for approximately 24 h. Electrodes should be kept in neutral buffer solution or in water. After 30–50 measurements a calibration must be carried out. At least once a day a calibration must take place.

For calibration, two buffer solutions, usually pH 7.0 and 4.0 or near these values, are taken from the refrigerator (where they should be stored to prevent microbial growth that affects the pH value). The solution has to be warmed up to the ambient temperature of the calibration pH solution. After initial cleaning of the combined glass electrode with distilled water, the electrode is inserted into the standard pH 7 buffer solution with agitation and the instrument is adjusted, taking approximately 20 s to reach the pH of the calibration buffer (e.g., 6.98).

The glass electrode is removed from the first buffer and cleaned thoroughly with distilled water, then it is inserted into the second standard pH solution, the pH 4 buffer. After 20 s of agitation and a stable reading, the pH meter is then set to this second standard buffer value.

The glass electrode is taken out, cleaned again with water, and the procedure starting with the pH 7 buffer is repeated until the values of both calibrating buffers read stable. In many modern instruments, clear stepwise instructions are displayed to facilitate calibration.

In most cases two buffers are absolutely necessary. A linear calibration curve – the linearity between pH 4 and 7 can be assumed – is defined either by two points (two calibration buffers) or one point and a constant slope. However, a constant slope recommended sometimes by the manufacturers cannot be guaranteed with an electrode in regular use as an electrode ages. This is why calibration with two buffers is strongly recommended.

Electrode deterioration is noted when the electrode cannot be calibrated by the process described above. Then it is either too old or it should be reactivated. To do this, the electrode surface is first cleaned with warm water (<45 °C) to dissolve fat films, then the electrode is inserted into a protease solution (pepsin, chymotrypsin, papain) and left there at room temperature for 1 h. After cleaning with water, the calibration procedure should be repeated. If the result is not satisfactory, repeat the protease cleaning step. If successful calibration is not achieved after carrying out the cleaning process three times, the electrode should be changed.

Although modern solid-state chip electrodes are robust, they still need cleaning and the recommendations of the manufacturer must be followed. Calibration must also be carried out with these electrodes.

It should be kept in mind that a pH electrode does not have the same reliability and stability as a calibrated thermometer, which merely has to be checked once in a while. pH electrodes

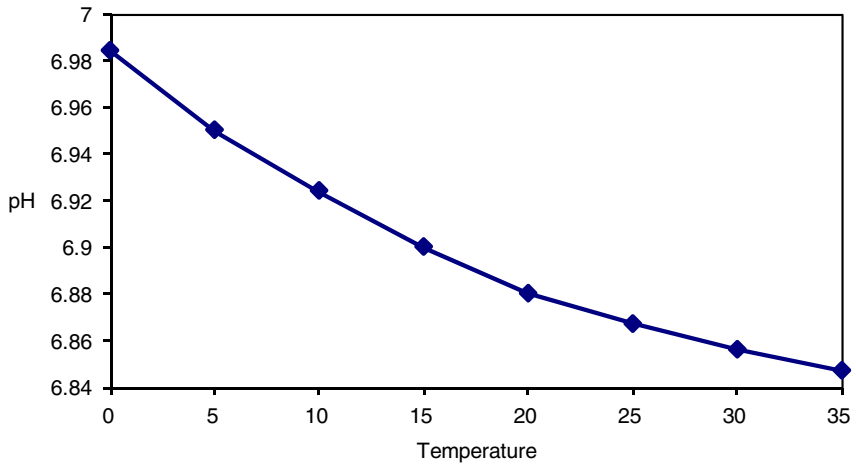

Figure 4 The effect of temperature on a phosphate buffer.

must be calibrated regularly as many factors may influence the ability of the measuring glass surface to exchange H^+ against other cations.

Conclusion

The pH of meat is an important indicator of meat quality characteristics. It can be used to detect PSE and DFD meat and it can monitor manufacturing processes. Nowadays, pH measurements are done with either glass electrodes or solid-state chip electrodes, but they need frequent calibration. Owing to temperature differences during measurement, the accuracy of a measurement is no more than to one decimal place.

Protein Functionality

YL Xiong, University of Kentucky, Lexington, KY, USA

This article is a revision of the previous edition article by YL Xiong, volume 1, pp 218–225, © 2004, Elsevier Ltd.

Glossary

Adhesion/binding A process that binds meat particles together as in restructured products.
Emulsification A process that disrupts fat into small particles, which are stabilized by a protein coating and dispersed in a heterogeneous aqueous matrix consisting of salt-soluble myofibrillar proteins, segments of muscle fibers and myofibrils, connective tissue fibers, collagen fragments, and various ingredients.
Functionality Physicochemical performance of muscle proteins in meat processing.
Gelation A process by which proteins interact to form a three-dimensional aggregated network that entraps a large amount of water.
Meat batter A meat emulsion that is multiphasic and heterogeneous, which differs from the simple oil-in-water or water-in-oil emulsion.
Solubility The percentage (w/w) of the original protein dissolved in an aqueous solution under specific extraction conditions.
Surimi A washed muscle mince or alkali/acid extract that is concentrated with myofibrillar protein.
Water binding The immobilization of water within muscle fiber or meta-homogenate through interaction of proteins with water or physical entrapment in protein matrixes.

Introduction

Definition of Functionality

The term 'functionality,' as used in meat science and discussed in this article, generally refers to the physicochemical performance of muscle proteins in meat processing. It should be distinguished from nutritional functionality, which describes the health-promoting effect of certain proteins and various other components indigenous to food materials. Thus, functional properties of muscle proteins include texture-forming and related properties, namely, water binding, fiber swelling, solubility/extractability, gelation, emulsification, and meat particle adhesion/binding. Although muscle proteins, particularly those soluble in the cytosol, can be excellent surfactants and, hence, are capable of stabilizing foams, their foaming behavior is generally considered a nuisance because, except in some ethnic foods (e.g., mousses), the foams produced hinder the operation of processing equipment. Therefore, foaming properties will be excluded from this article.

Types and Roles of Muscle Proteins

The three groups of muscle proteins – sarcoplasmic proteins (water soluble), myofibrillar proteins (soluble in solutions of >0.5 ionic strength), and stromal proteins (soluble in alkaline or acid solution) – play different roles in meat processing. Generally, sarcoplasmic proteins are relatively small in size. They are of high surface activity and, therefore, can act as emulsifiers and have a strong tendency to generate foams. Stromal proteins, which consist mainly of collagen molecules found in the connective tissues epimysium, perimysium, and endomysium, have a limited role in the structure and texture formation in comminuted meats. However, when sufficiently hydrated through slow, moist cooking, collagen is converted into gelatin, which exhibits remarkable water-binding capacity and readily forms a cold-set gel. Myofibrillar proteins, however, have the ability to impart multiple functionalities, including gelation, emulsification, water binding, and adhesion. The versatility of this protein group lends itself to the development of a variety of texturized, restructured meat products, such as luncheon meats, boneless turkey hams, and various frankfurter-type meat items.

Factors Affecting Protein Functionality

Large variations in quality attributes exist between muscle foods produced by different processors, or even within the same type of products (e.g., frankfurters). Much of the variation is caused not only by the use of different nonmeat ingredients but also by the specific functionality that muscle proteins impart under given processing conditions. The amino acid composition and peptide sequence, the spatial arrangement of the protein structure, the size (mass) and shape of the protein molecules, the solubility characteristics, the concentration of extracted proteins in the aqueous phase, surface hydrophobicity, and muscle fiber types are some of the most important intrinsic factors that can influence protein functionality. However, pH, temperature, cooking rate, degree of comminution, oxidation, and the presence of various nonprotein components such as lipids, carbohydrates, minerals, acids, as well as many other processing factors that influence protein structures and interactions can all profoundly affect protein functionality. Hence, to obtain a desirable product quality, it is imperative to maintain a delicate balance between different intrinsic and extrinsic factors.

Water Binding

Water Compartments in Muscle Foods

Proteins play a critical role in immobilizing water in meat and meat products and, hence, contribute to overall juiciness and tenderness of cooked meat. Water binding, as one of the important functional properties of muscle proteins, will be described briefly. The water present in meat or meat products can be both indigenous and extraneous (pumped, injected, etc.). Physicochemically, the water in meat exists either in a bound form or in a free state. Bound water is tightly associated with proteins through hydrogen bonds and ion–dipole interactions, which are influenced by the surface charge and polarity of the proteins. In intact muscle, free water is held via capillarity in different compartments, namely, in the spaces between myofilaments, between myofibrils, and outside the fibers. During postmortem aging, the proteolytic degradation of cytoskeleton (titin), while improving meat tenderness, can weaken water binding in muscle and increase drip loss. In comminuted products, a large portion of water is also retained via entrapment in the matrix of myofibrillar protein gels and, in some cases, gelatin gels. The interfilamental spacing, measuring approximately 320 Å between thick (myosin) filaments, is not constant. It varies with fiber type, sarcomere length, the contractile state, pH, ionic strength, the presence of certain divalent cations and phosphates, the redox potential, and many other factors. Denaturing conditions, such as rapid acid accumulation (postmortem glycolysis) while the muscle temperature remains high, lead to reduced water binding in meat; an example of meat having a poor water-binding capacity is the so-called 'pale, soft, exudative' pork, turkey, and chicken.

Effect of Salts on Water Binding

Because the bulk of water in muscle is confined within the myofibrils in the spaces between the thick (myosin) and thin (actin) filaments, any chemical, physical, or enzymatic means that increase the interfilamental spaces, i.e., expand the myofibril lattices, can bring about enhanced water binding in meat. The use of salt (NaCl or KCl) and phosphates to improve water retention in cooked meats is based on this principle. As a conventional practice, extraneous water, together with salt and phosphates, is incorporated into fresh meat through injection, marination, or tumbling to improve the product cooking yield and juiciness. Hydration and retention of added water are made possible through the NaCl- and phosphate-induced myofibril expansion and, hence, transverse swelling.

Effect of Phosphates on Water Binding

High concentrations of NaCl (usually greater than 0.6 mol l^{-1}), impart high ionic strengths (Γ), depolarize myosin filaments, whereas low concentrations of phosphates (5–15 mmol l^{-1}), notably sodium pyrophosphate and tripolyphosphate, are capable of dissociating actomyosin. Different types of phosphates, used singly or in combinations at a total level not exceeding 0.5% of the final product weight, are commonly incorporated into processed meats. Depending on the country, the use of specific phosphates is subjected to different regulations. In the presence of magnesium, the dissociation effect of pyrophosphate is very similar to that exerted by adenosine tripolyphosphate (ATP). These biochemical processes result in the weakening of the myofibril structure, thereby allowing water molecules to more readily diffuse into the interfilamental spaces to increase the extent of fiber hydration. Substantial muscle fiber swelling occurs as the NaCl concentration is raised to approximately 0.6 mol l^{-1} in the absence of phosphate, or 0.5 mol l^{-1} in the presence of as little as 10 mmol l^{-1} pyrophosphate (Figure 1). In many cases, myofibrils start to swell even at 0.4 mol l^{-1} NaCl when pyrophosphate or tripolyphosphate is also present, and this will depend on the degree of muscle fiber contraction (actomyosin cross-linking) and freshness of meat, and can vary between muscle types. In general, the extent of swelling and hydration continues until 1.0 mol l^{-1} NaCl (approximately 4.0% of muscle weight) is incorporated where the swollen fiber will start to shrink due to a salting-out effect.

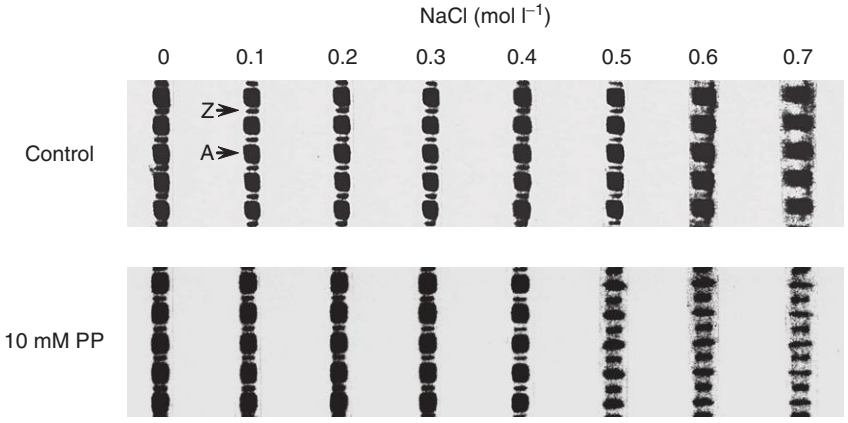

Figure 1 Ultrastructural changes in myofibrils treated by irrigation with NaCl solutions in the presence or absence of sodium pyrophosphate (PP) at pH 6.0. The A-band (A) and Z-line (Z) are indicated.

Solubility

Definition

Solubility of muscle proteins refers to the percentage (w/w) of the original protein that dissolves into the aqueous solution under specific extraction conditions. It is a manifestation of the equilibrium between the solute (protein) and the solvent (water). Solubility of proteins is of primary importance in meat processing as it is closely related to many other functional processes of proteins. For example, gelation, emulsification, adhesion, and water immobilization in comminuted and restructured muscle foods are the results of interactions of soluble myofibrillar proteins with various meat components. In the meat science literature, the term 'protein solubility' is often used interchangeably with 'protein extractability', assuming that proteins, once solubilized in a certain buffer, can be readily extracted.

Protein Structure and Solubility

Protein structure is one of the important determinants for its solubility characteristics. Most proteins belonging to the sarcoplasmic protein family are of a globular structure and are relatively small in size (most between 30 and 65 kDa) with a single cooperative domain. The surface of these protein molecules is made up of charged and noncharged polar amino acid side-chain groups, giving an isoelectric point (pI, where protein solubility is minimal) close to neutrality, far from the typical pH of meat (5.5–5.8). These structural features enable sarcoplasmic proteins to be naturally soluble in water, independently of ionic strength. However, myofibrillar proteins in muscle are associated with one another into a highly organized structural unit – the myofibril. Their isoelectric points are relatively low (pH 5.0–6.0) to allow for the unique structural arrangement and interaction between different segments of the polypeptides. Thus, myofibrillar proteins are insoluble at the physiological ionic strength. Collagen, which is insoluble in salt solution under normal meat-processing conditions, can be rendered soluble either through long-time moist heating or through limited acid/alkaline hydrolysis. These treatment conditions permit the disruption of collagen fibrils and dissociation of tropocollagen complexes, thereby facilitating the interaction of the individual collagen peptides with water.

Effect of Ionic Strength on Protein Solubility

The relationship between ionic strength (Γ, approximately equivalent to the molar concentration of NaCl) and solubility of myofibrillar protein is illustrated in Figure 2. When minced muscle is washed extensively to remove most ions through the dilution effect, a great net surface charge is established, attributed mainly to the ionizable side-chain groups and the minute quantity of small ions present. A further dilution in excessive amounts of deionized water to a Γ of 0.0003–0.001 will disintegrate the myofibrils. Although this will give myofibrillar proteins a high extractability and solubility, an ionic strength this low is rarely encountered in meat processing and is therefore of little practical significance. The solubility reaches

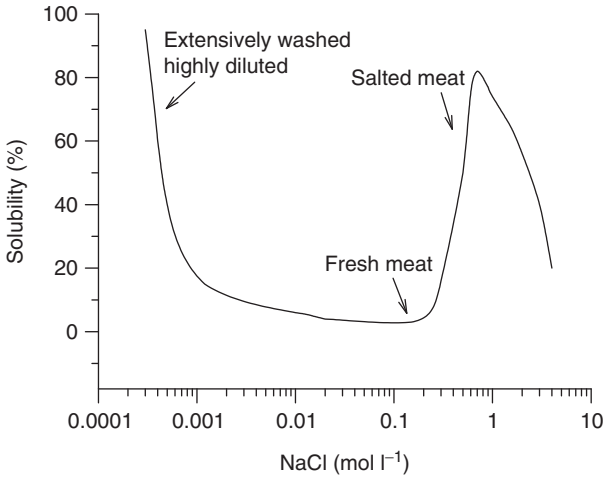

Figure 2 Schematic representation of the ionic strength–solubility relationship of muscle myofibrillar protein. The ionic strength is expressed as the molar concentration of NaCl.

a minimum within the 0.03–0.2 ionic strength range where protein surface charges are shielded by the surrounding small ionic elements (e.g., Na^+ and Cl^-). As the ionic strength is increased further, myofibrillar proteins will again reach a soluble state owing to weakening of protein–protein interactions and dissociation of myofilaments. In muscle food processing, extraction of myofibrillar proteins into the aqueous solution is achieved through the addition of salt and polyphosphates to the meat formulation, raising the pH of the meat ingredient solution, and prolonging the mixing time (massaging, tumbling, or chopping). Aside from its effect to depolymerize myosin filaments, NaCl at elevated concentrations lowers the isoelectric point of myosin so that it carries a greater net charge within the normal range of meat pH. An increased electric double layer surrounding protein molecules allows for a better hydration and solubility.

Effect of Phosphates on Protein Solubility

The effect of pyrophosphate and tripolyphosphate on myofobrillar protein solubility is remarkable. In the absence of phosphate, myosin extraction begins at the center of the A-bands (the dark regions or blocks in the myofibril). When sodium pyrophosphate is present, protein extraction begins at both ends of the A-band (Figure 1). Because the actomyosin cross-bridges are absent at the center of the A-band but are located at the ends of the A-band, it can be inferred that pyrophosphate functions as a lubrication agent, that is, it dissociates the actomyosin complex in a way similar to ATP, leading to a separation of thick and thin myofilaments. Sodium tripolyphoshate has an effect very similar to that of sodium pyrophosphate, and it is believed that tripolyphosphate is hydrolyzed to pyrophosphate by endogenous phosphatase before it becomes functionally active. There is evidence that myosin also has tripolyphosphatase activity. Other phosphate compounds, especially those with a cyclic or ring structure, are generally less efficient than the shorter-chain phosphates for protein extraction.

Effect of Muscle Fiber Type on Protein Solubility

The design of meat-processing protocols should be done in the context of muscle or fiber types. In general, myofibrillar proteins from fast-twitch glycolytic (white) fibers are more readily extracted than those from slow-twitch oxidative (red) fibers, and the former also respond more effectively to phosphate treatment. The disparity is attributed to several factors. First, proteins located in the myofibrils must overcome structural barriers and hindrances. Histologically, white myofibrils contain narrower Z-disks than red myofibrils, and the major structural protein in the Z-disk, α-actinin, has different morphology (isoforms) for red and white myofibrils. Several other minor structural proteins, for example, M-protein, C-protein, H-protein, and X-protein, also differ morphologically between fiber types. Furthermore, some proteins that make up the Z-disks in white muscle are more susceptible to early postmortem proteolytic degradation, especially in the presence of salt. The structural changes are accompanied by increased extraction of both thick and thin filaments. Experimental evidence suggests that the M-protein may serve as a transverse structural constraint to myosin extraction and is crucial for the extraction of total myofibrillar protein. Second, myosin, the most prevalent protein component inside the muscle, exists in various isoforms that are fiber-type-specific. Different myosin isoforms are known to differ in physicochemical characteristics, morphology, and solubility. Hence, even if the thick filaments are depolymerized, the different solubilities between white and red myosin constitute another conspicuous factor that influences the total amount of extractable protein from white and red muscles.

Gelation

Definition

The ability to form a gel (gelation) is one of the most important physicochemical features of muscle proteins occurring in meat processing. Gelation in muscle foods is a result of unfolding and subsequent association of extracted (soluble) protein molecules to form aggregates and strands. When aggregation reaches a certain critical level, a continuous, three-dimensional gel network structure is created, which consists of cross-linked peptides or aggregates with a large amount of entrapped water:

$$\chi P_N \overset{\text{Heating}}{\Longrightarrow} \underset{\text{(Denaturation)}}{\chi P_D} \overset{\text{Heating}}{\Longrightarrow} \underset{\text{(Aggregation)}}{(P_D)_\phi,\ (P_D)_P} \overset{\text{Heating/cooling}}{\Longrightarrow} \underset{\text{(Cross-linking)}}{(P_D)_\phi -\ (P_D)_P -}$$

where χ is the total number of native (P_N) or denatured (P_D) protein molecules, and ϕ and P (ϕ+P+$\cdots$=χ) are the number of molecules that are aggregated at a certain point of the gelation process.

Adhesive Role of Gels

The gels formed act as adhesive to bind comminuted meat particles and offer a three-dimensional network to stabilize emulsified fat globules and entrap flavor compounds and other meat ingredients, as well as a complex capillary system to immobilize moisture. Hence, protein gelation is responsible for an array of texture-related quality traits in products such as sausage, frankfurters, boneless hams, meat rolls, and various luncheon meats. For processed muscle foods with a large amount of added water, protein gelation is obviously of particular importance.

Role of Different Muscle Proteins

As is true of water binding and hydration, myofibrillar proteins are largely responsible for gelation that takes place in processed muscle foods. In comparison, sarcoplasmic proteins exhibit a poor gelling ability, although in some cases they may reinforce the myofibrillar protein gels. Collagen and elastin, which comprise the connective tissue in meat, have a minimal role in gelation because normal meat-processing conditions rarely allow them to be sufficiently hydrated and extracted. The right-handed triple α-helix of collagen molecules does not unfold into single strands until approximately 65 °C (approaching the end temperature of cooking). However, once extracted, collagen can form a rubbery cold-set gel. Therefore, pregelatinized collagen or collagen extracts from pork and chicken skins, as well as finely minced connective tissue, are sometimes utilized in the manufacture of cold delicatessen meats.

Myosin and Mixed Myofibrillar Protein Gels

Myofibrillar protein gels formed in muscle foods are generally heat induced. Two types of gels can be produced from myofibrillar proteins – the myosin gel and the mixed myofibrillar protein gel. Myosin forms filaments at ionic strengths close to the physiological condition. Hence, it can form a somewhat brittle gel at low concentrations of salt (0.15–0.20 mol l^{-1} NaCl, or ~0.6–0.8% in meat). Because this ionic condition is seldom employed in the process of producing 'texturized' meat (which requires at least 0.5 mol l^{-1} NaCl (~2% in meat) to ensure an adequate protein extraction and solubility, myosin gelation at the low salt condition is of little practical significance. However, mixed myofibrillar protein gels, also referred to as 'myofibrillar protein gels' and sometimes as 'actomyosin gels' or 'salt-soluble protein gels,' are the gels formed in most processed meats. However, even in the mixed-protein system, the myosin portion of the actomyosin remains the most important gelling protein. The contribution to the rigidity of myosin or actomyosin gels by the different segments of myosin is believed to follow the order: rod > light meromyosin > heavy meromyosin > the S-1 subunit.

Mechanism of Gel Formation

The mechanism for myofibrillar protein gelation under meat-processing conditions (0.5–0.6 mol l^{-1} NaCl, pH 6.0–6.5) has been researched extensively. Using extracted myosin as a model protein, the following sequential changes have been established for heat-induced myosin gelation (Figure 3). Unfolding of myosin head (S1 subfragment) commences at 35 °C and leads to the formation of dimers and oligomers via head–head interactions. Disulfide linkages are not required for

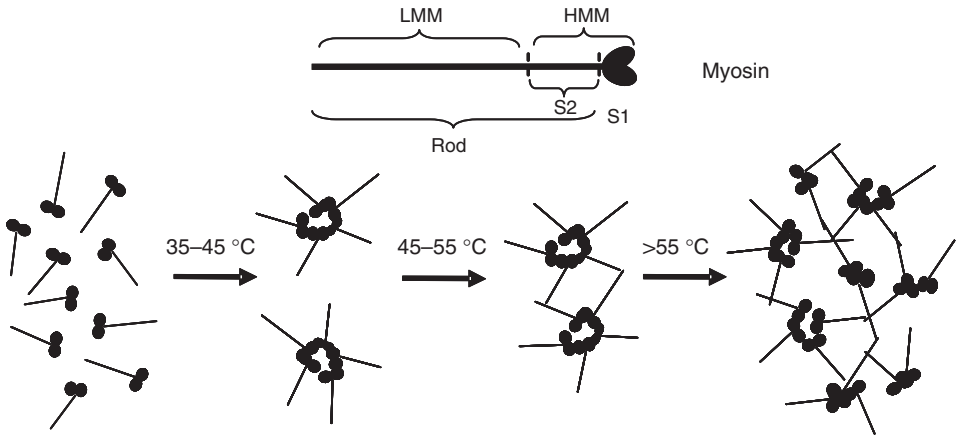

Figure 3 Schematic representation of heat-induced aggregation of myosin during gelation in the presence of 0.6 mol l^{-1} NaCl at pH 6.0–6.5. Myosin parts obtained by enzymatic hydrolysis are indicated (light meromyosin, LMM; heavy meromyosin, HMM; rod; subfragment 1, S1; and subfragment 2, S2).

the initiation of the interactions. As the temperature increases to 40–45 °C, a globular mass is formed that consists of a tightly associated head clump with tails radiating outward, resembling the shape of a Black Widow spider. At above 45 °C, oligomers coexist with the aggregates formed by the coalescence of two or more oligomers. From 55 °C, these oligomers aggregate further, apparently involving tail–tail (rod) cross-linking to form particles that make up the strands of the gel networks. The microstructure and viscoelasticity of the ultimate gels are dictated by the specific protein aggregation pattern, which is influenced by the heating rate and other processing and ingredient factors.

Effect of Processing Protocols on Gelation

Because the continuous network system in the gel is a result of ordered aggregation of soluble proteins, meat-processing protocols, including both the processing condition and the product formulation, must be carefully controlled. Myofibrillar protein gel strength increases exponentially with the protein concentration. Thus, factors that affect the extraction of myofibrillar proteins, including pH, temperature, ionic strength, muscle rigor state and postmortem aging time, polyphosphates, and time of blending of meat with salt, can all influence protein gelation. Many of the same factors, as well as others such as rate of heating, reducing or oxidizing compounds, polysaccharides, lipids, nonmeat proteins, divalent cations, the myosin:actin ratio in the actomyosin complex, endogenous proteases, and muscle fiber types, also affect protein–protein interaction and, hence, play an active role in protein gelation. In general, mixed myofibrillar proteins have an optimum gelling capacity at pH approximately 6.0, a Γ of 0.6–0.8, and a temperature approximately 65 °C. A slow-heating process is desirable because it allows for progressive protein denaturation, which favors ordered protein–protein association. Cross-bridging agents or factors, such as minute quantities of Ca^{2+} (<5 mmol l^{-1}), dehydroascorbate, and hydrogen peroxide (which induce limited protein oxidation to promote disulfide and carbonyl-amine bond formation), and the enzyme transglutaminase (E.C. 2.3.2.13, which catalyzes lysine–glutamine cross-linking through an acyl transfer reaction), have been widely observed to enhance the gelation of myofibrillar proteins.

Gelling Properties from Different Muscles and Fiber Types

The gelling properties of myofibrillar proteins are fiber-type-dependent. Proteins from white fibers (e.g., pectoralis major from chicken and cutaneous trunci from beef) have a greater tendency to gel on heating, and the gel storage modulus (G′, the elastic component of gel) is generally higher when compared with proteins from red fibers (e.g., gastrocnemius from chicken; masseter from beef) under similar processing conditions (Figure 4). The discrepancy is attributed to structural and solubility differences that are exhibited by different protein isomers, particularly myosin, and can be explained by the fact that white fiber myosin usually forms elongated filaments rather than short aggregates seen in red fiber myosin in 0.1–0.6 mol l^{-1} NaCl solutions. For some animal species and muscle types (e.g., the fish Pacific Whiting and Alaska Pollock, and beef cardiac muscle), the presence of endogenous catheptic enzymes (H, B, L, etc.) can cause considerable gel weakening when the product is cooked through the 45–60 °C temperature range. This gel-weakening phenomenon is a particular nuisance in some surimi (washed muscle mince, a crude myofibrillar protein concentrate) or surimi-based foods. Protease inhibitors such as egg white and potato extract are therefore desirable and can be used to inhibit the deleterious effect. Although beef plasma powder provides strong protease inhibition, it is no longer used in the surmi industry due to the concern with bovine spongiform encephalopathy (or commonly referred to as the 'mad cow disease'). Furthermore, sodium pyrophosphate and tripolyphosphate, though facilitating protein extraction, tend to interfere with protein gel matrix formation for both white and red muscle fiber types. Hence, the use of these phosphates should be minimized in products that already contain high concentrations of NaCl where protein extraction is not a limiting factor to gel formation.

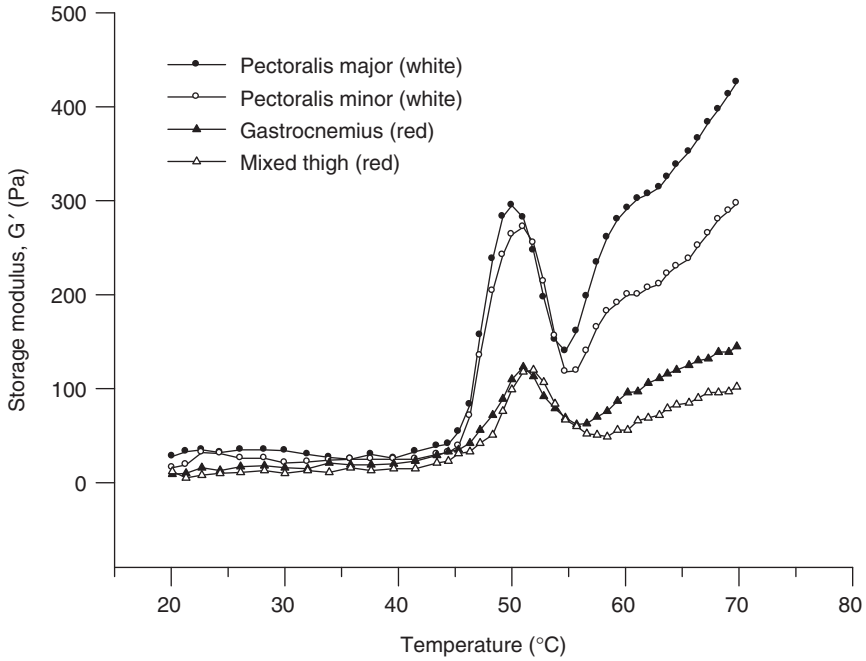

Figure 4 Typical rheology curves of chicken white (fast-twitch) and red (slow-twitch) muscle myofibrillar proteins in 0.6 mol l^{-1} at pH 6.0. The storage modulus, *G′*, represents elasticity of the gels.

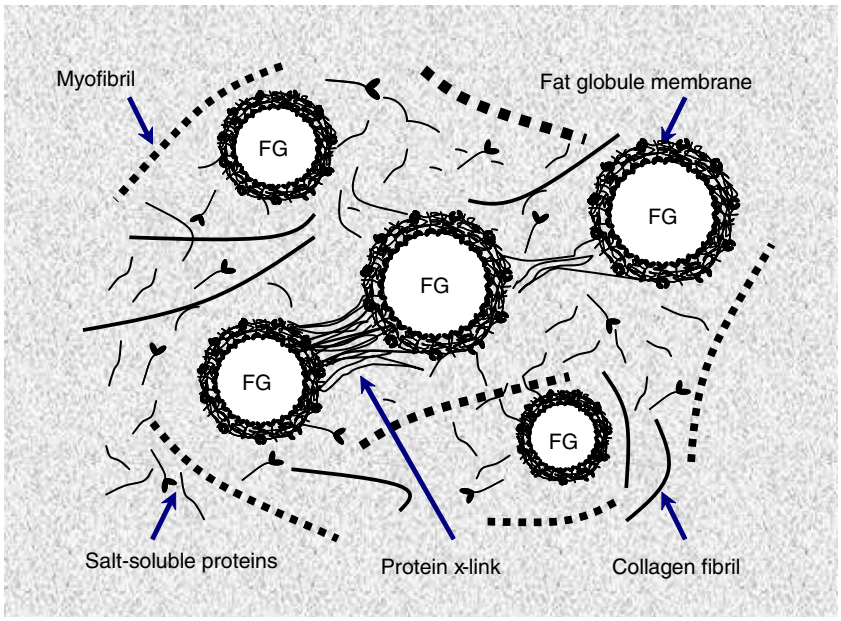

Figure 5 Schematic representation of a typical meat emulsion (batter). FG, fat globule.

Emulsification

Characteristics of Meat Emulsion

Muscle foods made from finely chopped or comminuted meat in the presence of fat are regarded as emulsion-type products. A meat emulsion differs from the classical emulsion in that the fat globules are dispersed and stabilized in an aqueous matrix system consisting of salt-soluble myofibrillar proteins, segments of muscle fibers and myofibrils, connective tissue fibers, collagen fragments, and various ingredients (Figure 5). Thus, a meat emulsion is commonly referred to as a 'meat batter' to reflect its multiphasic, multicomponent nature.

How an Emulsion is Formed

As with most other proteins, muscle proteins are amphoteric molecules possessing both polar and nonpolar groups or

structural segments. Hence, on the input of mechanical energy through the shearing process known as 'emulsification', proteins can adsorb at the fat–water interface where the hydrophobic groups will anchor into the fat and the hydrophilic groups will extend into the aqueous phase. Such structural orientation at the fat–water interface is thermodynamically favored because it leads to a reduction of total free energy of the meat batter. A slow, continuous comminution (chopping) process is usually adequate to reduce the fat particle size to the micrometer range while extracting myosin or actomyosin to form a coating surrounding the fat particles. To aid in protein adsorption, the meat batter during chopping should reach a certain elevated temperature (generally 15–20 °C, depending on animal species or degree of saturation of lipids) to soften fat, which allows efficient fat particle size reductions.

Proteins Involved in Emulsion Formation and Stabilization

The ability of muscle proteins to form a viscoelastic and flexible membrane (i.e., a coating) around the fat globule is a critical factor for emulsion formation and stabilization. The contribution of individual muscle proteins to meat emulsion stability follows the order: myosin > actomyosin > sarcoplasmic protein > actin > collagen. During emulsification, myosin (prerigor) or actomyosin (postrigor) is rapidly and preferentially adsorbed at the fat–water interface. The superior emulsifying ability of myosin to any other proteins, especially at low protein concentrations, is attributed to myosin's unique structural characteristics. First, the unequal distribution of polar versus nonpolar amino acids in different segments of myosin, i.e., a prevalence of hydrophobic residues in the globular head region or the S1 subfragment versus a preponderance of hydrophilic groups in the rod-shaped tail portion, makes myosin an ideal emulsifier. Moreover, myosin has a high length-to-diameter ratio (roughly 40:1), a structure that is conducive to protein–protein interaction and molecular flexibility at the interface. Because of its insolubility, collagen does not directly participate in the meat emulsification process. The presence of collagen fibrils may help strengthen the protein encapsulation; however, on cooking to above 60 °C, collagen fibrils start to shrink, resulting in a disruption of the emulsion matrix and rupture of the fat droplets. Hence, an excess amount of connective tissue should be avoided in the manufacture of emulsified muscle foods.

Another mechanism for meat batter stabilization is physical entrapment of fat particles in the protein matrix formed largely through protein–protein interactions. Although fat particles without an integral protein coating can be immobilized in protein gels, those with a thick and flexible membrane can interact, through the adsorbed proteins at the membrane, with proteins in the continuous phase, thereby further enhancing the stability of the meat batter. Thus, physicochemical and rheological properties of the fat globule membrane and the viscoelastic characteristics of the continuous protein matrices both contribute to emulsion stability in comminuted muscle foods.

Glossary

Calpains (*μ*-calpain, *m*-calpain, and calpain 3) Cysteine proteinases that are activated by calcium and degrade myofibrillar proteins during the postrigor phase.

Electrical stimulation (ES) Subjecting a carcass to electrical input to increase post mortem glycolysis rate and pH decline. It decreases WHC.

Enhancement Direct injection of brine containing salt, phosphates, ammonium hydroxide, and/or other ingredients for the purpose of improving flavor, tenderness, and juiciness.

Magnesium adenosine tripolyphosphate (Mg-ATP) The presence or absence of Mg-ATP controls whether or not there is energy for contraction (myosin-actin interaction).

Water-holding capacity (WHC) The ability of meat to hold onto its own or added water.

Introduction

Water is the major component of muscle tissue – striated muscle is approximately 75% water. This water is structurally arranged in layers around polar molecules and between layers of cellular materials. It has restricted movement due to a variety of forces. Approximately 5% of the water contained in muscle tissue exists as the 'true hydration water' bound to proteins by monomolecular or multimolecular adsorption. This water is not 'free'; it has an ice-like structure (liquid crystal), is unfreezable, is unaffected by charges on the muscle protein (pH), and unavailable to participate in reactions. The remaining water is free to move around with some restrictions. Water immobilized in one compartment can move to another compartment under various types of stress (Figure 1). Water immobilized within the network of cellular protein membranes (intracellular water) resides either between the proteins composing the contractile units or in the sarcoplasm. Water also exists in the extracellular spaces.

'Water-holding capacity (WHC)' is the ability of meat to hold onto its own or added water when force (heat, pressure) is applied. The majority of WHC resides in the water located in the intermolecular spaces between the salt-soluble proteins (actin and myosin) of muscle tissue where it is held in place by capillary force. The space between myosin and actin/tropomyosin varies between 320 and 570 Å depending on pH, ionic strength, osmotic pressure, and sarcomere length. The interfilamental space is maintained by electrostatic forces that operate over relatively long distances. Factors that alter the spatial arrangement of the myofilaments can alter the amount of water immobilized in this compartment. Factors, both intrinsic and extrinsic, that alter the spatial arrangement of the myofilaments include alterations in net charge induced by pH changes, screening of charges by anions/cations, presence of divalent cations (Mg^{2+} and Ca^{2+}), denaturing conditions that alter protein conformation (rapid pH decline while temperature is still high), and presence and condition of plasticizing agents such as adenosine tripolyphosphate (ATP) as well as enzymes (ATPase) and cofactors necessary for plasticizer function in prevention of myofibrillar protein crosslinking.

Contractile Proteins – Actin and Myosin

Divalent cations (Mg^{2+} and Ca^{2+}) alone can combine with two negatively charged reactive groups on the contractile proteins pulling them more closely together (Figure 2). The reactive groups are prevented from interacting with water because the charged groups are screened and because the reduction in interprotein space sterically precludes the presence of substantial numbers of water molecules. Replacing these

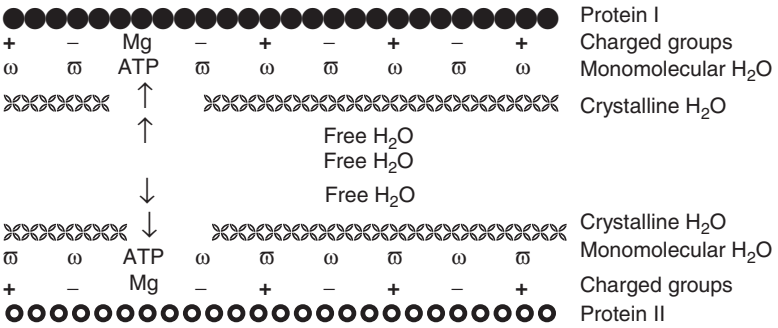

Figure 1 Arrangement of interfilamental water.

 doi:10.1016/B978-0-12-384731-7.00247-6

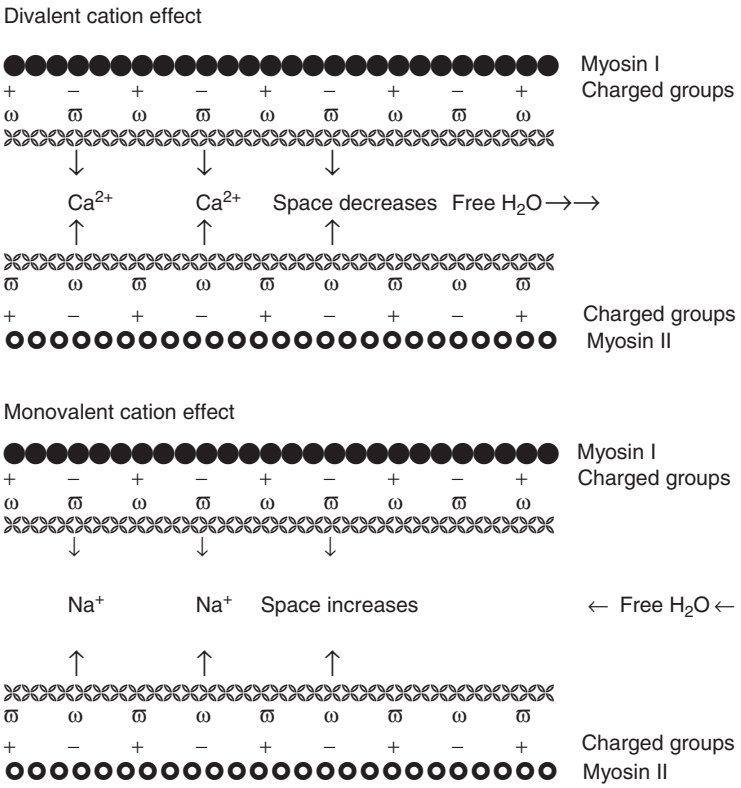

Figure 2 Divalent and monovalent cation effects on free water.

divalent cations with monovalent cations (Na^+ and K^+) substantially reduces this effect (see 'Effect of Salt').

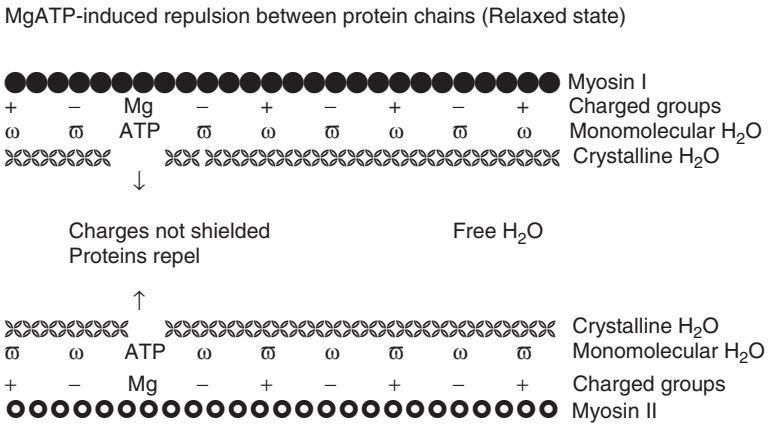
In living tissue, Mg-ATP bound to myosin allows electrostatic repulsion within the protein preventing release of ATP, and myosin binding to actin (Figure 3). Stimulation by nerve impulse causes the sarcoplasmic reticulum (SR) to release Ca^{2+}, which is bound by troponin-C. The presence of Ca^{2+} cancels or shields the negative charge on Mg-ATP, which allows water to move into the space between the protein. Ca^{2+} allows a conformational change in the protein, which activates Mg-ATP ase catalysis of Mg-ATP to Mg–ADP^- providing energy for muscle contraction. ATP is also consumed when the SR pumps Ca^{2+} back into the organelle. ATP is regenerated via aerobic glycolysis of glycogen and fatty acids. In prerigor meat, cross-linking between actin and myosin is prevented by Mg-ATP. In this situation, pH alterations can easily increase electrostatic repulsion between proteins (Figure 4), and increases in ionic strength can then attract water by osmotic force. Even so, the degree to which these proteins can move apart is constrained by actin filament attachment to the Z-line and myosin filament attachment to the M-line. During the postmortem period, when oxygen is no longer available, cells metabolize glycogen via anaerobic pathways producing lactic acid-lowering tissue pH, and ATP is regenerated by creatine kinase. Once creatine phosphate is consumed, ATP can no longer be regenerated, and actin and myosin cross-link resulting in sarcomere shortening. Contraction and rigor result.

In postrigor meat, introduction of neutral-pH solutions can introduce sufficient –OH and –H ions to shield most of the charged groups on the amino acids such that the proteins repel each other allowing free water to enter (Figure 5).

Temperature has major effects on the rate of these reactions and the degree to which they proceed because (1) many are enzymatic and (2) alterations in pH in combination with temperature can denature proteins, both structural and enzyme, resulting in loss of functionality. Protein functionality is discussed in detail in another part of this encyclopedia. Muscle does not shorten at prerigor temperatures of ≥20 °C because the activity of the Ca^{2+} pump in the SR is relatively high, maintaining sufficiently low Ca^{2+} concentrations around the myofilament, blocking the effect of the troponin-tropomyosin system on actin-myosin interaction.

Effect of pH

The pH of minimum WHC of the principle muscle proteins is 5.4–5.5, which coincides with their isoelectric points. The minimum WHC of meat occurs approximately at pH 5.0, which corresponds to the isoelectric point of actomyosin (Figure 6). Salt-soluble proteins are completely soluble above pH 5.9 but are 95% insoluble below pH 4.9 with peak solubility occurring between 5.7 and 6.0. When water is added to muscle tissue, between pH 5.1 and 4.4, swelling occurs across and along the muscle fiber axis. Increases in muscle fiber diameter were much more important to total muscle swelling than increases in sarcomere length. The pH is inversely correlated with fiber diameter ($r = -0.76$) but much less so with



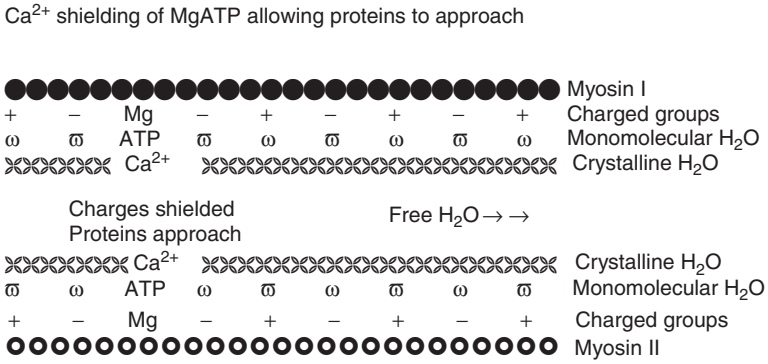


Figure 3 Cation (Ca^{2+}) shielding of mgATP and its effect on water held between proteins.

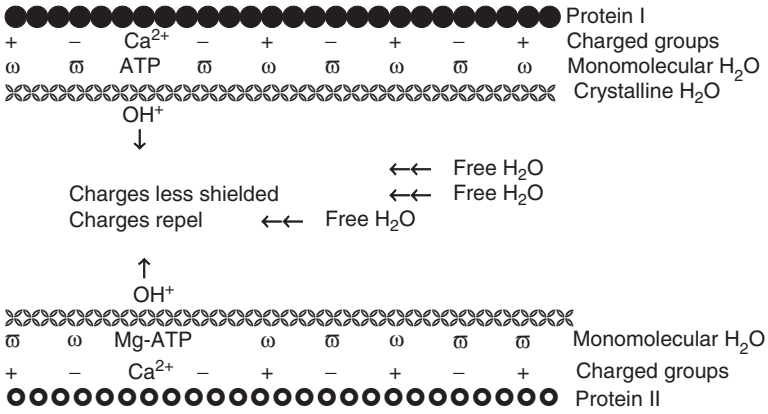

Figure 4 Effect of hydroxyl ion shielding of calcium–magnesium–ATP on water located in the myofibril.

sarcomere length (r=−0.39). As pH approaches 4.0, muscles containing predominantly white fibers continue to swell, whereas those containing predominantly red fibers shrink. This behavior has been explained by differences in buffering capacity as predominantly red fiber muscles have lower buffering capacity than white fiber muscles under acidic conditions. Maximum precipitation of sarcoplasmic proteins occurs between pH 4.8 and 5.2 regardless of temperature, however, at 37 °C and above, high pH no longer protects these proteins. The pH-induced precipitation of sarcoplasmic protein onto myofibrillar proteins decreases WHC as well as other quality characteristics of meat.

Efforts to increase WHC in meat have centered on maintaining or increasing pH during the postmortem period. Injection

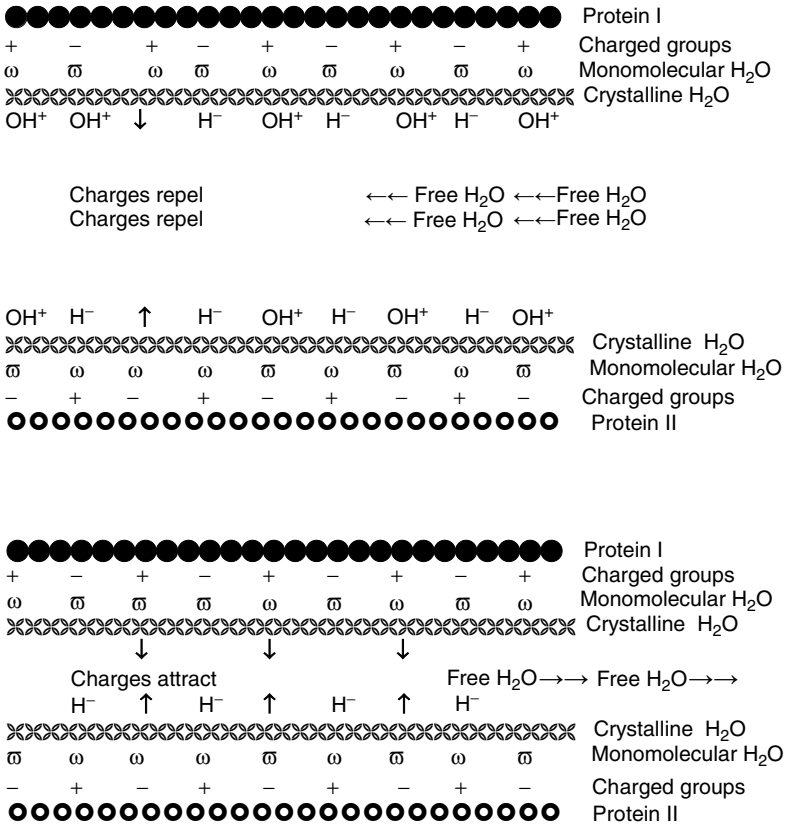

Figure 5 Effect of neutral pH (top) and low pH (bottom) on myofibrillar swelling.

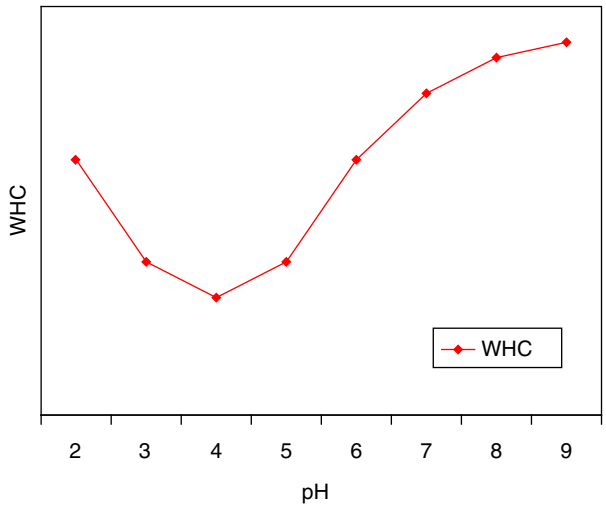

Figure 6 Effect of pH on WHC.

of adrenaline before slaughter to reduce intracellular glycogen content at slaughter such that postmortem anaerobic glycolysis to lactic acid is limited does produce meat with high postmortem pH and high WHC. Addition of pH-increasing agents such as high molecular weight phosphates and sodium bicarbonate also increase postmortem pH and WHC to some degree.

Effect of Rigor

Sarcomere shortening and pH decrease have major implications for WHC of muscle tissue. Loss of the ability to conduct aerobic metabolism results in a shift to anaerobic metabolism wherein the muscle uses glycogen to generate energy, however, it is only broken down to lactic acid and ATP is not regenerated. The significant reduction in pH is ultimately responsible for loss of protein denaturation, which makes major contributions to WHC. Immediately after slaughter, meat has excellent WHC due to the combined effects of high levels of ATP and high pH, which exist in prerigor tissue. WHC decreases during the immediate 12–24 h postmortem period during which time, ATP is enzymatically broken down and pH decreases as lactic acid forms. Rigor mortis commences in beef (bovine neck muscle) when the pH drops to 5.9 and ATP level drops to 1 μmol g^{-1}. Between pH 6.6 and 6.1 (prerigor) a small, linear decrease in myofibrillar protein solubility occurs. Protein solubility decreases dramatically as pH drops from 6.0 to 5.6. Readjusting pH to prerigor levels increases protein solubility, however, it remains much lower than that of original prerigor protein. ATP breakdown is continuous between pH 6.9 and 5.8. Taken together, this implies that the slight WHC decreases seen in the early postmortem period are a direct result of pH on muscle proteins, whereas the dramatic losses occurring during rigor are primarily due to ATP disappearance (2/3) with the remainder due to pH (1/3).

During the rigor process, muscle cells undergo both longitudinal and lateral contraction, usually within 24 h. The pressure differences between intra- and extra-cellular water compartments, which have built up during contraction are equalized very slowly.

Postmortem Glycolysis Rate

Rapid postmortem glycolysis has been associated with the high drip loss and poor WHC and color of pale, soft exudative (PSE) pork. This may be a result of myosin denaturation when a carcass experiences a low pH and a high temperature or it may be due to denaturation of sarcoplasmic proteins and subsequent precipitation onto the myofibrils. Genetic defects, such as stress susceptibility in swine, which increases postmortem glycolysis rate, produces meat with reduced WHC, which experiences high fluid losses when cooked.

Electrical stimulation (ES) of the carcass increases postmortem glycolysis rate that results in a decreased WHC as the muscle enters rigor mortis and ages rapidly. ES-induced pH decline (<6.0), while the carcass is still $>30\,^{\circ}C$, decreases Ca^{2+}-enhanced myofibrillar ATPase activity, which implies potential myosin denaturation but such denaturation stops when muscles enter rigor mortis. This can be enhanced with electrical stimulation. ATPase activity is inversely correlated with WHC.

Effect of Temperature

Immediate postmortem temperature can have significant effects on WHC. Loss of circulatory competency allows metabolic heat to accumulate allowing carcass temperatures to increase to more than 42 °C. If pH decrease is dramatic (usually during the first 45–60 min postmortem) the combined effect can produce denaturation of myofibrillar proteins such that WHC is ultimately quite low even if ultimate pH (24 h) is within normal ranges (early rigor with electrical stimulation modifies this effect in cattle). Pigs homozygotic recessive for malignant hypothermia (nn, halothane reactors) exemplify the effects of rapid postmortem temperature increase and pH decrease. Meat from these animals is commonly PSE and has poor WHC. Likewise, pigs with defects in the ryanodine receptor gene suffer from excessive pH decline, which produces abnormally acidic conditions in the meat. Ultimate pH is highly correlated with WHC and color of poultry meat as well.

At temperatures above 25 °C, sarcoplasmic proteins begin to precipitate onto myofibrillar proteins. This phenomenon appears to be related to alterations in the isoelectric point of the fibrillar proteins (from 5.0 to 7.7) allowing for intermolecular reactions between myofibrillar and sarcoplasmic proteins, which displace water and reduce solubility.

Effect of Ageing

The initial source of drip is intracellular water from myosin denaturation and loss from muscle fibers that continues through the prerigor period. Ageing commences postmortem. Water loss is driven by a pH and calcium-induced shrinkage of myofibrils during early rigor development. It is influenced primarily by the extent of sarcomere shortening (shrinkage induced by rigor). Initially, an intact cytoskeleton is necessary to translate shrinkage of myofibrils into shrinkage of the whole cell. The whole cell shrinks both lengthwise and across its diameter. Adjacent myofibrils are connected by desmin-containing filaments; peripheral myofibrils are connected to the sarcolemma by vinculin-containing structures. This highly structured, crosslinked arrangement initially leaves little room, physically, for water. During ageing, calpain proteinases degrade some of these protein interactions so that, as the cytoskeleton denatures, more water is released during tenderization. This degradation of the cytoskeleton allows the inflow of water previously expelled during rigor and released through cytoskeletal degradation. This inflow may be driven by the difference in protein concentration, which exists between intra- and extra-cellular compartments. In the prerigor intact muscle cell, all of the myofibrillar and sarcoplasmic protein exists in the intracellular compartment. During ageing, protein, primarily cytoskeletal, is lost in the drip. As ageing progresses, however, the protein concentration in the intracellular compartment appears to be the driving force attracting water back into the cell after the cytoskeleton is degraded.

Substantial shifts in electrolytes (calcium, magnesium, potassium, and phosphates) occur during ageing. Divalent ion exchange with monovalent ions frees reactive polar groups on proteins to interact with water and removes some of the steric effects that limit available space for water molecules.

Effect of Salt (NaCl)

Prerigor WHC can be retained for several days by adding NaCl to comminuted tissue in spite of the fact that NaCl and particle-size reduction increase ATP breakdown and glycolysis. Addition of up to 2% NaCl increases swelling of (beef) muscle tissue when water is added. However, addition of 3–5% NaCl causes decreased swelling followed by a rapid increase between 5% and 10% NaCl. Initial swelling has been related to replacement of calcium on meat proteins with sodium. Decreased swelling between 3% and 5% NaCl appears to be due to exchange of magnesium and potassium for sodium, whereas the rapid swelling between 5% and 10% NaCl appears to be a result of ionic effects on meat proteins. Neutral salts increase WHC of meat with high ATP levels and/or high pH to a much greater degree than after ATP depletion or after pH had declined to near the pI of myofibrillar proteins (pH 5.0). If salts are added to prerigor meat, attracting water into the interfilamental spaces, the swelling may be so great that the proximate distance between filaments is no longer conducive to actomyosin crosslinking, which normally occurs subsequent to ATP depletion. More water can be immobilized in the interfilamental spaces of higher pH tissue due to repulsion of charged proteins.

Effect of Phosphates

The sodium salts of various phosphates have long been known to increase WHC and muscle tissue swelling, and decrease both drip and cook losses. The effects of phosphates on meat

swelling appear to be related to their relative effects on pH with the exception of tetrasodium pyrophosphate (TP), which produces a swelling effect in excess of its ability to raise pH. Commercial phosphates with a pH of 9.0–10.0 can raise tissue pH above the pI by increasing the net negative charge on the myofibrillar proteins causing them to repel each other allowing water to enter. However, it must be noted that the buffering capacity of meat proteins is substantial; so much so that, in relevant quantities, phosphate with pH 10 shifts the meat pH by only 0.1–0.2 pH units, which would be expected to have negligible effects on WHC unless the tissue was at or very close to the muscle protein pI.

Low-molecular weight inorganic phosphates can react directly with actomyosin. This effect is related to breakdown of low-molecular weight phosphates to pyrophosphate (PP) and diphosphate by muscle ATPase, which has a specific swelling effect on lean meat in addition to its pH effect and its ability to split actomyosin. It has been suggested that phosphates are effective in increasing WHC to the extent that they are hydrolyzed to pyrophophate by endogenous enzymes (ATPase). PP-induced dissociation of the actomyosin complex is dependent on both pH and ionic strength. The affinity of actomyosin for tripolyphosphate (TPP) increases in the presence of high NaCl concentrations and calcium and magnesium. The mode of action is that the sodium from NaCl at high ionic strength forms an Na–myosinate complex that strengthens the affinity of actomyosin for PP and TPP. PP may then form a divalent metal-polyphosphate complex that also increases actomyosin for polyphosphates. It may be that calcium remains attached to one filament, the PP then complexes with it to prevent calcium from binding to an adjacent filament. In general, the reaction is comprised of the formation of a divalent metal-phosphate complex that acts as a normal salt with salt-free actomyosin in a way similar to organic polyphophates such as ATP.

In the presence of little or no salt, the highly polymerized inorganic phosphates, such as hexametaphosphate, bind directly to the positively charged groups on the actomyosin complex. Univalent cations compete with the phosphate for the binding site on the actomyosin molecule leaving the phosphate to behave like a normal salt increasing the ionic strength. The increase in hydration of actomyosin may occur because polyphosphates are capable of eliminating the alkaline earth metals bound to structural proteins. A significant negative correlation exists between WHC and calcium and magnesium content in beef muscle tissue. Based on enzyme studies, it appears that polyphosphate, rather than chelating calcium and magnesium, forms a divalent-metal polyphosphate complex and acts as a normal salt on actomyosin. Therefore, the presence of bound calcium facilitates the approach of polyphosphates to the protein (such that polyphosphate can be split to PP). Cleavage of the actomyosin bond allows the protein fragments to spread and water to enter.

The actions of NaCl and phosphate on actomyosin can be summarized as follows:

NaCl is a neutral salt. The first effect on muscle cells is osmotic. As membrane integrity is destroyed, semipermeability is lost and the salts migrate into the fibers. When NaCl is used in meat, which is on the basic side (pH 5.3–5.7) of the isoelectric point of actomyosin (pI = 5.0), the binding of the Cl^- anions to positively charged protein side groups screens the positive charge and breaks salt bridges allowing the protein strands to spread resulting in greater hydration. Binding of the anions shifts the pI to a lower pH. In the absence of a plasticizer such as ATP or polyphosphate, actomyosin can only be split at pH values <1.0 or >7.0. Phosphates, which are salts of weak acids, also dissociate to anions and cations. At pH values above the pI of the proteins, the anions eliminate the alkaline earth metals bound to structural proteins increasing WHC as actin and myosin are released from each other. Calcium is removed by ion exchange and the intramolecular bonds break. Salts with polyvalent anions are most effective (polyphosphates, citrate, and oxalate). Elimination of calcium inactivates ATP hydrolysis and results in hydration of actomyosin. Exchange of bound calcium is most effective at pH values above the pI because the cations crosslink carboxyl groups of the protein.

Effect of Ionic Strength

Myofibrillar proteins are more soluble at higher ionic strengths. High ionic strength extraction solutions can dissociate actomyosin complexes into higher mole ratios of myosin to actin than can lower ionic strength solutions. Hexametaphosphate, TPP, and PP all have the capacity for increasing the ionic strength. Polyphosphates provide approximately the same degree of ionic strength as NaCl on a weight percent basis; although polyphosphates have higher valence anions, they dissociate to a lesser extent. NaCl levels of 0.6 mol l^{-1} (~2.4% of muscle weight) significantly increases ionic strength and increases fiber swelling.

Phosphate solutions vary dramatically in pH. A 1% (w/v) solution of some commonly used phosphates have pH values of approximately:

Tetrasodium pyrophosphate	10.5
Sodium tripolyphosphate	9.8
Sodium hexametaphosphate	7.0
Sodium acid pyrophosphate	4.2

Addition of NaCl plus polyphosphates increases meat hydration with a maximum effect after 16 h in storage at 0 °C. Swelling is twice as great with TP at salt levels up to 10% as with NaCl alone. Tetrasodium PP is generally the most effective phosphate for increasing WHC with respect to both the presence and absence of NaCl (Table 1). Addition of NaCl slightly decreases pH and greatly increases WHC.

Effect of High-Pressure Processing

Subjecting beef to 300–650 MPa at room temperature increases expressible moisture whereas pressurizing frozen beef decreases expressible moisture. Salt addition also reduces high-pressure induced drip loss. Pressurization can improve the ability of meat samples to hold free water, however, drip losses can increase.

High pressure partially inhibits postmortem metabolism resulting in lower muscle lactate levels and higher pH values.

It also reduces cook and drip loss in pork loins and hams. Subjecting enhanced pork loins to hydrodynamic pressure reduces drip losses compared to controls. Pressure-treating lamb has been shown to cause a 94% contraction in sarcomere measurements and extensive fiber disruption in addition to pH decrease. Cooking loss was also lower in pressure-treated samples.

Histological studies have shown that high pressure induces structural weakening of intramuscular connective tissue, especially the perimysium. Ageing time (to achieve beef tenderness) can be halved by subjecting the beef to pulsed electrohydraulic shock.

Heating under pressure is known to increase tenderness. It has been suggested that this improvement is a result of strengthened myfibrillar structure that, when sheared by mastication, allows the crack to pass through the meat (brittle fracture) rather than dissipating into a visco-elastic structure. Adequate cathepsin activity must have occurred to achieve this effect. However, pressure in combination with freezing induces nearly complete denaturation of actin and significant denaturation of myosin, whereas connective proteins remain practically unaltered.

Effect of Ammonium Hydroxide

Enhancement systems are generally composed of water, salt, and phosphate. Injection of these solutions has shown to increase water-binding capacity and tenderness. The chloride ions of salt are thought to bind to the myofilaments increasing the electrostatic repulsive force between them allowing additional water into the space, which is by capillary forces. Reducing NaCl concentration reduces the moisture absorptivity and increases the drip and free water loss. Phosphates increase the swelling of muscle fibers as they shield the charges allowing water to flow in and become immobilized in the myofibril lattice. Sodium polyphosphate in injection brines improves WHC, as evidenced by reduced drip loss, thaw loss, and cooking loss values. In the presence of phosphates, the concentration of chlorine needed for maximum swelling is reduced. Ammonium hydroxide has been used to replace some or all of the phosphates in injection brines in an effort to increase meat tenderness.

Adding 0.5%, 1.0%, or 2.0% ammonium hydroxide to ground beef has been shown to increase pH and WHC of ground buffalo patties. Marinating buffalo meat with 0.1–1.0% solutions of ammonium hydroxide also increased pH, WHC, collagen solubility, total and salt-soluble protein extractability, and cooking yield. Based on scanning and transmission electron microscopy, breakdown of endothelium layers surrounding muscle fibers and weakening of Z-discs was evident in samples containing 0.1% and 0.5% ammonium hydroxide. As pump level (and total ammonium hydroxide introduced) increases from 0% to 30% in beef chuck and round muscles, pH increases as does soft, mushy texture.

Using 1% ammonium hydroxide in place of 4.5% sodium-based phosphates in injection brines has been shown to have no effect on consumer evaluation of beef loin. Ammonium hydroxide produced beef loin steaks with comparable tenderness and palatability. The pH of ammonium hydroxide-containing steaks is slightly higher (pH 5.96) than that of control steaks (pH 5.86). Cook loss was slightly lower in control steaks than in ammonium hydroxide-injected steaks. Compared to alkaline-based (3.6% sodium chloride, adjusted to pH 10 with ammonium hydroxide) injection solutions, phosphate-injected steaks performed better than alkaline-injected steaks (cook yield, WHC, lipid oxidation, color stability, tenderness, juiciness, and purge loss. They also experience less purge than alkaline-injected steaks. Lamb injected with an ammonium hydroxide-containing enhancement solution exhibits higher cooked moisture retention and sensory quality characteristics. Ammonium hydroxide appears to have no effect on sarcomere length or desmin degradation.

Effect of Calpain

Much of the water in the muscle is trapped in cell structures, intra- and extra-myofibrillar spaces. Changes in the intracellular structure of the cell can influence the ability of muscle

cells to retain water. During rigor, lateral shrinkage of the myofibrils is transmitted to the entire cell if proteins linking myofibrils together and to the cell membrane (desmin) are not degraded. Degradation of cytoskeletal proteins can increase muscle cell shrinkage resulting in drip loss. In particular, desmin proteolysis contributes to greater WHC.

Calpains and cathepsins are cysteine proteinases that affect glycolysis and loss of myofilament integrity and play a key role in WHC. The calpain proteolytic system consists of at least three proteases, μ-calpain, *m*-calpain, and calpain 3, and an inhibitor of μ- and *m*-calpain, calpastatin. This system plays a key role in postmortem proteolysis. When activated by calcium, the calpains degrade substrates, but also autolyze, leading to loss of activity. Activation of μ-calpain probably occurs before meat pH levels fall to 6.1–6.2.

A sequential degradation of the structural proteins postmortem, where calpain initiates the disruption and destabilization of the myofibrillar structure, allows the enzymes that degrade myosin and actin to act. Calpains can be regulated by a nitric oxide donor S-nitrosoglutathione, which can nitrosylate calpain in both the absence and the presence of calcium especially at pH 6.5. The combination of S-nitrosoglutathione and calcium affect *m*- and μ-calpain activity and regulate μ-calpain autolysis rate. In pork, a specific CAST gene (CAST EU137105:g.76 872AA) affects both postmortem calpain activation time and drip loss.

During the postmortem period, desmin and vinculin degrade gradually whereas talin degrades rapidly, which is consistent with the hypothesis that degradation of the cytoskeleton slowly removes the linkage between lateral structures resulting in shrinkage of myofibrils and of the entire muscle fibers, which removes the force that causes flow into the extracellular space. Inflow of previously expelled water is then possible, which increases WHC.

Colocalization of active *m*-calpain with beta-1 integrin has been observed on the cytoplasmic side of the cell membrane. Calpain inhibits integrin degradation and opening of drip channels. It has been suggested that the opening of drip channels may be a consequence of calpain-mediated degradation of cell surface integrins. High levels of intact integrin at one day postmortem negatively correlates with cumulative drip loss. High levels of intact integrin at 5 days postmortem correlates negatively cumulative purge loss.

Emulsions and Batters

RW Mandigo and GA Sullivan, University of Nebraska-Lincoln, Lincoln, NE, USA

This article is a revision of the previous edition article by R.W. Mandigo, O. Esquivel, volume 1, pp 266–271, © 2004 Elsevier Ltd.

Glossary

Emulsifier A protein or other compound with polar and nonpolar regions able to form a stable matrix of two immiscible compounds.

Emulsion An intimate mixture (colloidal suspension) of two immiscible liquids (oil and water), one dispersed in the other to form tiny droplets with the aid of an emulsifier.

Interfacial protein film (IPF) A stabilizing protein film containing myosin, which acts as an emulsifier.

Meat emulsions or batters Systems with proteins present in three different phases: the protein matrix, the aqueous phase, and the interfacial protein film, held together by a variety of attractive forces acting between them.

Introduction

General Description

The classical definition of an emulsion is an intimate mixture (colloidal suspension) of two immiscible liquids (oil and water), one dispersed in the other to form tiny droplets with the aid of an emulsifier. The best examples of products within this definition are mayonnaise or salad dressings based on vinegar and oil where the oil and water phases do not separate on standing. A less strict description of an emulsion is a two-phase system of a dispersion of solids in a liquid in which the solids are not miscible. The second description more accurately defines what is found in a meat system. The liquid phase is water and dissolved components whereas the solid phase is nondissolved meat components and added ingredients. In a meat system, the solid phase contains the muscle, fat, connective tissue from the meat, as well as other food ingredients such as cheese, nuts, fruits, and vegetables. Although meat products do not fit the more classical definitions of emulsions, meat emulsions and meat emulsifiers are similar in many ways and the terms are often applied.

The emulsifier in a meat system is a solubilized muscle protein. The sarcoplasmic proteins have very weak binding properties, whereas the solubilized myofibrillar proteins, including actin, myosin, and actomyosin, have powerful binding properties in a meat system. Stromal proteins from connective tissue sources have some properties resembling those of the myofibrillar proteins, but they also have certain properties that are often very difficult to manage in meat systems.

Importance of Emulsified Comminuted Products

Since early in recorded history, it has been a practice to use salt to control spoilage and to extend the food supply. There is evidence of this practice worldwide. The next step beyond salt curing for preservation was probably an early understanding of what we now know as salt solubilization of myofibrillar proteins and the ability to bind small pieces of muscle to other small pieces of muscle – early sausage making. Sometimes by word of mouth and at other times by independent discovery, people in various regions of the world, of different cultures and religions, found ways to use the available meat, often combined with various available flavor modifiers including fruits, vegetables, spices, and the local salt with its inherent contaminants. Most importantly, the muscles of animals, birds, and fish respond similarly to the technology. Larger pieces of muscle became salt cured; whole-muscle products and small pieces of meat (muscle, connective tissue and fat) became sausage products. Although the names of meat products may vary widely, the common thread has been the need

for preservation, the requirement for a variety of flavors and products, and the need to ensure the availability of the meat over extended periods, with great environmental and survival challenges. Virtually all historical records make references to what we now call cured meats and sausages products.

Emulsification – the act of applying the emulsifier to the comminuted meat (of fine or minute particle size) – is what sausage and processed meat processors have done for centuries. Understanding these techniques and having a thorough understanding of protein solubilization and binding to other proteins, fat, water, and other inclusions, are essential for the production of processed meat products ranging from sausages to hams, corned beef, pastrami, and bacon. Regardless of whether tiny particles or large muscles and portions of muscles, it would not be possible to provide consumers with a wide array of processed meat products available worldwide having nearly endless variations and representing ethnic cultures and constantly changing consumer interests. This variety results from the understanding of how to produce emulsified meat products.

Meat Proteins

General Classification

Myofibrillar proteins, many of which can be solubilized with salt, are clearly the proteins of main interest in the development of emulsifiers to bind together muscle pieces in processed meats. The water-soluble sarcoplasmic proteins take part in the binding of meat but are usually considered weak in terms of binding strength. The amount of salt needed to solubilize myofibrillar proteins, such as actin, myosin, and actomyosin, is usually either that of a 7% brine solution or a dry salt addition of between 4.5% and 5% based on the weight of the meat. Solubilization of these proteins in water from the meat or added water provides an emulsifier that, through mechanical action, coats the surface of the fat particles, muscle particles, connective tissue, and any other nonmeat inclusions in the meat mix. When all particles of the meat mix are completely coated with the emulsifier, the mix is placed into restraints such as fibrous casings or metal moulds for large whole-muscle products and in natural, cellulose, collagen, or plastic casings for small-diameter sausages. During the subsequent cooking and other processing steps, the solubilized or emulsified proteins that are coating the meat pieces are heat denatured and bind the particles together to form sausages or processed meat products.

Protein Extraction

The salt-soluble proteins that are solubilized during the mincing, mixing, and mechanical processing steps become the binder to hold the meat mixture or emulsion together. A sufficient amount of emulsifier is important, because too little will result in insufficient binding, often resulting in a soft texture or meat that appears to crumble and fall apart. Excessive production of the emulsifier followed by heat processing may result in a hard texture, often characterized as tough and rubber like. Because the proteins have been made soluble and are used functionally, but not created or degraded, the amount or quality of protein in the sausage or processed meat is not altered.

Myofibrillar Protein Functionality

Under most commercial conditions, the functionality of the salt-soluble proteins may be altered by a number of processing steps. Denaturation of these proteins is similar to any form of denaturation. Heat denaturation is the most common, but the influence of dehydration, salt addition, acidity changes from pH shifts during fermentation, moisture loss, and protein denaturation during freezing may also lead to loss of functionality. These may influence the further processing of the meat during steps such as fermentation, smoking, drying, and chilling.

Meat Emulsion Matrix

Meat emulsions are made by mixing or chopping meat and water with the addition of salt until a fine, protein-rich slurry is formed. This matrix or emulsifier is then capable of binding fat, water, and other inclusions. During cooking, the salt-soluble proteins (emulsifier) cross-link and coagulate, and this results in an immobilization of the fat, water, and other constituents.

Many attempts have been made to define meat emulsions or batters, and several different viewpoints exist. It is generally accepted that finely comminuted meat products are multiphase systems containing various elements: true solutions, gels, emulsified fat, and air. These components are held together by a variety of attractive forces acting between them, i.e., the meat emulsion or meat batter. In such a system, proteins are present in three different phases: the protein matrix, the aqueous phase, and the interfacial protein film (IPF), and the types and amounts of proteins present in each phase influence the textural properties and stability of the cooked product.

Two main models have been proposed to explain the structure of these food systems: the emulsion theory and the physical entrapment theory.

Emulsion Theory

Classic emulsions consist of two immiscible liquid phases, one dispersed in the other as a colloidal suspension. Another less strict approach defines an emulsion as the system formed by two immiscible phases, one being discontinuous and the other being continuous. In meat emulsions, fat globules and other inclusions of different sizes and composition are the solid discontinuous part, which is dispersed in a continuous aqueous solution containing salt-soluble myofibrillar proteins and other particles such as insoluble proteins, muscle fibers, and connective tissue.

During meat comminution and mixing, a considerable amount of energy goes into the system. This can create a thermodynamically unstable condition. The salt-soluble proteins surround the fat globules, forming a stabilizing protein

film or IPF membrane. The main protein involved in the formation of the IPF is myosin, which acts as an emulsifier, thereby reducing the interfacial tension and stabilizing the emulsion. Myosin orients itself with the heavy meromyosin (HMM) head facing the hydrophobic phase (fat globules) and the light meromyosin tail oriented toward the aqueous phase.

The formation of the protein emulsifier film is an entropy-driven process that reduces the free energy of the system. The alignment of the HMM heads around the fat globules allows for a greater entropy of the surrounding water molecules, thus decreasing the free energy. This film formation around the fat globules has been demonstrated with microphotographs, which provide clear evidence of an emulsification process and of the importance of the IPF for meat batter stabilization.

Physical Entrapment Theory

This theory proposes that the salt-soluble myofibrillar proteins in the continuous phase exist in a sol form, which turns into a gel on cooking. Soluble myofibrillar proteins present in the continuous phase may exhibit three types of interactions or attraction forces: protein–protein, protein–water, and protein–fat. When balanced protein–protein and protein–solute interactions exist, protein molecules may create an ordered network governed by a combination of intermolecular interactions including hydrogen bonding, electrostatic attractions, van der Waals forces, and hydrophobic interactions. During heating, myofibrillar proteins start to denature, leaving several hydrophobic domains exposed. Hydrophobic interactions are then initiated and further aggregation, seeking thermodynamic stability, leads to gelation and to the formation of the characteristic network of protein fibers. This protein aggregation during cooking immobilizes the fat globules by binding them to the matrix and preventing coalescence. Physical entrapment of fat and other particles therefore occurs as a result of this phase change during thermal processing.

Comparing these two theories, it appears that formation of the meat emulsion or batter is a combination of an effective emulsifying film surrounding all particles including the fat globules, connective tissue protein, and other solid inclusions with the physical restriction and binding given by the ordered protein network. Many factors influence the extent to which either of these two mechanisms is involved in the structural properties and stability of the system.

Emulsion/Batter Stability

Meat emulsions/batters are stabilized after cooking when fat globules and other elements are immobilized by gelation of the protein matrix and the characteristic properties of the finished product are attained. The stabilization of fat, water, and other elements in the system is therefore essential for the sensory acceptability of the products.

Fat loss from a meat batter can be associated with initial moisture losses during cooking due to the formation of channels through the matrix that allow migration of water and melted fat to the surface of the product. Emulsion stability can be measured by the amount of moisture loss or fat coalescence. In successful products, these two defects are minimal when all particles, regardless of particle size, are completely covered with sufficient quantities of the myofibrillar protein emulsifier. Three major factors contribute to fat stabilization: the biophysical properties of the protein film surrounding the fat globules, the gelation properties of the protein matrix, and the physical characteristics and cell integrity of the fat. Water retention, however, is influenced by the pH and the amount of extracted salt-soluble protein in the solution. Batter stability is commonly influenced by the thermal process, the biochemical state of the muscle proteins, the ionic environment, and the pH. Variations of these factors beyond relatively restricted boundaries may cause instability.

Interfacial Protein Film Formation and Gelation

Although the emulsifying properties of the protein film play a major role in fat stabilization, the gel formed by the protein matrix has a high water-binding capacity and strong elastic properties. Protein hydrophobicity is particularly important for effective formation of the IPF, and protein–protein interactions are important during the formation of a successful soluble protein network. Myofibrillar proteins, which are interfacially absorbed, lose their ability to gel but bind to the protein matrix of the meat batter. Irreversible heat setting of this protein network ultimately stabilizes the system. The ionic environment of the meat system is important for IPF formation and heat-induced gelation. Pale, soft, and exudative (PSE) pork reduces the extractability and functionality of myofibrillar proteins. Disintegration of the muscle structure and solubilization of proteins as a result of high ionic strength are required for the creation of a three-dimensional gel structure, which then supports water binding through capillary forces and immobilizes protein emulsifier-coated fat globules and other inclusions, such as vegetables, fruits, nuts, cheese, salt, or vinegar-cured inclusions. The concentration and type of salt in the formula for the comminution process affect the amount of actin, actomyosin, myosin, and other proteins extracted from the lean meat, and this has a direct influence on batter stability. Studies have shown that reducing sodium chloride (NaCl) levels from 2.5% to 1.5% resulted in a reduced stability with an unacceptable texture due to a reduction of nearly 50% of the total proteins extracted to form the IPF. In general, NaCl and lithium chloride (LiCl) are capable of extracting myofibrillar proteins more efficiently than other chlorides such as potassium chloride (KCl), or the divalent salts magnesium chloride ($MgCl_2$) and calcium chloride ($CaCl_2$).

A significant factor for batter stability is the size of the relative interfacial surface, which is determined by the degree of fat disintegration and the amount of fat added. Thus both the quantity and particle size of fat are critically important, as an adequate amount of the emulsifier is needed to coat the complete surface area of the fat. Provided that enough soluble myofibrillar protein is present in the aqueous phase, the stability is greater when the size of the fat particles is smaller. Short chopping times result in interfacial surfaces with thick layers of myofibrillar segments around the fat globules and without efficient distribution of protein and fat throughout the interface. This is not favorable for stability. As the

interfacial surface increases, the protein layer and fat particles are more evenly distributed and balanced protein–water, protein–lipid, and protein–protein interactions are established. This leads to optimum stability. If the relative interfacial surface is too large (e.g., owing to high fat addition levels or too small particle sizes of the fat), the protein film around the fat globules becomes thinner and its mechanical strength decreases, which may lead to instability when the fat expands during thermal processing. Also, excessive amounts of protein could be withdrawn from the continuous phase, reducing protein–protein interactions and proper gelation during heating. Protein aggregates might be absorbed at the interface of more than one fat globule, resulting in a decrease in the system's flexibility and shear resistance. The result is poor fat stability and a loose noncohesive product after cooking.

If enough soluble myofibrillar protein is present in the aqueous phase, the presence of sufficient fat seems to play an important role. In fat-reduced batters, a relatively large proportion of the hydrophobic regions of the protein molecules are not utilized; this causes a shift in the absorption pattern, with reduced water-holding ability, and purge after cooking can be significantly increased. The higher the amount of fat – up to approximately 30% – the smaller is the degree of shrinkage of the protein structure, resulting in better processing yields. Reduced-fat products therefore require increased nonmeat ingredients for improved functionality, particularly for the binding of additional water.

The thickness of the IPF may also influence the emulsion stability. High endpoint chopping temperatures can result in an overly thick and inflexible protein envelope, which ruptures owing to thermal fat expansion. Thinner protein films have pores through which small amounts of melted fat can escape. Batter stability is therefore related to the thickness of the IPF coating, the fat content, and the integrity and density of the surrounding matrix and its response to thermal processing.

Particle size

The texture of sausage or processed meat is a function of the interaction of meat and nonmeat ingredients in addition to the particle and the amount of emulsifying capacity of the solubilized proteins. All components in the meat mixture must be completely covered with the salt-solubilized myofibrillar proteins or the emulsifier. The amount of emulsifier needed is thus determined by the amount of surface area of all particles. The amount of emulsifier increases dramatically, and the particles become smaller through the mechanical actions of the cutting of the particles and the increasing surface area that is developed.

Fat Characteristics and Processing Conditions

Several aspects of the characteristics of fat are important for emulsion stability. Reports indicate that shorter-chain saturated fatty acids and triacylglycerol are easier to emulsify than longer-chain counterparts and that the degree of saturation also plays a role. At similar chain lengths, less-saturated fatty acids are easier to emulsify than saturated fatty acids. There seems to be a relationship between the fat melting point and the degree of fat dispersion and absorption by the IPF at the fat–water interface.

Batter viscosity decreases at temperatures above the fat melting point, and as the fat particles are less dense than the aqueous phase they tend to float to the surface. This could prevent the fat globules from being coated by the IPF. The IPF-coated fat particles are less prone to coalesce during heat processing. Experiments evaluating fats of different melting characteristics at various temperatures reveal that at low-fat additions, all types of fats can produce stable emulsions, whereas at higher fat levels, high-melting fats produced more stable emulsions than that of low-melting fats, irrespective of temperature reached during emulsification. As a general rule, it is recommended to attain endpoint chopping temperatures below 18, 12, and 8 °C for beef, pork, and poultry fats, respectively.

Batter failure may occur when unfavorable conditions are present in the raw state or when changes taking place during cooking create unstable conditions. It is, for example, very important to reduce the particle size of both the myofibrillar structure, connective tissue, and the fat tissue and to achieve an even distribution of the different components of the system with the mechanical action. However, excessive chopping is detrimental to batter stability, mainly because of melting of fat, denaturation of the salt-soluble proteins, and disruption of the protein matrix. Extreme shear action may also result in a too large surface with a need for more salt-soluble myofibrillar protein. There is, therefore, a thinner and less-stable protein film around the fat globules. During thermal processing, the protein matrix undergoes several transition stages. At 40–50 °C myosin starts to denature and gelation begins; approximately 60 °C, when collagen melts, the major thermal transition takes place, and the structure is further consolidated between 72 and 83 °C when the actin is denatured. Fat within the system starts melting before any thermal protein denaturation occurs and as a consequence it is molten before the protein matrix gelation is completed. The presence of sufficient emulsifier is therefore essential to stabilize the fat in the system before protein gelation. Both the IPF and the protein matrix structure must be stable and cohesive, so that the expanding liquefied fat does not exude from the batter and coalesce in pockets.

