high temperatures for a long time, causing nonuniformity of treatment and increasing the risk of local microbial growth.

This nonuniformity is greatest for large products and when the heat transfer rate is fast. During external thawing (in air or water), the surface and corners of a carton or large piece of meat can stay at high temperatures for a long time, causing microbial and other quality problems. A compromise must be made between speed of thawing and uniformity of treatment.

The thawing time of a piece of food can be calculated by a variety of methods ranging from simple approximations to rigorous computer calculations. For most practical purposes, a simple formula proposed by Cleland *et al.* and reported in Pham (see Further Reading) is adequate for external thawing, if the food can be approximated by a simple shape: slab, long cylinder, or sphere. The thawing time depends mainly on the following factors:

- the surrounding temperature
- the heat transfer coefficient (HTC), a number that measures how easily heat is transferred from the surroundings to the product. High air velocity around the product, or using water instead of air will increase the HTC, while wrapping will reduce it
- the shape and thickness of the product, which determines how far the heat has to travel from the surface to the center
- the composition of the meat, especially its water and fat contents

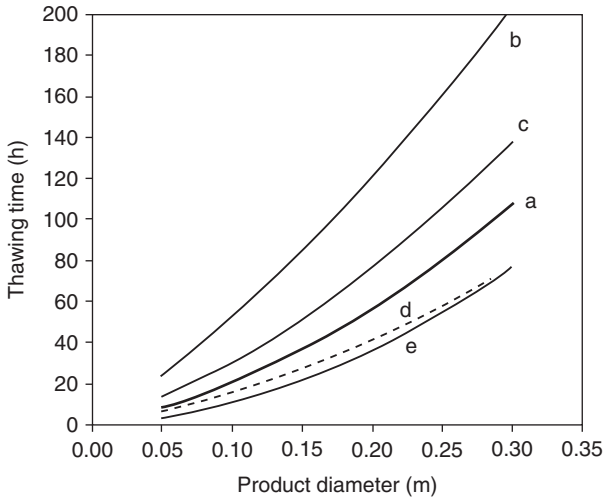

Figure 3 Effect of various factors on the thawing time of a cylinder of meat. (a) Base conditions: air at 1 m s^{-1}, 5 °C, no wrap. (b) 0 m s^{-1}, (c) polythene wrapped, (d) 10 °C, (e) water thawing.

Figure 3 illustrates how some of these factors affect the thawing time for a cylinder of meat. It can be seen that when the diameter is doubled, the thawing time increases by a factor of 3–4. Thawing in still air increases the thawing time by a factor of 2–3 compared to air moving at 1 m s^{-1}. A polythene wrap increases thawing time by approximately 30–50%, whereas raising the air temperature to 10 °C decreases it by 20–30%. Changing from air to water is more effective for small products.

During internal thawing (as in microwave thawing), heating concentrates in certain spots, depending on the shape, size, and composition of the product. There may even be some local cooking of the meat while the rest is still frozen. These problems will be looked at in more detail in the section on thawing methods.

Meat Quality Aspects

The quality factors that are of most concern in meat thawing are microbial growth, drip loss, and the appearance and palatability of the product.

Microbial Growth

Microbial growth is the most important factor because it affects the safety of the product. Microorganisms include molds, yeast, and bacteria, with the last being most important from a health and safety point of view. Microbial growth is affected by temperature, water activity (relative humidity of the meat), pH, and

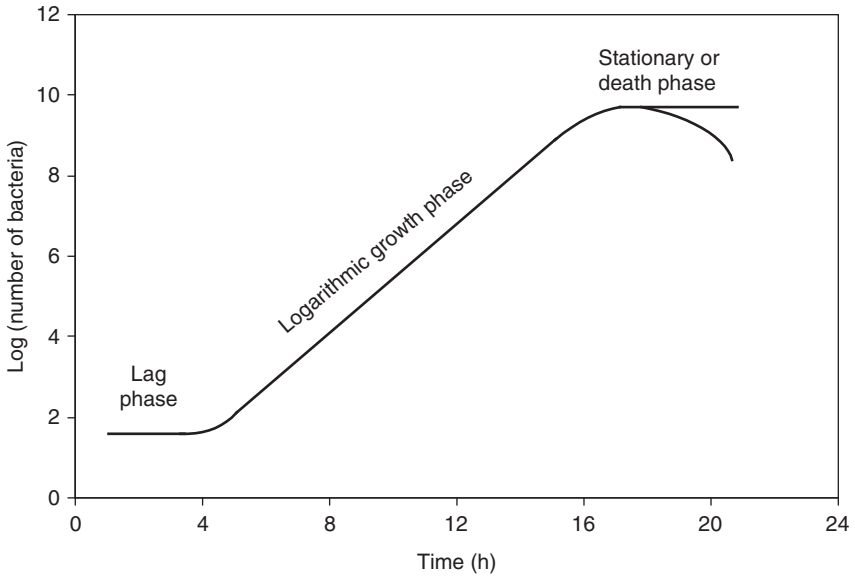

Figure 4 Typical bacterial growth curve at constant temperature.

the concentration of nutrients. During meat thawing, conditions for microbial growth are highly favorable (high water activity due to melted ice and/or water condensing on the surface, near-neutral pH, high availability of nutrients) and it is important to control growth by restricting temperature rise.

Below 5 °C, most pathogenic bacteria will not grow on meat and therefore it is often recommended (for example, by US Food and Drug Administration) that meat be kept at 5 °C or below at all times. However, there are several reasons for permitting the temperature to rise temporarily above this critical temperature. First, microbial growth normally occurs only on surfaces that have been exposed to contamination. Deep meat in whole cuts (not sliced, ground, diced, etc.) can therefore be allowed to rise temporarily above 5 °C in microwave thawing or other internal heating methods as long as it does not get cooked. Second, when temperature rises above the critical point, microorganisms must first pass through a lag phase that may last up to several hours (depending on temperature and other conditions) before growth starts (Figure 4). Therefore, when operating conditions are rigorously controlled and monitored, the 5 °C limit does not always need to be adhered to. Parts of the meat can be allowed to rise above it for some time, before being brought back down below the critical temperature. The extent of microbial growth can be calculated by a suitable model. An example is the Refrigeration Index used in the Australian meat industry, which is based on growth curves for *Escherichia coli*.

Computer software based on finite element methods are available commercially or as public domain (free) programs that will enable the temperature at various spots in the product to be predicted, and hence the potential for microbial growth can be calculated. This can help to design acceptable thawing regimes, although the results are often conservative because the programs are not yet capable of taking into account all the factors that may limit microbial growth.

In poorly controlled situations, such as in the home or when thawing is done commercially by untrained operators, it is best that thawing be carried out at 5 °C or below, i.e., in a refrigerator.

Water Loss

In air thawing, water loss may occur in two stages. First, some of the melted ice fails to be reabsorbed into the meat structure and is lost as drip. Second, in the later stages of air thawing, water may continue to be lost by evaporation. The extent of evaporation depends on air temperature and humidity, and can even be reversed (i.e., condensation can occur) if the air is at a higher temperature and humidity than the product. If thawing is carried out in water or humid air, water can be absorbed by the meat, causing weight gain.

Existing data on water loss during thawing are conflicting and inconclusive. Some experiments have shown that slow thawing causes higher drip losses, others that it reduces drip loss, and others have shown no definite influence. Various explanations have been proposed for the effect of thawing conditions on water loss, if any. On one hand, slow thawing is thought by some to cause meat proteins to denature as the meat spends long periods of time in a partly desiccated condition, with high solute concentration prevailing, at temperatures just below freezing, and the denatured proteins lose some of their water-binding capacity. On the other hand, fast thawing is thought to give water insufficient time to be reabsorbed into the cellular structure. It can easily be seen that these (hypothetical) effects act in opposite directions.

In addition, drip loss may be influenced by many factors before thawing: postmortem treatment, pH, cut surface to volume ratio, orientation of cut surface, rate of freezing, duration and temperature of frozen storage, and temperature fluctuations during frozen storage. The variability in these factors (which are never reported in complete detail) may have masked whatever effect of thawing conditions exists in the reported investigations.

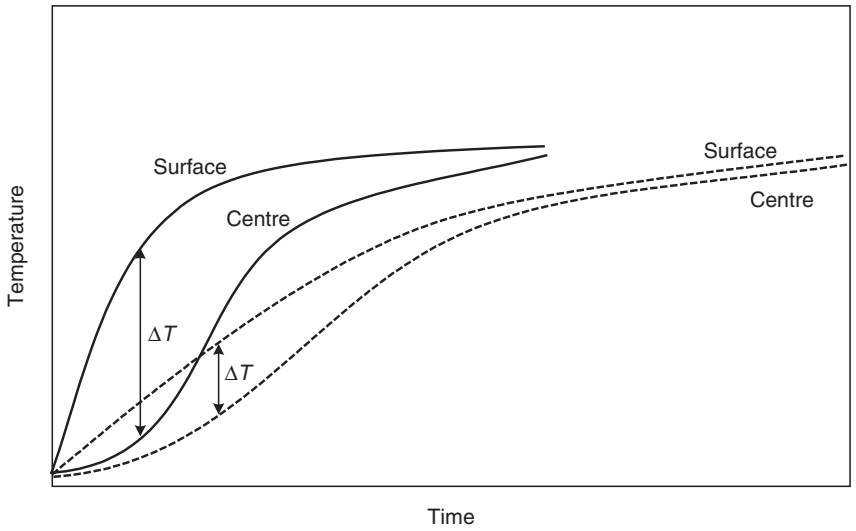

Figure 5 Temperature at center and surface of meat during thawing by external heating. ———— high surface heat transfer;- - - - - low surface heat transfer. ΔT: maximum temperature difference in product.

It is this author's opinion that, because in commercially frozen meat the ice is always extracellular, except perhaps for a thin surface layer in cryogenically frozen meat, the resorption effect would usually predominate and thus very fast thawing would not be desirable if drip loss is to be minimized. However, exposing thawed meat to air for longer than necessary will increase evaporative losses.

Appearance and Eating Quality

Various reports have shown that the appearance and eating quality (aroma, tenderness, and juiciness) of thawed meat do not seem to depend greatly on the thawing method, as long as the process does not run out of control. The exception is that meat thawed by direct contact with water may gain a bleached appearance, which is unsuitable for subsequent retail display.

In conclusion, because there is no conclusive evidence of the effect of thawing on drip loss, appearance, and eating quality (unless there is gross abuse, for example, when the product is left to thaw for far longer than needed), it seems reasonable to concentrate instead on optimizing thawing processes in terms of potential microbial growth. If meat is to be displayed after thawing, water thawing should be avoided because the meat surface may appear to be bleached. In all cases, the meat should be processed or returned to refrigeration as soon as thawing or tempering is completed.

Common Thawing Methods

Common thawing methods can be divided into external heating methods where heat flows from warm surroundings into the meat, such as thawing in air, flowing water, or under a spray; and internal heating methods, where heat is generated inside the product, as in microwave thawing or radio frequency (RF) thawing.

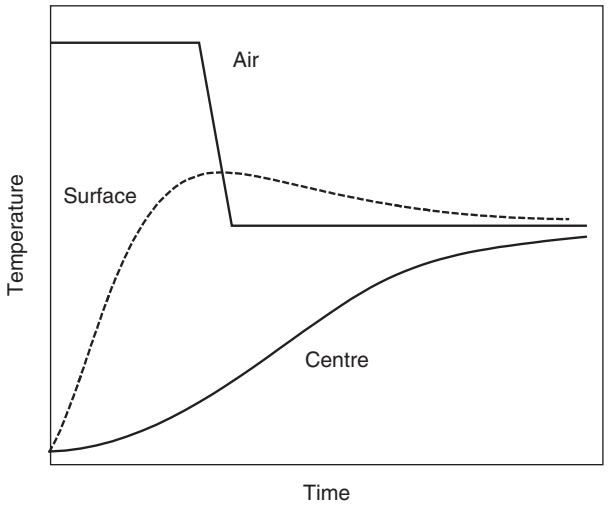

Figure 6 Product temperature history during two-stage thawing.

External Heating Methods

Air Thawing

Air thawing is quite common in industry and in the home, because it is easy to control and no special facility is needed. The drawback with air thawing is the low rate of heat transfer and hence long process time, especially when there is no forced air circulation. However, low surface heat transfer can be an advantage as it ensures that the product is heated relatively uniformly (see Figure 5). For this reason air heating is well suited to tempering, where a uniform final product temperature is desirable. Unwrapped meat thawed in air is more likely to lose water by evaporation, in addition to drip loss.

In industry, air thawing can be carried out in two stages: a high-temperature stage to inject heat quickly into the product, followed by a low-temperature stage (5 °C or below) to avoid microbial growth on the surface (Figure 6). The air velocity

may also be changed from high to low. Even though the surface of the product may briefly rise to temperatures that would allow microbial growth, microorganisms are not allowed to complete their lag phase, while thawing is accelerated. The optimum design of multistage thawing processes depends on the product shape, size, and composition, and it is unsafe to use a regime that has been developed for one product for a different product. Any thawing regime that involves air temperatures higher than 5 °C must be tailored to the product. For this reason no 'typical regime' can be given here. A number of regimes are listed by James and James (see Further Reading).

In the home or small, poorly equipped commercial premises, where there is practically no monitoring and control, the safest way is to thaw meat in the refrigerator, at a temperature of 5 °C or below, to prevent microbial growth. However, an hour or two in cool air will not pose significant risks, as long as the meat is put back into the refrigerator after that. After thawing is complete, the drip should be discarded to avoid an excessively moist surface.

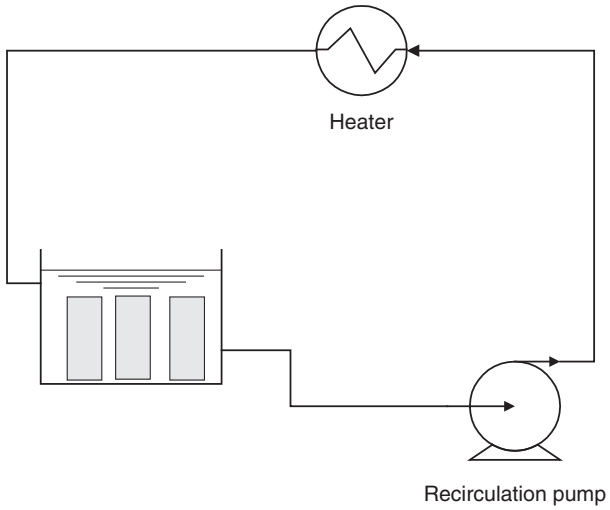

Figure 7 Immersion thawing.

Water Thawing

Water thawing can be carried out by immersing the product in a tank of water (Figure 7) or by spraying the product with water (Figure 8). The water should be reheated and circulated. The water should be changed frequently, preferably after each batch, together with thorough cleaning of the equipment, to prevent microbial growth. Water thawing is much faster than air thawing because water is a better carrier of heat than air (see Article 265: Refrigeration and Freezing Technology: Principles). The relative improvement in thawing time is greater for small products but is appreciable in all cases. Drip loss is reduced because the meat is in a moist environment (in fact, if the product is thawed by direct contact, a weight gain may be obtained). It is important to ensure that water circulates all around each piece of product, i.e., there is no dead zone in the tank. Spraying will ensure that there is no dead zone as long as the spray covers all exposed area (which can easily be checked visually).

Water thawing requires more specialized equipment and better control than air thawing. If unwrapped meat is thawed in water, there could be a high effluent load, with protein, blood, and solutes being leached out of the meat. Microbial growth and cross-contamination could also be a hazard, because the warm recirculating water is a good growth medium. Because microbial growth takes place only between 5 and 40 °C, fast thawing can be obtained by using water at approximately 45 °C (high temperature will cook the surface of the meat). This temperature is not allowable in air thawing or the water thawing of wrapped products, because, due to the lower surface heat transfer, the meat surface would remain below 45 °C and hence near the optimal temperature for growth. High water temperature should also be avoided in the water thawing of comminuted product, where microbial growth may occur inside the meat.

Owing to the high heat transfer rate, the product's surface temperature will usually be much higher than the center temperature and very close to the water temperature; hence, water cannot be used for tempering. In the home and small commercial premises, water thawing should be avoided because of the microbial risks, except for very small product with short thawing times.

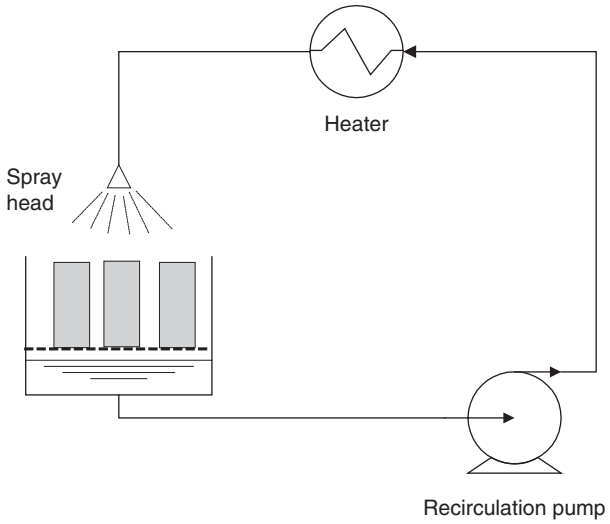

Figure 8 Spray thawing.

Vacuum Thawing

Vacuum thawing involves the introduction of steam into an evacuated chamber where the frozen product has been placed. Steam condenses readily on the surface of the meat giving a very high rate of heat transfer as it surrenders its latent heat. The low pressure depresses the condensation point of steam and ensures that the temperature stays low. Vacuum thawing is even faster than water thawing, especially for small products. Microbial contamination is negligible but growth of existing microorganisms can still occur if the surface temperature is suitable. Weight loss is low, or there may be a weight gain. With large cuts or blocks of meat, the thawing rate is limited

by heat conduction inside the meat and thus the advantage in thawing time will be less noticeable. Equipment for vacuum thawing is expensive, however, and the process must be carried out as a batch operation due to the need for evacuation.

Pressure-Assisted Thawing

High pressure causes a decrease in the freezing point. The maximum freezing point depression that can be obtained is approximately 21 °C at 210 MPa. Because the freezing point is lower, the difference between air and product temperatures can be increased by several times, causing the thawing time to decrease by approximately the same ratio. For example, at a surrounding temperature of 5 °C, the temperature difference between meat undergoing thawing (with a freezing point of −1 °C) and the surroundings is only 6 °C. If the freezing point is decreased to −7 °C by applying pressure, the temperature difference between environment and product and hence the thawing rate will double. Pressure-assisted thawing has been tested on pork and beef. For beef at pressures of up to 210 MPa the color, drip loss, cooking loss, and penetration force are not significantly affected. For pork at pressures of up to 100 MPa, quality factors are improved by pressure-assisted thawing. However, the application of pressure-assisted thawing is unlikely to be widespread for meat due to the cost of the equipment and small batch sizes.

Internal Heating Methods

Internal heating methods comprise electrical resistance heating and dielectric heating, the latter including heating by RF waves and microwave. Resistance heating is not widely used. Both RF (or capacitive) heating and microwave heating work on similar principles, the heat being generated inside the product by the rapid reorientation of dipolar molecules of water or other molecules under the influence of an alternating electromagnetic field. RF covers the frequency range 1–300 MHz, whereas microwave covers the range 300 MHz to 300 GHz. The equipment for generating and transmitting the alternating field differs: in RF the product is placed between two parallel plate electrodes, whereas in microwave it is placed in a chamber or tunnel with microwaves being generated and transmitted into the tunnel via one or more wave guides or antennas. RF can only be used with slab-shaped product that can be placed between the electrodes, whereas microwaves can be used on products of any shape.

Internal heating methods are much faster than external heating methods, because heat does not have to travel from the surface to the center of the product. However, a common problem with all these methods is uneven heat distribution, often leading to runaway heating. All materials are partially opaque to electromagnetic waves (if they were completely transparent, there would be no heating at all) and thus the surface layers will absorb more of the energy and heat up faster. The penetration depth increases with wavelength (decreases with frequency), and hence RF has more penetrating than low-frequency microwave, which is more penetrating than high-frequency microwave. However, the shape and orientation of the meat surface serves to focus the microwave, so that the center of a cylindrical or spherical product may heat up faster than the rest.

Nonuniform product composition will also cause problems. Fat, for example, is particularly effective at absorbing microwaves and may start to fry before the water melts. Ice has much lower absorbance than water, and thus any spot that melts first will preferentially absorb energy and quickly heat up, while the surrounding remains frozen. A mixture of cooked and frozen meat will then be obtained. Various methods are used to improve heat distribution: turntables, microwave stirrers, multiple antennas, and intermittent heating to allow the generated heat to disperse by conduction, but they do not completely solve the runaway heating problem.

For the reasons above, internal heating methods have not been widely used for thawing in industry, except for microwave tempering (not thawing), which is quite successful. In microwave tempering, no part of the product is allowed to rise above melting point, and therefore runaway heating is not likely to occur. The product should not be prewarmed in air before tempering but should be taken straight from cold storage, to avoid the prior thawing of corners and edges, which would lead to runaway heating. Carton-sized meat blocks can be tempered by microwave in approximately 10 min, as opposed to several days by air.

Conclusions

- Air thawing is the most easily applied thawing method, followed by water thawing.
- Microbial growth is the primary factor that determines the suitability of a thawing regime.
- Thawing time depends on the size and shape of the product, the temperature of the surroundings (for external heating), and the HTC, the last being a function of the thawing medium, the circulation velocity, and any wrapping present.
- As soon as thawing is completed, the product should be processed or returned to normal chilled storage conditions, to avoid microbial growth and quality loss.
- The effect of thawing conditions on drip loss and eating quality is not well known and is probably of little importance in the design of thawing processes.
- Two-stage thawing in air, with a short high-temperature period followed by a longer low-temperature period, can be carried out industrially but must be tailored to the product and closely controlled to avoid microbial growth at the surface.
- Computer software is available for calculating thawing time and designing thawing regimes to limit microbial growth.
- When conditions are not well controlled, thawing should be carried out in the refrigerator at 5 °C or below, although an hour or two in a cool room is acceptable.
- Water thawing is faster than air thawing but carries increased risks of cross-contamination and gives the meat a bleached appearance, which is unsuitable for retail display.
- Water thawing should not be used in the home or in small commercial premises.

- Microwave heating is highly effective for tempering to temperatures just below freezing, but not for complete thawing, due to runaway heating when complete melting occurs. It is important to avoid any heating before microwave tempering.
- Vacuum thawing is fast and hygienic but the equipment is very expensive.
- Pressure-assisted thawing is unlikely to become commercially viable.

RELIGIOUS SLAUGHTER

JE Shragge and MA Price, University of Alberta, Edmonton, AB, Canada

This article is a revision of the previous edition article by JE Shragge, MA Price, volume 3, pp 1162–1167, © 2004 Elsevier Ltd.

Glossary

Bedika A careful examination of the internal organs to ensure that the animal was healthy before slaughter.
Cincinnati pen A restraining device approved by the American Society for the Prevention of Cruelty to Animals for restraint in an upright position before slaughter.
al-Dhabh The Muslim method of ritual slaughter.
Halal Arabic word meaning 'lawful'; indicating a food acceptable for consumption by Muslims.
Kosher Hebrew word meaning 'fit'; indicating food acceptable for consumption by Jews.
Neveila Hebrew word indicating an animal that died of natural causes and so is not kosher.
Shechita Jewish ritual slaughter.
Stick The act of cutting open the throat of a meat animal.
Terefah Unfit for kosher consumption.
Weinberg casting pen An animal holding pen that could be rotated 180° on its long axis to permit an easier and more rapid neck cut.

Introduction

As human societies evolved from nomadic hunting and gathering to settled agriculture, they developed increasingly sophisticated techniques and rituals for harvesting meat from livestock. These grew out of the knowledge, understanding, and beliefs of the day. In some societies the rituals were enshrined in religious law, and the animals that were permitted for consumption were cataloged. In modern society, these systems of ritual slaughter sometimes find themselves in conflict with the standard operating procedures of high-speed, high-efficiency abattoirs; they have also been challenged in some quarters for being inconsistent with scientifically developed standards of animal welfare.

Since biblical times, adherents to the Jewish dietary rules have restricted their meat and fish intake to those classes of creatures conforming to theologically prescribed characteristics. The Mosaic Law of the Torah, Judaism's holiest scripture, further dictates that all birds and mammals (there is no stipulation for fish) destined for the Jewish table be killed according to a divinely revealed method of ritual slaughter – albeit the precise nature of the system is found nowhere in the Bible. Today, for a meat product to be deemed 'kosher' (Hebrew, 'fit') it must come from a biblically prescribed species of animal that has undergone shechita and that has been processed according to Jewish butchering methods. The consumption of meat from hunted animals is strictly prohibited.

The theological origins of Muslim slaughter are found in Islam's holiest book, the Q'uran. Only the meat from (permitted) animals killed according to the customs and methods of al-Dhabh may be deemed 'halal' (Arabic, 'lawful'), although Muslims are allowed to consume meat that has been hunted in accordance with religious guidelines. Whereas the rules of shechita require conscious slaughtering, animals killed in the halal process are, according to some Islamic authorities, permitted to be rendered temporarily unconscious before slaughter. The development of this practice has occurred relatively recently and is by no means universal; however, it has been adopted in a number of prominent meat-exporting nations and continues to grow in popularity.

Kosher Slaughtering (Shechita)

Theological Basis

In Leviticus XI:3–8, and in a slightly modified form in Deuteronomy XIV:3–8, the Torah dictates that mammals fit for consumption by Jews must be ruminant and have completely split hooves. For fish to be suitable, they must have scales and fins (Leviticus XI:9–12; Deuteronomy XIV:9–10). The Torah adjudges all birds to be clean and thus edible, except for those species that it specifically prohibits (Leviticus XI:13–20; Deuteronomy XIV:11–18). One of the chief exegetical conclusions that can be drawn from the proscribed avian species lists is that, in general, common domestic fowl are suitable whereas migratory species and birds of prey are an 'abomination' to eat.

The actual reference to the slaughter of food animals occurs in Deuteronomy XII:21. 'Thou shalt kill of thy herd and of thy flock, which the Lord hath given thee, as I have commanded thee, and thou shalt eat within thy gates, after all the desires of thy soul.' It is generally interpreted from this passage that there existed in Biblical times a canon of oral law (Hebrew, halacha) that was to be used as an exegetical guide for understanding and executing the written Torah.

With the razing of the Second Temple in 70 AD and the Roman persecutions that followed, the leading Jewish thinkers of the era began to commit the oral law to script. The fruit of their labors is the encyclopedic work known as the Mishnah (Hebrew, 'repetition'), the totality of Jewish oral law and tradition compiled during the second century AD. In the three centuries immediately following the creation of the Mishnah, learned halachic scholars in both Palestine and Babylonia began the process of interpreting the codified oral law. In doing so, they created a second body of commentary, often presented as a glossary to the text of the Mishnah, known as the Gemerah (Aramaic, 'tradition'). Contained within these two tracts, collectively known as the Talmud, is the basic philosophy guiding shechita. Subsequent rabbinical interpretations, particularly during the Middle Ages and Renaissance, increasingly refined the rules and defined the methods permissible in shechita, leading, ultimately, to the procedures in place today.

Basic Procedures

At its most fundamental level, kosher slaughter involves cutting the throat (sticking) and bleeding out (exsanguination) of a fully conscious, restrained animal by way of an expertly wielded, razor-sharp blade. The precise cause of death is cerebral hypoxia brought on by the severance of the carotid arteries and jugular veins. In most countries where shechita is practiced, legislation requires that it be performed in approved premises (usually a government-inspected abattoir) and be subject to governmental hygiene and welfare regulations in addition to the religious requirements.

The Talmud identifies five conditions or situations that, should any of them occur during slaughter, would render the entire carcass unfit for kosher consumption (Hebrew, neveila, referring to an animal that dies of natural causes):

1. Shehiya (delay): The throat must be cut with one, rapid continuous motion from start to finish. There cannot be any pause in the blade's motion.
2. Derassa (pressing): No upward or downward pressure may be exerted on the knife beyond that which is absolutely required to create the incision. Hacking cuts are specifically forbidden.
3. Chalada (digging): The incision must not close back on itself and cover the surface of the blade, which must be visible at all times. There can be no burrowing of the blade or stabbing action.
4. Hagrama (slipping): The incision must occur laterally across the throat between the larynx and the top of the inflated upper lung. The cartilaginous cricoid ring located below the larynx must be avoided, as must all other bony structures, in order not to damage the blade (see point 5).
5. Ikkur (tearing): The esophagus and trachea must be cleanly cut and not torn. To achieve this, the blade must be extremely sharp, without even the smallest nick or other imperfection. It must be examined immediately after sticking to determine whether any damage was incurred that would lead to a declaration of neveila on the carcass.

From these five definitive criteria of an acceptable slaughter, many other common characteristics of shechita may be understood. For example, it is recommended that the ritual knife (Hebrew, chalaf) have a broad, rectangular blade, with a length at least twice the width of the animal's neck, thus reducing the likelihood of chalada or shehiya. Typically, knives are 6 inches long for the slaughter of fowl and 18 inches long for cattle. In addition to creating the incision, the slaughterman (Hebrew, shochet) is responsible for ensuring that the blade is sharpened and that the cutting edge smooth and unblemished before and after every animal, or, in the case of fowl, entire lots of birds.

Bedika

If the act of sticking does not violate any of the five prohibited conditions, the shochet or his assistant will then carry out the next level of the kosher process: bedika. This involves an examination of various internal organs, which is made to ensure that the animal's health at the time of death met Talmudic standards of wellness. The Talmud defines eight pathological conditions in food animals, including missing organs, torn organ walls, bone fractures and perforated organs, which would render them unfit for kosher consumption (Hebrew, terefah). It is from this list that shechita's wholesale rejection of stunning is largely derived.

A postmortem examination of the lungs, initially via an incision in the thoracic cavity (on the ventral side) and later once the organs have been removed, is the focal point of bedika. The shochet's pulmonary inspection seeks chiefly to identify evidence of pleural adhesions that might, for example, indicate a punctured lung. If such masses are found during the initial inspection, they are carefully excised on the inspection table. The lungs are then filled with air and submerged in water as a test of pulmonary integrity. Air-tightness, indicating an absence of organ wall damage, is sufficient evidence for kosher certification (assuming the presence of no other prohibited condition). The significance that a bedika places on pulmonary integrity is predicated on the belief that any systemic morbidity in an animal would be evident in the lungs. Regardless of a shochet's verdict, any carcass from an animal processed in a licensed abattoir must ultimately be approved by a government inspector/veterinarian.

Halal Slaughtering (al-Dhabh)

Whilst shechita and al-Dhabh share several philosophical and practical characteristics, there is also much that is dissimilar about the two systems. The annual worldwide halal slaughter is dramatically larger than the yearly kosher kill, with most of the former occurring in the developing world. By contrast, the vast majority of kosher meat is processed under the animal welfare and technological standards of the industrialized west. Further, al-Dhabh is influenced to a great extent by the scriptural interpretation of local Islamic authorities and local customs, whereas the canonical nature of shechita promotes a greater level of homogeneity in its practice. There also exists no Islamic equivalent of the shochet; al-Dhabh retains the tradition of individual Muslims slaughtering their own livestock. As a consequence, millions of sheep, goats, and calves are slaughtered for the halal market outside licensed abattoirs every year. (In most Western jurisdictions, such as the

European Union (see Directive 93/119/EC), it is illegal to market meat from animals killed outside registered establishments.) The most significant difference, however, is that a great many Muslims will now accept as halal meat that has been produced from animals subjected to preslaughter stunning.

Theological Basis

The rules and specific interdictions respecting the Islamic slaughter of food animals are contained in several surah (Arabic, 'chapter') of the Q'uran. They are strictly concerned with the humane killing of God's creatures and not with sacrificial practice per se. The most basic and definitive characteristic of al-Dhabh, the requirement that Allah's name be pronounced at the moment of slaughter, is a product of Surah Al-An'am, 6:118: 'So eat of (meats) on which Allah's name hath been pronounced if ye have faith in His Signs.'

Like observant Jews, Muslims carry a staunch antipathy toward swine flesh, blood, and carrion, which is borne out of Surah Al-Baqara, 2:172–3. This passage, which reinforces the importance of invoking Allah's name during slaughter, states: 'O ye who believe! eat of the good things that We have provided for you and be grateful to Allah if it is Him ye worship/ He hath only forbidden you dead meat and blood and the flesh of swine and that on which any other name hath been invoked besides that of Allah….' In addition to these three foodstuffs, Islamic scholars have identified in the Q'uran several misadventures that can befall an animal that will render its flesh haram (Arabic, 'prohibited'). These include death by strangulation, a fall, goring, and violence from a wild creature.

Basic Procedures

Halal slaughtering may be conducted by any sane, sober, adult Muslim, who must follow the scriptural principles of al-Dhabh. The methodology may vary in detail from location to location, but in general the restrained animal has its carotid arteries and jugular veins severed via an incision in the neck made with a sharp knife. In cases where the knife is of a sufficient width, the stick can be performed with the same continuous slicing motion that is mandated by shechita. More often, however, a short, sometimes curved blade is employed, necessitating one or more stab incisions followed by retrograde severance of the major blood vessels of the neck. Other requirements include the following.

- The slaughterman must face the animal in the direction of Mecca and speak the name of Allah (and no other) either before or during the process. The precise nature of this practice, however, will depend on local customs.
- In the case of animals stunned before slaughter, the cause of death must be as a direct result of the stick and subsequent exsanguination (i.e., prolonged cerebral hypoxia, resulting from profound loss of blood) and not the stun itself. Owing to the requirement that animals must be alive at the time of slaughter, head-only electrical stunning, which has been shown to allow recovery, is the most commonly used method.
- The cut should result in a rapid and thorough exsanguination. It must also minimize pain. Knives must, therefore, be kept sharp.
- Knives must not be sharpened in front of animals before slaughter.
- The animal should be clean and not thirsty at the time of death.
- Animals (but not necessarily fowl) must not be slaughtered in the visual presence of other similarly destined animals.

The greater flexibility of al-Dhabh relative to shechita has facilitated the ever-increasing adoption of preslaughter stunning with the former. In the late 1970s, domestic and international Muslim authorities worked with representatives from government and industry in New Zealand in the development of a method of stunning that would be compatible with the principles set out in the Q'uran. It was agreed that any method that was not inherently painful and which would permit an animal both to regain consciousness and to eat within several minutes was acceptable. As a result, head-only electrical stunning was made mandatory for al-Dhabh in New Zealand. Preslaughter stunning is now a legal requirement for all slaughter of sheep, goats, and cattle in Australia, New Zealand, and a growing number of European and other nations. As a consequence, these jurisdictions have effectively outlawed kosher slaughter and permit the halal process only when it includes preslaughter stunning.

Restraint

Where ritual slaughter is performed without stunning, it becomes necessary to restrain the animal so that its neck can be presented to the knife and held relatively still until the stick is complete. Until the twentieth century, the common method of preparing a large animal for either shechita or al-Dhabh was to first 'cast' it to the ground using ropes and/or chains. The creature – most commonly an adult bovine; sheep and calves are small enough to be held manually or placed in an inverting cradle – was then secured until a slaughterman forcibly extended its neck for sticking.

A variation on this process, eventually mandated by US federal law (in 1906) did away with the casting step entirely. The stated purpose of the regulations was to prevent disease-causing filth from gaining entry to the interior of the carcass through the neck wound. As a result, sticking of animals lying prone on the floor was prohibited; consequently, shochetim were forced to adopt the practice of shackling and hoisting cattle directly to the rail. This procedure called for a single hind leg to be shackled by a chain (or rope) connected to a hoist on an overhead rail system. As the hoist was engaged, the animal's hind quarters were gradually lifted off of the ground. With an unnatural proportion of its body weight now borne by its fore legs, the bovine would inevitably crash, often head-first, onto the floor. Eventually, the creature would hang with its entire mass supported by its shackled leg. Both the 'cast with ropes' and 'shackle and hoist' methods were slow and awkward, and could be perilous to abattoir staff; furthermore, they were surely stressful to the animal and could lead ultimately to carcass damage sufficient for a ruling of terefah.

The first holding pen specially designed to improve both the humaneness and efficiency of shechita and al-Dhabh was developed in the UK in 1927. The Weinberg casting pen consisted of an adjustable enclosure, large enough for adult cattle, which

could be rotated on circular rails about its long axis. With a 180° turn, the animal became inverted, thus allowing for easier neck extension and a more rapid incision. This was hailed by many at the time as a great step forward, and in the United Kingdom became mandatory for religious slaughter in 1958.

However, the Weinberg casting pen was never embraced as a permanent solution to the problems associated with conscious restraint. Inverting any animal, but particularly a large ruminant, inevitably causes distress as well as potential suffocation through pressure of the abdominal contents on the thoracic cavity. These problems were addressed in the design of the first upright slaughter pen in 1963. Known as the ASPCA (American Society for the Prevention of Cruelty to Animals) or 'Cincinnati' pen, it provided for the gentle restraint of both the head and body of a still, standing animal (see Figure 1). With the animal's body supported ventrally and caudally within the enclosure, and its neck extended by a hydraulic chin lift, the physical force applied to the animal was greatly reduced.

Stunned versus Conscious Slaughter

Before preslaughter stunning of cattle became common, there was little rational basis on which to criticize religious slaughter from an animal welfare perspective. To all intents and purposes, all animals harvested for meat before the late nineteenth century were slaughtered in a fully conscious state. Stunning became more common in the twentieth century and was eventually enshrined in animal welfare legislation in many nations. This led to an increasingly spirited debate on the relative humaneness of bleeding conscious and unconscious animals. Until relatively recently, such discussions were more philosophical than scientific; however, the current focus on applied animal ethology research has facilitated a broadening of this debate.

Early devices for the stunning of cattle, such as the poleax and sledgehammer, unless wielded by an extremely skillful 'knocker,' probably did little to enhance the animal's preslaughter welfare. Similarly, before the advent of upright restraining systems it is likely that the struggle to restrain, stick, and bleed a fully conscious bovine for religious slaughter would have severely compromised its welfare. By the 1920s, however, the captive bolt pistol had been developed and refined to such a point that it was widely used to facilitate the secular slaughterman's craft. In those early days, however, it was probably more valued for its ability to reduce struggling and increase processing speeds than for any perceived improvement in welfare.

Modern research indicates that when a penetrating captive bolt stunning device is maintained and used properly, the

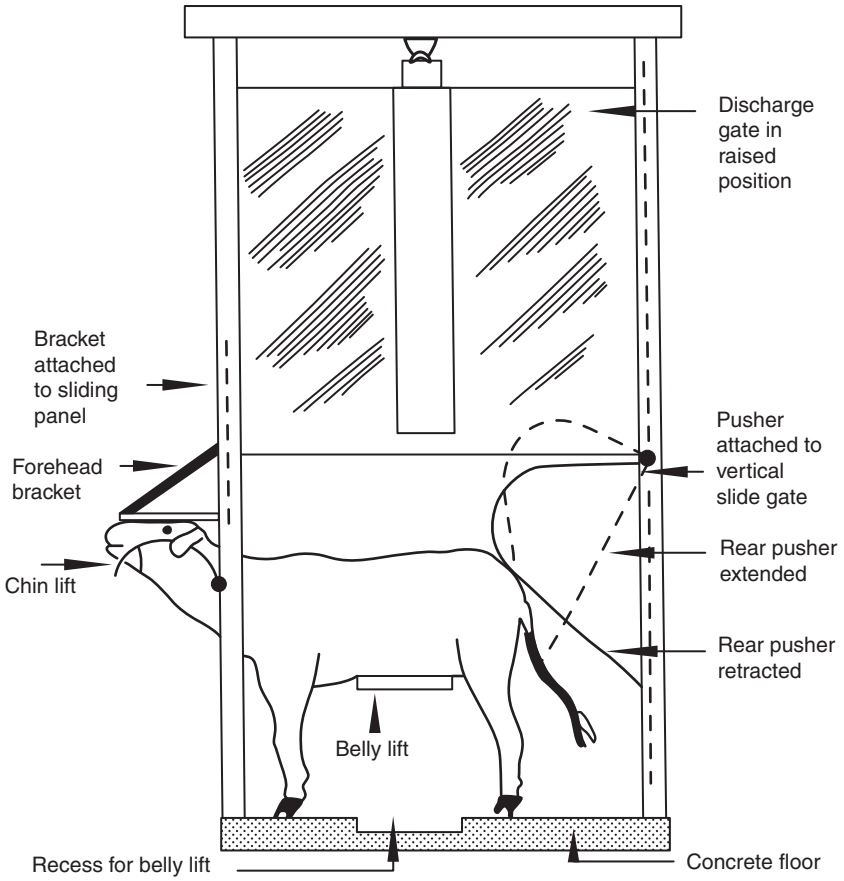

Figure 1 Modified ASPCA pen showing the animal in the correct position for low-stress restraint. Both the forehead and the back should be in level. Excessive pressure must be avoided. Reproduced from Grandin, T., Regenstein, J.M., 1994. Religious slaughter: a discussion for meat scientists. Meat Focus International 3, 115–123.

animal will be painlessly rendered insensible; however, because these devices cause such massive injury to the animal's brain, they effectively kill (or, at the very least, mortally wound) rather than temporarily stun. This point is crucial to any critical evaluation of religious slaughtering methods, which require that the animal be alive at the time of exsanguination. There can be no doubt that both the 'cast with ropes' and 'shackle and hoist' methods of religious preslaughter restraint are, by any reasonable, twenty-first century standard, inhumane. They commonly result in bruising, broken legs, and jaws, dislocated hips and gouged eyes, conditions that, paradoxically, would render a carcass neveila.

Appropriate restraint is a prerequisite to humane religious slaughter, and it is now clear that the ASPCA pen is an improvement on the Weinberg and other inversion-type pens. Research has demonstrated that adult cattle subject to shechita in an ASPCA pen show fewer physiological and behavioral symptoms of distress than those slaughtered while inverted. But the question remains: is it innately cruel to cut a fully conscious animal's throat? Certainly there is strong anecdotal evidence of humans feeling no pain in the face of massive, even fatal wounds; those, for example, received on the battlefield or as a result of a shark attack. The scholarly literature, too, contains numerous reports of cattle and calves displaying virtually no awareness of their throats having been cut during shechita. With their heads freed from restraint, stuck bovines will generally collapse immediately or else stand as normal, despite the gaping neck wound, until the onset of a hypoxic state.

With that said, most of the discussion on this issue has focused on adult cattle in part because their size and strength makes restraint far more difficult than for smaller animals. But there is also evidence showing that the delay in unconsciousness is species dependent because of differences in arterial architecture in relation to the brain. Bovines possess a vertebral arterial structure, which is absent in caprines and ovines, that will continue to supply the brain even following a complete ventral neck cut. As a consequence, cattle may take longer than goats and sheep to lose consciousness and the time taken may be more variable. Indeed, recent research with cattle and calves has shown that even when all procedures are properly conducted, some animals will remain conscious for a period of greater than 60 s after being stuck, during which time they may be expected to experience pain and distress. Other research using an electroencephalogram (EEG) has indicated that following a ventral neck incision nociceptive nerve fibers continued to carry noxious stimuli to the brain where they may be perceived as pain until the animal loses consciousness. It was also found that some animals regained their feet after collapsing, a sure sign of continued awareness.

The Future

Experimental evidence and industrial observations recorded for well over a century strongly indicate that the induction of permanent insensibility in the animal by way of a mechanical, electrical, or gas stunning device is a prerequisite for an ideal (i.e., humane, safe, and rapid) slaughter operation. Further, an increasing sensitivity to animal welfare is gradually leading to mandatory stunning in a number of jurisdictions, effectively rendering all kosher – and some halal – slaughter illegal. In other countries, though, including the United States and Canada, conscious slaughter continues to be tolerated in the name of religious freedom.

In the final analysis, it remains unclear whether the maximization of animal welfare and protection of minority rights are mutually exclusive goals. In fact, these two objectives are likely to become more compatible as religiously justifiable compromises are found to (a) reduce the frequency of conscious slaughter and (b) eliminate inappropriate methods of restraint and sticking. With respect to al-Dhabh, this may be manifest in community acquiescence to the mandatory stunning of all meat animals. In addition, the normalization of training, licensing, and supervision of Muslim slaughtermen by an appropriate authority may serve to improve standards and reduce the inconsistencies associated with halal slaughter. In the case of shechita, one technique that may reduce the potential for suffering – albeit, one that is currently shrouded in some controversy – is the administration of a stun immediately following sticking. A penetrating captive bolt pistol wielded by a skilled slaughterman could render a bovine insensible within 10 s of the shochet's stroke. Although this practice does not address all of the perceived welfare deficiencies of conscious slaughter and is not yet known to have been accepted by Jewish authorities, it certainly has the potential to minimize many of the most acute concerns. Despite the lack of its widespread adoption, postslaughter stunning of cattle does appear to represent a significant improvement in both the humaneness and efficiency of shechita. It is a procedure that deserves further study.

RESIDUES IN MEAT AND MEAT PRODUCTS

Contents

Feed and Drug Residues

J Fink-Gremmels, Utrecht University, Utrecht, The Netherlands

This article is a replaces of the previous edition article by S Croubels, E Daeseleire, S De Baere, P De Backer, D Courtheyn, volume 3, pp 1172–1187,© 2004, Elsevier Ltd.

Glossary

Acceptable daily intake (ADI) The amount of an undesirable substance or chemical residue that will not cause adverse health effects, even when consumed over the entire life span.

Exposure assessment Evaluation of the exposure of human consumers to potential harmful substances present in meat. It is based on human consumption patterns, taking into account vulnerable groups of the human population, such as high consumers of meat and meat products, children and the elderly, pregnant women, and diseased people.

Food chain The food chain describes all steps involved in the production of meat or meat products intended for human consumption. It starts with the food-producing animal and its environment and feed supplies, including animal health aspects and the use of therapeutic agents, and addresses meat processing and packing.

Illicit substances Substances that are not allowed to be used in food-producing animals or in their diet (feed), as they may adversely effect animal health and well-being, the quality of animal products, or cause a risk for consumers if residues of such substances enter the food chain.

Maximum permissible level (ML) The amount of an unavoidable food or feed contaminant that can be tolerated, as at this level under the conditions of normal consumption the amount reaching the consumer will not pose a health risk.

Maximum residue level (MRL) The tolerated maximum residue level of any substance that is used intentionally in the meat production chain, including substances that are applied to food producing animals such as veterinary drugs. This maximum residue level is based on the ADI and aims to avoid that consumers are exposed to harmful residues.

National Residue Control Plans (NRCP) Prescribed chemical analyses to identify potentially harmful residues in meat. NRCPs address undesirable residues of contaminants or veterinary medicinal product in meats and are established every year by the competent authorities taking into account the food chain information (risk factors) and the number of slaughter animals per animal species.

Premarketing authorization Any product that is used in food-producing animals or added to their diets requires a pre-marketing authorization. In this scientific evaluation conducted by the competent authorities, the safety of the product for the animal and the safety of animal products under the defined conditions of use is assessed. Products that are not safe are not licensed for use, and even for safe products a withdrawal period might be prescribed to avoid human exposure to residues in meat of meat products.

Risk assessment A complex scientific evaluation of exposure, the likelihood and nature of potential adverse health effects, the relation between such adverse effects and the (ingested) amount of a harmful chemical substance. Risk assessment provides the basis for legal measures (MRL or MLs) and aims to guarantee that the food is safe for all consumers.

Veterinary Medicinal Products (VMP) VMPs are medicines, also denoted as veterinary drugs, that are intended to be used in animals to cure or prevent diseases. Major classes of VMPs used in food-producing animals are antibiotics (to combat bacterial infections), antiparasitics (against parasites), and substances used in the control of pain in the animal.

 doi:10.1016/B978-0-12-384731-7.00238-5

Preamble

Animals come into contact with numerous chemical substances in their daily life, being either part of their environment or occurring in feed and fodder (grass, hay), water (offered drinking water or water ingested from rivers and lakes), and the air (industrial and urban air pollution). In addition, animals might be treated for infectious, parasitic, or other diseases with veterinary drugs, and residues of these treatments may form undesirable residues in animal tissue as well. The analysis of this entire food chain aims to prevent consumers from exposure to undesirable residues when consuming meat or meat products (Figure 1).

Terms of Reference and Definitions

As indicated in the title of this article, this short review aims to provide an overview of residues originating from feed and from the use of veterinary drugs (veterinary medicinal products (VMP)) in animals. This excludes a detailed discussion of residues from the environment, the use of pesticides and the occurrence of natural toxins in the diet of the animal. Contamination of meat and meat products with biological hazards, such a pathogenic bacteria, viruses, or parasites and the potential risks to public health are covered in other articles.

How Feed Is Defined

Animal feed includes any material that is offered to animals with the aim to meet the nutritional requirements of the individual animal at the different stages of life. In Europe, an extensive catalog of feed components that are permitted to be used for food producing animals (including slaughter animals) is published in Commission Regulation (European Union (EU) No 575/2011). Other catalogs of feed materials have been established for example by the US Food and Drug Administration or at the global level by the International Feed Industry Federation (IFIF). The main objective of these listings is to ensure animal health and well-being as well as to exclude toxic plants and potentially harmful waste products from animal feeds.

To improve animal health, natural feed materials can be fortified with so-called 'feed additives,' such as vitamins and minerals. Moreover, colorants, appetizers, and technical and zootechnical additives may be added to feeds to improve their quality and digestibility. These substances that are voluntarily added to feed, have to pass an evaluation procedure (marketing authorization) by the competent authorities (for details see Regulation (EC) no. 1831/2003). In this authorization process, the efficacy (benefit for the animal), safety for the animal, and safety (absence of any residues) of animal-derived products is assessed.

How Veterinary Drugs Are Defined

Veterinary drugs (VMPs) are pharmacologically active substances that are administered to animals in the case of disease. Prominent examples are the class of antibiotics that are used in the treatment of bacterial infections, antiparasitics applied in the control of endo- and ectoparasites, drugs that are used in the management of pain, or any other drug with a specific indication for use in a diseased animal. All VMPs used in animals have to undergo a premarketing approval process by the competent (national of EU) authorities, or have to be approved for use human patients (see Council Regulation (EC) No 37/2010 for the procedures applied in Europe). The premarketing approval process control the composition and pharmaceutical quality of a VMP, its efficacy for the claimed indications, its safety profile in the animal species for which it is licensed (this can included one or more animal species) and the safety for the applicant (farmer or veterinarian). In the case of food producing animals, the dossier includes also a special part in which the deposition of residues of the parent compound or its metabolites is studied and the possible impact of residues in edible tissues is assessed (see Section How Risk Assessment is Defined). This implies that only drugs that have passed this premarketing approval can be used in animals for the indications provided in the list of specific product characteristics. If potentially harmful residues of a VMP or its metabolites can be detected in edible tissue of an animal, the

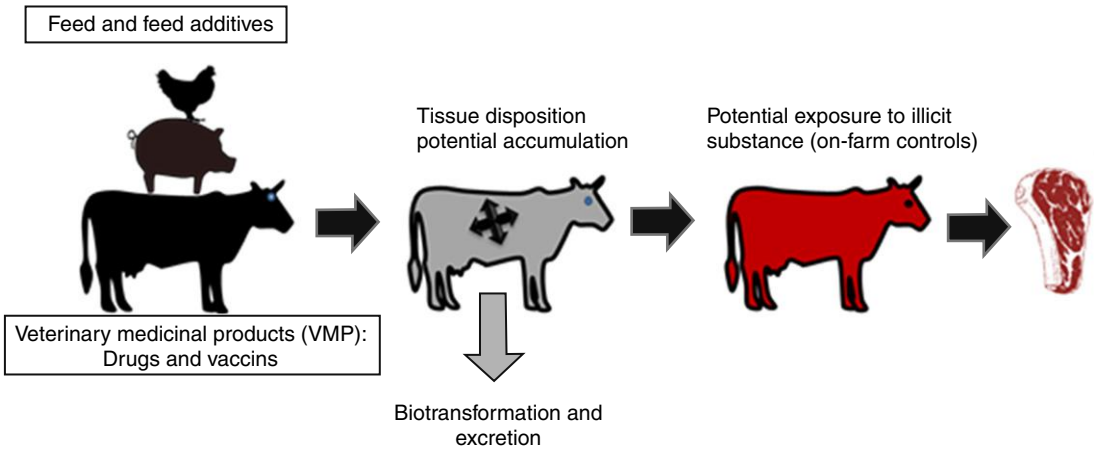

Figure 1 The food chain and the origin of chemical residues in meat.

competent authorities may prescribe a withdrawal period (time between last treatment and slaughter) to avoid that these residues will be present in consumable products (see Section Residues of Feed Additives and Veterinary Drugs).

How Meat Is Defined

In this article the term 'meat' refers to

- Muscle tissue including interstitial and body fat of slaughter animals including pig, poultry, ruminants (bovine species, sheep and goats), and horses (solipeds) and where appropriate rabbit and farmed game meat.
- Offal: edibles organs such as liver and kidney that are commonly collected for human consumption.

Several other parts of the carcass such as intestines, bladders, and stomachs that might be processed for sausage making, as well as local specialties such as tripe (rumen), legs and ears, and bone tissues (spare ribs) are considered as fresh meat and special regulations are in place to ensure that these products meet all criteria set for meat in general. Moreover, other foods of animal origin such as milk and eggs need to comply with the same food safety standards, but details of their evaluation is not within the scope of this review.

How Chemical Residues Are Defined

The term chemical residue refers to any substance originating from the production process of a given food and hence is not a natural constituent of meat. Residues can originate from very different sources or describe residual amounts of production aids (here feed additives or VMPs) that have been used in the life phase of the animal and that may be present in residual amounts in the carcass at the time of slaughter. The term residue covers not only the parent substance actually applied to or being ingested by the animal, but also metabolites such as substances that retain biological activity and hence require an assessment of potential adverse effects for meat consumers, or serve as an indicator of nonapproved use of drugs or other chemicals in/on the animal.

How Feed and Food Safety Is Defined

Considering the definition of feed or feed materials, it is obvious that these should be free of substances that are harmful for the animal. However, in the case of food-producing animals also the safety of animal products (food) needs to assessed. This so-called food chain assessment (from farm to fork) was first formalized in Europe with the enforcement of the General Food Law (Council Regulation (EC) Nr. 178/2002) (Regulation (EC) No 178/2002 of the European Parliament and the Council of 28 January 2002, laying down the general principle and requirements of food safety, and, establishing the European Food Safety Authority (EFSA). This approach is now common practice around the world and implies that for all substances that might be ingested with feed or water by the animal, maximum tolerance levels are established that are indeed based on a careful assessment of the potential risks for animal and human health. If during the life time of an animal chemical substances in the form of feed additives or VMPs (drugs) are used, the prerequisite for use are defined in a premarketing authorization procedure (see Section How Veterinary Drugs are Defined) again taking into account the potential risk for the animal (animal safety assessment) as well as the potential risk for the consumer of animal-derived products that may contain residual amounts (drug residues) of such substances.

How Risk Assessment Is Defined

In the frame of feed and food safety, risk assessment is defined as a standardized procedure taking into account the following criteria.

Hazard identification

The potential of a substance to cause an adverse effect in animals or the human consumer of animal-derived products.

Hazard characterization

The quantitative analysis of the dose–effect curve the quantity of residues in individual tissues and the potential risk for the consumer of animal-derived products.

Exposure assessment

The expected exposure of consumers following the common consumption quantities of an animal product.

Risk characterization and risk assessment

The assessment of the outcome of these previous assessment steps and an overall assessment of the potential risk for animals and the human consumer of animal-derived products as a guidance for risk avoidance or risk management strategies (Figure 2).

Feed Residues

Feed, presented either as natural forage or mixed feed contains a large diversity of chemical substances. The first step in the hazard identification of natural toxins and contaminants in animals feed materials is an analysis of the overall occurrence and the potential adverse effect in animals (toxicodynamics) under the conditions of current farming practice. Although previously descriptions of toxic effects were generally based on case studies, reporting clinical signs of intoxications in a target animal, current approaches aim to identify the mode of action (MoA) to identify potentially hazardous substances, to define intervention strategies and to set priorities for analytical surveys and hazard characterization.

In most cases, a prerequisite for a toxic effect is that the chemical substance under consideration is absorbed from the gastrointestinal tract of the animal and reaches the systemic blood circulation that distributes the substance into the different organs. This fate of a substance in the body of an animal is generally described as the kinetic phase (toxicokinetics) and includes also the biotransformation (metabolite formation) and the excretion with urine of feces. The absorption phase and hence the biological availability (the percentage of the

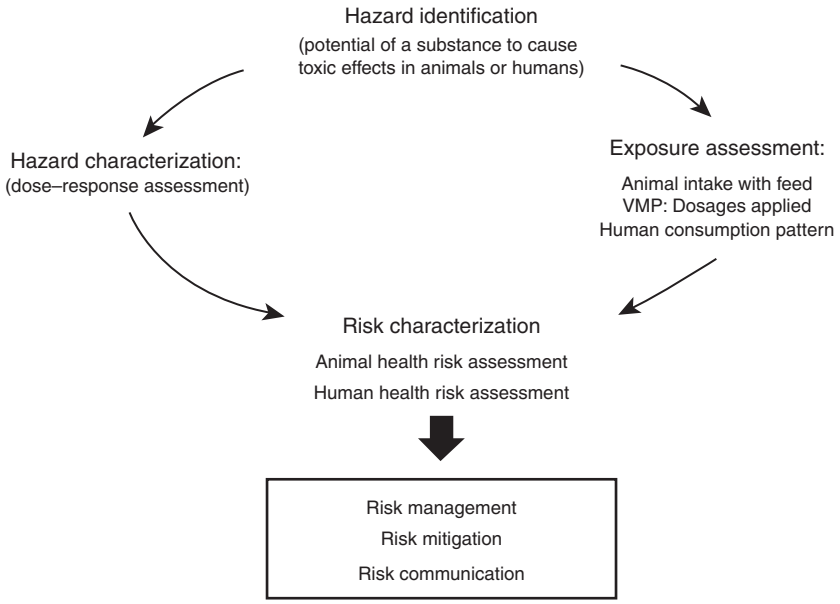

Figure 2 The individual steps leading to risk characterization.

toxin that reaches the systemic circulation) depend not only on the chemical structure of the substance under consideration, but also from the physiological and anatomical differences in the gastrointestinal tract of the animal. Ruminant species (cattle, sheep, goats, and others) share a system of forestomachs, of which particularly the rumen harbors a great diversity of microorganisms, such as bacteria, protozoa, and certain fungal species. The physiological function of this rumen flora is the digestion of fiber (cellulose) that otherwise could not be used as source of nutrients by mammalian species. This forestomach flora is not only able to transform or degrade many potential toxic substances occurring naturally in forage plants, but also as environmental pollutants that contaminate feed materials. The rumen is a very effective first defense making ruminants less sensitive to toxins than horses (solipeds) that are strict herbivorous species as well. The large bowl (cecal) fermentation of monogastric herbivors is less protective as small molecules, including most of the known toxic substances are already absorbed in the upper (proximal) intestines. Nevertheless, all herbivorous species during evolution have developed specific protection systems, such as efflux transporters and biotransformation enzymes expressed in the gut wall, to prevent toxins that are in the daily diet can reach the systemic circulation and exert toxic effects. Omnivores, like pigs and poultry (and of course carnivorous species) are less protected by nature and in turn are more vulnerable to undesirable substances in animal feeds.

A toxicokinetic analysis of undesirable substances in animal feeds addresses also the disposition in edible tissues as a concentration- and time-dependent process and hence identifies the possible risk of residue formation. Many chemical substances, particularly substances that are naturally occurring in (feed) plants, even if they are potentially toxic, are rapidly excreted and do not form residues in meat. In contrast, organic pollutants, of which the dioxins are one of the most prominent examples, have a low immediate toxicity and often no specific adverse effects can be observed in the animal. These substances, however, accumulate in the animal's body (fatty tissues) and are of high concern for the consumers of meat and organs like liver, kidney or other edible products tissues (milk and in particular, eggs). Human exposure is associated with adverse effects on the (neuro)immune system and in other cases with an increased risk to develop cancer. A similar accumulation in the animal's body is also observed for certain heavy metals, particularly for cadmium that accumulates in the kidneys (of animals and humans) during the entire lifespan and may occur in undesirable high concentrations even in horsemeat.

In a recent evaluation by the EFSA (2012–13) (Documents for all individual animal species are available in the free-access *European Food Safety Authority Journal*), it was concluded that feed contamination with dioxin and dioxin-like polychlorinated biphenyls (PCBs) is of high potential concern for consumers due to their specific toxicological profile and their accumulation in the food chain. Other potentially accumulating substances such as cadmium and non-dioxin like PCBs are of medium concern. For many related halogenated substances such as polybrominated diphenylethers and hexabromocyclododecanes and several perfluorinated compounds a decreasing environmental burden is noticed, but comprehensive data on potential residue formation in farm animals are currently lacking. To avoid adverse effects in consumers due to residues of these compounds in meats and other edible tissue, milk, and eggs, maximum permissible levels will be (or have been) set for feed and food and specific control measures of all feed materials (including imports) are enforced in all EU member states. The control of undesirable substances in animal feeds is governed by the Directive 2002/32/EC on Undesirable Substances in Animals Feeds.

Residues of Feed Additives and Veterinary Drugs

In contrast to natural toxins and environmental pollutants that may contaminate feed materials including water supplies of

food producing animals, feed additives, and veterinary drugs may be used only in animals if the individual substance has passed an intensive (scientific) evaluation and a premarketing authorization process by the competent authorities (see Sections How Feed is Defined and How Veterinary Drugs are Defined). This evaluation includes the assessment of the efficacy (claimed beneficial health effect) and animal safety under the conditions of use (including a safety margin for involuntary common mistakes in daily practice, such as poor mixing or incorrect dosing). An important task is the evaluation of potentially harmful residues of the parent compound or its metabolites in animal tissues, as described before. If the elimination of residual amounts of a feed additive or drug is slow, withdrawal times (time between last use and slaughter) will be set to ensure that the carcass is free of residues. In turn, if harmful residues seem to be unavoidable under the conditions of use, a substance is rejected and older substances that have been used in animals before the implementation of the European Food Law have been banned. This ban or prohibition of use applies to all substances that are potentially harmful for the consumer, particularly all substances that may contribute to the development or promotion of cancer.