Stabilization Mechanisms

Protein functionality characteristics such as emulsification, gelation, and water binding are determined by molecular interactions involving disulfide bonds, hydrogen bonds, electrostatic attractions, and hydrophobic interactions. Studies, utilizing chemical agents that modify the type of molecular force developed in the system, have been done to help understand their role and influence in the product attributes and acceptability. Disulfide bonds are not essential for fat and water binding in meat batters, but they are important in the raw state for development of an acceptable texture, influencing the springiness, cohesiveness, and hardness of the product. Protein hydrophobicity results in entropy-driven protein–protein interactions and aggregation required for the formation of a sufficiently cohesive and flexible gelling structure. Hydrophobic interactions are crucial in the IPF formation and

stabilization of the protein matrix, being the major force behind raw batter gelation. Hydrogen bonds and electrostatic attractions appear to have some importance and seem to participate in the binding of the IPF-coated fat globules to the protein matrix. However, if these forces are increased, the result may be excessive matrix aggregation in the raw state with well-interconnected channels throughout the batter. These can serve as routes for water losses during cooking.

Temperature of the meat mixture at stuffing or final handling before heat processing can have significant impact on the eating quality of the product, particularly the fat component in the finished sausage product. Variations in fatty composition and degree of saturation are influenced by source species. Final stuffing temperature for all beef emulsified products should be at either 4 °C or 20 °C for all beef formulations whereas the mixed meat final stuffing temperature should be between 13 and 16 °C. All pork or all poultry emulsions should remain at or below 13 °C. These temperatures reflect the heat of crystallization temperatures for all the beef fats compared to heat of crystallization temperatures for pork, poultry, and mixed species fats. Failure to follow these temperatures result in poor emulsion stability, product quality, and yields.

Stability Assessment

Emulsion breakdown can occur during the cooking process as a result of meat batter instability. Emulsion stability can be determined by the amount of fat and/or water released from the matrix after cooking. Unfortunately, there are no visible signs before cooking to indicate to the commercial processor that the problem will occur. Measuring the electrical conductivity of the raw batter can give some idea of emulsion stability, as a good continuous aqueous phase with the presence of salt will conduct electricity better than a batter in which fat separation has started to occur. Plotting electrical conductivity against time during the chopping process has been suggested as a way to visualize structural changes in the emulsion. Some authors have even found that fiber-optic probes can be used to predict the point at which an emulsion becomes unstable. However, even if such a point can be measured, it might be too late for the processor to correct the problem. A method commonly used for research requires that the raw batter is stuffed into polycarbonate syringe tubes and cooked under controlled conditions. Released fluids (fat, gelatinous liquid, and proteinaceous particles) after cooking and centrifugation are measured and the stability is related to the total loss as a percentage of the raw batter weight. This technique creates a performance track record of production and can be used to predict performance and expectations.

Emerging Trends

Low-Fat Meat Batter

Considerable work has been reported on a variety of approaches and potential nonmeat ingredients for low-fat and fat free sausage emulsions. Fat can be physically removed from the meat raw materials, although the cost and labor expenses are significant. Depending on the fat target in the formulation, there are serious limitations for cost and availability of very low-fat content raw materials. What appears to be nearly fat-free to the eye will in fact contain at least 3–5% fat. Thus, most low-fat strategies involve the binding of extra amounts of water or water-based broth solutions. This is usually accomplished with plant proteins, starches, or hydrocolloids.

Low-Salt Meat Batters

Low-salt concerns are usually described as low-sodium issues. Some success has been achieved with sodium-replaced salts including 'lite salt.' These salts are typically a 50% potassium chloride replacement. A serious concern should be focused on the impact of lowering the amount of salt in processed meat. From the basic processing standpoint, in order to extract enough protein to produce a heat-stable gel, a minimum of 1.4% or 1.75% sodium chloride (with added phosphates) is required for cooked sausages and lean meat products, respectively. Salt is one of the interventions used to control microbial growth, and nitrite salt is one of the most effective antibotulinum interventions. When salt levels decrease, the concern for safety increases and shelf life can decrease especially when product is abused with poor refrigeration temperatures. To help offset this potential problem, increased endpoint cooking temperatures for microbial control and more rapid chilling rates are being implemented. Processors must also address changes in flavor due to reducing the salt content and may be achieved through increasing spice content or through the use of other flavor enhancers.

Added Nonmeat Ingredients

Many nonmeat ingredients are being evaluated worldwide for their application to sausage emulsions and processed meats. The largest group involves products providing additional fiber, starch, protein, and hydrocolloid contents to control and maintain higher moisture levels in the finished products and to lower the amount of fat for nutritional claims. Added plant-based proteins, such as soy, have different gelation properties than meat proteins, and processes may need to be slightly modified to achieve desired product characteristics. A second group of newer ingredients involves intervention with sodium lactate, sodium diacetate, and bacteriocins as well as processing steps to improve postpackaging pasteurization. Both areas are being studied and evaluated for inclusion in processed meats in many countries.

Processing strategies to build strong emulsions with lower- or low-salt formulations

To achieve the ionic strength of the salt solution needed to solubilize sufficient myofibrillar protein to properly emulsify the meat system and all the inclusions as well as to develop the proper texture of the finished product, the sausage emulsification procedures need to be changed with lower final salt concentrations in the finished products. Salt concentrations historically were 4–5%. Today, the salt content is commonly at or near 2%, and pressure to reduce the salt content to even lower levels is desired.

Research indicates that to achieve the necessary level of emulsifier to bind the particles and create the desired eating texture, 4–5% salt is needed – clearly much higher than desired. Assuming 1.8–2.0% salt in the finished product, the strategy of using 30–40% of the leanest meat with all the available salt (formulated at 1.8–2.0%) would, for a short time during initial mixing, provide a temporary 4–5% salt strength, which would adequately create the needed emulsifier for the entire meat block. Then, the addition of the other nonmeat ingredients and the remaining 60–70% of the total meat in the formula would bring the final formulation to the desired salt content of 1.8–2.0%. Although this strategy allows good emulsifier development for current products, there is a point where other strategies will be required to develop sufficient emulsifiers for bind and eating texture.

Glossary

Functional foods Term relating to the implications of the different 'functional ingredients or functional components' (including proteins) in human health (enhancing health or reducing risk of disease), dealt with specifically in the section on 'Composition for Nutrition and Health Purposes.' That terminology must be clearly differentiated from the terminology defined below.

Functional properties and functionality Terms widely used throughout this article referring to any physicochemical property of a protein that allows protein molecules to interact among themselves and with their environment to produce or improve the quality and stability of the final meat product. Protein functionality determines the technological suitability of the protein and has an important role in food behavior during processing and storage, affecting many of the desirable physicochemical and sensory attributes of muscle foods.

Introduction

Many nonmeat ingredients are used in the manufacture of comminuted meat products; of these, protein-based ingredients are among the most important. They are very widely used, and in many cases there are specific norms regulating the amounts that can be used and which products they can be used in. The range of applicable nonmeat proteins from animal and plant sources is very large (Table 1).

This article discusses the use of various nonmeat proteins, their functionality, and their impact on the characteristics of comminuted meat products.

Functions of Nonmeat Proteins in Comminuted Meat Products

Nonmeat proteins are used as ingredients in meat products essentially for purposes of economy, functionality, and composition (nutrition and health).

Economics

In this connection, nonmeat proteins are used essentially to reduce costs and improve the processing yields of products to which they are added – economic dictates guide the right selection.

Functional Properties

Nonmeat proteins can be added to meat products for functional purposes. The characteristic qualities of comminuted processed meats (emulsion, particulate, sectioned, shaped, and restructured products) depend on the functional properties of the protein matrix (from meat and nonmeat sources). In the comminution process, the meat is mixed with salt and reduced to varying degrees of particle size to partially extract salt-soluble components. Subsequently, depending on the type of product, any fat is dispersed or emulsified within the protein sol matrix, which is then heated to produce setting or gelling of the emulsion and the protein matrix. Water-binding, fat-binding, emulsifying, and gelling properties play an important role in such meat systems. Nonmeat proteins are used to enhance one or more of these properties, although the functional benefits they confer will never equal those of high-quality lean meat. Additionally, some proteins can also be injected into whole muscle meats to achieve textural integrity. Tenderizing enzymes (of plant, fungal, or bacterial origin) have been used for their ability to make tough meat more palatable. The choice of nonmeat proteins in meat processing, how they are used and how they affect the characteristics of comminuted meat products, depends on a number of factors (Figure 1).

Water- and fat-holding properties

The ability of proteins to hold water and fat, as well as to retain these two components when heated and stored, is

Table 1 Nonmeat proteins used in the manufacture of comminuted meat products

Protein Source	
Animal	Milk
	Fish (surimi)
	Meat coproducts: connective tissue, blood, mechanically separated meat, and surimi-like materials
	Egg
Plant	Oilseeds: soy, sunflower, peanuts, cottonseed, and rapeseed
	Cereals/grains: corn, wheat, oat, and rice
	Legumes: peas, beans
Microbial	Yeast
	Streptoverticillium mobaraense (Transglutaminase, EC 2.3.2.13)

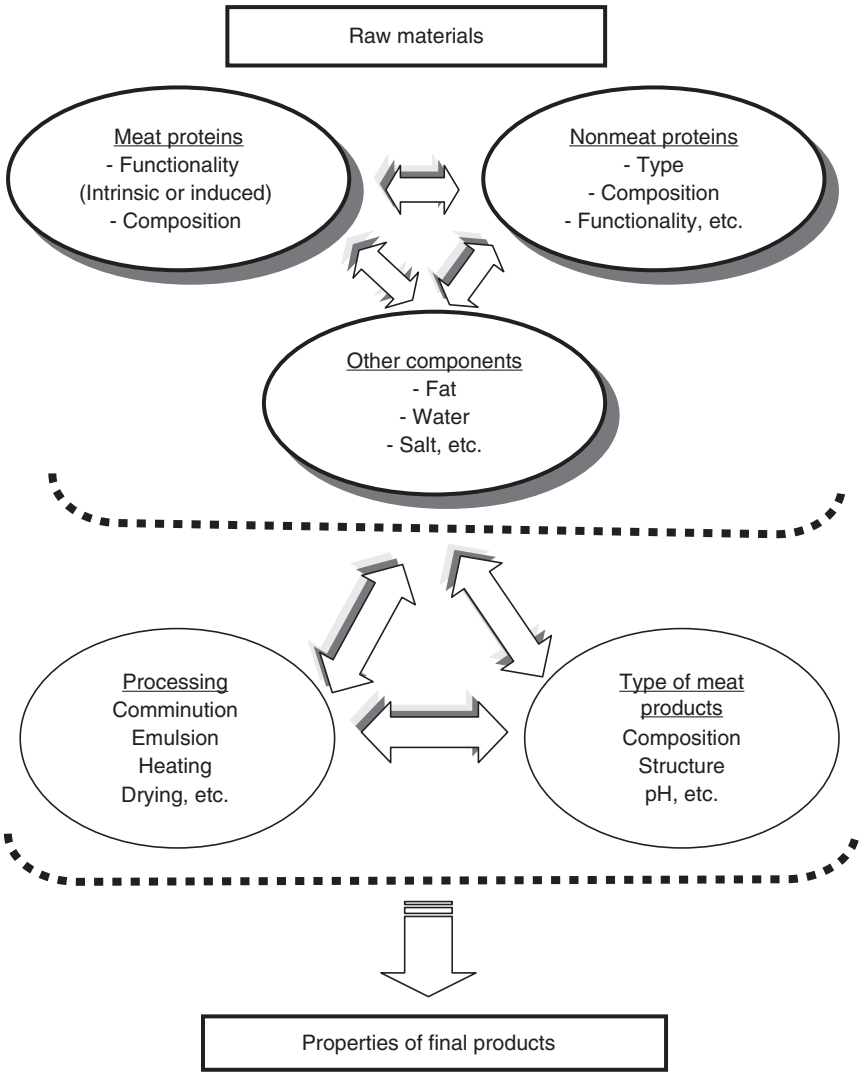

Figure 1 Relationship between the factors determining choice of nonmeat proteins and their effect on comminuted meat products.

crucial in the manufacture of processed meat products. These properties determine not only the final cook yield and the purge or drip loss on freezing and thawing, but also the final quality of the product (appearance, texture, color, juiciness, flavor, etc.). Different nonmeat proteins can be used to hold fat or water. The relative importance of holding water or fat depends on the kind of product involved. For example, in a full-fat meat emulsion, fat holding is the more important of the two, whereas in low-fat meat products, where part of the fat is replaced by water to reduce the calorific density, water-holding capacity is the key factor.

Emulsifying properties

A meat emulsion is a multiphase system consisting of a complex colloidal aqueous system (or matrix) of salts, proteins, and other soluble components in which solid components, including insoluble proteins and fat particles, are dispersed. The stability of meat emulsions, especially after heat processing, depends on the formation of a stable protein matrix gel in the continuous phase that entraps water as well as fat (gel/emulsion system). Nonmeat proteins can assist the formation and stabilization of meat gel/emulsion systems.

Gelation

The formation of a stable gel network is important for a range of functional properties of muscled-based foods, including holding of water, fat and particles, and texturization. There is a variety of ways in which two or more proteins can interact that will affect the properties of a multicomponent system. A number of possible models have been described for the spatial partitioning of a gelling protein (e.g., from meat) and a gelling or nongelling coingredient. These are: filled gels (where components are interspersed throughout the primary gel network); complex gels (where components are physically associated); and multicomponent gels (having an interpenetrating polymer network). When nonmuscle proteins (generally globular proteins, unlike the fibrillar proteins of muscle) are added, the resulting system may be considered qualitatively incompatible, semicompatible, or compatible. Depending on the degree of compatibility, the consequences may range from weakening

of the texture of the product through dilution of the meat protein (which is a highly functional component) or interference in gel formation, to strengthening of gel texture through reinforcement of the gel structure. Nonmeat proteins (e.g., transglutaminase) are also used as cold gelling agents for processed meat.

Proteins may be modified to change functionality for specific applications in meat processing. A number of nonmeat proteins (soy, wheat, and others) are texturized by various procedures to give specific textures and shapes, often so as to mimic the structure or appearance of meat. A number of nonmeat proteins (whey, milk, and egg proteins) are microparticulated to mimic certain properties of fat and are used to replace fats in low-fat processed meats. Flavor enhancers derived from nonmeat proteins (such as hydrolyzed vegetable protein or autolyzed yeast protein) are used to lend a more meat-like flavor. Animal and plant proteins (casein, whey protein, gelatin/collagen, fibrinogen, soy protein, wheat gluten, corn zein- water-insoluble prolamine from corn gluten, and egg albumen) have been used in edible films.

Therefore, the incorporation of nonmeat proteins influences the processing and physicochemical properties of comminuted meat products (Table 2).

Composition for Nutrition and Health Purposes

Nonmeat proteins can be used to provide nutritional benefits by lowering the calorie and cholesterol contents (when used as fat replacers) and by increasing the protein level and balancing the amino acid profile. Some nonmeat proteins (soy, sunflower, etc.) also contain health-enhancing components that make for reputedly healthier processed meats. For example, soy protein has been used to make a pork sausage whose consumption reportedly helps to maintain a proper blood cholesterol level (a functional meat product).

Animal Proteins

Milk Proteins

Milk yields a number of forms of milk proteins with a range of functional and nutritional attributes. These proteins are used as fillers, binders, and extenders in comminuted meat products (with normal and low fat content). The functional ability of such nonmeat protein ingredients derives from casein and whey, the two principal protein components of milk. In conjunction with various factors (composition, processing conditions in which they are derived, etc.), milk proteins can offer excellent functional properties such as solubility, water and fat binding, gelation, emulsion stability, and others, and they are widely accepted in the meat industry.

Nonfat dry milk (NFDM) is produced from pasteurized skim milk that is vacuum concentrated and spray-dried (skim milk powder). NFDM contains both casein and whey proteins along with lactose and minerals. It has been used as a functional protein ingredient in different comminuted meat products (frankfurter, bologna, roast, etc.) to improve emulsion stability, sensory characteristics (flavor, color, or juiciness) and water-binding properties (reduced cooking yields). Because calcium can influence the binding properties negatively, the low-calcium form of NFDM may improve functionality.

Caseinates are made from acid casein. Sodium caseinate is the most widely used in processed meats, although calcium and potassium caseinates are used when lower sodium formulation is required. The functional ability of caseinates lies in their molecular structure, a unique combination of electric charge and amino acid content (high-proline and low-sulphur), which prevents heat gelation and denaturation of caseinates and ensures high viscosity of caseinates in solution. They are not capable of binding meat pieces together because they do not gel during heating, but they do increase the gel strength. Caseinates, which are used usually in processed meats as emulsifiers to improve moistness and smoothness, are preferentially absorbed by the meat proteins at the fat–water interface. Because of the larger small fat globules created by the presence of milk proteins, the water loss during heating is reduced. Unlike vulnerable meat proteins, meat-based emulsions containing casein are less sensitive to temperature changes during processing (e.g., chopping). Processed meats such as hamburgers, nuggets, liver sausages, patties, frankfurters, and so forth have been formulated with caseinate, and, although its effect depends on a number of factors, it has generally been found to improve meat emulsion stability (more than many vegetable proteins), sensory attributes, and water-binding properties. It can be used in three different forms: as a prefabricated caseinate emulsion, in dry powder form at the beginning of the comminution process, and as a prefabricated gel.

Milk coprecipitates contain both casein and whey proteins and can be produced with a wide range of functional properties

Table 2 Influence of nonmeat proteins on processing and final characteristics of processed meat products

Aspect	*Area of influence*
Processing	Preparation conditions: form of addition, comminution, emulsifying, heating, etc.
	Raw meat batter properties: viscosity, chopping temperature, pH, etc.
	Thermal gelation process: gelling temperature, network and molecular interactions
	Cooking properties: yield, emulsion stability
Product characteristics	Binding of meat particles
	Slicing characteristics
	Cooking behavior: cooking loss, shrinkage, etc.
	Sensory attributes: appearance, color, flavur, palatability, texture, etc.
	Storage properties: microbial stability, vacuum purge accumulation, lipid oxidation, freeze–thaw stability, etc.

to perform a variety of functions in different comminuted meat products. Depending on the calcium content, coprecipitates can be good emulsifiers, can improve water-binding properties, and can serve as gelling agents and thickeners. Coprecipitates have been used in luncheon meats, bologna, nuggets, frankfurters, and other products.

Whey, a coproduct of cheese and casein manufacture, can be processed into a variety of forms including dried whey (2–13% protein), concentrates (35–80% protein), and isolates (>90% protein). Whey proteins present a strongly folded and organized globular structure. Under appropriate heating conditions, they unfold and build intermolecular disulfide bonds resulting in a gel matrix whose capillaries entrap water. Hydrophilic and hydrophobic regions on the protein surface provide emulsifying properties. The value of whey proteins as functional replacers or supplements of meat proteins in processed meats lies in their high functionality, and that functionality depends both on their origin and on further chemical modification. Whey proteins can bind a considerable amount of water by physical and chemical means, thus preventing moisture loss, improving yields, and reducing purge loss in vacuum-packed meats. They are very efficient emulsifiers of fat and oil, forming stable emulsions and helping improve appearance, mouthfeel, and juiciness. Whey protein products are used in a variety of processed meats (minced meats, emulsion products, coarse-ground products, whole muscle products) to improve flavor, texture, emulsification, water binding, cook yield, and product functional performance. Edible coatings based on whey proteins can be applied to frankfurters and other processed meats.

Surimi and Surimi-Like Materials

Surimi is stabilized myofibrillar protein obtained from mechanically deboned fish flesh that is washed with water, strained, and blended with cryoprotectants. The functional properties of surimi make it eminently suitable as an intermediate product for use in a variety of applications, and its very low fat content makes it ideal for low-fat meat products. It has also been proposed as an additive to processed red meat and poultry products to improve texture and water/fat holding. Surimi has been incorporated in varying proportions as a partial replacement for meat in various comminuted meat products, including frankfurters, bologna, restructured meats, and others.

In a more recent development, processes similar to those used in fish have been applied to various meat coproducts (beef heart, mechanically separated meat (MSM), etc.) to produce a surimi-like material for use as a functional ingredient in comminuted meat products such as sausages, patties, and the like.

Blood Proteins

Blood collected from a healthy animal, usually sterile, contains approximately 18% protein, whose amino acid composition is reasonably well balanced. Blood is used in food as an emulsifier, stabilizer, clarifier, color additive, etc., and it enhances the color of cured meat. In many meat products, however, it imparts undesirable characteristics (dark color and often unpalatable flavor), and it therefore offers more applications when separated into plasma protein (60–80%) and red cell fraction (20–40%).

Plasma proteins, which are mostly used in dry form, consist of various proteins, mainly albumin, globulins, and fibrinogen. They have been used to improve functional properties, to reduce formulation costs, and as a protease inhibitor. For purposes of meat processing, the outstanding functional property of plasma proteins is their exceptional gel-forming ability (primarily because of the albumin), which helps to impart good water-binding and meat particle-binding properties. Albumin gells at 85 °C and fibrinogen gells at 50 °C. Plasma protein also has excellent emulsifying and foaming properties. Plasma proteins have been used as gelling and binding agents in minced beef, frankfurters, bologna, pâtés, and other products.

The red cell fraction (34–38% protein) is dried to form a meal, or the haem group is removed to obtain globin. Globin protein has excellent foaming and emulsifying abilities and has been used in some meat derivates, although the high iron content may increase lipid oxidation. Other aspects that need to be considered are the dark color and off-flavor that haemoglobin-rich materials impart.

A blood-based system can be used to bind comminuted and large pieces of meat. The binding mechanism works through the combined blood-clotting action of fibrinogen, thrombin, and transglutaminase (factor XIIIa). Transglutaminase catalyzes protein polymerization and cross-linking through the formation of covalent bonds between protein molecules. It has been proposed as a cold-set binder of muscle protein on the ground that it would reduce the need for added sodium chloride and phosphate.

Mechanically Separated Meat

MSM makes an ingredient of excellent nutritional and functional value for comminuted meat products. MSM has good emulsifying capacity, emulsion stability, and water-holding capacity. MSM has been used in varying proportions in a large number of meat derivatives (minced meat, sausages, and other types of products). Generally speaking, as the proportion of MSM in the formula increases, flavor and overall acceptability scores decrease, the product is darker in color, and tenderness and juiciness scores rise.

There have been two European Union decisions affecting the use of MSM in processed meats. One (Decision 2000/418/EC) prohibits the use of meat separated from ruminant bones, and the other (Directives 2001/101/EC and 2002/86/EC) excludes poultry and pork MSM from the harmonized definition of 'meat' in the labeling of products containing them.

Egg Proteins

Egg proteins, derived from whole egg, yolk, or whites, are available in different forms for use in processed foods for their functional properties, such as foaming, binding and thickening ability, emulsifying ability, and moisture retention. Whole egg and egg white have been used in the formulation of

normal and low-fat meat products (meat patties, bologna, and others) and have proved very effective as binders for meat. They also have excellent nutritional properties. However, there is a drawback to their use in processed meats as they are relatively costly.

Connective Tissue Proteins

Connective tissue is composed of two proteins, collagen and elastin. Collagen, the more abundant of the two, produces gelatin by heat-denaturalization and partial hydrolysis. Connective tissue is present in comminuted meat products either as a natural component of the meat raw material or as a nonmeat ingredient. The use of collagen in processed meats is generally limited because on heating, collagen molecules shrink and gelatinize, which causes the release of gelatin. However, when properly handled, it can be a good functional ingredient for processed meats. Typically, trimmings with high connective tissue content are minced and added to comminuted meat products. As a rule, the meat in meat products should contain no more than 25% collagen to maintain their structure and acceptability. Collagen in comminuted meat products helps to stabilize the emulsion and to impart textural properties to products like burgers and sausages. The ability of gelatin to form water/fat emulsions that gel on cooling is considered important for some meat products. Thanks to its excellent water- and fat-absorption properties, collagen improves cooking yields and juiciness. It also reduces syneresis (purge) and hence shelf-life, because purge loss is a growth medium for bacteria. Collagen can potentially be used as a fat replacer in comminuted meat products.

The success of such nonmeat proteins as ingredients in the manufacture of comminuted processed meats will depend considerably on the source (basically pig skin and hide collagen, bone collagen, offal collagen, and skeletal muscle collagen), the preparation conditions, how the ingredient is used, and the nature of the product it is to be used in. A variety of procedures to improve the functionality of connective tissue proteins have been tested with a view to enhancing their potential as ingredients in comminuted meat products. These procedures include mechanical modification, enzymatic hydrolysis, acidic or alkaline phosphate treatment, and addition in a preemulsified or precooked form. Modified connective tissue has already been used in the formulation of low-fat processed meats. Collagen is also used in edible sausage casings.

Plant Protein Sources

Soy Proteins

Soy has always been one of the most widely used proteins in comminuted meat products. A variety of processes are used to produce soy flour and grits (52–56% protein), concentrates (70% protein), and isolates (≥90% protein) from soy beans and as coproducts of oil extraction. In each case, differences in composition and processing produce different characteristics, and these characteristics determine their particular application in a wide range of comminuted meat products. Soy flour and grits are chiefly used in minced meat systems as binders; however, both flour and grits give meat products a slightly bitter taste, which limits their use. Soy protein concentrates possess good water- and fat-holding abilities and emulsification properties and are used in emulsion-type sausages, luncheon meat, and meat patties. Soy isolates are excellent water and fat binders and possess both emulsifying and emulsion-stabilizing properties. Soy protein isolates aid in forming gels, which act as matrices to retain moisture, fats, and solids. Concentrates and isolates are most frequently used in finely ground sausages or emulsified meats. Textured soy products (flours, concentrates, or isolates) are extruded under high pressure and heat to give a specific texture and shape, frequently so as to mimic the structure or appearance of meat when hydrated. A major application of textured soy protein ingredients is in coarsely chopped or minced meats to be used for pizza topping, taco meats, meatballs, meat patties, and restructured steak.

Soy protein products are used primarily for their functional characteristics. The soy protein polymer chain contains both lipophilic and hydrophilic groups, so that the protein associates readily with both fat and water. This promotes the formation of stable oil and water emulsions when a protein dispersion is mixed with oil. Soy protein can associate with many different types of compounds, adhering to solid particles and acting as a binder or as a dispersing and suspending agent in solution. The functionality of soy protein in comminuted meat products is enhanced by prehydration or by the formation of a preemulsion in which fat, water, and soy protein are finely ground and then salt is added. The degree of hydration varies widely, but as a rule the end product will be firmer the lower the level of hydration. Salt assists the extraction of salt-soluble protein, but it has the opposite effect on soy protein, because it prevents hydration. For optimum functionality, therefore, soy protein must be fully hydrated before salt is added.

Soy protein has been reported to assist in the formation of a gel that acts as a matrix to retain moisture and fat and impart a desirable texture; however, under normal meat-processing conditions (temperature 65–73 °C, pH 5.5–6.0, and ionic strength 0.1–0.6), none of the major soy globulins exhibits any appreciable structural changes or hence any interaction with muscle proteins. Such lack of interaction is one of the main drawbacks to the use of soy protein as a functional ingredient in comminuted processed meats. Indeed, soy protein in high concentrations may act as a diluent, weakening the gel-forming capacity of meat proteins and so negatively affecting the texture of the finished product. Prior heating (90 °C) of soy protein improves its interaction with meat protein.

Soy protein can impart certain residual flavors or induce dilution of the natural flavor of the meat, depending on the type of derivative concerned.

Soy protein has been used as a fat replacer in the manufacture of low-fat (high-moisture) comminuted meat products.

Wheat Proteins

Wheat protein is one of the plant proteins (along with soy) most commonly utilized in meat products. The protein level of

finished wheat gluten products is typically 75–82% (dry basis). Vital wheat gluten, texturized wheat gluten, and isolated wheat gluten can be used in meat products. When hydrated, texturized wheat gluten has a fibrous structure that can be adapted to mimic the appearance and texture of beef, chicken, or pork. It has an excellent water-binding capacity.

Gluten protein functionality depends on the wheat source and the preparation process (separation, drying, extrusion, etc.). Gluten protein is eminently suitable for use as a nonmeat additive in meat products thanks to its unique functional properties. When mixed with water it can form a viscoelastic mass. Of particular importance to the meat industry are the binding and film-forming characteristics of gluten, which has the ability to interact with myosin.

Vital wheat gluten has been used in meat products as a binder, filler, or extender. When added to comminuted meat products such as frankfurters and bologna, it improves cooking yields, water-holding capacity, and batter stability. In restructured meats it imparts several benefits, such as enhanced viscoelasticity, color stability, firmness, juiciness, and moisture retention. In other meat pieces and processed meats, the binding ability of wheat gluten improves yield, cooking loss, adhesion, structural strength, rehydration properties, sliceability, and retention of sensory attributes. Also, texturized wheat gluten has been added to various meat products (burgers, nuggets, etc.) to improve physical properties and the taste perception of reformed patties or nuggets. Wheat proteins are potentially good nonmeat ingredients for use as extenders or binders in low-fat comminuted meat systems.

Corn Proteins

Corn gluten meals are coproducts of the corn wet-milling industry. Available products include corn meal (60% protein), defatted corn germ protein, and corn protein isolate (90% protein).

Corn germ protein is potentially a suitable protein additive for use as an extender in meat products such as frankfurters, bologna, and patties. When added to comminuted meat products, it improves cooking yield, water-holding capacity, and batter stability, although it can soften the texture of the product; also, the spice formulation may need to be altered. In low-fat meat products, the water-binding and texture-softening effects of corn germ protein are desirable qualities.

Other Vegetable Proteins

Nonmeat ingredients containing proteins from other plant sources have been used as binders and extenders in comminuted meat products.

Pea proteins is a coproduct of starch extraction from peas. It has good potential as an additive for emulsions and other meat products thanks to its promising functional properties (water and fat binding, emulsifying, whippability, and foam stability). Pea proteins in the form of flours, concentrates, and isolates (up to 90% protein) have been used in both normal- and low-fat sausages.

Different oilseed (other than soy) protein ingredients (sunflower, rapeseed, peanut, and cottonseed, in the form of flours, protein concentrates, protein isolates, and extrusions) have been used experimentally in minced meats, patties, and sausages. These generally improve cooking yield and emulsion stability and retard oxidative rancidity.

Rice products (flours and protein isolates), oat proteins, and bean products (flours) have been used in sausage meat.

Microbial Proteins

Several yeast-based ingredients can be used in comminuted processed meat as extenders or flavor enhancers. Dried yeasts (45–53% protein), coproducts of the brewing industry, are good protein extenders that can be used as emulsifiers in cooked and canned comminuted meat products. Yeast extracts, produced by autolysis, are widely used in processed meats because they impart a meat-like flavor.

Microbial transglutaminase (MTGase) has many potential applications in meat processing. MTGase can be used in combination with caseinate or collagen as a cold-set binder (reducing the need for added salt) for meat products that can be sold raw in the chilled state. Consumers and processors are increasingly interested in reducing the salt content of processed meats because of the potential health benefits. MTGase can also be a useful additive in cooked meat products.

Introduction

Food additives play a critical role in the manufacture of comminuted and whole muscle meat products. These products are frequently cured, and salt (sodium chloride, NaCl) is almost always a critical part of the cure. Other salts approved in the United States are potassium, calcium, and magnesium chlorides, but sodium chloride is by far the most popular in meat products, although there is a push today to reduce the salt (Na) content of meat products.

Salt

The purposes of using salt for curing can be summarized as follows:

Retardation of Bacterial Growth

Retardation of bacterial growth is the result of the cured muscles having a higher concentration of salt than bacterial cells. Most bacterial cell walls are semipermeable and allow water but not salt to pass through the cell walls. As a result of osmotic pressure, water passes this barrier from lower salt concentration (in the bacterial cell) to greater salt concentration (in the muscle tissue). Thus, the bacterial cell dehydrates, shrivels, and dies due to the lack of moisture.

Other reported effects of salt on bacterial growth in muscle tissue include the following:

- Chlorine ion is toxic to bacterial cells.
- Salt reduces oxygen solubility in muscle tissue and, because some microorganisms require oxygen to survive, this creates an environment that retards microbial growth.
- Salt is also an enzyme inhibitor and reduces the effectiveness of some bacterial photolytic enzymes.

Salt is quite toxic to most microorganisms, but molds and yeasts are not affected to the same extent. Upper limits for microbial growth in salt have been reported as:

Clostridium botulinum	10% NaCl
Staphylococcus aureus	15% NaCl
Most other bacteria	8% NaCl
Fermentative yeasts	10% NaCl
Oxidative yeasts up to	25% NaCl
Molds	18% NaCl
	some up to 22% NaCl

The preservative action of salt is considered to relate to the brine concentration (not the percentage of NaCl). This is calculated from eqn [1].

$$\text{Brine concentration} = \frac{\%\text{salt}}{\%\text{moisture} + \%\text{salt}} \times 100 \qquad [1]$$

The influence of brine concentration on microorganisms in muscle tissue is often listed as:

- 4–5% – Brine concentration is sufficient to protect properly treated sausages
- 5–6% – Brine concentration is sufficient to inhibit most bacteria
- 15% – Brine concentration can be tolerated by only a few bacteria

Other conditions in meat can also affect the influence of salt on microorganisms:

- Lower water content (as a result of drying): see brine concentration formula (eqn [1])
- Increased nitrite and nitrate levels (nitrate has less influence)
- Refrigerated storage: synergistic effect
- Lower pH: synergistic effect

Salt was the original food additive and its primary purpose was to preserve meat for future use as food. With refrigeration, it has become less important, but it is still useful as an extra hurdle in refrigerated storage of meat products. It is also essential in the extraction of salt-soluble protein that is essential in emulsion products.

Role of Salt in Emulsion Formation

Salt and water form a solution for extracting myosin from muscle fibers, and this protein solubilization increases emulsion stability, processing stability, water binding, and yield. It also reduces thawing and cooking losses. This is accomplished by the salt, water, and protein solution encapsulating fat in the mixture and forming an emulsion (which appears like a sponge that has absorbed fat). The smaller the fat particles (created by more chopping), the greater the surface area they contain, and this requires more protein coating material. If the fat is well coated and combined with a protein solution of high viscosity, the emulsion will be more stable. Salt contact time and concentration are both important to obtain maximum protein extraction. For example, a dwell time of 2 h results in approximately 60% of the potential protein extraction, 8 h results in 92%, and 24 h results in 97%. This is the purpose of 'preblending' (combining salt with muscle), thus increasing the dwell time and obtaining greater percentage of protein extraction. The advantage of preblending, in addition to the increased protein extraction, is that it allows utilization of some lower binding raw materials and allows time for chemical analysis to be completed. The salt level providing the greatest protein extraction is approximately 6–7%, but this salt level would make the final product too salty. Therefore, higher salt levels are usually used for high-protein tissue and lower levels for lower protein tissue; by mixing high- and low-binding ingredients, one can obtain an

 doi:10.1016/B978-0-12-384731-7.00141-0

appropriate final product salt content. Tumbling or massaging success also depends on salt-soluble extracted protein to hold these very small muscle pieces together to construct a solid appearing tissue.

Reduction of Heat Treatment for Canning

Salt and heat both reduce bacterial load, and the combination (the hurdle effect) of these two treatments allows the same bacterial reduction with reduced levels of either treatment. High canning temperatures reduce meat quality, and an additive (e.g., salt) that allows a reduction in temperature treatment is important. Therefore, most canned meat products contain salt and are also cured.

Flavor

Salt is a pleasant-tasting compound that is necessary in the diet (at $\sim$0.5 g day^{-1}) and is instinctively craved by most animals. Human consumption levels average 5 g day^{-1} with a range of 2–12 g. Perception of salt varies tremendously among individuals, and the salty flavor can be diminished by not chopping the product finely (coarse chop), by diluting the flavor as a result of consuming it with less salty foods, and by adding sugar.

Tenderization

If salt is placed on the surface of meat during aging or cooking, it dehydrates the meat and causes the tissue to toughen; if it is incorporated into the tissue, it increases tenderization dramatically.

Water Binding

Salt increases water binding, which increases yield and reduces thawing and cooking losses. This is accomplished by uncoiling the protein helix and by hydration of the protein, and salt-soluble protein solutions in an emulsion that coat finely formed globules of fat, providing binding that consist of meat, fat, and moisture.

Other Functions of Salt

- Variety: The addition of salt and most other additives offers a variety of meat products.
- Chilling and cooking: Salt is used in chilling water for chilling poultry and sausage products. When salt is mixed with water, it lowers the freezing point of the solution and allows chilling at temperatures below 0 °C. When salt is added to a cooking liquid, it raises the boiling point of the liquid and allows cooking at temperatures above 100 °C, which produces a tenderizing effect on the tissue.

Disadvantages of the Use of Salt

Salt promotes rancidity and thus shortens the shelf life of meat products (particularly frozen products). Salt also synergistically increases the catalytic effects of iron on oxidation. Aluminum clips on sausage casing oxidizes in a salt solution.

The salt level in comminuted products is not restricted by US regulations. Some dried cured pork products that are stored without refrigeration can have salt levels approximately 5.5%. Products that are stored under refrigeration will have lower salt levels. Levels of salt in brine-cured product in the United States average 2–3% (1.7–2% in Europe); bacon levels are 1.25–2%; Wiltshire sides 2.5%; hams 2.2–2.7%; fresh sausages 1.5–2% (2–2.5% when consumed after cooking); bologna or frankfurters 2.2–2.6%; restructured products 0.5–0.75%; and cured poultry products 2.8–3.3%. Brine concentration injected into a product that is going to be refrigerated is normally 5% and into a shelf-stable product is 17%. Salt used in meat products should be of high purity and should dissolve at a moderate rate.

Sweeteners

Sugars (normally sucrose, glucose, corn syrup solids, corn syrup, glucose syrup, malt syrup, and sometimes dextrose) are used in cured meats to protect color and to act as a synergist with antioxidants. Sorbitol can be used in frankfurters and knockwürst to sweeten, to facilitate removal of casings, and to reduce charring. The functions and effects of sugars include the following:

- Flavor: Sugar provides a sweetening and flavor-enhancing property. Approximately 0.5% sucrose (0.6% dextrose) is the taste threshold level. In cured meats, sucrose also reduces the harshness of salt. Sometimes special sugars (e.g., brown or maple) are added for their distinctive flavor properties. Various sugars have different sweetening levels and they are usually expressed as glucose or dextrose equivalents. Sugars with low glucose or dextrose level can be added at a higher level because the product will not taste sweet. Lactose (milk sugar) tends to reduce the harshness of liver in liver sausage.
- Color: Dextrose and corn syrup solids tend to caramelize and turn brown when heated; they char on prolonged heating. Cane and beet sugars are nonbrowning and are often used in fresh sausages and grilled products that are exposed to high heat. Sorbitol also does not brown with heat. Sweeteners are sometimes added to promote reducing conditions and improve cured color, but good cured color can be obtained in a product containing no sugar.
- Peelability: Peelability is improved by sugar because it attracts moisture.
- Retardation of bacterial growth: For sugar to retard bacterial growth, an extremely high level (e.g., 20–80%) is needed, and these levels are rarely found in western meat products. In fact, the level found in meat usually encourages bacterial growth. The level inhibiting growth for most bacteria is 50–60%, for food-poisoning bacteria 60%, for most yeasts 60%, for molds 80%, and for osmophilic yeasts 85%. Dextrose is often added to fermented products as an energy source for growth of desirable bacteria, which encourages acid production.
- Gas fermentation: In perishable canned products, sugars are often added (1% sucrose or 0.5% dextrose) to promote gas formation by anaerobic and aerobic spores, causing

cans to swell and thus giving an indication of improper processing or storage.

The level of sugar in cured products ranges from 0 to ~2% (some oriental products might have more than 20%). Hams usually contain 2% and frankfurters 0.5–1.5%. Dextrose addition ranges from 0.75% to 3.5%, and sugar should be adjusted to a lower level when milk products (lactose) are added and adjusted to a higher level when soy or other nonmeat proteins are added. Neither dextrose nor sucrose is restricted in the United States.

Nitrite or Nitrate

Nitrite is an essential ingredient in cured meat and may be supplied in the form of sodium nitrite ($NaNO_2$) or potassium nitrite (KNO_2) or may be derived by reduction of sodium or potassium nitrate compounds. Nitrate today is normally used only on long-cured products (e.g., dry-cured hams) and can be supplied in the form of sodium nitrate ($NaNO_3$; Chile saltpetre) or potassium nitrate (KNO_3; saltpetre or Bengal saltpetre). Nitrate can supply nitrite when it is reduced by bacterial action, but today it is used much less than in the past when long curing processes were normally employed. In the United States, both nitrite and nitrate must be kept under lock and key (bond room). Both nitrite and nitrate are sensitive to decomposition, and brines should be made with water below 4.5 °C. The major functions of nitrite include the following:

- Cured color development: Nitric oxide, a breakdown product of nitrite, combines with the principal meat pigment (myoglobin) to produce the typical cured meat color with the aid of heat. It is estimated that 20–30 ppm is needed to produce the commercial meat color.
- Safety and quality: Nitrite is bacteriostatic and there is a strong synergistic effect between salt and nitrite; these two preservatives provide an important aspect of protection against botulism. Nitrite also serves as a wholesomeness indicator, because a green color in cured products is almost always an indicator of spoilage.
- Flavor: Nitrite is thought to be responsible for the typical cured meat flavor. It is a powerful antioxidant and retards rancidity in meat products. This aids in the prevention of warmed-over flavor. It is postulated that nitric oxide combines with the iron of myoglobin and removes the iron catalyst from the oxidation cycle.

  If too much nitrite is added, or if it is added in a low-pH environment, a condition of nitrite burn (green discoloration) is evident. High levels of nitrite are toxic; therefore, maximum levels are established by regulations. In the United States, this is 156 ppm in most products, but only 120 ppm in bacon. Some countries impose considerably lower nitrite levels. Nitrite levels decrease drastically on processing, particularly with heat. Nitrous acid (HNO_2; a breakdown product of nitrite) can combine (particularly at high temperature and low pH) with secondary amines (RNH_2; found in muscle tissue and spices) to form nitrosamines ($R_2N–NO$), which have been shown to be carcinogenic if consumed at high levels. To date, nitrosamines have been found only at very low levels in meat products; inspection services continue to monitor this reaction, and processing techniques have been established to reduce even these low levels.

Reducing Compounds

Ascorbic acid and similar compounds (reductants) are used in cured meat and poultry products (not in fresh products) and may be supplied in the following forms.

- Ascorbic acid (vitamin C)
- Erythorbic acid (isoascorbic acid and D-araboascorbic acid)
- Sodium ascorbate
- Sodium erythorbate (sodium isoascorbate), a salt of erythorbate acid, is obtained from sugar; also a color fixative.

These compounds promote reducing conditions and encourage the following effects.

- Faster color development, important if time from chopping to cooking is less than 45 min.
- Resistance to color fading (antioxidative activity) during retail storage.
- Protection against rancidity (water-soluble antioxidant).
- Reduction of residual nitrite level.
- Conversion of nitrite to nitric oxide and of nitric dioxide (produced when nitrite reacts with oxygen) to nitric oxide.
- Reduction of metmyoglobin to myoglobin.
- Reduction of the amount of occluded oxygen.
- Possible aid in bacterial protection and retardation of nitrosamine formation.
- Reduction (ascorbic acid or its salt) of formation of green pigment, which might occur where meat touches metal smoke sticks.

In general, 470 ppm of the acid or 550 ppm of the salt can be utilized. In bacon, 550 ppm of the salt is utilized.

Cure Accelerators

Compounds that lower pH (acidulants) in cured meat alter the flavor, reduce bacterial growth, retard the action of many enzymes, increase the reaction rate of reducing compounds, aid peelability, produce a product with a better sliced shelf life, and accelerate a better meat color development. Compounds sometimes utilized in meat include:

- Citric acid, 547 ppm
- Sodium citrate, 547 ppm
- Glucono delta lactone (GDL; converts to gluconic acid), 0.5% (8 ounces per 100 pounds) in the United States; some countries use higher levels
- Fumaric acid (allows higher cooking temperature), 625 ppm
- Pyrophosphate, 5000 ppm

Sodium (or Potassium) Lactate

Lactate is reported to extend shelf life, enhance flavor, lower water activity, increase water-holding capacity, and have an

antimicrobial effect. It is sometimes used in the United States at up to12.5 g kg^{-1} of product; however, it is often used at lower levels due to its sodium content (1% sodium lactate = 0.6% chloride).

Phosphates

In many countries, phosphates are permitted and used for processed meat products to improve water-holding capacity and juiciness. A variety of sodium and potassium phosphates (tripolyphosphate, hexametaphosphate, and orthophosphate) are permitted at 0.5% in fresh beef, beef for further cooking, and cooked beef in the United States. Properties of basic phosphates include the following:

- Increasing pH of meat, which causes an increase in water-holding capacity and flavor protection. Phosphate and salt have a synergistic effect on water holding.
- Increasing juiciness, reducing refrigerator and thawing losses, decreasing cooking losses and increasing yield, making the product easier to slice, and reducing purge in canned products.
- Increasing emulsion stability by increasing extraction of salt-soluble proteins and reducing fat separation.
- Reducing rancidity and warmed-over flavor by acting as antioxidants due to metal (catalyst) chelating ability.
- Increasing water-holding capacity and reducing shrinkage during cooking by addition of sodium hydroxide (but not often used) with alkaline phosphates (four parts phosphate to one part sodium hydroxide; the combination not to exceed 0.5% of product).
- Reducing meat batter viscosity, which results in more uniform stuffing and reduced temperature rise on chopping.

Acid phosphates (e.g., sodium acid pyrophosphate) lower pH, accelerate color reaction rate, increase color and color retention, and protect from fading; however, the tissue has less water-holding capacity.

Water or Ice

Moisture is sometimes added to meat to distribute curing ingredients. This accelerates curing and helps to extract myosin, which increases binding, emulsion stability, processing stability, water-holding capacity, and yield. It can also be used to lower or to raise the temperature of the product during processing. It increases juiciness and lowers the per-unit-weight cost and is, therefore, controlled by regulation according to labeling utilized in the United States and many other countries. Added water is regulated in the United States via a calculation of the protein content multiplied by 4 – this is considered the natural water content in muscle tissue, and chemically analyzed water in excess of this quantity must be declared as added water. In Europe, the factor (nitrogen factor) is used to calculate added water. Hard water can cause discoloration. Overshowering of cooked products can remove nitrite and salt, which can encourage color fading and bacterial growth.

Binders, Emulsifiers, Extenders, or Fillers

A number of additives are permitted and used as binders, emulsifiers, extenders, or fillers in emulsion products. The labeling requirements vary and such additions are subject to different limits in various countries.

- Cereal and flour products often contain approximately 8% protein and absorb 2–3 times their weight of water. Such additives include: (1) corn and stone-ground flour hard gel; low protein (0.7%); (2) corn gluten (90% protein isolate); (3) dried whey (in some countries a dextrose minimum is required) used as a binder or extender; (4) oats, rolled or steel-cut types (the highest protein cereals); (5) oatmeal (12% protein); (6) rye; (7) rice (soft gel; 6% protein; absorbs 3–4 times its weight of water); (8) sunflower meal, used as a textured vegetable protein; (9) wheat (14% protein; rehydrates at 1.25 parts water to 1 part flour); (10) vital wheat gluten, retains viscoelastic properties; (11) potatoes, provide good binding properties; (12) soya (products with low protein (50%) that often have a bean-like flavor, protein isolate (90% protein) has less flavor problems and hydration rate is usually 2.5 to 1; (13) peanut (28% protein, which can be increased by defattening); (14) cottenseed; (15) tapioca; (16) barley (8% protein); (17) 'rusk' – stale, baked, spongy cracker that is ground (12–15% protein); (18) bread, baked and allowed to become stale; and (18) carrageen (source – seaweed).
- Lecithin and mono- and diglycerides act as emulsifiers and retard separation.
- Milk products give a smoothing effect and sheen to the surface and improve sliceability. Care is needed in their use because of lactose intolerance in some people. Milk products cannot be used in kosher meat products. Typical products used include (1) nonfat dry milk (38% protein; 8% calcium; high in reducing sugars, which may help color retention; good flavor; and light color); (2) sodium caseinate (90% protein or more; bland; light color; does not contain high levels of reducing sugars; some emulsifying capacity; and absorbs 4 times its weight of water); (3) calcium-reduced dried skim milk (calcium replaced by sodium, which increases the water-binding properties); and (4) dried whey (18–75% protein; enhances flavor and browning).
- Gelatin is a thickener obtained from collagen and is used in jelly loaves and canned hams, where it helps to contain purge and improve slicing
- Yeast protein, has a meat-like flavor
- Gums
- Blood (both whole and fractions)
- Single-cell protein (mixed protein extracted from pure or mixed cultures of algae, yeasts, fungi, or bacteria (grown on agricultural wastes))
- Hydrolyzed (source) protein (from plant or animal sources) alters flavor
- Modified (source not required) food starch thickens meat products

When incorporated into meat products, these additives (1) improve economy; (2) bind the product and absorb fat and water; (3) reduce shrink during cooking; (4) alter color

(usually lightening it unless a browning reaction occurs); (5) alter the nutritional value (amount depends on the product used and the quantity); (6) improve slicing and texture in some cases; (7) improve yield; and (8) alter flavor (depending on the additive).

Disadvantages are associated with the use of some additives: (1) soy can bind iron, making it less available; (2) vegetable proteins are often low in B vitamins, some trace minerals, calcium, and methionine; (3) trypsin inhibitors are present in uncooked soybeans; and (4) flatulence is sometimes associated with vegetable proteins.

The following additive quantity limitations are permitted in the United States (some countries permit higher amounts): (1) maximum of 3.5% in some sausages or meatloaves; (2) imitation sausage (US sausages not regulated by 'standard of identity' rules) may exceed 3.5%; (3) maximum 2% isolated soy protein in some sausages or meat loaves; (4) some cured ham items with appropriate labeling can contain 2% modified food starch, 2% sodium caseinate, 2% isolated soy protein, or 1.5% carrageenan.

Breading

Coating of meat with a batter or breading before cooking is becoming more popular.

- Polysaccharides give viscosity control: materials include (1) flours (wheat, corn, and potato) and (2) starches (wheat, corn, and pregelatinized starch to absorb water).
- Proteins used include (1) milk or whey proteins (increase adhesion, fry color, and flavor) and (2) egg white or albumin (provide body, structure, and crispness).
- Egg yolk is used for body, softness, and color.
- Fats or oils are used for tenderness and crispness.
- Leavening agents puff and increase fat absorption, which increases crispness.
- Water is used for suspension of ingredients, adjustment of viscosity, and adhesion.
- Seasonings are incorporated for flavoring.
- Sodium acid pyrophosphate can be included as a reducing compound.

In general, the US regulations allow 30% breading (some countries differ).

Flavoring Agents

Additives also influence flavor, but some are added primarily for the following purposes:

- Hydrolyzed plant protein (HPP) – produced from wheat, corn gluten, yeast, rice, soybean meal, or casein and often has a meat flavor. Usually used at the rate of 125–625 g per 100 kg.
- Monosodium glutamate (MSG) – 'flavor potentiator' or 'flavor body,' which makes taste buds more sensitive. Normal level of use is 60–180 g per 100 kg. Some people are sensitive to MSG.
- Smoke, natural or liquid, generated from wood – used for flavor, color, and increased preservation; forms a skin on the surface and acts as an antioxidant. Liquid has a less rounded flavor because some of the ingredients are not captured in the solvent utilized.

Nucleotides

Disodium guanylate and disodium inosinate are used as flavor potentiators at very low levels (0.01%; 100 ppm).

Spices

A multitude of natural, whole, ground, cracked, and rubbed spices, along with sterilized spices, oleoresins, and some dehydrated vegetables, are allowed in meat products. Spices are added for flavor, color, and texture, and because some of them have antioxidant and antibacterial properties. There is no US limit on quantities except for paprika, turmeric and saffron (coloring materials), and mustard and hydrolyzed protein (protein fillers). Spices are usually added at the rate of 250–500 g per 100 kg of meat.

Problems with spices can include discoloration of fresh products, short shelf life of spices (6–8 months with proper storage), high bacterial loads (mainly spores), and nonstandardization of flavoring potential.

Coloring

Surface coloring might be added to some products by using agents such as alkanet (brownish red), annatto (bixon-yellow to orange-red), carotene (yellow), saffron (orange-brown), chlorophyll (green), turmeric (yellow), coal tar dyes (a variety of colors; in the United States they must be approved by the FDA and are called certified food colors), titanium dioxide (white), and caramelized or extra dark brown sugar or caramel color (brown).

Starter Cultures (Lactic Acid Bacteria) or Added Acids

Low pH is sometimes used to give meat a distinctive 'tangy' flavor and to aid preservation. Lower pH can be obtained by adding live lactic acid bacteria with high salt and nitrite tolerance, which ferment sugars to acids (the preferred method), or by directly adding acids. Starter cultures are often stored in the freeze-dried or frozen state before use. These starter cultures are usually added at approximately 0.5%, and different microorganisms or mixtures of microorganisms have different optimum temperatures for growth. Dextrose is usually also added as a source of sugar. The final pH of fermented dried or semidried sausages is usually 4.6–5.4.

Antioxidants

Tocopherol (vitamin E) is a natural antioxidant. Butylated hydroxyanisole, butylated hydroxytoluene, glycine, nordihydroguaiaretic acid, propyl gallate, and resin guaiac are useful food antioxidants that in small concentrations help to retard

oxidation and rancidity and sometimes help to protect natural ingredients (e.g., vitamin A). Acids are sometimes combined with antioxidants to act as synergists by chelating metals that are catalysts for oxidation.

Enzymes

Plant enzymes, such as pepsin (from the papaya tree; most popular, degrades collagen and elastin), ficin (from figs; helps to degrade collagen and elastin), and bromelain (from pineapples), are sometimes used to tenderize meat tissue. Transglutaminase is an enzyme that is often described as 'meat glue' which is useful in connecting small meat pieces together to make a larger one very similar to the nonenzymatic effect of tumbling. Each of the enzymes has an optimum time/temperature and active concentration and each enzyme affects different structural components of the muscle fibers. Distribution of the enzyme in tissue is sometimes difficult, and a variety of techniques are used to assist in distribution. Overtenderization and mushiness may be encountered.

Preservatives

Salt and nitrite are often used in cured products. Much less used, and only in specific products, are ascorbate, benzoic acid, potassium sorbate, borates, and propylparaben. Additional preservatives are permitted in other countries.

Miscellaneous

Treatment with gases, irradiation, and application of packaging materials and casings are not strictly additives, but they do affect muscle tissue. Some examples are given below:

- Glycerin (humectants) helps to retain water.
- Carbon dioxide (CO_2, dry ice) is used primarily to chill meat ($-78.5\ ^{\circ}C$), but it has also been used to inhibit growth of microorganisms and to reduce fat oxidation. Ozone (O_3), produced by ultraviolet irradiation of oxygen, is an oxidizing agent and is bactericidal to airborne organisms. Unfortunately, it has little effect on organisms on the surface of meat products and accelerates rancidity in fat and formation of brown metmyoglobin on the muscle. It can be dangerous to personnel at high levels.
- Liquid nitrogen (N_2) is used to lower the temperature of, or to freeze, meat ($-195.8\ ^{\circ}C$).
- Vacuum and nitrogen are used in packaging systems to exclude oxygen, to reduce rancidity, and to retard growth of oxygen-requiring organisms.
- Microwave or radiofrequency heating, using waves at a frequency of 200 MHz or greater, used in cooking meat.
- Ionizing radiation from machines or radioactive compounds might be used for both pasteurization and sterilization.
- High hydrostatic pressure (high-pressure pasteurization) is a nonthermal process using water under very high hydrostatic pressure to produce foods that are safer, longer lasting, and have a more original flavor.
- Packaging materials contribute various properties: (1) Oxygen permeability allows oxygen to oxygenate the myoglobin pigment and produce a bright red color in fresh meat; polyvinyl chloride (PVC) is often used. (2) Low oxygen permeability in films used with cured meat excludes oxygen, so nitrosomyoglobin will not be oxidized to metmyoglobin, and it aids in controlling bacterial growth and oxidation. Polyvinylidene chloride (PVdC) is often used. (3) Heat shrinkability is exploited to exclude oxygen from irregular-shaped products, such as poultry.

Comminuted meat products start with the natural intact meat tissue and subdivide into smaller units and combine it with a large number of additives to change its physical and flavor profile, extending its shelf life and restructuring it into a semisolid structure. This changes consumer meat choices from approximately hundreds of choices to many thousands of meat items that have a variety of flavor combinations.

Spices and Flavorings

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

Introduction

Psychological and physiological responses when meat is eaten are from the flavor and aroma that stimulate saliva and gastric juices, which aid in digestion. The total sensation of taste is a combination of gustatory (taste) and olfactory (aroma) stimuli. Animal muscles that have a more intense flavor or game animals that have a more intense flavor are used more than muscles or species that have less intense flavor. An example is the comparison between white meat and dark meat in poultry. Carcass aging not only increases tenderness but also alters (usually improves) flavor. Species differences in flavor are usually attributed to the fat portion of the muscle. Flavor intensity increases with animal age and amount of marbling in the muscle. Cooking methods also alter flavor (e.g., moist vs. dry). Fat loss during cooking reduces not only juiciness and tenderness but also meat flavor. Flavor is also influenced by the animal's diets, with high concentrate diets being preferred (at least by Americans) to grass-fed diets. Some plants consumed by animals can also affect tissue flavor. Mature male (sometimes female) animals, primarily in swine, have an off-flavor referred to as 'boar odor.' Storage of precooked meat causes development of an undesirable flavor, referred to as 'warmed-over flavor.'

In addition to animal muscles' contribution to flavor, spices can drastically alter this flavor and are used in most sausage products. Culture and country of consumers frequently determine the spice quantity and combination preferred, and spices themselves are intertwined with world history. India, the major producer of spices, has a spice history that dates back 7000 years. As far back as 2600 BC, Egyptians added spices obtained from Asia to food for laborers building the great pyramids. Syria used cloves, which came from Indonesia, not long after that. Europe imported spices before Rome was founded, and in AD 40 Rome was obtaining spices from India. In AD 408, the Visigoths demanded a ransom in gold, silver, and pepper to call off the siege of Rome. Before the sixth century, Confucius in China was advocating the use of ginger, which came from the tropics. In the fifteenth century, Venice held a monopoly on the spice trade between the Orient and Europe. To counteract this, Spain and Portugal each financed many exploration parties to find a sea route to the spice world. Vasco da Gama rounded Africa's Cape of Good Hope and in 1489 arrived in Kozhikode, India, the world's greatest pepper-growing region. Spain financed Columbus to sail west, but instead of finding India, he discovered America and also found chilies that he called 'red peppers.' The Spanish also financed Magellan and a crew to circumnavigate the earth, and his crew found the Spice Islands and returned to Europe with a load of spices on board. In 1511, the Portuguese found the Banda Islands (Indonesia), the source of nutmeg and mace and, later, cloves. The Dutch East India Company formed in 1602 dealt primarily in spices and by 1670 was the richest corporation in the world.

In early history, pepper was often used as a portable method of transporting wealth. Currently, it is estimated that 500 000 tons of spices and herbs valued at US$1.5 billion (2008) are imported globally every year, and 46% of this supply comes from India. The leading producers of some of the major spices can be found in Table 1.

Today, spices are used primarily for food, but historical demand suggests that they often had other uses. In Egypt, for example, cassia and cinnamon were used in the embalming process, and anis, marjoram, and cumin were used to clean the innards of the dead. In Rome, many combinations of spices were used in food and beverages and also in medicine. In Asia, spices were used as an antiseptic and for cosmetic purposes. Like jewels they often were presented as gifts of state, collected like precious objects, used in some religious rituals, and used as a means of payment. Incense also became popular and spices were the main ingredients. In Europe, the early demand for spices was primarily for food, particularly when poor harvests and cold winters restricted the food supply. The only way to prevent starvation was to consume poorly preserved food in which spices, particularly pepper, masked the decay, especially in meat.

Characteristics and Components of Spices and Flavoring Agents

Specialized flavor taste buds are located in different regions of the tongue, and the four basic flavors can be sensed in the following areas:

- Sweetness: tip of the tongue
- Saltiness: front side of the tongue
- Sourness: rear side of tongue
- Bitterness: across the rear of the tongue

In addition to the flavor of spices, much of the total spice sensation comes from the aromatic component of the spice, which is detected by smell through the nose and throat. This flavor of spice can be altered by the amount of grinding (which

Table 1 Leading producers of some of the major spices

Spice; part of plant used	*Leading producers*
Allspice; ripe fruit	Jamaica
Bay Leaves; leaves	Turkey
Cardamom; ripe seed	India and Guatemala
Mustard; ripe seed	Northern United States and Canada
Nutmeg; ripe seed	Indonesia and Grenada
Paprika; ripe fruit	Hungary and Spain
Pepper; unripe fruit	India, Indonesia, and Brazil
Turmeric; rhizome	Southeast Asia, India, Peru, Australia, and West Indies
Vanilla; fruit	Madagascar and Uganda

 doi:10.1016/B978-0-12-384731-7.00139-2

Table 2 Spices and flavorings often used with animal products

Spice or flavoring (might be used in several forms)	*Properties when used with meat items or food items, cuisines in which they are incorporated, or origin of spices*	*Meats and products in which spice is sometimes used (others are possible) or purpose of the spice*[a]
Alcohol, cider, rum, and wine	Sharp; acidic; antimicrobial; and flavor	Most products
Allspice	Barbecue sauce; small quantities or extract might be used in ham, bacon, corned beef, and Canadian bacon	Beef, pork, and veal
Anis	Aromatic herb of carrot family	Beef, pork, poultry, and veal
Smoked bacon	Braunschweiger	Pork and pork liver
Basil	Popular cooking herb	Beef and poultry
Bay leaves	Laurel shrub with an aromatic oil	Beef, fish, pork, and veal
Cascarilla, cassia, gentian, orange peel, and quinine	Bitter	Beef, pork, and veal
Capsicum	Herb or shrub of nightshade family; peppers	Beef, pork, poultry, and veal
Caraway	Aniseed; fennel flavor	Beef, pork, poultry, and veal
Cardamom	Curries	Beef, pork, and veal
Cassia	Sweet, acidic, and prune flavor	Beef and pork
Cayenne	A pepper or pimento	Beef, pork, poultry, and veal
Celery seed	Roast, meatloaf, and stew	Beef, fish, and pork
Chilli pepper	Sweet, pungent, and burnt; Tex-Mex, chilli, and curry powder	Beef, cheese, fish, and poultry
Chives	Garden freshness	Beef, cheese, eggs, fish, pork, and veal
Cinnamon	Ham, bacon, corned beef, and Canadian bacon; small quantities or extract may be used	Beef, lamb, pork, poultry, and veal
Cloves	Sweet and aromatic; small quantities or extract may be used in ham, bacon, pork, beef, corned beef, and Canadian bacon	Pork and beef
Coriander	Sweet, aromatic, rose like; used in some frankfurters, smoked sausage, Polish cooking, sausage, dry sausage, and Wisconsin smoked sausage	Beef, pork, and veal
Corn syrup	Browning of bratwurst	Pork, beef, and veal
Cumin	Strong and musty; Tex-Mex and chilli powder	Beef, lamb, and veal
Curacao	Liqueur made from orange; brandy and gin	Beef and pork
Dextrose	Used in smoked sausage for browning	All species
Dill	Northern and Eastern Europe cooking	Beef, fish, pork, and veal
Fennel	Sweet and liquorice like; pepperoni, Italian sausage, and flavored meat items	Beef, pork, and poultry
Garlic	Strong, hearty, odored, and pungent; Polish sausage, summer sausage, beef summer sausage, mild Italian sausage, dry sausage, Italian and Chinese cooking, mild Italian sausage, beef frankfurters, bologna, salami, pepperoni, Tex-Mex, corned beef, small quantities or extract in ham, bacon, corned beef, and Canadian bacon; used to reduce tallow flavor in beef and used in sausage served cold	Pork and pork lever
Ginger	Strong and warm; root used as a condiment, often used with sage to prevent burning and burping	Beef, pork, and veal
Honey	Sweet nectar; flavoring, breakfast sausage, and ham	Pork
Horseradish	Tangy; condiment	Beef
Lactic acid	Produced by starter or natural fermentation; dry sausage, pepperoni, and summer sausage	Beef and pork
Lemon grass or fruit	Southeast Asian cooking	Beef, pork, poultry, and veal
Juniper	Used with venison, pheasant, and rabbit	Beef, game, and pork
Mace	Sweeter than nutmeg, stronger flavor, lighter color, and pungent; frankfurter and bologna	Beef and pork
Maple	Sweet; ham and bacon	Cured product
Marjoram	Polish, Italian, French, and Mexican cooking	Beef, lamb, pork, poultry, and veal
Mint	Many varieties of fragrant plant	Fish and lamb
Monosodium glutamate	Flavor enhancer; Chinese cooking; some are allergic to it	Chicken and pork
Mustard, permitted limit of 1.5%	Bitter, pungent (allyl isothiocyanate), and acrid. If heat treated (150° F) has no flavor but adds protein (28%) when incorporated into meat means that extra water can be added (each 1% added will give 0.75–1 cents saving/pound of product; Practical limit 1.5%). Frankfurter, bologna, salami, summer sausage, and rubs	
Nitrate and nitrite	Curing ingredient, inhibits bacterial growth, and also alters flavor	Nitrite is used in almost all cured products

(*Continued*)

Table 2 Continued

Spice or flavoring (might be used in several forms)	*Properties when used with meat items or food items, cuisines in which they are incorporated, or origin of spices*	*Meats and products in which spice is sometimes used (others are possible) or purpose of the spice*[a]
Nonfat dried milk	Sweet flavor; liverwurst	Liver products
Nutmeg	Sweet and pungent; used in frankfurters, dry sausage, bologna, and other sausages (cotto, cooked salami liverwurst, salami, bratwurst, and dry sausage); lighter flavor and darker color than that of mace	Beef, cheese, pork, and veal
Onion	Used in poultry and frankfurters	Beef, pork, veal, and poultry
Oregano	European and Mexican cooking	Beef, cheese, pork, poultry, and veal
Paprika	Sweet but in meat contributes little flavor; adds color; pepperoni, mild Italian	Beef, fish, lamb, pork, poultry, and veal
Parsley	Popular American herb	Beef, eggs, fish, pork, and veal
Pepper, black	Hot (mouth), spicy, and pungent; used in most sausage (2–8 oz; average 4/100 lbs. meat), smoked sausage, Polish and Italian cooking, fresh pork sausage, salami, cotto, pepperoni, bratwurst, summer sausage, dry sausage, Tex-Mex, and cotto (cooked salami, whole or cracked in salami)	Beef, fish, pork, poultry, and veal
Peppercorns	Salami	Beef
Pepper, red	Hot (throat), biting, and pungent; used at low levels in smoked sausage and Polish cooking, hot link fresh pork sausage, mild link, mild and hot Italian sausage, and pepperoni; often used in crushed form	Beef, pork, and veal
Pepper, white	Less pungent than black pepper and no black specks in light-colored emulsions; musty flavor; liverwurst	Beef, pork, poultry, and veal
Pimiento	A variety of red pepper	Beef, pork, and veal
Rosemary	Minty and sweet	Beef, pork, poultry, and lamb
Saffron	Very expensive	Fish
Sage	Bitter and aromatic; fresh pork sausage; hot, linked, and smoked sausage	Beef, cheese, fish, pork, and veal
Salt	NaCl: flavor and preservative	All cured products
Savory	Combination of mint, thyme, and pepper flavor	Beef and pork
Shallots	Garlic and onion; sweet flavor	Beef, eggs, fish, pork, poultry, and veal
Smoke, liquid, or natural	Used in frankfurters, smoked sausage, Wisconsin hot links, Polish products, and smoked bacon in liverwurst	Beef, pork, poultry, and veal
Soy sauce	Savory and heightens flavor; Eastern cooking	Beef, pork, poultry, and veal
Star anise	Strong liquorice flavor	Poultry
Sugar, corn syrup, dextrose, fructose, glucose, nonfat dry milk	Sweet and burnt; used in smoked sausage and Polish cooking; dextrose used for surface browning; nonfat dry milk used in liverwurst	Any product needing sweetening or a fermented or canned product needing a substrate for microorganisms
Tarragon	Rich robust flavor	Cheese, eggs, fish, and poultry
Thyme	Popular cooking herb	Beef, cheese, fish, lamb, pork, poultry, and veal
Turmeric	Southern Indian curry powders	Beef, fish, pork, lamb, and veal
Vegetables, many used		Used with many products
Vinegar, citric acid, and lactic acid		Beef, pork, poultry, and veal
Wine	Unique flavor of dry sausage	

[a]The same spices are used for wild or game animals as those appropriate for beef, pork, poultry, or veal (Lamb is not mentioned at all!) ('Properties' are not mentioned for all spices. For example, no property is mentioned for celery).

also influences the appearance of a light-colored product) and storage (time, temperature, sealed environment, relative humidity, and light).

By definition, spices (tropical aromatics) and herbs (temperate aromatics) are derived from plants and are used for preservation and during cooking for seasoning of food. They can be made from bark, blossoms, bulbs or tubers, fruits (berries), leaves, roots, seeds, and stems.

Natural spices or herbs are obtained from fruits and seeds and are sometimes processed only by drying and cleaning. They can be left whole or further processed by grinding, chopping, or dicing, in which case they contain a full complement of the spice flavor, color, and appearance. Whole or ground spices are usually added to the product when visual appearance is important. The processed particle size of spices determines the release and distribution of flavor. Whole spices,

however, are not soluble in brine solutions. A spice's flavor, flavor strength, and quality are subject to variation, depending on season, where and how it is grown, handling, transportation, and processing. Spices can also be a source of microorganisms, which can be incorporated into the food along with the spices. Methods of decontamination include radiation techniques, such as gamma, electronic, or UV; heating, microwave processing, or exposure to steam; treatment with ethylene oxide gas; or high-pressure processing. Some spices also have antimicrobial and antioxidant properties and can be incorporated into food to exploit these properties. However, spices alone cannot preserve meat products.

'Essential oils' are volatile, odoriferous components that are present in many plants and are normally obtained by steam distillation. Most components of essential oils are hydrocarbons (terpenes and sequiterpenes), oxygenated compounds (alcohol, esters, aldehydes, and ketones), and nonvolatile residues (waxes and paraffins). They contain only part of the spice profile and are often deficient in bitterness, spice hotness, sweetness, and other flavor components.

'Oleoresins' are prepared from spices or herbs by extraction with organic solvents (that are removed later in processing) and contain both the volatile portion (essential oils) and the nonvolatile extract that includes resins. For this reason, they are considered to contain a more complete flavor profile than essential oils. Both oleoresins and essential oils are microbiologically sterile and can be standardized for strength and flavor profile. Oleoresins can be incorporated with emulsifiers to make them water soluble or can be placed on soluble carriers, such as dextrose, flour, salt, or yeast to produce a dry product and to obtain a better distribution during mixing, thus avoiding 'hot spots.'

'Compounded flavors' are produced when ingredients are combined with amino acids to achieve a desired flavor result. 'Processed flavors' (e.g., Maillard reaction or nonenzymatic browning) are manufactured when meat, vegetable proteins, and reducing sugars (fructose, glucose, maltose, sucrose, or xylose) are combined in specific ratios and then reacted under controlled conditions, such as incorporating a catalyst and controlled pH, temperature, time, and water activity, to achieve the desired flavor product.

Applications of Spices

'Topical rubs' may be used alone or in conjunction with a brine and are employed to add color (paprika, turmeric, and annatto), visual appearance (which can also be developed by browning agents, such as caramel coloring, dextrose, or Maillose®), and flavor to the surface of meat products. They are usually used with other bulking ingredients, including corn syrup and dairy solids. Rubs are usually used at a rate of 2–5% of the meat product weight. Coextrusion has also been used to coat spices onto the surface of shaped meat products. Spices are sometimes adhered to paper, which is then wrapped around the meat tissue; on cooking, the spice is released to coat the external surface of the meat, and the paper is removed before consumption.

A 'brine' or 'marinade' system distributes flavors and functional ingredients into products. Flavoring ingredients must be water soluble (or emulsifiers must be used), must have fine particle size, and must be easily diffusible in the product for proper distribution of flavor and functional properties.

Other products can be added to meat as flavoring and these can be used for characterization purposes (lemon–pepper chicken), for process enhancement or replacement of a processing step (smoking and roasting), or for general flavor enhancement (hydrolyzed vegetable protein, yeast, and meaty flavors). Fermentation (natural or starter culture) drastically alters flavor due to the production of lactic acid and other metabolites of the microorganisms, because different bacteria produce different flavors. Lactic acid is the major chemical that alters flavor, but addition of it alone does not produce the same desirable flavor. A mixture of several microorganisms seems to produce a more desirable flavor than a single-strain starter culture.

Spices that are often added to animal products are identified in Table 2. Because the use of spices with meat is almost an art rather than a science; many thousands of combinations have been used by various processors and chefs to convert meat tissue into a tremendous variety of 'value-added' products. The levels often used for meat products are indicated in Table 3.

Table 3 Spice limits for meats

Spice	*Usage per 45.4 kg (100 lb) of meat product*	
	Minimum	*Maximum*
Salt (% of meat block)	0.45 kg (1%)	1.1 kg (2.5%) In cooked products, for example, bacon and dried products, this level can increase up to ~7%
Chili pepper	226 g (8 oz)	453 g (16 oz)
Coriander	28 g (1 oz)	170 g (6 oz)
Cumin	113 g (4 oz)	226 g (8 oz)
Fennel	84 g (3 oz)	340 g (12 oz)
Garlic	21 g (3/4 oz)	57 g (2 oz)
Ginger	1.8 g (1/16 oz)	14 g (1/2 oz)
Mustard	14 g (1/2 oz)	453 g (1%) heat treated
Nutmeg	7 g (1/4 oz)	57 g (2 oz)
Paprika	226 g (8 oz)	340 g (12 oz)
Pepper, black	57 g (2 oz)	226–453 g (8–16 oz)
Pepper, red	14 g (1/2 oz)	113–170 g (4–6 oz)
Sage	14 g (1/2 oz)	57 g (2 oz)
Sugar	None	0.5 kg (1%) (with 1.1 kg (2.5%) salt), often higher in dried Oriental products
Secondary spices	1.8 g (1/16 oz)	14 g (1/2 oz)

Usage

For spice combinations or recipes used with meat items, a complete list would run into the thousands, but some of the

Table 4 Spices used in some of the most popular items (per 45 kg meat/liver/bread)

Meat and spices used	*Fresh pork sausage*	*Frankfurters*	*Bologna*	*Liver sausage*
Beef		31 kg (70 lb)	36 kg (80 lb)	9 kg (20 lb)
Pork	45 kg (100 lb)	14 kg (30 lb)	9 kg (20 lb)	22 kg (50 lb)
Pork liver				9 kg (20 lb)
Bread or wheat flour				5 kg (10 lb)
Water		7–9 kg (15–20 lb)	9–13 kg (20–30 lb)	
Salt (% of meat block)	1.1 kg (2.5%)	1.1 kg (2.5%)	1.1 kg (2.5%)	1.1 kg (2.5%)
Sugar		226 g (8 oz)		
Nonfat dry milk				1 kg (2 lb)
Sodium nitrite		7 g (0.25 oz)	7 g (0.25 oz)	
Cardamom				28 g (1 oz)
Celery seed				28 g (1 oz)
Coriander		57 g (2 oz)	57 g (2 oz)	14 g (0.5 oz)
Mace		57 g (2 oz)		28 g (1 oz)
Onions				1–2 kg (2–4 lb)
Pepper, black	170 g (6 oz)	170 g (6 oz)	170 g (6 oz)	40 g (1.4 oz)
Sage	57 g (2 oz)

basic combinations can be found on the American Meat Institute web site.

Printed sources are listed under Further Reading.

Some of the combinations of spices used (thousands of variations are used) and a few of the most popular sausage types are listed in **Table 4**.

Labeling (United States)

The ingredient list shall include all meat items and the true names of spices and flavorings as well as other additives, such as monosodium glutamate, hydrolyzed vegetable, salt, sugar, flour, vegetable starch, etc. The ingredients are arranged in order of predominance except that spices might be designated either as spices or flavorings, and flavoring (including essential oils, oleoresins, and other spice extractives) might be designated as flavorings without naming each. Spices can be grouped as flavorings, but flavorings cannot be grouped as spices. Because labeling rules change periodically, a more detailed list can be found at the USDA, FSIS.

CLASSIFICATION OF CARCASSES

Contents

Beef Carcass Classification and Grading

P Allen, Teagasc Food Research Centre, Dublin, Ireland

This article is a revision of the previous edition article by P Allen, volume 1, pp 290–297, © 2004, Elsevier Ltd.

Glossary

Carcass classification The sorting of carcasses into classes according to descriptive criteria.
Carcass grading Assigning values to different classes.
Conformation The shape of a carcass taking account of the contours and the amount of soft tissue development.
Intramuscular fat (IMF) Fat deposits within a muscle.
Rib eye Common term for the longissimus muscle group.
Video image analysis (VIA) The process of taking images and deriving numerical and color data from them to predict features of interest.
Warner Bratzler A device fitted to a material's testing machine to determine the maximum resistance of a meat sample to shearing (hence Warner Bratzler Shear Force (WBSF)).

Purpose of Beef Carcass Classification

The main purposes of beef classification and grading schemes are to reward producers according to the quality of the carcasses they produce and to facilitate trade in carcasses by providing a common and unambiguous language for describing the commercially important attributes of carcasses and meat. Another purpose arises from the need for regulatory authorities to collect price information to enable market transparency and this requires a definition of a standard carcass on which comparisons may be based. Provided the attributes have a real value in trade and the classification is operated with sufficient accuracy for all sectors of the industry to have confidence in it, quality-based payments to producers are then linked to the classes or grades. This then becomes an effective means of giving signals about the type of carcasses desired by the market, and this should really mean eventual consumers. The extra returns that are available to producers who make adjustments to their production systems, for instance by using different breeds or improved lines or by making changes to the feeding system, should have the effect over time of changing the population of slaughter cattle in the direction of improved quality as defined by the market. This is most clearly demonstrated by the continuous reduction in fatness of pork carcasses over several decades in those countries that introduced effective grading schemes. Due to the longer generation time and the less clear signals being sent to producers, the effectiveness of beef carcass classification and grading schemes is less easily demonstrated, but the principle that effective schemes allied to meaningful price differentials will bring about change in the desired direction is nonetheless true.

Beef Carcass Classification in Europe

In 1980, a common system of classifying beef carcasses was agreed upon in the European Union (EU), the so-called EUROP system (Figure 1). The regulations state that beef

	Conformation				
Fat class	E	U	R	O	P
1					
2					
3					
4					
5					

Figure 1 The EU classification grid.

carcasses must be classified according to their conformation and fat cover by trained classifiers. For conformation classes, the letters E U R O P are used with E denoting carcasses with excellent conformation and P denoting poor conformation. There is an option to use an extra S (superior) class for carcasses with extremely good muscle development, such as double-muscled individuals. Fat cover is assessed on a five-point scale using the numbers 1–5, with 1 denoting low fat covering and 5 denoting high. Some countries subdivide each of the categories for conformation and fat into 3 subclasses to give 15 classes for conformation and fat. In other countries, the most common fat class or classes are subdivided into 2 or 3 subclasses. The category of carcass (sex/age) must also be specified in the classification and all carcasses must be dressed according to a detailed specification. Carcasses must be marked with the classification results. The classification results must be made available to producers and there are provisions for appeals by producers. Although the EUROP system does not attempt to estimate saleable yield, there is an underlying relationship between the descriptive scales for conformation and fat cover such that better conformed and leaner carcasses are likely to have a higher yield. Unlike many other classification or grading schemes, the EUROP system does not relate to meat quality.

National legislation governs the operation of the scheme in each member country. These include descriptions for conformation, fat cover and category classes (**Tables 1–3** for examples), and photographic standards. In most member countries classifiers are employees of the abattoir but in others they are employed either by a public authority (e.g., Greece, Ireland, and Portugal) or by a private company (e.g., Austria, Germany, The Netherlands, Great Britain, and Northern Ireland). In all cases the classifiers are highly trained and must be regularly monitored and retrained if necessary. Standards throughout the EU are maintained by an expert panel who visit each country on a regular basis to check that the classification results are in line with the EU standards. The classification scheme is used by the EU for price reporting and market intervention purposes, and by the industry for quality-based payments to producers and for carcass trading.

A significant development in the operation of the EUROP scheme was the decision in principle in May 2000 to allow mechanical grading using Video Image Analysis (VIA). This was followed in June 2003 by agreement on the rules for conducting calibration trials for mechanical systems and criteria for determining their accuracy. A scoring system was devised whereby scores are given for each carcass according to the size of the deviation of the score by the mechanical system from the median score of a panel of at least 5 classifiers, with no more than 2 classifiers coming from the country where the trial is conducted. Carcasses with zero deviation score 10. As the deviations increase, the scores awarded decrease and become negative. The scales are different for conformation and fat, recognizing the greater difficulty of assessing fat cover compared to conformation. The mechanical systems must score more than 600 points for both conformation and fat cover on a representative sample of 1000 carcasses. They also have to pass targets for bias and the slope of the regression line. Ireland was the first country to conduct a validation trial, which resulted in 25 VIA systems (VBS2000, E+V gmbh; Germany) being installed in their main export factories in 2004. Calibration trials followed in some countries and VIA systems have been installed in several countries. Classification information is returned to the supplier by the factory. In Ireland, over 90% of carcasses are classified by machine classification using VIA to carry out various measurements of the carcasses. As the determination of classification in this case is objective, no appeal is possible. In smaller plants,

Table 1 Conformation – Description of carcass profiles, in particular, the essential parts (round, back, and shoulder) in the Irish Statutory Instrument

Class	*Description*	
E – Excellent	All profiles convex to superconvex and exceptional muscle development	Round: very rounded and topside spreads markedly over the symphysis (symphysis pelvis) Back: wide and very thick, up to the shoulder; and rump very rounded
U – Very good	Profiles on the whole straight and very good muscle development	Round: rounded and topside spreads over the symphysis Back: wide and thick up to the shoulder and rump rounded Shoulder: rounded
R – Good	Profiles on the whole straight and good muscle development	Round: well developed and topside and rump are slightly rounded Back: still thick but less wide at the shoulder Shoulder: fairly well developed
O – Fair	Profiles straight to concave and average muscle development	Round: average development to lacking development Back: average thickness to lacking thickness, rump, and straight profile Shoulder: average development to almost flat
P^+ – Poor	Profiles straight to concave and poor muscle development	Round: elongated and poorly developed Back: narrow and thin Shoulder: flat and poorly fleshed spina of the scapula evident
P – Very poor	All profiles very concave and very poor muscle development	The round, back, and shoulder are very poorly developed with the outlines
P^- – Extremely poor	All profiles extremely concave and extremely poor muscle development	Little or no flesh covering on the round, back, and shoulder. All the bones of the skeleton are very apparent

Table 2 Degree of fat cover – Description of fat classes in the Irish Statutory Instrument

Class	*Description of amount of fat on the outside of carcass*	*Description of amount of fat in the thoracic cavity of carcass*
1 – Low	None to low fat cover	No fat
2 – Slight	Slight fat cover and flesh visible almost everywhere	Intercostal muscle clearly visible
3 – Average	Flesh, with the exception of the round and shoulder and almost everywhere covered with fat	Slight deposits of fat but intercostal muscles still visible
4L – Above average	Flesh covered with fat, but still partly visible on the round and shoulder and seams of fat prominent on the round	Distinctive fat deposits and intercostal muscles may be infiltrated with fat
4H – High	Flesh covered with fat, but small areas partly visible on the round, back, and shoulder and seams of fat very prominent on the round	Prominent fat deposits and intercostal muscles may be infiltrated with fat
5 – Very high	Entire carcass covered with fat and the round is almost completely covered with fat, so that the seams of fat are no longer clearly visible	Heavy fat deposits and intercostal muscles infiltrated with fat

Table 3 Categories of carcass in the Irish Statutory Instrument

Category	*Code*	*Description*
Young bull	A	Carcasses of uncastrated young male bovine animals of less than two years of age in which the cartilaginous extremities of the spinous processes of the first nine dorsal vertebrae do not show signs of ossification
Bull	B	Carcasses of other uncastrated male bovine animals
Steer	C	Carcasses of castrated male bovine animals
Cow	D	Carcasses of female bovine animals that have calved
Heifer	E	Carcasses of other female bovine animals

classification is carried out by factory employees who have been licensed by the Department of Agriculture, Food and the Marine. In these cases, the supplier can appeal the decision of the classifier to the slaughter plant.

Grading in the United States

A federal system of beef carcass grading was first introduced in 1927. The industry has changed considerably since then and the scheme has evolved to reflect these changes. The purposes of the scheme are to aid quality-based marketing of cattle and to provide a common language for carcass trading. Grading is voluntary and the service is provided by the US Department of Agriculture (USDA) on a cost-recovery basis.

Beef carcasses are graded according to quality and yield grades. The yield grades estimate the percentage of boneless, closely trimmed retail cuts from the high-value parts of the carcass – the round, loin, rib, and chuck. The grades are numbered 1–5, YG1 having the highest expected yield and YG5 the lowest (Table 4). The grades are calculated from a formula that includes the fat depth over the rib eye; the percentage kidney, pelvic, and heart fat (KPH); carcass weight; and rib eye area. The rib eye fat depth is measured at the 12th rib, three-quarters of the length of the rib eye from the chine bone, but skilled graders make an adjustment of this measurement to reflect unusual amounts of fat in other parts of the carcass. In other words, they assess how representative this fat depth is of total carcass fat. The amount of KPH fat is evaluated subjectively and expressed as a percentage of carcass weight, although one large processing company weighs carcasses before and after KPH fat removal so that actual percentage of KPH is determined. The area of the rib eye muscle is measured using a dot-grid. The US industry developed and the US Department of Agriculture's Agricultural Marketing Service approved the use of VIA for both yield grading and marbling assessment. Most beef processors have implemented this technology because of greater accuracy and uniformity in application of the grading standards. Figure 2 shows that fat thickness is measured at three locations rather than a single measurement.