Drug Residues and Consumer Risks

VMPs (commonly named veterinary drugs) can only be used in food producing animals if they have passed the above mentioned premarketing authorization procedure. This applies also for drugs (e.g., antibiotics or substances used in pain management) that have already achieved an authorization for use in humans. The detailed procedure of premarketing assessment includes an evaluation of the pharmaceutical product quality, the safety for the target animal species, the potential disposition of residues in edible tissues and finally the potential risk for the human consumer of animal-derived foods. The overall objective is risk avoidance, as these substances are used intentionally, and any risk for consumers is considered as unacceptable. To achieve this and to facilitate control measures (see Section National Residue Control Plans) maximum residue levels (MRLs) are established and published by the competent authorities. The 'MRL' is based on a No-adverse effect level (NOAEL) derived from studies in model animal species and is divided by an uncertainty factor (the default factor is 100, accounting for the extrapolation of animal data to humans and the variability within the human population) and defines the 'ADI' (acceptable daily intake by consumers of the food products such as meat, milk, and eggs). On the basis of the ADI (which guarantees the absence of undesirable effects in consumers over the entire lifespan) the MRL (permissible concentration in edible tissue) is calculated taking into account a high consumption of the animal-derived product (for meat the standard consumption of a high consumer is set to 300 g per day to which 100 g of liver and 50 g of fat and kidneys are added). Where necessary, a withdrawal period (time between use and slaughter) is prescribed to ensure that a carcass does not contain any drug residues that exceed the MRL. In the case of antibiotics, potential microbiological effects are evaluated as well.

For a number of compounds this risk assessment resulted in a high level of uncertainty, as genotoxic effects, and hence the possible contribution to the development of cancer could not be excluded entirely. These substances, including for example the group of 5-nitroimidazoles, nitrofurans, and individual substance such as chloramphenicol or aristolochic acid, have been banned for use in food producing animals (EC 37/2010, Annex Table 2).

In the recent reevaluation by the EFSA, noncompliant samples with drug residues of authorized substances were classified as being of negligible concern for consumers due to the precautionary safety margin applied during the establishment of the MRL values, and the nature of the drugs licensed for food producing animals in Europe. This is in contrast to the illicit use of non-authorized substances that may be of medium concern due to potential adverse health effects following long-term ingestions. To avoid such any repetitive exposure of consumers, the national residue control plans prescribe the routine control and targeted sampling of all slaughter animals.

Mandatory Residue Testing: National Residue Control Plans

Within the EU (a similar situation is present in other countries), Council Directive 96/23/EC prescribes the monitoring of residues in slaughter animals, defining the number (percentage) of slaughter animals that needs to be tested for the presence of residues. Each Member State has to present a National Residue Control Programmes (NRCPs) plan based on its specific animal husbandry system. The NRCP is annually updated and is evaluated by the Commission services (DG Health and Consumers) in cooperation with a statistic evaluation and assessment by the EFSA. NRCPs focus on the control of residues from contaminants identified as being of high concern for consumer health (within category B3), the illicit use of nonauthorized substances (within category A) and a general drug residue monitoring to check the compliance with drug use and withdrawal periods (categories B1 and B2). The analytical procedures applied in the framework of the NRCP controls are validated (performance criteria are set) to achieve a high quality standard and to allow a comparison of findings among individual Member States.

In Table 1 an aggregated summary of the results of the NRCPs (all results of the NRCPs are published on the EFSA website) over a period of 5 years is presented. This summary should serve as reliable indication of the results of the European residue control program, although it contains some minor uncertainties: such as for example the presence of two residues in one animal (counted twice), or the fact that from a large batch of slaughter animals (pigs, poultry, and calves) only a limited number of animals have been investigated while it can be assumed that more animals have been treated in the same way when they originated from the same farm and the same age group.

Considering the outcome of this unique and comprehensive survey it can be concluded that in all animal species the percentage of carcasses containing undesirable residues of veterinary drugs (VMPs and pharmacological active substances

Table 1 Residues in meat: Noncompliant samples of the European NRCP 2005–10

Animal species	*Nature of the residue*	*Total number of samples analyzed*	*Number of noncompliant samples*	*Noncompliant samples (%)*
Bovine (all age groups)	Veterinary drugs	282 557	618	0.22
	Illicit and banned substances	476 550	899	0.19
	Chemical elements (including cadmium)	18 798	439	2.3
	Pesticides and organic pollutants	25 216	38	0.15
Small ruminants (sheep and goats)	Veterinary drugs	99 167	235	0.24
	Illicit and banned substances	32 502	208	0.64
	Chemical elements (including cadmium)	6 205	164	2.64
	Pesticides and organic pollutants	13 773	35	0.25
Pigs (all age groups)	Veterinary drugs	502 406	833	0.07

	Illicit and banned substances	188 346	91	0.05
	Chemical elements (including cadmium)	10 689	52	0.49
	Pesticides and organic pollutants	16 709	9	0.05

Source: Data are derived from the reports to the EU Commission of 25 (27) EU Member States and have been aggregated by the European Food Safety Authority.

applied with feed such as coccidiostats) is rather low varying between 0.07% in pigs and 0.51% in poultry. Noncompliant results are expected when veterinary drugs are applied to the animal directly in the period before slaughter. This corresponds to the observation that older, fatting pigs in the last weeks before slaughter are seldom affected by diseases, whereas in poultry, for example, disease outbreaks are possible during the entire (very short) production period.

The categories 'illicit compounds' and banned substances comprise all residues of substances that are either illegal (illicit use) or banned (not licensed for use) in food producing animals (listed in Annex 2 of 37/2010 EC). The percentage of noncomplaint samples varied between 0.05% in poultry and 0.64% in sheep. The latter are apparently treated more frequently with substances not licensed for this animal species, which belongs in many Member States to the group of minor species, with a limited number of drugs licensed for therapeutic purposes.

The category of 'chemical elements' contains all toxic heavy metals including cadmium that accumulates in the kidneys and to a lesser extent in other tissues. The percentage of noncompliant samples ranges from 0.49% in poultry to 2.64% in small ruminants (predominantly sheep). The percentage of positive samples reflect the husbandry system and total lifespan of an animal, with a higher percentage of noncompliant samples in small ruminants and bovines, which are kept on pasture grass and ingest involuntarily earth and sands that contribute to the body burden. In contrast, poultry is kept mainly indoors and has a very short lifespan when used for chicken meat production. As in most cases, these residues of heavy metals are found in kidneys that are generally not consumed in large quantities (or only incidentally used), the overall contribution to human exposure is still considered to be low.

The category of pesticide residues comprises substances that are incidentally used in the control of pests in the direct environment of the animal, but more importantly that enter the food chain due to feed contamination. Although the statistic incidence of these residues is still low (0.05–0.25%), this category encompasses substances such as dioxins that are of high potential concern for the consumer, as they accumulate not only in animal tissues, but also in the body of a human consumer when exposed to residue containing foods.

Risk Mitigation, Risk Management, and Risk Communication

The increasing awareness that food safety is an inevitable right of consumers and the enforcement of strict regulations for has resulted in a continuous decline of the prevalence of undesirable residues in meat (muscle tissue and edible organs) in the past decade. Forthcoming strategies for risk mitigation will be built on further integration of the food chain assessment, aiming at an exchange of information (and mandatory reporting) of all the results of analytical feed (and environmental) controls for the presence of undesirable and potentially harmful substances and a full record of the use of veterinary drugs before the use of foods from animal origin. This could allow corrective measures to further reduce the prevalence of residues in carcasses, and hence meat and meat products. At the global level, the challenge for risk communication remains, to ensure that an equal level of food safety is achieved in all parts of the world. Risk communication should address also directly the consumer's concerns about undesirable residues in meat and other animal-derived products and explain the measures taken to guarantee that food is safe.

Glossary

Biogenic amines Low molecular alkaline substances with aliphatic, aromatic, or heterocyclic structure. They are biologically active and occur as metabolic products in animals and plants. In foodstuffs, they are formed mainly by microbial decarboxylation from the correspondent-free amino acids.

Heterocyclic amines The derivatives of quinoline, quinoxaline, and pyridine, all of them containing one amino group. During severe heating, these substances are formed from creatine, present in all animal tissues, other amino acids and monosaccharides.

Nitrosamines Carcinogenic and they are formed during a reaction of nitrite with secondary amines or N-substituted amides. Their formation is also possible with primary amines, diamines, and tertiary amines.

Polyamines Polyamines (spermine, spermidine, putrescine, and cadaverine) are natural components in meat that are biologically active and belong to the so-called natural, which are essential for cell growth and cell proliferation. Hence, besides being natural polyamines. Because polyamines are so important for cell proliferation, cancer growth also requires polyamines, most of them deriving from the diet.

Polycyclic aromatic hydrocarbons The organic compounds that consist of at least two aromatic rings without hetero atoms and substituents formed during incomplete combustion (smoking).

Introduction

Although residues in meat products may result from contamination of the raw material (as is, for instance, the case with pesticides, heavy metals, and antibiotics) they are first and foremost formed during product manufacture, i.e., they are associated with a particular process technology. The latter category of residues may be defined as undesirable substances, which as a rule are only formed in small amounts as by-products of a generally desirable processing procedure such as smoking, curing, and fermentation. In essence, their formation in small quantities is inevitable but when high concentrations are observed this is generally associated with mistakes as regards hygiene and/or process technology during product manufacture. The following procedures have been linked to these procedures (Table 1).

Biogenic Amines

Biogenic amines are low molecular alkaline substances with aliphatic, aromatic, or heterocyclic structure, they are biologically active and occur as metabolical products in animals and plants. In foodstuffs they are formed mainly by microbial decarboxylation from the correspondent-free amino acids as follows:

Histidine	Histamine
Tyrosine	Tyramine
Tryptophane	Tryptamine
Phenylalanine	Phenylethylamine
Lysine	Cadaverine
Ornithine	Putrescine and spermidine (putrescine +aminopropyl group)
	Spermine (spermindine+aminopropyl group)

Spermine and spermidine are actually not products of bacterial decarboxylation but are natural components in meat and are sometimes considered as an indicator of spoilage of meat. They are biologically active and together with putrescine and cadaverine belong to the so-called natural polyamines, which are essential for cell growth and cell proliferation. Hence, besides being natural polyamines putrescine and cadaverine are also biogenical amines as a result of microbial decarboxylation. Because polyamines are so important for cell proliferation, cancer growth also requires polyamines, most of them deriving from the diet. The toxicological effects of biogenical amines and polyamines are described in Table 2.

In heated products, for example, emulsified sausages or cooked ham, the occurrence of biogenical amines reflects the hygiene status of the raw material. If the amounts of biogenical amines in the heated product exceed concentrations of fresh meat usually below 10 mg kg^{-1}, it is likely that spoiled meat was included in its manufacture. Thus, the occurrence of elevated amounts of biogenical amines can be used as an indicator of the hygiene level of the raw material. In meat mixtures prepared from fresh and spoiled meat in different ratios,

Table 1 Processing steps associated with occurrence of residues

Processing step	*Associated residues*
Handling of raw material	Biogenical amines in heated products and fermented sausages
Smoking	Polycyclic hydrocarbons
Heating	Nitrosamines and heterocyclic amines
Fermentation	Biogenical amines
Packaging	Residues from plasticizers and additives
Cleaning and disinfection	Residues from these substances
Use of additives	Nitrosamines and residual additives

the concentration of putrescine, cadaverine, and also tyramine is higher with increasing percentages of spoiled meat.

In raw sausages purchased randomly from retail shops, tyramine, histamine, putrescine, and cadaverine were found in all samples at various concentrations (Table 3). Histamine content was varying from one producer to the other, suggesting a certain manufacturer-dependency. The concentrations of spermine and spermidine showed no remarkable differences (data not shown).

The pathway of amine formation in raw sausages is quite different in comparison with heated meat products. The occurrence of biogenical amines in raw sausages is a consequence of microbiological activity during fermentation. It cannot be excluded that some of the microorganisms that are predominant during fermentation (particularly lactic acid bacteria) have the ability to decarboxylate amino acids. Hence, commercial starter cultures should be controlled regarding their ability to form biogenical amines. Generally, enterobacteriaceae and pseudomonades that also have the ability to form biogenical amines are outcompeted by the fermentation flora. However, the ubiquitous anaerobic and amine-forming microorganisms cannot be suppressed by starters. These microorganisms are generally unable to metabolize proteins. Therefore, the substrates for decarboxylation have to be already available in the raw material. In most cases, excessive concentrations of amines cannot be detected in the raw material, but the occurrence of rather high amounts of the precursor amino acid leads to corresponding amounts of amines in the final product. Tyramine seems to be a very sensitive indicator for the detection of the use of long-stored and hygienically doubtful meat for the production of raw sausages. High amounts of putrescine, and to some extent also cadaverine, indicate the use of spoiled meat. An excessive formation of histamine could only be observed in the presence of specific microorganisms and is strongly dependent on specific flora present on the production site. Tryptamine and phenylethylamine could be found in very different concentrations, but spermine and spermidine do not increase during ripening. Although small amounts of biogenical amines cannot be avoided, an excessive formation of amines indicates that the raw material used for production was not in a hygienically perfect condition.

In sliced raw sausages, biogenical amines are formed only in products where the water/protein ratio is higher than approximately 1.8. This is due to the fact that the moisture content plays an important role in microbial growth.

As mentioned above, the use of hygienically doubtful meat for the production of raw sausages leads to increased formation of biogenical amines during ripening. Tyramine seems to be a very sensitive indicator. A further increase of biogenical amines in sliced raw fermented sausages can only be observed in products in which the moisture content allows bacterial activity.

Recently the European Food Safety Authority (EFSA) conducted a qualitative risk assessment of biogenical amines in fermented foods, using data from the scientific literature including consumption data. The study was focused on histamine and tyramine as these substances were considered as the most toxic and most relevant for food safety assessement of fermented foods. For healthy individuals, no adverse health effects were observed after exposure to 50 mg histamine and 600 mg

Table 2 Toxicological effects of biogenical amines

Amine	*Effect*
Histamine	Nausea, respiratory distress, hot flushes, sweating, heart palpitation, headache, bright red rash, oral burning, hypotension, and migraine
Tyramine	Hypertension, respiratory distress, migraine, hot flushes, sweating, and heart palpitation
Tryptamine	Hypertension, respiratory distress, hot flushes, sweating, and heart palpitation
Phenylethylamine	Hypertension and headache
Cadaverine	Hypotension and amplification of histamine effect
Putrescine	Hypotension, amplification of histamine effect, and effect on tumor growth
Spermidine/ spermine	Effect on tumor growth

(Eds.), COST 917 Biogenically Active Amines in Food, vol. 5, EUR 19882. Luxembourg: Office of the Official Publications of the European Community, pp. 88–94. ISBN: 02-894-1630-0.

tyramine per meal. For persons with histamine intolerance or those taking monoamino oxidase inhibitors, the limits are considerably lower. The aforementioned EFSA opinion concluded that further research on toxicity, control measures during production (including process hygiene in fermented foods), and validation of analytical methods is essential.

Polycyclic Aromatic Hydrocarbons

Meat products are often smoked with the intention to improve their sensory and microbiological condition. Smoke is prepared by incomplete burning of wood whereby the components of wood cellulose, hemicellulose, and lignin are degraded through pyrolysis. During this procedure, not only sensorically beneficial and preservative components (phenols, carbonyls, and organic acids) but also the carcinogenic, so-called polycyclic aromatic hydrocarbons (PAH) are formed.

Generally, the formation of PAH cannot be avoided, but taking relevant technological precautions (glowing temperature, cooling of the smoke, and kind of wood) the concentration can be reduced to an acceptable level. The formation of these substances begins at approximately 400 °C, which temperature is also slightly above the ideal temperature for pyrolysis (300–400 °C) and therefore for the building of the sensorically relevant, preservative substances. To reduce the formation of the PAH, the glowing temperature should be as low as possible and only hardwood (e.g., beech) should be used. Furthermore, the site of smoke production and the position of the product to be smoked should be far enough apart to allow the PAH to condense together with tar.

Approximately 40 polycyclic hydrocarbons have been detected in smoke with benz(a)pyrene suggested as a representative indicator. In 2008, EFSA recommended that relying merely on benzo(a)pyrene as a marker is unsuitable for detecting the occurrence of PAH in food. Rather, an approach is recommended relying on an analytical system with either four specific substances (PAH4 – benzo(a)pyrene, benz(a)anthracene, benzo(b)fluoranthene and chrysene) or with eight (PAH8 – PAH4 plus benzo(k)fluoranthene, benzo(g,h,i)perylene, dibenz(a,h)anthracene, and indeno(1,2,3-c,d)pyrene). Consequently, new maximum levels for the sum of four substances (PAH4) have been introduced, although maintaining a separate maximum level for benzo(a)pyrene. The EU regulation prescribes that for smoked meat and smoked meat products, the maximum residual amounts of benzo(a)pyrene should be 5.0 μg kg^{-1} until 31 August 2014 and 2.0 μg kg^{-1} as from 1 September 2014 and of PAH4 with 30 and 12 μg kg^{-1}, respectively.

Incidentally, polycyclic hydrocarbons are also formed during the burning of fat. This fact should especially be taken into consideration if the meat is barbecued using charcoal.

Residual Additives

Generally only such additives are allowed for use in foodstuffs, which are licensed and therefore represent no health risk for the consumer eating normal amounts of the food. An exception is sodium- or potassium-nitrite, which is used for the production of color-stable products. Nitrite is actually a poison and so this substance is only allowed to be sold admixed in sodium chloride (usual concentration of $NaNO_2$ in NaCl: 0.4–0.6% in Austria, 0.4–0.5% in Germany). According to the Food Additive Regulation of the EU not more than 150 mg $NaNO_2$ per kg can be added to meat products during production, but in the case of sterilized products ($F_0 > 3$) only 100 mg $NaNO_2$ per kg is permissible. The fact that ascorbic acid is used for rapid reduction of nitrite to nitric oxide explains additionally why only very small amounts of residual nitrite can be found in the final product. The main reason is the sequestering of oxygen in the batter by nitrite, which is oxidized to nitrate. The second curing agent nitrate per se is not very toxic but is excreted in the saliva and reduced to nitrite in the mouth. When curing meats with nitrate, the reduction of nitrate to nitrite is carried out by microorganisms. Consequently, undesirable amounts not only of nitrate but also of nitrite may be determined in the case of faults during production. The limit for adding nitrate according to the regulation mentioned above is 150 mg $NaNO_3$ per kg. For traditionally cured meat products like bacon, dry cured ham, or salami exceptions are prescribed in the regulations. Often, maximum residual amounts at the end of the production process instead of the maximum added amount are prescribed. Therefore, a toxicological risk from nitrates or nitrites itself is unlikely, however, the formation of nitrosamines remains a possibility.

Nitrosamines

Nitrosamines have been found to be carcinogenic and they are formed during a reaction of nitrite with secondary amines or *N*-substituted amides. Their formation is also possible with primary amines, diamines, and tertiary amines. The most carcinogenic nitrosamine is nitrosodimethylamine. In meat products nitrosopiperidine and nitrosopyrrolidine are important. The amines corresponding to these substances are cadaverine and putrescine, respectively, which can either be formed during fermentation or are originally present as part of the polyamine pool in meat. The formation of nitrosamines is mainly influenced by the amount of nitrite, the pH of the product and not by the concentration of amines. The ratio between nitrite and amine should be approximately 1:10. Nitrosamines can either be formed during commercial product manufacture and during preparation in the household, or in the stomach where acidity favors the reaction. The pH optima for formation of most nitrosamines lies between 1 and 3, for heterocyclic nitrosamines approximately at 3.8. The formation of nitrosamines is accelerated by increasing temperature and is hampered by increasing alkalinity. Halogen ions and the pseudohalogenide thiocyanate catalyze the reaction. The fact that thiocyanate is also a component of smoke from tobacco explains why an evaluated formation of nitrosamines can take place in the stomach of smokers, which may represent a risk as regards the development of stomach cancer. Formaldehyde also catalyzes the formation of nitrosamines by increasing the pH optimum of the reaction. Because formaldehyde is also a component of smoke, it has been suggested that the formation

of nitrosamines is facilitated in meat products, which are cured as well as smoked.

The fact that nitrosamines may be formed in the stomach is the reason why nitrate can also not be rated as toxicologically harmless. Nitrate is excreted in the saliva and is reduced to nitrite in the mouth. The sources of nitrate are mainly vegetables and potable water and not cured meat products.

Whereas in pasteurized sausages and cooked ham nitrosamines are generally not detected, this is often the case in small quantities in raw fermented sausages and raw ham. Recent data show that the concentration in raw sausages and raw ham ranges from 'not detectable' (n.d.) to 5 $\mu g\,kg^{-1}$ for dimethylnitrosamine, from n.d. to $>5\,\mu g\,kg^{-1}$ for nitrosopiperidine, and from n.d. to 0.5 $\mu g\,kg^{-1}$. Although most of the values of dimethylnitrosamine were between 0.5 and 1 $\mu g\,kg^{-1}$, the predominant part of the two other nitrosamines was below 0.5 $\mu g\,kg^{-1}$ for nitrosopyrrolidine. Further sources of nitrosamines in higher concentrations are fried and cured products where nitrosopyrrolidine is developed by thermal cleavage of carbon dioxide from nitrosoproline. Proline can be nitrosated easily; its reaction product nitrosoproline is not carcinogenic. Black pepper may be the reason for the formation of nitrosopiperidine, paprika for nitrosopyrrolidine. Formation of nitrosopyrrolidine is promoted by heating over 170 °C, i.e., during frying of bacon and dry heating of 'Bavarian Leberkäse' (resulting in crust formation), but also when salami is used on pizzas. In the latter case, the possible presence of putrescine and cadaverine increases the risk of nitrosamine formation.

Lowering the added nitrite and nitrate to meat products, the use of ascorbic acid for rapid and complete reduction of nitrite to nitroxide, and the decrease of nitrate in vegetables and in potable water are considered to contribute to the decrease in nitrosamine uptake. First of all, frying of cured products at high temperatures should be avoided, a simple precautionary measure within the responsibility of each consumer.

Heterocyclic Amines

At the end of the 1970s, Japanese researchers found that in the crust of barbecued sardines substances could be detected, which according to the Ames test should be considered as mutagenic. They identified these substances as heterocyclic amines or more precisely as derivatives of quinoline, quinoxaline, and pyridine, all of them containing one amino group. During severe heating, these substances are formed from an amino acid and a monosaccharide provided creatine is present. Creatine is present in all animal tissues. The most important and also the most carcinogenic substances are 2-amino-3-methyl-imidazol[4,5-f]quinoline (IQ), 2-amino-3,4-dimethyl-imidazol[4,5-f]quinoline (MeIQ), 2-amino-3,8-methyl-imidazol[4,5-f]quinoxaline (MeIQx), 2-amino-3,4,8-dimethyl-imidazol[4,5-f]quinoxaline (4,8-DiMeIQx), and 2-amino-1-methyl-6-phenyl-imidazol[4,5-b]pyridine (PhIP). So far, more than 20 of these substances are known. During heating of meat in boiling water or steam, no heterocyclic amines have been found. Only when temperatures increase the formation starts. The amount formed increases with higher temperature and longer heating times. PhIP is formed most abundantly with observed levels up to 480 $\mu g\,kg^{-1}$. The concentrations of the other amines are generally lower, i.e., ranging from n.d. to 15 $\mu g\,kg^{-1}$ IQ, MeIQx and 4,8-DiMeIQx and up to 50 $\mu g\,kg^{-1}$ for MeIQx.

Residues from Wrapping and Packaging Materials

Substances that can be a health risk or can affect smell and taste deterioration should generally not migrate into the foodstuff from the wrapping or packaging material or from artificial casing. The most common wrapping and packaging materials for meat and meat products are metal (tins) or plastic.

Modern cans are internally coated with an epoxy resin. This coating may release bisphenol-A-diglycerolether (BADGE) or bisphenol-F-diglycerolether (BFDGE), which migrate into the food. BADGE is an intermediate product during the production of these epoxy resins, which is degraded mainly after polymerization. Besides these very flexible coatings, also other added epoxy resins are applied, which are only polymerized partly so that the percentage of BADGE is increased. BADGE was found to be mutagenic in the Ames test, which could not be confirmed in animal experiments. However, as a guideline for the content of the sum of BADGE and BFDGE 1 $mg\,kg^{-1}$ food has been suggested.

Packagings and wrappings of plastic may contain residues of the correspondent monomer, for example, styrole in polystyrole, or residues of additives that are used in their production (catalysts, stabilizers, and emulsifiers). Furthermore, some other additives are able to migrate into the foodstuff, for example, antioxidants, antiblocking and antistatic agents, fillers, and pigment colorants. For packaging of fresh meat, soft and stretchable polyvinyl chloride foils are used, which contain diethylhexyladipiate (DEHA) and epoxidized soy bean oil (ESBO) as plasticizers.

Residues from Cleaning Agents and Disinfectants

Working areas, working surfaces, and equipment of meat processing plants must be cleaned and disinfected to remove residues from meat and fat and to avoid microbial residues. The proper procedure includes rinsing of the cleaned and disinfected surfaces and equipment with potable water to remove the disinfectants and to avoid contamination of meat. Consequently, transition of residues of cleaning agents and disinfectants is only possible when good practices are abused. A health risk is not caused by the direct uptake of these substances but – similar to antibiotics – microorganisms may be resistant against these substances. Unfortunately, prescribed monitoring procedures of the effect of cleaning and disinfection are targeted toward proving the absence of microorganisms, rather than the absence of disinfectants. As long as limits for cleaning agents and disinfectants are not laid down in directions, for example, within the European Union, this situation is unlikely to change.

Glossary

Appropriate Level of Protection (ALOP) The level of protection deemed appropriate by the World Trade Organization (WTO) member establishing a sanitary or phytosanitary measure to protect human, animal or plant life or health within its territory (WTO). This concept is also referred to as the acceptable level of risk.

Food Safety Objective (FSO) The maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the ALOP.

Good Hygienic Practice (GHP) Basic conditions and activities that is necessary to maintain a hygienic environment suitable for the production, handling and provision of safe food for human consumption.

Hazard A biological, chemical or physical agent, or condition in food with the potential to cause an adverse health effect.

Hazard Analysis and Critical Control Points (HACCPs) A system which identifies, evaluates, and controls hazards that are significant for food safety.

Performance Objective (PO) The maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food.

Safety factor (SF) A numerical factor, usually 10 or 100, applied as a safety margin to take into account uncertainty associated with quantitative estimates.

Introduction

Risk analysis is a formalized, scientifically based approach that is recognized by the World Trade Organization (WTO) as the tool for addressing food safety issues and on which food safety regulations are founded. When carried out correctly, risk analysis provides a tool for the identification, assessment, management, and communication of risk.

In the area of food safety, risk analysis approaches have been applied for many years to assess and manage chemical food hazards (e.g., food additives, veterinary drugs, and pesticides). Most recently, efforts have been made to develop risk analysis techniques for addressing microbiological food risks.

The application of risk analysis techniques is a discipline that develops constantly. This article attempts to provide an up-to-date overview of the concept and the individual steps of risk analysis, introducing the emerging concept of quantitative risk management based on the target expressions food safety objective (FSO) and Performance Objective (PO).

Purpose and Role

Traditionally, the approach to food safety control, both by the food industry and by public authorities, has been technical, ad hoc, and mainly reactive, based on utilization of experience obtained from many years of exposure to various hazards, taking into account local practices, traditions, and technological possibilities. This approach has proved insufficient to ensure public health and fair international trade in foods.

Analyses of the major food safety problems that have occurred through the last decades teach that these are, most of the time, the consequences of organizational deficiencies – an indication of a lack of effective global organization in approaching food safety.

Risk analysis provides an opportunity to address these organizational difficulties by the systematic integration of scientific understanding of the risks involved and the legitimization of decisions taken. The rationale for using a formal risk analysis approach has multiple components:

1. To assist in the control of multiple foodborne risks in a proactive and cost-effective way. The multiple aspects of food safety include:
   a. Potential microbiological foodborne risks (for instance, from 'classical' salmonellosis to emerging pathologies due to protozoa or viruses).
   b. Chemical/toxicological risks, such as naturally and environmentally occurring toxicants and residues of chemicals and drugs used.
   c. New areas of concern, such as endocrine perturbation, allergenicity, genetic engineering, etc.

 doi:10.1016/B978-0-12-384731-7.00166-5

2. To support national food safety regulation by providing a sound, science-based, systematic, and target-focused tool that in addition facilitates fair international trade. The Agreement on Sanitary and Phytosanitary Measures (SPS Agreement) of the WTO has established the tenet that 'members shall assure that their sanitary and phytosanitary measures are based on an assessment, as appropriate to the circumstances, of the risk to human, animal, or plant life or health, taking into account risk assessment techniques developed by relevant international organizations.' Codex Alimentarius is in the process of establishing international principles and guidelines for risk analysis.
3. To address the increase in the social unacceptability of food risks. As food becomes objectively safer, the remaining and occasional risks are even less tolerated by the public at large, a trend that is enhanced by the general public feeling increasingly alienated from food safety control activities (decisions are perceived to be mainly the affair of the food industry and/or the public agencies with relevant jurisdiction).

However, the application of the risk analysis concept also has some disadvantages when it is used to support national food legislation. Many legislative measures are multifunctional as they address public health issues as well as other issues such as wholesomeness/suitability of foods, environmental protection, and basic animal welfare. Therefore, the challenge for legislators is to achieve sufficient transparency in the objectives of any such measure to avoid confusion.

Risk analysis is usually described as a process consisting of three elements: risk assessment, risk management, and risk communication. It is a decision-oriented process, and making decisions is a managerial activity.

Hazards and Risks

The technical meaning of the terms 'hazards' and 'risks' is often confused. This is mainly due to translation problems as, in many languages, these terms are directly translated into the same word. Although they are often synonymous in everyday life, they have taken different meanings in the technical language used in risk analysis.

A hazard is a biological, chemical, or physical agent in food, or a condition of food, with the potential to cause an adverse health effect (Codex Alimentarius). Risk is the function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard in food (Codex Alimentarius). In more common words, risk is the likelihood and severity of a failure causing death or illness among consumers. For instance, the probability of humans being affected by the presence (or number) of a pathogenic microorganism in the food is the risk, whereas the microorganism itself is the hazard.

The same confusion exists between the terms 'risk analysis' and 'hazard analysis' (of the hazard analysis and critical control point (HACCP) system). In current practice, hazard analysis is targeted at one particular food produced in one particular food plant and is, in principle, independent of any presence of the same hazard in other foods; risk analysis is a more horizontal tool for use by a government to protect the health of the population.

Risk Assessment

Risk assessment is the scientific part of risk analysis that is initiated and commissioned by risk managers. The purpose is to estimate the severity and likelihood of harm from exposure to a certain hazard by furnishing all scientific data relevant to the evaluation. The output might, for example, be an estimate of annual rate of illness per 100 000 inhabitants or an estimate of the rate of human illness as a function of the incidence of consumption.

The scientific data needed are both qualitative and quantitative. They concern the nature and sources of the hazard, how it affects human health, and how it behaves under various conditions. In addition, scientifically based information on the potential exposure to humans is needed.

The risk assessment process comprises four steps: hazard identification, exposure assessment, hazard characterization, and risk characterization. The information is passed on to the risk managers to assist them in conducting the risk management process. Codex Alimentarius has established general principles for the conduct of risk assessments.

Hazard Identification

Hazard identification is predominantly a qualitative process, the purpose of which is to identify the hazards of concern in the food under study. Hazards can be identified from relevant data sources. Information on hazards can be obtained from the scientific literature, from databases such as those in the food industry and government agencies, and through expert consultation. Relevant information includes data obtained from, for instance, clinical studies, epidemiological studies and surveillance, laboratory animal studies, investigations of the characteristics of the hazards, the interaction between hazards and their environment through the food chain, and studies on analogous hazards and situations.

Exposure Assessment

The purpose of exposure assessment is to obtain a quantitative assessment of the actual or anticipated human exposure of a food hazard. It is normally based on realistic exposure scenarios, including the potential extent of food contamination and on actual dietary information. Susceptible and high-risk population groups with regard to acute, chronic (including long term), cumulative, and/or combined adverse health effects should also be brought into consideration. Typical factors considered include:

1. The frequency of food contamination and its level in the foods over time, which are influenced by
   a. The characteristics of the hazard,
   b. The nature and ecology of the food,
   c. The initial contamination of the raw material,
   d. The level of process controls,

e. The methods of processing, packaging, distribution, and storage of the foods.

2. Patterns of consumption, which relate to socioeconomic and cultural backgrounds, ethnicity, seasonality, age differences (population demographics), regional differences, and consumer preferences and behavior.

In practice, exposure assessment of foods can be qualitatively categorized according to (1) the likelihood that the foodstuff will or will not be contaminated at its source and (2) whether or not the level of the hazards in the food can increase over time, taking into account the potential for abusive handling.

Hazard Characterization

The purpose of hazard characterization is to provide a qualitative or quantitative description of the severity and duration of adverse effects that may result from the ingestion of a hazard in food. The level of the hazard that causes an adverse health effect (dose–response assessment) should be estimated if such data are obtainable.

Several important factors that are considered in hazard characterization relate both to the hazard itself and to the human host.

Factors related to the hazard include:

- Potential for the hazard to replicate,
- Virulence and infectivity of the hazard,
- Impact of interactions between the host and the environment,
- Potential for transfer of genetic material (e.g., antibiotic resistance and virulence factors),
- Potential for spread through secondary and tertiary transmission,
- Incubation period (clinical symptoms can be substantially delayed following exposure),
- Potential for changed pathogenicity due to the attributes of a food, for example, fat content.

Factors related to the host include:

- Genetic factors,
- Increased susceptibility due to breakdowns of physiological barriers,
- Individual host susceptibility characteristics, such as age, health and medication status, concurrent infections, immune status, and previous exposure history,
- Population characteristics, such as population immunity and population behavior, and persistence of the organism in the population.

Risk Characterization

Risk characterization represents the integration of the results of hazard identification, hazard characterization, and exposure assessment, the purpose being to provide qualitative or quantitative estimates of the likelihood and severity of the adverse effects that could occur in a given population. The data may permit only a qualitative estimate of risk. The degree of confidence in the final estimation of risk depends on the variability, uncertainty, and assumptions made in all previous steps.

Variability represents heterogeneity within biological systems and populations, whereas uncertainty represents a lack of precise knowledge, associated either with the data themselves or with the choice of model, and both arise at all steps of the risk assessment process:

- Hazard identification, where uncertainty or variability may arise because of (1) misclassification of the agent; (2) the potential unreliability of the screening method used for identifying the hazard; or (3) problems in extrapolating the information provided by the screening test for predicting human hazards.
- Hazard characterization, where uncertainty and variability arise when extrapolating from high to low doses and from one species to another and when considering varying sensitivities within human populations. When models are used, additional uncertainty as to whether they represent actual biological processes is introduced. For instance, the transfer of data from animal studies into estimates relating to humans involves uncertainties. For this reason, a 100-fold safety factor (SF) is often applied to account for likely interspecies differences in susceptibility.
- Exposure assessment, where many uncertainties arise owing to lack of detailed data on, for example, the level of the agent in food, the frequency, duration and magnitude of human intake of food products, changes in concentration of the chemical or microbiological agent during storage, and processing and preparation of the food product. There is also a great deal of variability in dietary habits.
- Risk characterization, where uncertainty and variability arise because of the uncertainties and variability involved in its constituent steps and in the model used for constructing the distribution of individual or population risk.

Risk Assessment of Chemical Hazards

Chemical risk assessment in one form or another has been applied to evaluation of various chemical hazards in foods for many years. Assessments of food additives, of veterinary drug residues, and of contaminants differ fundamentally because food additives and veterinary drugs are deliberately added to food or administered to the animal, whereas contaminants are unavoidable. Further, contaminants generally demonstrate greater potential toxicity, as additives and veterinary drugs are normally subjected to safety evaluation before first use. Food additives and veterinary drugs can be easily controlled, whereas the elimination of contaminants from foods incurs costs, such as reduction in food availability and/or affordability.

Joint FAO/WHO Expert Committee on Food Additives (JECFA) and Joint FAO/WHO Meeting on Pesticide Residues (JMPR) have traditionally carried out a so-called safety assessments of food additives, food contaminants, veterinary drug residues, and pesticide residues. 'Safety assessments' is a scientifically based process consisting of:

1. Determination of a no observable effect level (NOEL).
2. Subsequent application of SFs to establish an acceptable daily intake (ADI) or tolerable daily intake (TDI).

3. Comparison of the ADI or TDI with probable exposure to the agent.

The approach is somewhat different from risk assessment but it does have the advantage of avoiding problems associated with deciding on an acceptable level of risk.

The acceptable or tolerable intake is an indication of both the magnitude and the duration of acceptable intake. The ADI usually represents an acceptable average daily intake for the lifespan of an individual. TDIs for contaminants should be compared with intake surveys of appropriate duration. In cases where no threshold is thought to exist, such as for aflatoxins, JECFA does not allocate tolerable intake values but recommends that the level of contaminant in food be reduced to as low as reasonably achievable (ALARA). The ALARA level is regarded as the concentration of a substance that cannot be eliminated from a food without having to discard that food or severely compromising the availability of major food supplies.

Codex Alimentarius has initiated a process intended to align the 'safety assessment' with the risk analysis approach.

Microbiological Risk Assessment

The risk assessment process was originally developed for chemicals. Extending the practice to pathogens poses significant difficulties. Accordingly, most microbial risk assessments currently have a qualitative base. However, in recent years, the interest in qualitative approaches to microbial food safety has dramatically increased and quantitative models for specific pathogen–food combinations have been developed.

One difficulty relates to the fact that pathogens can multiply as food moves from the farm to the table, making intake assessment very difficult. In addition, many gaps exist in the data, limiting the precision necessary for quantitative risk assessments. For example, little information is available to estimate accurately the relationship between the quantity of a biological agent and the frequency and magnitude of adverse human health effects, particularly for susceptible populations. Further, risk assessment of raw food (e.g., raw chicken) is further complicated as it has to take into account the probabilities of cross-contamination of other foods in the kitchen during domestic handling and preparation by the consumer.

Pathogens multiply and die, and their biological interactions are complex. The contamination levels of the raw material entering the food chain dictate the character of the initial microflora, but this can be markedly modified by subsequent events. Additionally, there are marked differences in the virulence and pathogenicity of animal and environmental strains, and the individual interactions of host and pathogen are highly variable.

Factors to consider for exposure assessment include the frequency and level of contamination of raw materials and the possibilities of postcontamination and cross-contamination levels in the food during shelf life. The characteristics of the pathogenic agent; the microbiological ecology of the food; the level of basic hygiene; sanitation and process controls; and the methods of processing, packaging, distribution, and storage of the foods all impact on these factors.

Pathogen levels may be kept low, for example, by proper time–temperature controls during food processing, but they can substantially increase under abusive conditions. Therefore, the exposure assessment should include different scenarios describing the pathways from production to consumption and should be constructed to predict the range of possible exposures.

Scenario trees constructed for all steps from production and processing to intended end uses of a food describe the pathway for exposure, and targeted research is often required to accumulate appropriate microbiological data. Predictive modeling is playing an important role in this respect. Unfortunately, dose–response data to allow the hazard characterization component are currently very limited.

Because of the wide variability inherent in much microbial data, Monte Carlo simulation modeling is increasingly being used to generate probabilistic risk estimates that are biologically realistic. The FAO and WHO have recently established an expert body system, Joint Expert Committee for Microbiological Risk Assessments (JEMRA), which operates similarly to JECFA and JMPR and whose tasks are to carry out microbiological risk assessments.

Physical Risk Assessment

Risk assessment for physical hazards can be readily achieved. The characteristics of the hazard do not usually change once they have been introduced to the food, and adverse health effects can usually be subjected to simple ranking systems to generate estimates of risk.

Risk Management

Risk management is a continuing process and constitutes the managerial and political part of risk analysis. It concerns the transfer of the results of risk assessment into actions in accordance with established political priorities. Risk management sets priorities, commissions risk assessments, and implements, monitors, and reviews the chosen strategies and options.

The risk management process comprises four steps: risk evaluation, risk management options assessment, implementation, and monitoring and review.

Risk management is traditionally semiquantitative but, owing to improvements in risk assessment disciplines and statistical models, a development toward fully quantitative risk management has been initiated.

Risk Evaluation

The initial part of the risk management process sets the stage for a risk assessment and evaluates the outcome of the risk assessment process, which should result in a risk estimate.

Risk profiling

A risk profile is developed when a new food safety problem has been identified or if surveillance information shows an unacceptable level or an increase in the level of a disease or a hazard. The food safety problem and its context are briefly

described, including the size and nature of the problem, available data, type of foods involved, main sources, the values expected to be placed at risk (e.g., human health and economic concerns), stakeholders' perceptions, distribution of risks and benefits, and what immediate actions may be necessary, including whether a risk assessment should be carried out. The risk profile assists the risk manager in identifying the questions that need to be answered by the risk assessment.

Target setting and appropriate level of protection

The targets for the risk management activity should be identified as early as possible to guide the rest of the decision-making process. However, the results of a subsequent risk assessment process and subsequent steps of risk management may identify needs to modify or redefine the targets.

Any target should be related to the appropriate level of protection (ALOP) – defined by the WTO (through the SPS Agreement) as the level of protection deemed appropriate by the member state to protect human life within its territory. An ALOP can be implicit or explicit. An implicit ALOP is most often stated in terms of broad public health goals or in relation to legal requirements ('reasonable certainty of no harm'). However, effective implementation of the ALOP may benefit from a more explicit articulation of public health expectations. An explicit description of an ALOP may be in terms of the probability of an adverse public health consequence or the incidence of disease (e.g., the number of cases per 100 000 population per year). Usually, when no significant food-related public health problem exists, the ALOP is the level obtained from the sanitary measures already practiced.

The key point in the SPS Agreement is that any sanitary measure has to be based on science. A government cannot restrict trade or maintain a restriction against scientific evidence. Science can, of course, be misused. Therefore, the scientific agreement also specifies that the scientific approach applicable rests on the scientific assessment principles and evaluation procedures established by international organizations, such as Codex Alimentarius.

The SPS Agreement recognizes governments' rights to decide what they regard as the ALOP, or in other words, the right to decide on the appropriate level of risk that should be valid on their territory. Accordingly, the level of protection may differ between countries, but it shall be determined using harmonized risk analysis procedures. The importance of transparency in the risk assessments carried out is, therefore, obvious. A government must be able to show which factors it has considered and what the results have been of its considerations. This is to ensure that potential differences between the regulations of two countries (e.g., differing maximum limits) are not due to differences in scientific evidence but only to differences in the politically decided acceptance levels.

Decisions on ALOP should be determined primarily by human health considerations, but other factors may legitimately be taken into account, such as technological feasibility and economic, political, or social concerns.

Different approaches to acceptable levels include:

- 'Zero-risk' policies, for example, *de minimis*, ADI.
- Risk-balancing policies, for example, cost–benefit, or ALARA.
- Risk threshold policies, for example, specified levels of risk deemed acceptable.
- Risk comparison policies, for example, comparison between sources and precedence.
- Procedural approaches, for example, negotiation and consensus building.

Risk assessment policy

Risk assessment policy setting serves to protect the essential scientific independence and integrity of the risk assessment. It provides guidelines for value judgments and policy choices that may be needed at specific decision points in the risk assessment process and addresses how to ensure transparency, clarity, and consistency of outcome and how to deal with uncertainties (e.g., application of SFs).

The JECFA and JMPR use the following risk assessment policies at specific decision points in their work.

- Reliance on animal models to establish potential human effects.
- Use of body weight scaling for interspecies comparison.
- Assumption that absorption in animals is approximately the same.
- Use of a 100-fold SF to account for likely interspecies and intraspecies differences in susceptibility, with guidelines for deviations that are permitted in specified situations.
- Decision not to assign ADIs and TDIs to food additives, veterinary drugs, and pesticides that are found to be genotoxic carcinogens.
- Establishment of temporary ADIs and TDIs for additives and residues of veterinary drugs pending submission of requested data.

Commissioning of risk assessments

Commissioning of the risk assessment process is a risk management activity that aims at ensuring that the needs of the risk managers are addressed and that resources are used in the most effective way. Typically, it includes clear statements of purpose and scope of the assessment addressing the risk management targets.

Consideration of the result of risk assessment

When the results of the risk assessment are available, a risk estimate is established. Risk estimates should take into account variability, uncertainties, and assumptions made during the risk assessment process. The need for taking action to reduce the risk is then decided.

Risk Management Options Assessment

Risk management option assessment typically includes four steps:

- Identification of available management options.
- Selection of preferred management option, including consideration of an ALOP.
- Evaluation of impact on other factors of the preferred management options.

Table 1 Risk management options

• Establishing regulatory requirements and/or creating incentives for the introduction of specific food safety management tools (e.g., good agricultural practices, good hygienic practices (GHPs), HACCP or HACCP-like tools, and product tracing systems) or for changes in attitudes in food preparation, handling, and use that will likely contribute to risk reduction in exposure to hazards.
• Establishing public inspection schemes and certification and approval procedures.
• Carrying out educational and/or information programs to the population at large and/or affected subgroups about steps they can take to reduce their exposure to hazards.
• Setting FSOs for ready-to-eat foods in general or for specific groups/types of food.
• Advising on POs at specified stages in the food/feed chain where such levels generically apply and are of critical importance to the overall chain performance.
• Establishing control measures, such as codes of practice or performance criteria specifying 'safe harbor' or 'default' measures for such parties that do not have the means to establish appropriate measures themselves or who elect to adopt such control measures.
• Prohibiting foods/feeds with a substantiated history of contamination or toxicity.
• Requiring import certificates for certain products.
• Promulgating awareness, education, and training programs or, where appropriate, initiating public inspections/audits to stimulate (1) prevention of contamination and/or introduction of pathogens being addressed at all relevant stages in the food/feed chain, including reduction in the level of specific pathogens in primary production; (2) products being labeled properly with consumer information regarding additional guarantees of safety or information being provided that either instructs regarding safe handling practices or warns regarding microbiological hazards that are likely to occur and for which adequate controls are unavailable.

- Final management decision targeted at appropriate stages throughout the food chain.

Identification of available options

Risk management options include consideration of all general and hazard-specific measures. Examples are listed in Table 1. A number of socioeconomic and technological factors may be taken into account and these could, for instance, result in the best management option being:

- Control at the source rather than later in the food chain.
- Regulation through prescribed and detailed good hygienic practice (GHP) rather than, for example, mandating the individual application of HACCP principles (e.g., for small businesses).
- Food safety verification through end-product testing rather than reliance on HACCP systems (for instance, where the origin of the food is unknown).

Selection of options

The SPS Agreement states that sanitary measures must not be more trade restrictive than required to achieve the ALOP, taking into account technical and economic feasibility. A measure would be more trade restrictive than required if another equivalent and reasonably achievable measure were significantly less restrictive.

The outcome of the risk management process for a specific hazard will differ in various societies owing to natural or cultural differences. Such a difference can be scientifically justified, for instance, in relation to the exposure situations in different countries. Differences in established levels of a hazard may, for instance, be justified where the average body weight differs and where relatively little average consumption permits higher threshold levels in a particular food. Also, the prevalence of various foodborne pathogens in the food chain and variation in foodborne disease patterns may justify different risk management outcomes.

In selecting the preferred option, the consequences of impact on other factors should be estimated, such as:

- Impact on consumption patterns (e.g., nutritional consequences of restricting food availability).
- Possible introduction of substitute risks (i.e., increasing another risk by reducing one risk; for instance, increasing microbial risks when not allowing the use of preservatives).
- Impact on public acceptability of measures that interfere with cultural patterns and traditions (e.g., restriction in the availability of tartare (raw minced beef)).

Equivalence

Differences in regulatory food safety systems inevitably exist between countries. Therefore, determination of the equivalence in the sanitary measures applied in importing and exporting countries is becoming a priority issue in international trade. The SPS Agreement requires that sanitary measures of other countries be accepted as equivalent, even if they differ from their own or others, if the exporting country objectively demonstrates that its measures achieve the ALOP established by the importing country.

Codex Alimentarius has developed a framework for the determination of equivalence that requires the development and application of principles and guidelines similar to the risk analysis approach.

Monitoring and Reviewing Implemented Risk Management

An important part of risk management is monitoring whether it is effective, for instance, through ongoing gathering, analysis, and interpretation of data to determine how well risk management activities have been performed and to determine what steps may need to be taken next to better improve public health. Monitoring and surveillance activities provide important information for reviewing whether the ALOPs are being achieved. In most cases, monitoring and reviewing public health outcomes will be a measure of the effectiveness of regulatory food control programs.

Reviews are also necessary when new data become available that might substantively alter the conclusions of a risk assessment or its associated degree of uncertainty. Such data include new information on the virulence, the prevalence and levels of the hazards in foods, the proportion of sensitive populations, changes in dietary intake patterns, changes in food processing patterns, as well as data from epidemiological studies and surveillance and monitoring programs in relation to foodborne diseases.

Quantitative Risk Management

The philosophy behind quantitative risk management is the full recognition of the fact that food safety (i.e., that the food is safe when consumed) is the result of a continuum of control measures (all actions and activities that impact the level of hazards in food) applied along the whole food chain, from the production of feed material to the preparation of the food by the consumer. Quantitative risk management activities address the whole continuum and not individual parts of the food chain in isolation.

Traditionally, the stringency of a food safety system has been articulated using control measures at various points within the food chain; the actual impact on consumers' exposure to a hazard has, at best, been inferred. For instance, risk management in the earlier stages of a food chain is traditionally based on the development and implementation of codes or guidelines on GHP. In many countries these are developed and established by public health authorities and are intended to be applied uniformly, independently of HACCP plans at the manufacturing level. In other words, the quality of raw materials is often defined by public health authorities, and it is left to the HACCP system of the manufacturer to adapt controls to the hazard levels resulting from compliance with these codes. As a result, the continuum is not fully assured (e.g., new hazards or sporadically occurring hazards at primary production levels that require immediate action cannot wait to be addressed by the amended codes of practices in place). Further, the HACCP concept introduced in the 1990s introduced a systematic approach to identifying hazards that need to be controlled by a particular establishment (focusing on the food manufacturing stage) and for the identification and management of key control measures applied directly to the food. However, this system does not address the degree of stringency needed in regard of food safety outcomes.

With the development of risk assessment techniques, it is increasingly possible to derive the maximum tolerable consumers' exposure in relation to the degree of acceptable risk. Quantitative risk management is aimed at achieving a coherent food chain approach that achieves this.

The key objective for the quantitative risk management approach will be to provide guidance on the stringency required to control a specific risk through the identification of targets for acceptable hazard levels at various stages along the food chain and to ensure that these targets are mutually linked to the ALOP.

Food Safety Objective

Recognizing the difficulty of relating control measures directly to an ALOP, the concept of FSO has been introduced to assist in the practical implementation of an ALOP. Conceptually, the FSO can be viewed as the consumers' maximum level of exposure to a hazard that provides or contributes to the ALOP. As such, an FSO articulates the overall performance expected of a food chain in order to reach a stated or implied public health goal. The overall performance results from the level of control achieved by the food safety system deployed from 'farm to fork.'

FSOs express the tolerable level of exposure to consumers in terms of the maximum level of a hazard (or maximum frequency of occurrence of a hazard) in a food at the time of consumption. FSOs can be established for the following purposes:

- To translate the ALOP (whether explicit or implicit) into a more useful parameter for interested parties and to encourage change in operational food safety management, or in the behavior of consumers, in order to enhance the safety of certain products.
- For communication to parties involved in food trade: implemented FSOs may not be universally common and will take into account national and regional situations.
- By the food businesses to design their operational food safety management systems, for example, through selecting appropriate target levels in the end products and to determine the necessary control measures to achieve them.
- To encourage the use in food businesses of quantitative HACCP and other food safety management systems.

Other Quantitative Food Safety Targets

Quantitative risk management requires that additional risk-based milestones be established that articulate how different stages of the overall food safety systems must function to achieve the ultimate food safety outcome required (e.g., the FSO). As a means of addressing this need, two related terms, PO and Performance Criterion (PC), have been introduced.

Performance Objective

The purpose of a PO is to articulate the maximum level of a hazard in a food at a particular stage in the food chain that provides or contributes to an FSO.

The etiology of some foodborne diseases predominantly involves the direct consumption of a contaminated ready-to-eat food (e.g., *Listeria monocytogenes* in soft cheese, *Staphylococcus aureus* in fermented meats, and *Salmonella* in fresh product). In this instance, the consumers' risks are determined by the frequency and extent of contamination in the product at the moment of ingestion. To manage the exposure to consumers of hazards associated with such foods, the establishment of FSOs is appropriate.

With other combinations of disease and foods (particularly raw products that are cooked just before consumption), the etiology of a disease involves cross-contamination. Here a raw food serves as a source of a contamination for other ready-to-eat foods, i.e., ones that are not cooked just before consumption (examples include *Campylobacter jejuni* on raw poultry and *Salmonella* on raw foods of animal origin). The consumers' risks are determined by the frequency and the quantitative level of contamination of the raw product and by the level of the

pathogen after final cooking (except in the case of appropriate cooking to kill pathogens). To manage the exposure to consumers of hazards associated with such foods, the establishment of POs will be appropriate, provided that there is a valid link between it and the FSO that it is trying to address.

Within the HACCP context, a PO is equivalent to 'acceptable level' of a hazard in the end product. A PO intended at a specific step in the food chain for a product that is delivered from one establishment to another for further processing is established taking into account knowledge, such as (1) the probability and extent of growth under specified storage and transport conditions and (2) the requirements of the other establishment to enable it to meet the PO for the further processed product. A PO intended for a ready-to-eat food at the point of delivery from the processing establishment is established taking into account knowledge of (1) the probability and extent of growth under specified storage, transport, and distribution conditions, (2) the expected shelf life, and (3) the expected changes in hazard levels during preparation by the consumer.

Performance Criterion

How the required PO can be achieved can be articulated through Performance Criteria (PCs). A PC expresses the change (effect) in the level of a hazard in a product that must be achieved by the application of one or more control measures to provide or contributes to a PO. The change required can be a minimum reduction, a maximum increase, or no change, depending on the nature and use of the control measures. This can be conceptualized in eqn [1].

$$\text{Performance Criterion} = [\log_{10}(C_0) - \log_{10}(C)] + \log_{10}(\text{SF}) \quad [1]$$

where C_0 and C are the initial and final (i.e., after application of the control measure) concentrations of the hazard, respectively. An SF can be imposed to take into account uncertainties in the effects of subsequent control measures. (For instance, if C_0 is 10 cfu (colony-forming units) of the hazard per gram and if the final concentration C has to be no more than 10^{-6} cfu of the hazard per gram with an SF of 100, then the PC is equal to 12; thus the calculation specifies that the control measure must deliver a performance of a 12 log reduction in the concentration of the pathogen.)

The following conceptual eqn [2] can help express the dynamics in the hazard control applied by a food business:

$$H_0 - \sum R + \sum I \leq \text{PO or FSO} \quad [2]$$

where H_0 is the initial concentration of the hazard, $\sum R$ is the sum of reductions (PCs) in the hazard concentration achieved by control measures and $\sum I$ is the sum of increases (PCs) in hazard concentration as a result of growth and/or contamination.

Risk Communication

Risk communication is the third component of risk analysis and is a central and integral part of effective food safety management.

Every stage of risk management should rely on a wide exchange of information and opinions about risk between risk managers, risk assessors, and all other stakeholders concerned about or affected by the problem and the risk management decision. Risk communication and the involvement of stakeholders are crucial for open, transparent, and effective decision making. Communication of correct and updated risk assessment information to the food manufacturers is also crucial to enable them to conduct correct hazard analyses and designs of HACCP plans.

Risk communication aids in considering the different, and at times conflicting, interpretations of the nature and magnitude of the risk; it offers the opportunity to bridge gaps in understanding, language, values, and perceptions; it ensures that public values are considered; and it generates better-accepted and more readily implemented risk management decisions. In brief, it supports democratic decision making. Poor risk communication will almost always increase conflict and distrust over risk management decisions.

Glossary

Bite The resistance of the surface as the consumer initially bites into a sausage.
Collagen A stromal protein that is the major component of animal skin and intestinal tract.
Cooked sausage A sausage that has been fully cooked during thermal processing. May or may not be smoked as well.
Dry sausage Dry sausages have lost approximately 30% of original weight during subsequent processing. Exact definition may be subject to regulatory requirements.
Semidry sausage Semidry sausages have lost approximately 15% of original weight during subsequent processing. Exact definition may be subject to regulatory requirements.

Animal Casings

In any discussion of sausage casings, it is necessary to begin with the oldest of our packaging materials for sausage: the animal casing. For centuries, animal casings have been the traditional containers for sausage materials and are still associated with high-quality sausage products. They offer a unique combination of properties that provide valuable processing characteristics and fit the requirements for natural products, which are increasingly more popular. The material, made from the animals' intestinal tract that is used for the casings, is actually the submucosa, a collagen layer that provides the strength to the particular organ. For the most part, with a few exceptions, the fatty outer layers of muscle are removed along with the inner layer, the mucosa. Because the material used is collagen, the treatment of the casing at the slaughtering plant and during subsequent steps in casing processing has a very definite effect on the utility of the final product.

As in the case of all collagen materials, the collagen in casings is hardened and rendered less soluble by the application of salt. This is essentially the same process used in the curing of hides. Thus, the salting of the casing at the slaughtering plant has a great deal to do with appropriate curing and the final quality of the finished casing.

The collagen material that is the basic structure of animal casings has unique characteristics that are applicable during processing. Initially, as the collagen is exposed to heat and drying, it becomes less permeable to moisture. This drying also affects smoke penetration. For this reason, the initial step in the processing of a sausage in animal casings requires drying to develop the appropriate smoke permeability. Once the smoke is applied, and the desired smoke color and concentration are attained, further drying will render the casing virtually impermeable to moisture. It can then be cooked in a variety of ways, including steam cooking, without injuring the final product. In fact, at one time it was customary to apply the smoke and dry the casing in the smokehouse and then finish, particularly small-diameter products, by water cooking. This variable permeability becomes a very useful tool in further processing and enables the animal casing to accommodate a wide variety of conditions.

Small-diameter animal casings are derived from the small intestines of hogs and sheep (Figures 1 and 2). The sheep casings are the smallest in diameter and are also the most tender. These are the most adaptable to fresh sausages, where there is no further processing to tenderize the casing, as well as to small-diameter cooked and smoked sausages. There are different grades of sheep casing. The B grade has small holes

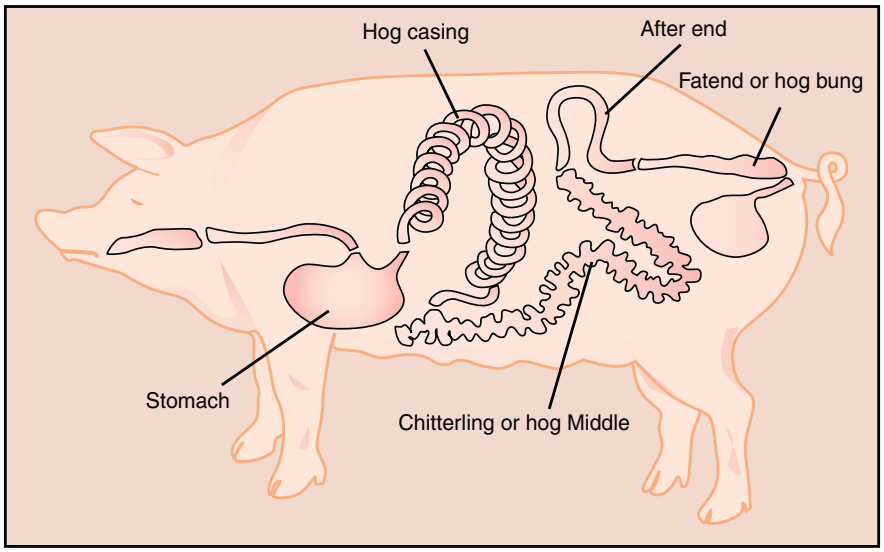

Figure 1 Hog intestines.

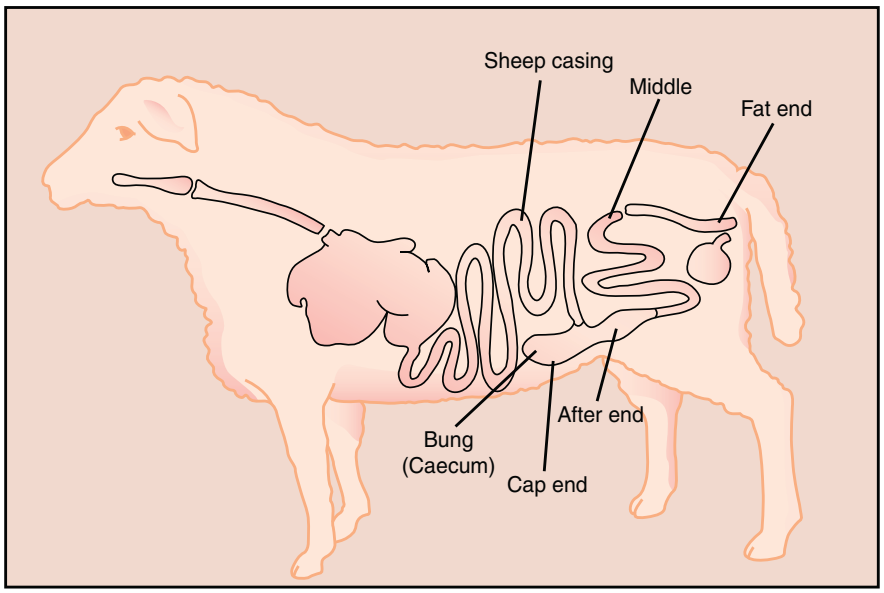

Figure 2 Sheep intestines.

and is applicable primarily to coarse-ground fresh sausage. The A grade is most applicable to an emulsion-type sausage. Hog casings are used for some types of fresh sausage as well as a variety of smoked, dry, and semidry sausages. They are somewhat less tender than sheep casings.

Sheep and hog casings are sold in bundles or hanks comprising of 91 m of casing. Diameters of sheep casings range from 16 mm to approximately 28 mm. Hog casings range from 30 mm to approximately 44 mm. They are normally grouped in 2 mm increments.

Casings of a small diameter are available in a variety of forms. They can be dry salted, and then require flushing before use. During the flushing process, the casing can be examined for strength, punctures, and conformance to size specifications. Preflushed casings are packed in a brine solution. Pretubed casings are shirred onto a plastic sleeve; these can then be transferred directly to the stuffing horn. To improve production efficiency, some processors will flush the casings in a separate location and then shirr them onto a stainless steel mandrel, so that they can be quickly applied to the stuffing horn.