The yield grades have descriptions in terms of the external and internal fat deposits and a stepwise procedure is used to determine the yield grade. First, the preliminary yield grade is determined from the fat measurement over the rib eye. This

Table 4 USDA yield grades

Yield grade	*% BCTRC*[a]
1	$\geq$52.3
2	52.3–50.0
3	50.0–47.7
4	47.7–45.4
5	$<$45.5

[a]BCTRC = 51.34–5.78 (fat opposite rib eye, in.) – 0.46 (percentage KPH fat) – 0.0093 (carcass weight, pounds) + 0.74 (rib eye area, in.^{2}).
Abbreviation: BCTRC, Boneless, closely trimmed retail cuts.

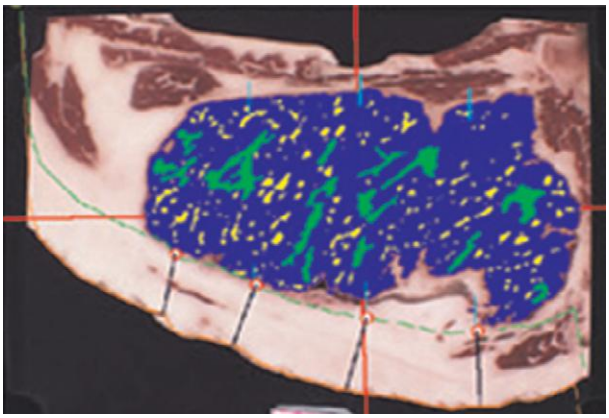

Figure 2 Example of an image captured by a video image analysis instrument used in instrument grading in the US Four fat thickness measurements, longissimus muscle area, and marbling are measured and interpreted by computer software.

Table 5 USDA marbling grades

Quality grade	*Marbling score*
Prime^{+}	Abundant$^{00–100}$
Prime^{0}	Moderately Abundant$^{00–100}$
Prime^{-}	Slightly Abundant$^{00–100}$
Choice^{+}	Moderate$^{00–100}$
Choice^{0}	Modest$^{00–100}$
Choice^{-}	Small$^{00–100}$
Select^{+}	Slight$^{50–100}$
Select^{-}	Slight$^{00–49}$
Standard^{+}	Traces$^{34–100}$
Standard^{0}	Practically Devoid$^{67–100}$ to Traces$^{00–33}$
Standard^{-}	Practically Devoid$^{00–66}$

Table 6 USDA maturity grades

Carcass maturity	*Approximate live age*
A	9–30 months
B	30–42 months
C	42–72 months
D	72–96 months
E	>96 months

is then adjusted for rib eye area relative to the carcass weight, then for the percentage KPH fat. The VIA system also predicts the percentage meat yield in addition to the yield grade, but price adjustments mostly are based on yield grades.

Beef quality grades are designed to sort carcasses according to their expected meat color and palatability, which is a combination of tenderness, juiciness, and flavor. Quality grading is based primarily not only on visual marbling, reflecting the amount of intramuscular fat, but also on maturity. Graders evaluate the amount of marbling fat in the rib eye muscle after carcasses have been ribbed between the 12th and 13th ribs. Quality grades are called Prime (most marbling), Choice, Select, and Standard (least marbling) (Table 5). Each quality grade is divided into one to three marbling score subclasses, for example, Prime is divided into Abundant, Moderately Abundant, and Slightly Abundant. Each degree of marbling is divided into 100 subunits, but in practice marbling scores are generally referred to in tenths within each marbling grade, for example, Slightly Abundant^{90}, Moderately Abundant^{50}, etc. Most large beef processing plants utilize VIA instrument assessment of marbling using hand-held rib eye cameras. Extensive study and testing by the USDA has shown greater precision in VIA assessment of marbling than when graded by trained graders.

Maturity is the second criterion of beef quality grading. Maturity refers to the physiological age of animals rather than the chronological age and is used mainly because the latter is generally not available but also because physiological age can be affected by factors such as nutrition, gender, and biological type of cattle. The indicators of maturity are the bone characteristics (the degree of ossification of the cartilage of the sacral and lumbar vertebrae) and the spinous processes of the thoracic vertebrae (greater ossification relates to older physiological age). Maturity is also based on the color of the rib eye muscle (darkens with age) and texture (becomes more coarse with age). Carcass maturity grades are labeled A–E, A being 9–30 months and E being over 96 months (Table 6). Carcasses are separately assessed for maturity based on ossification (Table 7) and on lean color and texture (Table 8) and, when the two do not agree, a balancing is carried out with more weighting on the bone score.

The final quality grade is determined by combining the marbling and maturity scores according to a detailed plan (Table 9). A stepwise procedure is used to determine the final quality grades of Prime, Choice, Select, Standard, Commercial,

Table 7 USDA skeletal ossification grades

Maturity group					
Vertebrae	*A*	*B*	*C*	*D*	*E*
Sacral	Distinct separation	Completely fused	Completely fused	Completely fused	Completely fused
Lumbar	No ossification	Nearly completely ossified	Completely ossified	Completely ossified	Completely ossified
Thoracic	No ossification	Some ossification	Partly ossified	Considerable ossification (outlines of buttons are still visible)	Extensive ossification (outlines of buttons are barely visible)
Thoracic buttons	0–10%	10–35%	35–70%	70–90%	>90%

Utility, and Cutter. Grades of Commercial, Utility, and Cutter typically are from cows that are more than 42 months of age (C, D, or E maturity).

The USDA recently approved (2013) a system by which processors, retailers, or purveyors can label beef cuts as 'guaranteed tender' or 'guaranteed very tender' based on either Warner–Bratzler or slice shear force. It is anticipated that this system will be utilized in conjunction with grades to assure acceptable eating experiences for consumers a high percentage of the time, or it could diminish the importance of grades.

Grading in Australia

Meat and Livestock Australia (MLA) has conducted extensive literature research and testing in development of the VIAscan objective grading instruments and more recently the Meat Standards Australia (MSA) grading program. The former involves the use of VIA technology to predict the saleable yield of carcasses from measurements taken from a video image captured as carcasses pass the system. The MSA program is a totally different approach and merits further attention here.

The MSA grading aims to ensure the quality of beef rather than the quantity. This is driven by a desire to meet the requirements of consumers for a guaranteed positive eating quality experience every time they buy a certain cut of beef. The approach taken was to analyze the factors along the meat

Figure 3 Stamp that will be placed on meat cuts/packages that meet specifications of MSA 'Optimization' and MSA 'Index' to enhance the value of MSA to the supply chain and to support continual growth and development of the MSA program.

Table 8 USDA lean maturity descriptions

Maturity	*Lean color*	*Lean texture*
A	Light cherry red	Very fine
B	Light cherry red to slightly dark red	Fine
C	Moderately light red to moderately dark red	Moderately fine
D	Moderately dark red to dark red	Slightly coarse
E	Dark red to very dark red	Coarse

Table 10 Classification of yield score

Grade	*Yield estimated percentage*	*Specification*
A	72% and above	Yield of total cuts is above average range
B	69% and above and under 72%	Average
C	Under 69%	Below average range

Table 9 Relationship between marbling, maturity, and carcass quality grade[a]

Degree of marbling	*Maturity*[b] *A*[c]	*B*	*C*	*D*	*E*	*Degree of marbling*
Abundant						Abundant
Moderately Abundant	Prime					Moderately Abundant
Slightly Abundant						Slightly Abundant
Moderate			Commercial			Moderate
Modest	Choice					Modest
Small						Small
Slight	Select			Utility		Slight
Traces					Cutter	Traces
Practically Devoid	Standard					Practically Devoid

[a]Assumes that firmness of lean is comparably developed with the degree of marbling and that the carcass is not a 'dark cutter.'
[b]Maturity increases from left to right (A through E).
[c]The A maturity portion of the figure is the only portion applicable to bullock carcasses.

supply chain that affect eating quality, from conception right through to consumption. MSA call this a PACCP (Palatability Assessed Critical Control Points) approach, adapting the terminology from food safety (HACCP). Considerable research has been carried out to determine the individual and combined effects of these factors on the four main eating quality traits of tenderness, juiciness, flavor, and overall liking as assessed by consumers. Consumers were asked to rate cooked samples for these four attributes on a scale of 0–100. A combined meat quality score (MQS) is then determined using appropriate weightings for each attribute. These scores are then converted to quality ratings using thresholds. The ratings are 2-star (ungraded), 3-star (good everyday quality), 4-star (better than everyday quality), and 5-star (premium quality). Using a large database of samples of known background (production, carcass characteristics, and processing factors) cooked by different methods to strict protocols and tasted by a large number of consumers, a mathematical model was developed to predict the quality grade for each cut, cooked by a number of methods, from the recorded factors. The database is continually added to and revised versions of the model are derived at intervals. Both producers and processors must sign up to the scheme in order for the meat to be MSA graded. Trained graders are based in the factory to record pH, hump height (to estimate percentage of *Bos indicus*), ossification, marbling, fat depth over rib eye, rib eye area, and color of the lean and fat.

The MSA scheme is voluntary and the number of MSA graded carcasses has grown steadily each year since its introduction. It is more than a carcass grading scheme; rather it is more of a quality assurance program. Because it is consumer driven, it indicates the direction that grading schemes must follow in the future if beef is to compete successfully with other meats. MSA is designed to take the guesswork out of buying and cooking Australian red meat. MSA involves all sectors of the supply chain from paddock to plate. A wide range of cattle management practices, processing systems, cuts, aging periods, and cooking methods have been researched to

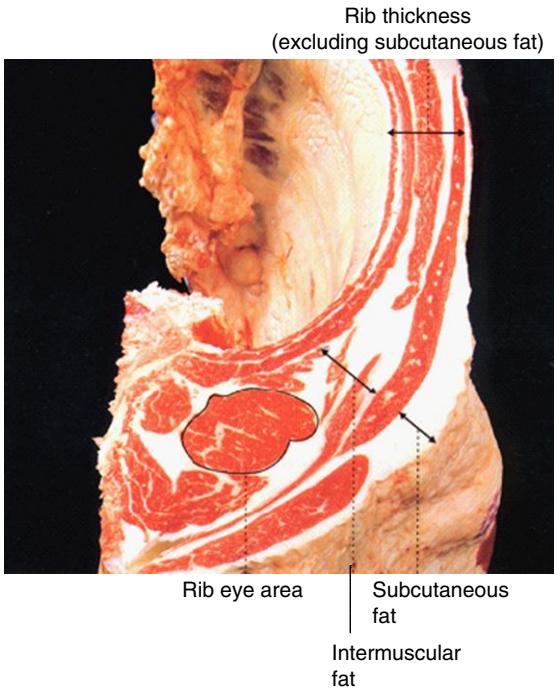

Figure 4 Carcass measurements on the 6th to 7th rib.

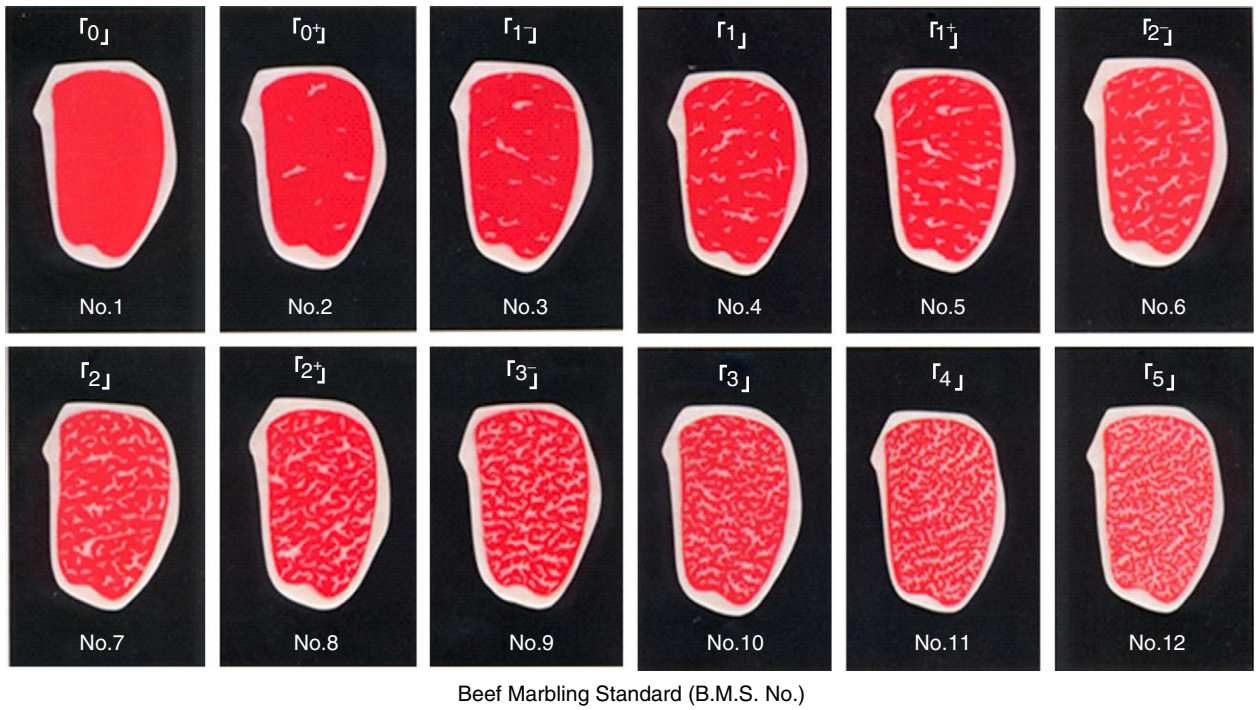

Figure 5 Beef Marbling Standard (B.M.S. No.).

determine the impact each has on eating quality. There were two significant updates occurring to the MSA beef program in 2013 to be rolled out over the next 18 months. These are called (1) MSA optimization and (2) MSA index. Both of these initiatives are aimed at enhancing the value of MSA to the supply chain and support the continual growth and development of the MSA program (Figure 3).

Indeed, other countries have appreciated this and have tested the MSA model. Even though the model is based on Australian beef and Australian consumers, it has proved to be quite robust with trials in several countries (e.g., Ireland, France, and Korea) being favorable.

Grading in Japan

The beef carcass grading system in Japan is implemented according to the guidelines of the 'Beef Carcass Grading Standard' established by the Japan Meat Grading Association. This standard was established in 1988 and consists of the evaluation of 'yield' and 'meat quality.'

Table 11 Classification of beef marbling grade

Grade		*Beef Marbling Standard (B.M.S.) No.*
5	Excellent	No. 8–12
4	Good	No. 5–7
3	Average	No. 3–4
2	Below average	No. 2
1	Poor	No. 1

Table 12 Fat area ratio and crude fat content of beef marbling standard model

Beef Marbling Standard (B.M.S.) No.	*Fat area ratio (X%)*	*Crude fat (Y%)*[a]
12	45.4	33.0
11	41.4	29.8
10	35.1	24.8
9	31.8	22.2
8	25.2	16.9
7	22.5	14.8
6	19.1	12.1
5	14.9	8.8
4	9.6	4.6
3	6.2	1.9
2	2.4	–
1	0.0	–

[a]Crude fat content was calculated by the regression equation ($Y = 0.793X - 3.04$, Kuchida, K., Kono, S., Konishi, K., *et al.*, 2000. Prediction of crude fat content of longissimus muscle of beef using the ratio of fat area calculated from computer image analysis: Comparison of regression equations for prediction using different input devices at different stations. Journal of Animal Science 78 (4), 799–803).

Grading Procedure

Yield score

The yield score is classified into three grades – A, B, and C, determined by the estimated percentage yield (Table 10). This percentage is calculated by a multiple regression equation as follows:

$$\text{Yield estimated percentage } (\%) = 67.37 + (0.130 \times \text{rib eye area } (\text{cm}^2)) + (0.667 \times \text{rib thickness } (\text{cm})) - (0.025 \times \text{cold left side weight } (\text{kg})) - (0.896 \times \text{subcutaneous fat thickness } (\text{cm}))$$

where rib eye area, rib thickness, and subcutaneous fat thickness must be measured on the 6th to 7th rib section of the left side (Figure 4). Note: Add 2.049% for Wagyu (Japanese Black breed) carcasses.

The yield score can be reduced by one rank if the intermuscular fat thickness is rather thick compared to the left side weight and rib eye area, or if the round is too thin and the proportions of the fore and hind quarters appears to be undesirable.

Meat quality score

The MQS is classified into five grades, No. 1–5. The grades are determined in terms of (1) beef marbling, (2) meat color and brightness, (3) firmness and texture of the meat, and (4) color, luster, and quality of the fat. Each item is classified into five grades as follows, and the MQS is graded down to the lowest grade among these items.

(1) Beef marbling
Marbling is evaluated by the Beef Marbling Standard (B.M.S.) prepared as twelve continuous models (No. 1: poor, No. 12: very abundant, Figure 5), and graded according to Table 11. The evaluation sites are the longissimus thoracis, dorsal semispinalis dorsi, and semispinalis capitis muscles on the 6th to 7th rib cross section.

The relationship between B.M.S. number and fat concentration is shown in Table 12.

(2) Color and brightness of meat
The meat color is evaluated by the Beef Color Standard (B.C.S.), represented by seven standards (No. 1: light, No. 7: dark, Figure 6). The brightness of meat is evaluated by visual appraisal. Both factors are considered in the final decision of this item (Table 13). The evaluation sites are the same as for the determination of marbling.

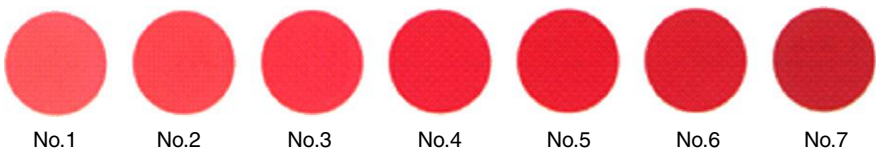

Figure 6 Beef color standard.

(3) Firmness and texture of the meat
The firmness and texture of the meat are evaluated by visual appraisal and both factors are considered in the final decision of this item (Table 14). Evaluation sites are the same as for marbling.

(4) Color, luster, and quality of the fat
The fat color is evaluated by the Beef Fat Standard (B.F.S.), represented by seven standards (No. 1: white, No. 7: yellow, Figure 7). The luster and quality of the fat are evaluated simultaneously by visual appraisal. These three factors are considered in the final decision of this item (Table 15). The evaluation sites are the subcutaneous fat and intermuscular fat on the 6th to 7th rib cross section and the external and internal fat of the carcass.

Stamping of the yield and meat quality score on the carcass

Three grades (A, B, and C) for yield and five grades (No. 1–5) for meat quality make a total of 15 grades, hence the mark of one class from A5 to C1 is stamped on the carcasses.

Damage indication by superscript stamp

A carcass recognized as having any damage is stamped with a superscript mark classified according to the type of damage (Table 16).

Table 13 Classification of color and brightness grade

Grade		Beef Color Standard (B.C.S.) No.	Brightness
5	Very good	No. 3–5	Very good
4	Good	No. 2–6	Good
3	Average	No. 1–6	Average
2	Below average	No. 1–7	Below average
1	Inferior	A grade except grade 2–5	

Table 14 Classification of firmness and texture grade

Grade	Firmness	Texture
5	Very good	Very fine
4	Good	Fine
3	Average	Average
2	Below average	Below average
1	Inferior	Coarse

Cumulated records on graded carcasses

Cumulated records on graded carcasses of 2002 are indicated in Table 17. Grade B was the most common yield grade, while Grade 2 was the most common meat quality grade.

Relationship between carcass price and meat quality grade

Fatty beef, such as 'Kobe beef,' is highly valued in Japan. Thus beef carcass prices are mainly determined by the degree of marbling, although breed also has an effect (Figure 8).

Feeding system for the production of highly marbled beef

Beef marbling is an important factor in determining the palatability of beef. It is affected by several factors, including breed, feed, and finishing period. Vitamin A is also known to

Table 15 Classification of fat color, luster, and quality grade

Grade		Beef Fat Standard (B.F.S.) No.	Luster and quality
5	Excellent	No. 1–4	Excellent
4	Good	No. 1–5	Good
3	Average	No. 1–6	Average
2	Below average	No. 1–7	Below average
1	Inferior	A grade except grade 2–5

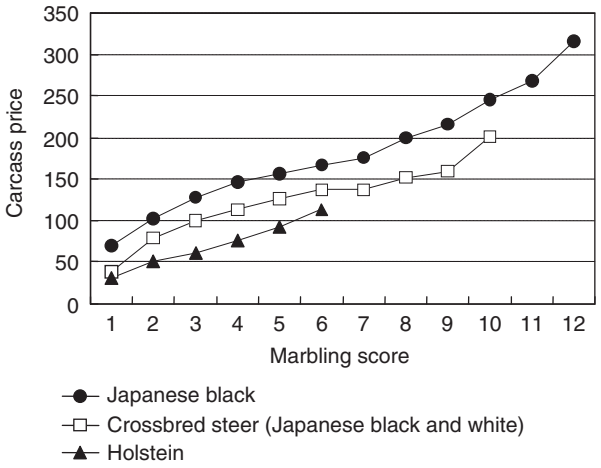

Figure 8 Relationship between marbling score and carcass price in a major meat wholesale market at.

affect marbling as evidenced by reports of retinal suppression of adipogenesis and by a report that a low level of serum Vitamin A results in a high degree of marbling. Vitamin A intake is, therefore, restricted during the late-early to middle-fattening stages, which is about 15–23 months of age in the case of Japanese Black steers.

Pig Carcass Classification

EV Olsen, Danish Technological Institute, Roskilde, Denmark

This article is a revision of the previous edition article by EV Olsen, volume 1, pp 301–306, © 2004, Elsevier Ltd.

Glossary

Accuracy Common term for both repeatability and reproducibility.
Calibration A method to transform online measurements to an estimate value of lean meat content.
Computed tomography Computed tomography (CT) is a method that involves digital image processing. In this context the different signals related to fat, meat, and bone are utilized.
Lean meat content The amount of muscle of a carcass or cut that can be estimated by dissection carried out manually or by CT.
Online instrumentation Instrumentation to measure meat content attributes in real time.
Reference method Method that is used by agreement as defining the attribute such as lean meat.

Introduction

When Britain became an industrialized society and thus obtained a higher standard of living, high-quality bacon and similar products were required. This is indirectly the main reason for the classification system that is prevalent today. The complete system includes several interacting elements. Although the agricultural structure varies from one country to another, the principles are the same and can be described very briefly. Basically, pig producers deliver their pigs to a slaughterhouse producing primary products. The products are sold to customers, including a mixture of processing companies, retail shops, and ultimately to the consumers. Higher standards of living have resulted in a demand for high-quality products, and in this connection quality is identified as leanness. To meet the demand, farmers will require a breeding system, and a payment system reflecting the quality demand will motivate farmers to produce the lean pigs desired by the market. Consequently, the quality – the leanness – needs to be evaluated. Initially, classifiers at slaughterhouses in Europe performed the evaluation visually, but later online instruments were implemented to ensure objective evaluation. The instruments were used to measure the visible backfat thickness, which was initially the primary measure together with a subjective evaluation of the proportion between lean meat and fat in the carcass. However, it was observed that the thicknesses of the loin muscle and the backfat above the muscle were correlated with the lean meat content. The precision was acceptable, and the aim of the measurements was to express the percentage of lean meat rather than a subjective grading result. Consequently, the measurements became indirect measurements, and a calibration of the instruments was needed, together with a reference method.

There was a considerable trade in pigmeat between the European countries. A quotation for pig carcasses on a common basis was therefore established within the European Community (EC) so as to have a comparable basis for the price of a standard quality. The European Commission has specified a common scale, which expresses the leanness by intervals of percentages for the lean meat content, the so-called EUROP Community scale. To ensure that the scale is estimated correctly, common rules are established for calibrating the online measuring equipment. It is also specified that a monitoring system must be in place to ensure that the methods for assessing the lean meat content are applied correctly.

In what is now the European Union (EU), the reference for leanness is expressed by the amount of lean meat in a carcass as estimated by dissection. In other pig-producing countries around the world, the amount of saleable meat is often used as the reference. However, the concept is the same. This article deals only with the EU classification methods.

Reference

Subjective Assessments

The first EU classification scheme was based on the assessments carried out visually by trained staff inspecting the midline of the half-carcass and the complete carcass. The scheme reflected the proportion of lean meat by a subjective assessment of the meat-bearing parts of the carcass and the thickness of the backfat. No information exists about the precision of the method. Although an effective monitoring system might have existed, only the repeatability would have been acceptable. The reproducibility of subjective systems will always cause problems, and this was also the case in the EU system. Consequently, the Commission accepted classification based on measurements with online instruments in 1984 and defined the EUROP Community scale. Instrumental classification became obligatory in 1989.

Reference for Instrument Calibration

A precondition for instrumental classification is a reference, and the first problem is to define the carcass presentation. In the EU, the standard presentation of a carcass is defined as 'the

 doi:10.1016/B978-0-12-384731-7.00062-3

Figure 1 Cutting of the carcass before dissection according to the EU reference method. EC project G6RD-CT-1999-00127 EUPIGCLASS. Photo: Reinhard Höreth, Max Rubner-Institut.

body of a slaughtered pig, bled and eviscerated, whole or divided down the midline, without tongue, bristles, hooves, genital organs, flare fat, kidneys, and diaphragm'. The next step is to estimate the content of lean meat. The first reference method was based on dissection into lean meat, fat, bones, sinews, and hide, and the lean meat was defined as 'all red transverse-striped muscle meat from all parts of the carcass, which can be dissected with a knife'. The method is probably relatively precise, although the reproducibility has never been estimated, but it is also very time-consuming and costly. This was the reason for considering a new reference. In 1996, a new reference method called partial dissection was established based on dissection of four main cuts (shoulder, loin, belly, and hind leg), and the reference lean meat content was defined as the weight of lean meat in the four cuts plus the weight of the tenderloin in relation to the total weight of the half-carcass. In addition, a scale factor of 1.3 was used to obtain approximately the same level as before.

In 2008, the definition was changed again because of the results from a joint European experiment. By changing the divisor in the defining equation to be the weight of only the four cuts and the tenderloin instead of the total carcass weight, the accuracy is improved considerably. It was estimated that a new scale factor of 0.89 would yield the same level as a total dissection. At the same time, both total dissection and partial dissection (new definition) became legal reference methods.

Accuracy of Reference

The accuracy of the EU reference method has been estimated by a European research team. The term 'accuracy' is the common term for both repeatability and reproducibility of the dissection method and refers to the ISO standard. The estimation is complicated because only two replicates are possible – the left and right sides of the carcass. Natural variation and inaccurate carcass splitting result in the two sides not being completely identical, and identical replicates are needed to estimate the accuracy. However, no alternatives exist and the problem has to be dealt with carefully. The experiment consisted of a sample selected in each of four countries. In each country, two slaughterhouses were involved to ensure a representative sample for the country. At each slaughterhouse 16 carcasses were selected in three fat groups and balanced with respect to gender. A team of eight butchers, representing eight EU countries, dissected the carcasses. The butchers worked in pairs (all combinations of pairs) and they dissected the two sides independently of each other, that is, they divided the half carcass into 12 pieces (Figure 1) and dissected the four main cuts only.

The repeatability standard deviation of the 1996 definition was estimated at 0.9 lean% and the standard deviation related to the butchers was estimated at 0.7 lean%, giving an estimate of the reproducibility standard deviation of 1.1 lean%. Although the reproducibility is relatively good compared with the population, which typically varies approximately 3 lean% (standard deviation), the variation between butchers can cause a systematic difference between different calibrations of online instruments of up to 2 or 3 units of lean%. The procedure for dividing the half carcass into 12 pieces seems to be the most sensitive part of the process, whereas the dissection itself was rather uniform. The 2008 definition reduced the reproducibility standard deviation to 0.8 lean% (repeatability standard deviation to 0.5 lean%).

Alternative Reference Method

In 2008, it became possible to replace the assessment of the lean meat percentage by dissection using a method based on computer tomography (CT) (Figure 2). This was possible on the condition that satisfactory comparative dissection results are provided. Two approved methods have been developed in Denmark and Germany, respectively, based on complete CT scanning of carcasses. The two methods are basically different regarding the representation of data from CT scanning. Data representation is by either images (contextual segmentation) or spectra (multivariate methods). Both methods are comparable to manual dissection either because of high correlation except from a scaling factor or because the method

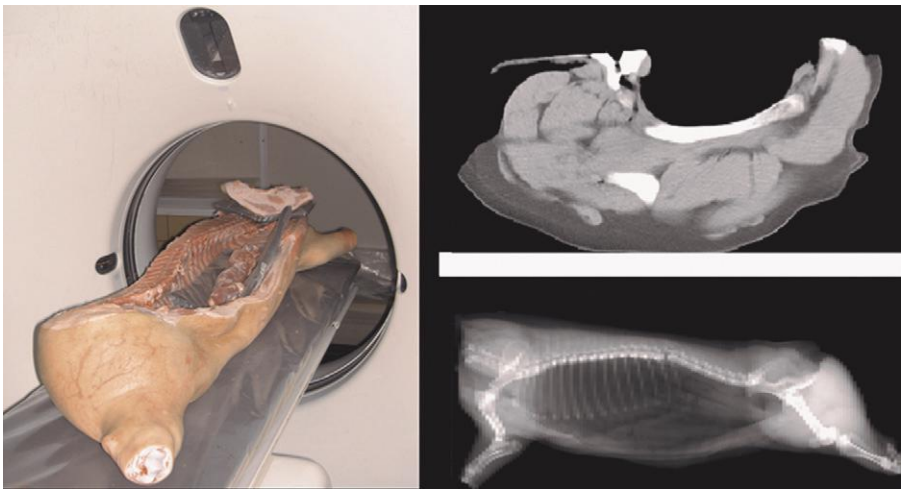

Figure 2 Computed Tomography as reference method. To the right an example of a tomogram and a topogram.

includes multivariate regression using the results from manual dissection as depended variable. Both the methods are valid as references for the lean meat percentage in pig populations similar to the population used to estimate the methods.

Intermediate Methods

Although the partial dissection method is less costly than the total dissection, some users have been looking for cheaper alternative calibration methods. These methods are characterized as cost-effective methods or intermediate methods, and special statistical methods (double regression and similar methods) have been developed to utilize the cheaper methods in an appropriate way.

Online Instruments

These methods can be characterized in various ways: invasive/noninvasive, split-line/back measurement, and manual/automatic measurement. The best method for a specific situation depends on the number of pigs slaughtered per day, the slaughter rate of the killing line, the desired accuracy and possibly the technological strategy at the slaughterhouse.

Noninvasive/Split-Line Methods

The simplest instrument is a measuring ruler, which some slaughterhouses made use of in the 1930s. The method is in use even today, and is generally known as the 'Zwei-Punkt' (ZP) procedure. The main principle of the method is to measure the thickness of fat and muscle, but various procedures exist together with different types of instruments such as callipers both for reading and for electronic data capture (Figure 3). Methods based on vision technology are also available.

Invasive/Back Measurement Methods (Probe Instruments)

The first probe instrument was developed in the 1950s (in Denmark). It was an optical probe, a metal tube mounted in a pistol grip and with a knife at the end. Inside the tube was a system of mirrors and, after inserting the probe into the carcass, it was possible visually to identify the line between fat and muscle and thus the thickness of subcutaneous fat at a specific location. In the next generation of probe instruments, the mirrors were replaced with a measuring technique based on electrical conductivity, utilizing the fact that fat and meat conduct electricity differently. Not only the fat thickness, but also the thickness of the loin muscle, was measured automatically, and it was soon also possible to capture the data electronically. In the third generation (Figure 4), the measuring technique was light reflection utilizing the fact that fat and muscle reflect light, especially light in the near infrared area, differently; this technology is used in all types of probe instruments today.

Figure 3 Example of Zwei-Punkt (ZP) instrument.

Noninvasive/Back Measurement Methods

The latest generation of instruments is based on ultrasound technology. The probe is replaced by a number of transducers and the technique exploits that an ultrasound reflection is

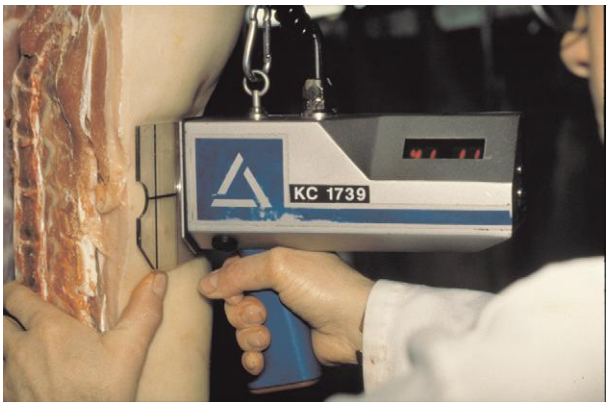

Figure 4 Example of a probe instrument. Photo: Danish Meat Research Institute.

produced each time a transition between two adjacent tissue areas occurs. Unfortunately, this will also happen from two adjacent areas of the same type of tissue, such as the layers of subcutaneous backfat on pigs. Consequently, the signal analysis must include a priori knowledge about the probable fat and meat proportions. The application is limited to slaughterhouses using a weak singeing technique, because strong singeing leaves air bubbles in the skin. The bubbles reflect strongly the ultrasound waves, and consequently no echoes can be detected from fat and muscle.

Manual/Automatic

There exist fully automatic systems based on probes, ultrasound, and vision. Prerequisites for these instruments are fast data processing together with advanced signal interpretation, such as artificial neural networks. The challenge is to establish a system, where data are handled automatically resulting in prediction of the lean meat content with high reliability. Often, a huge amount of data is obtained and only a small part of the data contains the information in question. The rest of the data is used to identify the position and validate the result.

Accuracy

The accuracy of online instruments depends on the prediction ability of the instrument, which is evaluated in the calibration procedure (see next section, Calibration). However, it also depends on the maintenance, the manual handling, and the measuring conditions. The European research team has estimated the accuracy of a variety of online methods. Investigations have been carried out in 12 countries, resulting in estimates of repeatability and reproducibility of ZP, ultrasound, and probe instruments. The reproducibility includes possible variation between different copies of the same type of instruments and differences between operators. It has been concluded that the variation between operators is generally more important than the variation between instruments. However, it is advisable to establish a monitoring system to ensure proper maintenance of the instruments and support and training of the staff.

Calibration

Online measuring methods only create indirect information about the content of lean meat, and it is therefore necessary to calibrate the instruments, i.e., to transform the information from the online measurements to an estimated value of the lean meat content. In the 1970s, research teams in Europe observed that a weighted average of the fat and muscle thicknesses at the middle of the back combined with one or two extra measurements estimated the lean meat content relatively precisely. In principle, the same method is used today, although it has been adapted to the new technologies.

To ensure that the calibration of the various instruments is carried out properly in the EU, the Commission has established certain requirements, and before a new type of instrument can be used in a member state or region, the Commission must approve the calibration. The procedure includes a number of steps:

- preparation of an experimental plan to be presented to the Commission;
- selection of sample of connected online and reference data;
- choosing an appropriate statistical method;
- establishment and assessment of a prediction formula, which must be reported to the Commission.

A team of European statisticians has prepared a handbook as a support for the preparation of new proposals.

Sampling

In general, calibration is based on a sample, but it is not obvious how the sampling should be done. It could be a representative and random sample or a stratified sample, and the reason for choosing a specific method would be to obtain a more robust prediction formula. The handbook mentioned in the Calibration section includes best practice and a number of examples.

Authorization of Prediction Formula

In 2008, the whole set of EU regulations were revised, including the requirements for the prediction ability of online methods. Classification (grading) methods shall be authorized only if the root mean squared error of prediction (RMSEP), computed by a full cross-validation technique or by a test set validation on a representative sample of at least 60 carcasses, is less than 2.5 lean% units. In addition, any outliers shall be included in the calculation of RMSEP.

Summary

In the beginning of the 1980s, the European Commission decided to harmonize the classification (grading) methods in the member states. The aim was to ensure uniform grading of pig carcasses to guarantee producers a fair payment based

on the weight and composition of their pigs and to make the market for the trade in pig carcasses more transparent. The Commission equated lean meat content with value and defined a Community scale, which is used to establish quotations for pig carcasses on a common basis and to make them comparable to the basic price valid for the standard quality.

Researchers in Europe are working with appropriate reference methods with respect to cost and accuracy. New technologies for both online methods and reference methods imply advanced data handling. The range of methods vary from very simple to highly advanced methods and it is a challenge to establish principles for authorization ensuring comparable results all over the EU.

Glossary

Collagen It is the main component of connective tissue. There are many types of collagen, of which the main ones in muscle are type I and type III, which are the focus of this article. In muscle, collagen forms the endomysium, perimysium, and the epimysium.

Collagen content With approximately 25–35% of the whole body protein content, collagen is the most abundant protein in mammals. It generally constitutes 1–2% of muscle tissue but may represent up to 6% of the weight in high tendinous muscles.

Collagen cross-linking The individual protein subunits of collagen are assembled together by covalent intermolecular cross-links, which increase the tensile strength of collagen. The number of cross-links generally increases with the age of the animals.

Collagen solubility While heating, molecular chains of collagen separate and solubilizes to gelatin. The solubilization of collagen decrease when the number of cross-links increase.

Proteoglycans These are heavily glycosolated proteins that are a filler substance between cells that regulate movement of molecules through the matrix and affect activity and stability of proteins and signaling molecules.

Introduction

Connective tissue is produced by fibroblasts and is the most abundant protein in mammals, making up approximately 30% of the total protein content. When mineralized, it is found in skeletal tissues including bone, teeth, and cartilage. The non-mineralized soft connective tissue is found in skin, tendon, ligament, adipose tissue, blood and lymphatic tissue, and the connective fiber framework in muscles. It contains a mixture of polysaccharides and fibrous proteins. The most abundant protein in connective tissue is collagen, but it also contains various other proteins (such as elastin, fibronectin, and laminin) and proteoglycans in varying proportions, depending on the organ. Connective tissue represents a small proportion of skeletal muscle and is mainly found in extracellular matrix of muscle fibers. However, the meat is the result of transformation of the muscle after slaughter of the livestock animal. Connective tissue content and composition significantly affects the quality of meat and meat products, particularly texture and water-holding capacity. For this reason, numerous scientific studies have been led to characterize its structure, organization, and composition in order to understand its role in determining meat quality.

Distribution, Composition, and Structure of Muscle Connective Tissue

Muscle connective tissue content varies from 1.5 to 15% of dry matter depending on muscle and muscle function. Intramuscular connective tissue is principally comprised of collagen and elastin proteins within a proteoglycan matrix. Muscle elastin content is approximately 0.1–0.2% of dry matter, except in semitendinosus and latissimus dorsi muscles, where it reaches approximately 2%. The vast majority of this connective tissue is composed of collagen in amounts ranging from 1.5% to approximately 10% of dry weight. Collagen I and III are the predominant types in muscle, but collagens IV, V, VI, XII, XIV, XV, and XIX are also present in minor quantities (Figure 1).

Collagen is composed of three polypeptide alpha chains with a simple repeating primary structure Gly–X–Y, where X is often proline and Y is often hydroxyproline. The three chains are assembled together to form a triple helix of tropocollagen. The tropocollagen molecules are assembled together to form fibrils that are then assembled to form collagen fibers (Figure 2).

The fibrous collagen is cross-linked by a mechanism based on aldehyde formation from lysine or hydroxylysine side chains. Fibrils and fibers are stabilized by intermolecular lysine-derived cross-links formed between lysine aldehyde or hydroxylysine aldehyde and hydroxylysine to form an aldimine or oxo-imine bond. These bonds are replaced during aging by stable multivalent mature cross-links, which are thought to link microfibrils and increase matrix stability. Thus, higher collagen cross-linking translates into higher mechanical strength.

From a structural standpoint, intramuscular connective tissue is divided into three main structures (see Figure 3).

Epimysium is a layer of dense irregular connective tissue that surrounds whole skeletal muscle. It protects muscles from

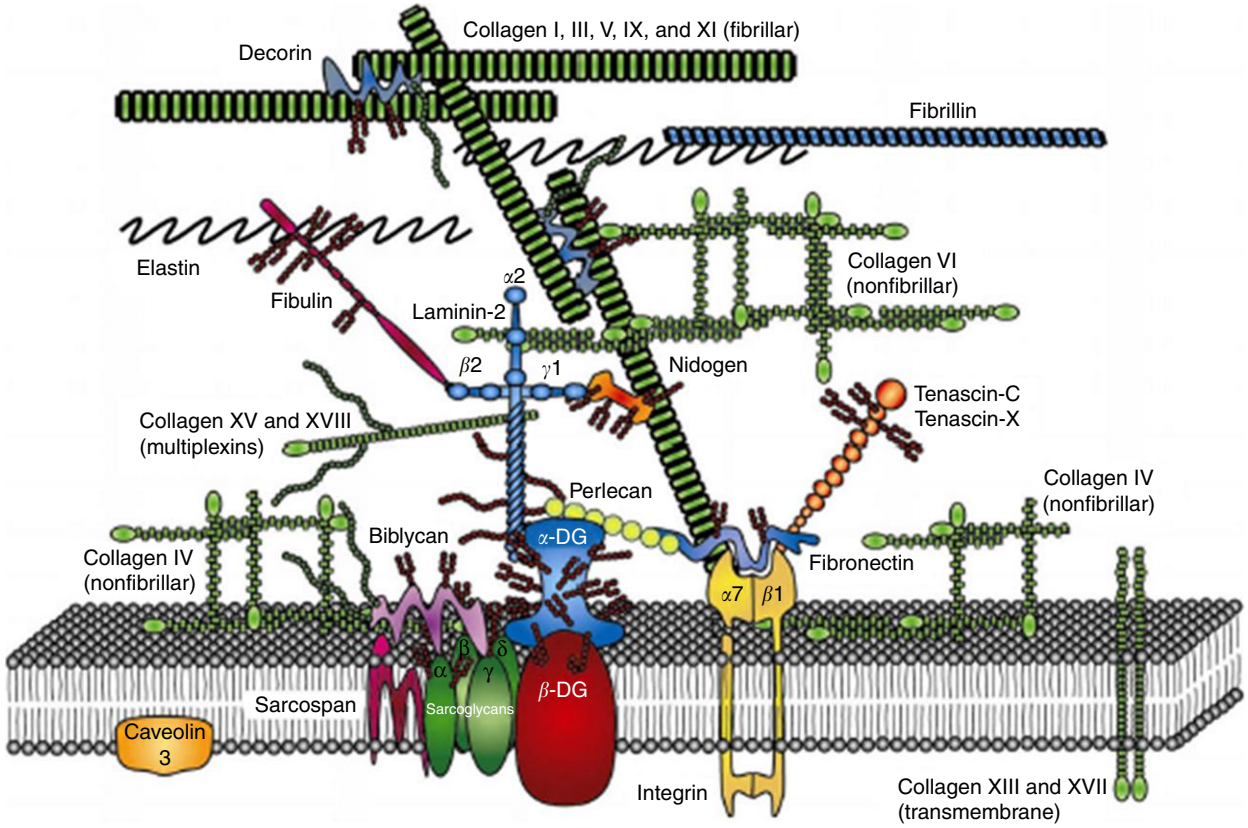

Figure 1 Representation of the muscle fiber extracellular matrix. Reproduced from Voermans, N.C., Bönnemann, C.G., Huijing, P.A., *et al.*, 2010. Clinical and molecular overlap between myopathies and inherited connective tissue diseases. Neuromuscular Disorder 18, 843–856.

friction against other muscles and bones. The epimysium is generally separated from the body of the muscle and need not be considered as a factor in meat texture, except in some meat products such as dry and cooked ham where muscles are intact.

Perimysium is a layer that separates bundles of muscle fibers within the muscle. It represents approximately 90% of total muscle connective tissue, where it is organized as a network of interconnected segments that vary extensively according to muscle type, species, age, and region in the

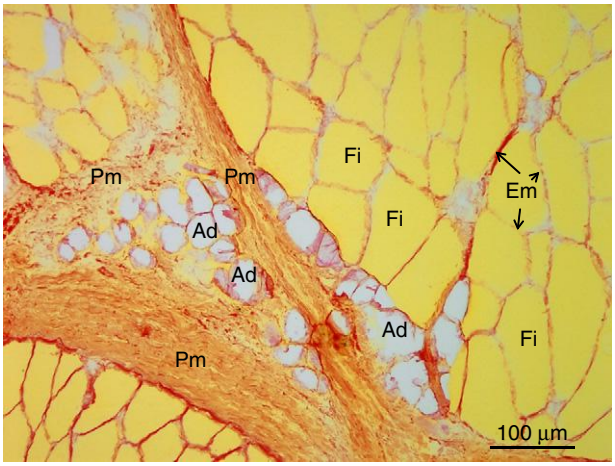

Figure 3 Transversal section of porcine longissimus thoracis muscle. Ad, Adipocyte; Em, endomysium; Fi, muscle fiber; Pm, perimysium.

muscle. The perimysium is usually arranged in large circular or pentagon-shaped fascicles several millimeters in diameter, with the smallest bundles, or primary perimysium, grouped within larger bundles of thicker perimysium, the secondary fascicles, which may be further organized by tertiary fascicles. Perimysium composition is highly variable and can change with nutrition and exercise. Strength muscles tend to have more collagen than postural muscles have, and collagen from old animals has significantly more cross-links than collagen from young ones.

Endomysium surrounds each muscle fiber. It is composed of basal lamina proteins, proteoglycans, and laminin, plus collagens I, III, and IV, and is very similar in all muscle types and even across species.

'*In vivo*' Function of Connective Tissue

Skeletal muscle connective tissue forms a network that plays a dynamic role in muscle differentiation and development. It serves as a supportive structure in skeletal muscle.

Connective tissue adheres to myofibers and fiber bundles, providing a scaffold that maintains muscle structure during contraction, and acts as an interface allowing fiber bundle sliding. Connective tissue provides the cell-to-cell connections both between individual muscle cells and between muscle cells and neighboring small blood vessels and nerves. It gives coherence and mechanical strength, functions as an elastic, stress-tolerant system, and distributes the forces of muscular contractions in both muscle and tendon. The muscle connective tissue participates in cell growth and tissue regeneration after damage.

The organization of muscle into fascicles separated by the perimysium reflects the need to accommodate shape changes as the muscle contracts, which is achieved by allowing fascicles to slide past each other. Functionally, different muscles have very different requirements in terms of accommodating the shear strains that necessarily occur as the muscle contracts and changes shape, which explains why the amounts and distribution of perimysial connective tissue varies so widely between functionally different muscles.

Connective Tissue Properties Related to Meat Texture

The content, nature, and heat solubility of collagen are key factor of meat tenderness.

Technological processes help to reduce the impact of connective tissue on the texture of meat products. Mincing, for example, can decrease the sensation of toughness in meat, whereas cooking, by solubilizing collagen, significantly reduces the mechanical strength of the connective tissue. Acidic marinating can also partially degrade the connective tissue, which may tenderize meat. However, some meats, like roasts and grilled meat, are consumed after maturation and short-term cooking, in which case cooking temperature at core of the meat piece remains too low to solubilize the collagen. As collagen content is relatively unaffected by the action of proteases during maturation, it ultimately defines the basal hardness of raw or undercooked meat. Thus, the less tender muscles, like pectoralis profundus, generally have high collagen concentrations and a high number of cross-links, whereas a tender muscle like Longissimus thoracis has a lower collagen concentration (1.86%) and fewer cross-links. It is assumed that collagen concentration and number of cross-links have a cumulative effect, leading to a negative impact on meat tenderness. Collagen type also plays a role in meat tenderness. Particularly, type-III collagen, which is more susceptible to proteases, is associated with tenderness, whereas type-XII and type-XIV collagen are thought to decrease total collagen solubility and therefore overall meat tenderness.

Method of Measuring Meat Texture

An important consideration when determining the connective tissue properties tied to texture is the texture measurement method used. In evaluating overall texture quality, and especially the contribution made by connective tissue, the best tests include adhesion force between fibers, peak shear force minus initial yield, and compression, which correlates well to sensory chewiness and texture. For example, old animals show increased adhesion force, decreased collagen solubility, and tougher meat. Understanding the mechanical properties of meat requires an assessment of large amounts of information about sample muscle fiber orientation, cooking temperature, fiber size, and the amount of connective tissue. Compression tests at 20–80% of the initial height of the sample with fibers perpendicular and parallel to the test tool can be used to estimate the relative contribution of each myofiber and connective tissue to the texture. These types of tests have shown that amount of connective tissue goes a long way toward explaining the between-breed and between-muscle differences in texture.

Sensory evaluation of the contribution of connective tissue to texture is not only the most sensitive and accurate but also the most laborious method. Results using this method follow the same trend as mechanical measures, indicating that collagen quantity is not a major factor in animals of the same age when comparing the same muscle type. Collagen content does explain some of the differences in sensory texture between different types of beef muscles, with the psoas and longissimus having low collagen content and tender texture, whereas biceps and pectoralis having high collagen content and tough texture. In

general, pork has similar connective tissue properties to beef, with a weak but significant relationship between hydroxyproline content and sensory tenderness, connective tissue, and flavor.

Biological Factors, Connective Tissue, and Meat Tenderness

In general, the content or quality of the connective tissue varies with biological factors.

Species

Structural characteristics are similar from one species to another. Longissimus muscle from young cattle, sheep, and pigs do not differ in collagen content and solubility, indicating that longissimus has similar collagen properties across species.

Breed

Textural differences can be related to connective tissue properties as well as aging potential. For example, *Bos indicus* breeds have a high collagen content, low collagen solubility, and a tough texture. However, a comparison between *B. indicus* and *Bos taurus* crosses did not find significant differences in collagen content or solubility, which may suggest that connective tissue only makes a significant contribution to texture in purebred *B. indicus* lines. Similarly, a comparison of six European and African breeds found little difference in collagen content and solubility. Compared with normal animals, double-muscled cattle have less collagen, higher collagen solubility, and low raw meat texture scores but similar cooked texture scores. *Bos taurus* breeds that mature late have high collagen solubility, and the rheology of the connective tissue is variable in raw samples but not in cooked ones. In conclusion, it seems that no consistent differences amongst breeds for texture-related connective tissue properties are evidenced.

Sex

The sex of animal could have an effect on the connective tissue content and quality. Comparisons on animals at the same age beyond puberty show that meat from uncastrated males is less tender than meat from castrated males, which, in turn, is less tender than meat from females. These variations can be partly explained by differences in collagen solubility. Thus, the lower collagen content in muscle from heifers at 13 and 24 months compared with young bulls is a key determinant of differences in tenderness between the two types of animals. Moreover, the meat of females is softer than that of bulls, as it has a lower collagen content and higher collagen solubility.

Age

Tenderness is highest in meat from very young animals but subsequently declines with age and physical activity, along with an increase in the amount of collagen and its degree of complexity. The increase in toughness is more linked to a reduction in collagen solubility than an increase in collagen content. The water solubility of collagen under the action of heat decreases gradually with increasing age, with the result that the meat progressively becomes less tender. These changes are usually attributed to a gradual increase in the number of stable intermolecular cross-links.

Many studies have shown a progressive age-related decrease in muscle collagen solubility and tenderness, with little or no change in total collagen content. Although most of these studies were done on ruminants, the pattern is a general feature of connective tissue. The change in solubility results in increased meat toughness in old animals and is the major factor shaping the contribution of connective tissue to meat quality. Very young animals have more collagen and elastin than mature animals have, but veal and lamb have a very soluble collagen and consequently a very tender meat. There is no evidence that elastin per se is associated with texture, despite the fact that its content varies.

Several studies on the effect of animal age on connective tissue-related meat texture showed that from 1 to 60 months, the textural properties of meat were significantly related to collagen content and its solubility. In the same studies, comparisons of muscle types showed that all 12 types were acceptably tender in animals of approximately 24 months of age or less. Myofiber toughness did not change markedly after 24 months of age, but the connective tissue toughness increased markedly in 10 of the 12 meat types in animals aged 3 years upward. In addition, an increased cross-sectional area of perimysium is observed with age. Perimysium becomes either thicker or has more branched bundles, provided no change in content occurs. Increasing age also results in firmer fiber adhesion by connective tissue. Furthermore, fiber adhesiveness is lost at 60 °C in meat from young animals but not old animals. This may be the property linking collagen solubility to cooked toughness, as it is also related to sensory chewiness.

Muscle Type and Connective Tissue Organization

Collagen and elastin contents differ severalfold between different muscle types. In general, the force muscles such as the biceps have more collagen than postural muscles such as the psoas have. In addition, perimysium volume and organization vary greatly between muscle types (see Figure 4). In the 1930s and 1940s, structural classification of muscle suggested that muscle type differences in texture were correlated to connective tissue content and organization. Muscle grain and muscle fascicles are known to vary significantly between muscle types. Fascicles vary in size, from approximately 1–10 mm, and shape and are hard to visualize and measure. A larger bundle size of fibers ensheathed in primary perimysium would presumably translate into a firmer meat texture, especially when the perimysium is thick and has extensive collagen cross-links that will not melt at cooking temperatures. Fascicle size is correlated to sensory tenderness and shear force texture. Thickness of the perimysium has been shown to be correlated to shear force in chicken and pork. Thicker perimysium melts more slowly and thicker regions have a different composition such as more type-I collagen, more heat-stable elastin, or more cross-links. However, veal also has thicker perimysium than that from mature animals, but the meat stays tender due to its high collagen solubility and small fiber size, which rules out a

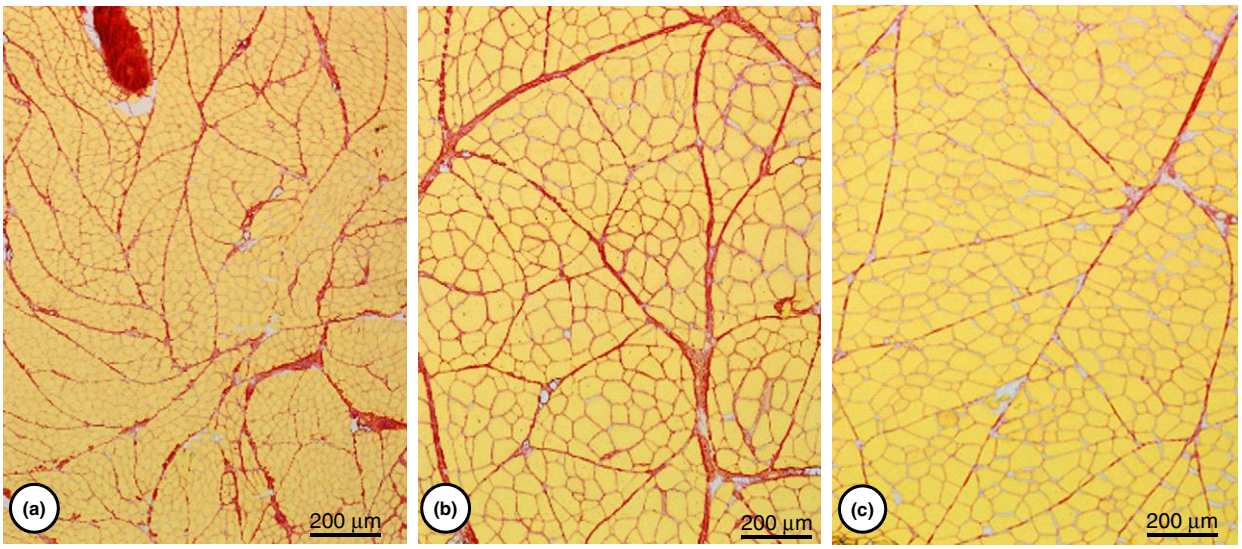

Figure 4 Differences in structural organization of pig muscles. (a) Masseter, (b) semitendinosus, and (c) longissimus thoracis. Connective tissue is stained in red and muscle fibers in yellow. The content and distribution of connective tissue depends on the muscle. Longissimus thoracis, which have less thicker perimysium than semitendinosus and masseter muscles, is more tender. Fiber size is smaller in masseter than in semitendinosus and longissimus thoracis.

systematic direct relationship between perimysium thickness and texture. As stated above, collagen can only influence shear force if it has more cross-links and is in greater quantity.

There have been attempts to link perimysium organization to meat quality, and a relationship has been found. Several research teams have used a qualitative grading system to show that perimysium organization varies with muscle type, species, and age. Semiquantification by image analysis on digital images coming from magnetic resonance imaging and histology techniques show that tough muscles have smaller fiber bundles.

The last property to discuss in this section is myofiber adhesion to perimysium and fiber–fiber adhesions. These are the most fragile structures in cooked meat. The initial fracture plane is usually at the endomysium–perimysium junction. When stress is applied parallel to the fiber plane, the fracture occurs in the endomysium, whereas when stress is applied perpendicular to the fiber plane, the fracture occurs at the perimysium–endomysium junction.

Postmortem Changes in Connective Tissue

There are changes in connective tissue that could play a role in tenderness and thus require further study.

Endomysium

It has been shown that the endomysium starts to detach from fibers as early as 6 h postmortem, and at least half of the endomysium is detached within 24 h.

The detachment of the endomysium may be related to the very rapid drop in shear force observed soon after rigor and may be a general aspect shaping the development of texture. The detachment of endomysium in callipyge sheep, even though the meat is very tough, demonstrates that it is marginally involved in meat texture properties. Nevertheless, endomysium detachment from sarcomeres remains a necessary first step for texture development. However, mechanical measures show that lateral adhesion of fibers by endomysium is stable postmortem and accounts for approximately a tenth of the longitudinal force of fibers. The contribution of endomysium to meat texture is, therefore, stable postmortem and very minor compared with the contribution of myofibers.

Perimysium

Perimysial collagen is degraded during storage. Transmission and scanning electron microscopy studies show that the structural integrity of the intramuscular connective tissue decreases during postmortem aging. The major postmortem change in perimysium is that myofibers separate from perimysium within 6 h. Perimysium seems to be the structure most vulnerable to meat shearing action. It has also been shown that the isometric tension of intramuscular collagen decreases at 21 days postmortem in beef. Furthermore, the breaking strength of the perimysial connective tissue in raw beef decreases during postmortem aging. The thermal shrinkage temperature of bovine intramuscular collagen decreases by 7–8 °C within 7 days postmortem. These structural changes are strongly related to the mechanical strength of meat, as demonstrated by shear measurements on raw muscle or uncooked intramuscular connective tissue structures. Proteoglycan degradation occurs at the same time frame as structural changes in connective tissue (Figure 5), but further studies are required to better understand the role of proteoglycans in texture.

Changes in Connective Tissue with Cooking

Elastin is very heat stable, and its properties are generally unaffected by cooking. However, elastin content in the

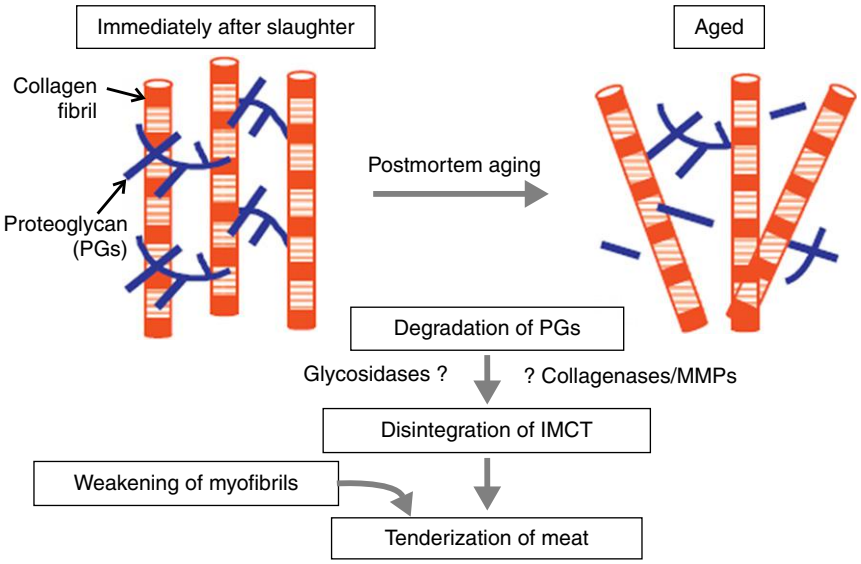

Figure 5 Proteoglycan involvment on intramuscular connective tissue changes during postmortem ageing. IMCT, Intramuscular connective tissue; PGs, Proteoglycans. Reproduced from Nishimura, T., 2010. The role of intramuscular connective tissue in meat texture. Animal Science Journal 81, 21–27, with permission from Japanese Society of Animal Science, John Wiley & Sons Ltd.

perimysium is generally low (0.1–0.2% of the total connective tissue) and its impact on meat texture is, therefore, considered as not significant. However, elastin may contribute to resistance to shear in the semitendinosus muscle, where elastin accounts for up to 40% of total connective tissue.

In contrast, collagens and proteoglycans are unstable to heat, and their properties are affected by cooking. The thermal denaturation of proteoglycans does not play a direct structural role in mechanical terms, but it can play a role in the thermal stability of collagen due to molecular interactions with collagen fibers.

Although, connective tissue makes the largest contribution to texture in raw or undercooked meat, myofibers make the largest contribution to texture in cooked meat. Cooking at temperatures of 60–70 °C causes gelation of most of the perimysium. The temperature for structural changes tends to vary between studies: Some authors report beef perimysium gelation at 70 °C and above, whereas others cite 60–63 °C. Using isolated fibers and small muscle samples it was demonstrated that perimysium changes its thermal mechanical property at 50–60 °C, before the myofibers toughen. These changes are mostly due to collagen melting. The contribution of connective tissue to meat texture declines as temperature increases.

Although thermal stability is well established as the major property determining the role of connective tissue in cooked meat texture, it is less clear how structure and composition variability affect the structural changes involved. Perimysium attributes like thickness are highly variable in cooked meat. Furthermore, elastin distribution as well as collagen type varies greatly within small regions of perimysium. The relationship of connective tissue structure and composition to thermal and mechanical properties of meat requires further study in order to better evaluate the specific influence of collagen type, elastin, or perimysium thickness.

When heated at more than 60–65 °C, the collagen molecule changes from its native helical ordered state to a randomly coiled structure, and fibrous collagen is converted from a fibrillar to a rubber-like amorphous structure. The destruction of hydrogen bonds in the molecule is accompanied by shrinkage of the collagen fibers. If collagen is free to shorten, it shrinks to one-quarter of its original length. The contraction of collagenous networks during cooking is a major mechanism by which collagen influences meat texture. The thermal contraction of collagen fibers and fibrils starts with a free contraction, after which there is a forced contraction where collagen fibers and fibrils apply pressure on muscles fibers and muscle fiber bundles. The more the collagen fiber contracts during heating, the lower its mechanical strength. As the thermal contraction of meat collagen fibers is limited by muscle fibers, the resistance of muscle fibers or muscle fiber bundles influences the ultimate elastic modulus of the collagen fibers. Moreover, the nature of the cross-links determines contraction strength, contraction amplitude, collagen solubilization, and the final mechanical properties of the connective tissue after heating. The thermal stability of collagen is related to the presence of heat-stable mature cross-links, which increase with age and contribute to toughness. At 70 °C, 42% of veal collagen is soluble compared with 2% solubility in beef from 10-year-old animals, and the thermal shrinkage temperature is 55 °C for veal and 70 °C for beef from 10-year-old animals. Collagenase digests 21% of the collagen in veal, whereas the percentage is approximately 10% in 10-year-old animals. These results indicate that the age-related toughness of cooked meat is directly associated with the change in collagen thermal stability.

The role of cross-links in meat quality is less clear in same-age animals. Stable cross-links do vary significantly by muscle type, with sheep longissimus having few and biceps many. But the tenderest muscle, the psoas, has a high number of

cross-links, yet it remains tender even at normal sarcomere lengths. These results suggest that both high collagen content and cross-link formation are needed for connective tissue in order to be able to influence toughness, as is the case in biceps muscle. Between-muscle differences in cross-link quantity have also been reported for beef, sheep, and goat. Several studies have failed to demonstrate a relationship between number of cross-links and collagen solubility. In addition, numerous studies have failed to find a relationship between cross-links and shear force in same-age animals, including two studies that measured five different types of cross-links. Consequently, a relationship can be ruled out between these cross-link types and shear force, especially as meat from callipyge sheep has relatively few cross-links but is still extremely tough. Therefore, it is not yet clear which cross-links are responsible for the age-related change in meat texture.

One hypothesis is that heat stability is the result of collagen interaction with decorin, which is found at every D-line (every 64 nm) along the collagen fibril, is heat stable, and cross-links collagen fibers. There is evidence that decorin is stable post-mortem, and there is little evidence that it has mechanical properties. However, decorin has not been yet sufficiently investigated to determine its importance in connective tissue stability at cooking temperatures, despite the fact that this may prove an important factor.

Conclusion

Skeletal muscle connective tissue is a supportive matrix composed of various fibrous proteins, primarily collagen. Many molecular interactions converge to stiffen the matrix, whose properties vary with the physiological and biological characteristics of source animals. The quantity, quality, and organization of this connective tissue depend on the muscle and its function in the body. Connective tissue changes as the animal matures, and the quantity and degree of cross-linking in muscle connective tissue are generally related to the basic toughness of animal meat. As it is impossible to fully control the characteristics of the muscle tissue, several strategies are employed in order to meet consumer expectations. The first is to sort the muscles according to their position on the carcass and their function, both of which are typically associated with connective tissue characteristics. Strength muscles are generally richer in cross-linked collagen and are oriented toward the production of minced meat or for long-term moist cooking processes to dissolve the collagen and tenderize the meats. Postural muscles are generally less collagen rich, and some are used as meat to grill. Therefore, it is possible to optimize meat tenderness by selecting breeds known for their low connective tissue content or by using young animals with lightly cross-linked collagen. Research to date has provided some insight to help elucidate the role and function of connective tissue in the muscle, to determine its composition and organization from the tissue level down to molecular level, and to assess its contribution to the organoleptic properties of the meat end product. Although the role of connective tissue in the mechanical properties of meat is generally understood, the properties of meat textures are complex and multifactorial, resulting from the behavior of connective tissue, muscle fibers, and interactions between these two muscle components. The future development of innovative technological processes that can degrade or even partially dissolve the connective tissue could improve the price and market value of those meat cuts known for their high mechanical strength.

Finally, food science research to date has mainly focused on connective tissue to understand its role in shaping meat texture, and it is only recently that the focus has shifted to also look at the nutritional qualities of meat. Although connective tissue by itself is not known for its nutritional value, its structural organization at different levels in whole tissue muscles may play a role in the distribution of small molecules of nutritional interest during various processes such as cooking, mincing, and cutting, thus resulting in a loss of micronutrients into exudates and/or cooking juices. The endomysium and perimysium envelopes are also more likely to limit the accessibility of digestive enzymes (pepsin, trypsin, and chymotrypsin) to the high nutritional value myofibrillar proteins. Such transformation processes, especially cooking, dissolve all or part of collagen depending on its degree of cross-linking and on the heating conditions. However, there is still a lack of data on the role played by the overall whole muscle tissue in the transfer of micronutrients and small molecules, and on the bioaccessibility of digestive enzymes in myofibrillar proteins.

CONVERSION OF MUSCLE TO MEAT

Contents

Aging

CE Devine, The New Zealand Institute for Plant and Food Research, Hamilton, New Zealand

This article is a revision of the previous edition article by CE Devine, volume 1, pp 330–338, © 2004, Elsevier Ltd.

Glossary

Calpains Components of the enzyme system that act on cytoskeletal proteins during meat tenderization.
Conditioning One of the terms used as meat enters rigor mortis.
Connective tissue/collagen Noncontractile fibrous proteins (epimysium, endomysium, and perimysium) that surround each muscle fiber – the amount and extent of cross-linking dictate the basal tenderness. Shrinkage occurs as a result of heating (e.g., during cooking) above the collagen shrink temperature.
Cooking Application of heat to meat that denatures the various proteins at different rates depending on the temperature that results in various textures of cooked meat.
Cytoskeletal proteins A set of structural proteins in muscle (includes titin, nebulin, desmin) that are denatured by calpains.
Drip or purge Water that increases over time arising from the cytoskeletal protein denaturation as meat tenderizes – it is different to that from myosin denaturation, which may also occur.
Electrical stimulation Application of an electric current through a carcass or primal cut post mortem that accelerates the rigor process.
Hot boning A process when the meat is removed from the carcass before rigor mortis in contrast to cold boning when meat is removed after rigor mortis.
Myofibrillar proteins The muscle contractile proteins actin and myosin.
Post mortem The period after slaughter when the pH falls until rigor mortis and subsequent aging.
Preslaughter The period before slaughter when factors such as stress can affect meat quality.
Protein denaturation A process whereby proteins lose their tertiary and secondary structure such as by application of acids or heat – water that is part of the tertiary structure may be released.
Rigor Occurs when individual muscle fibres are depleted of ATP; rigor mortis applies when all muscles that enter rigor become stiff.
Shear force The force (N) applied to a standardized piece of meat to shear it.
Shortening A process that occurs when prerigor muscle is cooled below 10 °C – additionally it also occurs as muscles enter rigor at high temperatures (rigor shortening).
Tenderization The enzymatic process that takes place after rigor mortis, which makes meat tender.
Ultimate pH The pH that is reached when muscles reach rigor mortis.

Introduction

Aging is the name given to the process of meat tenderization. The tenderization occurs through the action of endogenous muscle enzymes present in living muscles that are still available in postmortem meat. The extent and rate of aging can be influenced by virtually all aspects of production and processing, thus the term aging by itself needs to be qualified in some way. Aging is affected by the live animal's history before slaughter, including preslaughter stress effects; and it can be influenced to an even greater extent by the muscle's prerigor temperature, muscle shortening, electrical stimulation, and the

temperature and duration of aging ('rigor' is a term applied to the process of individual muscle fibres becoming depleted of adenosine triphosphate (ATP), whereas 'rigor mortis' is a term that refers to the muscle stiffness that occurs after all muscle fibres enter rigor). The rate of aging is different for different muscles of the same animal and for different animal species. The temperature at which meat ages and the packaging required are determined in a practical way by the need to ensure low levels of pathogenic and spoilage bacteria.

Meat, apart from fermented and specialty raw or dried products, is usually cooked before it is eaten with cooking temperatures also having a bearing on the final tenderness but the tenderness changes due to aging are independent of this. This article uses two modes of presenting data from meat cooking. Water bath cooking is an experimental procedure involving cooking meat in a bag in a water bath to a defined temperature, whereas dry heating has a heat source applied to steaks from above or below by a hot plate or hot air – this procedure is closer to what a consumer is used to. Raw meat is relatively tender but toughens slightly on initial cooking. Cooking at temperatures from 55 to 67 °C (various grades of rareness) reduces the red color and the meat then becomes tender (see Figure 1). At higher temperatures, the myofibrillar and connective-tissue proteins denature at different rates, and it is the properties of these denatured proteins that determine the texture of the different cuts of meat as well as changes related to cooking temperature. For example, at temperatures between 40 and 65 °C (various degrees of 'rareness') there is first a decrease in toughness then an increase in toughness caused by increasing aggregation of the denatured myofibrillar proteins, which is accompanied by a loss of fluid and shrinkage of the muscle fibres within the endomysial sheath. Connective-tissue shrinkage occurs at approximately 65–67 °C and is one of the causes of increasing toughness as the collagen in the endomysium and perimysium denatures further and more water is squeezed out. There is a steady rise in toughness up to 80 °C and with further increases in temperature above 80 °C, prolonged heating, as in stewing or casseroling, solubilizes collagen and there is a reduction in shear values. Collagen can be solubilized at lower temperatures, but this requires considerably longer cooking times. At temperatures from 70 °C upwards, the meat shifts from 'medium to well done.' The method of cooking chosen, from grilling to stewing, therefore depends on the type of cut and the connective-tissue content.

The process whereby muscle goes into rigor mortis is termed 'conditioning' by some workers and subsequent holding periods are termed 'aging.' Other workers use the term 'conditioning,' or alternatively 'aging,' for the whole process of going into rigor mortis together with further postmortem holding. Aging is the term used for the postrigor process throughout this article.

It has probably been known for millennia that, following the death of an animal, the muscle enters rigor mortis and becomes firm. Over time, rigor mortis 'resolves' somewhat and the meat becomes less firm and increasingly tender when

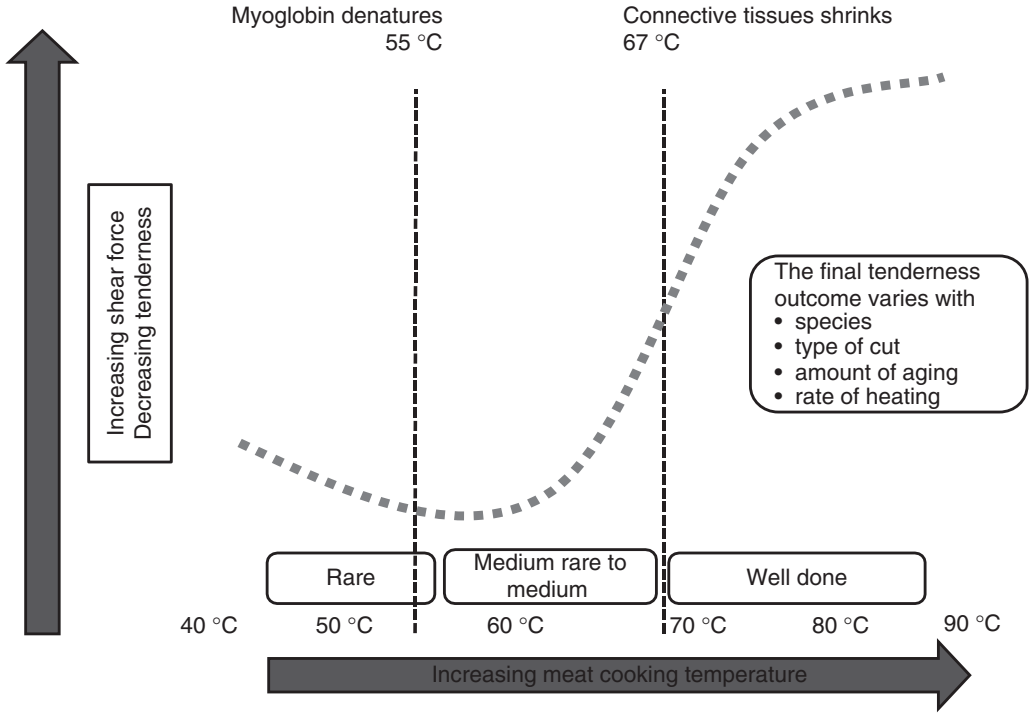

Figure 1 Aging tenderizes meat, but this tenderization is superimposed on other factors that also affect tenderness. This diagram considers the effects of cooking and broadly shows how the changes in shear value (an objective measure) or sensory panel score (a subjective measure) occur with increased heating temperatures (cooking). As the temperature rises, there is a slight increase in tenderness before toughness increases (dashed line). The final outcomes depend on species, type of cut, amount of aging, and rate of heating. Modified from Obuz, E., Dikeman, M.E., Grobbel, J.P., Stephens, J.W., Loughin, T.M., 2004. Beef Longissimus lumborum, and deep pectoralis Warner–Bratzler shear force is affected differently by endpoint temperature, cooking method, and USDA quality grade. Meat Science 68, 243–248.

cooked. It is perhaps because this takes time that the term aging arose. However, the time required depends on the relatively low ambient temperature conditions that are required to ensure that spoilage is not an issue.

Mechanism of Aging

Aging involves the breakdown of the muscle structural proteins (e.g., C-protein, M-protein, and the cytoskeletal proteins titin, nebulin, desmin, dystrophin, and vinculin) by endogenous enzymes termed 'calpains.' Structural proteins are those holding the contractile proteins together. The major contractile proteins, actin and myosin, however, are minimally involved in aging.

Among the potential enzymes involved, the calpains seem to be the best candidates for tenderizing meat (although other enzymes may also be involved). However, although the optimum pH is around neutral, they retain sufficient activity at the low pH of rigor mortis to be effective. Another group of compounds termed 'cathepsins,' which are contained in lysosomes that eventually rupture following rigor mortis, might also be involved. Once released from the lysosomes, cathepsins are optimally active at more acidic pH levels (pH 5.4–5.6) and may be involved in long-term aging.

Calpains, by acting on the structural proteins, can be regarded as the initiators of muscle degradation and remodelling in living animals, which is a normal process. The calpains first act on structural proteins, followed by the ATP-dependent ubiquitin/ proteasome pathway in muscle. The bulk of extracellular and intracellular protein is then degraded through other pathways such as the lysosomal pathway.

Calpains exist in two forms, μ- and m-calpain, which differ in their calcium requirements. μ-Calpain requires 1–30 μmol of calcium and m-calpain requires 100–750 μmol of calcium for half-maximal activity (this latter level of calcium is hardly ever reached throughout the whole cell and suggests that local high concentrations achieved in some way might be just as important). These levels of calcium also do not exist in the sarcoplasm of living cells except during a contraction, and the calpain is presumably not activated in this situation (see the discussion of calpastatin below).

Calpains are also autolyzed (broken down by their own activity), reducing their activity at high prerigor temperatures, especially above 30 °C; this activity is also initiated by calcium, the agent that initiates calpain activity. The activity of calpain in the living muscle is inhibited by 'calpastatin.' It has been suggested that, in meat, high levels of calpastatin inhibit aging, but this appears to be simplistic, especially as calpastatin is always present in excess and is clearly compartmentalized away from calpains in some way.

There is some evidence that the amount of calpastatin determines the speed of tenderization through regulation of calpain activity, and the ratio of calpain to calpastatin could be considered as an indicator of the activity of calpain and possibly of tenderization. However, the relationships may be merely associative, especially when pH effects are taken into account. The inhibition of calpain by calpastatin is pH-dependent, so that the calpastatin activity, measured under optimal conditions (pH 7.5), always exceeds the activity of μ-calpain. Under pH conditions prevailing in postmortem muscle (pH < 5.8), the calpain activity is reduced, but the effective activity of calpastatin is probably reduced much more, which may explain why μ-calpain can be active in postmortem muscle with an ultimate pH (pH_u) of 5.5–5.8. Even so, this does not explain the rapid tenderization of meat of a high pH_u. There is also a time-scale difference between the decline of calpain activity and tenderization. For example, at storage temperatures of 0–2 °C, calpain levels are low by 2 days postmortem and a significant amount of tenderization still occurs after that point.

Although enzyme action is considered to be the main mechanism in meat aging, some factors, such as the increase in ionic strength to twice the postmortem values, might also contribute to aging or at least influence it. Calcium weakening of the myofibrillar structure has been reported to do the same thing, but it has not yet been established as a significant mechanism; however, it could influence destabilization of myofibrillar structure, thus facilitating aging. There does not seem to be any large effect on the connective-tissue proteins over time, so aging is predominantly a myofibrillar activity.

When Does Aging Start?

After rigor mortis, aging mechanisms become fully activated across all fibres, but some aging will have taken place earlier in those fibres that have already reached rigor (i.e., ATP production ceases). Normal calpain-inhibiting mechanisms are in place before rigor in the remaining muscle fibres. Depending on initial glycogen concentrations, individual muscle fibres enter rigor sequentially, so aging commences gradually and some muscle fibres are aging while their neighbors have not yet entered rigor. The interplay of factors such as the rapid pH fall following electrical stimulation and the high temperatures maintained after rigor can dramatically change the commencement, extent, and subsequent speed of aging (aging enzymes appear to be protected from degradation at rigor mortis, so the earlier it occurs the better).

Effects of Temperature on Aging

The major influence on the rate of aging is the temperature of the meat. Whatever is the temperature of the meat, it ages rapidly at the start and then more slowly over time at an exponentially falling rate. This is shown in the exponential decay equation (eqn [1]).

$$F_t = F_\infty + (F_0 - F_\infty)e^{-kt} \quad [1]$$

In eqn [1], F_∞ = final aging shear force, F_0 = initial shear force, F_t = shear force at a given time, and k is the temperature-dependent aging rate constant, which is different for each muscle type. This implies that there is an initial shear value F_0, from which meat starts to tenderize (Figure 2). It is even different from one animal to another and, in the case of cattle and sheep, for a constant temperature, the value of the aging constant k can have a fourfold range. For many reasons, F_0 varies widely, depending on muscle shortening, the amount of connective tissue, the species involved, and procedures

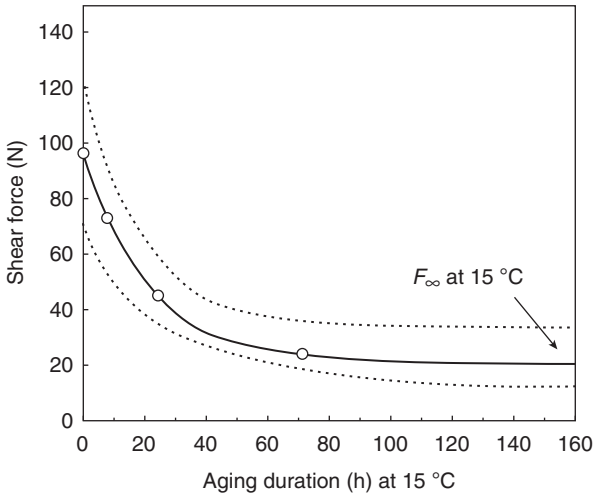

Figure 2 Curves for 64 electrically stimulated lamb m. longissimus thoracis et lumborum that entered full rigor mortis at 18 °C and aged at 15 °C (0 = mean values at each sampling time). The meat was cooked to 75 °C and sheared in a MIRINZ tenderometer. The mean aging curve (solid line) fits an exponential equation. The mean initial shear force value was 97 N, $F_\infty = 22$ N, aging constant k was 0.048. There is still a range of aging rates (also exponential) as shown by the two extremes (- - -) and as seen in **Figure 6** for stimulated and nonstimulated muscles. After 24 h, there is still a 25 N range in shear force. The aging is rapid in this figure because of the high temperature used; and in practice with temperatures of 0–4 °C the rate would be significantly slower (see **Figure 3**).

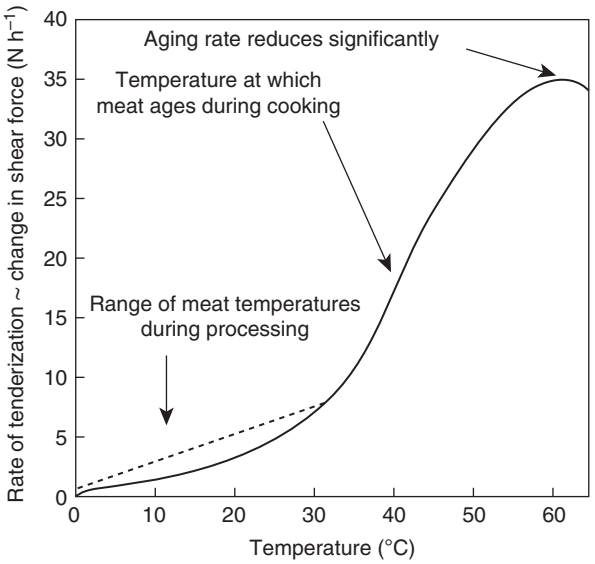

Figure 3 This diagram illustrates how the rate of tenderization of nonstimulated, unaged beef m. sternomandibularis proceeds with aging temperature (it will be different for other muscles, but the trends will be similar). The muscle went into rigor mortis at 15 °C, so that inhibition of aging due to high rigor mortis temperatures did not occur and then the meat was held at the required temperature. Aging rate increases with holding temperature. At 0 °C, the rate of tenderization is relatively slow and long holding periods are required. During carcass cooling, when temperatures initially higher than those finally attained during storage are encountered, or at even higher temperatures during cooking, the degree of aging has an important part to play in the final tenderness. However, at temperatures above approximately 65 °C, aging rate reduces significantly. Modified with permission from Davey, C.L., Gilbert, K.V., 1976. The temperature coefficient of beef aging. Journal of the Sciences of Food and Agriculture 27, 244–250, © John Wiley and Sons Ltd.

utilized, such as electrical stimulation. The final shear force F_∞ is influenced by, among other things, the rigor mortis temperature and pH_u, which are not addressed by the parameters of the equation.

In a typical meat-processing plant, the muscle temperature falls, depending on the chilling regimen, and the rate of aging is gradually reducing throughout processing until a stable storage temperature is reached. Aging continues and, given enough time, finally reaches the value for F_∞. The actual expected tenderness achieved can be modelled using eqn [1] in conjunction with the fall in temperature and taking into account the other prerigor conditions that modify glycolytic rate, including electrical stimulation.

As aging is temperature-dependent and carcasses are in a cooling environment, processes that produce an early rigor mortis while the carcasses are still relatively warm, such as electrical stimulation, ensure early rapid aging and also avoid the effects of cold shortening. However, there are other temperature effects that modify the rate and extent of aging.

At high constant prerigor mortis temperatures of approximately 35 °C, aging is inhibited in nonstimulated meat compared with rigor mortis at 15 °C. This situation does not apply following sufficient electrical stimulation to achieve a significant pH fall (e.g., to pH 6.3 approximately). The inhibiting mechanisms appear to involve inactivation of calpain known to be caused by holding meat at prolonged low pH and high temperatures preceding rigor mortis (see Biochemical factors affecting aging below): however, following rigor mortis they are unaffected.

The aging rate of meat (assuming aging potential has not been reduced by elevated prerigor temperature conditions) increases dramatically as the temperature rises and, for a 10 °C temperature rise, the rate increases 2.4 times. As expected, additional aging takes place during cooking (if F_∞ has not been reached), but ceases dramatically at a temperature of just above 65 °C (**Figure 3**).

In general, meat ages as it moves along the distribution system from harvest to consumer, but the optimal tenderness is not achieved unless aging is long enough in duration or takes place at elevated temperatures. High temperatures facilitate increased bacterial growth as well as resulting in faster meat aging: however, the deleterious effects of bacteria dominate, so low aging temperatures from −1.5 to 5 °C are used together with packaging that reduces the growth rate of pathogenic and spoilage bacteria. In practical terms, surface drying prevents microbial growth on the meat surfaces of whole carcasses, but it is not always practical. Vacuum packaging or modified-atmosphere packaging of cuts can ensure that bacterial growth is low under these circumstances. In certain species, such as deer and other game animals, extreme aging is often regarded as desirable because of the development of flavors that are not related to spoilage.

Variability in Tenderness and Aging

The initial tenderness of meat before significant aging that has taken place varies from one muscle to another, among individuals of the same species, and for different species. The tenderness of unaged meat and the extent of aging that take place on completion also depend on factors such as muscle shortening, which is usually hard to determine routinely. Highly shortened meat does not age and tenderize effectively, so that, in the worst case scenario of severe cold shortening, the meat is tough and appears not to be aged at all. Although tenderization has apparently been reduced depending on degree of shortening, many of the chemical changes associated with aging via the calpain system have still taken place (i.e., proteolysis) but, when cooked, the shortened muscle is tough. Even in cold-shortened meat, some muscle fibres will have entered rigor early and will be protected from cold shortening, so there will still be some small changes in tenderness over time. There are other factors adding to variability such as temperature variation across muscles during processing. As meat ages, tenderness variability across a single muscle reduces.

The sarcomere length of some commercially important muscles increases significantly when the carcass is hung from the pelvis rather than from the Achilles tendon. With pelvic suspension, there are dramatic early changes in tenderness with the increased sarcomere lengths, but the differences often even out over long aging durations, possibly due to connective tissue limitations. Such meat is consumer-ready much earlier than that from normally hung carcasses.

The extreme situation in the other direction is that of hot or warm boning, where prerigor meat is removed from the carcass skeletal attachments, so rigor shortening can occur if the temperature falls below 10 °C prerigor. Rigor shortening is least in the range 10–20 °C; therefore, if temperatures in this range are achieved prerigor mortis, then hot boned meat ages in a similar way to meat left on the carcass under skeletal restraint. Electrical stimulation lowers pH rapidly and significantly changes rigor rate with early commencement of aging, so any negative effects are minimized.

Physical Factors Influencing Aging

Tenderness depends not only on the extent of aging, but also on other compositional (connective tissue) and physical (shortening) factors such as pelvic suspension mentioned above and when muscles are restrained by wrapping. Thus, it is evident that the tenderness of meat or the extent of aging cannot be assessed visually. However, as meat ages, microscopic differences can be observed, such as the disintegration of Z-lines (normally in register in unaged meat) and the appearance of gaps at the A–I junction and between fibres; these changes are consistent with degradation of the structural or cytoskeletal proteins, such as titin, nebulin, desmin, dystrophin, and vinculin (Figure 4).

As mentioned above, proteolysis clearly occurs in both cold-shortened and unshortened meat, but interactions of the muscle proteins of shortened sarcomeres during meat cooking ensures the meat is tough. Whereas pelvic suspension ensures that tenderness commences early in the stretched muscles, the opposing muscles are slightly tougher, but the differences tend to even out over long aging durations.

The connective-tissue content of muscle also affects its tenderness. Connective tissue varies across muscles in a carcass and is hydrolyzed in certain cooking procedures, such as roasting and stewing. Thus, the connective tissue of various muscles of a carcass (type of cut) affects the end use of the various muscles or muscle groups. It appears that the changes in connective tissue during aging are small, and certainly not large enough to shift a given cut from a low-value to a high-value cut. However, connective-tissue changes may be significant for long aging durations.

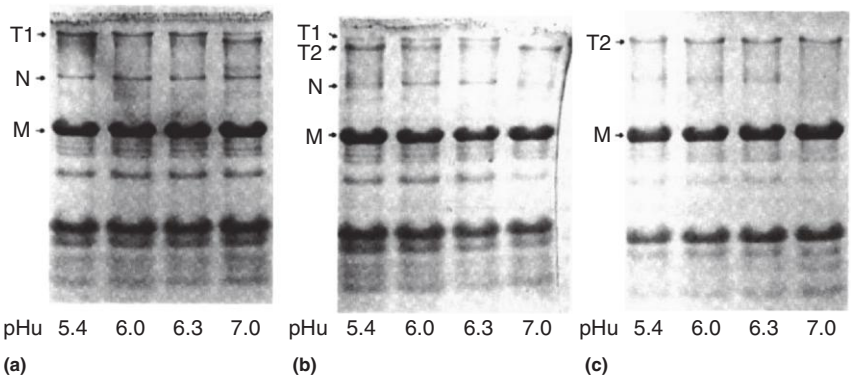

Figure 4 Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS–PAGE) of muscle sample of sheep m. longissimus thoracis et lumborum at different ultimate pH (pH_u), obtained after storage at 10 °C for 12 h (a), 24 h (b), and 48 h (c) after slaughter, shows the disappearance of the structural or cytoskeletal proteins titin (T) and nebulin (N) rather than the contractile proteins (Actin not indicated). Myosin (M) is unchanged. The titin band splits at high pH_u values, indicating more rapid aging. At 24 h, titin 2 has disappeared at pH 7 and the remaining titin bands are split. At 48 h, no titin 1 remains. The nebulin band takes longer to disappear at pH_u values of 6.0 and 6.3. The nebulin band disappears completely in (c). Reproduced from Watanabe, A., Devine, C.E., 1996. The effect of meat ultimate pH on rate of titin and nebulin degradation. Meat Science 43, 407–413.

Biochemical Factors Influencing Aging

There is some inhibition of aging following high prerigor mortis temperatures, and this appears to be greatest at 35 °C and least at 15 °C; it appears to be inactivation of the aging enzymes. This is shown in Figure 5, where it is also suggested that calpain levels change little in the early stages of pH fall during progression into rigor mortis and that it is only in the later stages of rigor mortis that a combination of elevated temperatures and low pH, acting in concert, reduce calpain activity. With electrical stimulation, these effects appear to be negligible commercially, although experimentally the greatest tenderness of meat is still achieved with careful temperature control when rigor mortis occurs close to 15 °C.

The degradation of the cytoskeletal proteins by calpain has consequences other than tenderization. As the meat ages, free water (e.g., released during centrifugation in experimental situations) increases exponentially from 6% to 16% throughout the aging period, whereas bound water, dry matter, and shear force decrease exponentially. Such observations were shown to be independent of prerigor holding temperatures from 4 to 35 °C. The water released over time by centrifugation studies can be correlated with studies where normal drip loss or purge increases over time as beef ages in a vacuum package and where drip loss increases exponentially in case-ready pork over a 7-day storage period at 6 °C. There are various water compartments in meat and such water loss from cytoskeletal proteins during aging should not be confused with the water produced from myosin denaturation in PSE pork that is related to prerigor temperatures and can mask that arising from aging. The degradation of the cytoskeletal proteins (and indeed denatured myosin) is also associated with a decrease in water binding. It has been suggested that the changes in water binding to the cytoskeletal proteins are responsible for the change in near-infrared (NIR) spectra related to tenderness. NIR is being developed as a nondestructive method to measure meat tenderness and other meat quality attributes online. A corollary is that as meat ages (tenderizes) there is an increase in drip. When aging is rapid, such as after electrical stimulation and the higher temperatures, drip increases more rapidly but there is no more drip for the equivalent tenderness achieved.

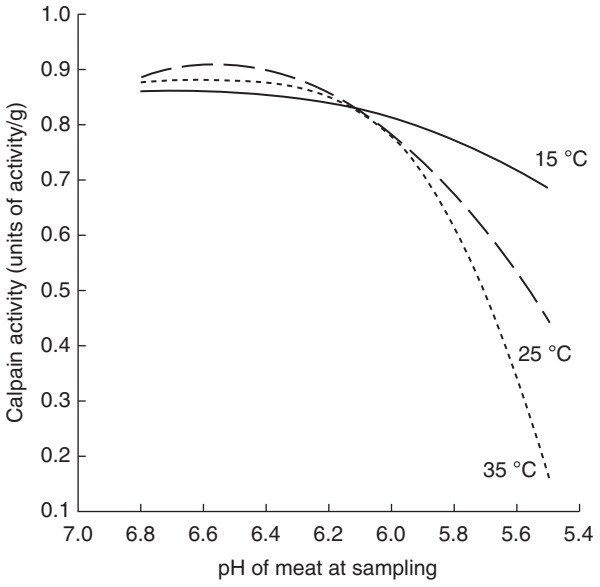

Figure 5 The changes in activity of calpain (the enzyme that appears to be responsible for meat aging) are related to the temperature of the meat while it is entering rigor mortis. In meat from unstimulated cattle held in different temperature conditions postslaughter, the μ-calpain postmortem activity begins to fall with the high-temperature and low-pH conditions of the meat before rigor mortis, the optimum temperature being 15 °C. This figure shows that, below pH 6.2 prerigor, high processing temperature conditions can reduce the enzymes available for aging, presumably owing to increased autolysis of the calpains, and hence will limit the rate of aging and final tenderness achieved. Modified from Simmons, N.J., Singh, K., Dobbie, P., Devine, C.E., 1996. The effect of prerigor holding temperature on calpain and calpastatin activity and meat tenderness. Proceedings of the 42nd International Congress of Meat Science and Technology, pp. 414–415. Lillehammer: International Congress of Meat Science and Technology (ICoMST).

Other Factors Influencing Aging

The rate of aging depends on the temperature postrigor; the extent of aging depends on preslaughter conditions (pH_u) and the immediate post rigor conditions. These all interact to affect meat tenderness at any given sampling time. It is clear that meat from different species have different degrees of tenderness and age in different ways. There are also various perceptions that stress, breed, sex, growth paths, different types of feeding, and the amount of marbling also affect tenderness and aging. There is no doubt that, with increasing amounts of fat (higher marbling score), there is less meat per bite, the meat has a lower shear force, and the consumer appreciation is greater because the meat slides down the throat more easily, but in the normal range of intramuscular fat there is likely to be little difference. Aging rate does not change merely because of fat.

When animals have been subjected to the same treatment, the measured initial tenderness, rate of aging, and final tenderness are hardly ever the same (see range in Figures 6 and 7). Although the sex of the animal does not directly affect aging rate, other characteristics, such as elevated pH_u (Figure 6), which might occur in bulls more often than in steers, will affect aging rate.

The aging constant is not the same for all animals in any experiment, suggesting that there are still other factors influencing aging rate. It has also been suggested that animals with higher protein turnover, i.e., faster-growing animals, are more tender and age to a higher degree of tenderness. It has been difficult to establish the veracity of these suggestions because many other factors such as animals being of different weights at the same age, may contribute by modifying chilling rates. Other factors could relate to preharvest effects, including level of nutrition and low levels of stress that are not enough to measurably influence pH_u.

Inclusion of β-agonists in a diet increases shear force, and certain genetic muscle developments, such as the callipyge condition in sheep, also distinctly reduce the rate and

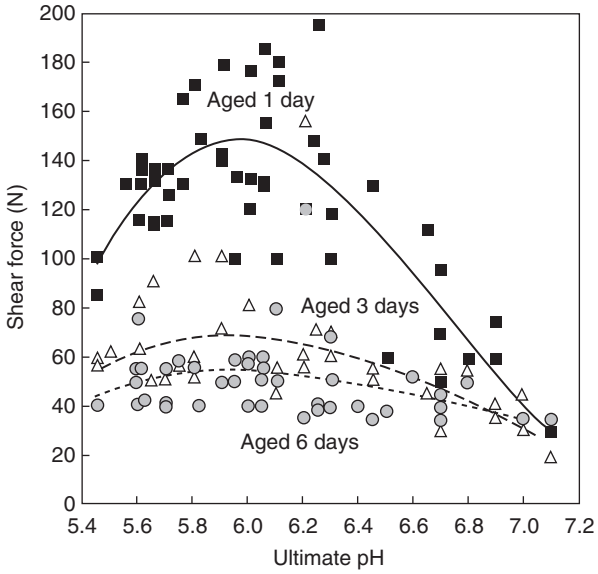

Figure 6 There are changes in rate of tenderization of meat resulting from preslaughter stress and this figure shows how wide the range of shear force values can be. Preslaughter stress results in glycogen depletion that raises ultimate pH (pH_u). The shear force values (from nonstimulated sheep m. longissimus thoracis et lumborum) are related to the pH_u values. After 1 day of aging, both high and low pH_u values result in tender meat, but meat with a moderate pH_u is tougher. However, after 6 days of aging at 10 °C, all meat eventually becomes tender. The higher shear force of the intermediate pH_u meat is a result of slower aging rather than other factors. In the pH range 5.5–5.9, a small increase in pH results in large increases in toughness. Modified from Watanabe, A., Daly, C.C., Devine, C.E., 1995. The effects of ultimate pH of meat on the tenderness changes during aging. Meat Science 42, 67–78.

extent of aging. However, a situation with excessive muscle development, termed 'double muscling' in cattle, seems to have the opposite effect in the Piedmontese breed and the meat is tender. *Bos indicus* cattle have higher levels of calpastatin than most *Bos Taurus* breeds, which results in less tender meat (but this effect is reduced with electricalstimulation). Addition of vitamin D to the diet, which raises the calcium levels that modify calpain activity, is also reported to accelerate aging, but there is no difference in tenderness at 14–21 days.

Hot Boning

Rapid chilling during prerigor-boning processing exacerbates shortening, and cold shortening in particular needs to be prevented to avoid toughness. This is not an issue if the meat is to be used for manufacturing. Without electrical stimulation, chilling cannot be too rapid and prerigor temperatures need to be close to 15 °C to minimize rigor shortening and maximize tenderness. Wrapping the meat tightly, or surrounding the meat in an elastic packaging material to limit expansion during contraction, also prevents shortening. Electrical stimulation ensures rapid rigor entry and the toughness due to enzyme inhibition at elevated temperatures is minimal.

Electrical Stimulation

If electrically stimulated and nonstimulated muscles enter rigor mortis at the same temperature and are aged at the same temperature, taking into account the fact that aging commences at rigor mortis (predictably reached at different times), the stimulated meat ages at a higher rate and is more tender (Figure 7). In commercial procedures, where stimulated muscles enter rigor mortis rapidly and immediately commence to age, the increases in tenderness are even more dramatic. It had been hypothesized that following electrical stimulation, when rigor mortis takes place at relatively high temperatures, there would be increased drip and a reduction of tenderization. Such high temperatures where they occur appear to be so transitory that they are of little concern and, in addition, once the meat is in rigor mortis, enzymes responsible for aging appear to be protected. Not only is stimulated meat more tender than nonstimulated meat, but several studies have shown that tropical breeds that are normally less tender than British and continental breeds also respond favorably to stimulation.

Following electrical stimulation, changes in the ultrastructure of the muscle shown in electron micrographs suggest that contracture nodes are formed, accompanied by fibre disruption that may facilitate the degradation of the myofibrillar structure during aging. This may be more important in red muscle fibres, where the disruption is greatest.

Different Species and Breeds

The mechanism of aging is likely to be the same for all species, but there are differences because of different glycolytic rates preceding aging and the differences in the rate of aging itself, even at the same temperature. The rate of aging in various meats decreases in the order

poultry→pork→lamb→beef

In the case of pork, there are possible differences in aging as a consequence of prerigor myosin denaturation.

In the case of poultry, the aging-rate constant (k) is approximately 0.2 at 4 °C and such a value is not reached even at 35 °C in the case of sheep and cattle. In poultry, cold shortening is not an issue, occurring around 2 °C, so poultry can be cooled in iced-water slushes but are not exposed long enough to fall below 2 °C. Even at these temperatures, optimum tenderness through aging occurs in 6–8 h (for chickens) and 12–24 h for turkeys and they can be frozen at this time. Rigor mortis at temperatures above 20 °C is even more detrimental to tenderness in poultry than in the case of other meats.

Factors That Reduce Aging

The aging of meat can be prevented by injection of zinc salts and certain enzymes that inhibit calpains. The final shear-force values obtained in such cases represent those of unaged meat.

Meat of an intermediate pH_u (pH 5.8–6.1) has been shown to be tougher than meat with a higher or lower pH_u (Preslaughter handling) so the relationship between shear force

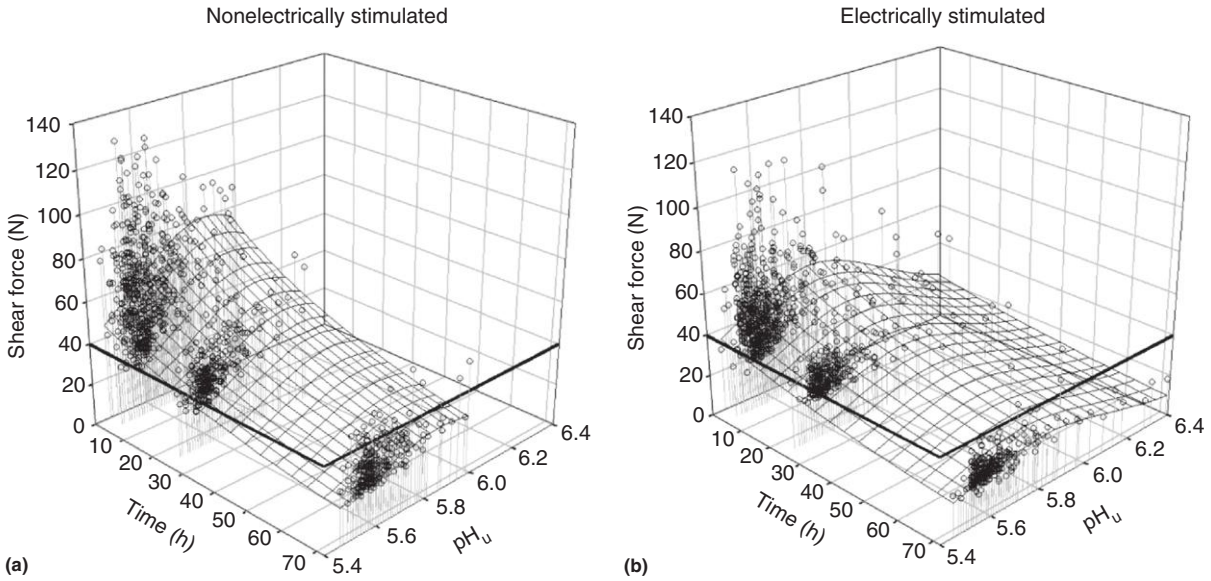

Figure 7 Three-dimensional plots showing the interrelationship between hours of aging (0, 4, 24, and 72) versus shear force and pH_u, for the longissimus et thoracis muscle of nonelectrically stimulated lambs (a) and electrically stimulated lambs (b) held at 15 °C for 72 h duration post rigor (at lower temperatures aging takes longer and equivalent values are reached at 4 °C for 8 days or up to 6 weeks at −1 °C). The individual shear values and drop lines onto ultimate pH are superimposed on the 3D mesh plot mean values. The mean shear force in the electrically stimulated group (b) is significantly lower and is less variable than the nonstimulated lambs (a) ($P<0.05$). A line is drawn at shear values of 40 N (moderate acceptability); superimposed and acceptable values are reached in 25–30 h for nonstimulated low pH_u muscles and within 10 h for stimulated muscles. High pH_u muscles tenderized very rapidly. At 72 h, all muscles became highly tender with the exception of those with intermediate pH_u values. The tenderness measurements (obtained with an Australian Warner–Bratzler device) commenced at rigor mortis – this was reached in 12 h for nonstimulated muscle and in 5 h for stimulated muscles. Modified from Devine, C.E., Lowe, T.E., Wells, R.W., *et al.*, 2006. Pre-slaughter stress arising from on-farm handling and its interactions with electrical stimulation on tenderness of lambs. Meat Science 73, 304–312.

and pH_u is best described by an inverted U-shaped curve (Figure 6). The rate of aging of intermediate-pH_u meat is slower than that of meat of a high or low pH_u (approximately 75% slower) and is a major contributor to toughness so that most meat never tenderizes significantly with prolonged aging. Although high-pH_u meat is more tender than low-pH_u meat, other properties of high-pH_u meat, such as a dark color and off-flavor, are not desirable. The relationship between pH_u and shear force appears to be similar for all species.

Injection of Calcium and Other Agents

Calcium-activated tenderization appears to be a useful method to accelerate aging. Calpains require calcium for activity, but optimum calcium levels may not be available in postrigor muscle to activate them fully. Calcium (5% w/v) can be injected into meat postrigor to activate calpains and thus to induce a more rapid and extensive tenderization. Following injection, cuts are vacuum-packaged and stored before consumption. The process is not so effective in prerigor meat, but can be used up to 14 days postmortem; however, if injected too early prerigor, calcium causes shortening that toughens meat. Calcium injection does not affect meat that is already tender and so does not make tender meat 'mushy.' It is reported to have little effect on other meat-quality traits and is effective on all breeds, cuts, or classes.

Postrigor injection of other salts, such as phosphate, increases aging rate and can overcome some effects of shortening. Marinating meat with acids does not dramatically improve tenderness unless the pH is below 4.5, although the flavors added can enhance consumer appreciation. There is also difficulty of penetration and the marinade may have to be injected.

Making the meat alkaline (e.g., by sprinkling or soaking with small amounts of sodium bicarbonate) does genuinely increase tenderness, possibly by a similar mechanism to that occurring in high-pH meat, but there have been reported minor texture changes and small flavor changes, although these can be masked with spices.

Subjection of meat to a steady, high-hydrostatic pressure tenderizes it and a recently developed procedure uses an explosive charge to generate a hydrodynamic shockwave, which is transmitted through water to the packaged meat so that it tenderizes rapidly.

Freezing and Thawing

When meat is frozen it does not age, although it is possible for some aging to occur in the latent heat phase during freezing. When meat thaws, it again begins to age, at a much faster rate, but there have been limited studies to quantify this effect. The process of freezing and thawing of meat also results in drip, much of which is eventually taken up again by the meat (if it remains in contact with the drip).

Measurement of Aging

Meat tenderness is the way consumers see one aspect of the property of meat: cooked meat becoming more tender and acceptable (higher scores) as the meat ages. To replicate consumers, a common procedure is to train panellists to evaluate meat attributes. Meat is cooked to a standard end-point temperature and maintained at this temperature when served to the panellists under standard lighting conditions. Measuring appreciation of tenderness through the use of a consumer panel provides more information than just tenderness and is influenced by the type of cut, amount of fat, and connective tissue, juiciness, cooking procedure, and cooking temperature effects, such as the well-known differences that exist between a well-cooked and a rare steak. Some evaluations use untrained people but, in the absence of training, there is a very wide range of scores for the various attributes. A more objective measure is obtained by shearing meat following standardized cooking procedures, for example, 70 (American Meat Science Association) to 75 °C (Meat Industry Research Institute of New Zealand (MIRINZ)) in a water bath or an electric belt grill system – the lower the shear value, the more tender the meat. There are several types of 'tenderometers' in use, for example, the Warner–Bratzler tenderometer and MIRINZ tenderometer. The absolute shear values depend on the type of tenderness-measuring device used (e.g., Warner–Bratzler values are 0.6 times MIRINZ values), but the rate of change over time, i.e., the aging rate, will be similar for all devices.

Ideally, one would like to measure the tenderness of raw meat. Cytoskeletal proteins degrade over time and alter a meat's integrity, so the consequences of protein degradation in raw meat can be determined by using the myofibrillar fragmentation index. This involves viewing myofibrillar length changes under a microscope or determining turbidity changes. The degradation of the cytoskeletal proteins is also associated with a decrease in their water binding and the increased water release changes the NIR spectra, and this can be correlated with tenderness. NIR has been developed as a nondestructive method to measure meat tenderness and can also measure other meat quality attributes on line. A corollary is that as meat ages (tenderizes) there is an increase in drip. When aging is rapid, such as after electrical stimulation and high temperatures that occur, drip increases and meat tenderizes more rapidly as expected but there is no more drip for the equivalent tenderness achieved.

Pulling all of the discussion points above, the shear force of meat decreases exponentially over time and is significantly modified by pH_u and electrical stimulation as shown in Figure 7. In this figure, lamb meat was held at a constant 15 °C (this ensures more rapid aging than at lower temperatures). The mean shear force in the electrically stimulated group is significantly lower at all aging points than the nonstimulated lambs ($P < 0.05$). The line drawn corresponding to shear values of 40 N (moderate acceptability) shows that acceptable values are reached in 25–30 h for nonstimulated, low pH_u muscles and within 10 h for stimulated muscles. Because of the considerable variability, long aging is needed for all meat to become acceptable – consumers' appreciation of tenderness is remembered by the tough outliers.

Packaging

The type of packaging does not affect the rate of aging. However, the extended time for which meat can be held at low temperatures in specialized packaging systems, such as vacuum packaging and controlled-atmosphere packaging, allows the meat to age for a long time and become tender, and at the same time reduces the development of spoilage and pathogenic bacteria. Dry aging is that traditionally applied to whole carcasses in a chiller where the dry surfaces prevent bacterial growth and the sterile interior of the muscles is maintained and the adjacent bone may have an effect on flavor – the carcass is later broken down for sale. Wet aging occurs in meat cuts placed in a vacuum package and the bone is usually not present – the meat can then tenderize en route to distribution and sale. There are reported to be differences in flavor between dry and wet aging.

Although freshness is the aim for most food products, it is clear that 'fresh' meat may not be optimal in tenderness. To some extent, meat can be customer-ready earlier by using electrical stimulation or a process such as tenderstretch (in which the carcass is suspended by the pelvis, thus stretching some muscle groups) where the initial tenderness, before aging, is high. In many distribution systems, especially the extreme of shipping vacuum-packaged or controlled-atmosphere packaged meat chilled to −1. 5 °C to distant markets, the meat ages in transit. The absence of a reliable way of determining meat tenderness in a nondestructive way means one must adhere to a belief in the controlled operation of meat distribution to obtain tender meat.

Color and Texture Deviations

G Monin and V Santé-Lhoutellier, INRA, Saint Genès Champanelle, France

Glossary

Color deviation Any change of color, such as browning or lightening.

Dark firm and dry Refers to the color and the texture of the meat.

HAL Halothane gene, the halothane gene increases the amount of lean in a carcass but equally increases the risk of development of PSE meat.

Pale, soft, and exudative (PSE) Refers to the color and the texture of the meat.

***PRKAG3* gene** Encodes a muscle-specific isoform of the regulatory γ subunit of adenosine monophosphate-activated protein kinase.

Introduction

Deviations from the 'normal' status resulting in an abnormal course of the conversion of muscle to meat are frequently observed, but discussion tends to focus solely on extremes. Deviation cannot be addressed without first defining normality, yet strikingly, there are no universally accepted criteria for defining 'normal' meat. Indeed, the expectations of meat consumers are roughly the same in most regions of the world – beef and mutton are expected to be red, pork more or less pink, veal very pale, and so on – and excessive drip is universally considered as undesirable. However, the thresholds for acceptability vary greatly from one region to another. Thus, it must be kept in mind that the concept of normality in meat quality is entirely relative and wholly dependent on the user's needs and habits.

Color and texture are influenced by numerous factors, both intrinsic and extrinsic to animals. Intrinsic factors include muscle features and stress reactivity; extrinsic factors include rearing conditions, preslaughter treatment, slaughter techniques, and carcass processing conditions. This article sets out to bring together the factors that produce variability.

Effects of Rigor Mortis and Aging Conditions on Texture and Color

During rigor mortis set-in, the main changes in muscle tissue influencing subsequent meat quality are stiffening and acidification due to glycogenolysis. In brief, the kinetics of acidification strongly affects water-holding capacity and color. This is well exemplified in pig muscle, which exhibits tremendous variability in both rate and extent of acidification (Figure 1).

In pigs harvested in good conditions, the white muscles reach a stable pH value (referred to as ultimate pH or pH_u) in the range 5.5–5.7 after a few hours. This leads to a decrease in water-holding capacity and color intensity, as the myofibrils shrink when pH descends to values close to the isoelectric point of most myofibrillar proteins, i.e., approximately 5. Myofibril shrinkage squeezes fluid out from the muscle cells, causing drip loss, and enhances the light-scattering power of the meat, contributing to lighter color intensity. If pH_u is increased because of a lack of muscle glycogen at slaughter, meat appears darker and drier. At normal pH_u, any increase in acidification rate is detrimental to both water-holding capacity and color intensity, as it promotes the denaturation of muscle proteins, especially myosin. Protein denaturation occurs when pH reaches low values while muscle temperature is still high. Myosin denaturation considerably increases myofibril shrinkage and also causes light scattering, thereby increasing drip loss

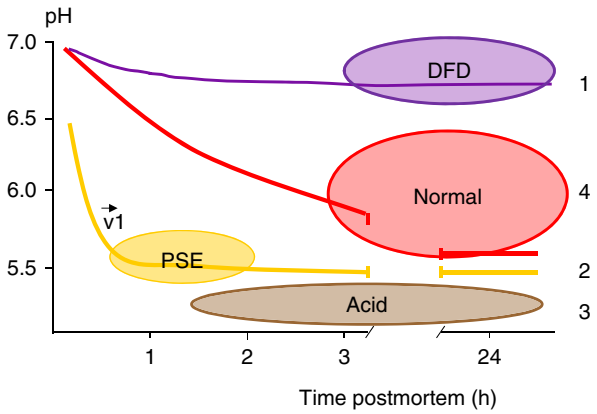

Figure 1 A schematic representation of the relationship between postmortem change of muscle pH and meat quality in pigs. When pH stays at a high value (1), irrespective of the rate of pH drop, meat is dark colored, dry, and firm to the touch, as the pH is far from the isoelectric point of myofibrillar proteins (pH = 5) and is termed dark, firm, and dry (DFD) meat. This condition is also found for bovine muscle. When the rate of pH drop is excessively fast (2) with a normal (i.e., in the range 5.5–5.7) or low ultimate pH (pH_u), extensive denaturation occurs, leading to what is termed pale, soft, and exudative (PSE) meat. When the rate of pH drop is normal but pH_u is lower than normal (3), the meat is called 'acid' or 'Hampshire-type' meat. Rate of pH drop has been considered according to French criteria as excessively fast when pH_{60} is <6, pH_u too high when >6.3, and pH too low when <5.5. Other countries may use different thresholds depending on local meat consumption patterns. Meat that is not outside of the thresholds (4) is considered 'normal.' Clearly, variation in the quality of 'normal' meat is still very high. Modified from Monin, G., 1988. Evolution post mortem du tissu musculaire et conséquences sur les qualités de la viande de porc. Journées de la recherche porcine 20, 201–214.

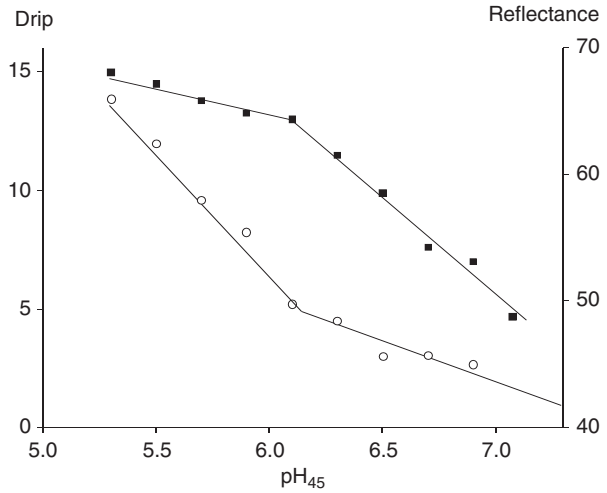

Figure 2 Relationships of drip loss (■) and reflectance (○) to pH_{45} in pig longissimus muscle. Points are the means of grouped data; the regression lines were drawn from calculations from the ungrouped data. Water-holding capacity decreases strongly at pH_{45} values above 6.1, with little effect on reflectance; the contrary is observed at pH_{45} values below 6.1. Thus, in meat with low or normal pH_u, high acidification rates give rise to PSE meat, whereas intermediate rates result in wetness but not paleness. Modified from Warriss, P.D., Brown, S.N., 1987. The relationship between initial pH, reflectance and exudation in pig muscle. Meat Science 20, 65–74.

and reducing color intensity. Moreover, myoglobin denaturation reduces the coloring strength of this pigment, which often comes with myoglobin oxidation. In extreme cases, the meat can look greyish or yellowish. The acidification rate is assessed via pH value at a given postmortem time, generally 45 or 60 min (pH values at these times are referred to as pH_{45} or pH_{60}, respectively). Water-holding capacity decreases strongly with pH_{45} values above 6.1, with little effect on reflectance; the contrary is observed at pH_{45} values below 6.1 (Figure 2). Thus, in meat with low or normal pH_u, high acidification rates give rise to paleness, softness, and exudation (PSE), whereas intermediate rates result in wetness but not paleness. Such defects are not found in meat with higher than normal pH_u, irrespective of the acidification rate, as pH does not reach the low values needed for significant protein denaturation.

The main pork quality deviations related to abnormal pH drop kinetics are schematized in Figure 1. Here, rate of acidification is considered excessive when pH_{60} is lower than 6. This high rate gives 'PSE' meat but only if pH_u is lower than 5.6. If pH_u is higher than a conventional set limit (which varies according to country between pH 5.8 and 6.3), meat is qualified as abnormal 'dark, firm, and dry (DFD)' meat. If pH_u is lower than 5.5, the meat is referred to as acid meat or 'Hampshire-type meat,' as this defect is frequent in Hampshire breed pigs.

The normal pattern of acidification varies considerably among species. The rate of postmortem pH drop in the main meat species follows the order poultry > pork > lamb > beef. Pigs show the strongest variation in acidification rates (0.2–0.5 pH units per hour). Extent of acidification is lower in poultry than in the other species, because poultry meat's pH_u is normally $\geq$5.7 against 5.4–5.7 in most muscles of the other species.

The main change occurring in meat after rigor mortis set-in is proteolysis, which results in tenderization. The among-species variation in rate of aging follows the same order as for acidification. In regard to color, discoloration occurs with time, as the red myoglobin is progressively oxidized to brown metmyoglobin. This discoloration is associated with a decline in quality.

Pale, Soft, and Exudative Meat

PSE pig carcasses have been described in Europe since as early as the nineteenth century. PSE meat is also frequently found in poultry and sometimes in beef, particularly young bulls. PSE is actually a somewhat confusing term, as it covers different kinds of defects whose only common trait is that they all result in paleness and drip. It is very important to clearly distinguish between the various kinds of PSE, because they differ on important traits, such as tenderness or flavor on top of the most evident deficiencies common to all of them. Moreover, the different PSEs result from different physiological or biochemical mechanisms and thus require different remedies.

Pork

Halothane Sensitivity

Bromochlorotrifluoroethane, or halothane, is a gaseous anesthetic widely used for human and animal surgery. Some pigs develop a malignant hyperthermia syndrome (MHS) when forced to breathe halothane or other halogenated anesthetics. The most evident symptoms of MHS are muscle rigidity, hyperthermia, metabolic acidosis, and arrhythmia. These are the expressions of an exacerbation of ATPase activity in the whole skeletal musculature. Generally, the animal dies after a few minutes. The MHS crisis can also occur during exposure to any of the numerous stresses occurring during an animal's life, such as mixing strange animals, aggressive interactions for establishment of social hierarchy, sustained muscle exercise, transportation, and slaughter.

Muscle ATPase activation is due to an explosive increase in sarcoplasmic free calcium. When occurring at slaughter, it induces a very fast postmortem drop in pH (Figure 3), leading to drip formation and discoloration (i.e., paleness) in most muscles. The loss of control of free Ca^{2+} level results from a mutation in the *HAL* gene encoding the ryanodine receptor in the calcium channel of the sarcoplasmic reticulum. The inheritance of halothane sensitivity is recessive. The *HAL* gene has two alleles: *N* (normal, dominant) and *n* (halothane sensitivity, recessive). *nn* pigs show high mortality during rearing (approximately 10-fold higher) and a high frequency of PSE meat at slaughter. The *n* allele appears to be incompletely recessive in terms of meat quality criteria, which implies that heterozygous pigs are more or less intermediate between the two homozygotes. This allele has marked positive effects on muscle development and carcass lean content (approximately +3–5% in *nn* compared with *NN* pigs), which explains its high frequency in some pig breeds. However, the halothane test does not distinguish Nn from nn. More

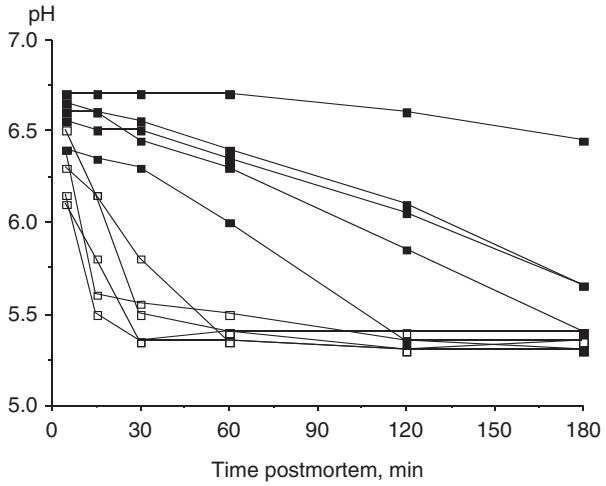

Figure 3 Postmortem pH changes in the longissimus muscle of halothane-negative (■) and halothane-positive (□) Piétrain pigs. Each curve represents one animal. All pigs came from the same herd and were killed on the same day in an experimental abattoir. Note the clear split between halothane-sensitive groups, despite the strong variation among halothane-negative pigs.

recently, a molecular genotyping method test by using a real-time PCR hybridization probe and applying it to the analysis of C1843T mutations of the Sus scrofa RYR1 gene has been developed.

In modern production systems, pigs fed for market are frequently bred by crossing specialized reproducer lines, as the sire line is especially meaty. Intense breed line selection for meatiness favors the *n* allele if no care is taken to control its frequency, which is close to 1 in some Piétrain and Landrace strains. The *HAL* genotype of the reproducers is routinely assessed using a DNA test. Mating an *nn* or *Nn* male with an *NN* female is a common practice, resulting in either 100% or 50% *Nn* market pigs, respectively, which presents some advantage in terms of carcass composition but at a cost of meat quality. Other breeders prefer to eliminate the *n* allele to produce only *NN* pigs. Choice of breeding strategy depends on the relative weights of meat quantity and quality in determining carcass value in a given marketing situation.

Fresh PSE meat from halothane-sensitive animals is less attractive than normal meat, mainly due to excessive drip and its very pale color. After cooking it is tougher than meat from *NN* pigs, primarily due to less advanced proteolysis during aging but also to higher cooking losses. Cooking loss is a matter of concern for the cooked ham industry, as processing yield is dramatically reduced, as well as for consumer appeal and eating quality.

PRKAG3 Gene

Another gene that has major effects on pork quality is the *PRKAG3* gene, also known as RN gene, which encodes a muscle-specific isoform of the regulatory γ subunit of the adenosine monophosphate-activated protein kinase, an enzyme regulating glycogen metabolism. A mutation in this gene (R200Q substitution, denoted RN^-) is responsible for a type of meat that is characterized by a normal rate of postmortem pH drop and that reaches a low ultimate pH, often called 'acid meat.' As it was first described in the Hampshire breed, where it has a very high frequency, it is sometimes known as 'Hampshire-type meat.' Acid meat is definitely pale, and somewhat soft and exudative, but less so than the PSE meat resulting from halothane sensitivity. In acid meat, paleness and exudation are related primarily to the meat pH being close to the isoelectric point of myofibrillar proteins, whereas in PSE meat they result mainly from extensive protein denaturation.

The normal allele (200R) is called rn^+. The mutated allele RN^- is dominant. It induces an accumulation of glycogen in the sarcoplasm of white muscle fibers (see muscle fiber types), with the result that muscle glycogen concentration increases with increased proportion of white fibers. Glycogen is increased by as much as 70% in the white muscles, allowing the production of more lactate during postmortem glycolysis and thus resulting in a lower pH_u. Protein content is lower, whereas lipid content is unchanged and water content is slightly higher (Table 1). Acid meat has been reported to be less tender than normal meat in France but tenderer in Sweden. In Sweden, acid meat is considered to have a higher sensory quality, as it is tastier. The residual glycogen could react with protein by cooking and thus enhance the development of Maillard reaction-like aroma. Moreover, this disagreement between these two countries might result from differences in cooking methods, such as typical cooking times and temperatures.

The main defect arising from acid meat is the weight loss occurring during meat processing by curing and cooking, particularly when no water-binding additive, such as polyphosphate, or extra protein is added. The increased weight loss results from both the lower ultimate pH and the higher water-to-protein ratio of the meat. Indeed, 1 g of glycogen binds 2–4 g of water, which is of the same order as the binding of water by proteins (approximately 3.3 g water per gram protein). Thus, in white muscle of RN^--carrier pigs, the water bound by glycogen is noticeably higher than in muscle from normal pigs. During postmortem glycolysis and further processing, glycogen is degraded and the corresponding bound water released. This results in an excess of water relative to the protein components available to hold it and in extra release of water during cooking.

Except for fresh meat marketed in a handful of countries, the RN^- gene is considered undesirable elsewhere. A DNA test is available for *RN* gene management in pig populations.

Another mutation in the *PRKAG3* gene (V199I substitution, denoted rn^*) has been shown to be associated with lower glycogen levels and higher ultimate pH, but its effects are low compared with those of the RN^- mutation. The frequency of this mutation depends on the pig lines considered but is not restricted to Hampshire pigs.

Stress-Induced Pale, Soft, and Exudative Meat

It has long been known that intense stress immediately before harvest can induce PSE meat, even in stress-resistant pigs. Stress-induced PSE lesions are generally less extensive than in the case of halothane sensitivity. In most cases, they remain limited to the deep parts of the ham, mainly the 'adductor' and the inner 'semimembranosus' muscles. Sometimes the lesions extend to other ham muscles and the 'longissimus' muscle.

Table 1 Effect of *RN* genotype on composition of *longissimus thoracis* muscle and meat quality. The acid meat resulting from the RN^- mutation (R200Q substitution in the *PRKAG3* gene) contains more glycogen and glycogen-bound water and less protein than normal meat (rn^+/rn^+). Higher glycogen levels result in lower pH_u in the most important loin and ham muscles. It is clear from the similarities between RN^-/RN^- and RN^-/rn^+ genotypes that the RN^- mutation is completely dominant

Trait	rn^+/rn^+	RN^-/RN^-	RN^-/rn^+	P^a
Glycolytic potential at rest (μmol g^{-1})[b,c]	167	304	277	<0.001
Glycolytic potential at slaughter (μmol g^{-1})[c]	110	224	196	<0.001
Moisture (% of wet tissue)	75.4	76.4	76.3	<0.001
Lipids (% of wet tissue)	1.42	1.31	1.34	0.63
Proteins (% of wet tissue)	22.2	20.5	20.6	<0.001
pH_u longissimus (loin)	5.74	5.54	5.53	<0.001
pH_u semimembranosus (ham)	5.75	5.52	5.54	<0.001
pH_u adductor femoris (ham)	5.92	5.56	5.54	<0.001

[a]Level of significance of the *RN* genotype effect.

[b]Glycolytic potential is an estimator of the content of glycolytic compounds liable to transform into lactic acid after death, expressed in %mol lactate per g; its value is close to double the actual glycogen level expressed in %mol glycosyl per gram wet tissue.

[c]At rest, determined from a biopsy on resting pigs during rearing; at slaughter, determined from a sample taken shortly after slaughter.

Influence of the 3 RN genotypes on chemical composition, enzyme activities, and myofiber characteristics of porcine skeletal muscle. Journal of Animal Science 77, 1482–1489.

The mechanisms underlying the occurrence of this kind of PSE meat are not totally understood. Preslaughter stress seems not always to be the cause of the lesions, as limited PSE zones are frequently observed even in pigs harvested under minimal-stress conditions. However, stress increases the extent and seriousness of the lesions. It probably acts by increasing muscle temperature and metabolic acidosis, particularly in cases involving aggressive interactions and struggling, which induce intense muscle work. In white muscle subjected to intense muscular work, intracellular pH can be reduced to values below 6.7 (Figure 4), whereas temperature is increased above the normal resting value (approximately 38 °C in the pig 'longissimus'). At harvest, muscle temperature is further increased by electrical stunning (sometimes by more than 1.5 °C in the longissimus), particularly when stunning is defective and prolonged as it prompts strong and prolonged muscle contractions. It is common to observe muscles with a temperature higher than 41 °C and a pH lower than 6.5 just after stunning, as these muscles experience extended protein denaturation after death. A deficiency in the control of free sarcoplasmic calcium is suspected, as the presence of the HAL^n allele increases the frequency and extent of lesions.

This defect is of particular concern in the cooked ham industry, as most cases are detected only at deboning, making it impossible to sort defective hams at entry into the processing lines. Ham muscles with PSE zones crumble easily during industrial slicing of cooked hams. This produces holes or splits in the slices, which make it nearly impossible to sell the meat prepacked. It has been reported that, in extreme cases, as much as half of the sliced material might be lost this way.

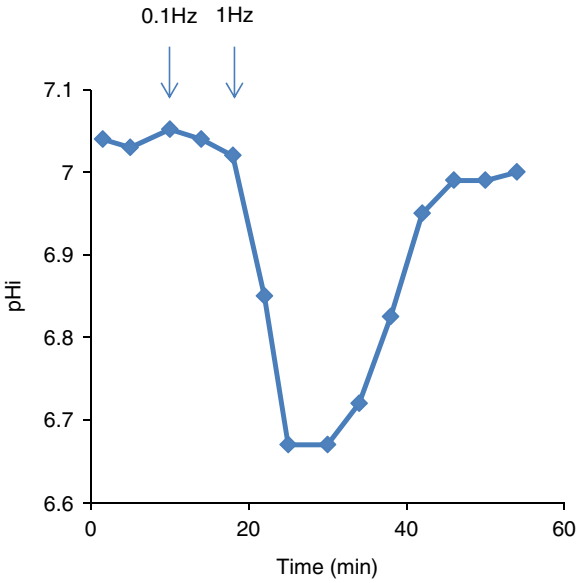

Figure 4 Change in intracellular pH (pH_i) of pig semimembranosus muscle during work: electrical stimulation. Piglets of 30 kg liveweight were anesthetized using pentobarbital; then, two platinum electrodes and an NMR (nuclear magnetic resonance) coil were fixed on the semimembranosus muscle and the animals were introduced into a NMR spectrometer. The muscle was electrically stimulated (0.1 Hz, 10 min; 1 Hz 10 min) via the electrodes, then allowed to rest for 20 min. pH was measured throughout the experiment using ^{31}P NMR spectrometry. Each point represents the average of 5 animals. Adapted from Miri, A., 1991. Application of Phosphorus-31 NMR to study of ante and post mortem metabolism in rabbit and pig muscles; relation with meat quality. PhD Thesis. University of Clermont-Ferrand.

Poor Chilling

As muscle temperature is critical for protein denaturation, slow chilling favors the occurrence of PSE meat. Modern slaughter plants are equipped with powerful chilling facilities that help to reduce the problem. However, in extreme cases it is impossible to chill the deep musculature rapidly enough to prevent protein denaturation and subsequently PSE meat and, at the same time, avoid cold shortening conditions occurring in slow-glycolysing muscle. (In the United States, most processing plants use blast chilling at -10 or -20 °F for 15–30 min followed by normal cooler chilling.)

Other Species

PSE beef has been reported to occur in carcasses of young bulls, but this defect is not frequent. The chilling of deep hind leg muscles is slow in cattle as the muscle mass is very thick. Thus, protein denaturation can occur if the rate of glycolysis is increased even slightly. However, the quality deviation of PSE beef is generally much less pronounced than that in PSE pork. For this reason, and due to its low frequency, there has been little research into PSE beef, and the physiological mechanisms underlying this defect remain unknown.

PSE meat is frequent in poultry, particularly in turkey breast muscles. As in pigs, it is associated with accelerated postmortem acidification (approximately 0.03 pH units per minute vs 0.06 in normal meat). Again, the physiological mechanisms responsible for this defect are unknown. There are some indications that preslaughter stress could play a prominent role. Some turkeys respond to halothane administration by leg stiffness, but this halothane sensitivity is not related to meat quality.

Rapid chilling after slaughter significantly reduces PSE in poultry. Chilling in ice water is particularly efficient but is banned in some countries. Acid meat is sometimes found in chicken but has not yet been tied to any gene mutation.

Dark, Firm, and Dry Meat

Carcasses with dark, purplish-red colored-meat are found in all meat species but are mainly a concern in cattle. The cuts of such meat are firm to the touch and dry, so the condition is called DFD or, specifically in cattle, dark-cutting (DC) beef. The darkness and lack of drip are related to the high pH values.

Lack of muscle glycogen at slaughter results from preslaughter stress, particularly during loading and transportation operations. Psychological stress, related to changes in physical and social environments, induces release of catecholamines, which increase glycogenolysis by activating muscle phosphorylase. Sustained muscle exercise requires mobilization of readily available muscle energy stores composed mainly of glycogen. Male animals are prone to DFD because of their excitable temperament and aggressive behavior, particularly in cattle. The in-carcass distribution of DFD meat depends on the species. In pigs, DFD is encountered mainly in the forequarters and deep ham muscles, as these body parts contain more slow red muscles, which, owing to their lower glycogen content, are more prone to DFD than white muscles. Conversely, in cattle, DFD affects mainly the hindquarters and the 'longissimus' muscle, although body distribution of muscles of different metabolic types is similar to pigs. This is probably due to the mounting behavior in this species, particularly in young bulls, which induces intense work in back muscles and hind legs. In sheep, the 'longissimus' muscle rarely shows DFD traits due to its high content of very glycogen-rich fast red fibers. In the United States, the incidence of dark-cutting beef is generally the highest in the fall when temperatures can drop rapidly from rather warm to cold within 12–24 h and cattle are then transported to harvest.

The discoloration of DFD meat is due to several factors. In high-pH meat, light scattering is reduced and muscle is more translucent at the cut surface, with the result that the color appears darker. Moreover, high pH allows mitochondria to continue respiration and thereby to consume oxygen, which enables the myoglobin to stay in its reduced form. The oxymyoglobin layer is very thin, and the purplish-red color of myoglobin predominates. Growth is optimal around neutral pH for most bacteria and so is favored in the higher range of meat pH values. This is particularly true for certain bacteria that are able to degrade sulfur amino acids, giving rise to hydrogen sulfite (H_2S), which has a very unpleasant odor. Moreover, high-pH meat has little carbohydrate, and consequently the bacteria present at its surface immediately degrade amino acids and cause early spoilage.

The main disadvantages of high-pH meats are discoloration and early spoilage when sold fresh. In beef, particularly from old animals, discoloration is accelerated by the high myoglobin content, prompting consumers to reject the product. In pigs, discoloration is only a concern in extreme cases, as most pig muscles have relatively low myoglobin content. Spoilage is particularly detrimental in beef, because aging is generally longer than in pork or lamb (weeks instead of days). A pH higher than 5.8 is generally considered unacceptable in beef, whereas pork is acceptable at up to pH 6.2, depending on local habits and ways of utilizing the meat.

Processing of meat joints by dry curing (dry hams, viande des Grisons, cecina) is successful if salt penetration is faster than microbial development in the depth of the joint. As high pH slows down salt penetration and accelerates bacterial growth, it favors putrefaction and is the main source of losses in the dry ham industry.

Cold Shortening

When carcasses are chilled too early after slaughter, some muscles contract. This effect, known as cold shortening, corresponds to a slow contracture and can exceed 50% of the muscle length when muscles are not restrained by skeletal attachments. Three conditions are needed for cold shortening to develop: temperature below 10 °C, pH above 6, and the presence of adenosine 5′ triphosphate (ATP). At lower pH and without ATP, contraction cannot occur. Cold shortening readily occurs in red muscles, mainly in beef and especially in lamb in some commercial conditions. In lamb, the acceleration of glycolysis by electrical stimulation reduces the possibility of cold-shortening temperatures occurring before rigor onset. In most pig and poultry muscles, acidification occurs too fast, and a pH <6 is generally reached before the temperature of 10 °C can be obtained. Cold-shortened meat remains tough, mainly due to its inability to tenderize even with prolonged aging, despite the fact that calpain enzyme activity remains. When beef and lamb muscle contraction is not noticeable, 'cold-induced toughening' can still occur. Thinly finished or very rapidly chilled carcasses are more susceptible to cold shortening or cold-induced toughening.

Double Muscling

Double muscling is the term used to designate a muscle hypertrophy characteristic of cattle and Texel sheep. It is due to

a mutation in the myostatin (MSTN) gene, which encodes the growth-regulating factor myostatin. Muscle hypertrophy arises from an increased total number of fibers. It is not uniform throughout the body, as some regions are isotrophic or even hypotrophic. It essentially affects the outer muscles, and it is more prominent in the hindquarters than in the forequarters.

Double-muscled animals are particularly appreciated in some European countries because of their substantial advantages in body composition/meat yield. Dressing yield is approximately 5% higher than in normal animals of the same sex, age, and breed. Carcass leanness and muscularity are superior, with percentage muscle in the carcass being approximately 10 percentage points higher (e.g., 80% vs. 70%) than in normal animals. However, double-muscled animals present some deficiencies. They are more susceptible to stress and are reputed to be more prone to dark-cutting conditions. Stress susceptibility is related to a lower overall respiratory capacity, as double-muscled animals have smaller heart and lungs and a lower blood oxygen capacity. Consequently, metabolic acidosis caused by exercise is more pronounced and more slowly compensated in double-muscled cattle than in normal cattle. This higher stress susceptibility could explain the more rapid postmortem glycolysis observed in double-muscled cattle. Proneness to DFD could be related to the higher proportion of glycolytic myofibers (particularly fast, white fibers), which are more susceptible to stress in terms of glycogen depletion.

Meat from nonstressed double-muscled animals is paler than normal due to its lower pigment content in relation to the higher proportion of fast, white fibers. It yields more drip and cooking losses, probably due to the faster postmortem pH drop. It is generally accepted that it is tenderer in some breeds mainly due to its lower connective tissue content, which might partly explain its appreciation in some European markets. However, higher shear force has been observed when cooking meat from double-muscled young bulls compared with normal individuals of the Belgian Blue breed. The cause of this difference is not known, although higher shear forces have been associated with lower calpain activity, differences in collagen solubility, and faster glycolysis.

Callipyge Sheep

The *callipyge* gene (CLPG) sheep phenotype has recently emerged in the US commercial sheep population. Callipyge lambs show extreme muscling with hypertrophy of the main hindquarter and loin muscles (in Greek, *kalli* means beautiful and *pyge* means buttock). The condition is due to the mutant allele (C) of the *callipyge* gene (normal allele *N*). The mode of inheritance of this type of trait, referred to as polar overdominance, forms a quite particular case, as only heterozygous animals (*CN*) that received the *C* allele from their sire express the callipyge phenotype, whereas the three other genotypes (*NN*, *CC*, and *NC*) are normal. Muscle hypertrophy is related to higher proportion of fast-twitch glycolytic fibers and muscle cell enlargement. Callipyge lambs have superior dressing percentages and carcass compositions. These advantages are counterbalanced by the fact that the hindquarter meat turns out much tougher. Muscles from Callipyge lambs have a higher calpastatin content, which inhibits both the rate and extent of postmortem proteolysis. Thus, tenderizing by aging is limited, and shear force values of 'longissimus' muscle from Callipyge lambs at 21 days 'postmortem' are comparable to those from normal lambs at 1 day postmortem. Moreover, callipyge animals have less marbling.

Muscle Degeneration

Muscle degeneration is sometimes observed in meat carcasses. It generally results from nutritional deficiencies, for example, in vitamin E or selenium, which give rise to serious disturbances in muscle cell metabolism and ultimately result in necrosis. A localized nonnutritional muscle degeneration known as focal myopathy occurs in turkey breast muscle, particularly the Pectoralis minor. Degenerative changes consist in necrosis, hypercontracted muscle fibers, proliferation of connective and fat tissue, and mononuclear cell infiltration into the necrotic areas. This condition has been related to local microischemia due to a low capillary-to-fiber ratio, and it is suspected to be a causative factor of PSE turkey breast muscle. In this respect, the meat shows some similarity with the PSE zones encountered in deep ham muscles of pigs, as described above.

Stress-induced muscle degeneration is sometimes found in beef skeletal muscles, particularly 'longissimus' and 'pectoralis' muscles. It affects mainly young cattle from muscular breeds. Lesions appear as zones with a pinkish to yellowish color. Texture is soft and even jelly-like in serious cases. Despite this PSE-like appearance, degenerated meat differs from PSE meat by its very high pH (>6.5). It results from long and stressful transport before harvest, as evidenced in France, where the condition proved fairly frequent in young bulls harvested after being transported several hundred kilometers by truck or train while it was lacking in similar animals killed close to the 'home' farm. It has been hypothesized that degenerative meat might be related to the action of catecholamines.

Glycogen

E Puolanne and K Immonen, University of Helsinki, Helsinki, Finland

Glossary

Glycogenolysis The break-down of glycogen to glucose-1-phosphate and glucose.

Glycogen debranching enzyme A double-function enzyme that moves three glucose units from the 1-6 branching point (transferase) and then 1,6-glucosidase removes the last glucose unit.

Glycogen phosphorylase A very fast enzyme that is capable to remove glucose-1-phosphate from nonbranched chains of glycogen, down to the fourth glucosyl unit from the 1-6-branching point.

Glycolysis (from *glycose*, an older term for glucose+*-lysis* degradation) The metabolic pathway that converts glucose $C_6H_{12}O_6$, into pyruvate, $CH_3COCOO^-+H^+$.

Introduction

Most of the time, blood will provide enough nutrients for the metabolism, and especially, for the energy production of the muscles. The principal portion of the energy produced in a muscle cell originates from the main nutrients; carbohydrates, volatile and nonvolatile fatty acids plus glycerol, and proteins. Fat, as free fatty acids, is an important source of energy at rest and during light exercise. In light exercise, the plasma content of free fatty acids increases within a few minutes, whereas during heavy exercise it decreases. In ruminants, short-chain free fatty acids (mainly acetate, propionate and butyrate) form the major proportion of the energy substrates with carbohydrates having a minor role (5–15%). Oxygen is required, in long terms for all kinds of energy production.

Muscles are able to produce/use 5 μmol of adenosine triphosphate (ATP) s^{-1} g^{-1} at maximum rate, and that appears to be universal across muscle tissues. The resting level of consumption is approximately 0.02–0.05 μmol ATP s^{-1} g^{-1}, and is used for maintaining membrane potentials, and fuelling the calcium pump that returns Ca^{++} back to the sarcoplasmic reticulum, the occasional contractile reactions between actin and myosin, as well as the anabolic reactions of molecule syntheses. ATP consumption also generates body heat.

The maximal rate of ATP consumption is at least 100 times greater than that of a resting muscle. Since the production and consumption of ATP must be equal at any given moment, the portion of ATP that cannot be provided by the oxidative metabolism must be produced anaerobically. This explains the existence of two mechanisms (aerobic and anaerobic) for ATP production. If indeed the aerobic production was to be able to cover the maximal level of energy consumption, the animal would, depending on species, need to have much larger organs (lungs, heart, circulatory system, organelles and enzymes for aerobic metabolism in fibres) than it currently has for obtaining and using oxygen. Since animals seldom need maximal energetic capacity over a sustained period of time in all of their muscles, a capacity for a full aerobic coverage would be an inefficient physiological 'investment.' Another mechanism has, therefore, developed for short bursts of energy.

Depending on the oxidative capacity of a muscle, the oxidative production/usage of energy can increase due to increased activity. In pigs, for example, the increase is less than 10 times the resting level, whereas in cattle, it is 20-fold, and in horses, almost 50-fold. The above mentioned figures are of course approximates, because the oxygen consumption within species depends on the fibre type composition and the basic tone of each muscle. The oxygen consumption of various muscles depends on their activity at a given moment, as does the blood flow through the muscles, as well as the relative amount of oxygen left in the muscles. At rest, for example, the blood flow through muscles may be 20% of the total flow. At maximal activity, however, the cardiac output increases tenfold, and 80% of it is circulated through muscles, which then utilize up to 90% of the passing oxygen. Together, these values translate to a 25-fold consumption of oxygen in comparison to a resting muscle.

The oxidative capacity of a body's total muscle mass seems to be in balance with the capacity of blood circulation. Animals with a high oxidative capacity (e.g., horse, reindeer) have relatively big lungs and hearts, and muscles that have dense capillary networks, compared to animals with less oxidative capacity (e.g., pig, chicken). Furthermore, breeding has had a significant effect on the oxidative capacity of domestic animals. The proportion of oxidative fibres is higher in the muscles of the wild pig than in the domesticated pigs, as is the capillary density. In wild pigs, 1 g of heart tissue serves 85 g of muscular tissue, whereas in domestic pigs it has to serve 140 g. In poultry, severe oxygen deficiency within the poorly capillarized Pectoralis muscle results in deep pectoral myopathy. The crucial importance of sufficient oxygen supply for muscle tissues cannot, therefore, be overly emphasized.

In a muscle fibre, glycogen is the energy reserve used in case the circulatory system cannot provide enough oxygen and nutrients. Glycogen breaks down to glucose phosphates that are utilised anaerobically or aerobically, depending on animal species and their level of physical and/or psychological stress. There is indirect evidence that in stress, triggered by adrenaline, glycogen is preferred even if there were other energy substrates available, i.e., even if the stress did not involve high physical activity. The lactate formed in the glycolysing fibres will be transported into the blood via monocarboxylate transporters (MCT) that move lactate through the cell membranes from the higher concentration toward the lower. Lactate is destined to be exported to the liver to be used as a substrate for the synthesis of glycogen or glucose-6-phosphate. While on its way, some of it will probably also be aerobically

 doi:10.1016/B978-0-12-384731-7.00245-2

utilized either by the oxidative muscle fibres or by the heart, if the lactate concentration in them is lower than that in blood.

Structure of Glycogen

Theoretical studies have revealed how the glycogen molecule has taken its form in the biological evolution. The glycogen molecule is optimized for storing a maximum amount of glucose in the smallest possible volume, and at the same time, for allowing a rapid release of glucose from its structure by glycogen phosphorylase (GP) (Figure 1). A 100 mM solution of glucose would create a high osmotic pressure, whereas the equivalent 0.002 mM of glycogen does not, the glycogen molecule being more a particle (granule) than an element in a solution. The maximum sized glycogen molecule/granule of a diameter of 40 nm contains approximately 55 000 glucose units, and 2100 nonreducing chain ends. The total molecular weight is approximately 10^7 Da. Each glycogen molecule has 40–50 GP dimers (or 20–25 tetramers) bound to it, facilitating the immediate and fast cleavage of the glucosyl units. Glycogen synthase (GS), glycogen branching enzyme (GBE), AMP-activated protein kinase (AMPK), as well as glycogen debranching enzyme (GDE) are also bound to the glycogen complex, and thus, readily available when needed. There are also several other proteins with regulatory roles bound to the complex (Figure 2).

In the core of the glycogen molecule is glycogenin (molecular weight (MW) 37 000), an enzyme-acting protein (glucosyltransferase) that serves as a primer for the molecule. In glycogen formation, uridine diphosphate moves the first eight glucosyl units to glycogenin after which GS takes over and extends the chain of glucosyl units via $\alpha(1\rightarrow4)$ linkages. Glycogen branching enzyme then transfers an A-chain of 6–7 glucosyl units forming an $\alpha(1\rightarrow6)$ linkage between the original chain and the transferred chain. A new branch point must be at least 4 glucosyl units apart from the previous branch point.

Theoretical calculations have shown that the optimal chain length is 13 (12–14) glucose units, and that it is optimal to have two branching points in each B-chain (Figure 1). Each level of chains forms a concentric tier, and all new tiers double the number of chains of the previous tier. After 12 tiers, the structure will turn self-limiting, eventually due to the spatial relations between the glycogen molecule and GS. The distance of four glucose units between the branching points thus leaves tails of 4 or 5 glucosyl units.

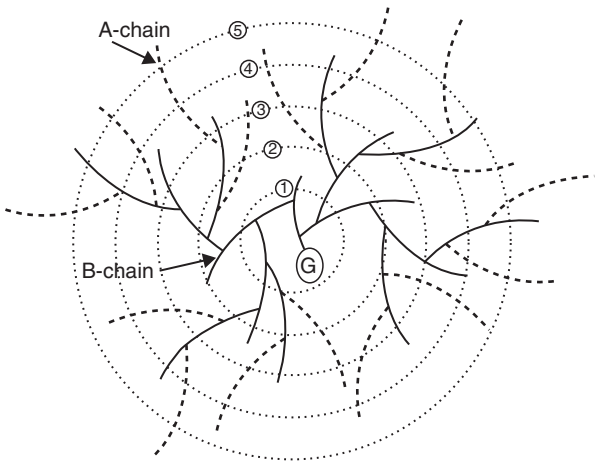

Figure 1 Glycogen molecule (5 tiers) according to Meléndez-Hevia and others. Each unbranched A (dotted line) and branched B (solid line) chain has 12–14 glucosyl residues. G = glycogenin. Figure 2 A schematic summary of proteins known to interact with glycogen. GDE, glycogen debranching enzyme; AMPK, AMP-activated protein kinase; GBE, glycogen branching enzyme; G_M and PP1R6, regulatory subunits of protein phosphate 1 PP1; GN, glycogenin; GNIP, glycogenin-interacting protein; GS, glycogen synthase; GSK, glycogen synthase kinase; GP, glycogen phosphatase; PhK, phosphorylase kinase; PTG, protein targeting to glycogen. Reproduced from Graham, T.E., Yuan, Z., Hill, A.K., Wilson, R.J., 2010. The regulation of muscle glycogen: The granule and its proteins. Review. Acta Physiologica 199, 489–498.

Until recently, glycogen was thought to exist as two separate forms: proglycogen and macroglycogen. Particles with molecular weight of 400 kDa are called proglycogen, which due to its protein content of approximately 10%, is insoluble in acidic solutions. Glycogen molecules of a much higher molecular weight are called macroglycogen, which in turn maintain its water-solubility even in acidic solutions due to the dominant abundance of carbohydrate. It has been postulated that proglycogen is utilised in severe stress as well as postmortem, whereas macroglycogen is used during endurance exercise, and less so postmortem. The existence of different glycogen pools has, however, been challenged. It has been concluded that instead of existing as two separate forms, there is a continuum of glycogen molecules of different size. It has also been claimed that muscle fibres accommodate glycogen in multiple sites; some free in cytosol, and some bound to the sarcoplasmic reticulum. There are, therefore, differences in both solubility and availability for use. Microscopically, the granules are most abundant between the myofibrils, but also inside the fibrils. In humans, the average diameter of a glycogen granule is 25 nm, i.e., tier 8 is mainly in use, and less than 20% of the granules have built all 12 tiers. In conclusion, glycogen particles are not of fixed molecular weight, but instead, are subject to on-going resynthesis or degradation depending on the level of physical activity and/or stress, as well as the nutritional status of the animal.

Metabolism of Glycogen

The main function of glycogen is to serve as a source of glucose for anaerobic glycolysis (includes glucose-1-P to pyruvate and, with the help of muscle-type lactate dehydrogenase, from pyruvate to lactate). Anaerobic glycolysis is a very rapid metabolic pathway producing 3 ATP of energy per glucosyl unit, the yield being much lower, however, than if pyruvate was utilised aerobically. The biochemical role of lactate formation is to regenerate NAD^+ for glycolysis, and one proton will be simultaneously bound to pyruvate when lactate is formed. There has been an intensive discussion over the source of such protons, and it seems that physiologists, dealing with the pH range of 7.2–6.4 of a dynamic living muscle, and meat and animal scientists, working with a broader range of pH, i.e., from 7.2 all the way down to the pH 5.0 of a more stable postmortem muscle, see the matter quite differently. The protons derive from earlier stages of glycolysis, so that different pK_a-values of glycolytic metabolites and phosphates at different postmortem pH-values relate to free proton formation. Irrespective of the sources of protons, and/or the buffering capacity of meat, there is an abundance of data confirming the linear negative correlation between lactate content and pH-value.

In the breakdown of glycogen, there are two enzymes directly involved: GP that releases glucose is strongly controlled by various factors, including hormonal, and GDE that disassembles the branch points. The rate of the process is limited by the availability of free HPO_4^{2-}. The pK_a value of H_2PO_4 is 7.2, and at pH 5, the pool of HPO_4^{2-} is virtually nonexistent.

GP (842 amino acids and a MW of 97.4 kDa) amounts to approximately 2% of the soluble proteins of a muscle, and has an immense acting capacity. GP is activated both by allosteric interactions as well as reversible phosphorylation. The inactive form *b*, of GP can be found in resting muscles, and is activated by a cascade involving epinephrine, calcium, cyclic AMP, AMP-activated protein kinase (which activates phosphorylase kinase), and inhibited, however, by glucose-6-P and ATP. GP is biologically active as a dimer of two identical subunits, but can also be found as a tetramer. There are dimeric GP molecules attached to each glycogen molecule/particle. Each GP monomer consists of two domains: the *C*-terminal domain (the one responsible for catalysing the reaction), and the *N*-terminal domain (responsible for regulation of the enzyme). The binding of phosphate or AMP at the effector sites leads to changes in the conformation of the protein, and increases the acceptance of glycogen at the active site. One subunit is being active whereas the other, as attached to the molecule, is regulating the activity.

When the outermost tier is full of glycosyl units, 50% of all glucose within a glycogen particle lies in the unbranched A-chains, whereas the remaining 50% constructs the B-chains, irrespective of the total number of tiers. GP can only cut 9 out of the 13 consecutive 1–4-linked glucosyl units of a linear A-chain. Thus, according to theoretical calculations, GP can initially cleave 34.6% of the glucosyl units of any glycogen particle. At the fourth glucosyl unit from the 1–6-linked branch, the activity of GP ceases.

The cascade for the activation of glycogenolysis is very effective. One epinephrine molecule bound to a receptor on a muscle fibre results in 400 000 glucose-1-P units cleaved by GP per second. This means that one molecule of GP can disassemble glycogen at a speed of 30 000 degradations per particle per second. Blood epinephrine concentration of 10^{-10} M generates an intercellular cyclic adenosine monophosphate (cAMP) concentration of 10^{-6} M. The relative concentrations of the three successive enzymes of the cascade; cAMP-dependent protein kinase, phosphorylase kinase and GP, occur as molar ratios of 1:10:240 including adrenalin at a ratio of 0.0001, indicating an effective amplification of the signal.

At the onset of muscle contraction, GP is activated from form *b* to form *a* by the increasing content of free cytosolic Ca^{++}, as well as by norepinephrine secreted from the motor-end-plates at the sarcolemma. GP then remains active in high concentrations of AMP and phosphate, and will be inhibited again when ATP and glucose-6-P levels have increased. Decreasing levels of ATP and glucose-6-P will start glycogenolysis. In case of nonintensive exercise, the increased blood supply of nutrients and oxygen quickly take over, and GP *a* is phosphorylated back to *b*. In a postmortem muscle of the pig, for example, GP stays in the form *b* for the first 10 min. It should be noted, however, that in a stressed animal, when creatine phosphate has been utilised, glycolysis starts earlier, even before slaughter. In this case, the reaction $CP^{2-}+ADP^{3-}+H^+ \rightarrow C+ATP^{4-}$ will not generate the initial buffering effect.

For the continuation of glycogenolysis, GDE must remove the 1–6 linkages. The rate of GDE is not more than 10% of that of GP. The biological significance for this may be that a controlling system is needed to stop excessive breakdown which would cause damages in the fibre. Also GDE is bound to the glycogen particle, and thus, always available. It has a

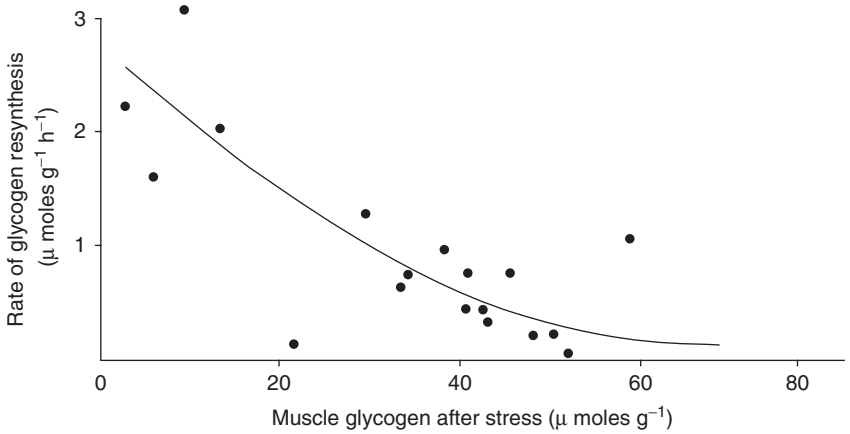

Figure 3 The relationship between muscle glycogen concentration and the rate of resynthesis in young bulls. Reproduced with permission from Tarrant, P.V., 1988. Animal behaviour and environment in the dark-cutting condition. In: Fabiansson, S.U., Shorthose, W.H., Warner, R.D. (Eds.), Dark-Cutting in Cattle and Sheep, pp. 8–18. Australian Meat and Live-stock Research & Development Corporation.

double function. In one end of the molecule, there is a transferase removing three glucosyl units and placing them at the end of another chain, most probably B, whereas in the other end of the enzyme complex there is 1,6-glucosidase activity cleaving the last remaining glucosyl unit as free glucose, which is then immediately phosphorylated. Finally, GDE will move further away from the A-chain thus allowing GP to function again. Very little is known about the control of GDE, except that it can only process A-chains of a length of four glucosyl units. It seems that glycogenolysis is independent on GDE at high glycogen concentrations, but at lower glycogen contents, GDE is of more relevance. GDE works optimally at a temperature range of 39–42 °C, and is not particularly sensitive to a lowering of pH. GDE is, however, very sensitive to low temperatures, and has hardly any activity at below 10 °C. It is, therefore, possible that postmortem, at low levels of glycogen, and in cold meat, GDE is rate-limiting.

GS is allosterically activated by glucose-6-phosphate. Contrary to GP, GS is thus active when high blood glucose concentrations lead to elevated intracellular glucose-6-phosphate. GS is inactivated by an on-going glycogenolysis, as the cAMP cascade ceases glycogen synthesis. GS is phosphorylated by protein kinase A as well as by phosphorylase kinase. Phosphorylation of GS promotes the '*b*' (less active) conformation. The cAMP cascade with AMPK having a central role thus controls the levels of glycogen. Also the intake of glucose into a fibre is controlled by AMPK. In the liver, glucose-1-phosphate may also, instead of being converted to glycogen, be converted into glucose-6-phosphate, which is then dephosphorylated for the release into the blood stream (from muscle fibres the charged glucose phosphates do not escape).

Once degraded, it takes a relatively long time to replenish the glycogen stores. There are, however, marked differences between species. In beef animals, the resynthesis is particularly slow, 1–2 mmol kg^{-1} h^{-1}, increasing only at very low glycogen stores (Figure 3). In race horses, during three consecutive bouts within 2 h, the glycogen content first decreases approximately 30%, and interestingly, an additional 20% during 4 h at rest. The recovery takes 3 days indicating that the consumption of carbohydrates is high after repetitive intensive exercises.

Effect of Glycogen Content on Meat Quality

The glycogen contents of animals at rest or just after slaughter have mostly been estimated with the glycolytic potential, i.e., the sum of glycogen, glucose, glucose-6-P and lactate, expressed as lactate equivalents. This is, in principle, a good indicator for antemortem glycogen levels. However, as one connects the relative contents of the above variables with the time postmortem, and especially, with the pH and buffering capacity, it soon becomes evident that in many cases it has not been all that significant of an indicator for meat quality due to complexity of the events. An alternative simple procedure has not, however, at least to date, been introduced for the retrospective determination of preslaughter glycogen contents. The analyses are indeed challenging, especially because glycogenolysis and glycolysis can proceed very rapidly during sample preparation and analysis. It is, therefore, very important to immediately freeze the fresh muscle samples in liquid nitrogen. A resting muscle biopsy taken before any measures of transportation, or just before slaughter, would make the most representative sample, provided that sampling and freezing are, again, carried out promptly.

The glycogen contents of resting muscles are usually at the levels of 80–100 mmol kg^{-1}, given as glucose, yet lower levels are frequently found at slaughter due to ante-mortem stress. In pigs, higher levels (of 120 or even 150 mmol kg^{-1}) are found, especially in the Hampshire, and Hampshire crossbreeds. Also in cattle, high resting levels (110–120 mmol kg^{-1}) can be found in animals that have first been depleted of glycogen, and then allowed to recover on a high energy diet. Pre-slaughter stress, such as transportation, invariably reduces glycogen contents. Although the glycogen levels of mammals are controlled by AMPK through PRKAG3 gene, the mechanism in poultry may be different. In chicken, the glycogen contents of the light Pectoralis major muscles are lower (below 100 mmol kg^{-1}) than in the light

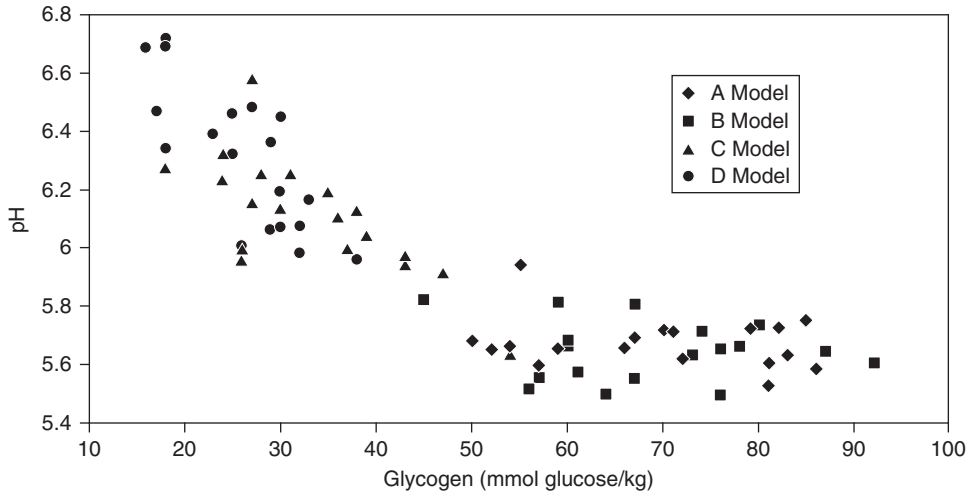

Figure 4 Ultimate pH and glycogen content immediately before slaughter in pig *M. longissimus dorsi*. A–D, various exercise intensities before slaughter. Reproduced from Henckel, P., Karlsson, A., Jensen, M.T., Oksbjerg, N., Søholm Petersen, J., 2002. Metabolic conditions in Porcine longissimus muscle immediately pre-slaughter and its influence on peri- and post mortem energy metabolism. Meat Science 62 (2), 145–155.

mammalian muscles, the buffering capacity, however, being higher. This may be because chicken use the Pectoralis muscles mainly for single intensive bursts for flight, followed then by an aerobic recovery.

The threshold glycogen content resulting in ultimate pH-values above the normal of 5.5 is 53 mmol kg^{-1} in pigs (Figure 4) and 57 in cattle. This means that any induced stress can last for quite some time without affecting the ultimate pH value, even with significant glycogen depletion. Especially in beef, the pyruvate resulting from glycolysis may also be immediately used aerobically by the fibre in question, or by another fibre of better aerobic status. In a young bull, the average rate of glycogen breakdown is 0.18 mmol kg^{-1} min^{-1}, the maximum being 0.39. The corresponding hourly rates would therefore be 11 and 23 mmol kg^{-1}, should the exercise truly last for hours.

There is an abundance of literature on the effects of animal stress on meat quality, and especially on the incidence of the pale, soft and exudative (PSE) meat, as well as the dark, firm and dry (DFD) meat. These aspects will be dealt elsewhere in this book (preslaughter treatment), and are therefore not discussed here in detail. However, the quality effects of preslaughter stress manifest themselves through glycogenolysis, and consequently, through the rate of pH fall, as well as the ultimate pH. When the muscles of pigs and poultry, and more seldom cattle, coming to slaughter have a high content of glycogen accompanied with low levels of creatine phosphate, low oxygen saturation, as well as high body temperature, glycogenolysis and glycolysis will start premortally, and remain rapid for the first few hours postmortem. This will result in a low pH at temperature still being high, and usually in a very low ultimate pH, causing PSE meat. On the contrary, when glycogen content is low already at rest, or has been consumed in a long-term (hours) stress, the consequent low level at slaughter results in a lower rate of pH fall and an elevated ultimate pH. High pH lowers the keeping quality of meat, as well as causes a nontypical taste to it, while increasing the water-holding capacity and tenderness. Glycogen reserves are hardly ever totally exhausted; approximately 10–20 mmol kg^{-1} always being left over, even in severely stressed cattle. The glycogenolysis may also cease at a point where, at least in theory, a sufficient amount is left yet to accommodate an additional pH fall of substantial size (Figure 5). It is not known whether the lower keeping quality is related to pH exclusively, or if also the low content of carbohydrate contributes to the alteration of the bacterial flora and/or its metabolism.

The liver can store 10% or more of its weight as glycogen, and release it into the blood as glucose. In a slaughter-weight pig, this equates to 150 g of glucose, or 2.4 MJ of energy, and corresponds to approximately 20% of the needs of basic daily metabolism.

Concluding Remarks

Livestock live normally a peaceful life without having to deal with frequent, long-lasting physical stress. Stress, namely, the secretion of epinephrine, increases glycogenolysis, and if psychological stress/excitement is accompanied with physical strain, it results in a very rapid use of glycogen. Various preslaughter treatments (collecting, regrouping with fighting and withdrawal of feed, marking, transport, slaughterhouse lairage, and finally, driving to stunning) involve potential physical and psychological stress factors that an animal may not have ever previously experienced. Furthermore, exposure to these treatments may continue from hours to several days, and thus, depending on species as well as the length and type of the logistic channel of each individual case, seriously jeopardize both animal welfare as well as meat quality. The quantity of research in carbohydrate metabolism is overwhelming, but the majority concerns humans and/or laboratory animals, and has been focused on living organisms, i.e., at pH 7.0 and temperature 37 °C. The decreasing pH and

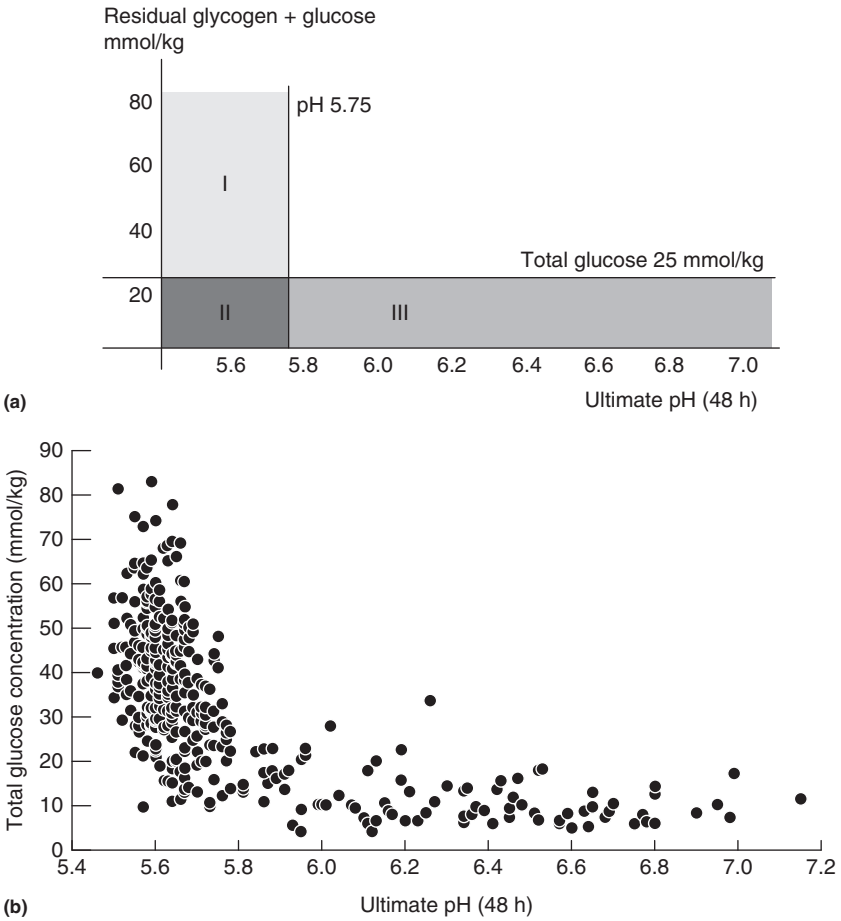

Figure 5 A suggestion (A) for beef quality categories based on the residual (48 h postmortem) glycogen+glucose content and ultimate pH (B). A I: low-stress, unproblematic; A II: medium-stress, potentially problematic; A III: high-stress, problematic. B shows that substantial amounts of glycogen may be found in chilled beef. temperature, however, induce changes in enzyme activities, and in the net charges of, for example, phosphates and glycolytic intermediates, thus greatly influencing the regulation of glycogenolysis and glycolysis. As examples, the scientific community does not fully agree from where protons are derived from postmortem, and what it is that stops glycolysis with more or less glycogen still left in the muscle. More research is needed to focus on postmortem biochemistry where pH and temperature are 'one-way downwards' variables, and the metabolic profile (glycogen, lipid and protein metabolisms in relation to energy supply and recovery) resulting from the various forms of animal stress needs to be studied in more detail.