During smoking and cooking, the initial critical steps of drying and smoke application must be watched very carefully. Before smoke is applied, the casing should be dried to the point at which it is tacky. If it is not, the smoke will penetrate through the casing and be deposited on the meat surface, thereby allowing for casing separation and causing a pale, dull appearance. By the same token, if the sausage is overdried, the smoke will essentially be deposited only on the outside surface

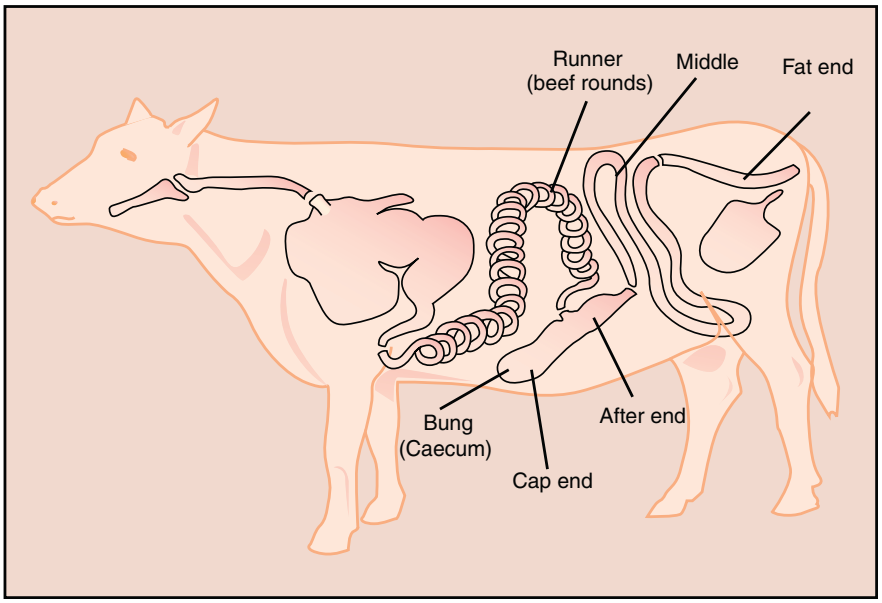

Figure 3 Beef intestines.

with very little flavor effect. Animal casings are ideally suited to liquid smoke application, either by drenching or by atomization.

There is a variety of larger-diameter natural casings available (Figure 3). Beef rounds, from the small intestine, are generally used for ring-type sausages. In terms of handling characteristics, the same type of handling as applied to sheep and hog casings can be used. Beef rounds are probably the largest-diameter casings that one would classify as still being edible from a palatability standpoint. Diameters range from 35 to 46 mm. They are sold in bundles or sets of 9, 18, or 30 m. Other beef casings are beef bung caps, ranging from 75 to 125 mm. These are used for some cooked as well as dry and semidry sausages and are sold by the piece. Beef middles, used for various dry and semidry sausages, range in diameter from 45 to 65 mm and are also sold by the piece. Beef bladders are used for some specialties such as mortadella. Some of these larger-diameter sausages require support when hanging; the support can be either a series of string loops or netting. Most beef casings would typically be removed from the sausage before consumption.

One type of large-diameter casing that is used quite often is the sewn casing, particularly the sewn bung. Sewn hog bungs are used not only for some salamis and cervelats but also for various types of liver products. Sometimes these sewn casings are lined with paper or with another type of animal casing such as hog bungs lined with beef middles. In the case of sewn bungs, the fat layer of the bung is left on the inside of the casing. Particular care should be applied to these casings to check the rancidity level of this fat layer. Salt triggers the development of rancidity and, unless these casings have been carefully and properly handled, rancidity of this fat layer could develop. Subsequently, this rancidity could be transferred to the finished product in the form of an off-flavor. Animal casings should be stored under refrigeration at a temperature of less than 4 °C.

Even when carefully graded, animal casings lack a degree of uniformity and are therefore somewhat limited in their machinability. For this reason, handling animal casings requires somewhat higher labor input than one would experience with the machine-made casings. This is where the processor must make some management decisions depending on the type of the product that is manufactured and the clientele to which it is to be sold.

Laminated Casings

Some large-diameter casings are made by laminating pieces of hog or sheep casings on a mandrel; the casing is subsequently dried. This gives a natural casing with uniform dimensions and also with the possibility of unique shapes. In addition, various netting patterns can be incorporated in the lamination. The primary use of this casing is for dry and semidry sausages.

Manufactured Collagen Casings

A logical development from the animal casing is a manufactured casing made from the same material chemically as the animal casing, that is, collagen. The manufactured collagen casing is commonly made from the regenerated corium layer of beef hides, though actually any source of collagen could be used. The collagen is solubilized and later extruded and hardened in a manner very similar to the production technique used for cellulose casings. Because of its chemical nature, namely collagen, it does have some of the same processing characteristics as the animal casings; however, collagen casings do not require soaking or rinsing steps before stuffing and product diameters of the stuffed sausages are much more uniform compared to animal casings. Once again, the drying step in the manufacture of cooked and smoked sausage is

critical, as is the ability of this casing to dry or to soften during processing of the sausage. Characteristics of these collagen casings vary with different manufacturers. It is therefore a good idea to approach the smokehouse processing of collagen casings on the basis of recommendations from the manufacturer.

As with animal casings, the application of heat together with drying and an acid, such as found in smoke, will toughen the material. The application of heat with moisture will tend to soften it. For this reason, cooking and smoking steps have to be carefully controlled to provide an acceptable 'bite' to the end product, but at the same time, not to soften the casings excessively so that they will drop in the smokehouse. Balancing of drying, smoking, and subsequent cooking steps is extremely critical.

There are a variety of types of collagen casings. Some are specifically designed for fresh sausage, others for cooked sausage, and still others for dry and semidry products like snack sticks. Because of performance differences and differences in tenderness, these specific types are not interchangeable. Collagen casings intended for fresh sausages are designed to be tender, because there will not be a high humidity cooking process applied to this product that would increase tenderness.

With the small-diameter collagen casings, there is another factor to be considered. This is the so-called 'wetting out' immediately after stuffing. When the meat is stuffed into these casings, the casings will absorb moisture from the meat. During this period of moisture absorption, the casing softens and becomes more pliable. If allowed to soften too much, it will not be machinable during the subsequent linking steps. The wetting out of a casing is highly dependent on the material that is stuffed into it, particularly from the standpoints of moisture content and temperature as well as the characteristics of the individual casing itself. Delay times between stuffing and subsequent linking need to be very carefully controlled if casing breakage is to be prevented. Proper wetting out before linking may also affect the performance of the sausage during cooking resulting in a 'dumb bell' effect, that is, protruding ends. This phenomenon can also result when the casings are overstuffed.

Processed meat collagen casings are also available for products that require cooking and smoking. These casings are designed to withstand linking and hanging and are available as colored casings. A type of collagen casing that is applicable to dry and some semidry sausages is made with a layer of collagen reinforced by a cotton or silk mesh or netting. These can also have built-in string loops to resemble the string-supported animal casings.

Collagen casings are available in a variety of sizes. Many of them are designed, in effect, to simulate the animal casings. Some have built-in curves and even built-in irregularities. Collagen casings are sometimes sewn into shapes to simulate a sewn animal casing.

Whereas collagen casing does not require refrigerated storage, the proper storage of collagen casings is critical. Collagen casings can be stored at room temperature but may dry out and become brittle if the original packaging is disturbed. The manufacturer's instructions for proper storage should be followed not only with collagen casings but also with all other casings as well.

For the most part, collagen casings lend themselves well to machine handling because they can be produced with uniform sizes. The manufacturers of both stuffing and linking machines as well as the casing manufacturers should be consulted, however, for appropriate information on how best to handle these particular manufactured casings.

Cellulose Casings

Cellulose casings are made from regenerated cellulose derived from high-grade wood pulp. Cellulose casings are divided into two groups: peelable and fibrous. Peelable cellulose casings are small-diameter casings that are permeable to smoke and moisture but relatively impermeable to fat and some of the larger organic molecules. The permeability can be affected by the moisture conditions surrounding the casings. Higher moisture conditions allow for a greater degree of permeability, whereas drying tends to reduce the permeability somewhat. However, these changes in permeability are not nearly as drastic as one finds in the animal casing. The sausage raw material is stuffed into the casing, the casing is linked, and the product is subsequently cooked (usually with smoke). The proteins at the surface of the sausage are denatured to form a skin, and after chilling, the casing is peeled to produce a skinless sausage. Because of their precise diameters, these casings lend themselves to high-speed linking and stuffing. If the stuffing and linking equipment is precisely controlled along with the further processing steps, precise link weights can be achieved, enabling exact unit weight packaging.

A number of key considerations in the application of peelable cellulose casings affect performance. Adherence to the manufacturer's recommended stuffing diameter (RSD) is one. Overstuffing can cause breakage and poor peelability. Understuffing can cause inexact link weights and contributes to fatting out during thermal processing. These casings are also sensitive to cooking and smoking cycles, and the correct cycle must be used for the particular type of product and the type of casing. There are two types of peelable cellulose, the 'regular' and 'enhanced' peelabilty, each requiring different processing conditions. Peelability is dependent on proper skin formation on the surface of the product. The sausage formulation must have sufficient protein to enable skin formation. Further, there needs to be some source of an acid such as those derived from smoke or liquid smoke to enable the surface coagulation of the protein. Moisture between the casing and sausage surface aids peelability. For this reason, a high humidity cooking step is usually applied at the end of the cooking cycle. Humectants such as dextrose in the formulation also will aid peelability.

Fibrous Casings

Larger-diameter cellulose casings are known as fibrous casings. Fibrous casings are made by impregnating a strong paper-like material with cellulose. The chief advantages of the fibrous casing are its machinability and its uniformity, which adapts it to high-speed operations. Fibrous casings require soaking before use to ensure sufficient pliability during stuffing. When

exact weight control is critical, cellulose casings for small-diameter products or fibrous for large-diameter products come into their own. All of these casings, when properly handled, have good dimensional stability.

There are specific types of fibrous casings for specific uses. For example, on a dry or semidry sausage, it may be necessary to have a casing that will shrink with the product as it dries. For this reason, casings with a special adherence coating are available. These casings adhere very tightly to the surface of the meat and, as the meat begins to shrink during drying, the casing will do likewise. If there were not this adherence at the meat-casing interface, the casing would loosen from the product. Where these casings are used, it is important that the processing steps be observed carefully. If too much moisture is applied before bonding between the protein-coated casing surface and the meat, the casing can be made to loosen from the product. For a product that is designed for slicing, a fibrous casing that is easily peelable is preferable. This casing can be stripped off of the finished product before the slicing operation. Long casing lengths have been employed in slicing operations, in order to minimize the rework from the ends. To maintain dimensional stability during cooking and processing, however, any product over approximately 60 cm long should be heat processed in the horizontal position to preclude dimensional distortion.

When casings are to be applied to a chunked product such as, a sectioned and formed ham, where air needs escape from the surface, a so-called prestuck casing is available. This has minute holes in the surface of the casing, which allow entrapped air to escape. Where large, whole-muscle pieces like hams are stuffed, it is often necessary to drill some large holes at the clipped end of the casing to allow the air to escape as the casing is being stuffed.

Moisture-proof fibrous casings are used for those products that will be water or steam cooked. For the most part, this applies to liver sausage, patés, and delicatessen loaves. A moisture barrier coating, such as polyvinylidene chloride (PVDC), is applied to the fibrous casing to make the casing moisture impervious. Depending on the manufacturer, this coating can be applied either to the inside or outside surface of the casing.

As with all other manufactured casings, it is very important to observe RSD and the manufacturer's recommendations for further processing. The best insurance for maximum performance is to ask the supplier for appropriate directions on proper use. Storage times, temperatures, and humidity should be observed, as all of these can drastically affect performance. The interior of these casings may be coated with a variety of flavorings such as liquid smoke that can ultimately transfer to the surface of the product. In effect, the processor can produce a smoked product without a traditional smoking step. In a similar manner, coloring agents such as caramel coloring can be applied. By applying smoke flavoring along with a dark coloring agent, it is possible to make a product with color and flavor similar to a heavily smoked 'black forest' ham.

Plastic Casings

In some cases, a moisture-impermeable material such as PVDC, mylar, polyethylene, or a polyamide (nylon) is used as a casing. Plastic casings are usually cost-effective but they may have drawbacks such as dimensional instability. These casings generally are impervious to moisture and smoke, although there are now some smoke- and moisture-permeable plastic casings on the market. Where the moisture-proof casings are used, and various flavorings are desired, these must be incorporated directly into the product or coated onto the inside of the casing. Colorings can be similarly applied to the surface of the product by coating them on the inside of the casing.

The impermeable plastic casings have the advantage of protecting the finished product from microbial contamination as long as the plastic casing remains intact.

Fabric Casings

Sewn cotton bags or tubes are used for some types of sausage. Typical was the use of a cotton bag to encase traditional fresh pork sausage made on the farm, particularly in the southern part of the USA. There are now a variety of fabric casings available, some of which are sewn and printed for novelty effects such as animals or holiday symbols. There are also sewn fabric casings that are spice coated on the inside for the purpose of transferring that spice coating to the surface of the finished sausage.

Coextrusion

A relatively recent technology is the coextrusion of collagen dough (the basic material from which collagen casings are formed) on the surface of a sausage raw material as it is extruded through the stuffing horn. The collagen is subsequently hardened to form the casing on the surface of the sausage. This then becomes a continuous process for the manufacture of an encased sausage. The process is applicable to fresh, cooked, and dry or semidry sausages. A more recent introduction is the use of an alginate slurry to encase the sausage as it is extruded. The alginate is hardened and the sausage is cooked, thus forming a sausage with an alginate casing. The process is similar to the coextrusion of collagen, except that the application of the alginate is by coating or enrobing rather than coextrusion as such.

In earlier years, this process required substantial investment in a single-product dedicated equipment. As technology has progressed, capital costs have lowered and production lines have become more flexible. The use of this essentially coextrusion technology is often coupled with packaging of the sausage in a single-layer impervious film where the final cooking steps are accomplished in the sealed package. The result is a product with extended shelf life and freedom from food borne pathogens assuming, of course, that the thermal processing steps are properly designed.

Glossary

Belly The side and underside of a pork carcass.
Butt The upper portion of the front leg or shoulder of a pork carcass. Often used for making sausage because it contains more connective tissue and is inherently not as tender as a roast or chop compared to other pork cuts.
Chub A short, cylindrical-shaped package typically used for bulk ground products, but may also be used for cooked products.
Die plate A perforated plate through which meat is forced during the grinding process.
Extrusion The process of forcing meat or other materials through a die plate, as occurs during the grinding process.
Fresh sausage 'Fresh' can mean uncooked, uncured, or both, in relation to sausage.
Link The process of twisting, or tying, a filled sausage casing to achieve the desired sausage length. It is also the single unit that sausages are merchandised in, when sold in a casing.
Picnic The lower portion of the front leg or shoulder of a pork carcass. Often used for making sausage because it contains more connective tissue and is inherently not as tender as a roast or chop compared to other pork cuts.
Ready-to-eat Meat products that are fully cooked and ready for consumers to eat directly from the package, without reheating.
Stuff The process of filling a sausage casing.

Introduction

Sausage is typically defined as a mixture of ground meat, combined with spices and seasonings. Sausage is often stuffed into some type of casing and linked, but loose sausage products are also available. Originally, sausage was made as a means to salvage value from trimmings and lower-value cuts of meat. As well as adding value to meat, over time, cooked sausage products have become convenient meat products, as they are 'ready-to-eat' (RTE) and are easy to eat in the form of a sandwich. Cooked sausage products also add great variety to consumers' food choices owing to an endless variety of spices and flavorings that are available when making these products. Traditionally, there were sausage products that were only sold as cooked products, however, processors are now offering many of their traditional fresh or uncooked sausage products in a cooked form. This article focuses on the production and descriptions of the most common types of cooked sausages.

List of Sausages

Andouille, Bangers, Berliner Bologna, Bierwurst, Bologna, Blood sausage, Bockwurst, Bratwurst, Brown and serve sausage, Braunschweiger, Chorizo, Cocktail frankfurters, Cooked or Cotto salami, Corn dogs, Frankfurters, Goetta, Hot dogs, Kielbasa, Knackwurst, Kuemmelwurst, Linguisa, Lyonerwurst, Mortadella, Paté, Pfefferwurst, Pizza toppings, Ready-to-eat products, Schinkenwurst, Scrapple, Smoked sausage, Smokie links, Taco fillings, Thuringer, Vienna Sausages, Water-holding capacity, Weisswurst, and Wieners,

Cooked Sausage Production

Cooked sausage products are made from a variety of cuts or trimmings from various types of meat (beef, pork, lamb, veal, turkey, chicken, etc.). Shoulder cuts, which consist of many

smaller muscles and typically contain more connective tissue, are often used to make sausage products. The 'picnic' portion of the pork shoulder is a good example of a shoulder cut used for making cooked sausage, and the 'butt' portion of the pork shoulder is often selected when a darker product color is desired. Also, the belly portion of a beef carcass, otherwise known as the beef 'plate,' is also used in sausage processing.

Meat from the entire carcass of older animals (e.g., cows and sows) would also be a potential raw material for making cooked sausages. Variety meats, such as livers and hearts, were traditionally used in some meat products, but are used to a lesser extent in sausage products made today.

Meat ingredients are first coarsely ground through a mincer with holes of approximately 12.5 mm (0.5 in.) (Figure 1). The grinding process is essentially an extrusion process and grinding of meat can be compared to the use of the child's toy, the 'Play-Doh Factory.' Meat (like the Play-Doh) is forced through a plate by the action of an auger, and as strands of meat are forced through the plate, revolving knives cut the strands into short particles (similar to how one might cut Play-Doh strands as they are formed after being forced through the die).

Following the coarse grinding process, the meat ingredients are mixed with the nonmeat ingredients, such as salt, sugar, water, nitrite, erythorbate, spices, and flavorings, until a uniform product is achieved.

Salt is added to cooked sausage products for flavor and preservation purposes, as well as for extracting and solubilizing proteins from the meat, which will assist in binding the ground meat particles together to result in the texture associated with cooked sausages.

Sugar (or other forms of sweeteners) is added as a flavoring, as well as to increase the water-holding capacity to prevent moisture loss from these products when they are cooked.

Water is added to cooked sausages to assist in the extraction of the meat proteins and to improve the binding ability of the ground meat particles. Added water also replaces the moisture that is lost from these products during cooking.

Nitrite is the key ingredient in making a 'cured' meat product and is added to give the products the characteristic cured color and flavor. Equally important, nitrite also has antimicrobial properties, preventing the growth of pathogenic bacteria such as *Clostridium botulinum*.

A 'cure accelerator' is typically used in production of cooked sausage products, particularly with modern processing systems, which allow minimal time for the cured color reaction. Cure accelerators include sodium erythorbate, sodium ascorbate, ascorbic acid, and sodium acid pyrophosphate.

Soy proteins bind water and are often added to pizza toppings and taco-filling meat products, as these products are typically served hot and it is critical that moisture and fat loss are minimized during the cooking and hot-holding of these products.

For a ground sausage product, in which protein extraction and binding are important for texture, the mixture is typically given a final grinding through a smaller plate before the final mixing process. The lean portion should be mixed as long as is feasible at the coldest temperature possible, with the salt (and phosphate, if used), to optimize protein extraction. After the fatter ingredients are added, mixing time should be minimized and the product kept as cold as possible to minimize fat smearing during stuffing. Paddle mixers are also preferred for extracting protein, while minimizing fat smearing and uniformly mixing multiple types of meat with nonmeat ingredients. The final grinding step can affect the texture of the product, because the grinder plate holes can have diameters ranging from 12.5 mm (0.5 in.) to 3 mm (0.13 in.). If the product includes nonmeat ingredients such as cheese, peppercorns, encapsulated acids, etc., then the final mixing step needs to follow the second grinding step.

The final grinding step should occur after the mixing step for ground products in which the particle definition is important, but in which the protein extraction for product binding is not so critical, such as cotto salami. Ribbon mixers should be avoided if particle definition is important. This is also true for products in which a more crumbly texture is desired. For a fine-chopped product, the meat mixture would be

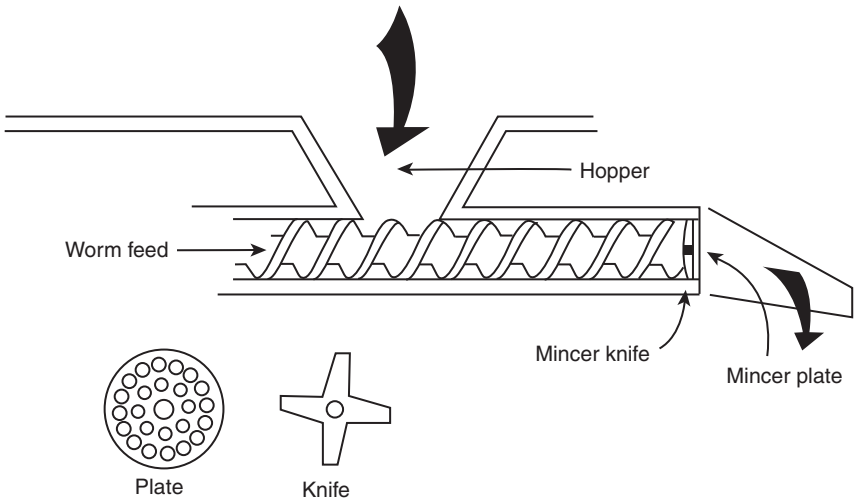

Figure 1 Cross-section of a meat grinder. Reproduced from Kramlich, W.E., Pearson, A.M., Tauber, F.W., 1975. Processed Meats. Westport, CT: AVI Publishing Company Inc., p. 124, with permission of Kluwer Academic Publishers.

chopped or emulsified using either a bowl chopper or an emulsifier.

Vacuum mixing removes air bubbles and pockets, which compacts meat volume and improves appearance of cooked sausage products. It is important for both the quality and the safety of the products to keep the temperature of the raw mixtures below 4 °C (40 °F). For coarse-ground sausages, stuffing the mixture below 4 °C prevents smearing of the fat particles along the inside wall of the casing, resulting in a more desirable particle definition.

After grinding, chopping, or emulsification, the mixture is stuffed into a casing to give it its distinctive shape and appearance, and the resultant sausage is then cooked in an oven, in water, or in oil. Sausages that are cooked in an oven are typically smoked, using either natural or liquid smoke. Figure 2 provides a flow chart of the production process.

Most cooked sausage products are fully cooked and are referred to as RTE products. RTE products can be eaten directly out of the package without further cooking.

The following discussion of cured and uncured cooked sausage products includes general characteristics of a variety of products. The USDA Food Safety Inspection Service has standards of identity for many of these products, as do many other countries. These standards of identity provide requirements that processors must meet in order to use product names on their labels, and these requirements may vary from country to country.

Cured Sausage Products

The majority of cooked sausages are cured, which involves the addition of sodium nitrite to the meat. Examples of cooked, cured sausage products include frankfurters, wieners, hot dogs, bologna, smoked sausage, Italian sausage, and braunschweiger or liver sausage.

Andouille

A spicy coarse-ground, smoked pork sausage, Andouille was introduced to the United States by French immigrants to Louisiana and is often associated with Cajun cuisine.

Berliner Bologna

Berliner is a German-style bologna, made from coarse-ground pork, mixed with pieces of ham and stuffed into large diameter casings. If this mixture is stuffed into a chub, it would be called leona bologna, and if stuffed into a smaller diameter casing it would be called jagdwurst.

Bierwurst

A large diameter, coarse-ground, cooked smoked sausage, of German origin, bierwurst is often stuffed into hog bungs (veined natural casings). It is like beef salami, however, it may contain pork. Garlic is a common flavoring for this product.

Bologna

Although bologna is most commonly made as a finely chopped product, it could be made with a coarse-ground texture, using grinder plate hole diameters ranging from 2.4 mm (0.09 in.) to 3 mm (0.13 in.) for the final grinding. Bologna is most often stuffed into larger-diameter (10–13 cm/4–5 in.) casings, but may be stuffed into beef rounds to make ring bologna. Large-diameter bologna is not typically smoked.

Additional information on finely chopped or emulsified bologna, as well as background and seasoning information, can be found in the article on emulsion sausages.

Braunschweiger

Braunschweiger is a smooth-textured liver sausage, typically made from finely chopped or coarsely ground pork trimmings, livers, and bacon trimmings, and cooked in moisture-impermeable casings in water. If stuffed into a natural casing, it can be smoked as well. Onion and nutmeg are common flavorings for this product. Smoked bacon provides additional flavor, particularly to braunschweiger. Nonfat dry milk is used to improve the harsh flavor of liver. If cooked meat is used instead of raw ingredients, a spreadable product (see section Paté) is produced.

Cocktail Frankfurters

Cocktail frankfurters are short, small-diameter frankfurters, made in a finely chopped form and typically used as appetizers. Currently, cocktail frankfurters are often produced by a co-extrusion process that does not require the use of a casing.

Cooked or Cotto Salami

Cooked or cotto salami are not dry sausages, as is Genoa salami, but are fully cooked products and need to be refrigerated before eating. Cotto salami is made using a large diameter casing, and is typically an all-beef product. It is a mildly flavored sausage, and may be smoked. Black pepper, particularly in the form of whole peppercorns, creates the flavor of cotto salami. Mustard is used heavily in cotto salami, and nutmeg is used in low levels. Other names for cooked salami include: Kosher salami, beef salami and beer salami.

Corn Dogs

Corn dogs are made by dipping frankfurters in a corn meal batter and frying them in oil. In the United States, corn dogs are limited to 65% batter and 35% frankfurter.

Fleischwurst

Fleischwurst is a large diameter, fine chopped German bologna, which typically contains pistachio nuts. Also known as Vienna Bologna, it may also be sold in rings and chubs.

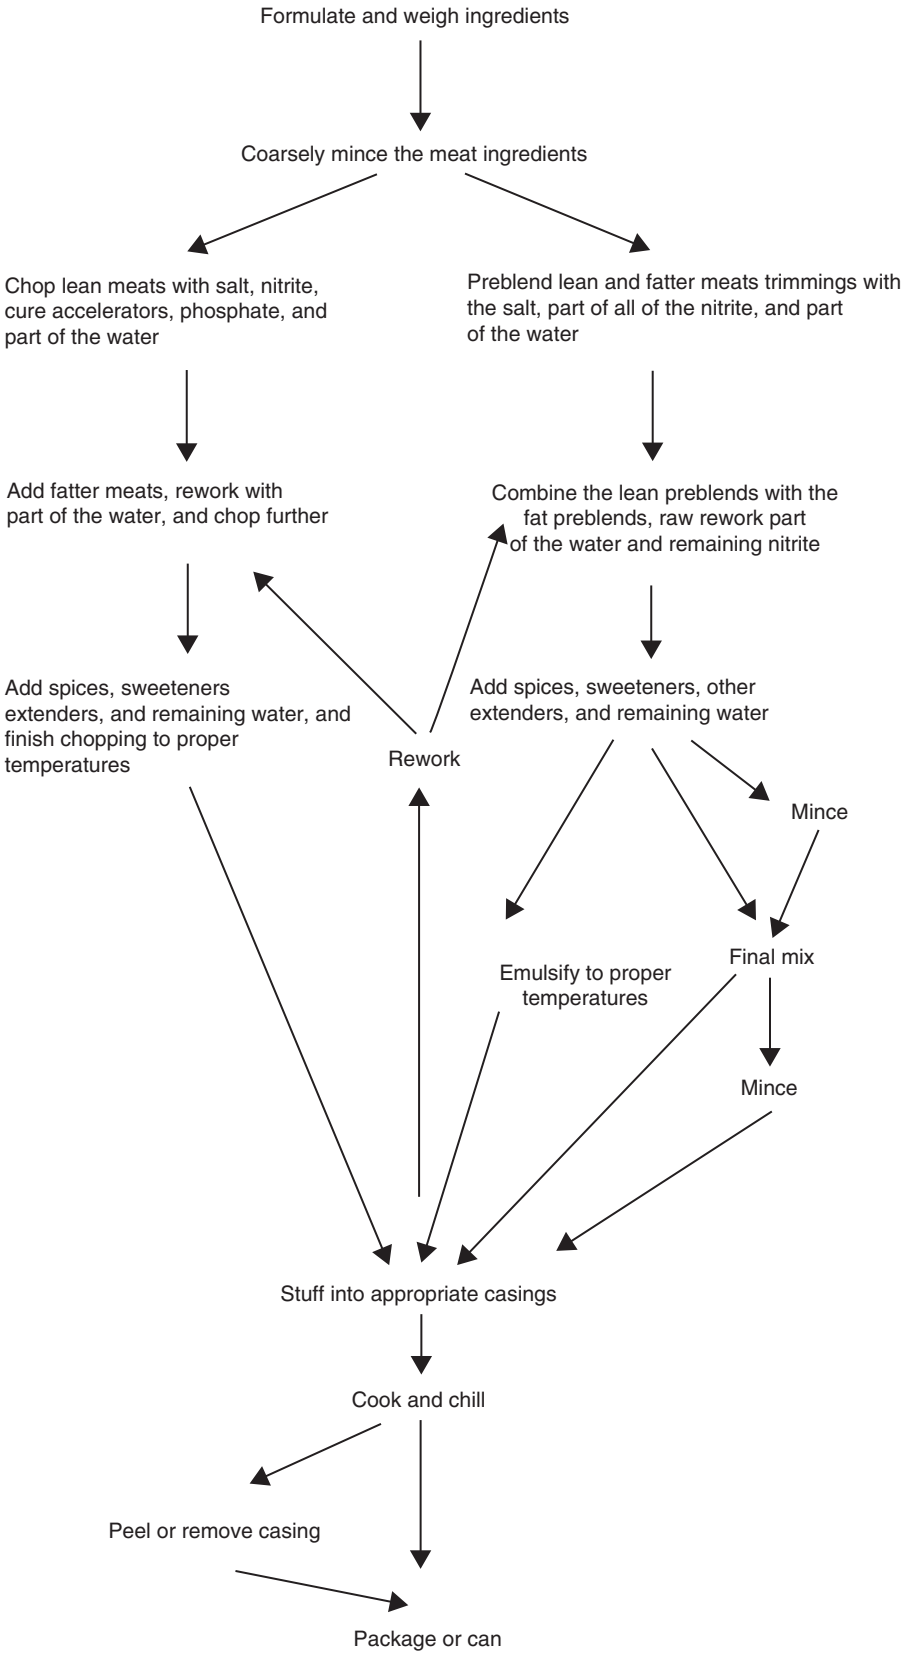

Figure 2 Flow chart for production of cooked sausage products.

Frankfurters, Wieners, and Hot Dogs

These products may be made in either a coarsely ground or finely chopped form. Coarsely ground frankfurters, wieners and hot dogs are made using grinder plates with hole diameters ranging from 2.3 mm (0.09 in.) to 3 mm (0.13 in.) for the final grinding, and are stuffed and cooked in either natural sheep or cellulose casings. These same products can be made in a finely chopped form using a chopper or emulsifier.

Kielbasa

Kielbasa is sold in many forms, but the word kielbasa is technically the Polish word for sausage, so it could be sold in the fresh or cooked and smoked form. Polska Kielbasa, or Polish Sausage, is the most common type of kielbasa in the United States. An uncured (fresh) and uncooked variety is also available. Typical Kielbasa flavors are primarily due to black pepper, dextrose, coriander, marjoram, nutmeg, garlic, and smoke.

Knackwurst

Knackwurst resembles a large-diameter frankfurter and is typically made of pork and beef. It may be made either as a finely chopped or coarse-ground product and is smoked. Garlic flavor is well pronounced in knackwurst.