Glycolysis

KO Honikel[†]

Glossary

Adenosine triphosphate (ATP) buffer ATP is the universal fuel for energy-consuming or energy-producing reactions in cells. A muscle cell, for example, can accumulate only a limited amount of ATP (5–15 mmol kg^{-1} tissue). The surplus ATP is stored in creatine phosphate (CP) as a buffer of energy, which, in a reaction step, is released in the form of a phosphate group and transferred to adenosine diphosphate (ADP): ADP + CP = ATP + creatine.

Catabolism The use of energy-rich compounds provided by food constituents, like carbohydrates, fat, and proteins, to keep up the steady state of metabolic pathways, the active transport of compounds through membranes, and to permit the movement of muscles in animal tissues.

Conditioning After death of an animal, the bloodstream stops and neither provides oxygen or nutrients to the cells nor removes reaction end products from the cells. Within a few hours postmortem, the energy metabolism of the muscle necessary for movement ends and the muscle gets stiff. Then rigor mortis occurs. The time span from death to rigor mortis is called conditioning. After this time, the real aging of the muscle starts.

Glycogenolysis The breakdown of glycogen to glucose-1-phosphate and further on via glycolysis.

Glycolysis (from glucose, an older general term for glucose + lysis degradation) The metabolic pathway that converts glucose ($C_6H_{12}O_6$) into pyruvate ($CH_3COCOO^- + H^+$), and ATP.

Hypoxanthine A purine base formed postmortem by splitting of ribose from inosine.

Inosine Formed postmortem from inosine monophosphate by dephosphorylation.

Inosine monophosphate Formed postmortem from adenosine monophosphate by deamination.

Anabolism versus Catabolism

Plants use energy from the sunlight to convert oxidized products, such as water (H_2O) and carbon dioxide (CO_2), into reduced products, such as carbohydrates. In the overall reaction [I], plants create glucose, releasing free oxygen into the atmosphere.

$$6CO_2 + 6H_2O \rightarrow C_6H_{12}O_6(\text{glucose}) + 6O_2 \qquad [\text{I}]$$

From the monocarbohydrates other compounds are formed, such as polysaccharides and fatty acids in their storable esterified form (triacylglycerols). In summary, the sunlight is used in plants to build up energy-conserving compounds in an anabolic way.

Animals use the energy-rich compounds of plants directly or indirectly through the food chain by breaking them down in a catabolic pathway. Thus, carbohydrates are broken down to pyruvate, which is further metabolized to acetyl-CoA when it meets the catabolic process of fatty acid breakdown in the subsequent citric acid cycle, at the end of which CO_2 and reduction equivalents (XH) are formed that again react with oxygen to form water.

Simultaneously, adenosine triphosphate (ATP) is formed in the oxidative phosphorylation pathway as a unique fuel for most of the energy-converting processes in the body (reaction [II]). Approximately 36 ATP molecules are built up per carbohydrate unit, such as glucose (reaction [II], $\gamma \approx 36$; ADP, adenosine diphosphate; P_i, inorganic phosphate).

$$\gamma ADP + \gamma P_i + 4XH + O_2 \rightarrow 2H_2O + \gamma ATP + 4X \qquad [\text{II}]$$

In living animals, oxygen is available to cells via the bloodstream so that catabolic processes can occur. The blood also transports the energy-rich compounds, such as glucose, to the cells forming the polysaccharide glycogen, a polymer of glucose, in surplus. After the breakdown of glycogen, the blood transports CO_2 and other degradation products to the liver or to the organs of excretion, such as the lungs and kidneys.

Uptake of energy-rich compounds helps in maintaining the organized steady state of reactions in cells, which is required to preserve the living state; moreover, these reactions produce heat to keep the body temperature constant. The surplus energy, as mentioned above, is stored in muscle cells as polysaccharide glycogen and creatine phosphate (CP) or in fat cells as triacylglycerols. When energy is required, these stores of CP, glycogen, and triacylglycerols are broken down, so that their energy can be used for the production of ATP.

In addition to the four chemical elements H, C, O, and P in the nutrients mentioned so far, nitrogen is also needed for the formation of proteins, which in muscles are the most recognizable parts with their filamental and fibrous structure in the muscle fibers. Protein formation requires energy, but protein degradation is used for energy production only at times of starvation.

In slaughter animals that provide muscle for meat, a surplus of energy is usually available. Muscle growth and fat depot formation is the purpose of animal production. Large muscles (requiring protein) and reduced fat depot growth are the aims of modern animal feeding.

At the time of harvest, all well-fed and unstressed animals contain some fat depots, have a reservoir of CP and glycogen, and exhibit a constant and high ATP concentration in their muscle cells.

[†]Deceased.

Catabolism Postmortem

During slaughter, the blood flow stops when the heart stops beating. Oxygen- and energy-rich compounds, such as glucose, are no longer transported to cells and metabolic products are not removed. The tissues sooner or later lose their steady metabolism that supports life. Following this, the well-ordered cellular structures begin to disintegrate.

Nerve cells cease to function within 15–30 min after death. Fat cells break down triacylglycerols to fatty acids very slowly, but postmortem the free fatty acids cannot be used for the formation of other energy-rich compounds, such as ATP, because the two carbon/hydrogen units ($-CH_2-CH_2-$) required for acetyl-CoA ($CH_3-CO-S-CoA$) need oxygen, which is no more available postmortem. Hence, fats remain relatively unchanged in meat.

Muscle cells can still use glycogen as an energy source, but, because of the lack of oxygen, the citric acid cycle and the oxidative phosphorylation pathway no longer function.

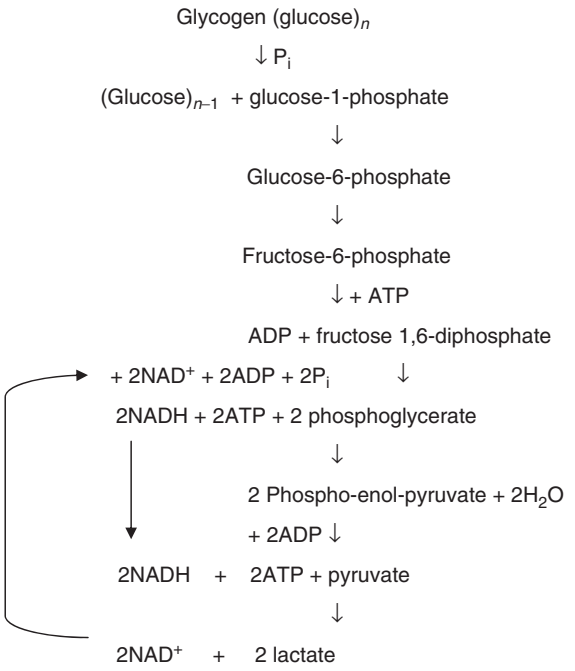
The pyruvate is not decarboxylated (splitting off CO_2) to the acetyl group (CH_3-CO). It is reduced to lactate (Figure 1). This is the endpoint of the anaerobic breakdown of glycogen in muscles postmortem.

The sequence of the breakdown of glycogen to lactate, in equilibrium with lactic acid, can be divided into three steps.

1. Muscle glycogen exists in two forms: low molecular weight proglycogen and high molecular weight macroglycogen molecules. The glycogen molecules consist of branched glucose chains (branching occurs every 4–6 glucose units). *In vivo*, most of the enzymes needed in glycogen metabolism are bound to glycogen. The degradation of glycogen to glucose units is catalyzed by the enzymes glycogen phosphorylase (GP) and glycogen debranching enzyme (GDE). The GDE breaks down the branching points of glycogen. There exist differences in GDE activity between fast twitch glycolytic muscles and slow twitch oxidative muscles. Differences in GDE activity among animal species and among different muscles of an animal also exist.

Glycogen is broken down postmortem via anaerobic pathways to lactate and results in acidification of muscles and has a great influence on meat quality. In pigs and cattle, higher GDE and GP activity exists in the fast twitch glycolytic muscles than in slow twitch oxidative muscles of the same animal. Thus, the high activity of these enzymes enables, for example, a faster rate of glycogenolysis (faster pH fall) in glycolytic M. longissimus dorsi than that in oxidative M. masseter. The relative ratios of GP and GDE activity were higher in fast twitch glycolytic muscles than in slow twitch oxidative muscles of all studied animals.

Chilling significantly decreases GDE activity and below 15 °C porcine GDE is almost inactive. Thus, the activity of GDE does not block rapid glycogenolysis with its fast pH decline when the temperature is high. This may be important in pale, soft, and exudative (PSE) meat, where the pH decreases rapidly at high temperatures, but rapid cooling could limit the activity of GDE and thus glycogenolysis. The effect of pH on GDE activity is only minor at the range normally found in postmortem muscles (pH 7.4 to 5.0). Thus, GDE is not the main factor determining the rate or the extent of postmortem glycogenolysis.



$$(Glucose)_n + ATP + 4ADP \rightarrow (glucose)_{n-1} + 2\ lactate + ADP + H_2O + 4ATP$$

Figure 1 The glycolytic pathway in muscles postmortem by the enzyme phosphorylase.

Both GDE and GP are needed for the complete degradation of glycogen. The activities of these glycogen-degrading enzymes are higher in porcine muscles than in bovine muscles. Some glycogen always remains in bovine muscles after the postmortem reaction sequence. The breaking of a glucose unit provides chemical energy or heat. GDE breaks off only a glucose unit; muscle GP forms a new chemical bond between the glucose unit and an inorganic phosphate.

$$(\text{Glucose})_n + P_i \rightarrow (\text{glucose})_{n-1} + \text{glucose-1-P} \qquad [III]$$

Energy of the glucose–glucose bond is transferred to the glucose–phosphate bond in glucose-1-P (glucose-1-phosphate). After further steps of conversion to glucose-6-P and fructose-6-P, a second phosphorylation with ATP occurs to fructose 1,6-diphosphate (Figure 1).

2. Splitting into C_3 units and energy conversion: the C_6 sugar with two phosphates, fructose 1,6-diphosphate, is split into two C_3-monophosphate units. With this splitting, energy is again released and two ATP molecules from the phosphorylation of two ADP are formed per unit of C_6-sugar.
3. Formation of lactate: finally, lactate is the endpoint of anaerobic glycolysis. This step is necessary to keep up redox equilibrium (NAD^+/NADH), where NAD, nicotinamide–adenine dinucleotide. In the breakdown from glucose to lactate, hydrogen ions are set free and the pH of muscles falls. The overall chemical reaction is shown at the bottom of Figure 1. Starting from glycogen, stochiometrically three ATP molecules are formed per glucose unit by the action of enzyme phosphorylase. If glucose, the monocarbohydrate, is used in the first step of glycolysis, it would consume one additional ATP molecule.

$$\text{Glucose} + \text{ATP} \rightarrow \text{glucose-6-P} + \text{ADP} \qquad [IV]$$

This would lead, at the endpoint of anaerobic glycolysis, to only two ATP molecules per glucose unit.

$$\text{Glucose} + 2P_i + 2\text{ADP} \rightarrow 2 \text{ lactic acid} + 2\text{ATP} \qquad [V]$$

Muscles postmortem use glycogen and GP preferentially and not glucose in anaerobic glycolysis. The free glucose in muscle cells remains unused postmortem.

With these sequences of reactions postmortem, ending in the formation of lactate/lactic acid and a fall of pH from ~7 to 5.5, glycogen is used to convert the energy in glycogen to ATP in order to maintain the necessary steady-state concentrations of ATP of 4–10 mmol kg^{-1} muscle until approximately a half of the glycogen has disappeared (pH ~ 6.3). Depending on muscle type and glycogen concentration in unstressed animals, the final pH ranges from 5.4 to 6.0 (mean ~ 5.5–5.6).

However, before glycolysis starts postmortem, CP keeps up the ATP concentration according to the following reaction.

$$\text{CP} + \text{ADP} \rightarrow \text{ATP} + \text{Creatine} \qquad [VI]$$

CP thus acts as an 'ATP buffer' in muscle cells; it amounts to 20–30 mmol kg^{-1} in resting muscles.

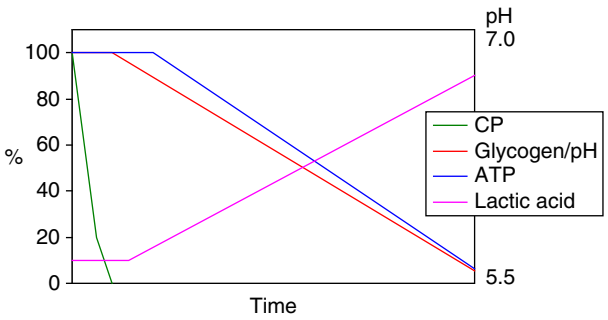


Figure 2 General postmortem changes in muscles. There are variations in concentrations and timescales among muscles and species. The concentrations at death are set to 100%.

Table 1 Timing of glycolysis in various muscles and species

Species	*Muscle*		*Time to reach pH 5.5–5.7 (h)*
Pork	Longissimus dorsi	Normal	6
		Pale, soft, and exudative	1
	Adductor	Normal	8
Chicken	Pectoralis		1.5
Beef	Longissimus dorsi		18
	Adductor		22
	Sternomandibularis		25
Lamb	Longissimus dorsi		16

Three stages of chemical change are observed during postmortem (Figure 2).

1. A period of a few minutes to 30 min after slaughter when no pH fall occurs. The ATP consumption is buffered by CP (reaction [VI]).
2. Fall of pH (from ~7.0) and lactic acid production, with initially constant ATP concentrations (1–3 h).
3. Exhaustion of ATP owing to the lack of glycogen and inactivation of glycolytic enzymes at 1–30 h after death. At the end, when no ATP is available any longer, the pH is ~5.5.

Time Course of Glycolysis

The rate of glycolysis varies among species and among muscles in a carcass. Glycolysis occurs faster in pork and poultry muscles than in beef and lamb (Table 1). In pork muscles, which are prone to PSE meat, the end of glycolysis occurs in 1 h or less (Figure 3). The basis for the various rates of glycolysis is the ATP consumption in muscle cells. Many processes need ATP as fuel: contraction, membrane transport, metabolic processes, and so on. As muscles and species, and with postmortem treatment (chilling rate and electrical stimulation), vary with regard to ATP consumption, the velocity of glycolysis varies accordingly.

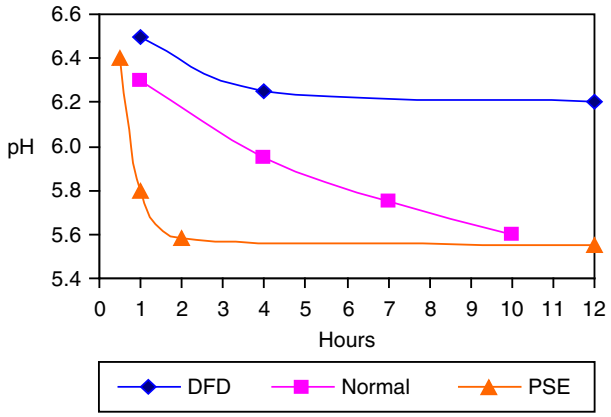

Figure 3 Postmortem changes in PSE, normal, and dark, firm, and dry (DFD) pork muscles.

Structural Changes Postmortem

ATP maintains the integrity of cellular structures, but its energy is also used for contraction – the mechanical work of muscles. The complexity of the involvement of ATP in muscle contraction is described in this article.

If ATP is exhausted, the fibrillar structures change with the formation of permanent bonds across the fibers. The muscle becomes stiff and enters into rigor mortis.

Consequences for Water Retention and Tenderness

With the fall in pH, the surface electric charge of proteins changes in the direction of equal numbers of positive and negative charges (the isoelectric point). As positive and negative charges attract each other, the water-filled myofibrillar structures shrink in volume. Immobilized water or movement-restricted water is squeezed out into the sarcoplasm, where it is much less immobilized. It is kept inside muscle cells primarily by the cellular membranes.

With the destruction of cellular membranes by enzymic (internal) or mechanical action (cutting and mincing), the 'bound' water of living muscle cells within intact cell walls is reduced and water is lost through the action of forces of gravity, pressure, and vacuum. The water-holding capacity (WHC) of meat is reduced by internal forces exerted by pH or shrinkage and disintegration of membranes as well as by external forces.

With the formation of cross-links between filaments, the meat becomes tough. The onset of rigor mortis marks the most rigid interaction in muscle and its toughest state. The rigid state is reduced by enzymic action during the aging period.

Consequences for Shelf Life and Flavor

With the fall of pH to 5.5, growth of a number of spoilage organisms is greatly slowed and meat is generally protected. Lactic acid additionally has a pleasant flavor. Furthermore, ATP that is converted to ADP is further degraded to adenosine monophosphate and from there to inosine monophosphate (IMP). IMP again has a desirable flavor. A long period of storage produces hypoxanthine from IMP via inosine. Hypoxanthine has a bitter flavor. During long storage, more and more free amino acids, such as glutamic acid, are formed from degraded proteins and influence flavor in a positive manner.

Abnormal Postmortem Changes

A serious problem for final meat quality can be created by either a very fast or an incomplete pH fall postmortem. A very fast pH fall (Figure 3) at the prevailing body temperature and above ~40–42 °C, which occurs primarily in stress-susceptible pigs, leads to PSE meat. These characteristics occur as a result of the early membrane leakage and protein denaturation, causing shrinkage of fibers.

An incomplete pH fall (e.g., not lower than 6.2, Figure 3) leads to advanced spoilage due to the high pH (less lactic acid). The reduced formation of lactic acid is due to antemortem stress that has already depleted glycogen stores. This meat is flat in taste because there is less lactic acid. It also converts IMP to hypoxanthine faster. The meat is called DFD meat in general or dark cutting beef (DCB) as less pH-induced shrinkage (higher WHC and firmer structure) leads to a darker color (no denaturation and higher oxygen binding).

Conditioning and Aging

In the period of anaerobic glycolysis during the depletion of available and usable energy compounds, the pH falls to ~5.5. This stage of chemical and structural change is called conditioning and is very responsive to outside factors in the conversion of muscle to meat.

Temperature, time, cutting, and carcass suspension influence the final quality characteristics. After the final pH is reached, the meat aging period occurs.

Glossary

Actin Thin filaments of striated muscle – involved in contraction.

Actomyosin The structure formed when actin and myosin are irreversibly bound during rigor.

Contraction This is an event when the muscle cell contracts on a stimulus and then relaxes.

Contracture This is a prolonged event from which there is usually no relaxation, for example, contracture during cold shortening or rigor shortening.

Cytoskeletal proteins A group of structural proteins not involved in contraction but involved in tenderization.

Ion pump Nerve impulses and muscle contraction function by the exchange of ions through intramuscular lipid bilayer membranes by ATP-driven ion pumps.

Myosin Thick filaments of striated muscle – involved in contraction.

Rigor Occurs when a single muscle fiber runs out of ATP. Rigor mortis occurs when all fibers run out of ATP after the death of an animal. When either of these occurs the actin and myosin cross bridges become bound together causing progressive stiffness.

Sarcoplasmic reticulum The sarcoplasmic reticulum (SR) (formally sarcotubular system) is a network of intracellular tubular bilayer membrane surrounding myofibrils and invaginations of the cell membrane (T tubules). Following a nerve impulse, Ca^{2+} ions from the SR (10^{-4} M) released into the myofibrillar space ($<10^{-7}$ M) initiate a contraction of the sarcomeres. During relaxation, Ca^{2+} ions are pumped back into the SR.

Troponin and tropomyosin These are control proteins on the actin filaments that bind calcium to cause muscle contraction.

Introduction

The main constituent parts of lean meat aside from water (73–75%) and proteins (21–22%) are lipids and lipoids of cellular and subcellular membranes, amounting to approximately 1–2%. Various inorganic ions (1%), vitamins, DNA, and many other precursor compounds such as amino acids and peptides from degraded proteins exist in minor amounts. In muscle of a living animal, the polysaccharide glycogen (0.7–1%) is also present.

Muscle is composed of fiber bundles (Figure 1) that are surrounded by a collagen network, the perimysium. Bundles are an aggregation of fibers; the latter represent the muscle cells. The fibers are between 20 and 100 μm in diameter and vary in length from a few millimeters to several centimetres. The cells are surrounded by a connective tissue sheath, the endomysium, and the cell membrane, the sarcolemma. Within the cell, approximately a thousand myofibrils are arranged in the direction parallel to the long axis of the cell. The myofibrils have a diameter of 1–2 μm and run the whole length of the muscle fiber. The fibrils are composed of thick and thin filaments that are well ordered in repeating units, the so-called sarcomeres (Figure 2).

The filaments are constructed of various myofibrillar proteins. Thick filaments consist mainly of myosin, a protein with a molecular weight of approximately 520 kDa and amounting to approximately 45% of the myofibrillar proteins. Thin filaments are composed of actin (20%), troponin, and tropomyosin (5% each).

Numerous other cytoskeletal proteins are involved in the sarcomere structure. One of these proteins, with 10% of the total myofibrillar weight, is titin. Titin is a high-molecular weight protein (3.7 million Da) of a longitudinal structure running parallel to the thick and thin filaments, which titin seems to arrange in their ordered state.

Contraction takes place when thick and thin filaments slide into each other, thus shortening the length of a sarcomere, which is 2–2.5 μm long in the resting state of a muscle (Figure 2). One sarcomere can shorten by approximately 0.7 μm. It is followed by relaxation.

The filaments, as well as other subcellular structures such as sarcoplasmic reticulum (SR), mitochondria, and lysosomes, are imbedded in the fluid of the sarcoplasm. The sarcoplasm contains dissolved proteins, salts, and other low-molecular weight compounds. It is believed that approximately 20% of the water of the cell is in the sarcoplasm; the major part is located in the myofibrillar space between and within the filaments.

Muscles serve the purpose of movement. Muscles in a living organism contract in response to a nerve stimulus that is transmitted into the muscle cell via t-tubules. Within the muscle cell, the contraction is caused by Ca^{2+} ions that increase to as high as 10^{-4} mol l^{-1}, and are released from the SR and bind to the troponin of the actin filament. Contraction – relaxation is a balance between Ca^{2+}released from the SR during a stimulus to bind to troponin on the actin filament (to initiate the contraction) and then reuptake of Ca^{2+}into the SR (relaxation). In the relaxed state, the Ca^{2+} concentration around myofilaments is approximately 10^{-7} mol l^{-1} or lower. Contraction uses adenosine triphosphate (ATP) as fuel. In muscles after death, before the onset of rigor mortis at a time

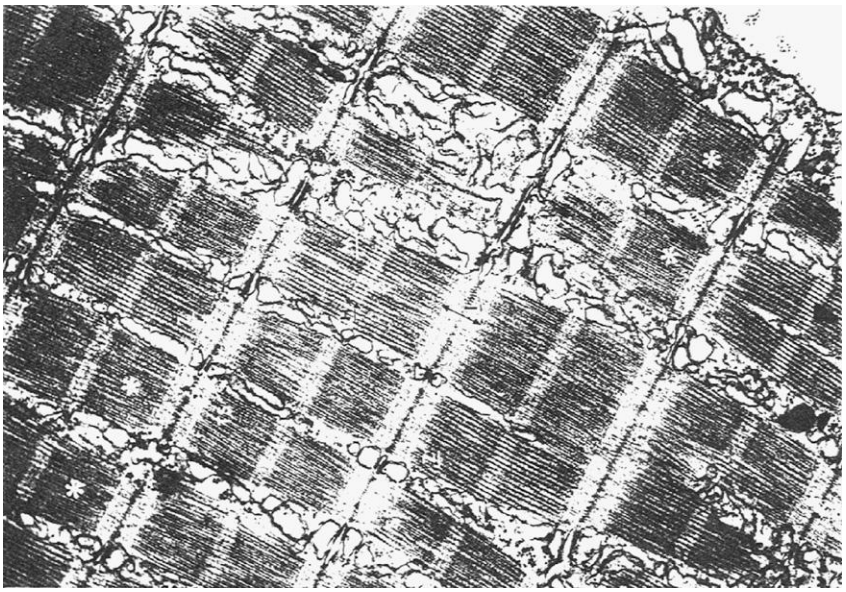

Figure 1 Electron-micrograph of a cross-striated muscle.

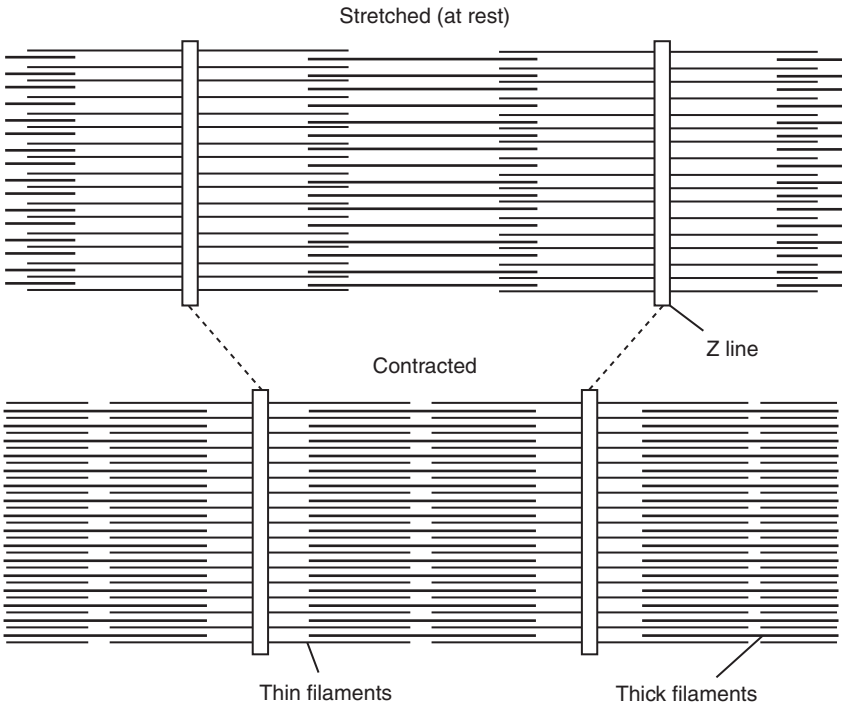

Figure 2 Schematic diagram of sarcomere structure at rest and contracted. Z-line and Z-disks are synonyms.

when ATP is still present in sufficient concentration, the myofibrils can contract if Ca^{2+} ions are released from the SR. This happens if muscles are chilled rapidly or very slowly (Figure 3). In both cases, more Ca^{2+} ions will be released and faster from the SR than the ATP-driven Ca^{2+} pump is pumping them back into the SR.

As mentioned above, on contraction the basic units of the fibrils (the sarcomeres) shorten by sliding of the thick and thin filaments into each other. As this occurs, the myofibrillar space decreases and a part of the water in the fibrils must be translocated into the sarcoplasmic space. As a contraction usually lasts only a short time in a living animal, the exchange of water from one substructure to another is rather short term and reversible. In contrast, after continuous shortening has occurred, as may be the case post mortem, the displacement of water from the myofilaments permanently increases the amount of sarcoplasmic water. This water is then no longer immobilized in and between the filaments. The effect of displacement is

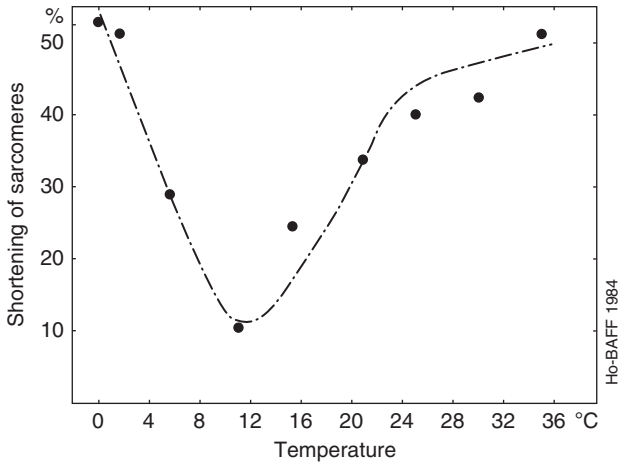

Figure 3 Influence of temperature on sarcomere shortening in the prerigor state; original sarcomere length (0% shortening) was 1.9 μm; m. longissimus dorsi of pork.

further enhanced after death as the pH falls from 7.0 to a value of approximately 5.5, causing shrinkage of myofilaments, but the still-intact cellular membrane that keeps the water as intracellular water for some time becomes permeable and water leaks out, appearing as drip at the surface.

Relaxed State of Muscles

In cross-striated muscles, from which the meat one eats comes, the filaments and fibrils are subdivided into sarcomeres limited by the *Z*-disks (Figures 1 and 2). These are the basic contractile units of the muscles. The sarcomeres are able to contract in the presence of ATP. As well as being used for contraction and the Ca^{2+} ion pump, ATP also keeps the thick and thin filaments separated (Figure 4) after the end of contraction (end of nerve impulse).

Thus, ATP has three functions in muscle contraction:

- It releases the myosin head from its position on the actin filament.
- By hydrolysis to adenosine diphosphate (ADP) plus inorganic phosphate, it releases chemical energy, which is converted to mechanical energy by 'spanning,' i.e., backward movement of the myosin head.
- At the end of a nerve impulse, the ATP-driven calcium pump transports Ca^{2+} ions into the SR, the disappearance of Ca^{2+} ions around troponin causing a positional change of the troponin/tropomyosin system and thus sterically inhibiting the binding of myosin to actin. The relaxed state of muscle is reached.

Contraction

Figure 4 shows that the cycle of contraction requires ATP as fuel to 'span' the myosin head. Contraction also requires Ca^{2+} ions, which bind to troponin to make the actin surface open for myosin binding. The 'spanned' head of myosin releases like the spring in a mouse trap after binding to actin, its mechanical energy moving the myosin head forward in relation to actin. ATP again releases the bound myosin from actin allowing relaxation.

Rigor Mortis

With the continuous production of ATP from ADP+phosphate via the anaerobic breakdown of glycogen to lactic acid/lactate, the pH falls. Owing to the pH fall, its influence on the various enzymes in the glycogenolysis pathway, and the diminishing concentration of glycogen, the resynthesis of ATP slows down. Below a certain concentration of ATP in the muscle cell the release of myosin heads from actin no longer takes place. Myosin and actin remain bound together to actomyosin (Figure 4(c)). Additionally, with the low ATP concentration the ATP-driven ion pump cannot cope with the release of Ca^{2+} ions from the SR. The onset of rigor mortis starts. Both events:

1. the binding of ATP to the myosin head (Figure 4(a)) ends and
2. the efficiency of the ion pump of the SR membrane is strongly reduced.

The time, post mortem at which these events occur is dependent on initial glycogen concentration, the temperature, and the pH as shown in Table 1 for the latter two factors in comparison to porcine and bovine muscles. The higher the temperature, the time of onset of rigor occurs earlier due to a faster turnover rate and at a higher pH value. The onset of rigor mortis is an event that eventually encompasses the whole muscle, but it occurs sequentially as each individual fiber runs out of ATP (termed rigor) depending on glycogen content in a cell. Therefore, not all possible actin–myosin cross-bridges in the muscle as a whole form at the same time. Owing to the differences between the cells the muscle can contract. The rigor contracture of a muscle in a carcass remains in the range of 10–15% shortening, whereas, as shown in Figure 3, the sarcomere length of a small excised piece of muscle produces a tension and gradually contracts much more – up to 50% of its resting length at higher temperatures.

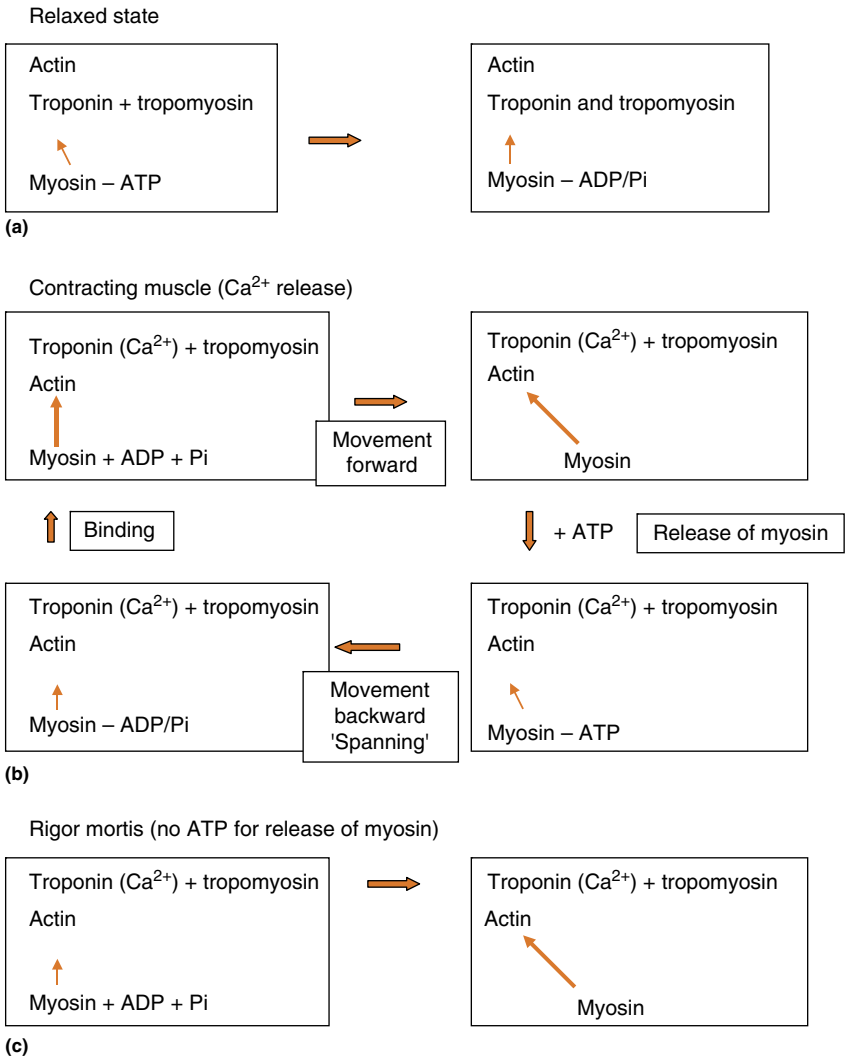

Figure 4 Schematic of the contraction cycle, relaxed state, and rigor muscle. The placing of troponin and tropomyosin, the regulating proteins, between myosin and actin symbolizes steric hindrance of the two regulatory proteins.

Table 1 Time and pH of onset of rigor mortis in two animal species at preset temperatures in m. sternomandibularis

Effect of holding temperature on rigor mortis

Species	*37 °C*				*20 °C*			
	1 h pH	*Onset of rigor mortis*		*Ultimate pH*	*1 h pH*	*Onset of rigor mortis*		*Ultimate pH*
		Time (h)	*pH*			*Time*	*pH*	
Bovine	6.85	3	6.05	5.5	6.8	9	5.85	5.5
Porcine	6.6	1.5	5.6	5.55	6.7	5	6.0	5.6

Rigor shortening takes place at the end of post mortem glycogenolysis and occurs at all temperatures. In contrast, the shortening at low temperatures called cold shortening (see Section Influence of temperature) takes places in the middle of glycogenolysis in the prerigor state. In theory, cold shortening could be reversed by enhancing the muscle temperature as enough ATP exists. Rigor shortening, the onset of rigor, and the rigor mortis itself cannot be reversed, only delayed, as they all occur due to the lack of ATP.

There are three abnormal types of rigor mortis:

1. If a muscle is frozen fast in the prerigor state, the forming of ice crystals prevents a cold shortening-like contraction. If such a frozen muscle is thawed fast or slow partially by ice

crystals disintegrated subcellular membranes like the SR release Ca^{2+} ions and an extreme contracture (<50% of the resting length of sarcomeres) occurs called thaw contracture. The final status is called thaw rigor. Not only are SR membranes disintegrated by the ice crystals but also the cellular membranes are not fully intact, and thus an extreme high and fast drip loss is observed.

2. The opposite sequence of events occurs in PSE muscles of pigs. The fast glycogen breakdown in PSE-prone muscles (pH in 45 min post mortem <5.8) is caused by a high ATP turnover by futile cycling of intermediates during the glycolytic pathway and/or the futile intention of pumping Ca^{2+} ions back via the leaky SR membrane. The latter is disintegrated by high temperatures >38 °C. The lack of ATP throughout the muscle leads to a fast onset of rigor mortis and full rigor within a short time. There is no or little rigor shortening in PSE muscles.
3. In electrically stimulated bovine muscles the pH falls within the stimulation period of a few minutes up to 0.6 pH units. During stimulation the temperature increases slightly to approximately 39 °C. This means that at pH values of approximately 6.5 and lower temperatures >37 °C prevail. The onset of rigor mortis in these stimulated muscles occurs at higher pH values (see Table 1) than in nonstimulated carcasses that are chilled during the prerigor pH fall. Thus, the onset of rigor and the development of full rigor occur fast and the rigor shortening is limited. The time within the rigor-shortening area of Figure 5 is rather short.

After full rigor mortis has occurred the binding of the myosin head to actin remains. Aging does not release the actomyosin complex. Other myofibrillar structures are involved in aging and tenderizing the meat.

It should be mentioned in this context that the addition of diphosphate (not mono- or triphosphate) can separate the myosin head and actin. However, a contraction cannot occur. But due to the release of actomyosin the myofibrillar structure can swell with the addition of water and salt. This reversal of the rigor mortis is used in sausage manufacturing for enhancing the water-holding capacity of meat batters. The pH-induced shrinkage can be overcome.

Influence of Temperature

It is well known that with lower temperatures the movement of molecules becomes slower and chemical reactions take place at reduced rates. Membrane transport is also retarded at lower temperatures. In a muscle, the membrane transport of Ca^{2+} out of and back into the SR is essential for switching muscle contraction on and off. Membranes are lipid bilayers that function in warm-blooded organisms at their normal body temperature. Lowering the temperature reduces their functionality. The membrane of the SR keeps Ca^{2+} ions at a concentration of 10^{-3}–10^{-4} mol l^{-1} inside the SR. At the myofibre level, the Ca^{2+} concentrations in the relaxed state are approximately 10^{-7} mol l^{-1}.

With a Ca^{2+} gradient of a thousand to ten thousand times concentration difference, the membrane is not totally impermeable. There is thus a small Ca^{2+} efflux into the myofibrillar space. With falling temperatures, the ATP-driven Ca^{2+} pump acting from the myofibrillar space to the SR becomes slower and the resulting efflux gradually increases. In bovine muscles at approximately 15 °C, the efflux and pump-driven influx are equal. Below 10 °C, the efflux is distinctly higher than that pumping into the SR. This means that as the Ca^{2+} concentration around the filaments increases, Ca^{2+} ions bind to troponin and, owing to the presence of ATP, a contracture occurs (Figures 3 and 4). The lower the temperature, the higher the Ca^{2+} concentration at the myofibres becomes and the more intense the contracture will be. Because of its occurrence at cold temperatures, this phenomenon is called 'cold shortening.' The degree of cold shortening is dependent on temperature but also on muscle and species. Darker muscles with more myoglobin also contain more mitochondria and are often the so-called slow-switch muscles with less SR than fast-switch lighter

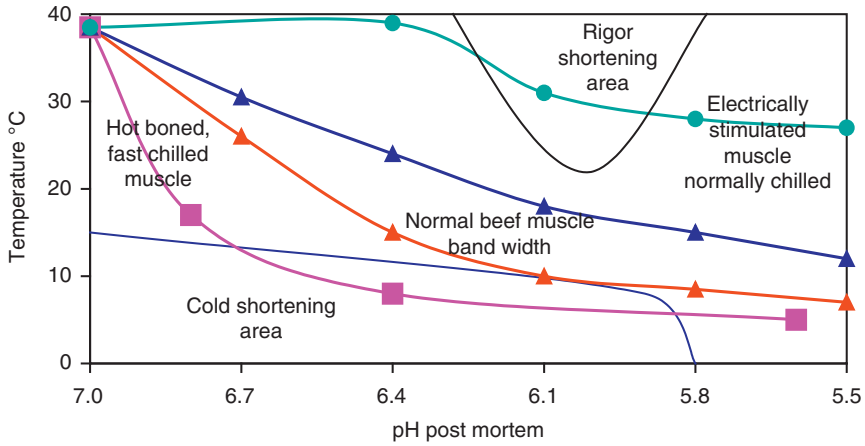

Figure 5 pH–Temperature relationship of a beef carcass chilling (band width due to different depth and metabolism of muscles and chilling regime) and the cold-shortening and rigor-shortening areas. For electrically stimulated muscles with inadequate stimulation, some rigor shortening can occur. With adequate stimulation, not only is rigor shortening insignificant but other advantages of stimulation such as faster and more complete tenderization emerge.

muscles. Mitochondria also contain Ca^{2+} ions, which are released in the anaerobic state. The presence of less SR means less effective Ca^{2+} pumping. Thus, the often darker slow-switch beef muscles start to contract below 15 °C and the lighter pork m. longissimus dorsi (fast-twitch muscle) below 7 °C.

Influence of Adenosine Triphosphate

As described in the article on glycolysis, the state of life is a metabolic equilibrium that keeps the ATP concentration in a muscle constant. An unstressed meat animal contains approximately 4–10 mmol ATP per kg of muscle at the moment of slaughter, depending on animal species and muscle type. The subsequent anaerobic glycogenolysis keeps the ATP concentration constant for some time. In addition, adenylate kinase converts the ADP that is formed back to ATP plus adenosine mono phosphate (AMP) as in eqn [1].

$$2ADP \rightarrow ATP + AMP \quad [1]$$

Postmortem, at a glycogen concentration of approximately 50% of its original value, the ATP concentration starts to fall, depending on the temperature dependence of the glycolytic enzymes as the meat is chilled. The pH falls in parallel. Below a certain ATP concentration, at temperatures below 15 °C and with falling pH, the Ca^{2+} pump in the SR membrane is unable to remove the Ca^{2+} efflux from the SR. Pumps are proteins and they are affected by pH and temperature. Whereas at 18 °C and pH 6.0 the SR Ca^{2+} pump is still effective, inactivation occurs at temperatures as high as 25 °C and below pH 6.0. A pH value of 6.0 or lower means lower ATP concentrations, but a contracture is still possible. Shortly afterwards, however, the ATP becomes exhausted and rigor mortis occurs.

Cold shortening and rigor shortening both occur for a similar reason – an increase in Ca^{2+} ions on the myofibres. Cold shortening is a prolonged contracture that occurs due to inefficiency of the Ca^{2+} pump in the SR membrane – Ca^{2+} leaks out and thus the fibers contract to produce a tension. Cold shortening commences as soon as the temperature falls below a certain value (15 °C in unfixed beef muscles, 7 °C in unfixed pork muscles, and close to 2 °C in poultry). Rigor shortening occurs gradually as each fiber contracts sequentially and late in glycgenolysis – it is completed at rigor mortis. As rigor shortening is greatest at high temperatures, a proper chilling regime prevents rigor shortening in a normal glycolysing muscle. Cold shortening can be prevented by moderate chilling or acceleration of glycolysis, example, by electrical stimulation.

Figure 5 shows a general scheme of the temperature–pH postmortem pH relationship for unstimulated beef carcasses. Normal chilling does not cause either cold shortening or rigor shortening in the temperature band between the cold-shortening and rigor-shortening areas. However, for electrically stimulated muscles, it could be expected that as the pH falls it could pass through a rigor-shortening area, and become tougher than expected, unless it was chilled rather fast. However, this does not happen in situations where it is used commercially and good electrical stimulation is used (sufficient current and duration). The paradox arises because of the sequential nature of rigor occurring in individual muscle fibers – those individual muscle fibers that enter rigor immediately or soon after electrical stimulation are protected from any further shortening. However, in some examples with relatively ineffective electrical stimulation, situations can arise where some rigor shortening could occur. Hot-boned and fast-chilled muscles may enter the cold-shortening area. Shortening in general, however it arises, is not good for the tenderness or the water-holding capacity of meat.

Influence on Tenderness

In an unshortened muscle, the sarcomeres are between 1.8 and 2.0 μm long. Overstretched muscles, such as the fillet in a carcass, can be up to 2.5 μm. With the onset of rigor mortis, because of the enhancement of Ca^{2+} concentration and the pH-driven shrinkage of filaments, the sarcomere length is reduced to approximately 1.6–1.8 μm. This represents approximately 10–15% shortening. Cold-shortened and rigor-shortened muscle cells are reduced by up to 50%. Even after aging shortened muscle exhibits enhanced shear forces (Figure 6). The parallelism between Figure 3 and Figure 6 is evident.

Influence on Water-Holding Capacity

As already noted, the water in the muscle cells (~75% by weight) is bound primarily within the filamental structure. The mobility of this water is retarded and it is referred to as immobilized water. Furthermore, the cellular membrane with its lipid bilayers keeps the water inside the cells. Even after changes within the myofibrillar structures when water is moved to the sarcoplasm it stays for some time within the intact cell wall.

With falling pH, postmortem and/or shortening of sarcomeres, the fibrillar structure shrinks and water moves to the sarcoplasm. This water is fairly freely mobile, but as mentioned above it is initially kept inside the cell. With ongoing aging, however, the water passes through the membrane into the extracellular space collecting between the cells. Whereas in muscle of a live animal at approximately pH 7 the filaments take up most of the muscle space, with postmortem shrinkage

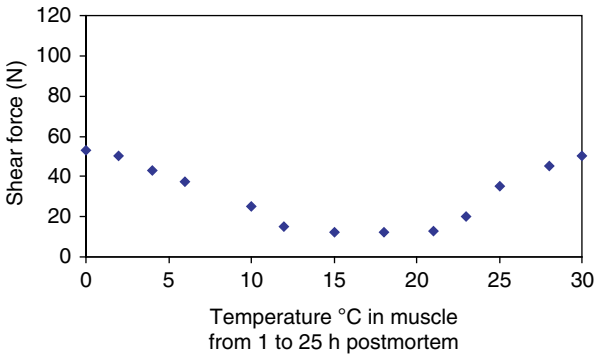

Figure 6 Shear force (N) in beef m. longissimus dorsi muscle pieces kept unrestrained at the temperatures indicated from 1–25 h postmortem; subsequent ageing was at 5 °C for 2 weeks.

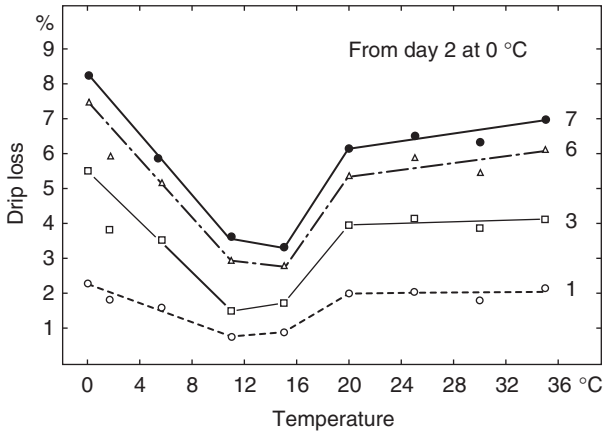

Figure 7 Relationship between temperature of incubation during the first 24 h post mortem of m. cleidomastoideus and drip loss of muscle cubes (about 30 g) after storage for 1, 3, 6, and 7 days postmortem. From day 2 the samples were stored at 0 °C.

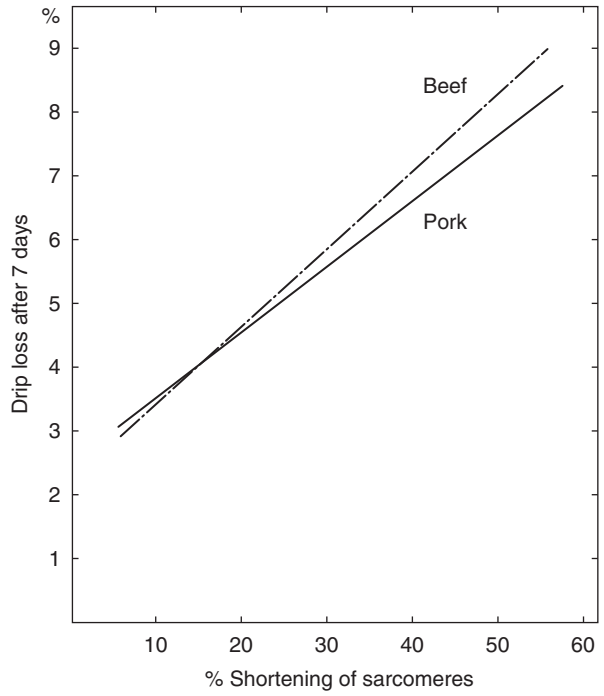

Figure 8 Relationship of cold shortening and rigor shortening on drip loss at 7 days post mortem. At 1–24 h the muscles were kept between 0 °C and 32 °C. All muscles were stored at 2 °C from day 1 to 7 in beef and pork: m. longissimus dorsi.

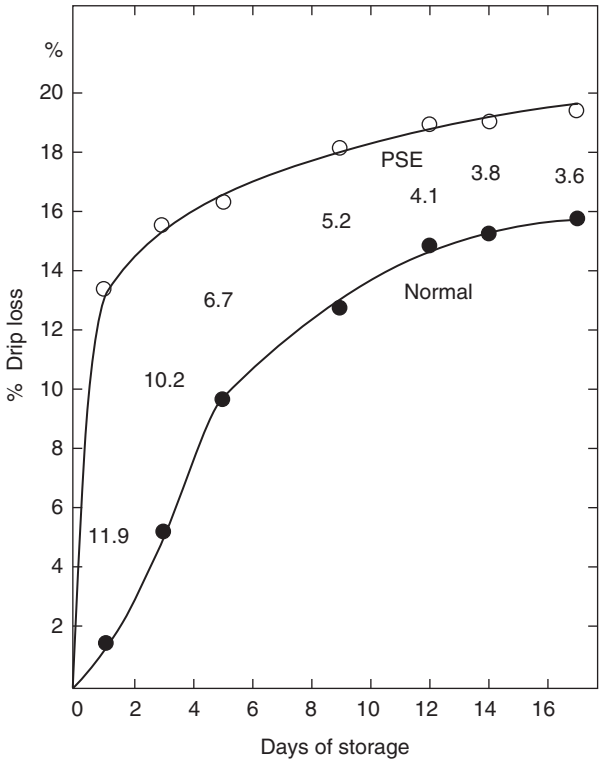

Figure 9 Drip loss from the m. longissimus dorsi of a pig carcass stored at 0 °C; the same muscle was taken for both experiments with $pH_1 = 5.8$; PSE meat was produced by slow chilling (25 °C air up to 120 min postmortem); normal meat by rapid chilling (1 h postmortem in a 20 °C water bath); the figures between the curves represent the difference in drip.

of the fibers the intracellular sarcoplasmic space increases and the extracellular space fills with water. In a muscle at approximately pH 7, more than 95% of the water is within cells; some days postmortem, approximately 15% is in the extracellular space. From these capillary-like channels, the water appears as drip at the surface of the meat. All kinds of meat undergoing a pH fall from approximately 7.0 to 5.5 lose drip water. Drip loss commences at 1 day post mortem following rigor mortis and increases with time of storage (Figure 7). DFD (dark, firm, dry) meat with a high ultimate pH (>6.2) loses less drip.

If in addition to the pH-induced shrinkage a contraction occurs as shown in Figure 2, as mentioned above, the space of the contracted sarcomeres is further reduced. This means that even more water is forced from the fibrillar structures and consequently enhances drip during storage.

In cold-shortened and rigor-shortened muscle, the drip loss increases (Figure 7). This is evident in Figure 8. In beef and pork, the shortening has a linear relationship to drip loss at day 7.

In addition to pH-induced fiber shrinkage, the cellular membrane plays a role in drip loss. In muscle prone to the PSE (pale, soft, exudative) condition, the high temperatures shortly after slaughter (40–42 °C) and the already low pH lead to early membrane destruction. In PSE muscles, drip loss occurs with virtually no time lag (Figure 9). The strongest increase occurs in the first 2 days. This seems to be a minor issue in beef and lamb.

In cold-shortened and rigor-shortened muscles there is a close relationship between shortening on the one hand and shear force and drip loss on the other, as can be seen by comparison of Figures 3, 6, 7, and 8. Rigor mortis is unavoidable, but shortening can be avoided.

Slaughter-Line Operation and Pig Meat Quality

V Santé-Lhoutellier and G Monin, INRA, Saint Genès Champanelle, France

This article is a revision of the previous edition article by G Monin, volume 1, pp. 338–343, © 2004, Elsevier Ltd.

Glossary

Blood splash The presence of blood in the muscle leading to increasing meat trimming.
Carcass dressing Different operations leading to smooth skin surface.
Lairage Animal handling facilities at abattoirs, including pens, waterpoints, and shower.
On farm handling Operation of gathering the animals before loading them in the truck for transportation to the abattoir.
Stunning A method to render animal unconscious.

Introduction

The pig slaughtering process includes a number of operations, each of which has an effect on meat quality: transportation, lairage, driving the pigs to stunning, stunning, exsanguination, dressing, and chilling the carcasses. Over the past few decades, huge progress has been made with respect to mechanization and hygiene. However, in developed countries, meat processors, consumers, and authorities alike have all continuously increased their quality requirements, while at the same time, legislation aimed at protecting animals has been considerably strengthened. These trends have sparked abundant research, which has resulted in recommendations designed to optimize meat and carcass quality plus animal welfare.

Stress and Meat Quality

Many of the major traits governing pork quality, including technological and sensory qualities, are affected by animal conditions at slaughter. The slaughter process subjects the animals to a number of aversive situations, i.e., situations they perceive as aggressive, which induce psychological and physical stress. Reactions include various physiological and metabolic changes, the most important being increased blood 'stress hormones' (catecholamines and corticoids) and increased body temperature. High body temperature at death accelerates postmortem metabolism, thus favoring the occurrence of pale, soft, and exudative (PSE) meat. Adrenaline (one of the catecholamines) lowers muscle glycogen levels, which can increase meat pH and tends to prevent PSE. Preslaughter stress thus has contrasting effects on pork quality. Prolonging animal exposure to aversive conditions before slaughter will tend to increase meat pH, which improves meat quality, as long as the pH stays under a threshold pH value corresponding to dry, firm, and dark (DFD) meat. Intense stress applied shortly before or during slaughter tends to accelerate muscle metabolism and increase muscle temperature, giving rise to accelerated postmortem muscle acidification which favors PSE meat.

Beyond physical quality, the concept of ethical quality is becoming increasingly paramount for consumers. Ethical quality is related to production systems that are more or less environmentally friendly and socially acceptable. Animal welfare is one of the main components of ethical slaughter conditions.

Transport from the Farm to the Abattoir

In industrialized countries, most animals are transported from the farm to a specialized preslaughter facility called lairage. The abattoir will generally anticipate a lairage time to serve as a buffer between the animal's arrival and slaughter, to ensure a smooth and consistent workflow rate.

On-Farm Handling and Loading

The transfer of pigs from the farm to the abattoir is difficult for both workers and the animals. The animals are suddenly confronted with a situation that is new to them: the change of environment, mixing with unknown animals, noise, etc. Furthermore, pigs have to be fasted before transportation, because slaughtering pigs while they have a full digestive tract makes evisceration more difficult: full stomachs often get pierced, so their content can contaminate the carcass. Moreover, fasting has two important positive effects: it reduces mortality during transport and tends to increase meat pH by reducing muscle glycogen content. Fasting pigs for more than 24 h would result in significant carcass weight loss. To avoid such a negative effect, it is sometimes recommended that the last feed should be given 18–24 h before slaughter. However, there is no general consensus on the ideal duration of fasting before slaughter, and Danish statutory requirements, for example, state that pigs must be fed and watered if they are kept more than 12 h in lairage in order to meet animal welfare requirements.

On the farm, a loading area is recommended. If the premises are not correctly designed, driving animals to trucks can be prove difficult and lead to rough handling by the personnel. Brutal handling must be avoided, not only for ethical but also economic reasons. In fact, beyond the potentially harmful effects on meat quality, rough handling can result in carcass defects such as bruising, scratches, and lacerations that can ultimately justify rejection of carcass cuts, especially for dry-curing ham. Use of electric goads must be avoided as far as

 doi:10.1016/B978-0-12-384731-7.00100-8

possible. Blows with rubber tubes and, even worse, blows with metal or wooden objects must be absolutely banned. A well designed loading area: (1) allows solely those animals sorted for slaughter to be fasted, thus avoiding negative effects on the growth of the remaining pigs; (2) facilitates loading of the pigs into trucks, thereby diminishing the stress factors leading to carcass and meat quality defects; and (3) decreases the sanitary risk tied to allowing transport staff to enter the farm. Loading the pigs is made easier by the use of elevator floors. If ramps are used for access to trucks, their slope should be less than 20°.

The pigs should be led from the fattening pens into the loading area in small groups, preferably 4–6 h after their last meal. If possible, mixing animals from different fattening pens should be avoided during the waiting period and throughout transport so as not to disturb the established social hierarchy, which would result in fighting and aggressive activity. Fighting causes skin damage and bruising, as well as muscle glycogen loss that can result in DFD meat. Manual or automatic showering is desirable, especially during hot weather, in order to calm and refresh the pigs. The pigs should have access to water, as dehydration is a source of decrease in carcass weight and is particularly a risk when the temperature is high.

Transportation

Trucks used for transport must be covered, effectively ventilated and equipped with nonskid floors to prevent the animals slipping and falling, which can result in bruising, dislocations, and even fractures. To avoid high levels of mortality, the temperature should not exceed 30 °C inside the vehicles to keep within the pigs' thermal neutrality range, although this requirement is difficult to meet in many countries. Where high temperatures are unavoidable, showering can help. Loading density is important from both economic and animal welfare perspectives. When density is increased, transport cost decreases, whereas aggressiveness and consequently fighting, skin damage, and rectal prolapses increase with density. The loading density recommended in the European Union is 235 kg m^{-2} for animals of 90–100 kg body weight. In fact density should be adapted according to ambient temperature, and should be decreased when temperature increases. In Canada, the recommended densities are as follows: 294 kg m^{-2} at a temperature lower than 16 °C, 263 kg m^{-2} between 16 and 23 °C, and 244 kg m^{-2} above 23 °C. There is continued debate over the effects of loading density on meat quality traits. For short journeys, the effect is minor, but dependent on genetic type. For long journeys (more than 36 h), there are some reports that meat pH is increased.

Transport duration and driving conditions have effects on meat quality. The effects of short transportation are minor if conditions are correct (smooth driving, efficient ventilation, and loading density not too high). Frequency of PSE meat decreases and frequency of DFD meat increases with transport time, as a consequence of the muscle glycogenolysis activated by increased blood adrenaline, physical activity and fatigue. There is little experimental data on the effects of long transport times. Feeding pigs during long transport reduces body weight loss but has little effect on meat pH. European Union guidelines recommend that when transport duration is exceeds 24 h, the pigs should be unloaded, fed, and rested for 24 h. However, some specialists consider that unloading and reloading is undesirable as it sparks muscle activity and excitation, making it preferable to feed and rest the pigs inside the vehicle.

The recommendations for unloading the pigs on arrival at the abattoir are much the same as those given above for loading at the farm. The unloading area should be well illuminated, the ramps and the off-loading area should be flat or have a positive slope, the corridors should be wide enough to allow several pigs to walk abreast, be straight or have a long radius of curvature, and open into pens that can be divided by mobile partitions or inner doors. Brutal handling should again be prevented, and as far as possible, pigs originating from different fattening pens should not be allowed to mix.

Lairage at the Abattoir

Pigs must spend a minimum time in lairage in the abattoir so as to minimize meat quality defects. Slaughter immediately after transport can result in an increase in the frequency of PSE meat (Table 1). This is partly attributed to the increase in body temperature that occurs during transport, which can be reduced during resting in the lairage. Lairage at the abattoir should not have to take more than a few hours if the recommendations given above for loading and transportation are followed. In fact, lairage provides the opportunity for further aggressive interactions that activate muscle glycogenolysis and can ultimately lead to DFD meat. The optimal lairage time is 2–4 h. It is consequently necessary to provide a lairage capacity of at least six times the number of pigs killed per hour. It is advisable to shower the pigs during lairage if the ambient temperature is higher than 15 °C. This accelerates the return of body temperature to normal resting values, and generally calms the animals. Showering is carried out using fixed and preferably programmable facilities allowing the showering period to be broken down into stages; for instance, pigs in lairage for 2 h seem to prefer several short showers rather than one long continuous shower.

Table 1 Frequency of PSE and DFD meat in relation to lairage period. PSE was evaluated during cutting the day after slaughter. DFD is defined as a pH value in at least one muscle >6.5 or pH value in two or three muscles >6.1 on the day after slaughter

Time in lairage (h)	*Number of pigs*	*PSE (%)*	*DFD (%)*	*Total defects (%)*
–0	175	13.1	3.4	14.5
–2	174	7.5	10.3	17.8
–4	177	4.0	6.2	10.2
–24	81	2.5	7.4	9.9

Slaughtering

Stunning and Exsanguination

Driving pigs to stunning constitutes a stress factor with potentially marked effects on meat quality, as it occurs immediately before slaughter. The path from lairage area to stunning must allow several pigs to walk abreast in order to respect their herd instinct and avoid unnecessary fear and excitement. It must be well illuminated and, if possible, be straight with solid walls. In most cases, the pigs are led in single file to a restraining conveyor which introduces them into the stunning machine. Time spent in the conveyor should be as short as possible, as it is a cause of excitement. In the most modern stunning facilities, restraining conveyors are replaced by straddle conveyors that support animals under the sternum and belly and are less aversive for the pigs. In some carbon dioxide gas stunning facilities, pigs are allowed to enter the machine in small groups (five to six animals). It has been reported that group stunning considerably reduces excitement and consequently PSE frequency, whereas other studies have found no effect on occurrence of PSE but higher skin lacerations.

Stunning of meat animals is mandatory in industrialized countries. This obligation aims to:

- Reduce animal suffering.
- Make the work easier and thus allow higher workflow rates.
- Improve worker safety.

Modern abattoirs rely on two main stunning methods: electrical and gas stunning (e.g., CO_2). Electrical stunning is most widespread, but gas stunning is making headway. Electrical stunning can be carried out with a low-voltage (70–90 V) electrical current, which needs a 10–15 s application for efficient immobilization. However, it does not guarantee complete insensitivity, making it unacceptable from an animal welfare standpoint. Higher voltages (250–270 V) can reduce application times down to1 s or less. High-voltage stunning is preferred on slaughter lines with high workflow rates, but it entails full automation of the stunning system (restraining, electrode positioning, application of current, and animal ejection) to ensure staff safety. If the electrical current is applied through the head only, most pigs survive and may recover consciousness if exsanguination is delayed. Current can be applied head-to-back or head-and-heart to allow flows through the heart, which gives rise to cardiac fibrillation leading to irreversible cardiac arrest. In the most perfected automated systems, optimal positioning (ear-to-ear) of the main electrodes is obtained by video-image control.

Gas stunning is achieved by immersing the pigs in an air–carbon dioxide mixture (generally 65–80% carbon dioxide) until they lose consciousness. This stunning method has been criticized as less humane than electrical stunning due to the long time required for loss of consciousness, i.e., several seconds for the gas stunning. The real level of discomfort generated by gas stunning has been a matter of much debate, and needs to be fully elucidated. However, gas stunning also presents some advantage from the animal welfare point of view: it enables the pigs to be handled in groups, and avoids the risk of misplacement of the stunning electrodes.

Electrical stunning can generate violent muscle contractions and convulsions, which generate blood spots, blood splashes and even fractures, often associated with extended hemorrhaging, which requires trimming consequently resulting in financial losses. Shoulder fractures are frequent when pigs are electrically stunned while standing, and their prevalence is considerably reduced by using a restraining device. Vertebral fractures are observed when applying current head-to-back. In this case, there is relatively little hemorrhage due to the cardiac arrest, which stops blood circulation. Blood splashes are reportedly less with high voltages, and also occur less frequently when using straddle conveyors, in which pigs are not pressed on their sides as with retraining conveyors (Table 2). To minimize blood splashes, the time interval between stunning and exsanguinations should be kept as short as possible, preferably at less than 10 s. This is made possible by horizontal bleeding, where the pig is ejected from the stunning machine directly onto the bleeding table and shackling and hanging take place after, rather than before, bleeding. Horizontal bleeding also yields better meat quality, as the pigs struggle less, thus reducing the rate of postmortem muscle acidification. Moreover, with vertical bleeding, the muscles of the leg by which the pig is suspended are subject to strong constraints and show a faster pH drop than the muscles in the free leg. Vertical bleeding is, however, preferable in terms of the bacteriological quality of the blood, provided that sticking is done with a hollow knife.

Fractures and hemorrhages are relatively rare with gas stunning (Table 2), which is another factor explaining why more and more slaughter plants are implementing this method.

Carcass Dressing

In most countries, the first step in carcass dressing is dehairing. The most common carcass dressing procedure involves

Table 2 Frequency of blood spots in deboned pig loins according to stunning method quality

Stunning conditions	*♯ Abattoirs*	*Class 1 (%)*	*Class 2 (%)*	*Class 3 (%)*
High voltage, high rate, restraining conveyor	5	51.6–54.5	29.0–42.0	4.0–18.8
High voltage, medium rate, restraining conveyor	4	38.0–61.5	27.2–48.0	1.9–23.3
Medium voltage, high rate, straddle conveyor	2	70.5–90.7	9.3–27.4	0–2.1
Carbon dioxide stunning	1	85.0	14.5	0.5

successive scalding, dehairing, singeing, and polishing operations. Dehairing can be performed by singeing and scratching without previous scalding, but it results in appearance defects such as burst skin and a less smooth skin surface. Two processes can be used for scalding, which is carried out at a temperature of 60–65 °C: immersing the carcass in hot water for a few minutes, or steam-scalding. Even though the skin surface is submitted to high temperatures, there is no noticeable increase in deep muscle temperature during dehairing, and consequently this operation has little effect on meat quality other than cooking at the sticking wound and possibly entry of bacteria into the sticking wound. In some East-European and Far-East countries, where the pig leather industry is active, pigs are dehided. This method (dehiding) is better from both microbiological and meat quality perspectives. Chilling is more efficient, resulting in a darker color and lower drip. The economic interest in dehiding depends on whether there are markets for the hide to yield good value. A disadvantage of dehiding is that it is not compatible with dry ham production.

Chilling

Carcasses are chilled in order to increase the shelf-life of the meat before further processing or consumption. Chilling not only prevents growth of the microorganisms present on the carcasses after slaughter, but also has marked favorable effects on cutting yield, as it reduces postmortem muscle acidification rate and can thus improve water-holding capacity and color intensity. However, these effects generally remain little (Table 3) due to the rapidity of postmortem biochemical changes in pig muscle: in most cases, carcass temperature cannot be dropped rapidly enough to prevent protein denaturation. Fast chilling is particularly unable to prevent PSE in carcasses from halothane-sensitive pigs or from pigs that were heavily stressed at slaughter. Furthermore, fast chilling can result in increased meat toughness due to cold shortening. This effect is more marked when the postmortem pH drop is slow. Electrical stimulation has been proposed as a way to avoid cold-toughening, but research carried out in Denmark concluded that stimulation is not economically attractive as it generally leads to a deterioration in meat quality, i.e., increased drip loss and higher frequency of PSE meat. However the electrical stimulation can be used if it is associated with the appropriate chilling method.

COOKING OF MEAT

Contents

Cooking of Meat

C Bejerholm, MA Tørngren, and MD Aaslyng, Danish Meat Research Institute, Taastrup, Denmark

Glossary

Actin One of the main myofibrillar proteins of meat.
Denaturation A change in the tertiary structure of proteins.
Maillard reactions A cascade of chemical reactions taking place when meat is heated. These are responsible for the fried, roasted flavor of meat.
Myoglobin The pigment protein of meat.
Myosin One of the main myofibrillar proteins of meat.

Introduction

With the exception of specially dried and fermented products, meat is generally cooked before consumption. Biochemical and physical changes occur during the heating process and these changes affect microbiological quality and sensory characteristics. Furthermore, the heating of meat results in better digestibility and, to some extent, in a change of the nutritive value.

The method of cooking is one of the major factors that affects the eating quality of meat. Meat is cooked using different media for heat transfer, such as dry heat methods (roasting, broiling, or panfrying), moist heat methods (boiling or braising), or microwave cooking (electromagnetic energy). Sometimes a combination of dry and moist heat methods is used. The cooking method chosen should be appropriate to the type of meat, the amount of connective tissue, and the shape and size of the meat. In studies and trials, it must be clear whether the cooking method is to be used for experimental purposes or for common consumer practice. For experimental purposes, the method must be standardized and controlled and must not overshadow the effects of the treatment. If it is to be used by consumers, the method should result in a good eating quality.

Changes in Meat during Heating

During cooking, the core temperature of the meat increases from approximately 0 °C to as much as 85 °C. The surface temperature of the meat can be very high – up to 300 °C – depending on the cooking method. The increase in temperature results in a tremendous change in both the structure and the water distribution in the meat. Water is lost as cooking loss, fat melts and drips out, and the texture and flavor change (Figure 1).

The cooking loss starts to develop around 40 °C. In meat with low pH (below 5.4 for pork), cooking loss begins as low as around 30 °C. The rate of development of cooking loss is greatest between 50 and 70 °C, after which it falls again.

These changes in cooking loss can be explained by the changes in the meat structure. In a nuclear magnetic resonance study, a shift in the water populations was seen at 46 °C: the water within the myofibrils diminished, whereas the water in the intermyofibrillar space increased. The sarcoplasmic proteins, α-actinin and myosin, begin to denature in the temperature interval from 40 to 50 °C, and a transverse shrinkage of the myofibrils begins at 45 °C. This can explain the change in water distribution and the initiation of the cooking loss. In the temperature interval from 50 to 60 °C, where the rate of the cooking loss is largest, sarcomere length decreases and

 doi:10.1016/B978-0-12-384731-7.00187-2

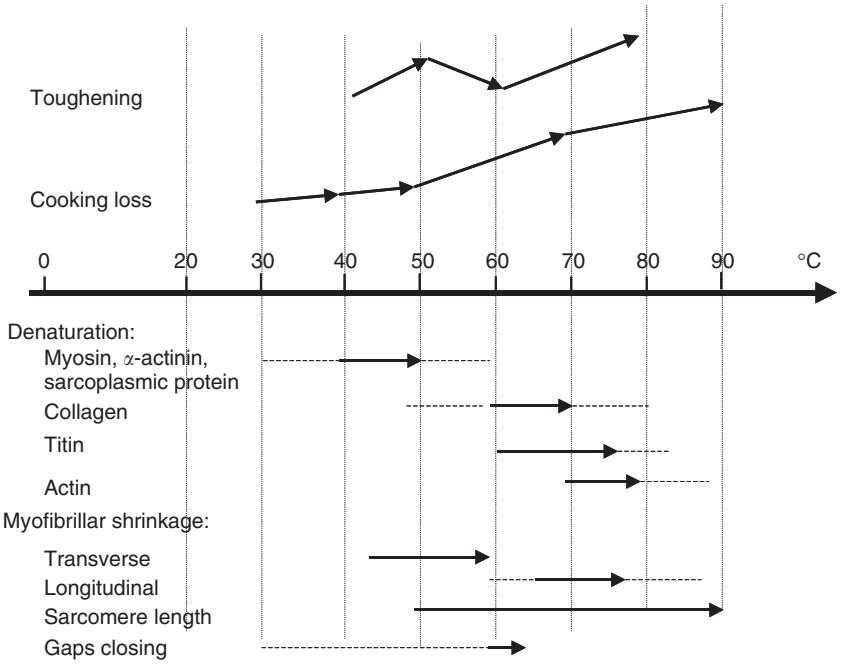

Figure 1 Changes in meat during heating.

collagen starts to denature. At 60 °C, the gaps between the fibers are closed and a parallel shrinkage of the myofibrils begins. This might be due to water being expelled from the meat matrix with a high concentration of proteins. The decreasing sarcomere length and the shrinkage of the myofibrils continue with further heating, and it is not understood why the rate of cooking loss decreases.

Myoglobin begins to denature around 60 °C. The denaturation of myoglobin is responsible for the change in color from a raw meat appearance to a cooked meat appearance. The maximum precipitation of myoglobin pigment occurs in the range 60–67 °C. The heat-induced color change of the meat also depends on the oxidative status of the myoglobin before cooking.

In general, the denaturation of myosin and actin results in toughening of the meat. In a model system, the toughness of a whole muscle increases up to 50 °C, followed by a decrease to approximately 60 °C; with further temperature rise, the meat becomes tougher again. The first rise in toughness can be explained by denaturation of myosin. The decrease in toughness between 50 and 60 °C is most likely due to a partial denaturation and shrinkage of the collagen fibers in the intramuscular connective tissue. From 60 °C, the cytoskeletal protein titin begins to denature and later, at 70–80 °C, actin also denatures, which can explain the second increase in toughening. At high temperatures, above 75 °C, the collagen reaches a soluble gelatinized state. In muscles rich in connective tissue, softening of the texture is, therefore, seen at very high core temperatures. Collagen can also be solubilized at a lower temperature when given enough time and can be aided by moist heat cooking.

The Heating Process in Meat

The rate of heating in meat depends on the coefficient of conductivity in meat and the surface temperature of meat. The surface temperature of meat is affected by the temperature of the heating source (e.g., oven temperature) as well as the air circulation and the relative humidity. Increasing air circulation improves heat conduction and increases the evaporation from the surface of meat, whereas high humidity improves heat conduction but reduces evaporation. The heat absorbed in meat causes a temperature rise by heat conduction through meat from the surface to the center. The rate of temperature rise in meat is different at different depths of a meat cut (roast). Cooking to a certain core temperature in the center of roasts produces meat with layers of different doneness, depending on the heating method and temperature. A low heating temperature (<100 °C) yields a more homogeneous appearance and less distinct layers of doneness compared with traditional oven roasting at 160–200 °C. Figure 2 indicates two different temperature profiles: the low heating temperature gives a slow temperature rise in meat compared with the higher heating temperature.

Main Cooking Methods

Conventional cooking methods use conduction, convection, and radiation as media for heat transfer, whereas unconventional methods use energy supplied in other forms, such as microwaves. Three main factors differ among the various cooking techniques: the temperature at the surface of meat, the temperature profile through meat, and the method of heat transfer (contact, air, water, steam, or microwaves). Cooking of meat often involves more than one type of heat transfer. When selecting a cooking method, attention should be paid to the type of meat involved. Muscles with a high content of connective tissue normally yield less tender meat; accordingly, a moist heating method, such as braising or

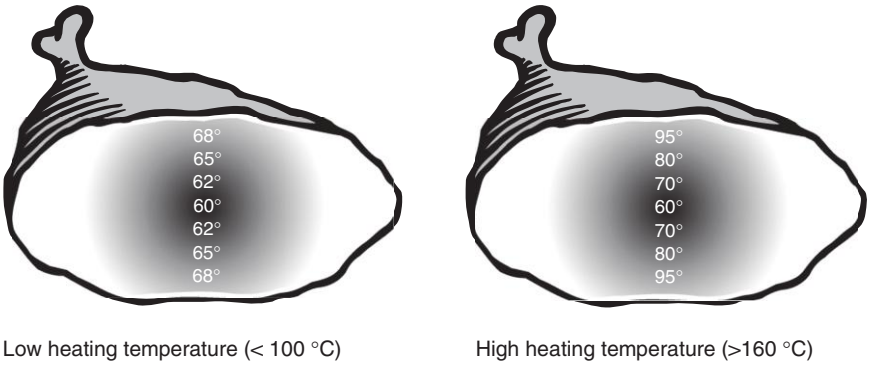

Figure 2 Illustration of temperature profiles in roasts cooked at low and high temperatures.

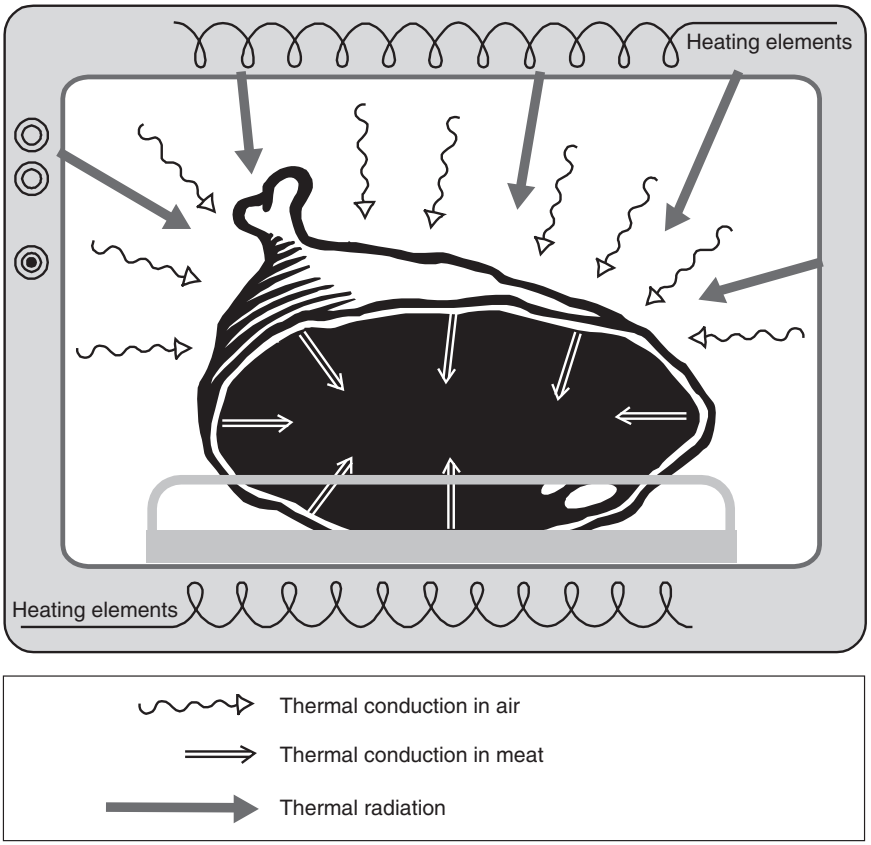

Figure 3 Illustration of heat transfer to a roast when cooked in an oven.

cooking in liquid (stewing or boiling) or cooking at a low temperature for a long time, is recommended. Dry heat methods, such as roasting, broiling, and panfrying, are used for cooking muscles with a low content of connective tissue.

Roasting

In roasting, transfer of heat is accomplished by a combination of conduction, convection, and radiation (Figure 3). The heat is transmitted to meat by normal or forced air convection (high-velocity air) in a closed oven, often preheated. Large meat pieces are placed on a rack in a roasting pan for even circulation of heat around meat. Normally, meat is not covered and is not turned during cooking. The rate of heat transfer in an oven depends on temperature and air velocity; a forced air convection oven produces a faster temperature rise than a conventional oven. Oven roasting can apply the temperature in two different ways: a constant oven cooking temperature at approximately 150–160 °C or roasting at a high temperature of up to 250 °C followed by a lower temperature of approximately 150 °C until the required core temperature is obtained. The use of the constant oven temperature of 150–160 °C throughout the cooking period results in lower cooking loss compared with a high starting temperature. The constant temperature method also ensures that the surface of meat becomes brown due to the Maillard reaction; this method is recommended for tender meat

with a low content of connective tissue. If the cooking condition is changed to a combination of convection and steam, the method can be used for less tender meat.

Broiling

Broiling is a dry heat method in which meat is cooked using direct radiant heat. The heat source may be an oven broiler, an electric broiler, or an outdoor grill, with the meat placed either above or below the heat source. The heat radiates from one direction, so meat must be turned during cooking. The method is used for cuts with a low content of connective tissue, such as steaks, chops, and patties. The cooking time is short.

Low-Temperature Cooking

Low-temperature cooking uses a constant oven cooking temperature below 100 °C, resulting in a very slow heating profile. The meat is placed in the oven as for the roasting method. Compared with normal oven roasting at 150–160 °C, the cooking time is two to three times longer, and because of the low temperature, minimal Maillard reactions occur on the surface and the appearance is like that of boiled meat. Prebrowning is, therefore, recommended to improve appearance. This method is useful for meat with a high content of connective tissue or for cuts of meat containing different muscles that differ in collagen content. 'Prime rib' is prepared by cooking at a low temperature for more than 8 h. The method can be combined with steam and is often used by the catering sector and for institutional food service.

Pan Broiling/Panfrying

Pan broiling and panfrying are methods by which small, thin cuts, such as chops, steaks, or patties, are cooked by direct heat conduction. Heat is transmitted by contact between the pan and the meat. Meat is placed in a preheated, uncovered frying pan and cooked with or without added fat. The meat should be turned frequently. The cooking time is relatively short because of the high frying temperature, and the meat surface becomes brown because of the Maillard reaction. This quick method is not recommended for meat with high connective tissue content because the tenderizing effect of converting collagen into gelatin cannot be accomplished. This is a method commonly used by consumers.

Braising/Casseroling

These are moist cooking methods, especially used for meat with a high content of connective tissue where maximum tenderization is required. The meat is often prebrowned and then placed in a covered pan to which some liquid, often a small amount of water, is added. The meat is cooked slowly in the moist atmosphere, and the maximum temperature reached is not higher than 100 °C.

Boiling/Stewing/Water Bath

These are methods of cooking in liquid and therefore constitute moist cooking methods like braising. The meat is placed in a pan and covered with water. Normally, the meat is not prebrowned. As the heat exchange medium is water, the maximum temperature reached is not higher than 100 °C. The method is used for meat with low as well as high content of connective tissue. If cooking is prolonged, meat with high connective tissue content will become tender because the collagen dissolves. Meat reaches the final endpoint temperature faster when cooked in water than when cooked in air of equal temperature, because the specific heat of water is higher than that of air. For experimental and research purposes, cooking in a regulated water bath is often used. Small meat samples are sealed in plastic bags and immersed in the water bath with a set temperature below 100 °C.

Microwave Cooking

Microwave cooking is a very popular method, especially for defrosting and reheating precooked meat. The principle of microwave cooking is conversion of electromagnetic energy into thermal energy within meat. During cooking, microwave energy is absorbed by rotation of water molecules and translation of ionic components in meat; the water content and the dissolved ion content are, therefore, important factors. In practice, meat is placed in a container suitable for microwave cooking, covered with a film wrap or a suitable lid, and then cooked in the microwave oven. Cooking time depends on the cooking rate, i.e., the power output (watts). Total cooking time can be decreased by one-third to one-half of that in conventional cooking in an oven. Weight of meat mass, shape, composition, and temperature before cooking are factors that influence the duration of microwave cooking. A problem with microwave cooking is that the surface of the meat does not brown because no Maillard reactions occur owing to the relatively low meat surface temperature and the low temperature of the surrounding air. If the microwave oven is supplemented with another heat source, such as convection, browning of the surface occurs. Other methods used for browning of the surface include the use of a special browning dish or a special metallic film that is responsible for some of the microwave energy being absorbed and converted into heat. Another problem with microwave cooking is uneven heating; for this reason the method is not recommended for meat with a high content of connective tissue, because the tenderizing effect of converting collagen into gelatin is not achievable within the short cooking time. Compared with conventional cooking methods, microwave cooking often results in a greater cooking loss and decreased tenderness, but this depends on the microwave setting (power output).

Sous Vide

The sous vide method for preparation of meat was introduced in the 1970s. It is used for industrial production of meat or meals for the food service industry or for consumers through retail sale. The meat is vacuum packed and cooked at a temperature < 100 °C using precisely controlled heating and then rapidly cooled. The meat is reheated after a period of chilled storage. The advantage of using vacuum packaging before cooking is the prevention of evaporative losses during cooking

and elimination of oxidation during storage. Owing to the low temperature, the sous vide method has a positive effect on tenderness compared with conventional oven cooking and results in an easily controlled and uniform doneness of meat. Sous vide cooking reduces vegetative bacteria to a safe level in a combination of time and temperature. Extended cooking time increases collagen solubility.

Other Cooking Methods

Belt Grill Cooking

With belt grilling, meat is cooked by conduction on both sides simultaneously. Heat transmission is affected by contact between meat and heat source. Meat is conveyed between preheated plates or belts without added fat and does not have to be turned. The cooking time is relatively short owing to the high temperature.

Clamshell Grilling

A clamshell grill is a cheaper domestic cooker using the same principle as a belt grill cooker.

Temperature Control and Timetable

When cooking meat, it is important to control the core temperature or the endpoint temperature to achieve the ideal degree of doneness. A timetable is only a guideline for an approximate cooking time. Variation in cooking time depends on cooking method, cooking equipment, size, and shape of the meat cut as well as fat and bone content. Boneless meat cooks more quickly than meat with bones. It is important that control of the core temperature in the meat is precise. This means inserting the thermocouple of the thermometer into the geometric center of the meat without touching either bone or fat. With low-temperature cooking, it is easier to measure the internal temperature exactly because of the slow rise of temperature rise in meat (Figure 2).

Resting Period after Cooking

When the meat has been cooked and removed from the heating medium, the core temperature continues to increase, because the cooking process goes on inside meat. The final endpoint temperature after the resting period depends on the cooking method, the cooking temperature, and whether or not the meat is covered with foil. In general, the higher the temperature of the heating medium, the larger is the residual heat and the higher is the final temperature after resting. Postcooking temperature rise is greater for microwave cooking. The resting period is often 15–30 min. The reason for recommending a resting period, as described in many cookery books, is that the juice in the meat can redistribute and the meat remains juicy after being cut into slices. However, a recent study has reported that pork and beef remain juicy even when being cut into slices immediately after cooking.

Effects of Cooking Methods on the Eating Quality of Meat

It is well known that different cooking methods, core temperatures, and types of muscles result in different eating qualities. Three main factors differ depending on cooking method: the temperature at the surface of meat, the temperature profile through meat, and the method of heat transfer. The temperature at the surface is important for the color, odor, and flavor of meat. Temperature gradient influences the rate and extent of the changes of protein structure in the meat, whereas the method of heat transfer influences the odor, flavor, and color. In general, optimal tenderness and juiciness and minimum cooking loss in meat are achieved when it is cooked at moderate to low temperatures. With respect to odor and flavor, higher temperatures yield different flavor perceptions compared with low cooking temperatures. Numerous studies have indicated a poorer eating quality in meat with increasing internal temperature.

Effect of Cooking on Color

The color of meat is a combination of the amount of myoglobin and the reflectance of protein. Raw meat has a bright pink or red color that depends on the nature and composition of meat (see Changes in Meat during Heating). Color is influenced by heat treatment (cooking method) and endpoint temperature. Increase in endpoint temperature increases the brown color and decreases the pink color. Dry heat methods, especially panfrying, influence the surface color: a brownish color is achieved compared with the moist heating methods where no browning effect is seen.

Effect of Cooking on Odor and Flavor

Flavor is a combination of taste and aroma. Taste is a sensation related to the tongue, whereas aroma is a sensation of volatile compounds related to the epithelia of the nose. Flavor comprises a combination of nonvolatile and volatile compounds. Odor and flavor of raw meat are bland, weak, and blood like. When meat is heated, several odors and flavors are produced through heat-induced changes in amino acids, carbohydrates, and fat. Many types of heat-induced reactions result in the production of meat flavors. Amino acids and reducing sugars react when heated above 110 °C; this thermally induced reaction is called the Maillard reaction and is important in developing meat flavor. The Maillard reaction is influenced by the method of heat transfer. Dry heat methods, especially panfrying, increase the amount of Maillard reaction and moist heat methods prevent the reactions from taking place. A similar effect is achieved using roasting bags when cooking meat in an oven. In addition to the Maillard reaction, lipid degradation products are responsible for developing meat flavor during heating. The lipid degradation reactions take place at a much lower temperature than the Maillard reaction and the flavoring compounds can, therefore, be produced not only on the surface of meat but throughout meat. Lipid-derived flavor compounds are very important for the meaty

flavor and are said to be responsible for the species-specific flavor.

Effect of Cooking on Texture

The texture of meat determines the feeling in the mouth perceived during chewing. When meat is introduced into the mouth, the structure is intact. During chewing, the meat structure is broken down and soaked in saliva until it is in a state suitable for swallowing. The attributes related to texture can be divided into three groups:

- Attributes relating to the breaking-down process (hardness, tenderness, etc.)
- Attributes relating to the structure during chewing (fibrousness, crumbliness, and elasticity)
- Attributes relating to the end of chewing (chewing time and chewing rest).

In general, these attributes are highly correlated, but they can, to some extent, also vary independently between cuts, depending on the cooking method.

Changes in the texture of meat during cooking are due to heat-induced structural changes combined with enzymatic breakdown of proteins. The effect of the time/temperature factor and the core temperature depends on the composition of meat. The M. biceps femoris (BF, outer hind leg muscle) has a high content of connective tissue. It gains more in tenderness when heated slowly than the M. longissimus dorsi (LD, loin), which is low in connective tissue (Figure 4).

The effect of core temperature on tenderness depends both on the meat cut (content of connective tissue) and the heating rate. In BF, the tenderness decreases when the core temperature increases from 65 to 75 °C (Figure 5). As meat is slowly heated further up to 80 °C, connective tissue begins to soften and gelatinize and BF becomes more tender. LD, however, becomes less tender when the core temperature increases from 60 to 80 °C, probably owing to the denaturation of actin and myofibrillar toughening. Heating at low temperatures in an oven increases the overall tenderness of the meat compared with the use of medium and high oven temperatures (Figure 6). The effect is largest at 60 °C core temperature and decreases up to 80 °C core temperature. In selecting the optimal core temperature during cooking, attention must be paid to both the muscle and the cooking method. Cooking at temperatures below 100 °C for a long time increases tenderness of meat, but too low temperature does not increase tenderness. Cooking at 58 °C resulted in more tender meat compared with that at 53 °C for

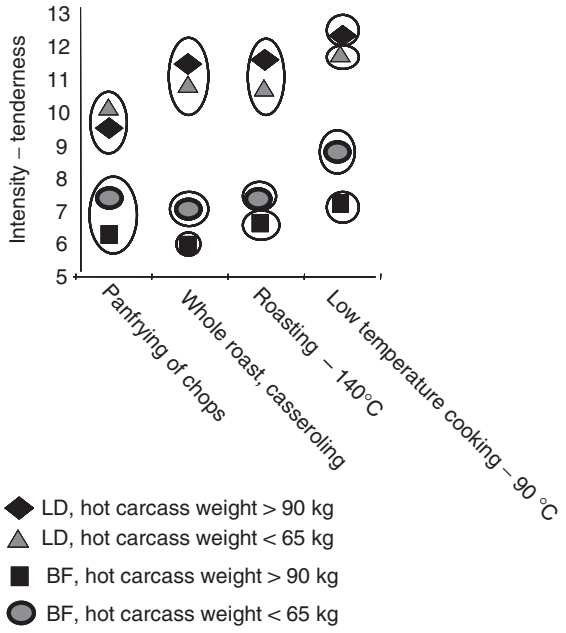

Figure 4 The effect of cooking method on the tenderness of a pork muscle with a high content of connective tissue compared with one with low content of connective tissue. Different symbols enclosed in the same circle indicate significant differences ($p < .05$). LD, M. longissimus dorsi; BF, M. biceps femoris. Food Quality and Preference 15, 19–30.

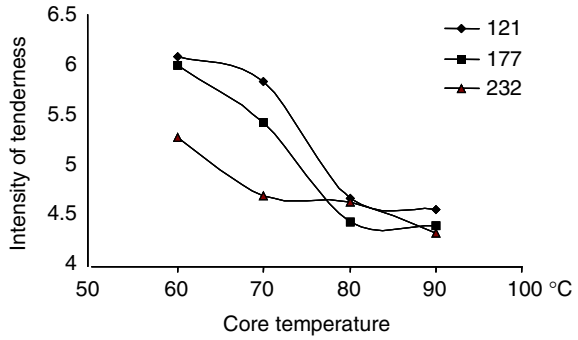

Figure 6 The effect of core temperature on the tenderness of beef M. longissimus dorsi, depending on oven temperature. Tenderness is expressed on a 9-point scale from 0 (extremely tough) to 9 (extremely tender). Data plotted from Cross, H.R., Stansfield, M.S., Koch, E.J., 1976. Beef palatability as affected by cooking rate and final internal temperature. Journal of Animal Science 43 (1), 114–121.

both beef and pork, but meat at both temperatures was very tender for chicken. No difference was seen in tenderness between 58 and 63 °C cooking temperature.

The effect of core temperature on juiciness depends more on the cooking method than on the amount of connective tissue in meat. Cooking loss is generally larger when roasting than when panfrying because of the longer cooking time. Increasing the oven temperature results in less juicy meat at the same core temperature. At 65 °C core temperature, there is no difference between roasting and panfrying. With increasing core temperature, the decrease in juiciness is faster when meat is cooked in an oven compared with panfrying, irrespective of the cut.

Effect of Cooking on Weight Loss

Cooking loss increases as core temperature increases (see Changes in Meat during Heating; Figure 1). The actual amount of cooking loss depends on the cooking method and the amount of connective tissue in meat. Cooking methods with a very short cooking time, such as panfrying, result in a lower cooking loss than conventional oven cooking methods at the same core temperature. The correlation between cooking time and cooking loss is not linear, as cooking loss is determined by a combination of cooking time and heating rate. Low-temperature cooking results in lower cooking loss compared with cooking at conventional temperatures. Compared with broiling, roasting results in a lower cooking loss owing to the gentler heating. Cooking loss also differs among cuts. Cuts with a high amount of connective tissue have a higher cooking loss than those with a lower amount of connective tissue. The higher the core temperature, the smaller the difference is between muscle types. Moreover, at 80 °C or more, only minor differences exist among cooking methods and cuts with different amounts of connective tissue.

This article is a revision of the previous edition article by RB Pegg, F Shahidi, volume 2, pp 570–578, © 2004 Elsevier Ltd.

Introduction

Flavor is an important sensory characteristic that contributes to the overall palatability of muscle foods. Qualitatively and quantitatively, the flavors associated with cooked meats have proven to be extremely difficult to characterize for both the sensory analyst and the flavor chemist. This is because the sensory impression of meat flavor is influenced not only by compounds contributing to the sensation of taste but more importantly also by those stimulating the olfactory organ. To complicate matters, there is no one single compound or class of compounds that are accountable for meat flavor. Numerous constituents resulting from a myriad of reactions during thermal processing of meat are responsible for the flavor one associates with each animal species. Ultimately, it is the chemical composition of fresh meat that gives the basis for development of a desirable aroma during thermal processing.

The Precursors of Meat Flavor

The meat matrix is very complex: its macroconstituents include water, proteins, and lipids, whereas its microconstituents include vitamins (notably B vitamins), peptides, sugars (e.g., ribose), nucleotides, and their metabolites. Raw meat itself does not have much flavor: it has a slight serum-like odor and a blood-like taste. During postmortem aging, hydrolytic activity generates a reservoir of precursor molecules, reactive flavor chemicals, and intermediates, which during thermal processing react/degrade to give the desirable taste tactile properties and aroma characteristics associated with finished meat products. For the generation of meat flavor to occur, meat and meat products must be heated/cooked/thermally processed. Thermal processing induces a complex network of chemical reactions among the nonvolatile components of lean and fatty tissues present in meat and yields a heterogeneous system containing many volatile compounds with odoriferous properties, smaller nonvolatile compounds with taste properties, as well as flavor potentiators and synergists. The type of thermal processing employed, such as grilling, roasting, broiling, stewing, boiling, or smoking, and the final internal temperature of the product contribute significantly to the formation and stability of both volatile and nonvolatile compounds and are, therefore, related, at least to some extent, to the differences in the overall meat flavor sensation.

The present working theory is that aroma volatiles are derived from nonvolatile precursors in the lean and fatty tissues of meat during cooking. These precursors can be further subdivided into water- and lipid-soluble components. Basically, meat aroma is the composite sensation of low molecular weight products of the Maillard reaction (i.e., a nonenzymatic browning reaction between amino groups, such as those associated with amino acids, and with a carbonyl group of a reducing sugar) as well as the thermal melting and oxidative degradation of lipids. Lipids would also more likely participate in the Maillard reaction, as the carbonyls produced from lipid oxidation can replace the carbonyls on reducing sugars. These oxidation products can produce desirable flavors such as those in fried foods, but some lipid oxidation reactions often result in negative flavors. A detailed discussion on the role of the Maillard reaction, as it relates to meat flavor development, is discussed in another article.

A delicate balance exists between the aroma volatiles generated from Maillard and lipid reactions as well as their interaction with one another and molecular oxygen. It is this balance that dictates whether the desirable meaty/savory, fatty flavor or warmed-over or off-flavors will result. Although the odor threshold values (OTVs) of sulfur- and nitrogen-containing heterocyclic compounds, which contribute to meaty/savory notes, are lower than those of lipid-derived volatiles, changes in meat flavor are the result of a dynamic process. With time, the levels of lipid-derived compounds increase and eventually overwhelm the desirable meaty notes of products, even though many of these compounds' OTVs are several degrees of magnitude greater than those of the heterocyclic compounds. Such changes to the perception of meat flavor make its characterization difficult.

Makeup of Meat Flavor: Taste and Odor

Flavor is a wide sweeping term that encompasses not only the taste and aroma associated with cooked meat but also the intangibles like texture, mouthfeel, and temperature sensation. The human tongue has millions of gustatory receptors in which one uses to identify taste. There are only five recognized classes of taste: sweet, sour, salty, bitter, and umami (i.e., a Japanese term for a fifth basic taste that is triggered by some amino acids, peptides, and their salts, notably monosodium glutamate). Umami is difficult to translate, but some equivalent English terms are savory, essence, pungent, deliciousness, and meaty. However, it is the volatile constituents of meat that account for the dominant sensory phenomenon that one refers to as flavor.

To date, more than 1000 compounds have been identified in the aroma profiles of cooked meat products. The volatiles are a combination of low molecular weight products from the degradation of amino acids and lipids via oxidation as well as further reaction products from these aforementioned degradation compounds. The resulting products include a broad array of compounds from varying classes of chemicals: these

include hydrocarbons, aldehydes, alcohols, ketones, carboxylic acids, ethers, esters, lactones, and *S*-, *N*-, and *O*-containing heterocyclic compounds. Some examples are provided in Figure 1.

There is a simplified theory: it states that the basic flavor of cooked meat is similar to all species, that is, flavors derived from protein breakdown (e.g., Maillard reaction) and from the formation of heterocyclic compounds such as pyrazines, pyrroles, thiazoles, oxazolines, thiolanes, thiophenes, and furans are similar. The species-specific flavors come from the lipid constituents of meat. It is the melting and/or oxidation of lipid constituents that contributes toward the species-specific flavors identified in meat products. It is now known that lipid oxidation products interact with Maillard reaction products to generate new flavors associated with cooked meat. So, the foregoing theory is an oversimplification of what actually happens in terms of meat flavor generation; nevertheless, it provides a good basis for discussion.

Sources of Heat-Induced Meat Flavor

The Decomposition of Individual Substances

The degradation of mono- and oligosaccharides to yield volatile compounds involves temperatures greater than those generally associated with the cooking of meat. Nevertheless, some decomposition of simple sugars to furanones and furfurals can occur during cooking/heating/thermal processing of meat. Amino acids tend to be more stable and unlikely to undergo pyrolysis. Only along the surface of grilled or roasted meat, where localized dehydration allows the temperature to

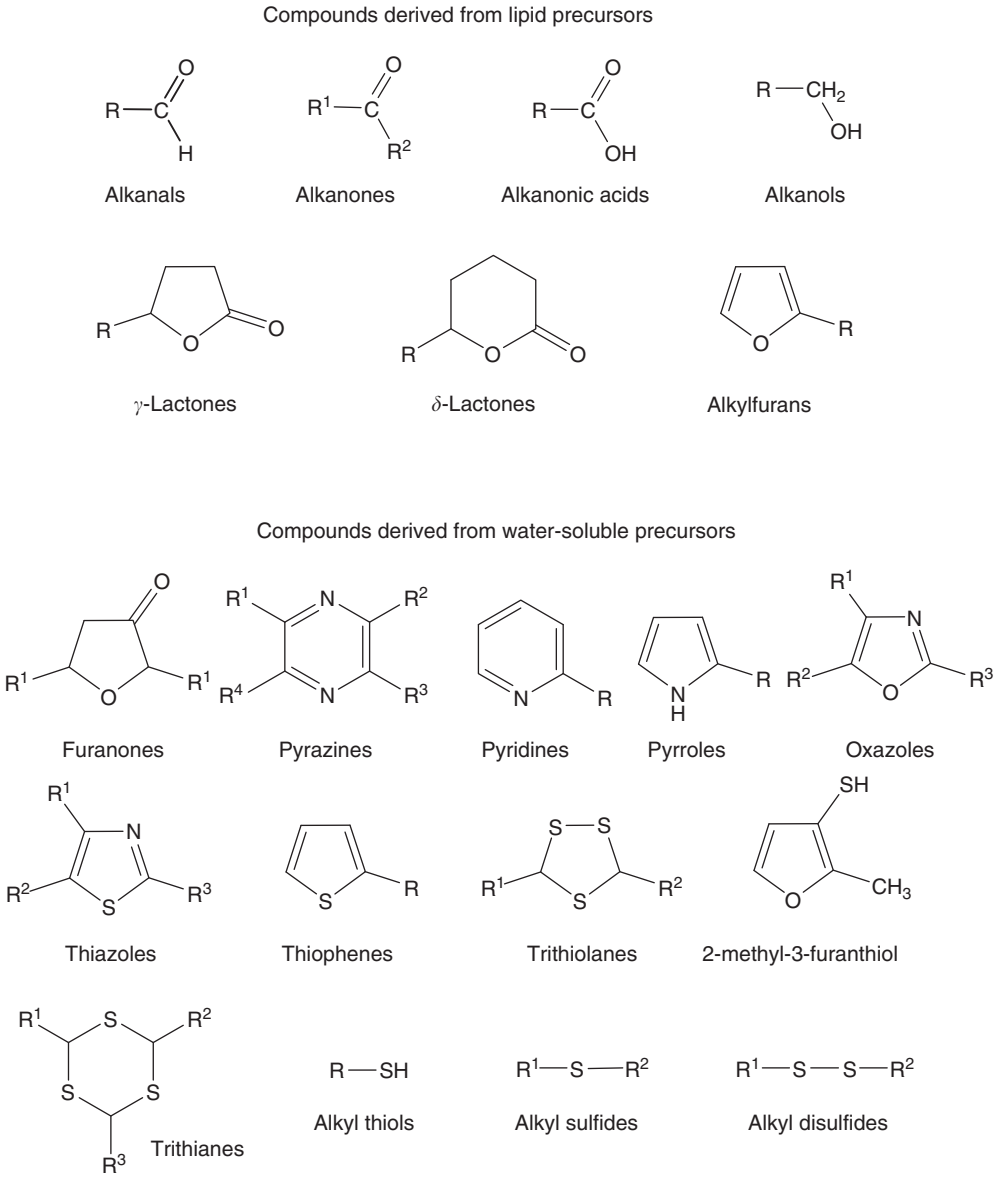

Figure 1 Some classes of volatile compounds generated during the cooking of meat. Reprinted from Mottram, D.S., 1998. Flavor formation in meat and meat products: A review. Food Chemistry 62, 415–424.

rise significantly above the boiling point of water, does pyrolysis of amino acids take place, and this results in decarboxylation and deamination reactions. Breakdown of protein into oligopeptides, peptides, and free amino acids is also important because these protein subunits, monomers, or their salts are taste active but contribute very little to the aroma of cooked meat. During heat processing, free amino acids in meat, like cysteine, react with reducing sugars (products of glycolysis) via the Maillard reaction to generate aroma volatiles. Products of one reaction often become precursors for another. One can begin to appreciate why the chemistry underlying meat flavor is a complex topic.

Thiamine (i.e., vitamin B_1) is an important microconstituent in the meat matrix that significantly impacts meat flavor development. It is a sulfur-containing compound with a thiazole and pyrimidine ring system. When meat is thermally processed, the vitamin degrades and potent aromas are generated, of which some have been described as meaty. Thiamine's breakdown products include thiophenes, thiazoles, furans, furanthiols, hydrogen sulfide, and bicyclic heterocyclic compounds. An important degradation product from thiamine is 5-hydroxy-3-mercapto-2-pentanone: this very reactive compound is the intermediate for a number of thiols, including 2-methyl-4,5-dihydro-3-furanthiol and 2-methyl-3-furanthiol as well as the mercaptoketones.

The breakdown of lipid constituents and their subsequent oxidation, as it relates to cooked meat flavor, is described in a separate section below.

Maillard Reaction/Advanced Glycation Endproducts

Although a description of the Maillard reaction, as it relates to meat and meat products, is presented in detail in another article, a brief overview of the reaction is provided for the sake of completeness. Free amino groups of amino acids or peptides in meat can react with reducing sugars in the presence of heat. They undergo a series of complex nonenzymatic browning reactions known simply as the Maillard reaction. Maillard reaction products are sometimes intermediates for further reactions and in other cases, end products. There is confusion at times in the terminology with advanced glycation endproducts (AGE), which are the result of a chain of reactions after an initial glycation reaction. The Maillard reaction, which does not require the very high temperatures associated with sugar caramelization and protein pyrolysis, is one of the most important routes for the generation of flavors in cooked foods. Its products include high molecular weight brown-colored compounds, known as melanoidins, and volatile aroma compounds. The first step of the Maillard reaction in a complex series of interactions involves the formation of an *N*-substituted glycosylamine via the addition of the carbonyl group of the open-chain form of a reducing sugar with a primary amino group of an amino acid, peptide, or protein. The *N*-glycosylamine rearranges itself, forming an Amadori compound, which can degrade further, thus generating compounds such as furfurals, furanones, and dicarbonyls. These compounds may themselves make some contribution to meat flavor but are more important as substrates in the generation of other aroma volatiles. For example, they can interact with reactive compounds such as amines, amino acids, hydrogen sulfide, thiols, ammonia, acetaldehyde, and other aldehydes. These further reactions lead to many important classes of meat flavor compounds such as pyrazines, oxazoles, thiophenes, thiazoles, and other heterocyclic compounds. As will be outlined below, sulfur compounds derived from the interaction of cysteine and ribose seem to be particularly important for the characteristic aroma of meat. Although the Maillard reaction can take place in aqueous solution, it occurs much more readily at low moisture levels; hence, in meat, flavor compounds produced by the Maillard reaction tend to form on the surface of the product where some dehydration has occurred.

Lipid Oxidation

In the early 1960s, two researchers suggested that meat aroma, derived from water-soluble precursors of lean tissue, was similar in all cooked meat and that the characteristic species differences were due to the contribution of volatiles derived from the lipid fraction. It was postulated that lipids provide volatile compounds that give the characteristic flavors of different species and that elimination of the lipid-derived flavors should reveal the true-to-nature flavor of meat itself. Fat influences flavor by producing organoleptically significant quantities of carbonyl compounds (i.e., aldehydes and ketones) as a result of oxidation from unsaturated fatty acids and by acting as a depot of fat-soluble compounds that volatilize on thermal processing. The spectrum of secondary products of lipid oxidation will depend, of course, on the fatty acid composition of adipose and intramuscular tissues, which vary from one species to another and may be influenced by diet. For example, the deposited lipids of monogastric animals, essentially pigs and poultry, can be influenced by the fatty acid patterns in the animals' diet. With the meat industry edging further into the functional foods sector, researchers have been attempting to increase omega-3 fatty acid levels in the meat from monogastrics. However, quality challenges of these functional meats in the form of oxidation/off-flavors exist in the cooked products, even with the supplementation of vitamin E to the diet.

One of the main functions of thermal processing is to generate aroma and flavor precursors from lipids, many of which possess intense odors, as well as to allow intimate mixing of fat- and water-soluble compounds. Yet, lipids alone are not responsible for the species-characteristic aromas. A study reported that the addition of pork backfat to either beef or pork lean meat resulted in a substantial increase in hexanal levels after thermal processing of the preparations but only small changes in most other volatiles. The lack of a relationship between aroma constituents and subcutaneous fat levels suggested that the triacylglycerols of adipose tissue may not be the main precursors for volatiles; instead, intramuscular triacylglycerols and structural phospholipids were deemed to be important.

Interaction between Lipid Oxidation and Maillard Reaction Products

Sensory panels and consumer studies have also failed to find a direct relationship between the flavor of lean meat and the

quantity of fat on the carcass; thus, giving credence to early meat flavor research that meatiness was associated with the water-soluble flavor precursors, whereas species characteristics were derived from the lipids. The aroma of cooked meat is dominated by lipid-derived volatiles and such volatiles are expected to have some effect on meaty flavor.

Triacylglycerols and structural phospholipids have been carefully studied in relation to meat flavor development. In a nutshell, phospholipids play a key role during the thermal generation of meat aroma. In a study where inter- and intramuscular triacylglycerols were extracted from lean meat samples before cooking, the aroma of the thermally processed products indicated that removal of these fats had little effect on the meaty aroma and the volatile compounds were formed on heating of the samples; in fact, one could not differentiate the aroma profile from that of untreated material. This was not the case, however, when phospholipids were also extracted from the muscle tissue. Elimination of phospholipids along with the triacylglycerols resulted in a marked loss in the perceived meatiness of the overall aroma, and the odor descriptor changed from that of meaty to roast or biscuit like. Another significant observation was that removal of phospholipids from the meat before thermal processing brought about a significant increase in certain volatile heterocyclic compounds, notably alkyl pyrazines. As the primary source of these compounds in cooked meat comes via the Maillard reaction, it appeared that interaction of phospholipids or their degradation products in the Maillard reaction is important for the characteristic aroma of cooked meat. In a model system study containing cysteine and ribose, the interaction of phospholipids in the Maillard reaction of these two substrates not only increased the meaty aroma of the reaction mixture but also increased the number of compounds possessing meaty notes. In other words, research has suggested that the interaction between phospholipids and the Maillard reaction can affect meat flavor in three ways: (1) lipid–Maillard reaction products can have their own aroma characteristics; (2) compounds with low OTVs derived from lipid oxidation, such as unsaturated aldehydes, can react with Maillard intermediates and thereby reduce their contribution to rancid and other odors (e.g., green note); and (3) important Maillard intermediates, such as ammonia and hydrogen sulfide, can react with lipid-derived volatiles, thereby reducing their availability for the formation of cooked flavors.

Species Effect

The chemistry of compounds bringing about distinctive species-related flavors of ruminant meats remains obscure. The characteristic flavor of different meat species is generally believed to be derived from their respective lipid profiles. The interaction of lipid constituents with other meat components (e.g., Maillard reaction products, as outlined above) is most likely involved. Numerous reports have shown that the chemical nature of many flavor volatiles of meat from different species is similar qualitatively but different quantitatively. Lamb, mutton, and goat meat are, however, exceptions. A number of volatile, medium-chain fatty acids (C_5–C_{12}), including some methyl-branched chain homologs, have been identified in cooked sheep and goat meats. These saturated fatty acids have not been reported in other meats and were associated with the characteristic 'sweaty' flavor of cooked sheep meat that results in its low consumer acceptance in many countries. In particular, 4-methyloctanoic, 4-ethyloctanoic, and 4-methylnonanoic acids are considered to be primarily responsible for this off-flavor. It has also been reported that mutton aromas contain a higher concentration of 3,5-dimethyl-1,2,4-trithiolane and 2,4,6-trimethylperhydro-1,3,5-dithiazine (thialdine) as compared with those of other species. Additional sulfur-containing compounds were present at notable concentrations and this was attributed to the high content of sulfurous amino acids in mutton as compared with those of beef and pork. Similarly, a marked concentration of alkyl-substituted heterocycles and alkylphenols was noted in mutton volatiles.

Other Effects

Antemortem factors such as the breed, sex, nutritional status, and age of the animal; preharvest stress/handling conditions; and postmortem factors like muscle type, myoglobin content, pH, and thermal processing conditions (i.e., moist heat, dry heat, microwave, convection oven, and final endpoint cook temperature) of the meat products, including the type and duration of storage, all contribute to and affect the flavor of meat. Another important parameter in relation to meat flavor is the diet that animals are fed. For instance, ruminants either graze on grass or are fed hay and silage diets. For those animals feeding on pastoral lands with its great biodiversity, the diets are often switched over to cereal or grain-based ones a number of weeks before harvest, as a means to improve the flavor characteristics of the resultant meat. Skatole (i.e., 3-methylindole) is a natural product that animals ingest from pastoral lands. In sheep meat, skatole in combination with the branched-chain fatty acids discussed above can impart objectionable flavors to the meat products derived from these animals. The effect of skatole is less noticeable in cattle, but the consumption of grass also causes animals to accumulate larger concentrations of linoleic and α-linolenic acids and their derivates (e.g., conjugated linoleic acid). Consequently, any detectable pastoral flavor in meat products tends to result from oxidation products of α-linolenic acid.

As described in the warmed-over flavor (WOF) article, researchers are supplementing the feed of domesticated species with dietary antioxidants like vitamin E. Supplementation in the form of α-tocopheryl acetate to the diet of monogastric animals before harvest can, in some cases, improve the flavor of finished products by minimizing the potential for WOF development. This effect has been seen in a number of studies where the basal diets of hogs have been supplemented with increasing levels of α-tocopheryl acetate. A progressive increase in the concentration of α-tocopherol has been found in the muscle tissue, mitochondria, and microsomes of hogs. α-Tocopherol migrates into muscle cell membranes, where it lies adjacent to highly oxidizable phospholipids; this localization makes it a particularly effective antioxidant. Sensory studies of meat products have confirmed that vitamin E supplementation can prolong flavor freshness of cooked products

and retard WOF development. As aforementioned, the addition of α-tocopheryl acetate to omega-3 fortified diets (e.g., in the form of flaxseed) of monogastrics does not always sufficiently curb oxidation of polyunsaturated fatty acids.

Desirable Meaty Aromas of Cooked Meat

In studying meat aroma, two realities exist: first, a means in which to 'trap' meat flavor volatiles and second, a way to separate and identify the odor impact compounds. Analyzing the volatile organic compounds that impact meat flavor is not an easy task. As noted above, more than 1000 compounds have been identified in the volatile constituents of cooked red meats and poultry by gas chromatographic–mass spectrometric techniques. Obtaining useful information from the analysis of meat volatiles, however, can be even more challenging than the isolation/identification steps themselves. The critical question becomes, "What is the relative sensory significance of these thermally derived volatiles?" The answer is not totally clear, but many volatiles are relatively unimportant. For example, aliphatic and aromatic hydrocarbons, saturated alcohols, carboxylic acids, esters, ethers, and carbonyl compounds (i.e., aldehydes and ketones) are probably not the main contributors to desirable meaty flavor. Rather, lactones; acyclic sulfur-containing compounds (i.e., mercaptans and sulfides); nonaromatic heterocyclic compounds containing sulfur, nitrogen, or oxygen (e.g., hydrofuranoids); and aromatic heterocyclic compounds containing sulfur, nitrogen, or oxygen (e.g., pyrazines and thiophenes) possessed characteristic meaty flavor notes. Whether a compound is a key aroma impact substance depends on both its concentration and OTV. Gas chromatography–olfactometry (GC–O) coupled with aroma extraction dilution analysis has assisted with identifying key aroma impact compounds in cooked meat.

The importance of sulfur-containing heterocyclic compounds in the volatiles of cooked meats should not be underestimated. Although these compounds are present in very low concentrations, their parts-per-billion OTVs make them potent aroma compounds. As an example, 2-methyl-3-(methylthio) furan was identified in cooked beef and found to have an OTV of 0.05 $\mu g\,kg^{-1}$ and a meaty aroma at levels below 1 $\mu g\,kg^{-1}$. The interest in such compounds stems partly from research into developing simulated meat flavorings with desirable meaty aroma characteristics for use in processed food products. Dr. Donald Mottram and his research group in the United Kingdom have carried out extensive work on characterizing the importance of heterocycles in desirable meaty aromas.

The breakdown of cysteine (e.g., via hydrolysis or Strecker degradation) and thiamine in meat gives hydrogen sulfide, which is critical in the formation of *S*-containing heterocycles. Hydrogen sulfide can react with dicarbonyls, furanones, and furfurals – most likely generated from inosine 5′-monophosphate, ribose 5-phosphate, and ribose via the Maillard reaction – to yield thiol and mercaptoketone derivatives. These derivatives can undergo oxidation and result in quite a number of symmetrical and unsymmetrical disulfides; some of these are depicted in Figure 2. Various odor descriptors from GC–O studies have been employed to characterize some of these compounds and include the following: cooked meat, meaty, brothy, pungent, fried onion, sulfury, fatty, nutty, and roasted. Heterocyclic compounds with one, two, or three sulfur atoms in five and six-membered rings are much more prevalent in boiled than in roasted meats. The meaty character of some sulfur-containing compounds depends on the position of the thiol group and the degree of unsaturation. For instance, furans and thiophenes with a thiol group in the 3-position and their related disulfides have been reported to possess strong meat-like aromas with very low OTVs, whereas those with the thiol in the 2-position were characterized as being burnt and sulfurous. One researcher noted that the best meat-like aroma is produced when there is a methyl group adjacent to the thiol moiety and the ring contains at least one double bond. A complication in the analysis of such compounds arises from the fact that the aroma of these sulfur volatiles, which is pleasant at the levels found in meat, becomes objectionable at higher concentrations. Therefore, when assessing the flavor quality of muscle foods, both qualitative and quantitative aspects of volatiles must be considered.

Flavor of Nitrite-Cured Meat

Nitrites and nitrates are unique ingredients found in processed cured meat products. Nitrite plays a multifunctional role in the meat matrix: it is responsible for the development of the characteristic color associated with cured meat; a distinct flavor that distinguishes the flavor of cured ham from cooked, uncured pork, and this may be related to the antioxidative capacity it imparts; and in combination with sodium chloride, it suppresses the outgrowth and production of toxin from the anaerobic bacterium, *Clostridium botulinum*.

The mechanism by which nitrite imparts a characteristic cured flavor to thermally processed meat and meat products (i.e., a flavor that distinguishes cooked ham from pork) is unclear. Nevertheless, cured meat flavor is probably a composite sensation derived from contributions of many odoriferous compounds. Research into cured meat flavor has been divided into two main areas, namely, the sensory evaluation of flavor imparted to meat by nitrite and the qualitative and quantitative identification of volatile and nonvolatile components responsible for it, but caution must be exercised. A compound-by-compound search of meat flavor volatiles might misidentify the true nature of cured meat flavor, because a mixture of two or more odors can produce an aroma that is perceived as qualitatively distinct from the odors of their components.

Nitrite's role in the development of thermally derived cured meat flavor involves its antioxidative activity, which retards the breakdown of unsaturated fatty acids and the formation of secondary oxidation products. Numerous researchers have attempted to identify the volatile compounds generated during the thermal processing of cured meat. The results indicate that all compounds identified were also contributors to the aroma of uncured cooked meat. Some important research in the 1960s involved the examination of the volatile constituents isolated from uncured and cured hams by gas chromatography. Qualitatively, the volatile compounds of cured ham were similar to uncured hams but were quantitatively

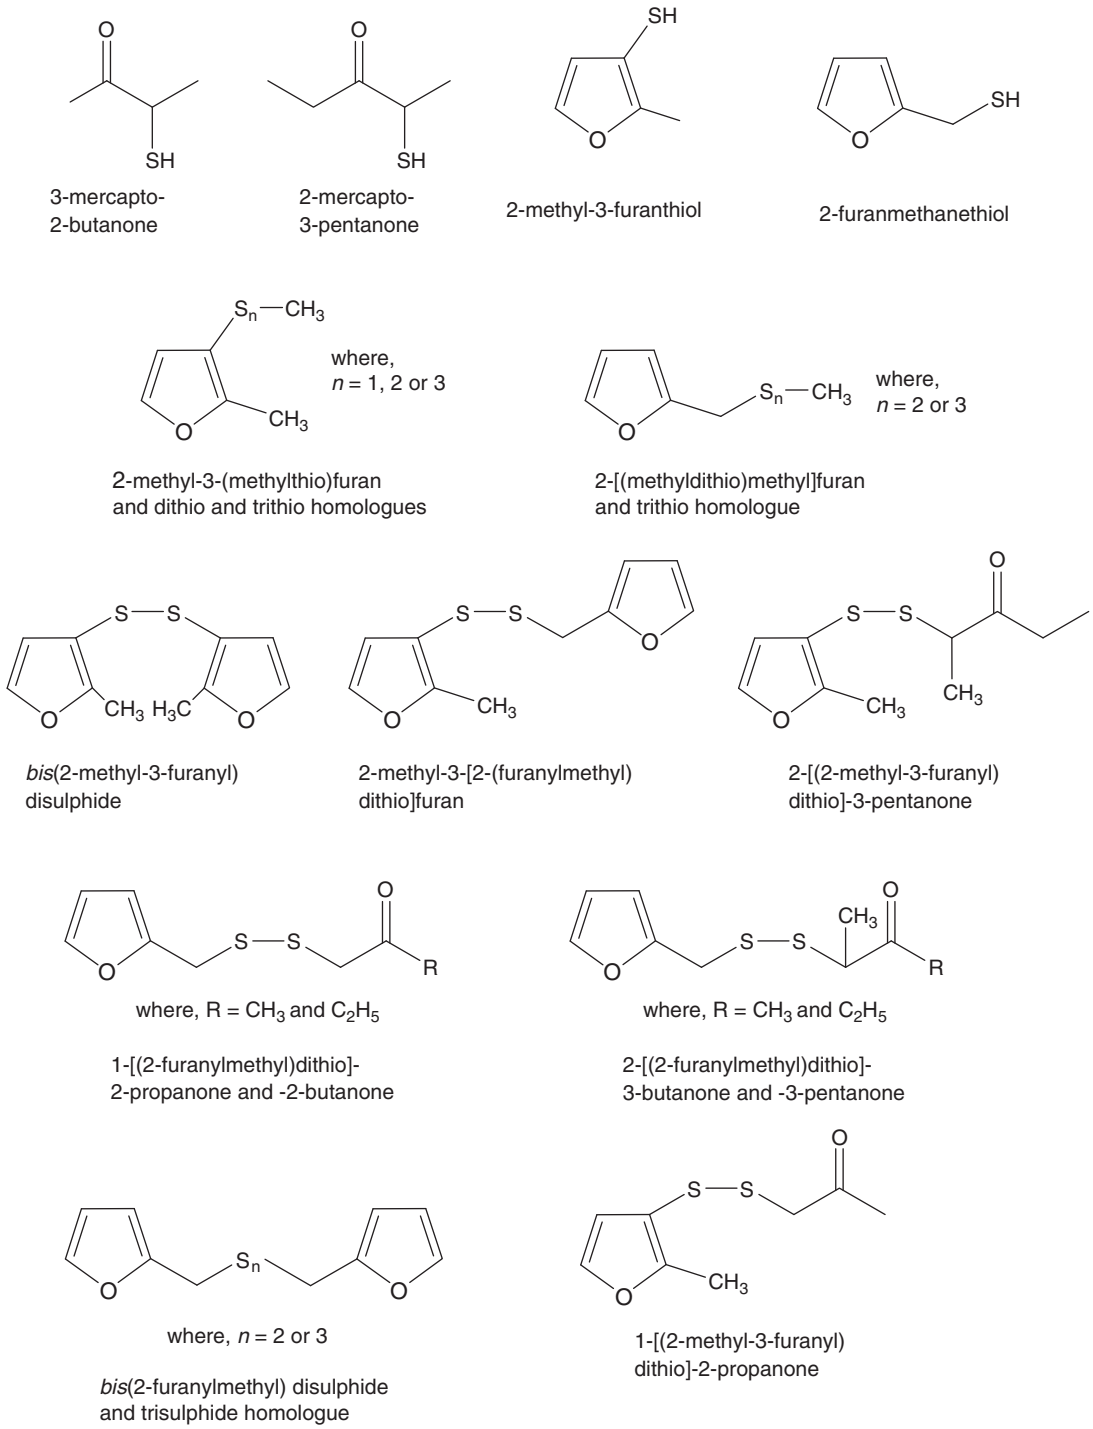

Figure 2 Some thiols and sulfides detected in the headspace volatiles of heated meat systems. Adapted from Mottram, D.S., Madruga, M.S., 1994. Important sulfur-containing aroma volatiles in meat. different. Hexanal and pentanal were present in appreciable amounts in the volatiles of uncured but were barely detectable in the volatiles of cured ham. It was suggested that the absence of these aldehydes and those of higher molecular weight aldehydes was responsible for the flavor differences between cured and uncured hams. It was also noted that the volatiles, after passage through a solution of 2,4-dinitrophenylhydrazine (2,4-DNPH), had the characteristic cured-ham aroma, regardless of whether cured or uncured hams were used. Cured and uncured chicken and beef volatiles, after stripping their carbonyl compounds by passage through 2,4-DNPH solutions, also possessed an aroma similar to that of

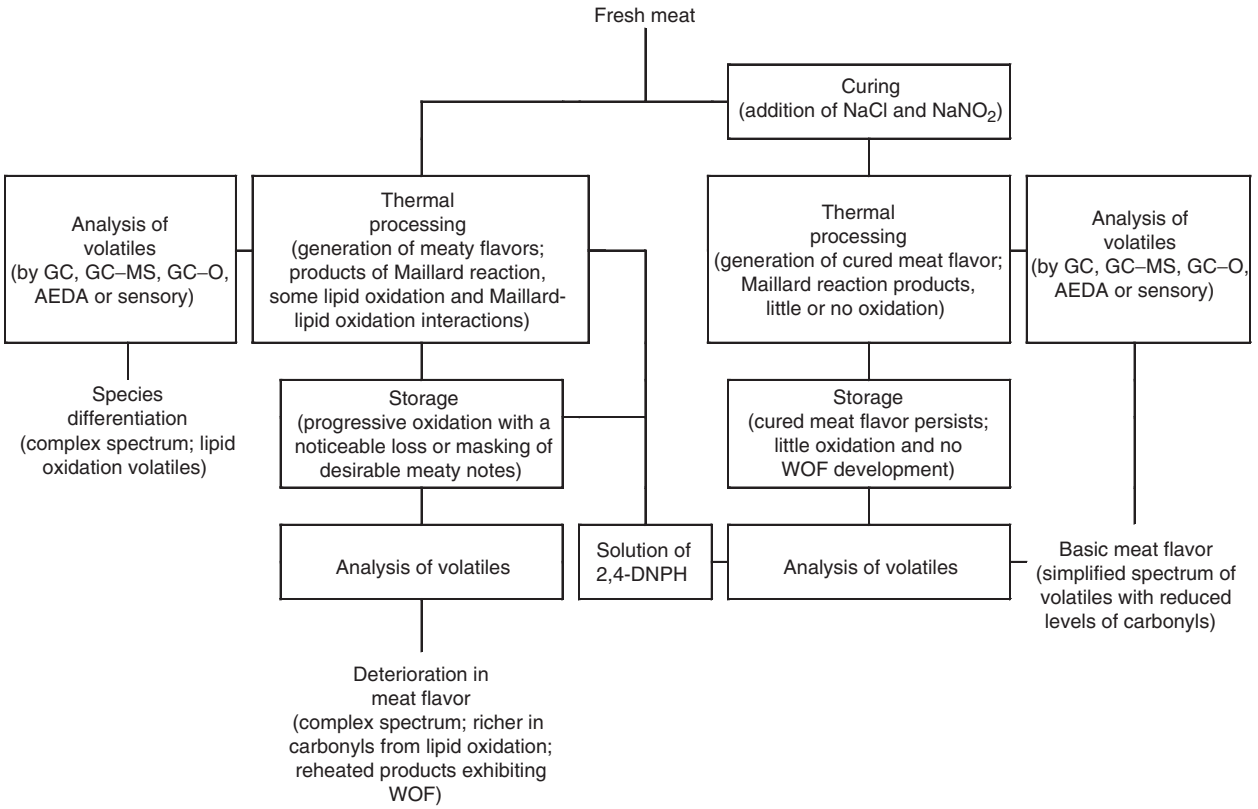

Figure 3 Consequence of thermal processing, nitrite curing, and storage on meat flavor. cured ham. A conclusion reached was that treating meat with nitrite does not seem to contribute any new volatile compounds to the flavor of cooked meats, with the exception of nitrogen oxides that are not present in cooked uncured meat. Therefore, it was postulated that cured-ham aroma represents the basic flavor of meat derived from precursors other than triacylglycerols and that the aromas of various types of cooked meat depend on the spectrum of carbonyl compounds derived by lipid oxidation.

An oversimplistic view attempting to provide a unifying theory on the origin of the thermally generated flavor of meat, species differentiation, and off-flavor development is provided in Figure 3. It postulates that meat acquires its characteristic species-specific flavor on cooking from volatile carbonyl compounds formed by oxidation of its lipid components (i.e., primarily phospholipids) and their reaction products after interaction with Maillard reaction products. Further oxidation during storage of cooked meat results in the deterioration of desirable meaty notes. Curing with nitrite suppresses the formation of oxidation products. Hence, it may be assumed that the flavor of nitrite-cured meats is actually the true-to-nature flavor of meat from different species without being influenced by overtone carbonyls derived from oxidation of their lipid components. The postulate, however, does not easily explain the fact that the intensity of cured meat flavor in bacon has been reported to be proportional to the level of ingoing nitrite levels, whereas the characteristic 'mutton' flavor is persistent regardless of the level of nitrite used in curing of sheepmeat.

Glossary

Convection, thermal Mechanism for heat transfer. The process of heat transfer through a liquid or gas by means of circulating currents caused by changes in density.

Heat transfer coefficient Coefficient used in thermodynamics to calculate heat transfer, typically by convection or phase change, between a fluid and a solid.

Pasteurization A form of heat treatment that kills certain vegetative bacteria and spoilage organisms in milk and other foods. Temperatures below 100 °C are used.

Radiation, thermal It is a mechanism for heat transfer. Electromagnetic radiation generated by the thermal motion of charged particles in matter. All matter with a temperature greater than absolute zero emits thermal radiation.

Refrigeration It is defined as the process of removing heat from any substance to (1) render the substance colder, for example, reduce temperature, (2) change its state, for example, water to ice, (3) maintain its state, for example, preserving foods, storing ice.

Introduction

Cooking is the most common heat treatment applied to meat; its primary aim is to cause structural and chemical changes that will make the meat more palatable. Industrially, the aim is more often to pasteurize the meat, for example, kill vegetative pathogens and spoilage organisms and to extend the safe shelf life of the product, with the consumer completing the cooking process at home. Sterilization extends the shelf life even further by killing all of the microorganisms present, including the spores.

The organoleptic changes that are caused by heat treatment (doneness, flavor, firmness, consistency, and cured-meat color development) are time–temperature-dependent processes. The basic effect of the heat treatment is the coagulation of meat proteins. Between 70 and 80 °C, the majority of meat proteins are completely coagulated; these structural changes of proteins are responsible for the characteristic firmness of heat-treated meat products. Products containing connective tissue become tenderer owing to solubilization of the collagen (gelling), such as cuts of meat. Frankfurters have an elastic firmness, and on reheating before consumption become even firmer. Products such as meat paste that are in a liquid state before heating change, becoming more viscous and attain a 'spreadable' consistency.

There are also a number of other heat treatments used during slaughtering operations for both red and poultry meat production. Poultry and pork carcasses are scalded, and pork carcasses singed. Surface heat decontamination processes have also been developed for meat.

Sterilization

Commercial sterilization is intended to produce an ambient stable product with a long shelf life by destroying both microbial and enzyme activity. The severity of the heat treatment produces substantial changes in the nutritional and sensory qualities of the meat. 'Commercial' sterilization implies that there is a very low probability of the survival of microorganisms that are injurious to human health. It does not, however, mean that there are no microorganisms left in the food.

Although the pH of meat is generally slightly acidic, it is considered a low acid food (pH higher than 4.5) in danger of supporting *Clostridium botulinum* and so must be given a severe enough treatment to inactivate spores of this organism. Although these spores are not as resistant as the spores of some other *Clostridium* and *Bacillus* types, *C. botulinum* is capable of producing lethal toxins, sometimes without swelling the container or obvious alteration of the appearance of the product. Because this organism presents a public health risk, recommended heat treatments must have a large safety margin.

The severity of heat processes for canned meat products is measured in terms of F_0 values, which means that the product received a heat treatment with the same inactivating effect as exposure for one minute at 121 °C. For example, one minute at 121 °C gives the same amount of inactivation of spores as 4 min at 115 °C or 13 min at 110 °C, for example, all those processes have the same F_0 value. The F_0 value for the majority of canned meat products ranges between 1 and 10. Meat processed in large cans requires longer processing times to allow for heat penetration; consequently, closer to the surface F_0 values can be between 20 and 25.

Traditional canning is a nonsteady state heat transfer process in which a container is heated, held at a given temperature for a given time, and then cooled. The whole heating/holding/cooling cycle contributes to the sterilization. The vessels used for sterilization are commonly called retorts and the process retorting. Heat can be provided by three methods, each being more suitable for different containers.

Traditionally canned meats, such as corned beef, are processed by steam inside a pressure vessel. Latent heat is transferred to the food when the saturated steam condenses on the outside of the container. Air must be removed from the retort to prevent it forming a noncondensable area around the can and preventing the steam condensing on the surface. After sterilization the cans are usually cooled with water. An overpressure is used to prevent strain on the can seams (pressure

cooling). When the food has cooled to below 100 °C, the overpressure of air is removed and cooling continues to approximately 40 °C. At this temperature, moisture on the can dries to prevent surface corrosion, and allow label adhesives set more rapidly.

Meats and meat products in glass containers or flexible pouches are processed under hot water with an overpressure of air. Processing meat products in glass containers is slower than in cans or pouches because the glass has a lower thermal conductivity and has to be thicker to provide adequate strength. There is also a higher risk of thermal shock during processing glass containers. Although the plastics used for pouches have a low thermal conductivity, the thinness of the plastic and the smaller cross-section of the container means that processing is often faster than for cans. The flexible nature of the pouches and their use for liquid or semiliquid meat products, such as sauces and chili con carne, can cause a problem. Vertical packs promote better circulation of hot water in the retort, but frames are needed to prevent the pouches from bulging at the bottom, which would increase the thickness of the pouch and hence decrease the rate of heat penetration and increase the process time. Processing the pouches horizontally ensures that the thickness is constant across the pouch. Alternatively, the packs can be circulated through an agitated system where the motion of the water stirs the packs, ensuring mixing of the contents and good heat transfer, provided the system has been properly designed.

An alternative to steam or hot water is direct flame heating. Flame sterilization involves heating cans by passing them over a gas flame. This method is extremely fast because the flame is at temperatures in excess of 1500 °C and internal temperatures can reach 116 °C in a few minutes. The cans are closed under a very high vacuum then pass through a four-stage process: the cans are first preheated in steam; the cans then pass over a gas flame while agitated to stir the contents; the cans are held for the required holding time; then the cans are cooled. The entire operation of preheat, process to 130 °C, hold and cool can take only 12 min. However, the process is limited to low viscosity liquids or solids, such as cubed beef or ham. The internal pressure in the can during processing is very high (275 kPa at 130 °C), and this may strain the can seams and limits the process to small cans.

These processes can be batch or continuous. Continuous retorts permit close control over the processing conditions; gradual changes in the pressure inside the food container can be made and therefore less stress is placed on the container than with batch equipment. However, they are less flexible than batch systems, and in practice, are used for the production of high-volume products where there is no requirement to regularly change the container size or processing conditions.

Cooking (Pasteurization)

Many commercial pasteurization processes differ little from those used in the catering and domestic environments. Often, with the exception of meat products that are to be eaten cold (i.e., ready-to-eat products), the heat treatment is carried out to pasteurize (kill the vegetative pathogenic and spoilage microorganisms) and not necessarily cook them, because they will often be heated by the consumer before ingestion. Pasteurized products require chilled or frozen storage to prevent proliferation of any microorganisms not killed in the pasteurization process. The time to chill the product from cook temperatures is often as important as the internal cooked temperature attained.

The microbiological criteria for pasteurized meats is often based on *Listeria monocytogenes* (considered the most dangerous heat-tolerant pathogen in many chilled products), with a recommendation to cook to 70 °C for 2 min, or equivalent. *C. botulinum* is viewed as a potential hazard in vacuum-packed products and requires a much more severe treatment, 10 min at 90 °C, or equivalent.

Textbooks on cooking use a wide variety of terms to describe cooking (Table 1). Conventional commercial cooking systems for meat joints and products are based on roasting/baking, boiling, or frying methods. Microwaves are commonly used in reheating, and some cooking processes and ohmic heating has been advocated for some products.

Surface heat transfer coefficients with foodstuffs in boiling and frying operations are much higher than in hot air ovens (Figure 1). However, in unpressurised systems water temperatures are below 100 °C and the temperature difference between the food and cooking environment can be much less than in a hot air oven operating at 200–360 °C. Condensing steam results in high surface heat transfer coefficients but is only suitable for a small range of products.

Hot Air

The majority of cooked meat and many individual meat products are roasted or baked in hot air ovens. These ovens

Table 1 Common cooking methods/terms

Boiling	Cooking of foods in a liquid, usually stock or water
Steaming	Cooking in moist heat where the water exists as a vapor, generally above 100 °C
Stewing	Slow cooking in a small quantity of water, stock, or sauce in which the food is always cut up and the food and cooking liquid are served together
Roasting	The subjection of food to the action of heat in an oven, or while it is roastingon a spit; in both cases, fat is used as a basting agent
Braising	A combination of roasting and stewing in a pan with a tight-fitting lid
Baking	Same as roasting, except no fat is used
Grilling/broiling	Cooking with radiated heat
Shallow frying	Cooking the food in hot shallow fat in a pan
Deep frying	Cooking the food by completely submerging it in hot fat
Microwaving	A colloquial term for microwave cooking

commonly consist of either a compartment with shelves for the product or a long tunnel through which the product is transported on a conveyor belt. The heat transfer medium is air, which is sometimes mixed with steam. The heat transfer mechanism is either natural convection or forced convection by means of fans. The heating rate is controlled by the air velocity over the product, the air temperature, the condensation of steam, and the thermal properties of the product. Belt speed can be varied to achieve the required residence time. To some extent, heat is also transferred via radiation from the walls, shelves, and elements (Table 2).

Forced convection tunnel ovens may be divided into different sections with different temperature zones if required as in the baking of meat pies. Typical air temperatures range from 150 to 250 °C and heat transfer coefficients between 20 and 90 $Wm^{-2}K^{-1}$. However, in cooking operations for large joints, low temperatures (75–90 °C) and high humidities are used to minimize weight loss. Long cooking times (up to 16 h) are required in large joints such as beef topsides or hams used for sliced products.

Smokehouse cooking, often used for bacon smoking, is a specialist form of hot air cooking.

Steam

Steam cooking is heating in saturated air, at atmospheric pressure this is at 100 °C, at lower pressures the temperature is below 100 °C, whereas at high pressures the temperature is above 100 °C. Latent heat is given up as the steam condenses at the meat surface, leading to higher heat transfers than are possible with air. However, unless the process is pressurized the surface temperature is restricted to 100 °C, thus browning and other reactions associated with roast meat do not occur. This is not a problem with products that are traditionally boiled, such as gammons. Otherwise steam cooking can be combined with a second-stage radiant or hot air cooking stage to impart the characteristic roast appearance and flavor.

Direct injection of steam can be used for heating meat stews, soups, and similar products.

Steam at pressures greater than atmospheric is generally associated with retorting (canning) but it is also employed in the production of pasteurized soups, stews, etc. Higher temperatures lead to faster processing times and can lead to the retention of nutrients that are damaged by long processing.

Hot Water

Open top vessels and closed pressurized vessels are used for the cooking of meat containing mixtures that make up pie and pasty fillings, curries, stroganoff, chicken chasseur, Chinese and Italian dishes, etc.

An open top vessel is used in many small- and medium-scale operations. The advantage of such systems are low cost, ease of cleaning, and versatility. As they are open topped, they allow components to be conveniently added at different times through the cooking process.

The disadvantages in open top vessels are that considerable temperature stratification occurs, with differences of up to 50 °C. The vessels are also energy inefficient with up to 15% of heat lost to the environment via evaporation from the surface. Cooling is a major problem and often the vessel is emptied into a large bin that is allowed to cool in ambient temperatures or in a refrigerated room. Temperatures as high as 65 °C have been recorded in the center of bins after 16 h of 'cooling' and during this period the product continues to cook with a consequent deterioration in texture and flavor. Spore-forming bacteria will survive these cooking operations and proliferate at temperatures between 10 and 50 °C.

Closed pressurized vessels are water, and sometimes, vacuum-cooled. Numerous designs of vessels are available for a wide field of applications, including atmospheric and super atmospheric pressure operation, with or without agitation with various impeller types such as paddles, turbines, anchors, or propellers, and vessel shapes such as vertical, cylindrical, or hemispherical. Most vessels are of a double-skinned stainless

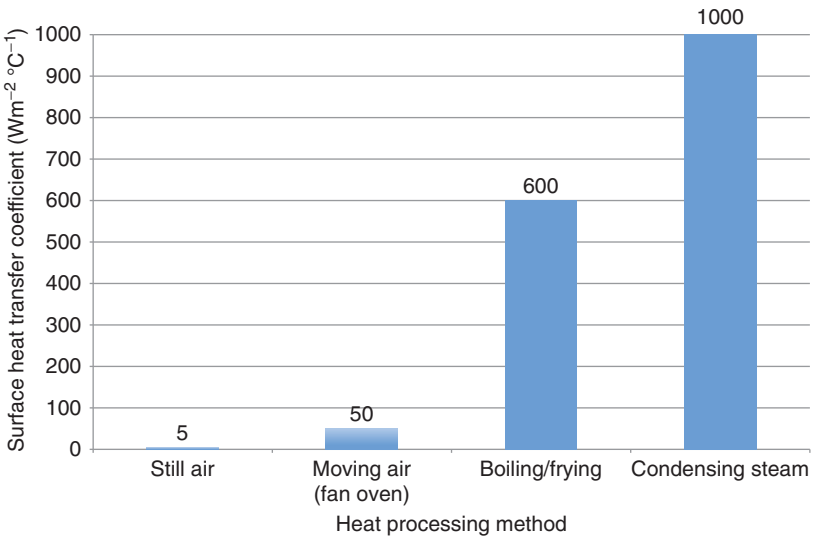

Figure 1 Typical heat transfer coefficients in cooking operations.

Table 2 Radiant heat sources

Type of emitter	*Maximum running temperature (°C)*	*Maximum intensity (kWm^{-2})*	*Maximum process temperature (°C)*	*Radiant heat (%)*	*Convective heat (%)*
Short wavelength					
Heat lamp	2200	10	300	75	25
Quartz tube	2200	80	600	80	20
Medium wavelength					
Quartz tube	950	60	500	55	45
Long wavelength

Ceramic element	700	40	400	50	50

steel design and are heated via steam in the jacket. Direct steam injection into the product is more efficient and reduces processing time. The design and operation of pressurized systems is dependent on:

- The optimum time–temperature relationship required during cooking and cooling for the range of products processed.
- Overall heat transfer coefficients and their variation with temperature, agitator speed and design, dimensions of vessel, and product characteristics.
- Optimum agitator design for each product.

Hot water may also be used to cook meats in plastic bags or metal moulds, like hams. Heat transfer is much greater than in air systems and the barriers used prevent weight loss. The products can be cooked in water baths, either batch or continuous, or using hot water sprays.

Hot Fat or Oil Frying

Many coated meat products such as rissoles, Kiev's, breaded chicken portions, etc., are deep fat fried. In deep fat frying, heat is transferred via convection from the oil to the product. The heat transfer coefficient has been found to vary during the process. As water from the product is evaporated, turbulence occurs in the fat causing an increased heat transfer rate. The temperature of the oil is usually between 160 and 180 °C, depending on the product being fried. The size of the deep fat fryer may differ from small batch oil baths to large continuous frying baths. In the case of a continuous system, a conveyor belt, often combined with a pushing paddle arrangement, transports the product through the bath.

Fat used for frying foods has to fulfill the following demands:

- A melting point below 37 °C in order not to cause an unpleasant feeling in the mouth.
- A neutral flavor.
- Withstand frying temperatures for long periods without foaming due to polymerization and oxidation.
- A high smoking temperature.

Heated fats and oils rapidly become oxidized and off-flavors can readily be picked up by the meat being fried. It is usual practice to replace part of the oil at the end of each production cycle.

Radiant

Radiant heating (grilling) primarily involves the infrared portion of the electromagnetic spectrum. Radiant heat transfer is very high and high surface temperatures can be attained, with rapid onset of browning reactions and charring, although not all the heat transfer is radiant (Table 2). For this reason its use is restricted to thin pieces of meat, or in combination with other heating systems (such as conventional air heating, or after steam cooking) to brown the surface of larger products. Electrical elements or flames can be used as the heat source (Table 2). In some cases, flames are used directly to char the surface to impart a barbeque appearance/flavor.

Extrusion

Extrusion cooking cannot be applied to conventional meat products but can be used to produce new and novel products. Basic extrusion cookers consist of a screw rotating within a barrel. Meat and other ingredients are carried through the barrel by the screw through a constriction toward the end of the barrel and are combined through mechanical work and heat into a viscous dough. The dough leaves through a die, with accompanying pressure release, cooling, and moisture loss. Heating can be applied directly to the barrel or via steam injection into the ingredients. A significant amount of heating is also provided by the mechanical energy input used to drive the extruder screw; this can account to 50–100% of the total energy input.

Dielectric

Dielectric heating is a generic term that includes both microwave and radio frequency heating. It is important to recognize that microwaves and radio frequency radiation are a form of energy, not a form of heat, and are only turned into heat when they interact with a material. When they are intercepted by dielectric materials such as food, they interact with the dielectric material, giving up energy, which results in a temperature increase within the material. There are two main mechanisms in which heat is produced in dielectric materials: ionic polarization and dipole rotation. The major heating mechanism in microwave heating is dipole rotation, in which polar molecules (water being the most common polar material in foods) are rotated by the alternating microwave field

resulting in frictional heat generation. Ionic conductivity is more important during radio frequency heating and occurs when ions in solution move in response to an electric field; the ions are accelerated and collide with each other converting kinetic energy into heat.

In many countries, microwave-heating systems are restricted to two frequency bands close to 896 or 2450 MHz. The designs can be separated into resonant cavity systems or waveguide systems. The resonant cavity system is essentially an oven with a conveyor belt passing through it. Absorbent end loads or radio frequency chokes, or both, prevent microwave energy emission from the oven above established limits. The waveguide system is made from a standard waveguide folded back and forth on itself with a slot running through, normal to the fold, through which the conveyor transports the food product.

The main reasons for considering the use of microwaves are to accelerate the process, improve quality, reduce costs, and increase yield.

Uses in the meat industry of microwave technology have included the tempering of frozen meat blocks, precooking of chicken portions and sliced bacon, burger cooking, and frankfurter processing. Radio frequency has found few meat-based applications, but combination hot air/radio frequency baking ovens have been developed and used for cooking meat pies and pastries.

Ohmic Heating

The ohmic heating effect occurs when an electrical current is passed through an electrically conducting product. The idea has been around the last century but within past 20 years new and improved materials and designs have led to commercial systems for continuous flow ohmic heating becoming available. The main interest in this technology is from food manufacturers who wish to aseptically process particulate foods.

Conventional methods of heating particulate foods rely on heating of the liquid phase to transfer heat to the solid phase, which necessitates the overprocessing of the liquid phase to ensure that the center of each solid particle receives sufficient heat treatment. This results in reduced quality due to the destruction of flavors and nutrients and mechanical damage to the outside of the particulate. The advantage of ohmic heating in this respect is that liquid and particulate are heated virtually simultaneously without large temperature gradients being produced. The product is heated by internal generation but does not suffer from the temperature nonuniformity commonly associated with microwave heating.

The applicability of ohmic heating is dependent on the product being electrically conductive, which is the case with most food preparations as they contain a percentage of free water with dissolved ionic salts.

The equipment consists of a column of electrodes with tubular spacers in between, mounted in a near vertical position with the product flow upward. The column is configured so that each heating section has the same electrical impedance; hence the interconnecting tubes increase in length as the product electrical conductivity increases with progressively increasing temperature as it is pumped up the column. Control parameters include the inlet temperature, mass flow rate, outlet temperature, back pressure, and electrical power. Product temperatures of 90–95 °C can be obtained at a pressure of two bar and 120–140 °C at four bar. Systems range from small 5 kW laboratory systems capable of a throughput of 50 kg h^{-1} to a 600 kW model capable of 6 tons h^{-1}.

Thermal Surface Decontamination Processes

There is often no terminal step (such as cooking) to eliminate pathogenic organisms from most of red and white meat until it reaches the consumer. The consumer is relied upon to adequately cook the meat sufficiently to kill any bacteria injurious to health before ingestion. A number of thermal intervention processes have been applied to red meat and poultry carcasses to reduce surface microbial contamination without changing the intrinsic nature of the raw meat.

Hot Water

Hot water can be applied as a spray, deluge, or by immersion at temperatures of between 60 and 90 °C. Sprays can be applied manually or preferably via automated spraying cabinets. Deluge systems employ sheets of water and are reported to be more effective than sprays at covering the surface of a carcass. Immersion is effective but difficult to engineer for large carcasses, such as beef carcasses.

Hot-water treatments are often reported to initially impart a slight 'milky' or 'ghostly' appearance to the surface of the carcass; this diminishes on cooling and is virtually undetectable after 24 h storage in chill.

Steam

Steam at 100 °C has a substantially higher heat capacity than the same amount of water at that temperature. If steam is allowed to condense onto the surface of meat then it has the ability to rapidly raise the surface temperature of the meat. One very attractive feature of condensing steam is its ability to penetrate cavities and condense on any cold surface. Commercial steam cabinet decontamination systems for beef carcasses are in use in the USA. High-temperature pressurized steam systems and low-pressure vacuum steam systems have been investigated for treating poultry carcasses and cuts of meat at temperatures above and below 100 °C, respectively, but the batch nature of such processes has restricted their development, at present.

Scalding

Pork and poultry carcasses are both subjected to a scalding operation during processing. The carcasses are treated with hot water or steam to loosen the hair or feather in the follicle to aid their removal. The time and temperature of the heat treatment are primarily determined by the need for efficient removal of the bristles or feathers by the dehairer/defeatherer. Too low a temperature and the hair/feathers will not be loosened and too high a temperature and the skin will be

cooked and the hair/feathers difficult to remove. The simplest equipment consists of a tank into which the carcass is lowered by a hoist. The water is heated by oil, gas, electricity, or an open steam pipe. Alternatively, vertical cabinets utilizing hot-water sprays or steam can be used. Temperatures between 58 and 62 are normally used for 5–6 min for pig carcasses, whereas temperatures of 50–51 °C for 3.5 min are employed for 'soft' scalded chicken carcasses destined for chilling, or 56–58 °C for 2–2.5 min for 'hard' scalded carcasses destined for freezing.

Singeing

Residual hair left on a pig carcass after the scalding/dehairing process is burnt by singeing. The carcass is subjected to an exposed high temperature flame either with a hand-held gas torch or in automated systems that transport the pig into a furnace running at 1000 °C for as little as 6 s. During singeing, any water remaining on the surface of the carcass and in the outer layers of the skin evaporates. The heat denatures the collagen fibers in the epidermis and the skin shrinks. Any charred hair and surface dirt are removed in a final polishing/scrapping operation.

Glossary

Heterocyclic compounds The cyclic compounds generated during Maillard reaction that contain nitrogen, oxygen, or sulfur atoms or their combination in the ring.
Lipid oxidation aldehydes The aldehydes generated from oxidation of lipids, including phospholipids.
Maillard browning The nonenzymatic Maillard reaction that leads to the formation of brown colors.
Maillard reaction A nonenzymatic reaction occurring on heat processing of meat between reducing sugars and amino group of free amino acids, peptides, and proteins.
Meat flavor Is affected by both volatile compounds responsible for the aroma of products and the nonvolatiles responsible for taste effects.

Introduction

Flavor is an important aspect of food quality and in the case of cooked meats, it determines their overall acceptability. Raw meat has little or no aroma and only a blood-like taste. The flavor of meat is thermally derived, and each type of cooked meat has a characteristic flavor based on the animal, presence of other ingredients, and the type of heat processing (i.e., roasting, grilling, and stewing) employed. The nonvolatile taste active compounds and the volatile aroma constituents generated from meat during thermal processing contribute mainly to the specific cooked meat flavor. Other sensations such as mouth feel, texture, and juiciness also affect the overall flavor attributes of cooked meat. Yet, it is the flavor volatiles of cooked meat that determine the product's aroma and have a profound effect on sensory acceptability even before the meat product is consumed.

Both water-soluble components (e.g., amino acids, peptides, carbohydrates, nucleotides, thiamine) and lipids in raw meat contribute to the development of meat flavor. The main reactions that occur during cooking and generate aroma volatiles are the Maillard reaction (i.e., a nonenzymatic browning reaction between amino acids and reducing sugars), the breakdown and oxidation of lipid constituents, and the degradation of vitamins, particularly thiamine. Intermediary products from these primary reactions can function as precursors and react with other degradation products of meat, depending on the cooking conditions employed, to form a large number of volatiles responsible for the characteristic flavor of cooked meat. To date, more than a thousand volatile compounds have been identified from cooked meat systems; Figure 1 illustrates some important classes of volatile compounds that have been identified.

The occurrence of the Maillard reaction is very important when meat is cooked, because it generates a large number of compounds that contribute to meat flavor. Most flavor compounds of cooked meats with roasted, boiled, and meaty notes are generated via the Maillard reaction and are generally *N*-, *S*-, *O*-heterocyclics. The Maillard reaction is also associated with brown color formation, and for this reason is often referred to as the 'browning' or 'nonenzymatic browning' reaction. The brown pigments, known as melanoidins, contain variable amounts of nitrogen and have differing molecular weights and solubilities in water. The dark brown color on the surface of roasted meats is a key factor in consumers' acceptance of these products. Several other changes in the characteristics of cooked meat may also result from Maillard-type reactions and include the production of bioactive compounds with beneficial (i.e., compounds with antioxidant properties) or toxic (e.g., imidazoles) effects, a loss of nutritional quality (especially of proteins), and modification to the product's texture.

The Maillard Reaction

In 1912 at the University of Nancy, France, Louis Camille Maillard first observed the generation of different odors and the formation of brown colored pigments after heating amino acids in the presence of various sugars. The term 'Maillard reaction' was thereafter used to describe the complex series of chemical reactions between carbonyl compounds, especially those of reducing sugars, and primary or secondary amino groups in foods. Browning in most foods is a combined result of the Maillard reaction and caramelization and depends on the product formulation and processing conditions. The ingredients present affect the formation of Maillard reaction products (MRP). In this connection, protein hydrolysates obtained by enzymatic hydrolysis of mechanically deboned chicken meat and the resultant MRPs produced at 90 °C and 100 °C possessed good antioxidant activity and also positively affected the texture and sensory properties of Cantonese sausages. In another study, honey-lysine MRP had an antioxidant effect in linoleic acid emulsion and when honey was added to turkey meat, it enhanced antioxidant properties of the meat as reflected in its thiobarbituric acid reactive substances values. Hence, ingredients present can affect the flavor quality of cooked muscle food products.

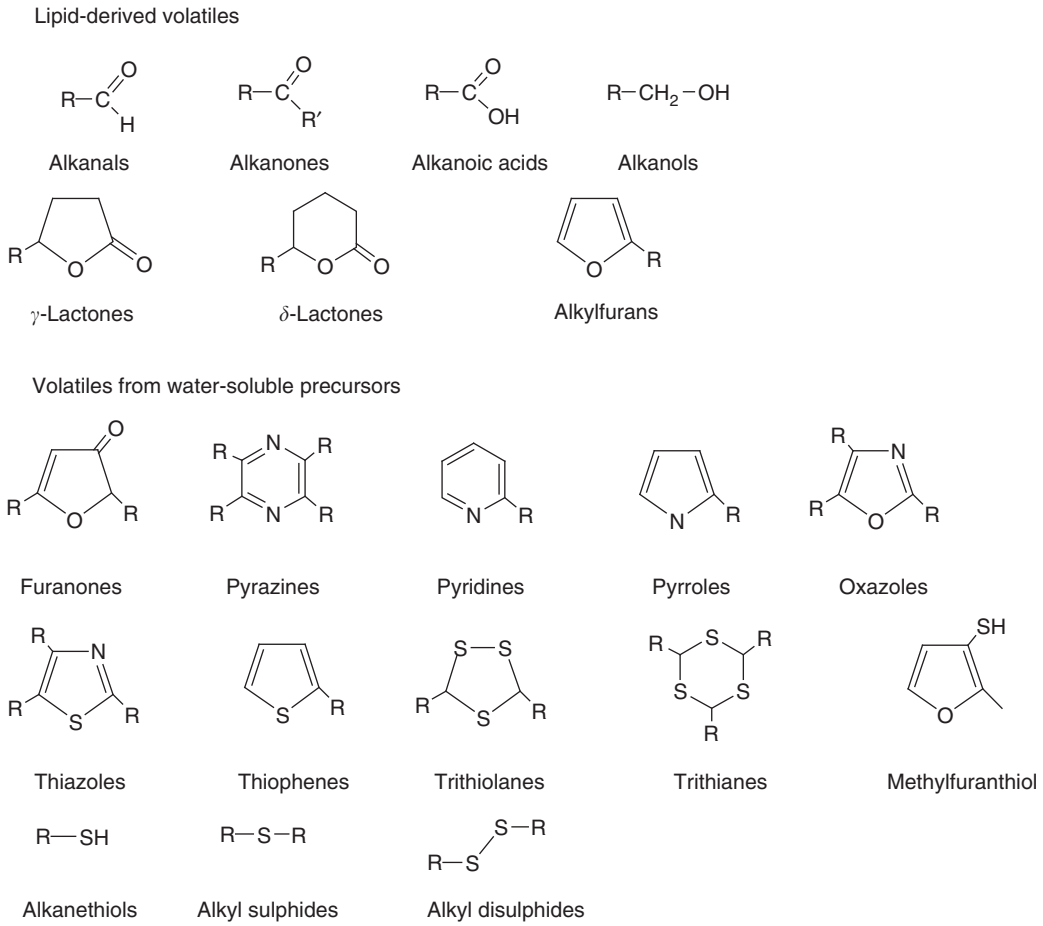

Figure 1 Some classes of volatile compounds produced during the cooking of meat. Reproduced from Shahidi, F., Rubin, L.J., D'Souza, L.A., 1986. Meat flavour volatiles: A review of the composition, techniques, analyses and sensory evaluation. CRC Critical Reviews in Food Science and Nutrition 24, 141–243 and Mottram, D.S., 1998. Flavour formation in meat and meat products: A review. Food Chemistry 62, 415–424.

The actual products formed from the Maillard reaction in biological systems depend on the temperature and time (duration) of cooking, water activity/moisture content, pH, as well as the nature and concentration of the reactants involved. An increase in the formation of brown-colored pigments (i.e., melanoidins) and low-molecular weight flavor compounds in cooked foods significantly correlated with higher cooking temperatures. The optimum rate for the Maillard reaction occurs at a water activity of 0.65–0.75. In other words, the Maillard reaction proceeds more readily at low moisture levels, and the flavor compounds generated are associated mostly with the exterior areas of meat, which have been dehydrated during cooking.

Early Stages of the Maillard Reaction

The initial stages of the Maillard reaction have been well studied. The mechanism proposed by Hodge (1953) the so-called Hodge-scheme to describe the initial stages of the reaction still provides the basis for our understanding of this reaction. The beginning reactions are depicted in Figure 2. Some researchers have suggested that the cyclic pyranose and furanose conformations of sugars are more likely to be involved in the reactions, as they are most abundant in aqueous solution.

To initiate the Maillard reaction, a carbonyl group from the open chain of an aldose sugar reacts reversibly with an amino group of an amino acid, peptide, protein, or other compound possessing a primary or a secondary amino moiety, followed by water elimination leading to an intermediate imine, which cyclizes to produce a glycosylamine (i.e., *N*-glycoside). The Schiff base formed from a hexose and an amino compound may not necessarily cyclize to the glycosylamine and rearrange to form the key intermediate, an 1,2-enaminol, in this primary step of the Maillard reaction. The 1,2-enaminol has three possibilities in which to further react. One possibility is that, it undergoes Amadori rearrangement to yield 1-amino-1-deoxyketose (i.e., an Amadori compound). At higher pH, however, 2,3-enolization is favored and β-elimination of the amine affords a 1-deoxydicarbonyl compound (i.e., 1-deoxyosone). The reaction between ketosugars (e.g., fructose) and amines follows a similar sequence of reactions to form an *N*-ketosylamine, which undergoes a Heyns rearrangement to give a 2-amino-2-deoxyaldose. A second possibility is that, at lower pH, 1,2-enolization of the Amadori product occurs, and the

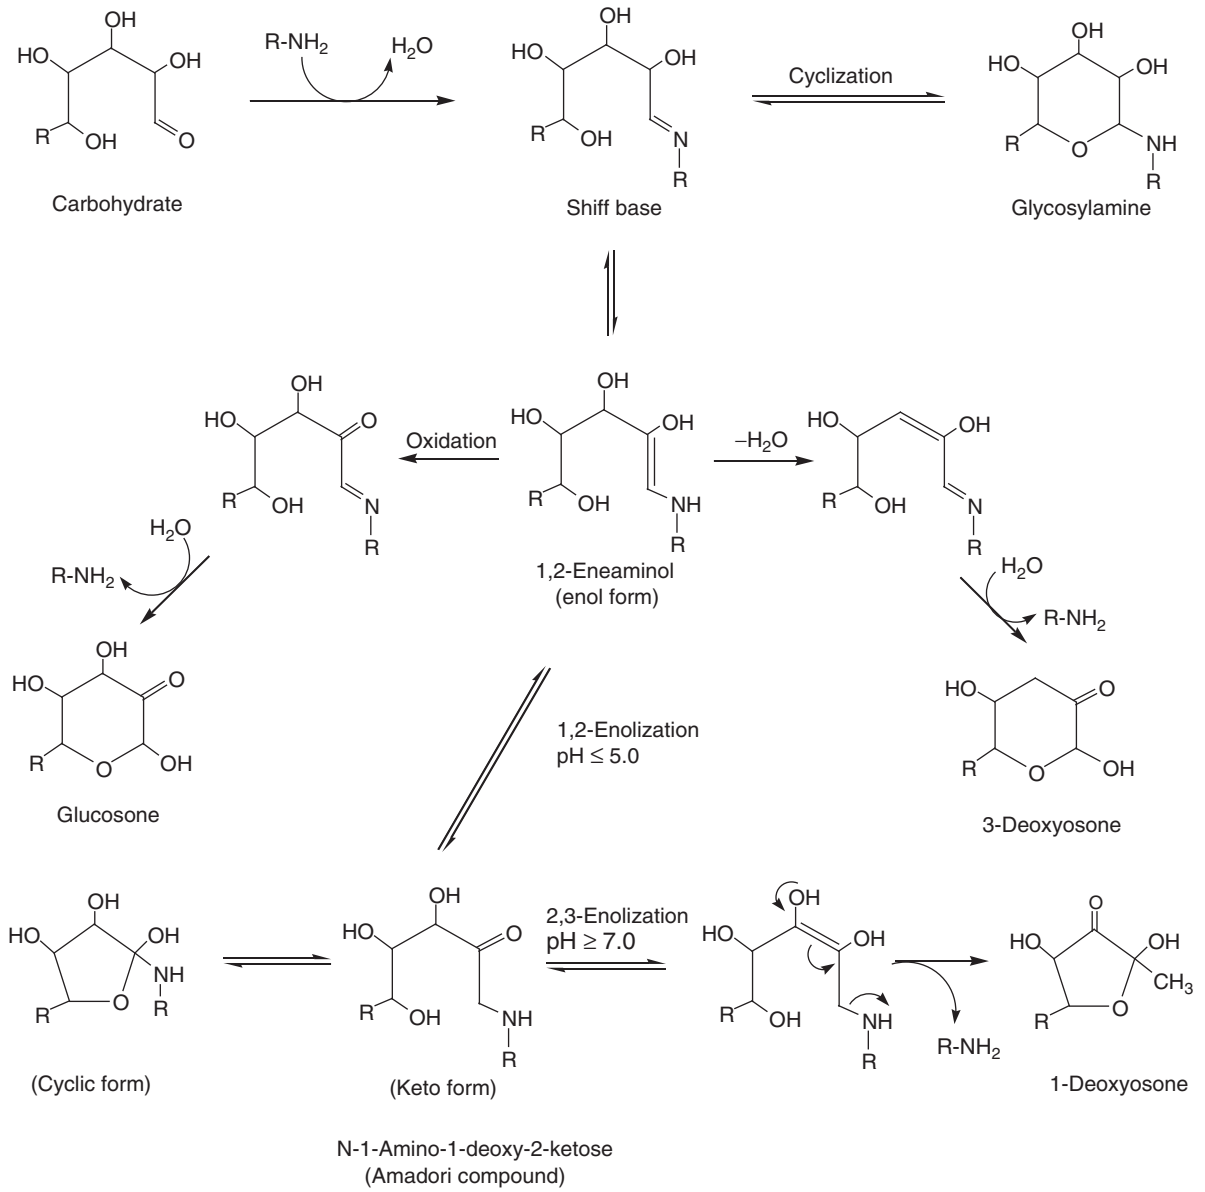

Figure 2 Primary reaction pathways of the Maillard reaction. Modified from Schieberle, P., Hofmann, T., 2002. New results on the formation of important Maillard aroma compounds. In: Swift, K.A.D. (Ed.), Advances in Flavour and Fragrances: From the Sensation to the Synthesis. Cambridge, UK: Special publications of the Royal Society of Chemistry, pp. 163–177, with permission from RSC.

1,2-enaminol formed can lose a molecule of water to yield 3-deoxyosone after hydrolysis of the intermediary α-oxoimine (Figure 2). Thirdly, oxidation of the 1,2-enaminol may take place generating an α-oxoimine, which after hydrolysis forms a hexosone.

The reaction intermediates so formed are thermally unstable and can degrade to a number of flavor compounds (i.e., *N*-, *S*-, *O*-heterocyclics) by the so-called advanced Maillard reaction during further heat treatment. The types of reaction that can take place during the degradation of formed reductones and dehydroreductones include dehydration reactions while maintaining the carbohydrate skeleton, retroaldol reactions leading to fission products, aldol-type reactions of generated fission products, substitution of oxygen-containing compounds by nitrogen and sulfur atoms, redox reactions, and Strecker reactions. Some of the reaction pathways leading to the formation of key intermediary flavor compounds in meat are illustrated in Figures 3 and 4. These compounds can react with other Maillard reaction degradation products as well as with other constituents of the meat matrix (e.g., lipid oxidation products) to form characteristic flavor compounds in cooked meats.

Dehydration and cyclization of 1-deoxyosone lead to the formation of 4-hydroxy-5-methyl-3(2*H*)-furanone from pentoses and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol) from hexoses. Maltol (3-hydroxy-2-methyl-4*H*-pyran-4-one), 5-hydroxy-5,6-dihydromaltol, isomaltol [1-(3-hydroxy-2-furanyl)-ethanone], and cyclotene are other important dehydration

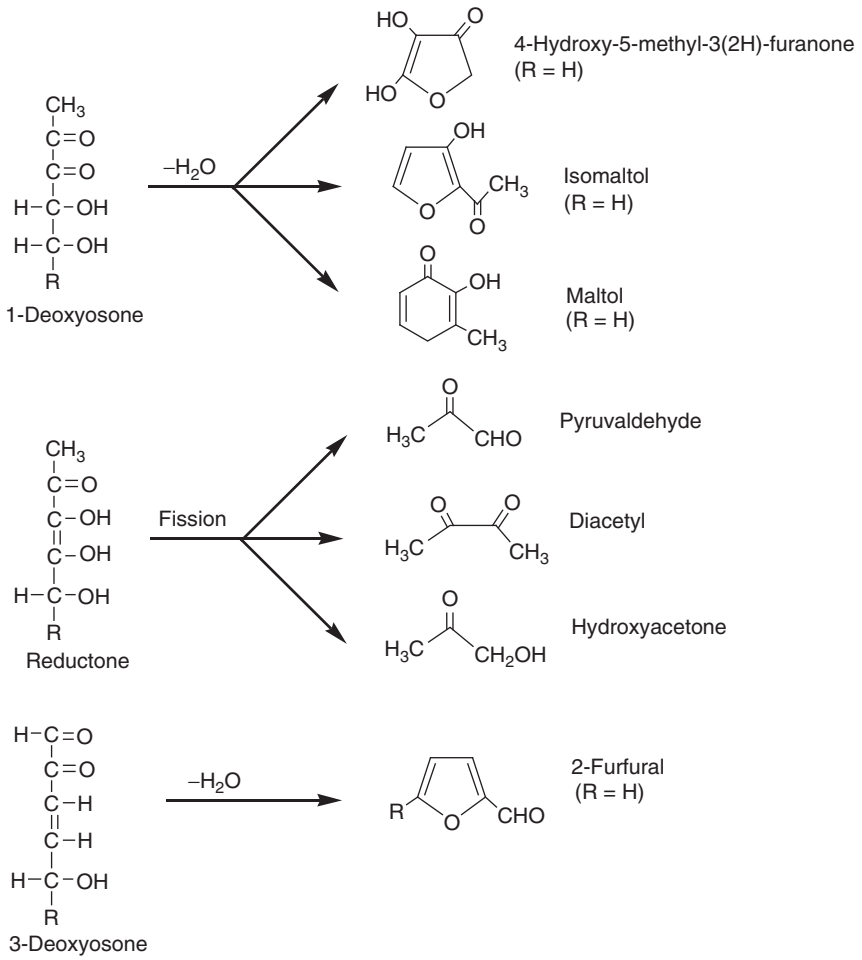

Figure 3 Degradation of Maillard reaction intermediates to form important meat flavor precursors. Reproduced from Bailey, M.E., 1998. Maillard reactions and meat flavour development. In: Shahidi, F. (Ed.), Flavour of Meat, Meat Products and Seafoods. London: Blackie Academic and Professional, pp. 267–289, with permission from Blackie Academic.

products of hexoses (Figure 4). Cyclotene can also be formed by condensation of hydroxyacetone. Degradation of 3-deoxyosones produces 5-hydroxymethyl-2-furfural from hexoses and 2-furfural from pentoses. These furfural derivatives react readily with ammonia and hydrogen sulfide to give many heterocyclic flavor compounds in cooked meats.