Kuemmelwurst

Also called Carawaywurst, Kuemmelwurst is a loop- or ring-cooked sausage, containing caraway seeds.

Linguisa

Linguisa is a highly spiced coarse-ground, smoked pork sausage, originating from Portugal.

Lyonerwurst

Lyonerwurst is a fine-ground, beef and pork sausage that contains green peppercorns and is smoked and cooked.

Mettwurst

This product was originally made in a couple of ways in its native Germany. In southern Germany, it was made of pork, smoked and sold as a raw, spreadable product, like teewurst. In northern Germany, it was made similarly, but was dried longer during the smoking process to make a dry product. In the United States, it is made primarily as a linked, cooked, and smoked sausage product.

Mortadella

Mortadella is essentially a fine chopped bologna, with chunks of pork fat added. The base emulsion is typically made from both pork and beef and stuffed into beef bladders. Mortadella may also be sold as a dry or semidry product.

Paté

Paté is made from fresh livers and cooked meats, cooked in a moisture-impermeable casing. This product lacks the binding of liver sausages made from raw meat ingredients and is therefore a spreadable product.

Pfefferwurst

Pfefferwurst is a German-style sausage containing whole peppercorns.

Ring Bologna

Ring bologna is a finely chopped or ground product stuffed into a beef bung, in a loop typically weighing 0.5 kg (1 lb).

Schinkenwurst

Schinkenwurst is a large diameter, German product made by adding ham chunks to a pork and beef emulsion. It is similar to Berliner Bologna, except that Schinkenwurst is made from finely chopped base emulsion and does not contain garlic.

Smoked Sausage

Smoked sausage is typically a coarsely ground product, stuffed into either hog casings or cellulose casings (30–40 mm/1.19–1.5 in. diameter) and smoked. If stuffed into a cellulose casing, which is removed to make a skinless sausage, links are made approximately 12.5 cm (5 in.) long. If stuffed into natural hog casings, smoked sausage is most often not linked, but full strands are looped to make approximately 500 g loops. Typical smoked sausage flavors are primarily due to black pepper, dextrose, and smoke. Red pepper and coriander are occasionally added.

Smokie Links

These are small-diameter, coarsely ground, smoked sausages, which are most commonly co-extruded (so that a casing is not used) and heavily smoked.

Thuringer

Although most thuringer products are semidried (e.g., thuringer cervelot), some are cooked, without drying. It is typically made from pork, sometimes beef, with a pork breakfast link flavor, using marjoram instead of sage. It is sometimes called thuringer bratwurst. This product may also be sold fresh.

Vienna Sausages

Vienna sausages are short small-diameter frankfurters made in a finely chopped form, often cut (open ends) from long lengths of stuffed casings and sold in cans or glass jars. Spices typically used to make Vienna sausages include red pepper, onion powder, cloves, nutmeg, and coriander.

Uncured Cooked Sausage Products

There are a number of uncured products that are sold as cooked products, such as Bockwurst, cooked bratwurst, 'brown and serve' sausage, pizza toppings, etc. Many of these were originally sold as raw products, but more recently have been made available as cooked and RTE products. Some companies have developed cured versions of these products, which have traditionally been uncured.

Bangers

A mildly seasoned, British sausage, which contains rusk or other cereal fillers. The name supposedly comes from the noise it makes when cooked at high temperatures in a frying pay. Typically Bangers are not cured or smoked.

Blood Sausage

A sausage typically made from pork blood and either pork skins, diced back fat or diced pork jowls, and is mildly seasoned. This product is known as blatwurst in Germany, and is very dark in color. A related product, blood and tongue sausage, contains diced, cured, and cooked tongue and may contain ground clove. Blood sausage is typically available in either rings or chubs.

Bockwurst

The traditional bockwurst contains veal and pork, milk, egg, chives, and parsley, with spices similar to those in frankfurters, stuffed into 25 mm (1 in.) diameter casings and cooked in water, but not smoked. It is similar to bratwurst. Originally, bockwurst was sold as a fresh (raw) product, but it is now most often sold as a cooked product, because of its highly perishable nature.

Bratwurst

Bratwurst originates from Germany as an uncooked sausage, but it may also be sold as a cooked or smoked sausage. Traditionally, bratwurst were uncured, however, they are also available as cured sausages. Translated from German, bratwurst means 'sausage for frying,' and it was historically made from pork and veal, and stuffed into casings that were 30 mm (1.25 in.) in diameter and made as 100 mm (4 in.) long links.

Brown and Serve Sausage

These are precooked, uncured sausages, most often targeted as breakfast sausages. They may be stuffed into natural or collagen casings, but are also often extruded into the shape of a sausage link without using a casing. This product was designed for convenience of the preparer and is most commonly used in the food service industry. This product may be sold as links or as patties.

Chorizo

This product is made using a variety of methods, each unique to the various Spanish-speaking countries. Some chorizos are dried, some are a traditional cooked sausage, some are a loose sausage used in other dishes, and some are a fresh sausage. Precooked chorizos are made using pork and are typically hot and heavily spiced.

Goetta

Unique to Cincinnati, OH, this German product is similar to scrapple; however, it is made using pork and rolled oats, rather than corn meal. This product is typically stuffed into either a natural or artificial casing; however, it has a loose texture and is often added to scrambled eggs or other dishes.

Pizza Toppings

These are precooked, often uncured, sausage chunks or crumbles. The product is sold in bulk form, not in a casing, and does not fit the standard identity for sausage products. Pizza toppings are most often cooked in jacketed kettles, continuous thermal screw systems, or continuous belt ovens. In the United States, there is no standard of identity for pizza toppings.

Scrapple

An ethnic product of Pennsylvania Dutch people, this product is believed to be the first pork product to be developed in the United States. It is essentially a mush, consisting of ground pork trimmings (scraps), spices, and corn meal, and is an early example of early settlers' attempts to avoid wasting anything from the pork carcass. This product is typically cooked in a loaf pan, sliced, and fried in butter as a breakfast item. Another Pennsylvania Dutch name for this product is pon haus. An Irish version of this product is called pudding. And, German settlers in Cincinnati, OH, and northern Kentucky made a similar product known as goetta, however, goetta contains oatmeal, rather than corn meal, and is sold in a sliceable form and in a casing as a loose meat for addition to other entrees.

Taco Fillings

These are precooked, often uncured, seasoned meat crumbles that are used in tacos, burritos, and other 'Tex-Mex' type products. This product is sold in bulk form, not in a casing, and does not fit the standard identity for sausage products. Taco fillings are most often cooked in jacketed kettle or continuous thermal screw systems.

Weisswurst

This name means white sausage in German. It is an uncured sausage, similar to bratwurst, typically made of pork and veal. It is more commonly called bockwurst, if it contains milk and eggs.

Glossary

Decarboxylases Enzymes that transform an amino acid into an amine.

Glycolysis Enzymatic breakdown of carbohydrates with the formation of pyruvic acid and lactic acid and the release of energy in the form of ATP.

Lipase Enzyme that catalyzes the release of fatty acids by hydrolysis of triacylglycerols at positions 1 and 3.

Lipolysis Enzymatic breakdown of lipids with the formation of free fatty acids.

Peptidases Enzymes that catalyze the release of an amino acid from the amino terminus of a peptide (exopeptidases) or that hydrolyze myofibrillar proteins to polypeptides (cathepsins and calpains).

Proteolysis Enzymatic breakdown of proteins with the formation of peptides and free amino acids.

Water activity (a_w) Indicates the availability of water in food and is defined as the ratio of the equilibrium water vapor pressure over the system to that of the vapor pressure of pure water at the same temperature.

Introduction

Dry and semidry sausages constitute products with a long history of consumption. In fact, drying and fermentation may be considered as some of the oldest ways of preservation of meat. The use of drying probably originated in areas with mild winters and relatively low rainfall, like the Mediterranean area, due to its particular climate that allows natural drying and ripening. Dry fermented sausages were already produced and consumed by ancient Romans and Greeks. However, the use of cooking and smoking was applied in northern and colder areas where the climate did not allow natural drying.

The application of pure bacterial cultures as starters constituted a relevant technological advance in the manufacture of fermented sausages. The lack of consistency in quality and safety due to the typical use of back-slopping, a common practice when producing traditional sausages, could be overcome with the advent of such starter cultures.

In general, it is very difficult to classify fermented sausages because of the different processing technologies applied and the large variety of different products available in the market with very different appearance, texture, color, and flavor. One of the most extended definitions, dry and semidry, is mainly based on the extent of drying.

Definitions of Dry and Semidry Fermented Sausages

The main classification of fermented sausages is usually based on the extent of drying and degree of water loss. For a given sausage, this is usually in correlation with the time of ripening. So, fermented sausages may be defined as semidry when the weight loss is less than 20% or dry when the weight loss is greater than 30%. The length of the ripening period will vary depending on the kind of product, the desired final quality and its diameter. Semidry sausages are generally stable at ambient temperature because of a combination of lowered pH (<5.3) and lowered water activity ($a_w<0.95$). This stability is sometimes enhanced by heat treatment and/or smoking to inactivate most undesirable microorganisms except resistant spores. Dry sausages have lower a_w values (usually <0.89) as a consequence of the extensive drying, which make them stable even if the pH is not lowered so much. These sausages may be smoked but never cooked.

There are also large differences depending on the type of processing technology (use of starters, temperature applied, surface molds, smoking, etc.). For instance, traditional sausages are manufactured at low temperatures, using natural casings and without the addition of starter cultures. However, most of the industrial sausages produced worldwide involve the use of starter cultures. In some particular cases, chemical acidulants (e.g., glucono-delta-lactone) may be used; of course, there is no fermentation in this type of product and the sensory quality is rather poor due to the lack of flavor. Also, the presence of surface mold growth is desired by some populations whereas others request mold-free surface. The same can be said about smoking. Culture and gastronomic heritage have a strong influence on the type of products preferred by each particular population.

Technology of Dry and Semidry Sausages

It is important to use raw materials and ingredients of high hygienic standard because there are no alternative ways for efficient reduction of the initial microbial contamination. Once the hygienic requirements are met, care must be taken for the composition of the sausages in order to obtain a good quality. The right amount and type (mono-, di-, oligosaccharides) of carbohydrates must be used to regulate the lactic acid production. A low concentration ($<2\%$) of curing salts (generally a mixture of 0.5% $NaNO_2$ and 99.5% NaCl) favors the growth of undesirable microorganisms more than starter cultures; a high concentration ($>4\%$) inhibits the growth of the starter cultures. A relatively high concentration ($>10^5$–10^6 organisms per gram in sausage) and high

 doi:10.1016/B978-0-12-384731-7.00142-2

metabolic activity of the starter culture is a precondition for a good sausage. Nitrite is very reactive and exerts specific protection against *Clostridium botulinum*. When nitrate is used, as for the slow-cured traditional sausages, the enzyme nitrate reductase slowly generates nitrite. It is important to control the amounts of nitrate and/or nitrite added to the initial mixture to those amounts strictly necessary for protection against botulism due to the risk of generation of N-nitroso compounds which have toxic effects.

An acceptable compromise is also necessary for the right fermentation and ripening temperature, considering the temperature requirement of the starter culture. To achieve an optimal rate of weight loss, an essential requirement from both the economic and quality points of view, the drying rate has to be controlled very carefully by adjusting the differences between relative humidity (RH) and equilibrium relative humidity (ERH) and air velocity depending on the type (low- or high-acid) and the diameter of the product. The typical process flow of dry sausage manufacturing is shown in **Figure 1**.

For the manufacture of dry and semidry sausages only casings with water vapor permeability should be used. Natural casings and some types of artificial casings are appropriate. For large-diameter sausages (salamis, 60–70 mm), natural casings from equine and bovine sources have previously been used; but due to an insufficient supply (horse) and because of the risk of bovine spongiform encephalopathy (BSE) (cattle), artificial casings are primarily used now. Artificial casings are usually based on cellulose or collagen because such materials have good water vapor permeability, which makes them suitable for dry sausage production. For smaller diameter sausages (25–38 mm), natural hog casing (small intestine) and collagen casings are mainly used. For intermediate calibers (40–50 mm), artificial casings are the appropriate choice.

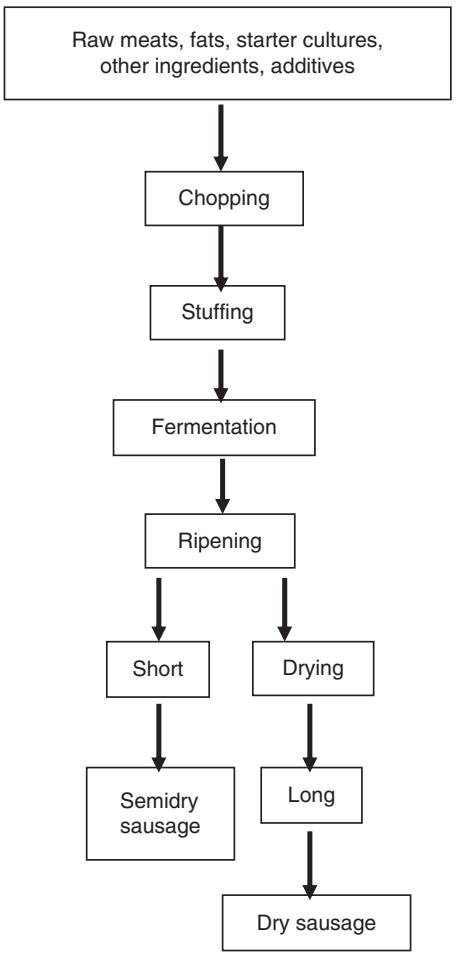

Figure 1 Process flow for dry and semidry sausage manufacture.

Sausages can be classified depending on different criteria; acidity rate, mincing size, starter addition, diameter, and type of casing used. A classification of dry fermented sausages can be done based on the manufacturing process, either industrial or traditional, considering traditional sausages those with no starter culture added. In addition, the industrial sausages can be separated into those submitted to a fermentation step (fast-fermented) and those not submitted to a distinct fermentation process (slow-fermented), resulting in high-acid or low-acid sausages, respectively.

Traditional dry sausages (naturally fermented sausages) are those manufactured in an artisanal way without the use of a starter culture. These sausages present a high diversity in sensory properties and are highly appreciated by consumers. These sausages are based on the natural fermentation of the meat batter through the autochthonous flora. Generally, these sausages reach a final pH greater than 5 and are therefore considered low-acid sausages. However, this manufacturing process is slow and may include safety problems. The low-acid dry sausages tolerate only slow drying rates that can be controlled via the relative humidity and the velocity of the drying air; with closer RH and ERH values, higher air velocity can be applied, and vice versa. Temperature has to be kept low ($<15\,^{\circ}C$) to control the growth of harmful microbes. In addition, traditional sausages dried for a long time use both nitrite and nitrate as curing agents.

Industrial dry sausages are manufactured using starter cultures in order to increase the quality and safety of the meat product. These sausages can be also manufactured with or without a distinct fermentation step. It is generally accepted to name those submitted to a step including fermentation conditions as fast-fermented sausages, and those without a distinct fermentation step as slow-fermented. The fast-fermented sausages can be processed by two different fermentation treatments or conditions; long fermentation done with constant conditions for 1–3 days at 18–24 °C or short fermentation using fermentation conditions and dwell times for up to 24 h. The fast-fermentation conditions favor the growth of lactic acid bacteria and the pH decline to values lower than 5. However, very fast pH decline can negatively affect the color of the product due to the inhibition of coagulase negative staphylococci (CNS) and also, result in an excessive acid taste that may be rejected by consumers. The fast-fermented sausages are dried for a relatively short time and only nitrite is used as the curing agent. These high-acid sausages can also be manufactured using glucono-delta-lactone (GDL) as an acidifying agent.

In the case of slow-fermented sausages that are not submitted to a distinct fermentation step, the process consists of a first stage where low temperatures are applied (10 °C) and then, the sausages are dried at higher temperatures (16–18 °C)

in order to dry and develop the sensory characteristics. These slow-fermented sausages have a mild pH decline (pH > 5), and are also known as low-acid sausages, but are considered safe because the starter added in the process improves the microbial safety of the product.

Semidry sausages with low pH tolerate relatively fast drying rates because the pH of the sausage is close to the isoelectric point of muscle protein, and the loosely bound moisture is easily lost. Starter cultures generally require higher temperatures (20 °C and above in Northern Europe and up to 37 °C in the United States) for their growth and metabolism, but the resulting pH decline controls the growth of harmful microorganisms. The smaller diameter products represent less risk in drying for both types of sausages.

Because elevated temperature also favors undesirable microorganisms, acidification should proceed as soon as possible for safety reasons. According to the voluntary guidelines of the American Meat Institute, the time elapsed until the pH drops below 5.3 can be up to 80 h if the temperature is 24 °C, but only 24 h if the incubation temperature is 38 °C. These guidelines are intended primarily to control coagulase-positive *Staphylococcus aureus*.

Cold smoking is applied in some cases and in some countries, less often in Mediterranean countries. Smoking has several advantages in addition to the special and typical flavoring effect. It helps by combating surface growth of undesirable microorganisms, and through its antioxidative effect it improves the stability of the product. Owing to the NO components in these products, color formation and color stability are also enhanced to some extent.

One of the main inhibitory factors against pathogenic and spoilage microorganisms in dry and semidry sausage is the low water activity. If a_w is low enough (< 0.89), it gives sufficient inhibition *per se* and the product becomes practically stable and safe regardless of the pH value. If it is higher (e.g., 0.95), combination with a low pH is necessary to ensure food safety. If the pH goes below 5.3, a product with an $a_w \leq 0.95$ becomes stable and safe. Reduction of a_w is usually achieved by adding common salt and especially by drying. In China another method is applied: in addition to a low amount of salt, a high amount (20–25%) of sugar is added, and a high drying temperature (50 °C or above) is used. Because small diameter sausages are usually manufactured in China, the required a_w decline is achieved quickly. The taste of these Chinese products is completely different from that of European or American types.

Processing Changes

During fermentation, ripening and drying significant changes take place resulting in a product with characteristic sensory qualities and a high level of safety.

During fermentation, the pH is reduced as a result of breakdown of carbohydrate to lactic acid (Figure 2). Application of homo-fermentative lactic starters is desirable because these only produce lactic acid as a major product with only very minor amounts of other components. Proteins coagulate due to the pH decline as a consequence of lactic acid generation and accumulation, giving better product cohesiveness and good sliceability. The low pH and the reduction in a_w during drying contribute to the selection of the microflora. The pH increases slightly in the later stages of drying as a result of the generation of free amino acids and ammonia.

One of the most important changes during processing is the weight loss as a consequence of loss of moisture by drying (Figure 2). This weight loss tends to be larger for long-ripened products (reaching up to 40%) and this is why they are also named dry sausages (Figure 3). The a_w value decreases in parallel with the weight loss. But for semidry sausages, the loss is lower (less than 20%). The final moisture of long-ripened sausages can be as low as 20%. The moisture:protein ratio (M:P) in this case is most often below 1.5:1. With short-ripened products, the weight is lost more rapidly due to the low pH and because the drying time is shorter. The typical weight loss with these items ranges from 15% to 25%, and the final moisture content of 30–40% gives sufficient stability and safety at a pH below 5.3. The M:P ratio in this case is above 1.5:1. In the case of nitrate (if used) and nitrite, the usual levels by the end of the process are generally very low (Figure 4).

The drying rate also depends on the initial moisture content, which can be adjusted by changing the meat to fat ratio or by lowering the moisture content with dry ingredients (nonmeat protein, oligosaccharides, etc.). If the initial moisture content is low owing to a higher fat content (lower a_w), the drying rate is slower than with higher initial moisture.

Flavor Development

The flavor of dry sausages is based on many chemical and biochemical reactions that occur during the fermentation and ripening/drying stages. Aroma formation is a complex process that generally begins with the enzymatic hydrolysis of protein and fat, generating flavor precursors. These precursors, free amino acids and free fatty acids, act as substrates for further chemical and microbial reactions generating flavor compounds. Also, fermentation of carbohydrates and spices contributes to dry sausage flavor.

Muscle enzymes (e.g., cathepsin D) play an important role only at the beginning of the ripening. In general, the enzymes from microorganisms play an active role in the breakdown of proteins and lipids by proteolysis and lipolysis, respectively (Table 1). Proteolytic enzymes hydrolyze muscle proteins and as a consequence, the amount of myofibrillar and sarcoplasmic proteins decreases whereas the concentrations of nonprotein nitrogen (NPN) compounds, polypeptides, amino-N and ammonia-N, increases, the latter contributing to the pH increase. Some lactobacilli (*Lactobacillus casei*, *Lactobacillus plantarum*) show an intense proteolytic activity whereas others (micrococci, staphylococci) contribute to lipolysis. Enzymes are affected by pH, a_w and temperature; the activity of cathepsin D is enhanced by a lower pH whereas aminopeptidases, active in the breakdown to amino acids, is enhanced by neutral pH. Molds are also active in the proteolysis as well as in other processes that have significance in mold-ripened sausages.

Endo- and exoenzymes take part in the lipolysis process, which play a decisive role in aroma formation. This rather complicated process can be characterized by hydrolytic and oxidative changes. Lipolysis consists of the enzymatic

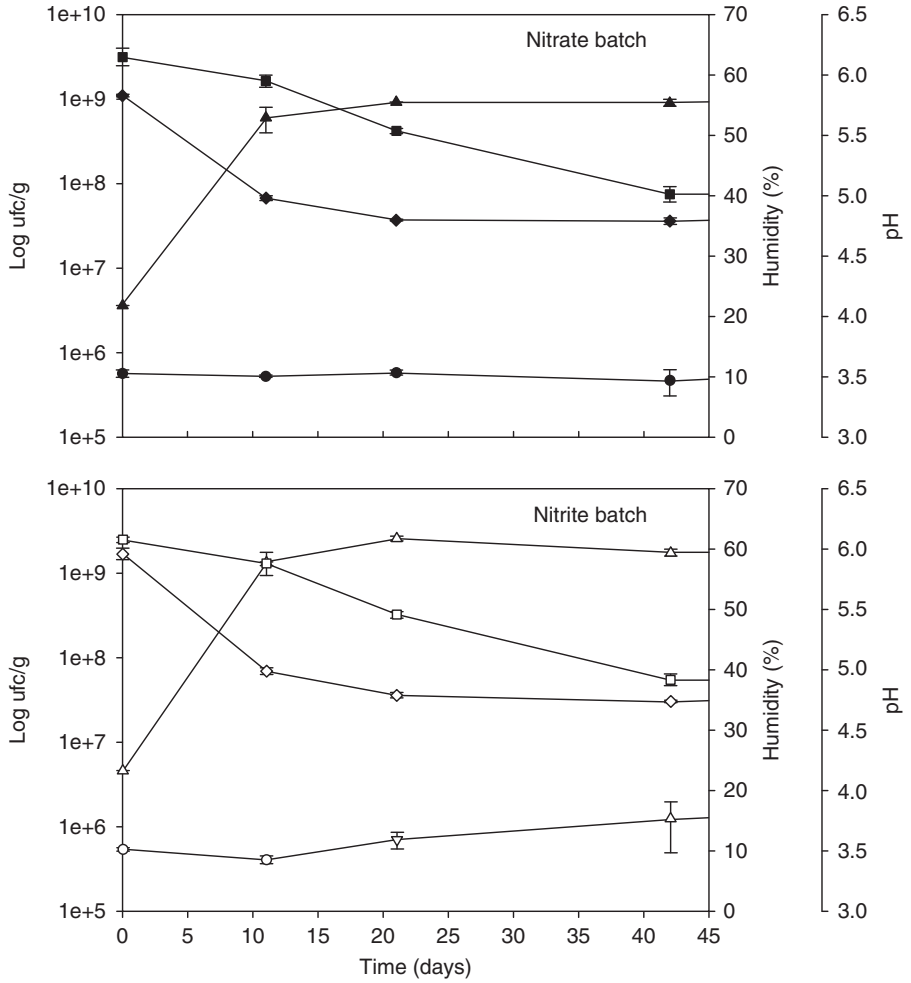

Figure 2 Changes in physico-chemical and microbiological parameters in slow-fermented sausages manufactured with nitrite or nitrate as curing agent. Lactic acid bacteria (LAB, ▲), staphylococci (●), pH (◇), and humidity (■).

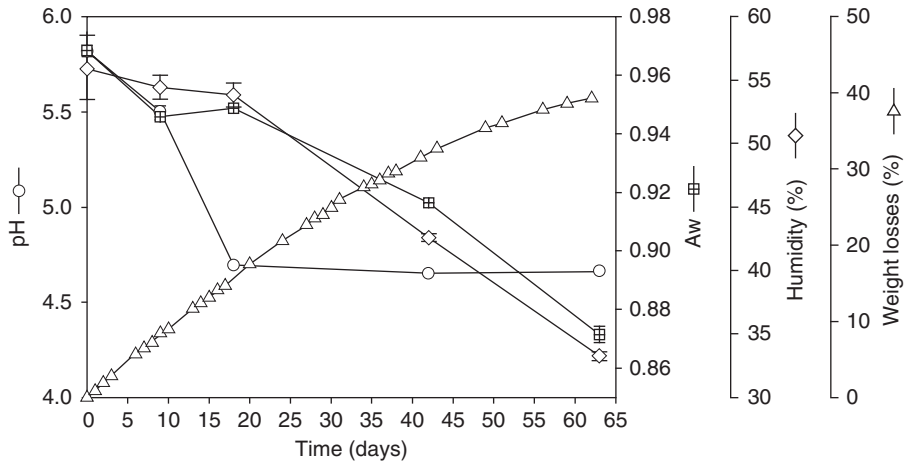

Figure 3 Changes in physico-chemical parameters in slow-fermented sausages manufactured with nitrite and nitrate as curing agent.

hydrolysis of muscle and adipose tissues generating free fatty acids. The initial free fatty acid content in the meat batter is approximately 1–2% of the total fatty acid content and it can increase up to 5% during the process. Many factors affect the lipolysis process such as processing parameters (curing agents, spices, starter cultures, pH) and the raw material used.

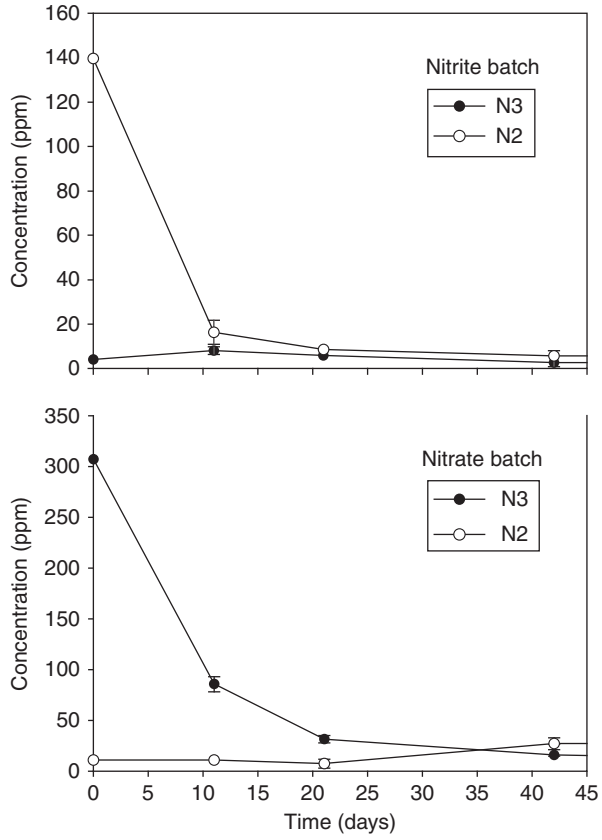

Figure 4 Changes in nitrite (N2) and nitrate (N3) concentrations in slow-fermented sausages manufactured with nitrite or nitrate as curing agent. Reproduced from Olivares, A., Navarro, J.L., Flores, M., 2009. Establishment of the contribution of volatile compounds to the aroma of fermented sausages at different stages of processing and storage. Food Chemistry 115, 1464–1472.

Finally, dry sausage flavor is generated through chemical and microbial reactions. The most important reaction is the chemical fat auto-oxidation that affects primarily the unsaturated free fatty acids. Depending on the metabolic pathway and its extent, lipid oxidation may contribute to develop a desirable flavor, but may also cause off-flavors. Lipid oxidation is autocatalytic and is mostly associated with unsaturated fatty acids; this is also why higher concentrations of unsaturated fatty acids in the sausage have an adverse effect. An excess of unsaturated fatty acids can occur, if the fat of animals on diets high in these fatty acids is used or if a significant amount of fat is replaced by vegetable oil in the recipe. Both of these may occur with an intention of improving the saturated:unsaturated fatty acid ratio with the aim of producing healthier food.

The extent of oxidation can be reduced either by using an antioxidant (not always successful when the drying lasts several months) or by smoking. Mold growth on the surface also helps by protecting lipids against light and oxidation by consuming oxygen, and by physical protection against access of oxygen to the fat.

In addition, other chemical reactions take part during the dry sausage process, such as the Strecker degradation of amino acids. Although the pH and temperature of the process limit this reaction, the low a_w, long ripening times and the increase in free amino acids favors the Strecker degradation. Moreover, other amino acid degradation reactions result from microbial metabolism (Table 1).

The microbial metabolism is responsible for the generation of many flavor compounds through different reactions; fermentation of carbohydrates, microbial amino acids degradation, lipid beta-oxidation, and staphylococci esterase activity. The fermentation of carbohydrates is performed in anaerobiosis through lactic acid bacteria producing lactic acid and other volatile compounds with high aroma properties (diacetyl, acetaldehyde, ethanol, acetic, propionic, butanoic acids, etc.). Microbial amino acid degradation is mainly done by coagulase negative staphylococci and yeasts (*Debaryomyces hansenii*) generating many aroma compounds through the degradation of sulfur, aromatic, and branched chain amino acids. Generally, these reactions are performed through a transamination reaction and a further decarboxylation reaction of the amino acid producing aromatic aldehydes. The lipid beta-oxidation is an oxidation reaction performed by the microbial metabolism (mainly *Staphylococcus* and yeast) generating short chain fatty acids and beta-ketoacids that are further decarboxylated producing methyl ketones that can be reduced to secondary alcohols. Finally, the staphylococci esterase activity produces ester compounds (mainly ethyl esters) through the use of an acid and alcohol by the esterase activity present in *Staphylococcus*. The generation of ester compounds is highly dependent on the substrates present in the sausage and the *Staphylococcus* strain used.

Hundreds of volatile compounds have been identified in dry sausages although not all of them contribute to the aroma. The differences in aroma compounds between naturally dry fermented and industrial dry fermented sausages are shown in Table 2. Many of the identified volatile compounds contribute to different aroma notes in both sausages such as acetic acid (vinegar odor), hexanal (fresh cut grass odor), 1-octen-3-ol (mushroom odor), methyl-3-methyl-butanonate (fruity odor) and 4-methylphenol (stable odor). However, several aroma active compounds were exclusively detected in one of the sausages being the detection frequency (DF) value, an indication of aroma potency (Table 2). Naturally dry fermented sausages were characterized by a highest proportion of ethyl ester compounds contributing to fruity and floral notes whereas industrial dry fermented sausages were characterized by aldehydes, compounds contributing to green, herbal, and tallowy odors.

Color Development

The intensity of color depends on the concentration of myoglobin in the meat used as raw material. Nitrite is depleted during ripening/drying. In fact, nitrite is reduced to nitric oxide and reacts with myoglobin to generate nitrosomyoglobin giving sausages a typical bright-red cured color. When only nitrate is used, which is the case of traditional dry sausages, an initial reduction to nitrite through the action of nitrate reductase is needed. Afterwards, nitrite rapidly reduces into nitric oxide that reacts with myoglobin. In these sausages, it is essential that pH does not drop below 5.0 because nitrate

Table 1 Examples of the main biochemical and sensory effects of purified enzymes isolated from microorganisms used as starter cultures in fermented meats

Group of enzymes	*Microorganism of origin*	*Main biochemical actions*	*Main sensory effects*
Aminopeptidase, tri- and di-peptidase, dipeptidyl-peptidase	Lactic acid bacteria and yeasts	Exopeptidase, generation of free amino acids and/or small peptides	Increase of free amino acids for flavor development
Catalase	Lactic acid bacteria	Dismutation of hydrogen peroxide into water and oxygen	Antioxidant properties. Decrease in the level of volatiles arising from lipid oxidation
Lipase	Lactic acid bacteria and Micrococcaceae	Generation of free fatty acids	Increase of free fatty acids for flavor development. Acceleration of maturation
Superoxide dismutase	Micrococcaceae	Detoxification of superoxide radicals into water and oxygen	Antioxidant properties. Decrease in the level of volatiles arising from lipid oxidation
β-Oxidation and thioesterase activity	Micrococcaceae	β-Oxidation involved in the synthesis of methyl ketones	Contribution to the cured aroma
Decarboxylase	Micrococcaceae	Final step of the β-decarboxylation process leading to CO_2 and methyl ketone	Increase in the levels of methyl ketones contributing to the cured aroma
Nitrate reductase	Micrococcaceae	Reduction of nitrate to nitrite	Nitrite generation. Antioxidant properties
Glutaminase	Yeasts	L-Glutamine amidohydrolase	Neutralisation of acidity by ammonium generation and flavor enhancement through the generation of L-glutamate
Protease	Yeasts and molds	Endopeptidase, able to hydrolyze sarcoplasmic and/or myofibrillar proteins	Protein degradation during meat fermentation and reduction of hardness. Acceleration of proteolysis

reductase is inhibited at lower pH values and thus nitrate would not be reduced to nitrite.

Texture Development

Texture development is the result of chemical and physical processes. Owing to the decline of pH during fermentation, myofibrillar proteins tend to coagulate and thus increase the product consistency which is then accelerated during the drying process. Of course, the consistency of the sausage depends on the extent of drying and subsequent water losses; dry sausages usually have a hard texture. However, the consistency may be soft if there is an excess of fat and water. So, the final texture depends on the degree of drying, pH decline, amount of fat, and extent of proteolysis, especially of myofibrillar proteins. A good consistency is necessary for an adequate sliceability of the product.

Safety of Dry and Semidry Fermented Sausages

Important conditions for assuring safe and stable dry and semidry sausages are the raw materials and ingredients of high hygienic quality and good manufacturing practices (GMP) and good hygienic practices (GHP) observed during manufacturing. The low temperature used for traditional sausages inhibits the growth of harmful microorganisms, and the reduction of the water activity inactivates most of them. In the case of semidry sausages, the low pH and the low a_w together inhibit growth and inactivate most of the harmful microbes.

Some pathogenic bacteria (*Listeria*, *Staphylococcus*, enterohaemorrhagic *Escherichia coli*) can tolerate the a_w reduction, whereas others (*Salmonella*, coliforms, clostridia) are destroyed during drying. As for staphylococci, low temperature and low pH are inhibitory for growth, and low a_w is inhibitory for enterotoxin formation. Enterohaemorrhagic *E. coli* (EHEC) are resistant to low water activity, although they are also inactivated (due to metabolic exhaustion) under the influence of a relatively low a_w for long periods at ambient temperature. Most spoilage bacteria are also inactivated due to the conditions found in the sausage.

In semidry sausages with low pH, staphylococci are also inhibited and inactivated in addition to Gram-negative microorganisms, but *Listeria* and EHEC strains may survive. This makes it even more important to use high-quality raw materials for raw fermented sausages. Highly active starter cultures also contribute to inactivation of harmful microorganisms by their high number (competition for nutrients), the rapid pH decline and eventually by the production of specific inhibitory substances (antibiotics, bacteriocins). Some semidry sausages are heat-treated, either immediately after stuffing or after a short period of fermentation. The heat treatment is sufficient to kill practically all vegetative forms of microorganisms and the less resistant spores. This ensures good hygienic conditions for drying.

Mycotoxic molds such as *Aspergillus* or *Penicillium* may release toxins so that the presence of a mold cover on the surface of sausages may be controlled. Preventive measures consist of inhibiting the growth of mycotoxic mold strains and the production of toxins by using nontoxigenic mold starters, the use of low temperature, control of relative humidity, and/or the application of smoking.

Table 2 Aromatic compounds in (traditional) naturally fermented and industrial fermented sausages

KI[a]	*Compound*	*Gas chromatography-olfactometry (GC-O) descriptor*	*DF*[b]	
			Naturally fermented sausage	*Industrial fermented sausage*
472	Methanethiol	Rotten	7	10

Biogenic amines (tyramine, phenylethylamine, histamine, tryptamine, putrescine, cadaverine, agmatine) may be formed during fermentation by microorganisms that have decarboxylase activity. Amines may cause potential toxic effects in consumers due to the vasoactive and psychoactive properties of these compounds. These effects are more severe in those consumers treated with inhibitors of monoamine oxidase (IMAO) drugs. In most cases, biogenic amines are formed as a consequence of the activity of contaminant bacteria. Preventive measures consist of controlling the hygiene quality of raw materials as well as verifying the absence of decarboxylase activity in the microflora used as starter cultures.

Finally, the shelf-life of dry and semidry sausages depends on the combination of several factors, namely, pH, a_w, temperature of storage and type of packaging. Other factors that limit the shelf-life of these products are the extent of physical changes (i.e., fat melting or hardness due to excessive drying) and chemical changes (i.e., rancidity, discoloration) that occur in these products during the drying process.

Emulsion

CL Knipe, Ohio State University, Columbus, OH, USA

Glossary

Cellulose casings Sausage casings made from cotton linters, which need to be removed before the sausage is eaten.

Chub A short, cylindrically shaped package typically used for bulk ground products but may also be used for cooked products.

Coextrusion The process of forming sausage into a cylindrical shape while simultaneously coating the sausage with a layer of collagen. The collagen sets up on the surface of the sausage to serve as a casing.

Link The process of twisting, or tying, a filled sausage casing to achieve the desired sausage length. Moreover, it is the single unit that sausages are merchandised in when sold in a casing.

Protein extraction The process of dissolving proteins from meat by mixing a salt solution with the meat.

Salt-soluble proteins Proteins that can be dissolved or extracted from the fibrous structure of muscle by using a salt solution and some form of size reduction and mixing.

Stuff The process of filling a sausage casing.

Introduction

Emulsion-type sausage products are made by finely chopping meat to form a stable mixture that binds water and traps and holds fat to form the characteristic texture of an emulsified product when cooked. The stable meat mixture is formed by extracting salt-soluble proteins from the meat ingredients by using either a bowl chopper or a combination of a mixer and an emulsifier. The mixing action of both the mixer and the bowl chopper creates a more even distribution of the functional nonmeat ingredients, such as salt (sodium chloride) and alkaline phosphates, with the meat and added water. Salt and phosphates are considered functional ingredients, as they alter the salt-soluble proteins in the meat in such a way that the proteins are more easily extracted and solubilized from the fibrous meat tissue. Salt increases the ability of meat to hold water during cooking, i.e., its water-holding capacity. Alkaline phosphates adjust the pH of the meat mixture to a point of higher water-holding capacity and protein extraction.

There is a synergistic effect of the combination of salt and phosphates on protein extraction and water-holding capacity of the meat mixture. The pyrophosphate form of the alkaline phosphates commonly used in producing emulsions has been shown to partially reverse the formation of actomyosin, returning some of the actin and myosin to their separate prerigor forms. Myosin is the most functional of the muscle proteins in terms of ease of extraction in a salt solution and the binding ability of the mixture when cooked.

The meat ingredients are commonly preblended with a portion of the meat block to maximize the functional properties of the added salt and water. Preblending is done by mixing coarse-minced pieces of 0.5 in. (1.5 cm or larger) meat trimmings with salt and water and held at refrigerated temperature for up to 72 h. This holding period allows time for the salt and water to migrate into the meat trimmings to enhance the protein extraction and the water-holding capacity of the meat. This process is most effective when applied to the lean portion of the mixture, because the protein content is much higher in the lean portion. However, it is known that salt stabilizes the fat cells against melting during the cooking process. For emulsified or finely chopped emulsions or batters, it has been shown that phosphates are not needed if the preblending procedure is used.

Air incorporated into the finely chopped batter is undesirable, both from the standpoint of binding ability of the protein and the visual appearance of the final product. Vacuum chopping, mixing, and emulsification are important factors in removing this air.

The extracted protein, also known as a protein exudate, serves as the protein glue to bind the protein fibers together into a viscous matrix, which traps or holds the fat particles and water in the product when the product is cooked. Ice is often added during the chopping process to keep the meat mixture cold during the time the chopping and mixing would normally cause a temperature increase in the mixture. By keeping the mixture cold longer, the chopping and mixing times are maximized, thus maximizing the extraction of the salt-soluble proteins. The water that results from the melting ice further dissolves the added salt to form a salt solution that aids the extraction of the salt-soluble proteins. If the mixture becomes too warm, the fat in the mixture may become soft and melt, forming unsightly fat pockets on the surface of the products that become apparent during the cooking process.

Comminution Methods

The two basic processes for forming a finely chopped mixture are mixing–emulsifying and chopping. Both processes share the initial coarse grinding process that reduces meat chunks to manageable-sized meat particles.

The more traditional process of chopping involves the use of a bowl chopper or cutter (Figures 1 and 3), in which the protein extraction process can be maximized by first adding lean meat ingredients, salt, and ice or water first, to maximize protein extraction from the lean meat components, before the less functional or desirable ingredients are added to the chopper. With a bowl chopper, the variable speeds of the

knives and the bowl allow extremes in action from simple mixing to high-speed emulsification. This process also allows the chopper operator to have control of the temperature of the mixture, which is important for the protein extraction process as well as for the stability of the fat component, particularly for products containing traditional fat levels. Proper use of the mixing speeds of a chopper also allows a processor to add nonmeat ingredients, such as cheese, pickles, pimentos, olives, etc., without damaging or more finely cutting these inclusions. The major disadvantage to the chopping process is that the chopper has a fixed limit to its capacity, making the process a batch process. This results in lower production volumes, compared with the mixing–emulsifying processes.

The mixing–emulsifying process involves two steps – a mixing step and an emulsifying step (Figures 2 and 3). Although some protein extraction occurs during the mixing and emulsifying steps, it is normally not as efficient as with the chopper process. Once all the ingredients are sufficiently mixed, the mixture is added to an emulsifier, which is a high-speed mincer or grinder. The emulsifying process is a high-volume, continuous process in which a finer texture is achieved, compared with that produced using a bowl chopper. Traditionally, the operator had less control of the mixture temperature, and the meat mixture temperature rise was proportional to the number of times the mixture was passed through the emulsifier. New technology now allows more precise control of the meat batter temperature as it exits the emulsifier.

Combining the chopping process with the emulsifying process takes advantage of optimizing both protein extraction with chopping and the finer texture of the emulsifying process.

In the true sense of the word 'emulsion,' a meat emulsion is considered to be a misnomer. True food emulsions involve an emulsifying agent, a protein, which binds to both fat and water to prevent the fat separating from the water (effectively allowing the fat to be dissolved and distributed in the water). In its role as an emulsifying agent, the hydrophobic end of the protein binds to the fat and the hydrophilic end of the protein binds to the water. In the case of meat emulsion, there are so many other factors affecting the stability of the mixture – such as muscle fibers, connective tissue, etc. – that the true emulsion theory probably does not apply. The final, finely chopped or emulsified, mixture is better described as a batter, mixture, or matrix than as an emulsion; however, the word emulsion continues to be most commonly used in the meat industry.

Emulsification Procedures

Whether mixing or chopping, the lean meat should be combined first with the salt and part of the water, usually approximately one-third of the total water to be added (Figure 3). If sodium nitrite and a 'cure accelerator' (sodium erythorbate, sodium ascorbate, ascorbic acid, or sodium acid pyrophosphate) are used, they should be added in the early stages with the lean meat ingredients. For chopping of emulsions, the fatter meat and another third of the water should be added, once sufficient protein extraction from the leaner meat has occurred. Finally, the spices, binders, cooked rework, etc. are added, along with the final third of the water, and chopping continues until the emulsion reaches the proper temperature.

In the case of a chopped emulsion, the final chopping temperature, before stuffing, would be determined by the dominant type of fat in the meat ingredients used (Table 1). These final chopping temperature guidelines are due to the inherent crystallization and melting temperatures of fatty acids of different species. Beef fat is unusual in that it has two final endpoint temperature ranges. Companies that traditionally make all-beef emulsified products typically use the lower temperature of 4 °C (40 °F). When using a mixer–emulsifier combination, preblended lean and fat meat mixtures are combined in a mixer, to which the spices, binders, cooked rework, etc. are added (Figure 3). The mixing process should continue only until the meat mixture has reached a

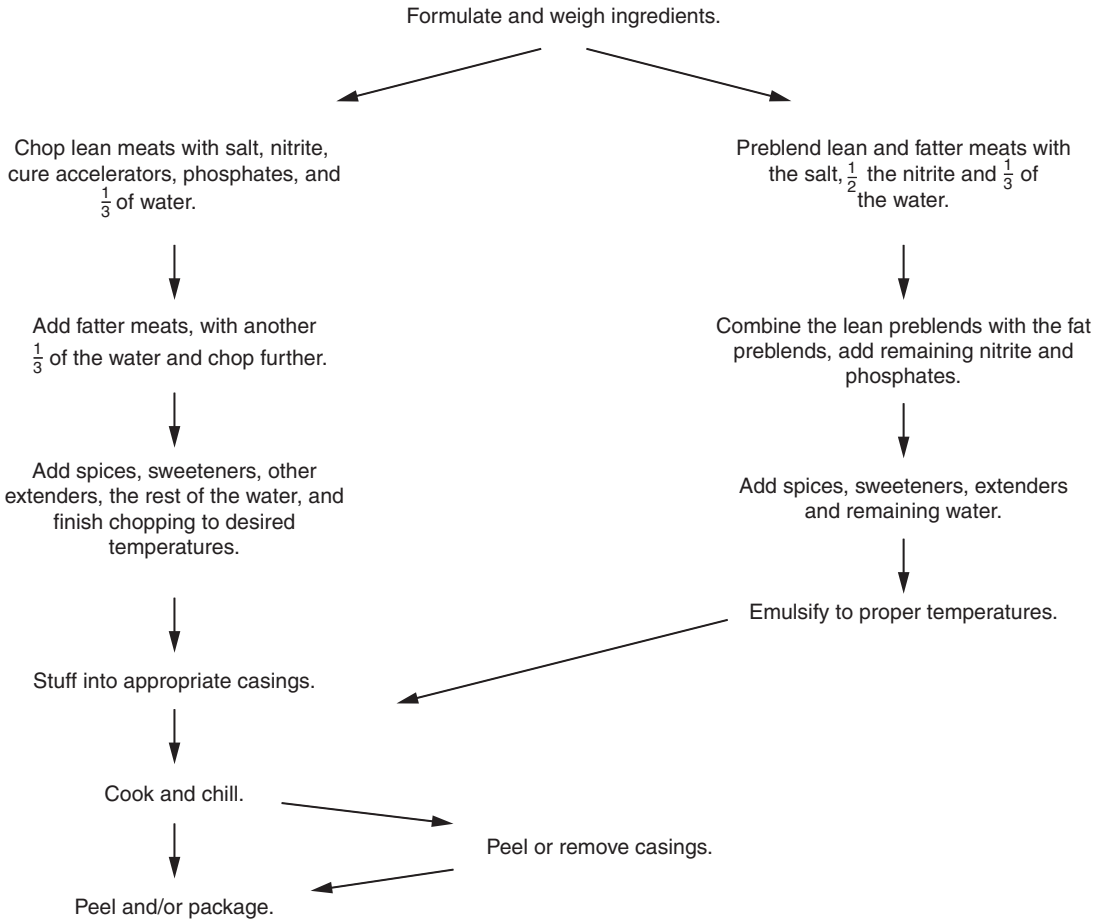

Figure 3 Flow chart for producing emulsified meat products.

Table 1 Final emulsion temperatures based on the formula's predominant fat source

Predominant source of fat	*Final emulsion temperatures in °C (°F)*
Chicken or turkey	7 °C (45 °F)
Pork	12–15 °C (55–60 °F)
Beef	4 °C (40 °F) or 18–24 °C (65–75 °F)

temperature 5–7 °C below the proper final emulsion temperature (Table 1). More precisely, the temperature difference between the final mixing and emulsifying should equal the temperature rise that is typical for the number of passes that the product is sent through the emulsifier. This mixture is then passed through an emulsifier one or more times, depending on the equipment and the temperature rise.

After chopping or emulsification, the mixture is stuffed into a casing to give it its distinctive shape and appearance and is then cooked either in an oven or in water. Cooked sausages that are cooked in an oven are typically smoked, using either natural or liquid smoke. Most cooked sausage products are fully cooked and referred to as ready-to-eat products.

The emulsion production system just described is based on the use of meat proteins as a base material. Some cooked sausage products, such as spreadable liver sausage or paté, are made without using the binding ability of raw meat proteins. The nonbinding materials in these products are essentially trapped in the cooked meat mixture. This lack of bind allows the product to be spreadable. There is also a sliceable version of liver sausage, which does depend on the bind of meat proteins discussed previously.

Rind Emulsions

Emulsions can also be made using pork rinds or skins. Rind emulsions are made by first cooking the pork rinds in water. The cooked rinds are then finely chopped, and sodium caseinate or soy isolate is added to stabilize the collagen and fat in the chopped rinds. This product is then chilled and added as a fat replacement ingredient in emulsified products.

Fat Preemulsions

Fat preemulsions are made to stabilize fat against the stress of cooking the sausage, thereby preventing the fat from rendering out of the product during cooking. Either sodium caseinate or soy isolate can be added to fat during a chopping process and after this mixture has set up, it can be added as a stable fat source to lean meat in order to produce a fine-chopped or

emulsified meat product. As a pre-emulsion, the fat is less likely to melt during cooking process than the fat that has not been preemulsified.

Causes of Emulsion Failure

Emulsion formation is based on the successful use of meat and nonmeat ingredients, stuffing these into casings and cooking the resultant sausages. Emulsion failures, often referred to as 'fatting out,' most often result in fat separation from the meat mixture and coalescence of the fat on the surface of the product, just under the casing. Emulsion stability is typically as good as the weakest link in the whole process. Most commonly, emulsion failures are due to the inability of the lean meat ingredients to emulsify or trap the fat sufficiently to prevent fat separation. This could be due to insufficient levels of salt or phosphates, too much fat or water being added to the formula, or chopping or mixing to a too high or too low temperature before stuffing and cooking. Also, emulsion failure may be due to damaged proteins, resulting from using improperly frozen trimmings or trimmings that are too old and partially spoiled. Abusing an emulsion by pumping it too far or holding an emulsion too long between emulsification and cooking may also cause an emulsion breakdown. Emulsion failures may also occur with properly made emulsions that are either improperly stuffed into the casings or cooked too rapidly or at too high relative humidity in the oven.

Emulsion failure may also result from the formation of gel pockets under the casing, which is normally due to the use of high-collage meat ingredients in combination with high-humidity cooking processes.

Types of Emulsified Sausages

Examples of emulsified sausages include: frankfurters, wieners, hot dogs, bologna, white hots (cooked bratwurst), bockwurst, knockwurst, Braunschweiger, or liver sausage. The descriptions of these products, and more, follow.

Bockwurst

The traditional bockwurst contains veal and pork, milk, eggs, chives, and parsley and is seasoned similarly to frankfurters; however, bockwurst does not contain nitrite and is not smoked. Bockwurst is stuffed into 1 in. (25 mm) diameter casings and cooked in water. Originally, bockwurst was sold as a fresh (raw) product but is now most often sold as a cooked product, because of its highly perishable nature.

Bologna

Bologna, which originated from Bologna, Italy, is made much like frankfurters and wieners. Bologna is most often stuffed in larger diameter (4–5 in./10–13 cm diameter) casings, sold in chubs or sliced for use as cold sandwich meat. It is also available as ring bologna, in which beef rounds are used for the casing and stuffed as 1 lb (454 g) loops. Bologna could be made with a coarse-ground texture but most commonly is a finely chopped product.

Bolognas often have a similar flavor to hot dogs, but they often contain more garlic to enhance the flavor, as they are most often eaten cold. Mustard is heavily used in most bolognas. Large-diameter bologna is not typically smoked.

Braunschweiger

Braunschweiger, or liver sausage, is typically made from pork trimmings, livers, and bacon trimmings and cooked in moisture-impermeable casings in water. This product may be cured or uncured, spreadable or sliceable, or fine chopped or coarse minced. The spreadable liver sausages are not considered emulsified, because to retain spreadability protein-to-protein bind needs to be minimized. Onion, nutmeg, and smoked bacon are typical flavors found in liver sausages. Nonfat dry milk is used to soften the harsh flavor of the liver. If cooked meats are used instead of raw ingredients, a spreadable product (see paté) is produced.

Cocktail Frankfurters

These are short, small diameter, finely chopped frankfurters, typically used as appetizers. Currently, cocktail franks are often produced by a coextrusion process, which does not require the use of a casing.

Frankfurters

This product is believed to originate in Frankfurt, Germany in 1487. The name frankfurter is often used interchangeably with frank, wiener, and hot dog. Frankfurters are typically 3/4 to 1 in. (20–25 mm) in diameter and are linked in 5 in. (12.5 cm) lengths. Frankfurters are prepared using either a natural casing or a cellulose casing and are typically smoked. The cellulose casing is removed before packaging of this product, which results in what is called a skinless product. Skinless frankfurters make up more than 95% of this product category. Frankfurters are most commonly sold in the fine-chopped, emulsified form but may be made as a coarse-ground product. Frankfurters are most often sold in packages of 10 per pound (454 g).

The flavor of frankfurters is typically due to black pepper, nutmeg, and possibly coriander. Garlic and onion may also be used in frankfurters. Mustard is heavily used in most hot dogs. Other spices may be used to produce a particular regional flavor. Because they are normally eaten hot, frankfurters would not be as heavily spiced as bologna, which is most often eaten cold.

Hot Dogs

Officially, hot dogs are wieners or frankfurters, which are sold and eaten in a bun. Hot dogs were first seen in the late 1800s, at baseball games in the United States, at which vendors decided to use bread, instead of the 'gloves' that had been used previously, to hold the hot sausages while eating. Frankfurters were often called 'dachshund' or 'little dog' sausages by German vendors. Although there is not total agreement on the origin of the name 'hot dog,' one version is that a *New York Journal* sports cartoonist, Tad Dorgan, was not sure how to

spell 'dachshund' in a cartoon he was drawing, so he simply wrote 'hot dog!'

Knackwurst

Knackwurst sausages are very similar to frankfurters. They are made with a fine-chopped texture, except that they are made using a larger diameter casing (1½ in./4 cm) than most frankfurters and linked in 3–4 in. (7.5–10 cm) lengths. Knockwurst sausages are known for their garlic flavor.

Mettwurst

This product was originally made in a couple of ways in its native Germany. In Southern Germany, mettwurst is made of pork smoked and sold as a raw, spreadable product. In Northern Germany, it is made similarly, but it was dried longer during the smoking process to make a dry product. In the United States, it is made primarily as a linked, cooked, and smoked sausage product.

Paté

Paté is a finely comminuted product like other emulsified products, but in order to make it a spreadable product, the emulsification process (discussed earlier) is not used for this product. Paté is made from fresh livers and precooked pork and cooked in a moisture-impermeable casing. This product lacks the bind of liver sausages made from raw meat ingredients and is, therefore, a spreadable product.

Vienna Sausages

Vienna sausages are short, small-diameter frankfurters often cut (open ends) from long lengths of stuffed casings and sold in cans or glass jars.

White Hots

Also known as a cooked bratwurst, this product is made much like frankfurters except that its product contains no nitrite and is typically not smoked.

Wieners

Wieners originated in Vienna, Austria. The wiener is essentially the same as a frankfurter, with the exception that originally it was made primarily from veal, rather than from pork and beef. Currently, there is very little difference between a wiener and a frankfurter, and the names are often used interchangeably, even though wieners have been defined as being smaller than 20 mm in diameter and frankfurters as being 20 mm or larger.

Fresh

HW Ockerman and L Basu, The Ohio State University, Columbus, OH, USA

Glossary

Bockwurst German sausage made from ground pork, and/or lamb, turkey, chicken.
Hot boning Boning before chilling (before rigor).
Meat emulsion A two phase system, with the dispersed phase containing solid or liquid fat particles and the continuous containing water.
Mechanically deboned tissue (mechanically separated meat (MSM), mechanically recovered/reclaimed meat (MRM)) Obtained by forcing meat and bone, under high pressure through a sieve or similar device to separate the bone from the edible meat.
Mettwurst German strongly flavored sausage made from raw ground pork, which is preserved by curing and smoking.
Thuringer German mildly seasoned fresh or smoked sausage.

Introduction

Fresh sausage under the US regulations is defined as fresh, uncured (however, some are cured). Its taste, texture, tenderness, and color are related to the ratio of fat to lean content, and trimmings from primal cuts are often used as raw material. Ice or water is limited to 3% of the total formula. Fresh sausage must be stored under refrigeration and thoroughly cooked before consumption. Binders and extenders are permitted except when prohibited by regulation. There are essentially seven decisions when making fresh sausage: selection of raw materials (species, location of tissue in a carcass, fresh or frozen, and fat content); comminution of the tissue (emulsion to coarse grind); selection of seasonings (flavor) and additives (chemical and physical properties); mixing (uniformity); alteration of the protein (physical propersties and yield); shaping of product (selection of desired form and casing type, if used); and type of storage (normally refrigerated or frozen). Consumers are responsible for cooking (effecting flavor and safety of the sausage). The definition of fresh sausage is not always clear and covers a variety of items manufactured from meat tissue. Many nationalities often have their own specialities of fresh sausage that are tailored to their own organoleptic preferences. The most popular US fresh sausage is 'fresh pork sausage' made from individual pork cuts or from the total muscle mass of carcasses (e.g., whole hog carcasses), which is minced and seasoned. However, even the US fresh pork sausages can differ in texture, tissues used, seasonings, type of casings (or without casings), and meat/fat content. The most popular formats of pork sausages are links or patties that are usually consumed at breakfast with gravy (often pork sausage gravy) and eggs in a variety of cooking procedures. Fresh pork sausage is usually not smoked, but smoked variations are also available. All fresh sausages should be cooked before eating, even those that have been smoked.

Definitions

A definition (according to the US meat inspection) of fresh sausage can be found in the Code of Federal Regulations, 9 CFR 319 Subpart E.

'Fresh pork sausage' can be prepared from fresh or frozen pork, (not including pork by-products), can contain some mechanically separated (species) tissues, can be seasoned, cannot contain more than 50% fat in the finished product, and can contain a maximum of 3% water or ice.

'Fresh beef sausage' can be prepared from fresh or frozen beef (not including beef by-products), can contain some mechanically separated (species) tissues, can be seasoned, cannot contain more than 30% fat in the finished product, and can contain a maximum of 3% water or ice.

'Breakfast sausage' can be prepared from fresh or frozen meat (including meat by-products), can contain some mechanically separated (species) tissues, can be seasoned, cannot contain more than 50% fat in the finished product, and can contain a maximum of 3% water or ice.

'Whole hog sausage' is similar to 'fresh pork sausage' except that the pork must be in the same proportion as found in a single carcass and mechanically separated (species) tissue must likewise be in proportion of the species used.

'Italian sausage products' are more difficult to define because there are several subcategories, such as cured (must be in the product name) or uncured, cooked (must be in the product name) or uncooked, smoked (must be in the product name) or unsmoked, and seasoned (can include paprika, vegetables, and monosodium glutamate). They can include a maximum of 3% ice or water.

'Uncooked smoked sausage,' is smoked with hardwood or other nonresinous material, seasoned, and shall not contain more than 3% added moisture and no more than 50% fat.

'Pork sausage' or 'sausage meat' in the UK has 65% meat with 60% lean meat, of which 80% is pork; for beef and other sausages, the meat content is reduced to 50%, of which 50% must be lean meat and 50% must be named meat.

"Fresh Sausage" or "Sausage Meat" is usually pork but can contain some beef, chicken, and tripe. All fresh sausage should be cooked before serving.

"Smoked Sausage" is made from meat that is often cured (with some exceptions that take it out of some of the definitions of the fresh sausage category) and can be smoked and uncooked or smoked and cooked (excluded from fresh sausage category). Smoked-only products should be cooked before consuming.

Raw Materials

Tissues used for manufacturing fresh sausages should have a low bacterial count (because no heat is used to reduce their numbers) and the products should be handled under strict sanitation and the temperature should be maintained at or below 2 °C (35 °F) during mincing and mixing. The temperature should be lowered to 0 °C (32 °F) during holding and transit. For extended shelf life, the temperature could be lowered to −18 °C (0 °F) until shipped. Meats utilized for manufacturing include pork trimmings (e.g., 85–95% lean), regular pork trimmings, and cheek meat.

Color of the trimmings will influence the color of the sausage. Pale, soft, and exudative pork tissue will not only result in a lighter color but also result in more shrinkage when cooked. Dark, firm, and dry pork tissue will result in darker sausages with a pH more favorable for bacterial growth; however, this tissue will have increased water-holding capacity. The percentage of red (darker) as opposed to white (lighter) fibers in muscles is influenced by the animal's genetics and the location in the carcass, with the more active muscles (e.g., the heart, shank, neck, and many muscles in the fore quarter) being darker. Even in the hind leg area, different muscles have different amounts of pigmentation and different muscle fiber types. Species, age of the animal, and exercise will also influence the color. Beef and lamb tissues are usually darker than pork tissue, which is usually darker than chicken tissue. As animals age, muscles usually become darker, and as tissue dries out, it darkens. Mechanically deboned tissue contains more red pigment due to an increase in bone marrow and a decrease in connective tissue.

The quantity of connective tissue can have influence on tenderness and chewiness as well as on emulsifying stability in emulsified products. Again, the active shank muscles, cheek muscles, and a portion of the fore quarter are higher in connective tissues. However, fresh sausage is minced and is usually not an emulsion; therefore, tenderness and emulsifying stability are usually not a major problem. Fresh pork sausage in the US must use pork trimmings that do not exceed an average maximum of 50% trimmable fat. An entire pork carcass will yield approximately 50–70% of sausage tissue, if the whole carcass is utilized.

Seasoning varies according to the individuals manufacturing the products. Some of the more popular seasoning mixtures can be found in Table 1. In most cases, the proper blend must be selected to suit the required taste. There is a wide range of ethnic and regional preferences in seasoning. Areas that are more tropical and/or produce spices (e.g., India) generally prefer more spice intensity. Even in regions of the country that are in close proximity, flavor desirability can vary a great deal (e.g., fresh pork sausage with or without sage).