Retro-aldol (fission) reactions of 1-deoxyreductone (i.e., an equilibrium product of 1-deoxyosone) in a basic medium (pH > 5) can lead to the formation of very reactive carbonyl compounds such as pyruvaldehyde, diacetyl, dihydroxyacetone, glyoxal and hydroxyacetal, and acetic acid. These compounds participate in Strecker reactions to produce meat flavor compounds.

Strecker Reaction

The reaction between amino acids and α-dicarbonyl compounds (e.g., deoxyosones), which occur as intermediary or end products of other decomposition reactions of the Maillard reaction (e.g., diacetyl, pyruvaldehyde, hydroxyacetone), is one of the most important interactions relating to meat flavor generation. This reaction, termed the Strecker reaction, leads to the formation of an aldehyde, often called a Strecker aldehyde, which contains one less carbon atom than the original amino acid and carbon dioxide; meanwhile, the dicarbonyl, originating from saccharides, is converted into an α-aminoketone or aminoalcohol (Figure 5).

Aminoketones are important intermediates in the formation of several classes of heterocyclic compounds such as pyrazines, oxazoles, and thiazoles; all of which are powerful aroma constituents (Figure 1). If the amino acid is cysteine, the Strecker reaction leads to the formation of ammonia, hydrogen sulfide, and acetaldehyde; these three compounds are very important intermediates in the formation of different classes of flavor compounds in cooked meat. Sulfur compounds, derived from cysteine and ribose, are particularly significant for the generation of aroma notes characteristic of cooked meat.

Later Stages of the Maillard Reaction

As aforementioned, a number of oxygenated sugar degradation products are formed during the initial stages of the Maillard reaction in meat and undergo further interactions at the elevated temperatures associated with cooking. The

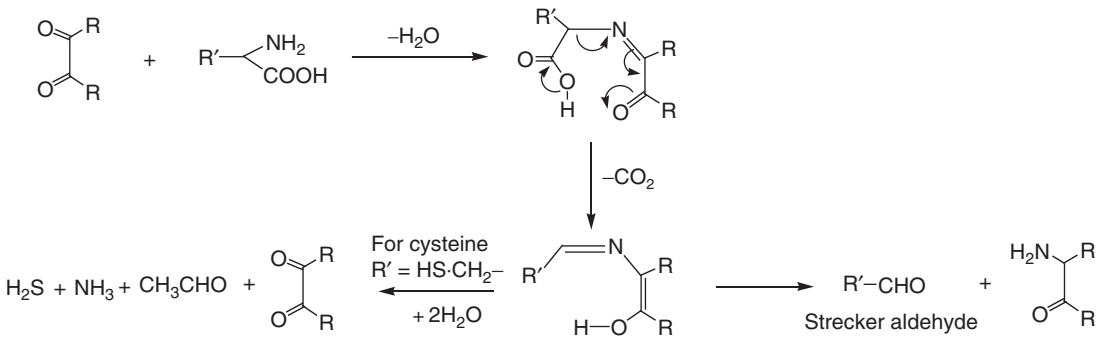

Figure 5 Strecker reaction of amino acids. Reproduced from Mottram, D.S., 1994. Flavor compounds formed during the Maillard reaction. In: Parliament, T.H., Morello, M.J., McGorrin, R.J. (Eds.), Thermally Generated Flavours. Maillard, Microwave and Extrusion Processes. ACS Symposium Series 543. Washington, DC: American Chemical Society, pp. 104–126, with permission from ACS.

Strecker reaction also leads to the production of many reactive compounds such as Strecker aldehydes, ammonia, and hydrogen sulfide. Many of these possess aroma or taste notes, as already commented upon, but they are also crucial intermediates for further flavor-forming reactions in meat during later stages of the Maillard reaction.

Meat Flavor Compounds from Maillard Reaction

Most of the flavor compounds generated via the Maillard reaction are *N*-, *S*-, *O*-heterocyclics and other sulfur-containing compounds that give roasted, boiled, and meaty aromas to cooked meat. These compounds contribute significantly to the

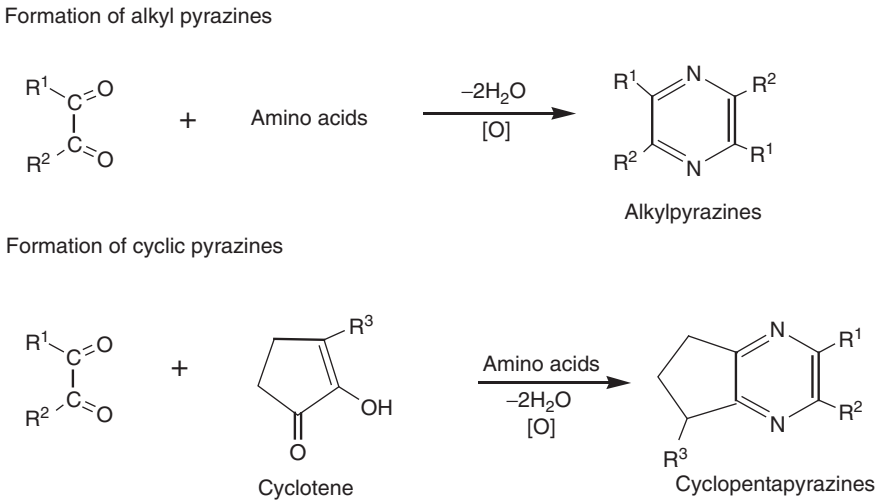

Figure 6 Reaction pathways proposed for the formation of pyrazines. Reproduced from Bailey, M.E., 1998. Maillard reactions and meat flavour development. In: Shahidi, F. (Ed.), Flavour of Meat, Meat Products and Seafoods. London: Blackie Academic and Professional, pp. 267–289, with permission from Blackie Academic.

overall aroma profile of cooked meat; they include furans, furanones, pyrazines, pyrroles, thiophenes, thiazoles (thiazolines), imidazoles, pyridines, oxazoles, cyclic ethylene sulfides, alkyl sulfides, and disulfides (Figure 1).

Oxygen-Containing Compounds

Early stages of the Maillard reaction produce oxygenated furans and pyrans, such as furfural, 5-methylfurfural, 2-acetylfuran, maltol, isomaltol, and furanones like 4-hydroxy-5-methyl-3(2*H*)-furanone (norfuraneol), and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol) (Figures 3 and 4). Usually, molecules having a planar enol-carbonyl structure in a cyclic dicarbonyl compound originate from sugars and elicit a caramel-like aroma. Most of the reaction products (e.g., maltol, ethylmaltol, dihydromaltol, 4-hydroxy-5-methyl-3(2*H*)-furanone, and norfuraneol) containing this structural element contribute to the 'caramel-like' odor of cooked meats. As previously mentioned, these compounds are also important intermediates in the formation of other *N*- and *S*-containing meat flavor volatiles during thermal processing. For example, sugar degradation products like maltol, isomaltol, 4-hydroxy-5-methyl-3(2*H*)-furanone, furaneol, and cyclotene can exchange oxygen in the ring with nitrogen and sulfur to produce other flavor compounds.

Nitrogen-Containing Compounds

Pyrazines

Pyrazines have been found in all meat species following cooking and constitute a major class of volatiles formed via the Maillard reaction. The nature and quantity of pyrazines generated during thermal processing are a function of the reaction conditions employed, such as moisture content, pH, temperature, and the duration (time) of cooking. Several mechanisms have been proposed for pyrazine formation by the Maillard reaction: one important route is the condensation of α-dicarbonyl compounds formed from the Strecker reaction with amino compounds to give alkylpyrazines (Figure 6).

Two other classes of compounds, mainly bicyclic products, 6,7-dihydro-5(*H*)-cyclopentapyrazines and pyrrolopyrazines, have also been reported in meat volatiles. Cyclopentapyrazines can be formed from the condensation of cyclic ketones such as cyclotene (Figure 6). The alkylpyrazines generally have nutty and roasted aromas, whereas cyclopentapyrazines have roasted, grilled, and species-related flavor notes of roasted meat. The pyrrolopyrazines have only been reported for meat. Recent evidence indicates that 3-deoxyglucosone is a chief precursor for pyrazine formation by retro-aldolization and 2,4-scission to yield pyruvaldehyde. Pyruvaldehyde is involved in the Strecker reaction to give dimethylpyrazine.

Formation of 48 pyrazines from beef, 36 from pork, and 16 from lamb have been documented. These are extremely important constituents of meat cooked at high temperatures and contribute mainly to the flavor of roasted meat. Pyrazines account for 77% of the total volatiles found in well-done grilled pork.

Oxazoles and oxazolines

Several oxazoles have been identified in cooked meats, and these possess green and vegetable-like aroma characteristics. The compound 2,4,5-trimethyl-3-oxazoline, with a woody, musty, and green note, has also been detected in boiled beef. However, contribution of oxazoles and oxazolines to the overall aroma of meat is not as significant as that of sulfur-containing compounds such as thiazoles and thiazolines, which possess closely related chemical structures.

Sulfur-Containing Compounds

Sulfur compounds, both aliphatic and heterocyclic, are among the most important volatiles formed during meat processing. Most occur at low concentrations, but their very low odor thresholds make them potent aroma compounds giving sulfurous, onion-like, and meaty aromas to cooked meat

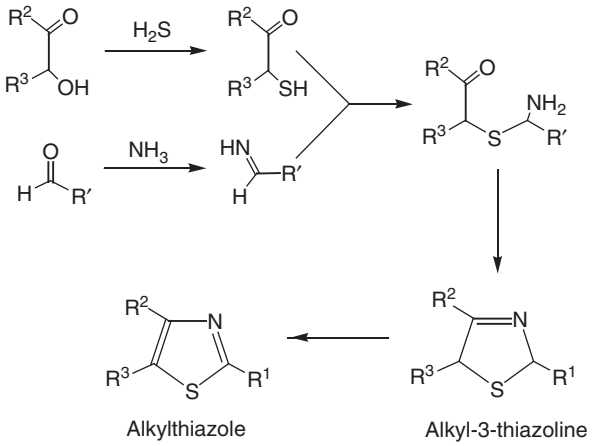

Figure 7 Route for the formation of thiazolines and thiazoles in the Maillard reaction from the reaction of hydroxyketones and aldehydes with ammonia and hydrogen sulfide. Reproduced from Mottram, D.S., 1998. Flavour formation in meat and meat products: A review. Food Chemistry 62, 415–424.

products. Hydrogen sulfide, produced from cysteine by hydrolysis or via the Strecker reaction, is an essential precursor in the formation of many sulfur-containing aroma compounds in meat during thermal processing.

The cooking method employed has a significant effect on the generation of sulfurous compounds. For example, more aliphatic thiols, sulfides, and disulfides have been reported in boiled beef compared to those of roast beef. Heterocyclic compounds with 1, 2, or 3 sulfur atoms in their 5- and 6-membered rings (e.g., thiophenes, trithilanes, trithianes) are formed in greater amounts in boiled meat than in roasted meat.

Thiazoles and thiazolines

These compounds are important constituents of roasted or fried meat, and their content increases with higher cooking temperatures. Most thiazoles present in meat are alkyl substituted, and their aroma depends on the nature and the number of alkyl moieties attached. A number of the di- and tri-alkyl derivatives formed in meat have been reported to possess roasted and meaty aroma characteristics. Some acetyl-substituted thiazoles and thiazolines have also been found in cooked meats.

One possible route for the formation of thiazoles and thiazolines is via the Maillard reaction, and this involves the action of ammonia and hydrogen sulfide in the presence of α-carbonyls, dicarbonyls, or hydroxyketones (Figure 7) derived from the Strecker reaction of amino acids in heated foods. However, lipid-derived aldehydes can also participate in this reaction during cooking and, in fact, long-chain trialkylthiazoles have been identified in the aromagrams of roast beef and fried chicken.

Thiophenes

Perhaps the most important flavor compounds arising from the Maillard reaction are the thiophenes and furans with methyl or sulfur groups at 1, 2, or 5 positions. These compounds give desirable 'meaty' aroma to cooked meat. Furans and thiophenes with a thiol group at the 3-position also possess a strong meaty-like aroma and have very low odor threshold values. There are a number of possible routes for the formation of thiophenes, involving the reaction of a sulfur compound derived from sulfur-containing amino acids (e.g., cysteine, cystine, methionine) or thiamine, with intermediary sugar degradation products from the Maillard reaction, such as deoxyosones. Another pathway has also been proposed for the formation of long-chain 2-alkylthiophenes from reactions involving hydrogen sulfide and the 2,4-alkadienals derived from the degradation of lipids.

Polysulfur heterocyclics

A number of polysulfur heterocyclics have been found in meat, and the formation of these compounds is very important for the desirable meaty aroma in cooked meats. Seventy-eight compounds having meat-like aromas have been reported, of which 65 are heterocyclic sulfur compounds and seven are sulfur-containing aliphatic compounds. The remaining six are nonsulfur-containing heterocyclics. The mechanisms of formation of a number of these cyclic-sulfur compounds in the aroma of cooked beef via the Maillard reaction or thermal degradation of thiamine have been reported.

Acetaldehyde, formed by the Strecker reaction of alanine during thermal processing, and other aldehydes can react with precursors such as hydrogen sulfide, ammonia, and methanethiol to yield a large number of heterocyclic and straight chain polysulfur compounds in meat (Figure 8). Under oxidative conditions, dialkyltrithiolanes are formed from *bis*-(1-mercaptoethyl)sulfide, whereas at low pH trialkyltrithianes are produced (Figure 8). At elevated temperatures, *bis*-(1-mercaptoethyl)sulfide isomerizes to trisulfides and leads to the formation of di- and tetrasulfides. Dithiazines and thiadiazines are generated in the presence of ammonia (Figure 8). Thus, the formation of these compounds in cooked meats depends on the reaction conditions (i.e., acidity and temperature of thermal processing) and the types of Strecker reaction products available for each of the reactions to proceed.

Sulfur compounds from furan-like components

As aforementioned, furans with a thiol group in the 3-position, and related disulfides, possess strong meat-like aromas with very low odor threshold values. The presence of 2-methyl-3-(methylthio)-furan and 2-methyl-3-(methyldithio)-furan in cooked beef has been reported; these compounds have odor thresholds of 50- and 10 parts-per-billion, respectively. In addition, 2-methyl-3-furanthiol and the corresponding disulfide, *bis*-(2-methyl-3-furanyl)disulfide (odor threshold of 0.02 ng kg^{-1}), have been identified as major contributors to the meaty aroma of cooked beef. In meat, 4-hydroxy-5-methyl-3(2*H*)-furanone, formed via dephosphorylation and dehydration of ribose phosphate (from ribonucleotides), reacts with hydrogen sulfide to yield the above mentioned meat flavor character impact compounds (Figure 9). Some other furan-like sulfur compounds (Figure 10), apart from those described above, have also been identified in cooked meats.

Oxidation of thiols formed via interaction of hydrogen sulfide with dicarbonyls, furanones, and furfurals (i.e., prominent products of the Maillard reaction) may provide other routes in the formation of furan sulfides and disulfides.

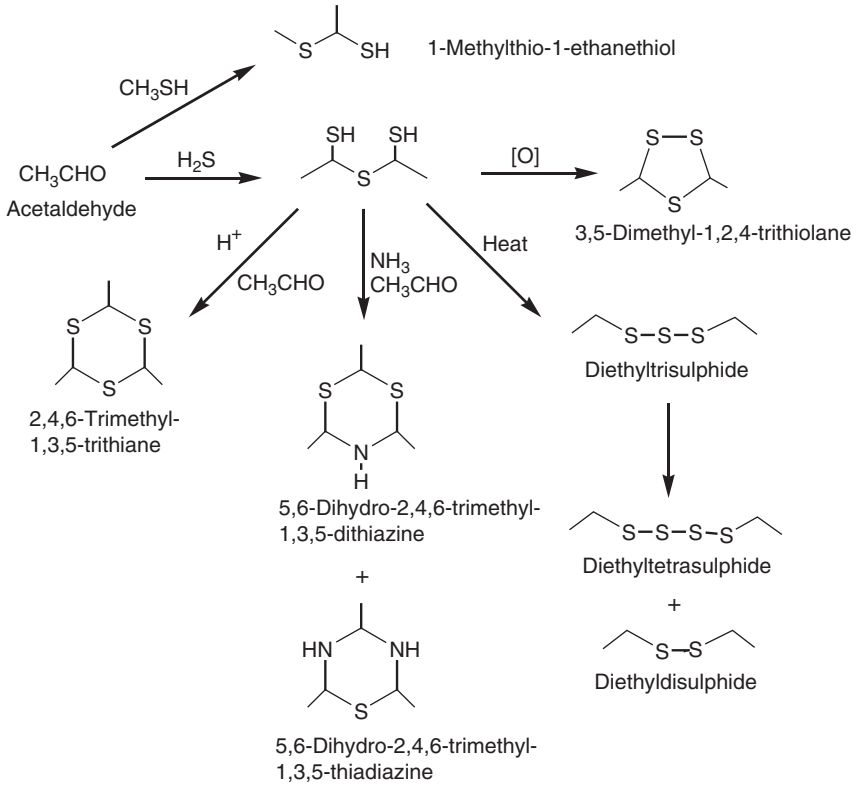

Figure 8 Formation of some sulfur-containing aroma compounds from reaction of acetaldehyde, hydrogen sulfide, ammonia, and methanethiol. Modified from Mottram, D.S., 1994. Flavor compounds formed during the Maillard reaction. In: Parliament, T.H., Morello, M.J., McGorrin, R.J. (Eds.), Thermally Generated Flavours. Maillard, Microwave and Extrusion Processes. Cyclotene (2-hydroxy-3-methylcyclopent-2-enone), another product of the Maillard reaction, formed from 5-hydroxy-5,6-dihydromaltol (Figure 4) and from the condensation of hydroxyacetone, can react with ammonia and hydrogen sulfide to generate volatile compounds with meaty aromas (e.g., 1,2,4-trithiolane, 5-trithiane, and 1,2,4,6-tetrathiepane) and a roasted beefy note (e.g., 2-methylcyclopentanone and 3-methylcyclopentanone). Isomaltol is also an important precursor of the heterocyclic compounds related to cooked meat flavor.

Meat Flavor Compounds from Lipid–Maillard Interactions

Both saturated and unsaturated aldehydes formed via autoxidation of lipids are among the major contributors to the volatile profile of cooked meats. At the same time, these aldehydes can participate in the Maillard reaction at both the initial and later stages during thermal processing of meat. Volatile compounds such as pyridines, pyrazines, thiophenes, thiazoles, and oxazoles with alkyl substituents are formed.

Novel sulfur compounds from lipid–Maillard interactions in cooked meat. In: Reineccius, G.A., Reineccius, T.A. (Eds.), Heteroatomic Aroma Compounds. ACS Symposium Series 826. Washington, DC: American Chemical Society, pp. 93–101, with permission from ACS.

A number of thiazoles with C_4–C_8 *n*-alkyl substituents in the 2-position have been reported in roast beef and fried chicken. Several other alkylthiazoles with longer 2-alkyl chains of C_{13}–C_{15} have been identified in the volatiles of heated beef and chicken, with the highest concentrations reported in beef heart muscle. Recently, a series of alkylthiazoles and alkyl-3-thiazolines were isolated from the volatiles of cooked beef and lamb (Figure 11); the amounts formed were greater in pressure-cooked meat than in grilled meat. Furthermore, the number and concentration of these compounds were much higher in meat from animals fed a linseed and fish oil diet than in the control diet devoid of them. Lipid-derived aldehydes can participate in the formation of long-chain 2-alkylthiazoles in heated meats. Reactions of aldehydes, hydroxyketones, ammonia, and hydrogen sulfide with one another, as illustrated in Figure 7, have already been discussed.

The compound 2-pentylpyridine has been identified in all major meat species; a likely route of its formation is via the reaction of *E,E*-2,4-decadienal with ammonia (Figure 12). Similar types of reactions between 2,4-alkadienals and hydrogen sulfide may be responsible for the formation of 2-alkylthiophenes and 2-alkyl-(2*H*)-thiapyrans (Figure 12).

Butyl- and pentyl-substituted pyrazines have been identified in cooked meats. The probable mechanism for their formation is via the reaction of pentanal or hexanal with a dihydropyrazine, formed by the condensation of two aminoketone molecules (Figure 13). Pentanal and hexanal, which are breakdown products of linoleic acid (18:2*n*6), also appear to be involved in the formation of 5-butyl-3-methyl-1,2,4-trithiolane and its 5-pentyl homologue. Both trithiolanes have been isolated from the volatiles of fried chicken and pork.

Volatile compounds derived from lipid-Maillard interactions of meat possess weak odor intensities (i.e., weak fatty, fried, and garlic-like notes) and high odor thresholds;

consequently, they may not contribute directly to the aroma of cooked meat. However, interactions between lipid degradation and MRP during thermal processing may modify the aroma compounds generated via the Maillard reaction and by lipid degradation and, therefore, have an indirect impact on the aroma profile of cooked meat. In particular, phospholipids and their degradation products inhibit reactions involved in the formation of heterocyclic aroma compounds via the Maillard reaction. Thus, the generation of sulfur-containing heterocyclics during thermal processing of meat may be curbed by this inhibition. This interaction may help to maintain the level of key sulfur compounds at their optimum concentrations in cooked products.

Maillard Browning

Besides aroma, the brown color formation due to the Maillard reaction (i.e., nonenzymatic browning) is a key factor in the overall acceptability of thermally processed foods such as roasted meat and coffee. Little is known, however, about the chromophores responsible and the reaction mechanisms leading to the formation of these brown color compounds from carbohydrates and amino acids. From studying reducing sugar/amino acid reaction mixtures, the chromophores identified as 'browning agents' can be divided into two classes: low-molecular weight colored compounds and high-molecular weight melanoidins. Model experiments indicate that condensation reactions between methylene-active intermediates (e.g., 4-hydroxy-5-methyl-3(2*H*)-furanone) and reactive carbonyl compounds (e.g., furan-2-aldehyde, acetaldehyde, acetone, pyrrolaldehydes, or 2-oxopropanal) generated during the Maillard reaction are the dominant reaction in nonenzymatic browning and aid in the formation of low-molecular weight colored compounds (Figure 14).

Besides the classical reaction pathway proposed by Hodge (Figure 2), model experiments have shown another reaction pathway leading to the formation of color in very early stages of the Maillard reaction and before Amadori rearrangement. The proposed mechanism involves cleavage of the sugar molecule with the production of glycolaldehyde imine; this product dimerizes and oxidizes to form a 1,4-dialkylpyrazinium radical cation (Figure 15) as an important intermediate. Early stages of browning in foods and beverages may be a result of this phenomenon.

Although the exact structures of high-molecular weight melanoidins have not been elucidated, it has been found that such compounds can be generated during thermal processing

of food by a cross-linking reaction between low-molecular weight MRP and high-molecular weight noncolored proteins. Lysine and arginine residues of protein help bind the carbohydrate-derived compounds to the protein backbone and produce the chromophoric substructures of melanoidins (Figure 16). Thus, proteins seem to act as noncolored skeletons of food melanoidins, to which different chromophoric substructures might be covalently bound through reactive side chains. Meat contains a fairly high protein content (e.g., 20–25% in lean muscle tissue) and the carbohydrate-induced oligomerization and browning of proteins may be involved in the formation of melanoidins during thermal processing of meat. This leads, at least to some extent, to the characteristic dark brown color associated with roasted meat.

Summary

The aroma of cooked meats is thermally derived, and the volatile compounds originate from both lipid- and water-soluble precursors. The Maillard reaction occurs during cooking of meat and is mainly responsible for the formation of a large number of heterocyclic compounds present in the volatile fraction of meat; these are responsible for the savory, roasted, and boiled flavors associated with cooked meat. Reducing sugars and amino acids of meat, notably ribose and cysteine, respectively, are important precursors for these reactions. Initial stages of the Maillard reaction lead to the formation of α-dicarbonyls such as 1-deoxyosones, 3-deoxyosones, and 1-deoxyreductones through Amadori and Heyns intermediates.

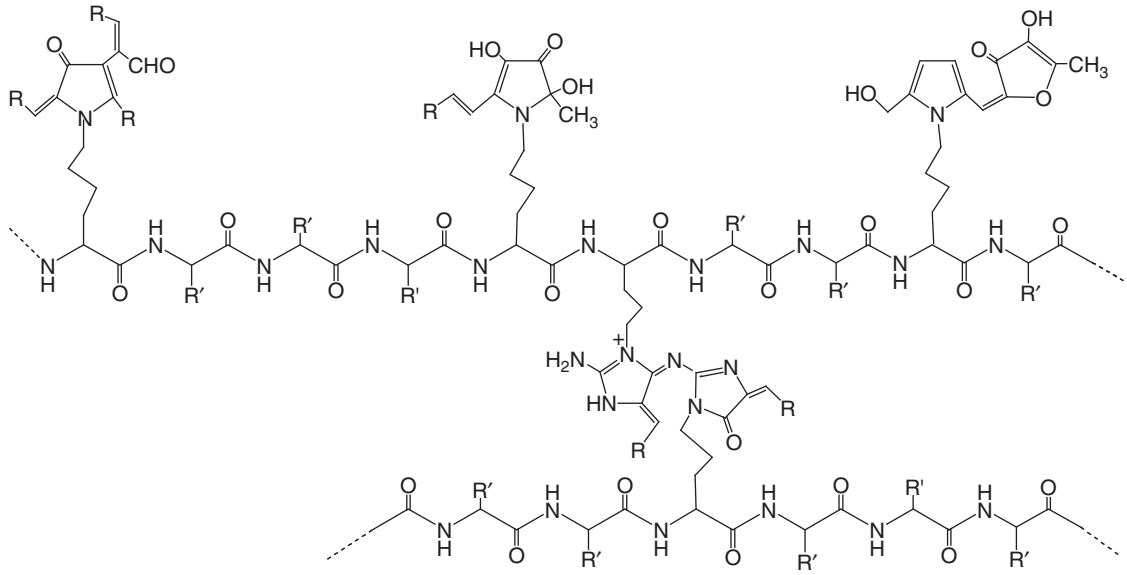

Figure 16 Chromophoric substructures involved in melanoidin formation. Reproduced from Hofmann, T., 2001. Structure, colour and formation of low- and high-molecular weight products formed by food-related Maillard-type reactions. In: Ames, J.M., Hofmann, T. (Eds.), Chemistry and Physiology of Selected Food Colorants. ACS Symposium Series 775. Washington, DC: American Chemical Society, pp. 134–151, with permission from ACS.

The breakdown of these compounds yields key intermediates such as furfurals, furanones, and other dicarbonyl compounds. Other related reactions (e.g., the Strecker reaction) lead to the formation of simple compounds such as aldehydes, ammonia, and hydrogen sulfide, which are precursors for further reactions. Many different interactions of these compounds subsequently result in the formation of important classes of aroma compounds like furans, furanones, pyrazines, pyrroles, thiophenes, thiazoles (thiazolines), imidazoles, pyridines, oxazoles, cyclic ethylene sulfides, alkylsulfides, and disulfides. Of these compounds, aromatic nitrogen derivatives such as pyrazines, *N*-, *S*-heterocyclics like thiazoles, 2-methyl-3-thio (or sulfide)-furans, 2-methyl-5-thio (or sulfide)-thiophenes, sulfur-substituted tetrahydrofuranones, and nonaromatic ring sulfur derivatives with two or more sulfur groups are particularly important for the meaty-roasted flavor of cooked meats.

Other constituents of the meat matrix, such as lipids, can react with products of the Maillard reaction. Lipid-derived aldehydes participate in Maillard reactions via reactions with hydrogen sulfide and ammonia to produce new volatile compounds. Lipid degradation products from phospholipids are particularly important and appear to control or limit the generation of sulfur compounds during thermal processing of meat. This process may be involved in the modification of flavor profiles of cooked meats and would depend on the type of meat (i.e., lean meat with less fat, meat with more unsaturated fatty acids) and reaction parameters (i.e., cooking method, temperature, duration of cooking) used.

Owing to the complexity of the nonvolatile MRP, very little is known about the compounds responsible for the typical brown color on the exterior areas of products. According to the model experiments, both high- and low-molecular weight colored compounds generated during thermal processing contribute to the brown color on the surface of cooked meats.

Introduction

Meat is a complex structure composed of muscle fibers, extracellular matrix, lipids, and water. The meat proteins are the main constituents that form the structure of the meat product. During heating they undergo significant structural changes and therefore the quality of the meat, mainly influenced by the meat structure, also changes significantly. Among the sarcoplasmic meat proteins there are globular proteins and enzymes. A typical example of globular proteins is myoglobin responsible for meat color. At increased temperatures the hydrophobic side chains of the compact globular proteins, in the aqueous environment, undergo expansion and partial unfolding, followed by association of unfolded proteins. The large degree of protein association decreases their solubility and precipitates are formed. If, however, the three-dimensional network is formed, a gel sets. These gels bind the water and are solid-like in their mechanical behavior. The fibrous proteins (actin, myosin, titin, collagen) have a lot of hydrogen bonds and show electrostatic interactions that keep the molecules in register in the large building blocks, which in turn are broken during heating. The fibrous proteins contract on cooking in contrast to the globular proteins, which expand. Physicochemical processes that occur in the meat tissue during heating, causing significant changes in the spatial arrangement of the meat proteins, affect the final physicochemical and sensory properties of the heated meat.

The method of heating is important too. For the same raw material, to achieve equivalent denaturation of proteins, more energy is needed during fast (40 °C min^{-1}) than during slow (5 °C min^{-1}) heating. Different heating rates dictate the rate of enzymatic and chemical reactions in the meat. They influence the conformation of the meat proteins, enzyme activity, solubility, and hydration and lead to thermal and hydrolytic rupture of peptide bonds, thermal degradation, and derivatization of amino acid residues, cross-linking, oxidation, and formation of sensory-active compounds. Most of those reactions can be reflected in the meat as either desirable or detrimental changes in color, flavor, juiciness, rheological properties, and enzyme activity, depending on the various combinations. These processes are affected by the temperature and time of heating, pH, oxidizing compounds, antioxidants, radicals, and other reactive constituents, especially reducing saccharides.

The susceptibility of the meat proteins to thermal denaturation depends on their structure, predominantly on the number of cross-links, but also on the simultaneous action of other denaturing agents. Salt bridges, side chain hydrogen bonds, and a large proportion of residues in α-helical conformation increase the thermal stability of proteins. The stabilizing effect is related to heating temperature. On the one hand, thermal changes cause a decrease of solubility due to aggregation of the myofibrillar proteins, but on the other hand, they lead to an increase in solubility as a result of the degradation of tertiary protein structures of intramuscular collagen. Further effects of heating are gel formation (in most types of sausages and meat products), hydrolytic changes, alteration in the rate of proteolysis, and modification of the nutritive value.

Chemical Changes in Meat Protein Systems

During heating of meat, conformational changes (heat denaturation) of the protein systems occur. These changes take place at a particular temperature, called the denaturation temperature. The next step in the structural changes during heating of meat are the protein–protein interactions resulting in loss of solubility and aggregation.

Sarcoplasmic Proteins (30% of Total Meat Proteins)

Most of the sarcoplasmic proteins denature between 40 and 67 °C, but their heat aggregation may extend up to 90 °C. The aggregated sarcoplasmic proteins can form a gel between the structural meat elements in such a way that they have a role in the texture of the heated meat. This fraction of proteins also includes enzymes. Some of them have a tenderizing effect. During heating of the beef muscles at a temperature below 60 °C for a long time (heating rate of 0.1 °C min^{-1}), the collagenases remain active in the meat, and tenderizing effect is achieved after 6 h, whereas they are inactived at faster heating at the end temperature of 70–80 °C.

Myofibrillar Proteins (65% of Total Meat Proteins)

Heating of these proteins to a temperature of 65 °C causes a progressive increase of the surface hydrophobicity, whereas at higher temperatures it decreases again. This suggests that a part of the hydrophobic residues participates in protein–protein interactions leading to formation of aggregate network. According to differential scanning calorimetry measurements, α-actinin is the most labile and becomes insoluble at 50 °C; myosin and actomyosin denature between 54 and 58 °C; actin between 80 and 83 °C; tropomyosin and troponin at above 80 °C; and titin from pork and beef at 78.4 °C and 75.6 °C, respectively.

The heat denaturation of myofibrillar proteins in solution usually results in a gel formation. It is caused by the fact that especially myosin forms gels at a very low concentration (0.5% w/w), compared to sarcoplasmic proteins (3% w/w). For purified myosin, the firmest gels are reached at 45 °C and pH

 doi:10.1016/B978-0-12-384731-7.00128-8

5.5 or at 60 °C and pH 6. Ionic strength and pH are important factors determining monomeric or filament structure of the myosin. At ionic strengths above 0.3 and at neutral pH, the myosin molecules are dispersed as monomers, forming a coarse network with large pores. At lower ionic strength the myosin molecules are assembled in filaments, and give a firmer gel. On heating, the gel formation of purified myosin occurs in two steps, in two separate temperature regions. The first part of the reaction (aggregation of the globular heads of myosin) occurs between 30 and 50 °C. The second stage (above 50 °C), connected with the structural changes in the helix structure of the myosin tails, leads to a network formation, where hydrophobic groups interact with each other. For the chicken-derived salt soluble myofibrillar proteins (SSP) heated in 0.6 M NaCl at pH 6, protein unfolding is observed at 30–32 °C, protein–protein association at 36–40 °C, and gelation at 45–50 °C. A lower degree of aggregation, better water-holding, and greater softness characterize the breast SSP gels, whereas a higher degree of aggregation and more hardness characterize the leg SSP gels.

Connective Tissue Proteins (5% of Total Meat Proteins)

The thermal denaturation of the meat collagen occurs in two steps. The first stage of the reaction is its shrinkage observed in the range of 53–65 °C. It involves the breakage of hydrogen bonds loosing up the fibrillar structure followed by the contraction of the collagen molecule up to one-quarter of its resting length. The second stage (gelatinization), running at approximately 70–80 °C, is connected with the breaking of heat-unstable intermolecular bonds. The degree of collagen shrinkage increases with the quantity of heat-stable (mature) links. In young animals the epimysium contains primarily heat-labile cross-links, the perimysium a mixture of heat-labile and heat-stable, and the endomysium of heat-stable cross-links. With increasing animal age, the amount of the heat-stable cross-links in the meat increases. Their higher levels lead to a development of greater tension in the connective tissue during heating. The shrinkage temperature of epimysial collagen is usually higher than that of other connective-tissue membranes in the muscle. The observations made by scanning electron microscopy (SEM) indicate that after heating of bovine sternomandibularis muscles at the temperature of 60 °C and 80 °C for 1 h, the epimysium does not show large changes, whereas the perimysial and endomysial collagen become granular at 60 °C and start to gelatinize at 80 °C. There are also differences in solubilization between different types of collagens. The highest thermal stability occurs in collagen of the endomysium, due to the large contribution of disulfide bonds in type IV collagen. The gelatinization of the intramuscular collagen depends also on the time of postmortem ageing of the meat, that probably results from changes in proteoglycans. In the 12-day-aged bovine semitendinosus (ST) muscles solubility of collagen is twice as high as in that aged for 5 days. During heating of the 5 day-aged bovine ST muscles by two methods in the range of temperatures between 50 and 100 °C, most of the soluble collagen is found at 70 °C during retorting and at 80 °C throughout roasting. During roasting of ST, when the temperature increases up to 90 °C, quantity of soluble collagen decreases in the meat aged for 5 days remaining at the same level in the 12 day-aged meat. Therefore, differences in the thermal collagen solubility of the intramuscular connective tissue are a consequence of differences in the proportion of the collagen types, the level of heat-stable cross-linking, and the level of glucosaminoglycans in the structure, as well as the time of postmortem ageing and the method of heating.

Heating also causes changes in pH, reducing activity, ion-binding properties, and enzyme activity. Slight upward change of pH (approximately 0.3 units) results from exposure of reactive groups of histidine. Increased reducing activity develops due to unfolding of the protein chains and exposition of sulphydryl groups. Conformational changes in proteins cause their ability to bind various ions, such as Mg^{2+} and Ca^{2+}.

Severe heating of the proteinaceous foods leads to a development of color and flavor compounds due to Maillard reactions and to thermal degradation of methionine and cysteine residues as well as other low-molecular weight compounds.

The meat fat melts during heating. Solubilization of collageneous connective tissue provides channels through which melted fat may diffuse, as a component of thermal leak.

Water-Holding Capacity

The raw meat contains 69–75% of water. Heating induces structural changes, which cause a decrease in water-holding capacity (WHC) of the meat. As the internal meat temperature increases, the WHC of meat decreases due to thermal denaturation of the meat proteins, especially myosin, which plays a significant role in water binding. During heating of meat, depending on the method, the amount of water decreases to 65% at internal temperature of 70 °C and to 60% at 90 °C. The water retention in the heated meat influences the quantity of the other basic constituents. The loss of water during heating of meat results from both evaporation and exudates. The fluid is drained by gravity from the cut surface of the meat, if the viscosity of the exudate is low enough and the capillary forces do not retain it. The loss of fluid arises predominantly from the longitudinal channels through the meat between the fiber bundles. In the raw muscle most of the water (80%) is held within the myofibrils. There are only changes in the water distribution, if the myofibrils change in volume. The fibers and fiber bundles shrink when their constituents (myofibrils) shrink, giving rise to the two extracellular fluid compartments around fibers and fiber bundles. The transverse shrinkage to the fiber axis, occuring mainly at 40–60 °C, widens the gap between the fibers and endomysium. At 60–70 °C the connective tissue network and the muscle fibers cooperatively shrink longitudinally. This shrinkage causes the highest increase in water losses during heating. For the samples of heated meat, the amount of water around fiber bundles increases up to 50 °C, in comparison with the raw meat, which seems to be in accordance with the transverse shrinkage of fibers and fiber bundles. Above 50 °C, these widened gaps diminish up to 70 °C, probably mainly due to the shrinkage of the connective tissue. The increase in extracellular space from 70 to 90 °C may be connected with a swelling of the

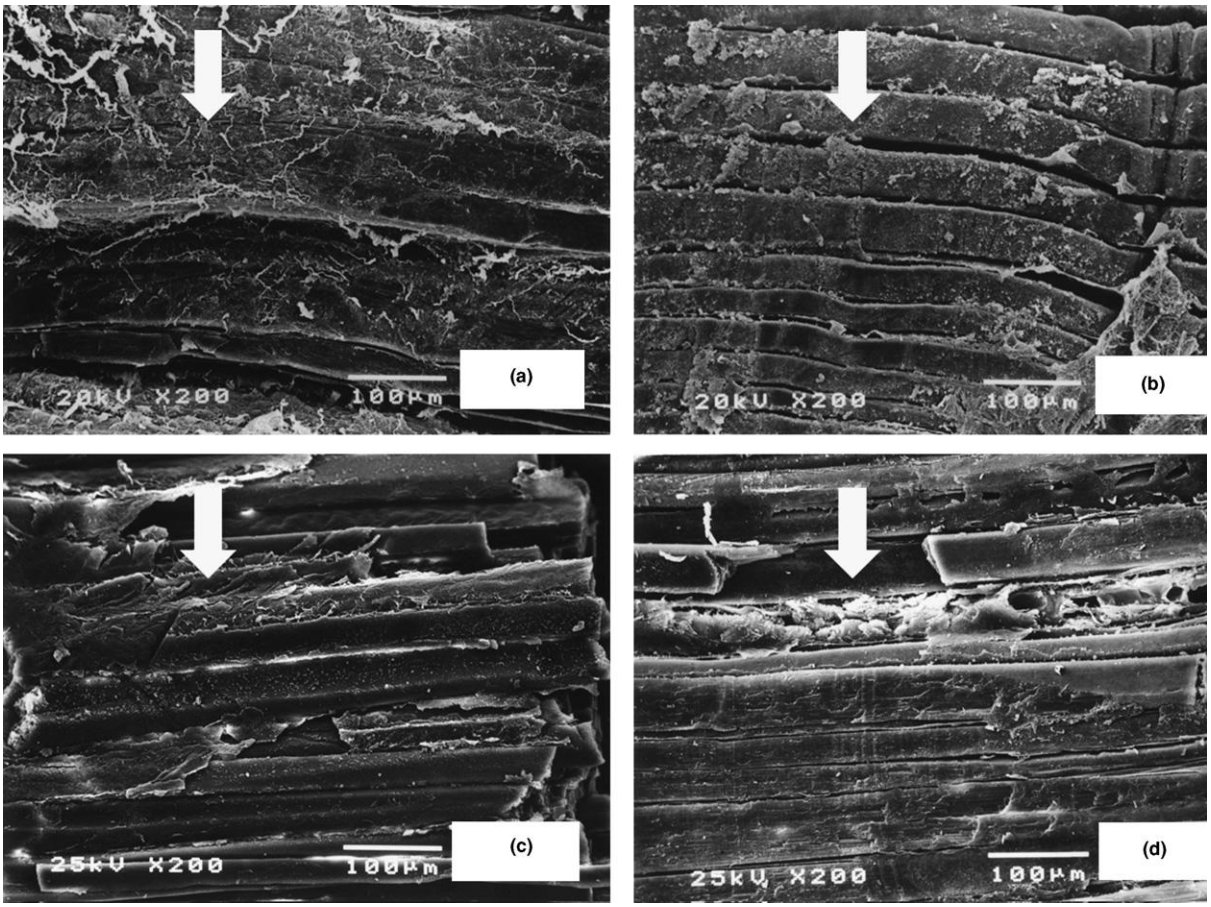

Figure 1 Connective tissue changes on heating. SEM micrographs of perimysium and endomysium from bull ST muscle: after ageing for 5 days at 4 °C and roasted to 70 °C (a) and to 90 °C (b); after ageing for 12 days at 4 °C and roasted to 70 °C (c) and to 90 °C (d). Reproduced from Palka, K., 2003. The influence of post-mortem ageing and roasting on the microstructure, texture and collagen solubility of bovine semitendinosus muscle. Meat Science 64, 191–198.

perimysium and solubilization of the intramuscular collagen, which occur at this range of temperature.

The extent of the loss of the fluid depends on the WHC of the tissue and the degree of its marbling. The highly marbled meat shrinks less during heating and remains juicier than the lower marbled meat. The subcutaneous fat also reduces moisture losses during dry heating (roasting).

The structural origin of water-holding in the whole meat and in the highly comminuted products is different. In the first, the crucial factor is the shrinkage or swelling of the myofibrils, and in the comminuted meat products, the ability of the meat proteins to form different types of gels. The comminution of meat with salt addition leads to solubilization of the meat proteins, which exists as a protein gel after heat treatment. The higher amounts of the soluble myofibrillar proteins create a dense protein network that holds more water.

Effects of Heating on Meat Microstructure

When the meat proteins are exposed to heating, they first lose their tertiary structure and undergo several changes in configuration. In general, thermal denaturation leads to a loss in protein solubility. These chemical changes are also associated with changes in the physical character of the meat tissues. Elastin, however, is not susceptible to effects of heat. The transverse shrinkage to the fiber axis occurs at 40–60 °C, which widens the gap already present at rigor between the fibers and their surrounding endomysium. There is a controversy regarding these observations. Some authors found no changes in the cross-sectional area on cooking of the neck muscle, whereas others found that the transverse shrinkage of both fibers and fiber bundles of bovine psoas major muscle starts at approximately 40 °C. There is also a disagreement between the results presented in the literature with regard to the temperature, in which the longitudinal shrinkage of the fiber starts. Some observations indicate that fibers do not shorten below 60 °C, and the others, that both sarcomere shortening and fiber shortening usually begin at temperatures of 40–50 °C. The divergence in the results may be due to the large biological diversity within a muscle as well as between different muscles. At 60–70 °C the connective tissue network and the muscle fibers shrink. This is mainly based on the fact that the perimysial collagen shrinks at approximately 64 °C.

In the bovine ST muscles aged for 5 or 12 days and roasted to internal temperatures in the range of 50–90 °C and then

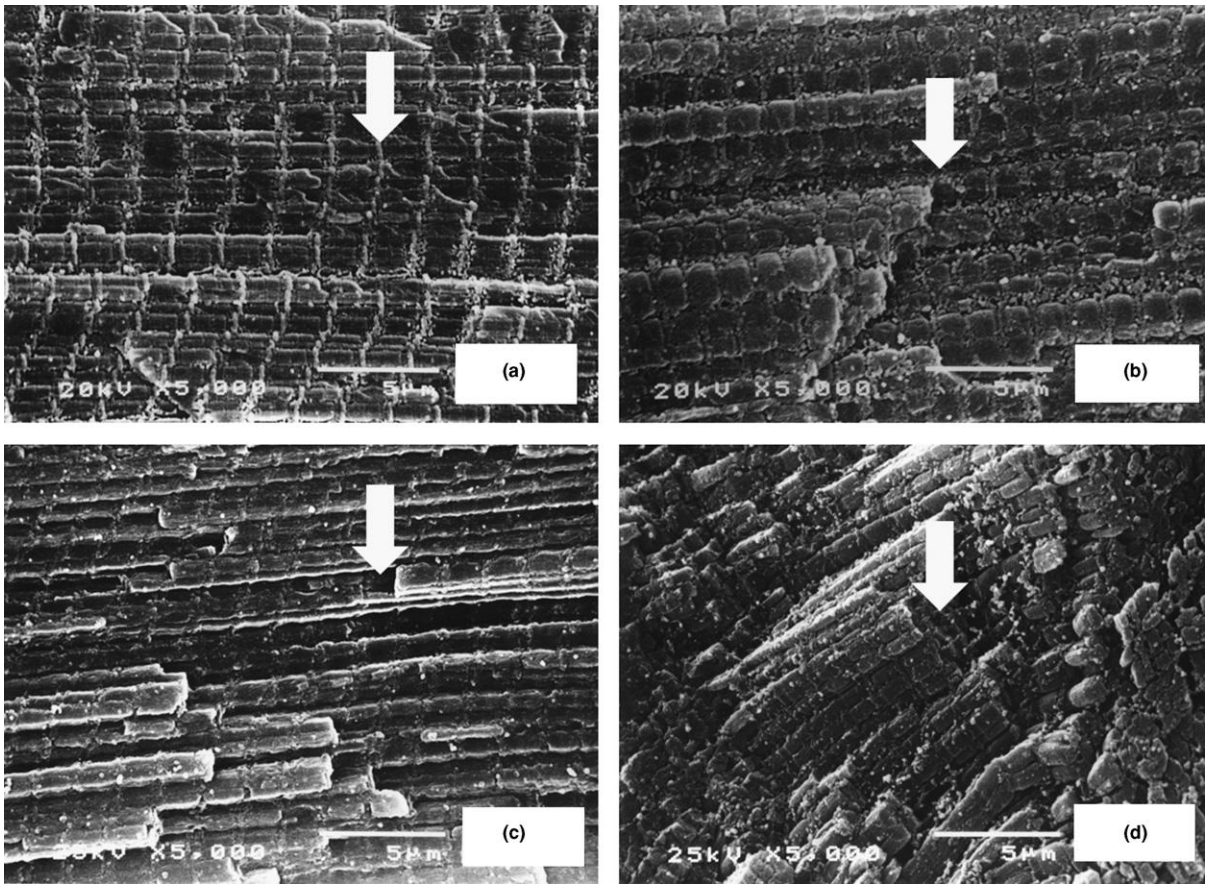

Figure 2 Myofibrillar changes on heating. SEM micrographs of myofibrils from bull ST muscle: after ageing for 5 days at 4 °C and roasted to 70 °C (a) and to 90 °C (b); after ageing for 12 days at 4 °C and roasted to 70 °C (c) and to 90 °C (d). Reproduced from Palka, K., 2003. The influence of post-mortem ageing and roasting on the microstructure, texture and collagen solubility of bovine semitendinosus muscle. Meat Science 64, 191–198.

visualized using SEM, no significant structural changes are seen at the internal temperature of 50 °C. However, in the range between 60 and 90 °C, significant changes occur both in the myofibrils and in the intramuscular connective tissue, and this is further affected by the degree of postmortem ageing. The changes in the connective-tissue structure of perimysium and endomysium during roasting of the 5-day-aged bull ST muscles to 70 °C are shown in Figure 1(a) and to 90 °C in Figure 1(b), for the 12 day-aged muscle, the changes are shown in Figure 1(c) and (d), respectively. The granulation of perimysium and the cracks of endomysium tubes are observed in 5 day-aged meat roasted to an internal temperature of 80–90 °C (Figure 1(b)), however, in 12 day-aged meat after roasting to 60–70 °C (Figure 1(c)). The changes in the myofibrillar structure during roasting of the 5-day-aged bull ST muscles to 70 °C are shown in Figure 2(a) and to 90 °C in Figure 2(b), whereas for the 12 day-aged muscle in Figure 2(c) and (d). In the 5 day-aged samples the disintegration of the myofibrillar structure starts at 70 °C (Figure 2(a)) and is considerable at 90 °C (Figure 2(b)). In the 12 day-aged meat roasted to 70 °C (Figure 2(c)), the degree of structural destruction is similar to that of 5 day-aged meat roasted to 90 °C (Figure 2(b)). At 90 °C complete disintegration of the myofibrillar structure of 12 day-aged meat is observed (Figure 2(d)).

As the endpoint temperature increases from 50 to 60 °C, there is a significant decrease in the fiber diameter. As the heating temperature is raised, the sarcomere length decreases, the effects being greater in the aged meat. The larger structural changes observed during roasting of the more aged meat may be a consequence of the changes during ageing in both the cytoskeletal proteins and the intramuscular connective tissue, leading to a weakening of the transversal and longitudinal integrity of the muscle fibers. In general, the microstructural changes are considerably less in the meat heated after 5-day ageing in comparison with the meat heated after 12-day ageing.

There is a high negative correlation ($r=-0.97$) between changes in the sarcomere length and the cooking losses during heating of the bovine ST at the temperature range of 50–120 °C (Figure 3).

Texture and Tenderness of Heated Meat

The rheological properties of meat result from changes in proteins, with the texture of the meat being affected mainly by the quantity and cross-linking of collagen; the morphological structure of the meat tissues; the biochemical state of the

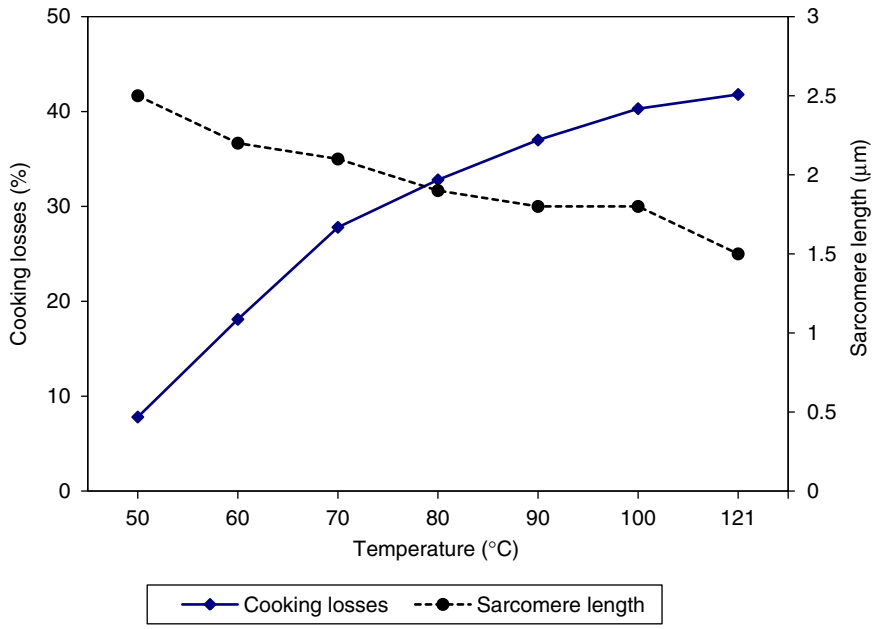

Figure 3 Effect of heating temperature on cooking losses (–) and sarcomere length (– – –) of beef ST muscle samples retorted after 5 days ageing at 4 °C. Reproduced from Palka, K., Daun, H., 1999. Changes in texture, cooking losses, and myofibrillar structure of bovine M. semitendinosus during heating. Meat Science 51, 237–243.

muscle pre- and postrigor; and the mechanical disintegration of the muscle structure.

The hardening of the myofibrillar structure and the gelatinization of the intramuscular collagen depend on the extent of the postmortem changes (ageing) related to the time-temperature regime. Generally, hardening of meat is observed throughout the heating. The first increase of meat hardness that occurs after heating in the range of 40–65 °C is mainly due to sarcoplasmic and actomyosin complex protein denaturation. A contribution of intramuscular connective tissue to the changes of toughness is relatively small, although heat-induced shrinkage of endomysium occurs. This is because the endomysium is an amorphous, nonfibrous sheet. However, some authors observed an increase in tenderness of the meat heated up to approximately 50 °C. The reason for this is probably the fact that the applied stress during mastication is reduced by viscous flow in the fluid-filled channels in between fibers and fiber bundles. The viscous flow then becomes lower as the elasticity of the meat increases in that temperature region. At above 65 °C elasticity acts adversely and impairs the tenderness, Warner–Brazler (WB) shear force increases significantly. The further hardening that occurs at 65–75 °C is connected with the drastic shrinking of the perimysium and continuation of the myofibrillar component shrinking. In the range of 75–80 °C, there is further shrinkage and dehydration of the actomyosin component. The collagen fibers begin to granulate, which can result in crispness of the perimysium. At this time the combining effects of the myofibrillar component and the perimysium are observed, and the increase in WB shear force becomes lower, compared with the second phase. At higher temperatures (80–90 °C), the overall influence of thermal-induced changes in the intramuscular connective tissue is a tenderizing effect, whereas the changes in myofibrillar proteins result in a toughening effect.

Meat hardness depends on the fiber size and the degree of sarcomere shortening during heating to 70 °C through tension caused by collagen fibers (mainly endomysium) shortening. This is also influenced by many of the differences in the histological structure and the amount of the collagen fibers type III and type I as well as differences in the collagen cross-linking. For example, mechanical resistance of the perimysium at the interface with the endomysium mostly affects hardness of the heated meat, whereas endomysium shrinkage may result in a tightening of the structure and squeezing out of intramuscular water. Prolonged heating of meat (4–6 h) at relatively low temperatures (50–60 °C) improves tenderness because of enzyme activity up until 60 °C.

Drip loss ranging from 20% to 40% of the original weight and shrinkage also has an effect on rheological properties. Meat with a high pH has lower cooking losses and is more tender after heating.

For the bovine ST and psoas major muscles at the same stage of ageing, boiled (100 °C), roasted (170 °C), or fried (160 °C) to the end temperature of 75 °C, WB shear force values are the highest for boiled, middle for roasted, and the lowest for fried muscles indicating that the method of heating is also important.

The sensory-evaluated toughness of the whole bovine biceps femoris muscle decreases drastically in the range of temperature from 55 to 60 °C, thereafter increases again up to 80 °C. For the comminuted meat products from the same muscle, the hardness increases over the whole temperature range and is significantly lower than the toughness of the whole meat at heating temperatures below 60 °C. It means that the spatial arrangement of the fibers is most important for the textural properties of the meat and the comminuted meat products.

Glossary

Chelators Organic chemicals that form two or more coordination bonds with a central metal ion. Heterocyclic rings are formed with the central metal atom as part of the ring.

Gas chromatography–mass spectrometry An analytical method that combines the features of gas–liquid chromatography and mass spectrometry to identify different substances within a test sample.

Heme compound An iron compound of protoporphyrin, which constitutes the pigment portion or protein-free part of the hemoglobin molecule and is responsible for its oxygen-carrying properties.

Maillard reaction products Any of hundreds of different compounds created as a result of the Maillard reaction (a process of nonenzymatic browning resulting from a chemical reaction between an amino acid and a reducing sugar). Many of the products are of interest for their flavor attributes, and also for their possible antioxidative properties.

Pyrolysis The thermochemical decomposition of organic material.

Singlet oxygen The electronically excited state of molecular oxygen, which is less stable than the more typical ground-state triplet oxygen.

Umami A strong meaty taste imparted by glutamate and certain other amino acids. It is often considered to be one of the basic taste sensations along with sweet, sour, bitter, and salty.

Introduction

It has been more than 50 years since the term 'warmed-over flavor' (WOF) was first coined in reference to a notable deterioration in the quality of cooked meat products following chilled storage followed by reheating. Even though still most frequently linked to chill-stored cooked meat, the term today is somewhat of a misnomer, as it may apply to deterioration of meat flavor in a variety of different contexts, including raw meat, meat served on warmers, and meat in frozen storage. The onset of the distinctive off-flavor was originally attributed solely to lipid oxidation, but it is now understood that protein oxidation is of importance as well. Meats that are cooked before storage are most susceptible to the development of noticeable off-flavors, because heat treatment accelerates the oxidative processes (the distinctive off-flavor can become readily apparent within just a few hours of thermal processing). Products develop an undesirable stale flavor, and at the same time desirable meaty flavor notes are lost. The stale off-flavors so formed have often been described as 'cardboard like,' 'painty,' and 'rancid'; they are considered most noticeable when refrigerated cooked meat products are reheated. The demand for precooked, ready-to-eat meat products in the marketplace and in fast-food franchises continues to grow, thereby expanding the concern of consumer exposure to WOF. However, a greater awareness of the process, along with improved methods of control, ensures the loss in quality of meat products due to the development of WOF, which occurs to a much lesser extent today than it did 50 years ago.

When the concern of WOF is raised, it is often in relation to comminuted products, such as meat loaves, chicken nuggets, and precooked burgers. Thus, it is generally accepted that any process involving disruption of the integrity of muscle tissue (such as cooking, grinding, mechanical deboning, massaging, or restructuring) enhances the development of WOF. Warmed-over flavor is also a big concern for the hotel/restaurant/institution service where processed convenience entrées or prepackaged cooked meat products are served. Prolonged holding of products containing meat at high temperatures (such as in a steam table) can produce undesirable flavors. Freezing can delay the onset of WOF development, but it does not prevent it. Stale or off-flavor notes, such as 'ice box,' 'rancid,' and 'freezer burn,' have been used to describe the phenomenon. The flavor compounds responsible for the off-flavor in stored fresh meat are qualitatively the same as in previously cooked meat, but the compounds occur at different concentrations and therefore create a somewhat different aroma profile. Because WOF development is a dynamic process of flavor change due principally to a cascade of oxidative events, an understanding of the mechanism(s) and prevention of its occurrence in meat and meat products are important to the food scientist.

Warmed-Over Flavor as a Consequence of Lipid Oxidation

WOF development is attributable mainly to lipid oxidation. Meat lipids are made up of intermuscular and intramuscular adipose tissues, and they contain both saturated and unsaturated fatty acids. The membrane lipids (i.e., the phospholipids) tend to possess the lion's share of the polyunsaturated fatty acids (PUFAs), and these are most prone to oxidation. Membranes are disrupted when meat is ground, chopped, or cooked, thereby releasing cell contents and exposing PUFAs to oxidative stress. Consequently, the process of WOF development can begin within hours of cooking the meat product, as compared with several days for the development of lipid oxidation in uncooked meat. Research has shown that subcutaneous fat from meat can produce approximately 50 volatile compounds during WOF development,

 doi:10.1016/B978-0-12-384731-7.00131-8

whereas intramuscular lipids can generate more than 200. There seems to be no question that oxidation of phospholipids is the primary source of off-flavor notes generated during WOF development.

Oxidation of the unsaturated C_{18} fatty acids found in meat (namely oleic, linoleic, and α-linolenic acids) produces low molecular weight aldehydes (C_3–C_{12}), which are believed to be partly responsible for the development of WOF and rancidity in cooked meats during storage. Hence, it can be reasonably hypothesized that meats containing higher levels of PUFAs should be more susceptible to oxidation. This is indeed the case as certain muscle tissue exhibits more of a propensity toward the development of WOF, with a key correlating factor being the degree of unsaturation in the tissue's fatty acids. Fish is most at risk followed by poultry, pork, beef, and lamb.

The initial stage in the oxidation of unsaturated fatty acids involves the formation of lipid free radicals – potent species that react with oxygen and propagate the process via a chain reaction. This phenomenon, commonly referred to as autoxidation, can be triggered by singlet oxygen, metal ions, heme compounds, UV light, and certain enzymes. Thermal processing results in changes to protein and lipid constituents of meat and destroys some of the natural reducing capabilities found in muscle tissue, which help to combat oxygen stress and free radical generation. During autoxidation, primary products of lipid oxidation (known as hydroperoxides) are formed. Lipid hydroperoxides are odorless and tasteless but quite unstable. Their degradation leads to the formation of a large number of secondary oxidation products, such as aldehydes, acids, alkanes, alkenes, ketones, alcohols, esters, epoxy compounds, and polymers. Aldehydic scission products of hydroperoxides, such as pentanal, hexanal, and *E,E*-2,4-decadienal, are of key interest, as these short-chain aldehydes give rise to the off-flavors known as 'warmed-over' and are very potent volatiles even at concentrations in the parts-per-billion range. When refrigerated cooked meats are warmed up/reheated, these active off-flavor compounds volatilize and the unpleasant WOF notes become more noticeable. Hexanal, which is the main oxidation breakdown product of linoleic acid, is sometimes monitored as an indicator of meat lipid oxidation.

Conflicting views exist concerning the role of heme and nonheme iron as it relates to lipid oxidation during cooking of meats and the subsequent formation of WOF in stored products. Some researchers have reported that heat treatment of meats releases ferrous iron from heme-containing compounds (such as myoglobin), which then acts as a primary catalyst in oxidative processes resulting in WOF. However, several investigations have suggested that the intact heme iron is in fact a stronger prooxidant in muscle tissue than iron that has been released. Data from heme-containing model system studies suggest that changes in protein structure occur during heating, which expose the heme cavity to the surrounding lipid hydroperoxides and thereby increase the prooxidative activity of the catalytic heme group. In other words, it is asserted that it is the heme compounds themselves and not free iron(II) or iron(III) which have considerable prooxidative activity at the concentrations relevant to meat.

Addition of sodium chloride is mandatory in meat formulation for flavor and functionality, but the chloride ions promote iron-catalyzed oxidation of unsaturated lipid constituents and therefore its use facilitates oxidation. Other trace metal ions, such as copper, that can be introduced to meat via water and processing equipment are also promoters of oxidation. These trace metal ions can react directly with lipids in oxidation reactions by reducing the energy of activation necessary for free radical formation or serving to catalyze the decomposition of formed lipid hydroperoxides.

Warmed-Over Flavor as a Consequence of Protein Oxidation

It was initially believed that lipid oxidation was the sole cause of WOF development, but in the late 1980s several researchers produced strong evidence that protein degradation reactions were also involved in WOF development. Flavor chemists have been quite interested in the chemical instability of sulfur-containing constituents in meat (i.e., sulfhydryl–disulfide interchanges in proteins and the degradation of sulfur-containing heteroatomic compounds) because breakdown of these compounds is believed to lead to a reduction in desirable meaty flavor notes. In an effort to better describe the complex series of chemical reactions that contribute to an overall increase in off-flavor notes and a loss in desirable meaty ones, the term 'meat flavor deterioration' (MFD) was proposed as an alternative to WOF. Although MFD may be a better expression for what is actually occurring, the term 'warmed-over flavor' and the WOF acronym are still routinely used in the scientific literature.

Although the intensity of the undesirable sensory notes has been positively correlated with the content of carbonyl compounds formed via lipid oxidation reactions, the decrease in flavor intensity of desirable notes can be attributable to both lipid oxidation and protein oxidation. Protein oxidation might decrease the concentration of those volatiles that contribute to desirable meaty flavor, whereas the off-flavors produced by lipid oxidation might 'mask' the perception of such desirable compounds. The reduction or disappearance in the sensory perception of 'meatiness' due to changes to heteroatomic compounds is probably important during the early days of storage when lipid oxidation-derived odors and flavors are not as concentrated, and flavor masking probably becomes the main factor during the later days of storage when WOF is more fully developed.

Another contributing factor to the dull flavor impact associated with WOF could be the loss of peptides to enzymatic degradation. Research has revealed that some meat enzymes remain active even after thermal processing and subsequent refrigeration of the product, including those that might break down peptides that are capable of stimulating the taste receptors to give a note of 'umami' (a Japanese term for a fifth basic taste that is triggered by some amino acids, translating roughly to 'savory' or 'meaty').

Sensory and Chemical Analysis in Relation to Warmed-Over Flavor

The contribution of sensory analysis toward the development of descriptors, definitions, and references to describe the

Table 1 Sensory descriptive terms with definitions developed for the evaluation of warmed-over flavor in ground chicken

Term	*Definition*	*Reference*	*Rating*[a]
Odors	*Aromatics associated with*		
Chicken brothy	Chicken broth	Chicken broth	12
Fishy	Cooked fish	Freshly cooked tilapia	10
Sulfury	Boiled egg yolk	Boiled egg yolk	5
Musty	Wet cardboard	Wet cardboard	4
Rancid	Oxidized oil	Oxidized flax seed oil	None[b]
Tastes	*Taste associated with*		
Sweet	Sucrose	5% sucrose	5
Sour	Citric acid	0.08% citric acid	5
Salty	Sodium chloride	0.5% sodium chloride	5
Bitter	Caffeine	0.05% caffeine	5
Umami	Monosodium glutamate	0.1% monosodium glutamate	7.5
Flavors	*Flavor associated with*		
Metallic/serumy	Blood or rare meat	Rare beef (top sirloin)	3
Cooked chicken	Cooked chicken breast	Boiled chicken breast	9
Fatty	Rendered chicken fat	Rendered chicken skin	8
Fishy	Cooked white fish	Freshly cooked tilapia	11
Rancid	Rancid/oxidized oil	Oxidized flax seed oil	6
Appearance			
Surface color	Color of the outer surface of the sample	Boiled chicken breast	1
		Rare beef (top sirloin)	14

[a]Ratings assigned according to a 15-point scale; a larger number signifies a greater degree of intensity for the associated trait within the reference sample.
[b]A rating was not determined for the reference sample of the 'rancid' odor term.
Source: Reproduced from Brannan, R.G., 2009. Effect of grape seed extract on descriptive sensory analysis of ground chicken during refrigerated storage. Meat Science 81, 589–595.

phenomenon of WOF in cooked meat products has come a long way in the last 50 years. Today, well defined sensory descriptive vocabularies for WOF have been prepared that allow trained panelists to accurately track the development of WOF with time. An example lexicon of flavor descriptors used for ground chicken is presented in Table 1. Such a vocabulary can be used by panelists to describe perceived sensory characteristics in a sample set – producing a perceptual map of the variations in a sample type. Sensory analysis can be employed alone or in combination with chemical/instrumental data to help explain and elucidate underlying sensory and chemical relationships. Data from the mid-1980s indicate that the sensory perception of WOF was similar across meat patties of beef, pork, chicken, and turkey, but the intensity of its occurrence varied among the samples. Some specific data on beef showed that the intensity of fresh cooked beef notes is strong immediately after cooking, but over time, cardboard notes develop and then disappear. At about the same time, there is a marked reduction in fresh beefy notes, and then oxidized notes begin to become apparent. For samples that had been stored for 3–7 days, oxidized/rancid/painty notes were dominant.

There are a variety of chemical methods to semiquantify WOF development in meat and meat products, including the measurement of changes in conjugated dienes and carbonyl values as well as the more recent employment of electronic noses and gas chromatography. Malon(di)aldehyde is a relatively minor product of autoxidation of PUFAs in muscle tissue, but its presence and concentration in meat products is commonly monitored as a marker of lipid oxidation by the classical 2-thiobarbituric acid (TBA) test. The TBA test involves the reaction of malonaldehyde in oxidized foods with the TBA reagent under acidic conditions; a pink adduct forms with a distinctive absorption maximum at 532 nm. The TBA test was once believed to be specific for malonaldehyde, but this is not so. In fact, the TBA method has been criticized for lacking specificity and adequate sensitivity toward the dialdehyde. Owing to the uncertainty about the exact identity of compounds that can react with the TBA reagent, the ambiguous term '2-thiobarbituric acid-reactive substances' (TBARS) is now commonly employed in lieu of TBA number or value. Nevertheless, determining the content of TBARS (i.e., often reported as mg malonaldehyde equivalents per kg meat) appears to be a useful indicator of meat quality deterioration. Recent studies have shown that TBARS are highly correlated with many of the sensory terms related to WOF. However, the importance of hexanal, a dominant volatile oxidation product of linoleic acid, as an indicator of the sensory perception of WOF development has been questioned. Hexanal has a characteristic 'tallowy' or 'green leafy' aroma, but this odor term was not strongly perceived as being associated with WOF odor terms (e.g., linseed oil like and cardboard like) during vocabulary development. Results from gas chromatography–mass spectrometry analyses have indicated that oxidation compounds, such as pentanal, 2-pentylfuran, octanal, nonanal, 1-octen-3-ol, and hexanal, covaried with the sensory descriptor green.

Preventive Strategies

It can be important to food scientists to understand how to control or limit WOF development in meat and meat products and to know what arsenal of countermeasures are available.

By examining the causes of off-flavor development, strategies can be designed to limit its occurrence. Curtailing the detrimental effect of WOF requires the inhibition of lipid oxidation, protein oxidation, the consumer's ability to detect the resulting reduction in sensory quality, or some combination thereof. Although much of the methods to diminish WOF have historically focused on the inhibition of lipid oxidation, it is important to note that these procedures have largely been considered effective measures against protein oxidation as well. The most recent evidence now shows that protein oxidation can, in fact, be inhibited very effectively by strategies that include the incorporation of primary antioxidants. Many find the most effective means of controlling WOF to be a comprehensive strategy that utilizes a combination of the approaches described below.

Meat Quality and Handling

The choice of meat is an important factor in the occurrence of lipid oxidation. Fish and other muscle tissues containing high levels of PUFAs exhibit more of a propensity toward off-flavor development. Chicken has less of a tendency to develop oxidized flavors than turkey due to the higher level of the antioxidant vitamin E in chicken; nevertheless, the problem will be worse in chicken thigh meat than in white meat, as the darker meat contains more lipids and heme iron. Fresh meat used in product formulations shows less of a tendency to develop WOF than older meat, as older meat will have more time to undergo enzymatic degradation processes, which generate autocatalytic compounds that can propagate oxidation. Endogenous antioxidant enzymes, such as catalase, glutathione peroxidase, and superoxide dismutase, continue to function postmortem at curbing lipid oxidation in uncooked muscle foods. However, their efficacy in this regard diminishes with increasing age of the meat. Ensuring that high quality meat is used in product formulations is critical.

In addition to quality meat selection, some steps can be taken at the operator level to limit WOF. Incorporating antioxidants into the product and reducing the time from cooking to plate are among the most effective and common means food service operators can utilize to minimize WOF. WOF can also be curbed by avoiding the use of steam tables and warming lights to hold products at elevated temperatures for long periods of time. Many fast-food franchises make an effort to ensure that their burger products stay under warming lights for relatively short periods so they do not lose that fresh-grilled flavor.

The actual cooking method employed for precooked products can also influence the extent of WOF. One might assume that grilling of meat would exaggerate the potential for WOF on account of the high temperatures to which lipid and protein constituents are subjected, but this is not so. In fact, thermal processes that employ very high temperatures, like grilling, seem to inhibit WOF development through the formation of antioxidant Maillard browning intermediates. Details of how this occurs have been discussed in a previous article. Similarly, conditions that favor browning, such as addition of glucose or smoke intermediates, can help to retard or inhibit WOF development.

Primary Antioxidants: Synthetic and Natural

Food technologists attempt to reduce the problem of WOF in meat products by adding food-grade antioxidants or ingredients that impart antioxidant properties. Primary antioxidants extend the induction period and delay the onset of fatty acid oxidation by acting as free radical acceptors or hydrogen atom donors. Such antioxidants trap free radicals directly and delay the free radical chain reaction in a concentration-dependent manner.

Synthetic compounds such as *tert*-butylhydroquinone, butylated hydroxyanisole, butylated hydroxytoluene, and propyl gallate are commonly employed antioxidants by the food industry. Their usage levels, however, are strictly regulated, and in recent years consumers have demonstrated reluctance to consume such compounds. Fortunately, there are a wide variety of natural alternatives that can also offer protection against oxidation in the form of food ingredients. The most common natural antioxidants utilized to fight WOF are vitamin E, extracts from rosemary and sage, and carotenoids such as β-carotene and lycopene. In addition, many other spices, fruits, and vegetables contain constituents with antioxidant properties that can provide benefits to a meat formulation. Reducing exposure of these antioxidants to oxygen and light enhances their effectiveness in minimizing WOF development.

The addition of spice and herb extracts to meat products has become a popular means of incorporating natural antioxidants and represents a 'consumer-friendly' option. Rosemary, oregano, and sage extracts have been of common use in recent years, oftentimes in combination with tocopherols and/or erythorbate. Rosemary in particular appears to be the most effective, as it contains a number of antioxidant compounds called diterpenes (including the highly active and prevalent carnosic acid). Because carnosic acid and rosmanol (another antioxidant constituent of rosemary) are odorless, manufacturers can develop spice-based ingredients with reduced flavor impact and increased protection against oxidation and the subsequent WOF development. Spice companies continue to develop new odorless extracts possessing antioxidant activity for addition to meat systems. Yeast extracts and its derived products also exhibit antioxidant properties due to the presence of glutathione, Maillard reaction products, and sulfur-containing amino acids. Papers that cite the benefits of new food ingredients against WOF appear frequently in the scientific literature, many of which describe the employment of novel plant extracts.

Dietary Antioxidants

Typically, antioxidants are added to meat products during formulation, but scientists have demonstrated the potential to increase the antioxidant capacity of muscle tissue before the animal being harvested. One such approach is to supplement the feed of domesticated species with dietary antioxidants. A number of studies with hogs and poultry have shown that supplementation of feed with vitamin E (typically as α-tocopheryl acetate) can minimize the potential for eventual WOF development. Additions to supplementation levels have been found to result in progressive increases in the

concentration of α-tocopherol in the resulting muscle tissue, mitochondria, and microsomes. α-Tocopherol migrates into muscle cell membranes, where it lies adjacent to highly oxidizable phospholipids; this localization makes α-tocopherol a particularly effective antioxidant. Sensory studies of meat products have shown that vitamin E supplementation can prolong flavor freshness, inhibit WOF development, and positively influence tenderness and juiciness.

Secondary Antioxidants

Secondary antioxidants inhibit oxidation by indirect means, such as scavenging oxygen or binding prooxidative compounds, and provide another method of reducing oxidation in meat products – most commonly via the incorporation of chelators. A chelator or sequestrant is a food additive that reacts with trace metal ions in foods and forms tightly bound complexes, thereby inhibiting the metal ion's catalytic action on lipid constituents. Typical chelators added to processed meat products are alkaline phosphates. Not only do alkaline phosphates improve the functionality of the meat product in question (via water-binding capacity, chewiness, and other textural attributes), but also they have the ability to complex with or 'chelate' free iron ions in the meat matrix. Furthermore, sodium tripolyphosphate, tetrasodium pyrophosphate, and sodium hexametaphosphate have the capability to complex with iron ions that are released from the heme moiety of myoglobin during thermal processing. The level of added phosphates must be controlled because additions of 0.5% or more tend to leave metallic and bitter tastes in the product. Citric, ascorbic, and ethylenediaminetetraacetic acids are additional common food-grade additives that help to stabilize metal ions by reducing their capability to act as oxidants. Ascorbic acid, its sodium salt (sodium ascorbate), and its isomer (erythorbate) also function synergistically with other antioxidants and added polyphosphates to give protection to meats against oxidative degradation.

Nitrites and Nitrates

Nitrites and nitrates are additives to meat products that perform multiple functional roles in the meat matrix, one of them being to retard oxidation and WOF development. The mechanism by which nitrites prevent oxidation within meat (and subsequently WOF development) is still a matter of discussion. Four different mechanisms have been proposed for the antioxidative effect of nitrite in meats: (1) formation of a stable complex between heme pigments and nitrite, thereby preventing the release of iron ions from the porphyrin molecule; (2) stabilization of unsaturated lipids within tissue membranes against oxidation; (3) chelation of metal ions; and (4) formation of antioxidative nitroso and nitrosyl compounds.

Natural and Liquid Smoke

Smoking is another popular meat preservation technique. Like nitrites, constituents of smoke (specifically, phenolic compounds) impart antioxidant properties to meat and meat products. Additionally, incomplete combustion of gases during natural smoke generation from the pyrolysis of hardwood can result in the formation of various nitrogen oxides, which can function in the curing process as nitrite does. Research has shown that certain smoke flavorings can reduce the occurrence of WOF and extend shelf life when added to fresh, precooked, and processed meats. Formulators can add liquid smoke to their products directly by atomizing, dipping, drenching, spraying, or injecting. Smoke ingredients with strong flavors can help to mask the perception of WOF, whereas flavorless smoke fractions can be employed at low levels in marination systems to reduce the development of WOF. In some cases, the incorporation of smoke flavors has reduced lipid oxidation by 20–30%. The flavors also contain certain carbonyls that react with amino groups of meat proteins to inhibit WOF production.

Packaging

Packaging is a physical means to reduce off-flavor development in meat and meat products. Because light and the presence of oxygen can accelerate oxidation, eliminating their exposure through packaging technologies will help. Vacuum packaging controls oxygen interactions at the meat surface, and thereby minimizes oxidation. This technique, coupled with nitrogen flushing or modified atmosphere packaging (e.g., 70% N_2 and 30% CO_2) techniques, can give substantial shelf life to finished products. Other packaging technologies, such as oxygen scavengers, can be added to the package as stand-alone units or be incorporated into the packaging film. Another approach employed by the packaging industry is the use of films that act as oxygen barriers. Edible films containing natural antioxidants have been examined as a means to control WOF development in cooked meat products, but the release and delivery of the actives require further elucidation. WOF development was recently inhibited by whey-based edible coatings of sausages, with the speculated mechanism being chelation by present carboxymethyl cellulose. In some cases, it is more effective to mix the antioxidant directly into the meat formulation, but this does not work for whole-muscle and some restructured meat products.

Flavor Masking

Flavor masking or other methods using flavors that modify the perception of off-notes can be effective tools in the fight against oxidative off-flavors in meat products. An example to which has already been eluded is that of smoking. Addition of complementary (i.e., savory) flavors from herbs and spices can not only inhibit lipid oxidation but also potentiate meat flavors, which might otherwise fade during processing and refrigerated storage. Beer flavoring is another ingredient that helps to reduce the flavor problems that occur during the reheating of meats. Beer flavoring's anti-WOF effect might be a function of the typical yeast notes found in the brew, as yeast-based flavors can improve and enhance flavors, mask bitterness, increase aroma, and also provide some protection against oxidation.

Masking agents that have been developed to cover other forms of off-flavors, such as metallic notes in high-intensity

sweeteners or beany notes in soybean products, have also been proven effective in masking WOF. Good masking agents will not have much flavor on their own when employed at low levels, but they are often coprocessed with compounds that impart desirable flavors (such as meaty flavor notes). Because the flavor can also mask certain desirable meaty notes if used at too high of a concentration, product testing is necessary to develop the best application level.

Another option is that of simply disguising the oxidative notes. For example, the highly flavored systems, such as those found in spicy Mexican or East Indian seasonings, can distract the consumer from any off-notes, because the sensations of heat and tanginess dominate the consumers' palate. Heavy spicing of meat products is common practice in countries where refrigerated storage is an issue.

In developing a flavor system designed to combat WOF, it is important to consider the overall desired flavor profile of the finished product. Both temperature and hold time during the cooking process influence the overall taste. To achieve an optimal flavor, it is generally recommended that spices and flavoring agents be incorporated at a slightly higher level than would be needed for immediate consumption. Once an appropriate flavor system is developed, it is incorporated into the product by means of a mix-in seasoning, rub, or marinade, depending on the type of product formulated. In a whole-muscle product, marination is recommended to enhance protection and minimize the possibility of off-notes developing within the internal area of the product. As the product's surface is more prone to oxidation than the interior of the meat, even topical application would still certainly help to minimize the formation of WOF notes.

Glossary

Brine Salt solution possibly together with nitrite and other agents.
Pickle curing Curing by dipping in brine.
Salt meter Measures salt content of the brine or product in solution.
Sea salt Salt from sea water.
Warmed-over flavor Off-flavor note in reheated cooked meat, especially poultry meat.

Introduction

Curing is one of the oldest meat preservation processes known to man. Treating of meat with a solution of salt (sodium chloride), or packing the meat in dry salt, preserved the meat. Salt helped in preventing microbial spoilage and other deteriorative processes occurring in meat and fish for a considerable period through a decrease in water activity. The ancient Sumerians around 3000 BC were the first to make use of salt for meat and fish preservation. Dead Sea salt was used in ancient Palestine as early as 1600 BC. The Chinese and Greeks also used rock salt to preserve meat and are credited with passing this practice on to the Romans, who included pickled meats in their diet.

As the use of salt from sea, desert, and rocks in preservation of meat spread, it was found that only certain types of salt helped in developing a desirable pink color and a special flavor in cured meat. Investigations in the nineteenth century revealed that sodium nitrate, present as an impurity in these salts, was the precursor responsible for developing the characteristic color and flavor in cured meat. Further, it was reported that nitrite, which was produced by microbial reduction of nitrate, was responsible for the curing effect. From subsequent experiments, it was proposed that the reaction of hemoproteins with nitric oxide (NO) derived from nitrite was the chemical basis for the color of cured meats. On the basis of these findings, the United States Department of Agriculture (USDA) regulated the use of sodium nitrite in meat curing in 1925.

Present-day meat curing practice involves the intentional addition of sodium nitrite and salt to meat. Ascorbates or erythorbates are usually incorporated as cure accelerators. Other additives, such as sweeteners, phosphates/polyphosphates, seasonings (e.g., spices and herbs), smoke, and other nonmeat extenders, may be included in the curing mixture to impart characteristic properties to the end product. Curing methods can be divided into three main categories, namely, dry, direct addition, and wet (brine) curing. Dry curing is the oldest traditional technique in which the curing ingredients are rubbed onto the surface of the meat. For direct addition, curing ingredients are added to the meat during mixing or chopping of the meat product. In the brine curing process, the curing ingredients are dissolved in water to form a pickle or brine, which is introduced to or injected into the meat.

Most of the processed meats available in North America today are cured in order to impart a desirable color, flavor, and texture plus a long shelf life to the end product. In addition, nitrite, together with sodium chloride, inhibits the formation of deadly neurotoxin by *Clostridium botulinum*. However, formation of *N*-nitrosamines from the reaction of nitrite with free amino acids and amines in some cured meat products, under certain heat processing conditions (e.g., high temperatures

 doi:10.1016/B978-0-12-384731-7.00112-4

associated with frying of bacon), or in the stomach of the consumer is a particular concern. Thus, attempts have been made to lower the amount of nitrite used or to find alternatives to it in meat curing. Research in the latter area has concentrated on formulating multicomponent alternatives, as it was recognized that a single compound could not duplicate the multifunctional properties of nitrite.

The Chemistry of Meat Curing

Although meat curing was originally used for preserving meat when it was plentiful, for use in times of scarcity, the need for preserving meat by curing alone has greatly diminished with the advent of sophisticated refrigeration and packaging techniques. Thus, the primary aim of present-day meat curing practices is to create flavor and appearance variations in food and to inhibit the outgrowth of *C. botulinum* spores. Another factor that has come to the forefront in modern curing practices is the increase of product yield and juiciness by incorporation of curing solutions. This can be achieved by using phosphates in the brine to increase the water-binding capacity of the meat by massaging and controlling other processing factors, such as smoking and cooking time, humidity, and the type of casing used.

Cured Meat Color

NO is derived from the added nitrite (or nitrate) in the curing formula. It helps in fixation of cured meat color by stabilizing the muscle pigment myoglobin, [MbFe(II)], through a reversible chemical bond formation. Nitrite is the conjugate base of nitrous acid (HNO_2). In an acidic environment, equilibrium is established between the ionized salt and the unionized nitrous acid, depending on the pH of the solution ($pK_a = 3.4$) (eqn [1]).

$$HNO_2 \rightleftharpoons H^+ + NO_2^- \qquad [1]$$

The concentration of HNO_2 in cured meat is very low (0.1–1.0%) at the usual pH values of meat (i.e., 5.5–6.5). Thus, the main reactive species in meat systems is dinitrogen trioxide (N_2O_3) (eqn [2]).

$$2HNO_2 \rightleftharpoons N_2O_3 + H_2O \qquad [2]$$

In the presence of reducing agents (HRd), such as ascorbic acid or ascorbate, and endogenous reducing groups or compounds in meat tissue, such as cysteine, reduced nicotinamide adenine dinucleotide, cytochromes, and quinones, NO is formed from N_2O_3, as shown in eqns [3] and [4].

$$N_2O_3 + HRd \equiv RdNO + HNO_2 \qquad [3]$$

$$RdNO \equiv Rd + NO \qquad [4]$$

The NO molecule has the ability to form very stable complexes with metal ions, such as iron. Thus, NO reacts with meat pigments to form a red-colored nitrosylmyoglobin [MbFe(II)NO]. The oxidized pigment metmyoglobin [MbFe (III)] is formed by the oxidation of myoglobin after the addition of nitrite to the meat. MbFe(III) can then react with NO to form an intermediate pigment, nitrosylmetmyoglobin (Figure 1). Autoreduction of nitrosylmetmyoglobin pigment by the endogenous and exogenous reductants in the postmortem muscle tissue forms nitrosylmyoglobin.

If MbFe(II) is present in meat after nitrite addition of nitrite, it can also react with NO to form MbFe(II)NO. However, formation of MbFe(II) NO in conventional curing occurs by the action of nitrite, as described in Figure 1.

During thermal processing of cured meats, the globin moiety of nitrosylmyoglobin denatures and separates from the iron atom and surrounds the heme moiety to form nitrosylprotoheme or the cooked cured-meat pigment with a characteristic pink color. Figure 2 illustrates the formation of cooked cured-meat pigment and its possible side reactions during the curing process and subsequent storage.

Salt (either sodium or potassium chloride) in the curing mixture accelerates the curing reaction owing to the formation of nitrosyl chloride (NOCl), which is a more powerful nitrosating species than N_2O_3 (eqn [5]).

$$HNO_2 + H^+ + Cl^- \rightleftharpoons NOCl + H_2O \qquad [5]$$

A lower pH accelerates the formation of nitrosating species (N_2O_3 and NOCl). For this reason, acidulants (e.g., glucano-δ-lactone) are sometimes added to the formulation in order to accelerate the curing process.

The cooked cured-meat pigment (i.e., nitrosylhemochrome) is quite stable to heat. However, the presence of light and oxygen may cause discoloration of cured meats. Proper packaging systems can be used to minimize product's exposure to light (e.g., translucent films) and oxygen (e.g., vacuum packaging). Furthermore, mixing, massaging, and stuffing of cured meats must be performed under vacuum to exclude oxygen.

Cured Meat Flavor

The characteristic flavor of cured meats is also due to the action of nitrite in the curing mixture. However, the chemical changes that are responsible for this flavor formation are not yet fully understood. The antioxidative role of nitrite in retarding the breakdown of unsaturated fatty acids and the formation of secondary lipid oxidation products may be the main processes involved in modifying the volatile profile of cooked cured meats by suppressing the formation of oxidation products, thus allowing the unique flavor associated with cured products to be revealed.

In the pickle curing process, halotolerant bacteria, such as *Vibrio* spp., have also been shown to affect the flavor volatiles formed. Volatile compounds, such as 2-methylbutanal and 3-methylbutanal, have been identified in meats cured with cover brines. These two compounds can react with hydrogen sulfide, ammonia, and ammonium sulfide in meat to form 3,5-diisobutyl-1,2,4-trithiolane and 5,6-dihydro-2,4,6-triisobutyl-4H-1,3,5-dithiazine, both of which are claimed to have cured meat aroma.

Owing to the amount of salt used in most curing processes, salt plays a vital role in determining overall flavor of cured meats. In addition, smoking and added seasonings and sugar (especially in fried bacon) also participate in determining the characteristic flavor of different cured meat products.

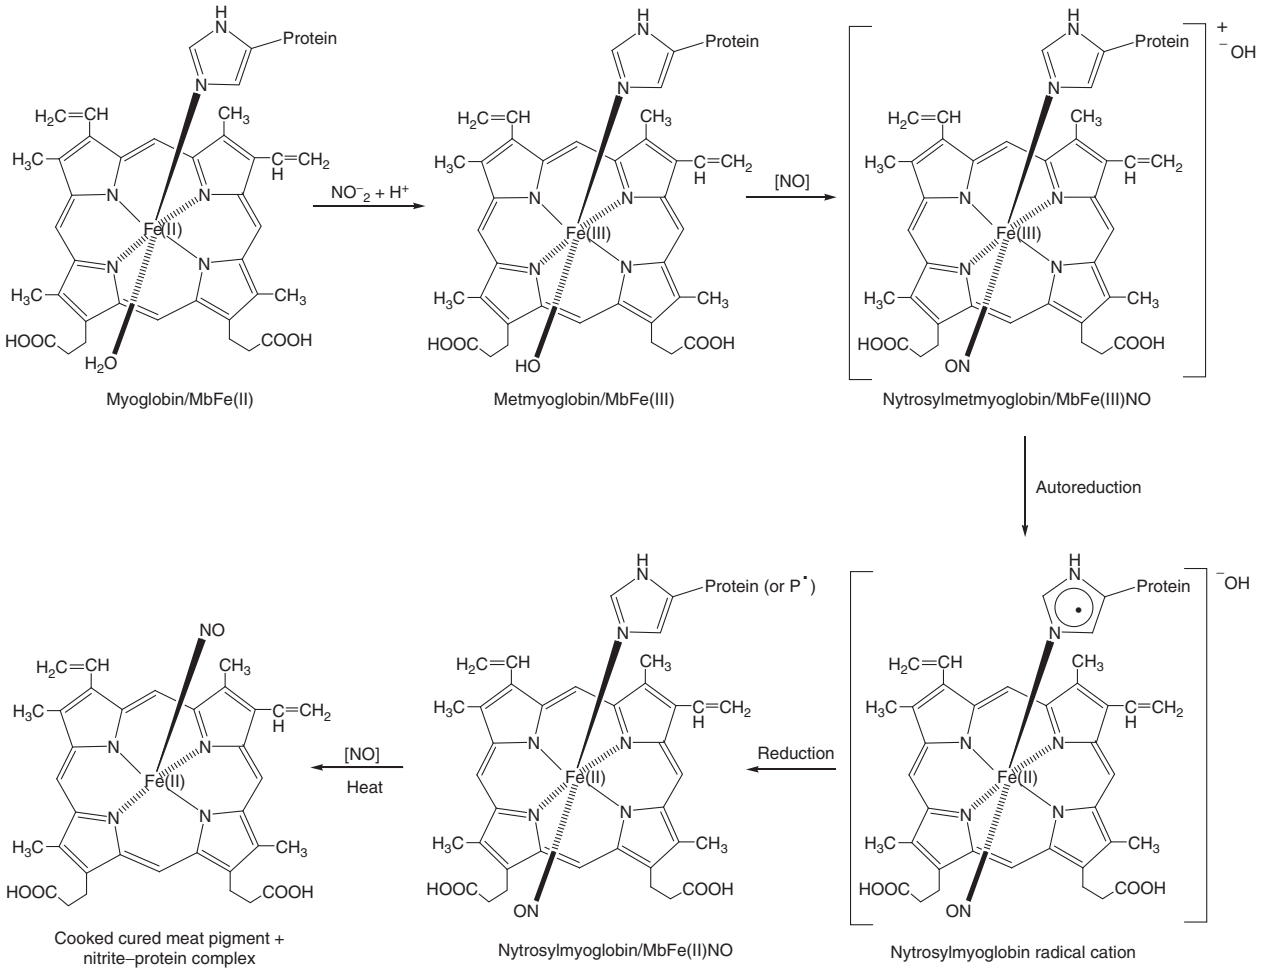

Figure 1 A new mechanism for the meat curing process. Reproduced from Killday, K.B., Tempesta, M.S., Bailey, M.E., Metral, C.J., 1988. Structural characterization of nitrosylhemochromogen of cooked cured meat: Implications in the meat curing reaction. Journal of Agricultural and Food Chemistry 36, 909–914.

Curing Ingredients and Their Role in Cured Meats

Salt (Sodium Chloride/Potassium Chloride)

Salt is the main ingredient used in all curing mixtures and it is used for the purpose of developing flavor and for solubilizing proteins that are important for emulsion stability of comminuted and restructured meat products. Salt also helps in controlling microbial action in cured meats by lowering the water activity. Sodium chloride is the salt most commonly used in brine solutions, and its usage level varies with the type of product, being 1–2% in sausages, 2–3% in hams, 1.2–1.8% in bacon, and 2–4% in jerkies. Approximately 0.4–0.7% of potassium chloride on a finished-weight basis is used in low-sodium meat products, but it may impart bitter and metallic flavor if used at $>0.75\%$.

Sodium Nitrite/Sodium Nitrate

Sodium nitrite (or nitrate) is the most important cure additive responsible for the typical color and flavor associated with cooked cured meats. It also provides oxidative stability to meat by preventing lipid oxidation and helps in controlling the development of warmed-over flavor in cooked, stored meats. Nitrite also serves as a vital bacteriostatic agent for control of the outgrowth of *C. botulinum*, particularly under conditions of product mishandling. However, addition of sodium nitrite to meat and meat products is highly regulated owing to the possible risk of formation of *N*-nitrosamine.

In Canada, maximum allowable limit for the use of sodium nitrite, potassium nitrite, or their combinations in preserved meat and meat products (e.g., hams, loins, shoulders, cooked sausages, and corned beef) is 200 ppm (20 g per 100 kg; equivalent to 0.32 oz nitrite per 100 lbs raw batch). However, the industry has taken steps to reduce the level of nitrite used in such products to 120–180 ppm. In pumped bacon, in-going nitrite levels usually do not exceed 120 ppm (i.e., 0.19 oz nitrite per 100 lbs meat) owing to the possible risk of *N*-nitrosamine formation. These regulated levels are based on the amounts used in the product formulation before any cooking, smoking, or fermentation and are usually added as a cure salt, such as Prague powder.

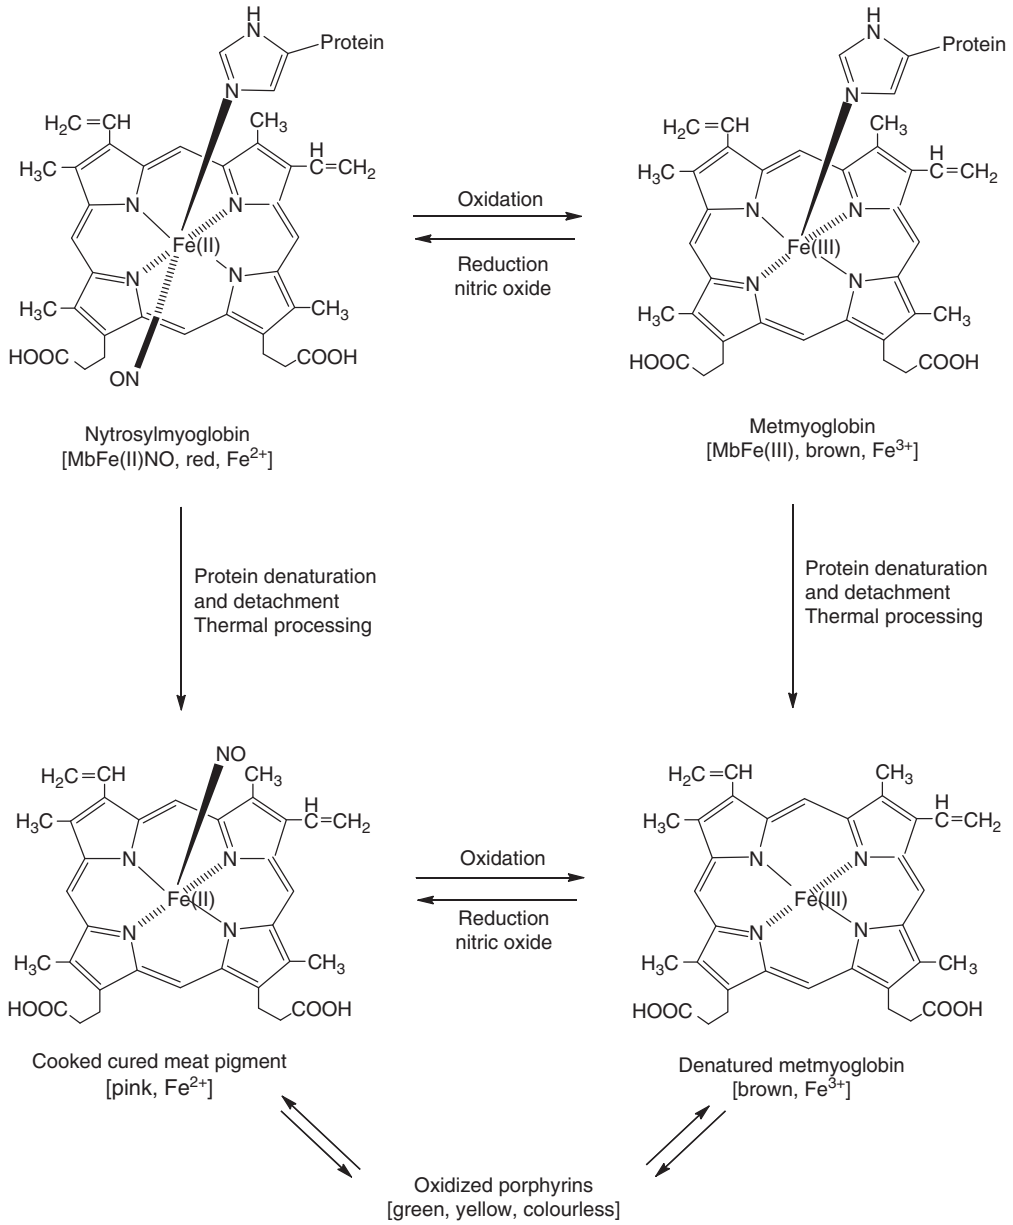

Figure 2 Some of the possible curing reactions that result from the addition of nitrite to meat. Reproduced from Bard, J., Townsend, W.E., 1978. Cured meats: Meat curing. In: Price, J.F., Schweigert, B.S. (Eds.), The Science of Meat and Meat Products, second ed. Westport: Food and Nutrition Press, pp. 452–470.

In the US, the Food Safety and Inspection Service (FSIS) regulations permit the use of sodium or potassium nitrite in all products except bacon at the following levels: 2 lb in 100 gallons of pickle at 10% pump or 200 ppm; 1 oz for each 100 lb of meat (60 g in 100 kg) in dry cure; and 0.25 oz per 100 lb meat or 156 ppm maximum in comminuted and (or) meat by-products. For immersion-cured and dry-cured bacon, in-going nitrite level limits according to FSIS are 120 and 200 ppm, respectively. Residual nitrite levels in the finished pumped bacon cannot exceed 40 ppm.

Use of sodium or potassium nitrate as a curing agent is limited to some specialty products that require a long cure, such as dry-cured country ham and dry or semidry sausages. For such specialty products produced in Canada, a maximum of 200 ppm of nitrate may be used in addition to the 200 ppm of nitrite. In the US, FSIS regulations permit the use of 3.5 oz of nitrate in 100 lb of meat (215 g per 100 kg) in dry-cured country ham, 700 ppm nitrate in pickle cure, and 2.75 oz of nitrate in 100 lb (170 g per 100 kg) chopped meat and (or) meat by-product.

Ascorbates/Erythorbates

Ascorbic acid, isoascorbic (erythorbic) acid, and their respective salts are widely used in ham, bacon, and corned beef

processing. Ascorbates are used in the curing process primarily to help improve and maintain the color (i.e., nitrosylhemochrome pigment) of cured meats. The primary function of ascorbic acid may be in reducing metmyoglobin to myoglobin, thus accelerating the overall curing reaction. Under suitable conditions, ascorbic acid also helps in the production of NO from nitrite or its derivatives in the curing mixture. Besides their role in color development, ascorbates and erythorbates have been shown to block the formation of carcinogenic *N*-nitrosamines in cooked cured meats (particularly in bacon).

The USDA FSIS regulations permit the addition of 547 ppm of ascorbic or erythorbic acid, or the molar equivalent of their sodium salts, per 100 lb of chopped meat. For pumping pickle, the level is 75 oz of ascorbic acid or 87.5 oz of sodium ascorbate per 100 gallons (i.e., 469 ppm ascorbic acid or 547 ppm sodium ascorbate) when the pickle is to be used at a level of 10% of green weight (weight of raw meat used for curing before employing any treatments, such as pumping, tumbling, or cooking).

Sweeteners

In addition to salt, nitrite, and nitrate, sugar is commonly used in the curing mixture. Sweeteners, such as table sugar (sucrose), brown sugar, dextrose, glucose solids, corn syrup solids, and lactose, can be added at different levels mainly to impart flavor and moderate the harshness of salt in certain products. Use of honey or maple syrup in small amounts during curing results in special flavor and aroma in cooked meats. Addition of reducing sugars (e.g., glucose solids and dextrose) to the brine also helps in browning reactions during thermal processing to produce a desirable color and a caramel flavor in some products, such as bacon. However, in some instances, the browning reaction may become too pronounced and could result in burned flavors and dark colors (e.g., rapid darkening of bacon on frying). Different levels of sugars, in the range 1–2%, are added to the brine during various commercial operations in order to lower the water activity of meat during curing and hence provide some preservative action in cured meats. When nitrates are used as curing agents, sugar enhances the growth of microorganisms that reduce nitrate to nitrite, the first step in the curing process.

Phosphates/Polyphosphates

Phosphates and polyphosphates are used primarily to increase the water-holding capacity of cured meat products. Alkaline phosphates increase the pH of the meat and also help in solubilizing muscle proteins in order to impart the water retention action. In addition to increased water binding (i.e., increase in product yield), phosphates improve the cured meat flavor by retention of natural juices and by reduction of oxidative rancidity and warmed-over flavor in reheated meats by chelation of prooxidant metal ions. They also help to improve retention of the cured meat color.

Phosphates that have been approved by the USDA for use in brine solutions include sodium acid pyrophosphate, monosodium phosphate, sodium hexametaphosphate, disodium phosphate, sodium tripolyphosphate, and sodium pyrophosphate as well as mono- and dipotassium phosphate, potassium tripolyphosphate, and potassium pyrophosphate. These phosphates may be added to the pickle for ham, bacon, pork shoulders, picnics, Boston butts, boneless butts, and pork loins in the USA and Canada. Use of acidic and alkaline phosphates and blends of phosphates is restricted to 5.0% in the pickle and 0.5% (usually used at 0.3%) in the finished product. In addition, use of sodium hydroxide in combination with phosphate, in a ratio not to exceed 1 part sodium hydroxide to 4 parts of phosphate, was approved by the USDA for meat formulations where a higher pH is desirable and feasible. However, care must be exercised in the way sodium hydroxide is used.

Tripolyphosphates and their combinations with hexametaphosphates are the most widely used phosphates for cured meat cuts, as they provide the proper pH, good solubility, calcium compatibility, and a high degree of protein-modifying effect. In some preparations, sodium acid pyrophosphate may be added to bacon and hams at a level of up to 0.5% to decrease pH and to accelerate cure development. However, acid phosphates are not typically used in sausage formulations, as a rapid pH decline can cause emulsion breakdown.

Seasonings

Different types and levels of seasonings are used in curing mixtures by meat processors to impart unique flavors and appearance to meat products. These include spices and their extracts, herbs, hydrolyzed plant and vegetable proteins, and autolyzed yeast. The most common flavorings used in brine preparation are extracts from pepper, cloves, allspice, and cinnamon. Garlic and onion flavorings may also be added. An aqueous smoke solution is sometimes introduced into the curing pickle to provide a smoked flavor. In addition to flavoring properties, certain spices and herbs used as seasonings act as antioxidants by reducing the rate of oxidative rancidity development in cured meats.

Brine Curing Process

Two fundamental procedures are used in meat curing: dry curing and brine curing. Although dry curing is the oldest method, brine curing has also been practiced for many years for the preservation of meat. In fact, a book dating from the reign of Augustus (63 BC to AD 14) contains directions for preservation of cooked meat in a brine solution containing water, mustard, vinegar, rock salt, and honey. The brine curing process uses the same ingredients as used in dry curing except that the cure mixture is dissolved in water to form a brine or pickle. In some cases, prepared brine may be used as a source of salt. Although the early application of curing used brines with high salt concentrations, mild cures with considerably lower salt concentrations are used in meat curing today due to the development of refrigeration techniques and owing to the trend toward reducing sodium consumption by health-conscious consumers. Present-day curing practices sometimes use a combination of dry curing and brine curing methods to produce certain specialty products.

Brine Preparation

A pickle cure may include: (1) water and salt (plain/salt pickle), (2) water, salt, and nitrite or nitrate, or (3) water, salt, nitrite or nitrate, and sugar (sweet pickle). Other ingredients, such as smoke, seasonings, ascorbates, and phosphates, may also be added to enhance or improve flavor and to speed up the curing process and increase product yield.

The amount of green weight to be pumped and the equipment design (e.g., the size of the curing tank; the rate of processing; the capability of weighing and measuring; and the quantity of pickle retained in the injector reservoir) are important factors that should be considered in determining the amount of brine to be prepared. Brine should also be formulated in the near-exact amount to prevent pickle being left over, as the age of the brine is very critical to the nitrite level. Appropriate and accurate scales should be used in measuring and checking weights of cure ingredients. All measurements of solid ingredients used to prepare the brine should be by weight. Liquids, such as water, however, can be measured by volume. If ice is used in the preparation of brine, its weight must be used in all calculations. The order of mixing the curing ingredients to permit complete dissolution and to reduce the nitrite and ascorbate depletion during pickle preparation would be: (1) water; (2) phosphates; (3) ascorbate; (4) salt, sugar, and flavorings; and (5) nitrite.

In most commercial curing operations, temperature of the curing room is held at 2–5 °C (36–40 °F) to retard bacterial growth during brine preparation and application and until salt penetration is complete. Experimental evidence indicates that a temperature near 0 °C is the optimal condition for the curing process and for storage of the curing pickles. Meat to be cured and water used in brine preparation should be cold enough (i.e., near 0 °C) to maintain the temperature of the brine and brine-treated meat close to 0 °C. At higher temperatures, microbial growth is accelerated. In addition, keeping the brine solution at temperatures above 15.6 °C for a long period in the air may result in oxidation of NO to the red nitrogen dioxide (NO_2). Agitation may also hasten the reaction with oxygen. This process can reduce the extent of MbFe(II)NO production and hence the extent of color and flavor formation in cured meats. Thus, proper refrigeration and close monitoring of the temperature of the brine is necessary.

In brine curing, brine preparation should be closely monitored and good sanitation maintained throughout the process. A salometer (a ballasted glass vacuum tube graduated in 'degrees') is used for testing the strength (density) or salinity of the pickle. If brine needs to be stored overnight, it must be kept cold and analyzed for nitrite and ascorbate before its use the next day. Curing tanks should be emptied and cleaned at least once a week to prevent growth of halophilic microorganisms.

Techniques of Brine Curing

Pickle curing (immersion curing)

In this process, meat products are immersed in brine until the cure ingredients penetrate the entire piece of meat. Sweet pickle with a salometer reading of 75–85° can be used for home curing; Table 1 lists the amounts of basic ingredients necessary to make such pickles. The pickle curing method can be used for thick and thin cuts of meat and stainless-steel or selected plastic containers are used to store the meat during curing in order to avoid corrosion problems.

Table 1 Sweet pickle formulations

Salt (kg)	*Sugar (kg)*	*Sodium nitrite (g)*	*Cold water (l)*	*Degree of pickle by Salometer at 40 °F*
4.5	1.4	7.5	15.1	95
4.1	1.4	7.5	15.1	90
4.5	1.4	7.5	18.9	85
3.6	1.4	7.5	15.1	85
3.6	1.4	7.5	18.9	75
2.7	1.4	7.5	15.1	70
3.2	1.4	7.5	18.9	65
2.7	1.4	7.5	18.9	60

Source: Data calculated based on Romans, J.R., Costello, W.J., Carlson, C.W., Greaser, M.L., Jones, K.W., 1994. Meat curing and smoking. In: The Meat We Eat. Danville, CA: Interscience Publishers Inc., pp. 727–772.

Curing times prescribed for the different strengths of pickles listed in Table 1 are: 85° pickle, 9 days per inch; 75° pickle, 11 days per inch; and 60° pickle, 13 days per inch. Meat cuts with a higher thickness should be placed at the bottom of the curing barrel and the lighter ones placed on the top. Sufficiently cold (i.e., temperature close to 0 °C) pickle (usually 33 l per 100 kg (4 gallons per 100 lb) of closely packed meat and 37–42 l per 100 kg (4.5–5 gallons per 100 lb) of loosely packed meat) should be poured to cover the meat when the hold-down plate of the tank is weighted down. The thickness of each meat layer should be recorded in order to determine the date when the layers are to be taken out. It is desirable to overhaul (repack/move and turn) meat once or twice during the curing period in order to permit the pickle to reach all parts of the meat.

The rate of diffusion of the curing ingredients depends on the size of the cut, the amount of fat covering, and the temperature during curing. As meat cuts used for curing can vary in size and ability to absorb brine, all parts of the meat may not absorb the same amount of cure. This is one disadvantage in using this process. Also, as brine penetration into meat cuts for the brine curing method is a relatively slow process and takes a fairly long time, spoilage can develop with large cuts of meat before curing is complete. Cure accelerators, such as ascorbates, are not used in brine solutions employed for pickle curing because the process is a fairly slow. However, alkaline phosphates can be used in pickle curing to retain the moisture in the meat. At present, this method is mostly used for curing of small meat items, such as tongues, corned beef, and hocks.

Pickle injection

Owing to the problem associated with pickle curing (i.e., brine soaking), curing ingredients are now more commonly injected into the meat parts in order to obtain a rapid and uniform distribution of the cure throughout the tissue. Several techniques are used for this purpose, such as arterial pumping, stitch pumping, spray pumping, and multineedle injection.

Arterial Pumping

For meat cuts where the vascular system remains relatively intact (e.g., hams and tongues), brine solution can be introduced into meat through the arterial system. Pickle is pumped into the femoral artery on the inside butt end of the ham by means of a needle connected to a pump at a pressure of 275–345 kPa (40–50 lbs per square inch). The strength of the brine (i.e., salt concentration) used in this process is usually approximately 65–80° salometers. Most commercial processes use a brine solution of 65° salometer and phosphates are also incorporated within regulatory levels to help water retention and to increase yield. Nitrite, instead of nitrate, is used in this method to obtain a level of 156 ppm nitrite in the injected product. Sugar is also incorporated into the brine at a prescribed level. Normally, arterial pumping adds 8–10% of brine by weight to the final product. It is advised to allow at least 24 h of refrigerated storage to permit not only equilibration of the cure but also fixation of the cured meat color. This is necessary because the vascular system is not uniform throughout the meat. However, this process is fairly slow, because pumping of brine has to be carried out carefully and gently in order to avoid bursting of arteries. It also requires a high labor input and careful handling during slaughter, cutting, and subsequent handling of meat cuts to ensure that the arteries remain intact and are not damaged. Uncured spots can develop in cured meat products, such as hams, due to damaged arteries.

Stitch and Spray Pumping

Stitch pumping involves introduction of the brine into various parts of the meat tissues using a single-orifice needle. The spray pumping method is a variation of stitch pumping that uses a needle having several openings along the length of the needle to allow for a more uniform distribution of the pickle. Curing time is greatly reduced by this process as the curing ingredients diffuse from inside as well as outside of the cut. Also, the salt is introduced to the center of the ham cut before spoilage has a chance to take place.

The brine strength varies depending on the amount of pickle to be pumped into the meat, the desired intensity of salty flavor, and the storage conditions. In normal commercial operations, approximately 65° salometer brine with 150 ppm nitrite and adequate alkaline phosphate is used for injection at approximately 10% by weight. The injections are usually made at several sites, as close together as possible. However, uniform distribution of the cure is greatly dependent on the operator and, with bone-in meat parts (e.g., bone-in ham), it is difficult to distribute the cure uniformly around bones. Thus, stitched meat cuts should be held under refrigeration, perhaps in a cover pickle, for 5–7 days to allow uniform distribution of the cure.

Multineedle Injection

This method is widely used in the industry for curing bacon and pork cuts, both bone-in and boneless. This process is very rapid, continuous, and cost effective and reduces the number of workers involved during the curing process. The principle is quite similar to the stitch pumping method but uses 100–250 stainless-steel needles at uniform distances for injection of the brine. A series of offset needles are used in most commercially available machines and, on activation, pickle is pumped until the desired weight is obtained. This process helps to achieve a rapid and uniform distribution of the cure. The quantity of brine injected can be controlled by adjusting belt speed and number of strokes per minute. Independently balanced and functioning needles permit brine injection to follow the configuration of the meat cuts more closely.

The pumping pressure must also be carefully controlled to avoid muscle tissue damage, loss of cure retention, and formation of open pockets of pickle in the meat. In addition, all air should be removed from the pumping system, or vacuum pumping should be used, to avoid incorporation of air into the product. Needles must be periodically checked and cleaned to insure uniform pumping and to avoid bacterial contamination. However, if microbes are present on the surface of a meat cut, they can pass into the interior of the meat during injection. More importantly, as this is a continuous operation (injection of several meat cuts per cycle), contamination can occur from one piece of meat to another. Thus, good sanitation practices are necessary during this process. Some processors recirculate the brine during multiple injections, and this can also result in recontamination. Fresh brine should be used for each batch of meat cuts when using this method.

Massaging and Tumbling

Physical processes, such as massaging and tumbling, are used for brine-treated meat cuts to draw out water-soluble proteins (mainly actomyosin) to the meat surface and enhance the overall water-binding capacity when the exuded proteins gel on heating. Simultaneously, massaging and tumbling result in an increase in the internal tissue temperature that increases penetration and distribution of the brine. These mechanical treatments have been shown to shorten the curing period to 24 h, partly by aiding the distribution of the curing salts. Vacuum tumblers are used to overcome problems of tissue softening and incorporation of air and thus foaming of the protein matrix that has been brought to the surface during tumbling. Some tumblers have brine injection needles built into the vacuum chamber to allow simultaneous injection and mechanical action.

Smoking, Cooking, and Drying of Brine-Cured Meats

Smoke, generally produced by slow combustion of sawdust from hardwood (consisting of approximately 40–60% cellulose, 20–30% hemicellulose, and 20–30% lignin), inhibits bacterial growth and lipid oxidation and imparts flavor to cured meat. Many cured meat products are smoked in order to achieve these objectives. The cooking step is important for cured meats for fixation of the characteristic cured meat color (i.e., formation of nitrosylhemochrome pigment) and flavor. Cooking and smoking are often carried out simultaneously. Either steam or gas can be used for cooking. The cooking and smoking cycle must be carefully controlled to obtain the desired color, flavor, yield, and destruction of microorganisms in the brine-treated meats. The temperature and time of cooking,

as well as the humidity, are the most important parameters to be controlled. The final temperature depends on the product and is expressed as the internal temperature achieved for the finished product. The USDA regulations require that the fully cooked meat products attain a minimum temperature of 64 °C. However, drying, one of the earliest forms of meat preservation, remains in use for the production of dry or semidry fermented sausages.

Critical Control Factors during the Brine Curing Process

During meat curing, the composition of the curing mixture (such as the amount of nitrite, ascorbate, and phosphates) and the processing conditions (such as curing time, order of mixing of curing ingredients, and temperature during curing) should be controlled to achieve the desired color and flavor in the cured meats. It must also be considered that the intensity of the cured meat color depends on the availability of meat pigments (i.e., myoglobin) to form nitrosylmyoglobin during curing. A more intense cured color will thus be achieved for corned beef, containing more heme pigments than that for cured ham, when the same amount of nitrite is added.

Nitrite in the brine exerts an antimicrobial effect and retards the formation of *C. botulinum* toxin. Salt also helps in controlling microbial growth in cured meats by lowering the water activity. Combination of the practices used commercially for production of safe cured meat include addition of sodium nitrite at an initial concentration of 75–150 ppm with a residual concentration of 20 ppm or more, a sodium chloride concentration of 1.5–2.0% (both on a product basis), heating of the product to approximately 71 °C, and maintenance of a good sanitation throughout the curing process in order to minimize bacterial contamination. In addition, cured meats must be stored at temperatures below 10 °C.

Water used for the preparation of brine should be potable and free from bacteria, as bacteria can interfere with the curing reactions. The use of chlorinated water can adversely affect cured meat flavor. Food-grade salt should be used for brine preparation to insure a good flavor and color. Trace impurities in salt, such as copper, iron, and chromium, can catalyze oxidative reactions in cured meat products. Phosphates added to the brine help by chelating metal ions in the brine and reduce their catalytic activity in flavor deterioration. During brine preparation, phosphates should be dissolved in water before the addition of salt, as the salt can reduce their solubility. If the level of phosphates in the brine is too high, or if the salt concentration is too high, phosphates may precipitate, hence reducing their effectiveness. Thus, the proportions of phosphates and salt added to the brine should be properly controlled. Another problem in using phosphates is the formation of disodium phosphate crystals on the surface of the cured products owing to the loss of moisture during the processing and storage of cooked cured meat products. This problem can be overcome by reducing the level of phosphates in the brine, maintaining adequate humidity during processing, and using proper packaging systems to reduce moisture losses during subsequent storage. Owing to the corrosive nature of phosphates, another critical point with phosphates is the use of stainless-steel or plastic equipment and containers for brine processing of meat.

Levels of nitrite used in cured meats should be within the regulatory limits in order to reduce possible risk of *N*-nitrosamine formation. Formation of compounds such as *N*-nitrosopyrrolidine has been found to occur in bacon when frying at high temperatures. Thus, a maximum/minimum level of 120 ppm sodium nitrite is used for bacon curing. Bacon should also contain the maximum permitted level (547 ppm) of ascorbate or erythorbate in order to reduce *N*-nitrosamine formation. Use of buffered curing premixes containing nitrite, seasonings, and other flavorings is no longer permitted due to the risk of *N*-nitrosamine formation. Nitrite and nitrate are packaged separately from flavorings and seasonings in commercial curing mixes, and these separately packaged ingredients are not to be combined until just before use. Nitrite and nitrate must be uniformly mixed with other cure ingredients in order to avoid unexpected problems due to the presence of toxic levels of ingredients in any product batches.

Sodium Reduction in Brined Products

High sodium intake has been associated with increased risk of hypertension. To reduce sodium intake, there are three ways to lower the content of sodium chloride in processed meats. The first is to partially replace sodium chloride with potassium chloride; it is the most commonly used process to date. However, potassium chloride has a slightly bitter taste and other substances may have to be added in order to mask this unwanted taste. In this connection, lysine hydrochloride may be used at approximately 1% in such products. Second, flavor enhancers may be added to the meat, although their combination with salt has proven to provide a salty taste. Third, the physical structure of sodium chloride can be changed so that a lower concentration of it can still provide the same salty taste. This method is still being studied.

Nitrite Reduction

Nitrite renders multiple effects in cured meats by preventing oxidation and allowing the true flavor of meat to reveal itself. It also produces a desirable color in cured meat products and inhibits microbial growth. Because of its efficiency, nitrite is very difficult to replace; therefore, the common practice is to reduce its level and add other substances to mimic its properties.

To inhibit lipid oxidation, antioxidants, such as spices like rosemary extracts, are added. Many of these antioxidants also have multiple benefits, such as antimicrobial effects. However, simply changing the food packaging and preparation procedures to reduce the meat's exposure to light and oxygen can help to reduce the lipid oxidation and production of free radicals, hence retaining the desirable flavor and color of the meat.

To mimic the multiple preservative effects of nitrite, different ingredients with varying effects must be added. Ingredients with naturally high nitrate content are useful preservatives, as nitrate can be reduced to nitrite with naturally occurring nitrate-reducing bacteria. Such ingredients include vegetables, such as celery and spices. Use of celery juice in production of the so-called nitrite-free meat products has

taken place, but products may contain higher levels of residual nitrite than their nitrite-cured counterparts. Another way to preserve meat without nitrite is to add antimicrobials, including spices, herbs, and their oils. However, such antimicrobials usually only inhibit the growth pathogens and food-spoiling organisms in one way, whereas nitrite inhibits their growth in multiple ways. For this reason, different types of antimicrobials are needed to duplicate the effect of nitrite.

Summary

Although the origin of meat curing is lost in antiquity, the empirical observation that salting can preserve meat was made several thousand years ago. The occurrence of nitrate impurities in rock salt was found to be responsible for color formation in cured products. Present-day meat curing practices use a mixture of salt (sodium and/or potassium chloride); nitrite (or nitrate in some specialty products); sugar; cure accelerators, such as ascorbates or erythorbates; curing adjuncts, such as phosphates; seasonings; and other nonmeat ingredients in regulated levels.

Dry curing, direct addition, and brine curing are the three fundamental procedures used in meat curing. Brine curing uses the same ingredients as in dry curing and direct addition (perhaps at different levels to achieve adequate curing), but the ingredients are dissolved in pure water in order to produce a pickle that can be used in pickle curing or injected into the meat cuts. Methods for brine injection can be arterial, stitch, or multineedle injection. Each of these methods has its own advantages and disadvantages. Most industrial curing processes use the multineedle injection method because it facilitates rapid curing and faster production rate (i.e., number of meat cuts pumped per minute). However, there are some critical control factors to be considered during brine preparation, injection, maturation, and thermal processing of meat in order to obtain the desired color, flavor, and microbial quality of cooked, cured products. Furthermore, the issue of sodium reduction is a recent interest in preparation of processed meat products.

Glossary

Decarboxylases Enzymes able to transform an amino acid into an amine.
Glycolysis Enzymatic breakdown of carbohydrates with the formation of pyruvic acid and lactic acid and the release of energy in the form of ATP.
Lipase Enzyme that catalyzes the release of fatty acids by hydrolysis of triacylglycerols at positions 1 and 3.
Lipolysis Enzymatic breakdown of lipids with the formation of free fatty acids.
Proteases Enzymes that catalyze the release of an amino acid from the amino terminus of a peptide (exopeptidases) or able to hydrolyze myofibrillar proteins to polypeptides (cathepsins and calpains).
Proteolysis Enzymatic breakdown of proteins with the formation of peptides and free amino acids.
Water activity (a_w) Indication of the availability of water in a food and is defined as the ratio of the equilibrium water vapor pressure over the system to the vapor pressure of pure water at the same temperature.

Introduction

The origin of dry cured meats is lost in ancient times and the processing of these products is varied depending on the particular customs and habits of each country. Dry cured ham constitutes one of the main and representative products obtained through dry curing. Consumption of dry cured ham is typical in Mediterranean countries where it is produced in substantial amounts (i.e., more than 30 million pieces per year in Spain). Some of the most well-known products are Spanish Iberian and Serrano hams, French Bayonne ham, Italian Parma and San Danielle hams and Portuguese presunto. Other dry cured hams produced in China are the Jinhua ham, Xuanwei ham and Rugao ham. In some cases, hams are submitted to short processes and smoked like the American Country-style and German Westphalia hams. In the European Union, the most famous hams are protected by designations of origin, being controlled by consortiums that guarantee the authenticity and quality of their products.

Dry curing consists of the application of a dry cure (no water added) containing salt, nitrate and/or nitrite and other agents like sugar and ascorbic or erythorbic acids. The process involves several stages: (1) a salting stage for the penetration of salt into the product by solubilization in the moisture of the meat, (2) a postsalting for salt diffusion and equalization through the entire piece and (3) a drying/ripening stage for water loss and development of numerous biochemical reactions affecting color, texture, and flavor. Dry curing is a traditional process, where the knowledge of the process has been transmitted from generation to generation. However, the need to obtain products of constant high quality, based on reproducible and controlled production processes, has prompted a considerable amount of scientific and technical research over the past 25 years. Today, there is a considerable amount of information available on the biochemical mechanisms involved in the process. Proteolysis and lipolysis constitute two groups of enzymatic reactions directly affecting protein and lipids, respectively, and resulting in important contributions to flavor and texture development. Proteins and lipids constitute the major chemical components of dry cured meat products, and their breakdown products are essential for flavor and texture.

Proteolysis

Proteolysis constitutes one of the most important groups of reactions responsible for degradation of sarcoplasmic and myofibrillar proteins and further hydrolysis of the generated polypeptides and peptides to small peptides and free amino acids. Skeletal muscle contains a wide variety of enzymes able to hydrolyze either internal peptide bonds (cathepsins and calpains) or peptide chains from their ends (tri- and di-peptidylpeptidases and aminopeptidases). Most of the enzymes are located in lysosomes, in the myofibrillar structure or bound to membranes, and have optimal pH near the values typically found in dry cured meats.

Action of Proteases During Dry Curing

The long processing time, several months or even years, allows for an intense action of muscle proteases. In general, these enzymes are quite stable and thus able to act for long periods of time. There are some exceptions like cathepsin D that tends to disappear approximately the sixth month of processing, and calpains which are restricted to the initial 2 weeks of the process owing to their rather poor stability. The full flow chart for the proteolysis during dry curing is shown in Figure 1. Initially, major protein breakdown, mostly due to calpains, is focused on Z-disc proteins, desmin and other major proteins like titin and nebulin. However, calpains are unstable and further protein breakdown, observed during the entire process, is due to cathepsins, especially cathepsins B and L. Polypeptides that are generated are further hydrolyzed to peptides within the range 2700–4500 Da, and most of those are further hydrolyzed to smaller peptides (below 1200 Da),

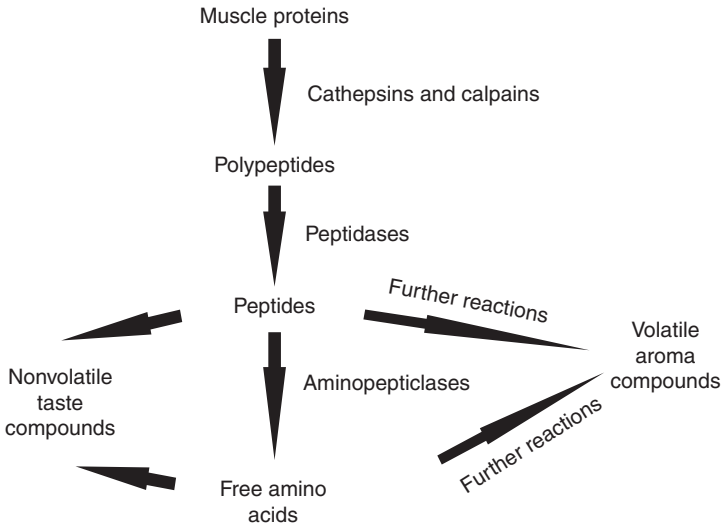

Figure 1 Flow chart showing the major important steps in muscle proteolysis during the processing of dry cured meats. Reprinted from Toldrá, F., 1998. Meat Science 49, s101–s110.

especially tripeptides and dipeptides by tripeptidylpeptidases and dipeptidylpeptidases, respectively. Peptide mappings, analyzed at different stages by reverse-phase HPLC and capillary electrophoresis, have confirmed the generation and/or increase of numerous peptides that have been further fractionated by size and fully sequenced by proteomics techniques. Savory fractions have been shown to be related to peptides within the range 1500–1700 Da. The generation of free amino acids by aminopeptidases constitutes the last step in the proteolysis chain. Some amino acids, mainly glutamic acid, alanine, leucine, lysine, valine and aspartic acid, are abundantly generated reaching amounts as high as 50–350 mg per 100 g of product by the end of the process. Alanyl aminopeptidase is the main exopeptidase involved in this process as it is the major aminopeptidase in muscle and has a wide substrate specificity. However, the generation of basic amino acids, arginine and lysine, is mainly due to aminopeptidase B. In general, the longer the process, higher is the amount of free amino acids generated. The combination of peptides and free amino acids together contribute to the characteristic taste of the product.

Proteolysis is important in dry curing and has many benefits for the final quality of the product although it needs to be controlled as an excess of proteolysis may impair the sensory characteristics and result in poor ratings by sensory panelists and consumers for the following reasons: (1) an excessive accumulation of low molecular weight nitrogen compounds (peptides and free amino acids), enhancing a bitter and metallic taste, (2) the presence of randomly distributed white crystals of tyrosine, making the product less attractive, and (3) excessive breakdown of myofibrillar proteins resulting in an undesirably soft product.

Lipolysis

The process of lipolysis can be considered as a group of enzymatic reactions affecting triacylglycerols and phospholipids.

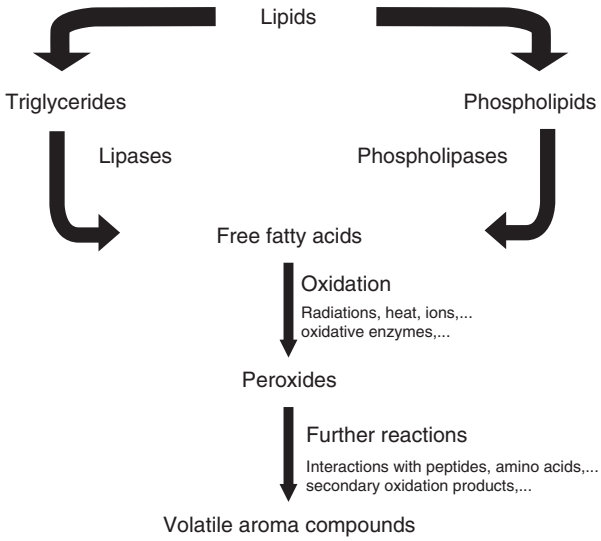

Figure 2 Flow chart showing the major important steps in muscle lipolysis and oxidation to volatile compounds during the processing of dry cured meats. Reprinted from Toldrá, F., 1998. Meat Science 49, s101–s110.

Free fatty acids are released in these reactions and act as precursors of further oxidative reactions leading to volatile aroma compounds as shown in Figure 2. Lysosomal acid lipase and neutral lipase are present in skeletal muscle and are able to hydrolyze tri- and di-acylglycerols at acid and neutral pH, respectively, and generate free fatty acids. Acid phospholipase also generates free fatty acids acting on phospholipids as substrate. Lysosomal acid lipase and acid phospholipase are located in lysosomes and have optimal pH near the pH values usually found in dry cured meats. Furthermore, both enzymes have shown good stability along the full process. The activity of lipases and phospholipases is higher in oxidative muscles than in glycolytic muscles. Acid and neutral esterases are also present in muscle tissue but the generation of short chain free

fatty acids is almost negligible suggesting that these enzymes have a minor role. In addition, esterase activity remains unaffected by the oxidative pattern of the muscle.

Hormone-sensitive lipase and mono-acylglycerol lipase are located in adipose tissue and are active at neutral pH. These lipases find good conditions for activity during dry curing and are responsible for the generation of free fatty acids from triacylglycerols and diacylglycerols and from monoacylglycerols, respectively.

Action of Lipases During Dry Curing

The rate of lipolysis is fast during the first 6 months but then decreases, reaching slower rates toward the end of the process. A great percentage of the generated free fatty acids in muscle occurs as a result of phospholipid hydrolysis, indicating a major role of phospholipases. In fact, the hydrolysis of phospholipids is very important for the final flavor of the product because they release long chain polyunsaturated fatty acids which are very sensitive to oxidation. Fatty acid profiles during the processing of dry cured meats usually reaches a maximum at some point but, before the end of the process, oxidation results in a decrease in long chain polyunsaturated fatty acids. Oxidation is favored by the presence of salt, action of oxidative enzymes like muscle lipoxygenases and cycloxygenases, drying/ripening temperatures, and long time for reactions. The minor amount of lysophospholipids can be explained by the high activity of lysophospholipases in relation to phospholipases. Triacylglycerols are hydrolyzed and also provide a significant amount of free fatty acids although at a lower rate. In this sense, the disappearance of triacylglycerols is correlated with the increase in di- and monoacylglycerols, as products of the hydrolytic action.

Triacylglycerols from adipose tissue also undergo an intense lipolysis during the salting and postsalting stages, with a substantial increase in free fatty acids. Hormone-sensitive lipase that remains active during the full ripening/drying period is the main enzyme responsible for lipolysis in the adipose tissue. Monoacylglycerols are further degraded to glycerol and the respective fatty acid by the mono-acylglycerol lipase. The generation rate, especially in mono and polyunsaturated fatty acids depends on the composition of the feed given to the pigs. This is of extreme importance for oxidative reactions that will generate different volatile compounds, and thus different aromas, depending on the composition in fatty acids.

Nucleotides Degradation During Dry Curing

Nucleotides experience an intensive enzymatic degradation during the dry curing process until almost complete disappearance at approximately 7 months. On the contrary, hypoxanthine and xanthine, as final products of the enzymatic cascade, are generated primarily during the first 7 months of dry curing, and remain for the rest of process. Hypoxanthine, which is generated at more than 15 μmol per gram of dry matter, might be considered as a potential biochemical marker of a minimum time of processing (7 months) in view of its evolution and stability.

Curing Factors Affecting Muscle Enzyme Activity

Curing agents and processing conditions exert different effects on the activity of muscle enzymes. Salt is a basic compound in dry curing processes and exerts a clear and important influence on muscle enzymes. Cathepsins D and H, dipeptidylpeptidases II and III and alanyl aminopeptidase are strongly inhibited by salt whereas calpains, aminopeptidase B, and lysosomal acid lipase are slightly activated, especially at low salt levels. Other curing agents like nitrate and nitrite, glucose, or ascorbic acid exert only a slight effect on the enzyme activity. Conditions such as temperature during drying and ripening are favorable for enzyme activity. However, the slightly acid pH of meat reduces the activity of strictly acid enzymes (i.e., cathepsin D) and neutral/basic enzymes (i.e., calpains, leucine and pyroglutamyl aminopeptidases, neutral lipase and esterase).

Microbial Evolution

Low bacterial counts are usually found inside the hams due to limiting factors like salt concentration, presence of nitrite and progressive water activity reduction. Microorganisms present in the natural flora of ham include *Lactobacillus sakei*, *Lactobacillus curvatus* and *Pediococcus pentosaceus*. They have good exo-proteolytic activity although its contribution to proteolysis is minimal owing to the low counts. *Staphylococcus xylosus* is also naturally present and has an important nitrate reductase activity that contributes to the reduction of nitrate to nitrite. Amines might be generated by decarboxylation of certain free amino acids as a consequence of undesirable bacterial growth having decarboxylase activity although low or negligible levels are usually found. Humidity and temperature must be taken into account, particularly in the air-conditioned rooms, to avoid growth and development of molds, usually *Penicillium*, and sometimes yeasts such as *Candida zeylanoides* and *Debaryomices hansenii*, on the outer surface of the hams.

Sensory Characteristics

Color

The intensity of color depends on the concentration of myoglobin, which varies depending on the type of muscle (myoglobin concentration is higher in muscles with oxidative pattern) and the age of the animal (myoglobin concentration tends to be higher in muscles from older animals). Nitrosomyoglobin is generated through the reaction of nitric oxide with myoglobin when nitrate and/or nitrite have been used, giving hams a typical bright-red cured color. Those hams without added nitrate or nitrite like Parma hams present a pink-red color that is attributed to the Zn protoporphyrin IX complex. Dark colors on the surface of the hams are typical after smoking treatment.

Texture

Proteolysis of key myofibrillar and associated proteins is responsible for tenderization. An intense degradation of the

myofibrillar structure is observed during dry curing. Major structural proteins like titin, nebulin, and troponin T as well as myosin heavy chain and α-actinin are severely proteolyzed. Two clear fragments corresponding to 150 and 85 kDa appear along the processing. Hams produced from pale, soft, exudative (PSE) meats show an absence of these fragments when compared to normal hams and there is a trend toward softer hams. In fact, the application of a texture analysis shows that PSE hams have lower hardness, springiness, cohesiveness, and chewiness values.

Texture of the product depends not only on the extent of myofibrillar protein breakdown but also on other factors like the extent of drying, the degradation of the connective tissue and the content of intramuscular fat which also exerts a positive influence on some texture and appearance traits.

Flavor

Flavor generation is strongly associated with the proteolysis and lipolysis phenomena. Taste is mainly associated with nonvolatile compounds accumulated by the end of the process (see Table 1) and, in fact, the concentration and composition of free amino acids and small peptides at the end of dry curing has been related to specific taste descriptors. For instance, the composition of peptides in savory fractions consisted of glutamic acid, glycine, alanine, valine, proline, histidine, and leucine. However, lysine and tyrosine have been correlated with aged taste whereas glutamic acid, aspartic acid, methionine, phenylalanine, tryptophan, lysine, leucine, and isoleucine have been correlated with the length of the drying and the fully ripened ham taste. The excessive accumulation of tryptophan, tyrosine and phenylalanine, in hams with a high level of proteolysis, is associated with a bitter taste. Nucleotides are strong taste enhancers but their concentration in dry cured meats is very low and in most of the cases below the sensory threshold value, and thus its contribution can be considered almost negligible. Only hypoxanthine, which is generated at concentrations higher than 15 $\mu mol\ g^{-1}$ dry matter, may contribute to bitter taste.

In the case of aroma, nearly 200 volatile compounds, most of them with impact on aroma perception, have so far been reported in dry cured meats. They are representative of most classes of organic compounds such as aldehydes, alcohols, hydrocarbons, pyrazines, ketones, esters, lactones, furans, sulfur and chloride compounds, carboxylic acids, etc. Some of these compounds are generated through oxidation of unsaturated fatty acids resulting from lipolysis, as shown in Figure 2. The generation of free amino acids like pyrazines, sulfide compounds, and branched-chain aldehydes during dry curing constitutes an important source of volatile compounds with important aromatic characteristics. The most representative classes of volatile compounds found in dry cured meats and the main routes for generation are listed in Table 2. The final flavor strongly depends on the specific aromas and odor thresholds for each particular volatile compound. In general, pleasant aroma is correlated with the presence of certain ketones, esters, aromatic hydrocarbons, and pyrazines.

Processing Control

The ability to control this complex system in a dry cured product is very important for economical and quality reasons. There are several ways to control the proteolytic and lipolytic activity in the hams: (1) the genetics and age of pigs exert a clear influence on the final quality of the products. Different enzyme profiles and composition have been detected depending on the specific crossbreed and age. The amount of lipids and marbling, very important for the sensory quality of the final product, also depend on the breed (i.e., the Duroc

Table 1 Major nonvolatile compounds generated or present in dry cured meats and the relative contribution of each to taste

Groups	*Main compounds*	*Contribution to taste*
Peptides	Many tri and dipeptides, carnosine and anserine	High
Free amino acids	Lysine, glutamic acid, aspartic acid, leucine, alanine, arginine, valine, serine, threonine, ...	High
Free fatty acids	18:1 *n*–9, 18:2 *n*–3, 16:0, 18:0, 20:4 *n*–6, 18:3 *n*–6, ...	Low
Nucleosides	Hypoxanthine, xanthine	Low/medium
Inorganic compounds	Sodium chloride	High

Table 2 Major classes of volatile compounds generated in the processing of dry cured meats and the relative contribution of each to final flavor

Groups of volatile compounds	*Main routes for generation*	*Odor threshold*	*Contribution to flavor*
Aliphatic hydrocarbons	Lipids auto oxidation	High	Very little
Aromatic hydrocarbons	Oxidative decomposition of lipids	High	Low
Aliphatic aldehydes	Oxidation of unsaturated fatty acids	Low	High
Branched-chain aldehydes	Strecker degradation of valine, leucine, and isoleucine	Low	High
Alcohols	Oxidative decomposition of lipids	High	Low
Ketones	Lipid oxidation	Low	High
Esters	Interaction of carboxylic acids and alcohols	Low	High
Pyrazines	Maillard reactions	Low	Medium
Sulfide compounds	Strecker degradation of sulfur-containing amino acids	Low	Medium

breed gives more intramuscular fat than many others) and age (i.e., higher lipids content as animal gets older), (2) the feed, especially the lipid composition in fatty acids, strongly affects the composition of pork fat and thus the final aroma of the dry cured meat because many volatile compounds arise from the oxidation of particular unsaturated fatty acids, (3) processing control of important parameters like temperature, relative humidity and air speed in computer-controlled curing rooms are important for drying and subsequent water loss from the product. The reduction in water activity affects enzymatic hydrolysis reactions, like proteolysis and lipolysis, lowering the rate of hydrolysis, and (4) the addition of salt affects muscle enzymes. Based on its proved inhibitory effect on cathepsins, salt may be used to prevent an excessive tenderness when using hams from pigs with high levels of cathepsin activity. The excess of cathepsin activity may be controlled in the raw material through rapid test kits and, in those cases with an excessive activity, the addition of an excess of salt constitutes an effective controlling measure because its inhibitory effect on cathepsins results in a slower protein breakdown.

Salt Reduction

Dietary intake of excessive amounts of sodium may have negative effects on the cardiovascular health of the consumers and following such medical concern, the meat industry has made serious efforts in recent years to reduce salt content in hams. The strategies to reduce the amount of salt used in the processing of dry cured ham consist of a direct reduction in the amount of added salt and/or partial replacement of sodium chloride by other chloride salts like potassium chloride, calcium chloride, and magnesium chloride. However, the percentage of replacement is restricted to less than 40% due to bitterness associated with an excess of potassium or metallic aftertastes associated with the presence of certain levels of calcium and magnesium.

Natural and Organic Cured Meat Products in the United States

JJ Sindelar, University of Wisconsin, Meat Science & Muscle Biology Laboratory, Madison, WI, USA

Glossary

Alternative curing The technology of using natural sources of nitrate and/or nitrite from plants, vegetables, etc. to cure.

Curing The addition of nitrite/nitrate with salt to a meat product to achieve improved preservation or the chemical entities of nitrite/nitrate.

Nitrite A pale yellow, nearly white, crystalline compound that is highly soluble in water and highly reactive functioning as an oxidizing, reducing or nitrosating agent, and is converted to a variety of related compounds when added to meat.

Nitrosamines It is also known as *N*-nitroso compounds. A class of chemical compounds classified as carcinogenic that can be formed in cured meat, primarily bacon, under special conditions where secondary amines are present, nitrite is available, and necessary pH and high temperatures exist.

Purified nitrite Nitrite that has been industrially produced by absorption of nitrogen oxides (NO_x), originating from the catalytic air oxidation of anhydrous ammonia, into aqueous sodium carbonate or sodium hydroxide.

Introduction

Natural and organic processed meats have been a very significant part of the explosive market growth that has occurred in natural and organic foods. Producers and processors have responded to consumer demand for foods perceived by many to be more healthy and wholesome than conventionally produced food products by offering more and more products labeled as 'natural' or 'organic.' To qualify as natural or organic in the US, foods must be produced and processed in accordance with United States Department of Agriculture (USDA) regulations that define these products. These products are also produced in other countries around the world, though specific regulations differ somewhat.

In most cases, natural and organic foods very closely resemble conventional products and do not differ in the typical characteristics expected by consumers. However, in the case of processed meat products such as hams, bacon, frankfurters, bologna, and others that are typically cured by addition of sodium nitrite, and sometimes sodium nitrate, the requirements for natural or organic marketing in the US do not permit addition of nitrite or nitrate and thus differences commonly exist. Therefore, a new category of 'uncured' processed meats often referred to as 'alternatively cured' products has been developed to provide consumers with the variety, convenience, and satisfaction of cured meat products while giving manufacturers the opportunity to meet consumer demand for natural and organic processed meat products.

Conventional Curing

Conventional Cured Meat Ingredients

Conventionally cured meat products are characterized and defined by the addition of nitrate and/or nitrite, which provide the distinctive properties that are common to all cured meat products. Saltpeter (potassium nitrate), first recognized as the original curing agent, was used in one form or another to cure meat for centuries before researchers, in the late 1800s, discovered that nitrate was actually being converted into nitrite by nitrate-reducing bacteria, and that nitrite was the true curing agent.

Nitrite is a highly reactive compound and it has become clear that the formation of nitric oxide (NO) from nitrite is a necessary prerequisite for many meat curing reactions. The addition of nitrite to cured meats fixes color, contributes to cured meat flavor, helps in the inhibition of the growth of microorganisms, specifically *Clostridium botulinum*, and effectively controls rancidity by inhibiting lipid oxidation. Sodium nitrite allows for the existence of meat and poultry products with unique colors, textures, and flavors that cannot be recreated by any other ingredient.

Regulations for the Conventional Curing Processes

Current regulations restrict the use of nitrite and nitrate in the US and vary depending on the method of curing used and the product that is being cured (see **Table 1**). Bacon is an exception to the general limits for using curing agents because of the potential for nitrosamine formation and as a result has more stringent curing regulations.

The curing accelerators permitted for use with nitrite are also restricted. Ascorbic and erythorbic acids, for example, cannot exceed 469 ppm (ppm) ingoing concentrations, while sodium ascorbate and erythorbate are limited to 547 ppm ingoing.

Alternative Curing – Systems and Labeling

Manufacturing Systems

Because the addition of purified nitrate and nitrite is prohibited for all 'natural,' 'organic,' or simply 'uncured' meat products to resemble traditionally cured meats, processors often utilize permitted natural ingredients and modified processing to achieve cured meat characteristics – a process that has become known as alternative curing.

 doi:10.1016/B978-0-12-384731-7.00116-1

Table 1 Maximum allowable added levels for curing ingredients in meat and poultry in the United States[a]

Curing agent	*Curing method*			
	Immersion cured (ppm)	*Massaged or pumped (ppm)*	*Comminuted (ppm)*	*Dry cured (ppm)*
Sodium Nitrite	200	200	156	625
Potassium Nitrite	200	200	156	625
Sodium Nitrate	700	700	1718	2187
Potassium Nitrate	700	700	1718	2187

[a]Limits are based on total formulation/brine weight for immersion cured, massaged, or pumped and raw meat (green) weight for comminuted or dry cured products.

The term 'alternative curing' is not officially recognized by the USDA, but refers to the original, ancient process that is the true origin of all modern cured meats. Alternative curing refers to the microbial conversion of naturally occurring nitrate, present in the environment, to nitrite, which then cures the meat in the same manner as if purified nitrite had been added. Because nitrate is an essential part of the total nitrogen cycle, naturally occurring nitrate can be present in the soil, sea water, various 'sea salts,' and green plants (including vegetables). Furthermore, many types of microorganisms in the environment have the ability to convert this naturally occurring nitrate into nitrite; thus, combining these two natural ingredients (vegetables or sea salt+harmless food-grade microorganisms) can result in a natural preservation system for meat.

In general, natural curing processes now fall within one of the following three categories.

Culture system

This process involves using a natural nitrate source material and a suitable meat culture. Both ingredients are added separately to the meat formulation and the nitrate conversion occurs in the meat during processing. Starter cultures containing a nitrate-reductase enzyme facilitate nitrate-to-nitrite conversion. The culture system used for alternative curing is driven by the culture concentration, and thus higher nitrite levels result from a greater percentage of culture used in the product formulation.

The main advantage of the culture system is that some of the nitrite produced immediately reacts with the meat pigments to begin the curing process. The primary disadvantages are (1) the potential lengthening of the thermal process to allow adequate conversion and (2) the 'lag period' sometimes required to generate the nitrite can make some specific meat products and processes more vulnerable to the initial growth of undesirable microorganisms.

Prebrine system

This process also involves the use of both a natural nitrate source and a suitable meat starter culture; however, the nitrate-to-nitrite reduction is accomplished by the meat processor, either partially or completely, in brine (liquid) before addition to the meat. The nitrate source and all, or a portion, of the meat culture, is first added to the brine, preferably without other ingredients. The nitrite is generated in solution by the microbial reduction of the added nitrate and is then subsequently added to the meat mix directly or via injection, after remaining ingredients have been added to the brine.

The advantage of this system is that nitrite produced in the brine can be measured and is available immediately for reaction when added to the meat, thus eliminating any 'lag period.' The main disadvantages are controlling the nitrate reduction in the liquid system and stabilizing the resulting nitrite produced to avoid nitrite loss before addition to the meat takes place.

Preconverted system

This most recent and most commonly used system developed for alternative curing involves the intentional preconversion of nitrate to nitrite and stabilization of the nitrite produced, which is all done by the ingredient supplier. The resulting product in liquid or dry form originates from the same natural nitrate source, with the original nitrate mostly converted into nitrite. The preconverted product already contains the nitrite and is simply used by the meat processor as a curing agent, similar to conventional curing procedures.

The main advantages of this system are the simplicity of adding a known quantity of nitrite and avoiding the use of viable microorganisms. The main disadvantages are, in general, (1) lower potential nitrite concentrations ultimately available for curing as opposed to using nitrate plus starter culture and (2) the handling of the preconverted product that is reactive (i.e., as with traditional nitrite cures).

Labeling Terms for Natural, Organic, and Uncured Processed Meats

The labeling terms 'natural,' 'organic,' and 'uncured' refer to three distinct meat and poultry product categories governed by separate USDA labeling policies and federal regulations. By definition, none of the three types of products can have added nitrate and nitrite.

Natural

Processed meats that are labeled 'natural' must comply with the definition of the term provided by the *USDA Food Standards and Labeling Policy Book*. This definition requires that a natural product "does not contain any artificial flavor or flavoring, coloring ingredient, or chemical preservative (as defined in 21 CFR 101.22), or any other artificial or synthetic ingredient; and the product and its ingredients are not more than minimally processed." The definitions for flavorings, coloring, and chemical preservatives can be found, as noted above, in Title 21 CFR, Chapter 1, Part 101, Subpart B

(101.22)-subtitled Labeling of Spices, Flavorings, Colorings, or Chemical Preservatives.

Furthermore, the term artificial color or coloring means any 'color additive' as found by definition in Title 21 CFR, Chapter 1, Part 70-Color Additives, Subpart A(f). The second relevant part of 21 CFR 101.22 is item number 5, which addresses chemical preservatives as follows: "The term chemical preservative means any chemical that, when added to food, tends to prevent or retard deterioration thereof, does not include common salt, sugars, vinegars, spices, oil extracted from spices, substances added to food by direct exposure thereof to wood smoke, or chemicals applied for their insecticidal or herbicidal properties…."

Organic

Products labeled 'organic' are much better defined and controlled than those labeled with 'natural' claims because organic products are governed by the Organic Foods Production Act (OFPA), first passed in 1990 as part of the 1990 Farm Bill. The OFPA authorized the USDA to create a National Organic Standards Board, which established a National List of Allowed and Prohibited Substances and developed National Organic Program (NOP) standards.

The NOP standards, implemented in 2002, specify methods, practices, and substances that are allowed for use for production, processing, and handling of organic foods. This means that products and ingredients used for organic foods must be certified as organic by a USDA-certified inspector. Meat, for example, must be raised using organic management and come from a certified farm. Ingredients used for processed products are clearly defined as permitted or prohibited in the OFPA National List.

Uncured

The Code of Federal Regulations (9 CFR 317.17) states that normal cured products ("to which nitrate or nitrite is permitted or required to be added…") can be made without nitrite or nitrate and labeled with such common or usual name or descriptive name when immediately preceded with the term 'uncured.' Additionally, specifically outlined, 'No nitrate or nitrite added' labeling is also required. All organic and natural products are uncured by definition, but not all uncured products are natural or organic.

General Labeling Regulations

The labeling for uncured, natural, and organic meat products is very confusing and has yet to be totally resolved, particularly with regard to 'alternative curing.' All three product categories do not permit the use of added purified nitrite or nitrate salts; however, natural sources of these chemicals are permitted. The main issue is the separate USDA regulation that requires the labeling of a traditionally cured meat product as 'uncured' if purified nitrate and nitrite are not added.

Specifically, "Any product, such as bacon and pepperoni, which is required to be labeled by a common or usual name or descriptive name in accordance with 9 CFR 317.2(c)(1) and to which nitrate or nitrite is permitted or required to be added may be prepared without nitrate or nitrite and labeled with such common or usual name or descriptive name when immediately preceded with the term 'Uncured' as part of the product name, provided that the product is found by the Administrator to be similar in size, flavor, consistency, and general appearance to such product as commonly prepared with nitrate or nitrite, or both. In addition, these products must bear the statements 'No Nitrate or Nitrite Added' and 'Not Preserved – Keep Refrigerated Below 40 °F at All Times' unless they have been thermally processed to 3 °F or more, fermented or pickled to pH of 4.6 or less, or dried to a water activity of 0.92 or less." Because these products are considered 'uncured' by the USDA, they must be processed accordingly.

With the growth of alternative curing, the USDA now requires 'uncured' products to have a qualifying statement, 'No Nitrates or Nitrites Added (except those occurring in sea salt and celery powder),' if any of the ingredients may contain naturally occurring nitrate or nitrite.

Only 'traditionally cured' products such as frankfurters, bacon, corned beef, pastrami, and pepperoni are required to follow the uncured labeling requirements for their natural, organic, and uncured alternatives. If the traditional product was not cured, such as oven roasted turkey breast, the natural alternative does not require uncured labeling.

Additionally, some alternatively cured product alternatives are exempt from the 'uncured' labeling requirements altogether if they meet the outlined USDA criteria such as (1) achieving a water activity of 0.92 or less or (2) having a brine concentration of ≥10%.

Alternative Curing – Manufacturing Ingredients

Alternative Curing Agents

Natural nitrate sources

Several natural nitrate sources are available for natural curing but the most common ingredients are based on celery juice or celery powder. This is a regularly available and consistent vegetable crop with relatively minimal negative sensory effects on meat product attributes such as flavor and color. Celery powder can also be labeled as 'natural flavor' according to USDA regulations and 'celery powder' is NOP approved for 'organic meat products' if 100% organic celery product with the same characteristics is not available. Celery juice is usually expressed as 'celery juice' on the label and is sold either in frozen or shelf-stable form depending on the concentration (brix) and pasteurization/packaging procedures. The main disadvantage of celery-based ingredients is that celery is considered an allergen or 'sensitizing agent,' and thus other vegetable ingredients suggested to be less allergenic than celery, such as Swiss chard, are being commercially developed. 'Sea salt' generally has not proved to be a consistent source of nitrate or nitrite and is no longer required for 'natural' labeling.

With any natural nitrate or nitrite source ingredient, it is important to understand and have specifications for 'nitrate' (NO_3^-) and/or 'nitrite' (NO_2^-) ions, which are the active components. Often expressed as 'sodium nitrate' ($NaNO_3$)

and/or 'sodium nitrite' ($NaNO_2$) as per the USDA regulations, the weight of the sodium salt is approximately 1.37x and 1.50x, respectively, of the nitrate or nitrite ions based on the atomic weight of each compound.

Natural preconverted nitrite sources

Most of the preconverted natural ingredients containing nitrite are manufactured by using similar natural nitrate sources (e.g., celery) and similar meat cultures for the nitrate conversion. In general, preconverted juices or powders contain concentrations varying from 10 to 25 000 ppm (1–2%) expressed as sodium nitrite. The final concentrations are limited by the initial nitrate concentrations present in the various vegetable materials. These products are available in both liquid and dry form and provide a designated minimum nitrite ion, either designated as the 'nitrite ion' concentration or expressed as 'sodium nitrite' salt concentration. As with any natural product, these 'preconverted' vegetable products exhibit some color and flavor attributes that make the products somewhat 'self-limiting' in usage. However, improvements in both nitrite concentration and flavor control have allowed for addition levels that can now attain the maximum regulatory limits outlined for purified nitrite.

Nitrate-Reducing Starter Cultures

Most meat cultures employed are harmless staphylococci strains that are also the most commonly used meat starter cultures worldwide. Originally, *Staphylococcus carnosus* was the most commonly used strain due to its nitrate reductase activity and previous successful use as a meat starter culture for color and flavor development. Because most existing *S. carnosus* strains were more active at relatively high temperatures (optimum at 90–100 F), the use of this starter culture in natural curing required elevated temperatures for the nitrate conversion, and thus the need for an 'incubation period.' Subsequently, other stains of staphylococci demonstrating higher nitrate reductase activity and functionality at lower temperatures were isolated and developed commercially. These 'second-generation' commercial meat cultures are a mixture of different *S. carnosus* strains (*S. carnosus* spp. *utilis*) and other staphylococci strains (i.e. *Staphylococcus vitulinus*). These culture blends are activated earlier in the process (at lower temperatures) and as a result are more efficient for nitrate conversion. The use of these blends results in overall higher nitrite generation and their use can minimize or even eliminate the need for an 'incubation period.'

Natural Curing Adjuncts

As with traditional curing, the addition of other natural compounds can enhance the natural curing process. Cherry powder and acerola juice and powder are products containing relatively high levels of natural occurring ascorbic acid, which is an oxygen scavenger (reductant) and metal ion sequestrant that serves as a curing accelerator. Citrus powders (e.g., lemon, lime) also contain naturally occurring ascorbic acid as well as citric acid, which are also effective as natural curing accelerators and antioxidant synergists.

Other Natural Ingredients

Antioxidants

A number of natural compounds with antioxidant activity exist. Rosemary and other herb extracts, as well as extracts of green tea and grape seed, serve as natural free radical scavengers inhibiting fat, protein, and meat pigment oxidation when incorporated into natural meat and poultry products.

Preservatives

Citrus juices and powders used as curing adjuncts are typically used at relatively low concentrations; however, when used at higher levels, they can serve a dual function as microbial inhibitors, particularly in combination with vinegar. Acetic acid, di-acetate, and acetates are proven antimicrobial ingredients and are available 'naturally' in the form of vinegar, specifically if the vinegar is considered 'minimally processed.' Technically, sodium lactates are not USDA approved for 'natural' labeling unless it can be shown that they are being used as 'flavoring agents' to extend shelf life and not as 'chemical preservatives' to extend shelf life. Generally, the acceptable level is less than 2%.

Binding and texturizing agents

Natural meat products commonly exhibit lower yields with looser texture and lower product pH because ingredients such as sodium phosphates are not allowed. For natural meat products some water-binding agents are approved if considered 'minimally processed.' Carageenan (seaweed) is the most commonly used, with some gums such as xanthan gum also being utilized. Raising the brine and/or product pH with added sodium bicarbonate or sodium carbonate can also achieve increased yields.

Flavorings

'Natural flavoring' has generally been defined by the USDA as the essential oil, oleoresin essence, or extractive, protein hydrolysate, distillate, or any product of roasting, heating, or enzymolysis that contains the flavoring constituents derived from natural sources such as spices, fruits, vegetables, plants, meats, and seafood. Celery, onion, and garlic powders are considered foods rather than spices and thus can be labeled as natural flavorings, while the respective juice derivatives must be labeled as 'juice,' for example, 'celery juice,' etc. (9 CFR, Part 318). Generally, if the flavoring is derived from natural sources and is considered minimally processed, it can be used in natural meat products. Often, the actual material from which the flavoring is derived must be either labeled or approved. In addition, 'spice oleoresins' are specifically mentioned as acceptable in natural meat products by the USDA.

Alternative Curing – Manufacturing Procedures

General Manufacturing Procedures

Aside from the replacement of normal curing ingredients, such as sodium nitrate and nitrite with natural curing ingredients, and the addition of an incubation step to allow for nitrate-to-nitrite reactions to occur (if a system with starter culture is

used), all other processing procedures can generally remain unchanged. Two steps in the process are, however, considered critical for the successful manufacture of alternatively cured products.

The first critical step is the level of ingoing nitrate/nitrite-containing source added. The highest amount possible should be added but care must be taken as levels that are too high can negatively affect finished product aroma or flavor. Ideally, the natural nitrate/nitrite-containing ingredient should be added at a level slightly lower than the amount that induces ingredient-related (e.g., vegetable-like) aromas and flavors in the finished product. This approach is preferred over following 'minimum recommended levels' suggested by manufacturers so that the greatest extent of curing can take place. The product itself, however, must also be taken into consideration because those products that are more heavily spiced (frankfurters, polish sausage, etc.) tend to allow for higher levels of nitrate/nitrite-containing ingredients before changes in aromas and flavors are detected.

The second critical step for successful alternative curing is incubation (if the culture system is used). The incubation step is where nitrate-to-nitrite conversion occurs and is commonly performed at the very beginning of thermal processing. However, in the case of multi-strain cultures, much of the necessary nitrate-to-nitrite conversion can potentially take place during product manufacture and before thermal processing. Thus, a thermal processing incubation step may be substantially shortened. Regardless of starter cultures used and their associated functional temperature properties, the amount of nitrite converted from nitrate during incubation is a function of both temperature and time. Incubation temperatures corresponding to the optimal activity of the specific starter culture are used in concert with an incubation time that provides enough time to allow for a high percentage of the nitrate to be converted to nitrite. As such, incubation is an extremely critical manufacturing step and proper control of this step can significantly impact the quality, shelf life quality, and safety of the finished product. A minimum of 2 h of incubation time, where product is held at optimal incubation temperature, is recommended.

Comminuted Sausage Manufacture

If ingredients that have been preconverted to nitrite are used for comminuted sausage, they may be directly added during the addition of other nonmeat ingredients. If a culture system is used, it is first advised to mix the culture in a portion of the formulation water to allow for better distribution when added to the meat mixture. In addition, because the starter cultures will go into suspension but will not go into solution when mixed with water, proper periodic agitation to maintain suspension is also important.

Whole Muscle Product Manufacture

Whole muscle product manufacture includes any product in which the incorporation of curing and/or other ingredients is accomplished by injection, tumbling, or immersion. If a preconverted system is used, ingredients may be directly added to the brine or solution with no additional processing changes needed. Thus, no changes in manufacturing practices are needed with the inclusion of preconverted ingredients. However, if a culture system is used, then special attention must be taken to ensure successful alternative curing. Because the starter culture is not water soluble, it must be injected or physically placed inside the meat so that it can come in contact and interact with the nitrate-containing ingredient. Tumbling or immersion methods would be ineffective, resulting in natural curing failure (e.g. uncured spots) because the starter culture would not be carried to the muscle interior by the tumbling or immersion curing process. As an example, a product in which tumbling is traditionally used as the means of incorporating a brine or solution must instead be injected. However, because vegetable juices/powders are water soluble, they could be carried to the muscle interior through tumbling or immersion practices.

'Alternatively Cured' Meat Product Challenges

Quality Implications

Lipid oxidation and cured meat color are the two quality-related challenges most often associated with alternative curing. Because lower levels of nitrite typically exist in alternatively cured products, the amount of unsaturated lipids in a product, the rate and extent of oxidation of those lipids at the time of processing, the length and type (frozen or refrigerated; aerobic or anaerobic packaging) of product storage, and the actual amount of nitrite generated during processing can have substantial effects on the oxidative stability of the lipids.

Cured color and the shelf life of that color are greatly impacted by good curing practices. Because little nitrite (<20 ppm) is necessary to induce a cured color and much more is needed to maintain that cured color throughout the stored shelf life ($\sim>50$–60 ppm), a false sense of product quality could result if inadequate alternative curing occurred because acceptable cured color could be present immediately after product manufacture but then rapidly fade within weeks, days, or even hours. To prevent this from occurring, maximizing the amount of nitrite generated will result in a more desirable amount of residual nitrite that can later be used for cured color regeneration during product shelf life.

The microbiological quality properties of alternative and organic meat products are also affected by alternative curing. As the level of nitrite and use of ingredients with antimicrobial properties decreases, nonpathogenic spoilage bacteria have greater ability to grow and can reduce product shelf life. Anaerobic packaging and temperature control can be used to help address microbiological quality changes and limit product quality deterioration.

Safety Implications

The safety of alternatively cured processed meats is a significant concern because nitrite is a very well-known and effective antimicrobial agent, particularly for preventing toxin production by *C. botulinum*. The issue for processed meats that use natural sources of nitrate in a culture system is that the

true amount of nitrite formed is unknown and impossible to measure because nitrite reacts quickly with meat components. Although the amount of detectable residual nitrite in these products is significant, it is typically less than that found in traditional, nitrite-cured products. Consequently, the microbial safety of processed meats manufactured with natural sources of nitrate is very difficult to assess without microbiological challenge studies. However, several studies have shown that the inclusion of ingredients possessing antimicrobial properties can significantly enhance the safety of the products. The preconverted system is not presented these same challenges, however care in ensuring adequate levels of nitrite are used to attain equivalent quality and safety results as with purified nitrite is important.

Physiology of Nitric Oxide

D Parthasarathy and NS Bryan, Texas Therapeutics Institute, Brown Foundation Institute of Molecular Medicine, The University of Texas Health Science Center at Houston, Houston, USA

Introduction

Salting as a means of preserving meat, poultry, fish, seafood, and vegetables predates written history and was essential in ancient times for providing nutrient-dense foods during scarcity or population migration and before refrigeration was an option. Meat curing is historically defined as the addition of salt to fresh meat cuts to remove moisture and reduce the water activity of the tissues to prevent spoilage. However, salt is poorly defined as there are many salts that can fulfill this activity although some are better than others. In ancient times, salt was obtained from crystalline deposits left by evaporating water from brine pools, seawater, or mining directly from the earth. As a consequence, it often contained natural contaminants such as sodium or potassium nitrate or nitrite that contributed directly to the curing reaction and the preservation process, although unrecognized at the time. These contaminants, nitrite and nitrate, as it was later learned, were the primary components in curing reactions. The reduction of nitrate (NO_3^-) salts to nitrite (NO_2^-) and then to gaseous NO and its subsequent reaction with myoglobin to form the nitrosyl–myoglobin complex forms the basis for cured meat flavor and color. It was also later realized that it is bacteria that first converts nitrate into nitrite, which is the mechanism underlying in the preservation of food. Nitrite in meat is responsible for inhibiting the growth of aerobic and anaerobic bacteria (especially the spores from *Clostridium botulinum*), retarding the development of rancidity during storage, developing and preserving the meat flavor and color, stabilizing the oxidative state of lipids in meat products.

At present most cured meats contain added sodium nitrite or cultured celery extract where the naturally contained nitrate is reduced to nitrite by a starter culture of bacteria. For many years, some epidemiological data have implicated that nitrite and nitrate in cured and processed meats are responsible for a number of human diseases including some cancers. Although modestly increased associations between consumption of foods containing nitrite and nitrate and certain cancers have been reported in some prospective epidemiological studies overall, findings across studies have been largely inconsistent and equivocal. Consequently, the overall burden of proof remains inconclusive. A biologically plausible mechanism for the carcinogenicity of ingested nitrate and nitrite involves endogenous *N*-nitrosation reactions. Although generally considered harmful due to the formation of *N*-nitrosamines, biomedical science over the past 20 years has recognized the nitrosation reaction as an essential fundamental process in mediated cell signaling. Despite this new emerging science on NO, nitrite, and nitrate, there are still very strict regulations of nitrate and nitrite levels in our food and drinking water.

In the early 1980s it was shown that, in addition to dietary exposure, nitrate and nitrite are also generated endogenously. Shortly thereafter, the entire L-arginine–nitric oxide synthase (NOS)-system was discovered and was found to be the major endogenous source of nitrate and nitrite, because NO is rapidly oxidized to these higher nitrogen oxides. Until recently, biologists considered nitrate and nitrite merely as inactive end-products of NO metabolism, but this view is rapidly changing. It is now clear that nitrite and nitrate can recycle *in vivo* and again form bioactive nitrogen oxides, including NO. Interestingly, commensal bacteria in the human oral cavity play a key role in the bioactivation of nitrate. A picture is emerging suggesting physiological, nutritional, as well as therapeutic roles for the nitrate–nitrite–NO pathway. Thus, instead of simply wasting the products of NO oxidation, mammals store and actively recycle it. Nitrite reduction to NO was first described in the stomach, where salivary nitrite forms NO non-enzymatically via acid-catalyzed reduction. Soon after this observation, researchers described NOS-independent nitrite reduction in the ischemic and acidic heart. In the past 10 years it has become evident that blood and tissue nitrite are reduced under physiological conditions to form NO and modulate blood flow. Subsequent studies show that a variety of enzymes and proteins can catalyze the one-electron reduction of nitrite to NO in blood and tissues. The authors will review the nitrate–nitrite–nitric oxide pathway in human physiology and highlight this fundamental pathway, which has been recently shown to afford enormous health benefits to humans. The picture that has emerged is that foods that contain nitrite and nitrate confer profound health benefits representing a complete change in paradigm requiring reconsideration of the risk-benefit analysis on nitrite and nitrate.

Nitric Oxide Biochemistry and Physiology

Before the nitrate–nitrite–NO pathway is reviewed, it is first necessary to describe the fundamental roles and production pathways for NO and its implications in health and disease to better appreciate the new-found role of nitrite and nitrate. The discovery of the mammalian biosynthesis of NO and its roles in the immune, cardiovascular, and nervous systems in the 1980s established a startling new paradigm in the history of cellular signaling mechanisms. Before that discovery, it was essentially inconceivable that cells would intentionally produce a toxic molecule as a messenger; NO was previously known as a common air pollutant, a constituent of cigarette smoke, and a toxic gas, which appears in the exhaust of automobiles and jet airplanes, causes acid rain, and destroys the ozone layer. Amazingly, despite this nasty reputation, it is now known that NO is one of a family of reactive signaling molecules, which includes both reactive nitrogen and reactive oxygen species that perform essential cellular functions in the body. This is, in fact, a hallmark example of the propensity of nature to seek out and exquisitely utilize the unique properties of unusual molecules. This same theme is emerging around

nitrite. Once considered an unwanted, toxic food additive and now considered an essential nutrient, much of the chemistry that was described centuries ago is now reemerging in human physiology. NO is one of the most important signaling molecules in the body, and is involved in virtually every organ system where it is responsible for modulating an astonishing variety of effects. NO has been shown to be involved in and affect (just to list a few major examples) neurotransmission, memory, stroke, glaucoma, and neural degeneration such as in Alzheimer's disease, pulmonary hypertension, penile erection, angiogenesis, wound healing, atherogenesis, inflammation such as arthritis, nephritis, colitis, autoimmune diseases (diabetes, inflammatory bowel disease), invading pathogens, tumors, asthma, tissue transplantation, septic shock, platelet aggregation and blood coagulation, sickle cell disease, gastrointestinal motility, hormone secretion, gene regulation, hemoglobin delivery of oxygen, stem cell proliferation and differentiation, and bronchodilation. One can then imagine the host of diseases or conditions that may be caused or affected by the body's dysregulation of NO production/signaling. Maintaining NO homeostasis is critical for optimal health and disease prevention, and understanding foods and diets that promote NO activity will have a profound effect on public health.