Binders and extenders are permitted (under the US regulations 9 CFR 319 Subpart E) in fresh sausage except where prohibited by regulations; for example, 'pork sausage' (9 CFR 319.140), 'beef sausage' (9 CFR 319.142), 'whole hog sausage' (9 CFR 319.144), and 'Italian sausage' (9 CFR 319.145).

Sex and age can influence boar taint, which can impart an undesirable flavor and odor to sausage products. Older, intact boars are the major (but not the only) contributors of this undesirable problem.

Casings

Sausage might be stuffed into casings, linked or not linked, or sold as sausage meat (loose or unstuffed). Natural casings are the small and large intestines of hogs and come in sizes of extra narrow (29 mm or less), narrow (28–32 mm), narrow medium (32–35 mm), English medium (35–38 mm), wide (38–43 mm), and extra wide (43 mm and above). Sheep casings can also be used; popular sizes are 20–22 and 24–26 mm. Animal casings are highly contaminated and fragile when removed from animal carcasses and must be cleaned immediately after harvest. Cleaning involves removal of mesentery, passage through a manure stripper, water soaking, passage through a crusher, further water soaking, passage through a mucosa stripper, passage through a finishing machine, and soaking in salt water. Factors that influence casing quality include age of animals, breed, fodder consumed, other factors related to animals (e.g., parasites), or conditions under which they were raised. After cleaning, the casings are sorted, salted, packed in salt, and shipped. Before the casings are used, they are often soaked in water to remove the excess salt. Reconstituted collagen (corium layer extracted from animal hides, usually beef) and extruded fibrous cellulose, polyethylene, and cloth casings or bags are also sometimes used.

Production and Types of Sausage

Prerigor sausage production (muscle removal from carcasses by hot boning before chilling) is gaining in popularity. This technique is particularly utilized when whole hog sausages are manufactured because tenderness is not a major problem when utilizing minced tissue. One major advantage of prerigor sausage manufacturing is extended shelf life (can almost be doubled) of the sausage as a result of the salt microbiologically stabilizing the fairly clean tissue before extensive microbial growth and increased chilling efficiency compared with chilling and then boning. Hot boning can also increase yield. Modern whole hog processors today often utilize 240–350 lbs (114–200 kg) butcher hogs to make this sausage. To facilitate mincing and mixing, ice or water may be used, provided it does not exceed 3% of the total ingredients used.

In principle, 'fresh sausage' is one of the simplest types of sausage to make, as it is usually neither cured and cooked nor smoked before being sold. It is simply minced tissue that is seasoned, mixed, and stuffed into a casing or sold in bulk.

The typical 'fresh pork sausage' is processed by mincing through a 12.5 mm (0.5 in.) plate, mixing, remincing through a 5 mm (0.18 in.) plate, stuffing, and then selling as fresh or frozen.

However, some products are cooked (meat precooked before manufacture). Some products after manufacturing are fried. Some are cold or hot smoked and then, in some cases, cooked (62 °C/142 °F; excluding it from the fresh sausage category). In some cases, the casing is peeled or the sausage may be molded rather than being in a casing. Precooked and peeled sausage is often called 'brown and serve' sausage.

Other types of fresh sausage are subsequently described.

1. *Pork sausage*: Owing to the large surface area exposed and the lack of heat treatment, maintaining an attractive color

	0.75 oz Nutmeg	3/8–1 oz Thyme	0–1 oz Rubbed sage	0–2 oz Coriander	1 oz Sage	0–4.8 oz Mustard seed	0–2 oz Coriander
	1 oz Thyme	2–5 oz Sage	2–8 oz Onion powder	0–4 oz Paprika	3 lbs Eggs		0–4 oz Garlic powder
				Sometimes starter culture	4.75 lbs Nonfat dry milk		0–3 oz Nutmeg

[a]Fresh country-style pork sausage' is ground a little coarser and is usually stuffed in casings 1–3/8 in. diameter, often unlinked or can be linked 8–10 in. long, or sold in bulk. It should be refrigerated before preparation and cooked before serving.
[b]Per 45 kg (100 lbs) of the meat block.

and shelf life in this sausage is difficult. Therefore, proper sanitation and product temperature at or below 0 °C (32 °F) should be maintained throughout the distribution and retail merchandising system as well as during home storage before cooking.

2. *Breakfast style*: This is a finely minced, all pork sausage that is seasoned with salt, pepper, and sage and stuffed into medium and large sheep casings, small hog casings, or regenerated collagen casings. It is linked in a variety of lengths to make different sizes of sausage. It is also merchandised in bulk and in patties. This product is rarely smoked, but it will not wrinkle if the smoking temperature is between 90 and 100 °F. This 'fresh' sausage is now also made precooked, often in links, but without casings or in patties (sometimes sold with biscuits). It is often sold at retail in the unfrozen state. The precooked product has a longer shelf life, and color is not a major merchandising problem.
3. *European pork and beef sausages*: These sausages can contain additional ingredients such as 10–15% binders (often rusks, stale ground bread), 11–26% water, phosphates, and a variety of seasonings, eggs, and tomatoes.
4. *American pork and beef fresh sausages*: Sausages that contain beef, in addition to pork, are sometimes smoked but are not cooked.
5. *'Smoked country-style pork sausage' and 'Smoked country-style sausage'*: These are smoked, uncooked sausages that should be cooked before consumption.
6. *Country style*: This type of sausage usually contains 10–20% beef and 80–90% pork. It is coarsely minced (0.18 in. or 5 mm plate) and does not contain sage. It is sold in bulk or stuffed into different sizes of hog casings or regenerated collagen casings and is not linked. This sausage is sometimes also smoked (2–3 h), and the added leaner beef will reduce wrinkling if the temperature does not get too high.
7. *Bratwurst*: This is a sausage manufactured from lean pork plus seasonings and sometimes with the addition of beef trimmings. Also, nonfat dried milk and eggs are sometimes incorporated. This mixture is minced through a 0.18 in. (5 mm) plate, stuffed into narrow hog casings, and usually not smoked, although the sausages can be smoked for 3–4 h at 120–130 °F. Sometimes, the product is also cooked (excludes it from the fresh sausage category) before it is sold at retail.
8. *Fresh Thuringer*: This is a beef sausage, sometimes with added pork, that is minced through a 6 mm (0.25 in.) plate and stuffed into medium casings. It may be cured and/or fermented, usually with a starter culture, and/or cooked before sale. If these treatments are used, it is excluded from the fresh sausage category.
9. *Bockwurst (white sausage)*: This is a veal or beef and/or pork sausage that often contains eggs and nonfat dried milk. It is minced through a 0.125 in. (3 mm) plate and stuffed into casings. It is very perishable and must be cooked before consumption.
10. *Mettwurst*: This is a pork or pork (30–80%) and beef (20–70%) sausage that is sometimes cured and stuffed into casings (1.5–1.75 in.), usually smoked and uncooked but should be cooked before consuming.
    a. Polish (Kielbasa): This is a pork or pork (70%) and beef (30%) sausage that is minced through a 6 mm (0.25 in.) plate, seasoned with garlic, stuffed into 1.5 in. casings, and cold or hot smoked; it should be cooked before consuming. It is sometimes cooked before retail sale.
    b. Italian pork sausage: Some varieties are uncooked, smoked sausage and should be cooked before consuming. 'Hamburger or burger' has several meanings to different people, depending on where it is purchased. Retail hamburger is simply fresh (uncooked) ground beef without any additives that is sold refrigerated, packaged with oxygen-permeable film or vacuum packed (which extends shelf life but the product is darker in color when opened), or frozen, thus fitting much of the definition of fresh sausage. Burger at retail is fresh ground beef often containing seasoning, additives, and/or cheese and vegetables, which is closer to the definition of fresh sausage. Hamburger and burger

Figure 1 Some of the forms of fresh Sausage. Top left: fresh pattey, top right: smoked, and bottom: fresh links.

if purchased at a fast-food restaurant is cooked (outside of fresh sausage category) and served with a bun (Figure 1).

'European fresh sausage-type products' include 'meat loaves,' 'meat pies,' 'puddings,' flans,' 'pates,' and fermented products such as 'salamis'.

Many other 'International products' also fall into the fresh category. For example, those containing soy can include 'Boerewors' (South Africa), 'Longaniza' (Philippines), 'Native Longaniza' (Philippines), 'Formulated Beef Patties' (USA), 'Formulated Gyro Patties' (Philippines), 'Mutton Patty or Maharaja' (India), 'Grilled Chicken Patty' (India), 'Beef Patty' (Indonesia), 'Pork Breakfast Patty' (USA), 'Turkey Sausage Patty' (USA), 'Turkey Breakfast Patty' (USA), 'Chicken Patty' (USA), 'Beef Kekaba' (Pakistan), 'Beef Burger' (Italy), 'Chicken Sausage' (Indonesia), 'Food Service Chicken Burger' (UK), 'Veal Pojarski Steak' (UK), 'Chicken Mignon' (UK), 'British Breakfast Banger' (UK), and 'Pizza Topping' (USA) from Hoogenkamp (2001).

Many more international fresh sausages containing other additives and extenders could be added to the list if space permitted.

Summary

Spices sometimes utilized in fresh sausages can be seen in Table 1, processing procedures are listed in Table 2, and finished forms for these fresh sausages are listed in Table 3. Because there

SENSORY AND MEAT QUALITY, OPTIMIZATION OF

M Dikeman, Kansas State University, Manhattan, KS, USA
CE Devine, The New Zealand Institute for Plant and Food Research, Hamilton, New Zealand

Glossary

Aging The process of meat tenderization and flavor intensification that occurs over time – it commences after rigor mortis.
Calpains Components of the enzyme system that acts on cytoskeletal proteins during meat tenderization.
Conditioning One of the terms used to describe the process when meat enters rigor mortis; it is sometimes used interchangeably with aging.
Connective tissue The noncontractile fibrous proteins (epimysium, endomysium, and perimysium) that are contained within or surround muscle fibers, bundles, and whole muscles – the amounts dictate the basal or 'background' tenderness.
Cooking Application of heat to meat that denatures the various proteins at different rates, depending on the temperature, resulting in various textures, colors, and flavors of cooked meat.
Harvest Used in preference to 'slaughter' in some countries and is the period from stunning to exsanguinations to processing of carcasses.
Myofibrillar proteins The muscle contractile proteins: actin and myosin.
Postmortem The period after harvest when the pH falls until rigor mortis and subsequent aging.
Preslaughter The period before harvest where factors such as stress can affect meat quality.
Rigor mortis A term where muscles stiffen after all muscle fibers enter rigor.
Shear force The force (N) applied to a standardized core, slice, or cube of meat to shear it.
Shortening A process that occurs when prerigor muscle is cooled below 10 °C – additionally, it also occurs as muscles enter rigor at high temperatures (rigor shortening).
Tenderization An enzymatic process that takes place after rigor mortis and makes meat tender.
Toughening Procedures that inadvertently cause meat to become difficult to bite or chew.

Introduction

Success of any product in the marketplace depends on its appeal and acceptability to consumers. Perceived quality, both at point of purchase and at point of consumption, usually depends on a combination of variables that are still screened and evaluated by human panels, even though many of the individual parameters can be measured or estimated by objective means. However, superimposed on the combinations of variables are national or cultural preferences for products. Brand names of products in many countries are important for the profitability of meat marketing and sales, but, in reality, brands are not an automatic guarantee of sensory aspects of quality. A shift to value-based marketing from the traditional commodity marketing system will require optimization of production and processing in order to guarantee quality.

This article briefly covers aspects of meat production, preslaughter stress, and processing that affect the sensory aspects of meat. Rather than merely providing satisfactory quality, these variables can interact to produce an optimum product by addressing the way meat animals are farmed and meat is processed. Other situations are more widely considered under texture variations. Endeavors to produce meat of optimum quality involve numerous technologies that are covered in articles throughout this Encyclopedia, impinging on aspects such as microbiological safety, processing, packaging, and transport. This article covers only those that have a direct effect on sensory aspects of eating quality of fresh meat. Processed meat products are not covered.

The sensory aspect of meat quality needs to be distinguished from food safety or the microbiological aspects of quality. In fact, the processing conditions for maximum food safety considerations often are contradictory to optimum sensory aspects of meat quality. It is informative to consider the way various aspects of refrigeration, microbiology, and meat quality interact by examining modeling processes.

The main requirement of consumers is palatability, which comprises tenderness, texture, juiciness, mouthfeel, and flavor with an overriding assurance of food safety. Tenderness is very important to consumers in most countries (high 'scores' indicate increasing desirability) and it is most conveniently determined objectively using a tenderometer (e.g., Warner–Bratzler shear instrument, Lee–Kramer instrument, or MIRINZ tenderometer), where low values indicate increasing desirability. Acceptability can occur over a range of values, so there is no

optimal value. A high degree of tenderness by itself does not guarantee a high degree of acceptance, for example, a high degree of tenderness is not necessarily acceptable if the meat is dry or mushy or contains off-flavors. In addition, other factors such as texture (affected by connective tissue content) and mouthfeel (conveyed by level of lipid components) are required for optimal palatability. Certainly, there should be a very desirable flavor and no off-flavors.

Visual Impact at Point of Sale

At the point of purchase, consumers depend almost exclusively on visual properties in order to assess perceived quality or on labels such as 'Prime' or 'Certified Angus Beef,' whereas at the point of consumption, they depend on olfactory, taste, and mouthfeel sensations to assess eating satisfaction. Hardly ever is there direct feedback from consumers to determine which visual attributes influence quality, but color generally is the most important trait affecting consumers' purchase decisions. Overlying the purchase aspects are obvious health-related concerns, such as levels of saturated fats or total fat content. An example is the level of marbling in meat, which is generally associated with desirable meat quality, particularly in beef. However, it has been shown that marbling accounts for only 12–14% of the variation in tenderness or even of other of palatability traits. Nevertheless, a certain degree of marbling is essential for optimum palatability, but excess marbling beyond a certain level does not increase palatability significantly. Also, marbling is not always seen as a positive attribute by some consumers, particularly those who are diet/health conscious.

Species, Gender, and Genetics

The factors influencing the sensory aspects of meat quality include intrinsic animal properties, such as gender, species, and genetics. To some extent, gender aspects, such as toughness in bulls, are related to a higher proportion of more insoluble collagen or stress effects, but gender-related effects, such as boar taint, are more predominant in males. Meat from cattle is generally less tender than meat from lambs and pigs. In general, tenderness and other palatability traits are often less desirable for intact males than for castrate males and females.

Genetics

Genetic properties of animals are important for obtaining the right characteristics for various production situations. Angus, Red Angus, Shorthorn and South Devon cattle, and Duroc and Berkshire swine breeds are best for high marbling. Animals with a *Bos indicus* content (≥50%) have generally less tender meat in most major muscles. However, with good electrical stimulation, these differences are less significant. Hindsaddle muscles of callipyge sheep are much less tender than those of normal sheep. Hampshire swine have tender meat but a lower water-holding capacity because of the Napole gene. Charolais or Simmental × Angus or Red Angus crosses of cattle optimize composition and meat quality. Heritability of tenderness and of marbling in cattle is approximately 0.40 and 0.50, respectively. Expected progeny differences for tenderness (measured by Warner–Bratzler shear force) have been published by some breed associations in the US. There are now commercially available genetic markers for beef and swine for quality traits. Within the beef industry, genetic markers for marbling and tenderness can be used. For swine, genetic markers for the Napole gene, the Halothane gene, and marbling are available.

Production

Production aspects, such as extensive pastoral management situations or intensive feedlot management situations, influence marbling and/or meat palatability traits. Feeding of supranutritional levels of vitamin E to cattle (e.g., 2000 IU α-tocopherol acetate kg^{-1} feed per day for at least 50 days) or pigs (e.g., up to 700 mg kg^{-1} α-tocopherol acetate from weaning to harvest) is a practical and effective way to improve meat color and can extend shelf life by 2 to nearly 5 days, with no reports of negative effects on feed intake or performance. It is suggested that this effect arises from accumulation of α-tocopherol in muscle tissue and this antioxidant delays both lipid and myoglobin oxidation and decreases drip loss. Such supplementation is less important for pasture-fed animals, for which there is usually sufficient vitamin E in the diet over most of the year.

Aggressive anabolic implants and some β-agonists can decrease tenderness. Growth rate and animal age influence connective tissue cross-linking that, in turn, affects tenderness. These characteristics mean that younger animals are preferred. Cattle and sheep finished on pasture produce meat that is different in color, flavor, and sometimes in tenderness than those finished on high grain diets. Consequently, there are two different consumer perceptions, and often preferences, of the subsequent quality from the two systems. Regardless of the production system, the rate of growth of muscle should be as near maximum as possible in order to minimize the negative role that collagen maturation can have on tenderness in cattle or lambs. It is probably fair to say that the best of both pasture and grain finishing systems is equally appreciated and depends on the quality characteristics to which consumers are accustomed.

Preslaughter

Even if genetic and production aspects are optimal, preslaughter factors can still modify the final product. Ideally, stress effects should be reduced by appropriate genetics, but some animals, such as Pietrain pigs (other pig breeds can also have similar effects), have an exceptionally fast glycolytic rate that can be triggered by immediate preslaughter events, leading to an aberrant meat quality defect known as pale, soft, and exudative (PSE) condition. In addition, stressing of normal pigs just before slaughter without allowing 2–4 h of rest can result in PSE pork. Long-term stress over 24 h can reduce muscle glycogen, leading to elevated ultimate pH values.

When the ultimate pH is in the range of 5.75–6.1, the meat is generally less tender, particularly for cattle, than the meat of lower ultimate pH. When the pH is too high, a condition such as dark, firm, and dry (DFD) is produced with meat that has undesirable color, flavor, and textural defects. Beef with high pH is acceptable for tenderness but not desirable for visual appearance or flavor. The DFD defect cannot be significantly modified by any aspects of processing once animals are harvested. To some extent, rapid chilling of pork carcasses can minimize PSE, but the rapid chilling can introduce other serious effects in non-PSE meat, such as cold toughening.

Processing

Assuming that intrinsic animal properties are optimal and preslaughter stress is minimal, the major extrinsic component of meat quality is processing. The effect can be so dramatic that it can override the benefits of any optimal production and preslaughter handling.

Cold Shortening and/or Toughening

When rapid chilling causes the meat temperature to fall below 8–10 °C while the pH is above 6, the muscles shorten to cause cold toughening. However, this situation does not occur in poultry until the muscle falls below a critical temperature of approximately 2 °C. The temperature for minimum shortening of muscle is 15 °C, although environmental temperatures may be well below this, and this is an optimum temperature for rigor mortis to occur. Cold shortening/toughening is more likely to occur in carcasses with thin fat covering. Therefore, rapid chilling to achieve microbiological safety has to be balanced with optimum temperature for tenderization.

Temperature and Reduced Aging

Mere avoidance of cold shortening by keeping temperatures elevated during processing can have another effect called 'hot toughening,' which really is a reduced aging capability rather than toughening per se. Hot toughening/reduced aging was previously labeled 'heat shortening,' but it now appears that the shortening, which does indeed occur, is not the main reason for toughening but rather the enzymes ordinarily responsible for tenderization are denatured, possibly through pH/temperature effects, with the result that the meat cannot tenderize to the same extent as in more conventional chilling. The protein denaturation that can occur also reduces juiciness and hence palatability. This so-called 'hot window,' where pH 6 is reached when muscle temperatures are above 30 °C, reduces palatability for nonelectrically stimulated beef and lamb. Heat toughening and reduced aging with rigor mortis occurring above 20 °C are far more significant in poultry than in sheep and cattle.

Electrical Stimulation

With a more rapid and controlled glycolysis induced by electrical stimulation, muscle pH values fall more rapidly, thus entering rigor mortis early and avoiding temperatures at which cold shortening/toughness would otherwise occur. For this reason, electrical stimulation has become a major processing technology. The situation in which a rapid fall in pH causes a PSE-like condition in pork is rare in beef and lamb, and once muscles are in rigor mortis, myosin denaturation is minimal. Thus, for electrically stimulated beef and lamb carcasses, not only does more rapid rigor mortis reduce myosin denaturation and drip, but also increasing stimulation effectiveness reduces the time to rigor and exposure to potential denaturation conditions. This occurs because some muscle fibers enter rigor almost immediately on stimulation and the rest of the muscle fibers rapidly follow. Some drip does eventually occur because tenderization occurring through cytoskeletal denaturation produces drip. The early appearance of drip following stimulation occurs as muscles tenderize rapidly, but there is no more drip for equivalent tenderization. Conditions that reduce drip generally reduce tenderization.

Tenderstretch

When carcasses are suspended by the pelvic bone (called 'tenderstretch'), some muscles are stretched, which minimizes or prevents shortening, although it cannot prevent it with extremely fast chilling. The tenderstretch method results in longer sarcomere lengths for some important muscles, consistent with tender meat. However, the hind legs fall in such a way that some leg and loin muscles may be shortened, but not to the degree that causes significant toughness. There are practical physical problems created in large plants with close rails with the hind legs extending laterally and cause movements of carcasses on rails difficult. Consequently, the 'tenderstretch' technique is not used in the larger North American plants. There are various modifications of this technology, such as 'tendercut,' in which the vertebrae are sawed at one or more places to allow some stretching of the longissimus muscle.

Hot and Cold Boning

The normal meat-processing situation in which the carcass is suspended by the Achilles tendon until rigor mortis, with subsequent boning the next day, is termed cold boning. Hot boning occurs when meat is excised before rigor mortis while carcass temperature is relatively warm, and as early as 45 min postslaughter. Rapid chilling of hot-boned meat can result in cold shortening, which is exacerbated by the absence of skeletal restraint. This is avoided to some extent by electrical stimulation because the accelerated rigor mortis occurs before the muscles have reached temperatures conducive to cold shortening. If the muscle temperatures are approximately 15 °C at rigor mortis, hot- and cold-boned meats are similar in tenderness.

If excised muscles are wrapped tightly during chilling, shortening can be minimized and the meat will be tender. A modification of this system has been developed in which the meat is fed into a tube containing a film that is stretched over the tube in such a way that allows the open tube to have meat placed in it. The stretched film then contracts to its prestretch dimensions over the meat, forcing out air and bringing the film into close contact with the meat product. The package

is then heat sealed and the meat is conditioned. The very tight packaging prevents muscle shortening.

Aging

Meat is actually least tender at the time rigor mortis is completed because of strong actin–myosin binding and minimal enzymatic proteolysis of the cytoskeletal proteins at that point but becomes tenderer over time by a process known as aging. Aging allows proteolysis (tenderization) to occur and has to be substantial in order for the full tenderness to be realized. It is fastest at warm temperatures, but clearly this has implications in terms of accelerated microbiological deterioration, so quality aspects still have to be considered in terms of food safety. At 15 °C, for example, it can safely be completed in 3–4 days, but other commercial aspects relating to food safety become an issue.

Aging of beef for a minimum of 10 days under commercial situations at a temperature of approximately 4 °C is often practiced. After electrical stimulation, aging commences earlier and at higher temperatures, so overall acceptable tenderness occurs earlier. Lower aging temperatures can be used; for chilled lamb held at −1.5 °C, the aging will take up to 6 weeks, allowing transport to markets distant from production and processing plants. However, it cannot overcome genetic contributions to toughness, toughness from low marbling scores, or toughness arising when the meat has been severely cold shortened. Aging can occur on the hanging carcass or wholesale cuts, where surface dryness prevents significant microbiological growth, or alternatively, the meat can be excised and placed in a vacuum package where the environmental conditions minimize spoilage situations. Tenderization is the same whether resulting from hanging of carcasses ('dry' aging) or storing of cuts in a vacuum bag ('wet' aging), but the flavor profile is reported to be different between dry and vacuum aging. 'Dry aging' results in a browner, roasted flavor, whereas 'wet aging' results in a more metallic, serumy flavor. Although the mechanism of aging is more likely to be the same for all species, there will be differences because of different glycolytic rates preceding aging and differences in the rate of aging itself, even at the same temperature. Poultry ages to an acceptable level in a few hours, pork takes longer, and beef and lamb take considerably longer again. The rapid growth of poultry and pigs to market weights mean that contributions from toughness associated with connective tissue are also lower.

Packaging and Storage

Packaging is covered in detail in other articles. Essentially, packaging is designed both for protection of the meat and for food safety. The packaging environment, of which there are many types, allows aging to develop to the stage at which meat has optimum quality. However, packaging is also important in that meat has to be shipped, not only within countries but also around the world. The storage conditions at low temperatures allow a high degree of aging to be achieved with minimal deterioration. Such meat is exceedingly well received by consumers because of the combination of microbiologically safe packaging and adequate aging.

Freezing of meat (either sufficiently slowly or at a rapid rate to avoid cold shortening) is used to preserve it. Frozen meat, if thawed before cooking and held for a few hours for water reuptake, is similar in palatability as fresh meat. Rapid thawing, such as at room temperature, will result in greater moisture loss and less juicy meat when cooked. However, there can be a significant problem if the meat is aged for long periods before freezing, in which case there can be some off-flavor development, such as rancidity.

Evaluation of Meat Quality Sensory Properties

Evaluation of meat objectively goes a long way to establishing protocols for producing high-quality meat acceptable to a wide range of consumers. However, in reality, sensory properties can only be measured by consumers or sensory evaluation panels. Both of these latter methodologies are expensive, primarily because they are very time consuming. Trained sensory panels consist of highly trained individuals who objectively evaluate the products. There are no accurate objectives or instrumental procedures for measuring flavor differences. Therefore, highly trained descriptive attribute or flavor profile panels are the most accurate methods for measuring them. However, in special markets, only consumers in those markets can be used for sensory evaluation. This makes it difficult for those countries that export meat products throughout the world and it adds to the costs of processing.

Cooking

The method, rate, and endpoint temperature of cooking can have highly significant effects on tenderness and palatability of meat and therefore constitute part of the major factors affecting the optimization of meat quality. Meat is cooked to kill microorganisms, to develop cooked flavors and aromas, and to improve tenderness of muscles with moderate to high levels of connective tissue. For muscles (cuts) with low levels of connective tissue, use of moderate to moderately high cooking temperatures in a dry environment (broiling and oven roasting) to endpoint temperatures of 60–70 °C optimizes tenderness. With moderately high, dry heat cooking on a belt grill, optimum tenderness of beef longissimus, biceps femoris, and deep pectoralis occurs at approximately 55, 60, and 60 °C, respectively. The primary advantage of higher levels of marbling is when meat is cooked to higher degrees of doneness. Cooking at a moderately high temperature and dry environment allows browning and development of cooked aromas and flavors and avoids toughening that results from excess moisture loss at higher endpoint temperatures. However, personal preferences for degree of doneness to attain desired flavor do not always allow optimum tenderness. With proper and controlled cooking, sufficient browning can result to optimize flavor and yet obtain optimum tenderness.

For cuts high in connective tissue, use of moist heat cooking (pot roasting and braising) at moderately low cooking temperatures optimizes tenderness by allowing conversion of connective tissue to gelatin without the toughening of muscle tissue itself that results from collagen shrinkage and associated

excess moisture loss. Maximum conversion of connective tissue to gelatin occurs when meat is in the temperature range 60–64 °C for a considerable time. An alternative to moist heat cooking is dry roasting at low temperatures for a relatively long time. This solubilizes the connective tissue without extensive collagen shrinkage and excessive moisture loss. It also allows browning and optimum aroma and flavor development.

Cooking meat to high endpoint temperatures (75–80 °C) causes myofibrillar toughening because of excessive moisture loss and shrinkage of the muscle fibers, but eventual tenderization occurs to some extent with solubilization of connective tissue. Conversely, the use of thin slices, as in a 'stir fry,' ensures that meat can be cooked to less than 70 °C rapidly but not be overcooked to the stage where connective tissue shrinkage causes toughness.

Guaranteed Tenderness

There is increasing interest in the US for guaranteeing acceptable tenderness of beef. The US Department of Agriculture's Agriculture Marketing Service has developed 'Standard Practice for Verifying Tenderness Marketing Claims Associated with Meat Cuts Derived from Beef.' The marketing claims that requirement can be used by all parties interested in highlighting production and marketing practices of tender beef. Because a significant proportion of beef is marketed before near maximum tenderization occurs, retail stores, restaurants, and food service operations might need to further age beef in order to meet the marketing claims criteria before it is sold to consumers. Because meat tenderizes throughout the distribution chain, measurements at packaging really need to be backed up by time and temperature monitoring. Marination and mechanical tenderization are considered 'noninherent' processes and are precluded from the use to meet tenderness requirements. Beef can be 'United States Department of Agriculture (USDA)-Certified Tender,' when Warner–Bratzler shear force (WBSF) is ≤4.4 kg (43.2 N) or slice shear force (SSF) is ≤20.0 kg (196.1 N), or 'USDA-Certified Very Tender,' when WBSF is ≤3.9 kg (38.2 N) or SSF is ≤15.3 kg (150 N). It is anticipated that this system will be used extensively. One major US beef processing company began using this program in 2013.

Conclusions

The optimization of sensory aspects of meat quality should not be considered as a single, unchangeable process. Factors to be considered depend on the end use of the meat and even the way meat is cooked. However, the main consumer requirement is palatability. Tenderness alone is not enough and other aspects of palatability, such as juiciness, texture, and flavor development, are also necessary.

SENSORY ASSESSMENT OF MEAT

MD Aaslyng, L Meinert, and C Bejerholm, Danish Meat Research Institute, Taastrup, Denmark
R Warner, CSIRO, Werribee, VIC, Australia

Glossary

Check all that apply (CATA) A sensory technique suitable for consumer studies. The consumers are presented with a list of words and are asked to check the words that describe the product.

Core temperature The temperature measured in the center of the meat.

Holistic by DMRI™ A sensory technique used in consumer studies. The consumers are presented with a list of abstract words such as appetizing, traditional, etc and are asked to rate the words depending on how descriptive they find them for the product.

International Standard Organization (ISO) An organization, which produces standards for various processes including that for sensory training and sensory laboratories.

Napping® A sensory technique which can be used both with a trained panel and consumers. The panelists are asked to place the samples on a piece of paper depending on how similar or different the products are.

Quantitative descriptive analysis (QDA) Describes the sensory profile of a product using trained assessors and standardized conditions.

Introduction

Sensory science has been defined as 'a method used to evoke, measure, analyze, and interpret those responses to products as perceived through the senses of sight, smell, touch, taste, and hearing,' and this applies to all food categories. The assessment of meat can be conducted for both hot and cold samples depending on the purpose of the given assessment and the product at hand. Sensory assessment can be conducted using trained panels, where the panelists are used to give an objective description of the product, or untrained consumer panels.

The assessment of meat faces several challenges including the inevitable animal-to-animal variation that always exists despite attempts to remove this factor. Variation within the same meat cut is also an important factor to consider while planning a study. Even small variations in cooking procedures can introduce variation in the samples. Planning and performing a sensory assessment of meat, including subsampling within muscles, therefore needs careful consideration.

This article describes the conduct of sensory panels using both trained and consumer panelists of fresh meat and processed meat products including visual, oral, and odor assessments. The terminology as well as the standardization of procedures including cooking and presentation are described. Specific description for the sensory assessment of pork, beef, and lamb is also described.

Assessment Performed by a Trained Panel

A trained panel consists of assessors who have, as a minimum, passed an initial screening and have received a general training procedure. This can be a systematic training such as that described in the ISO standard no. 8586-1. The assessment is most commonly performed in sensory booths located in a room designed for the purpose in which light and air can be controlled according to the ISO standard no. 8589. If these facilities are not available, it is still important to perform the assessment in a well-ventilated and quiet room (Figure 1).

Classical Sensory Methods for the Evaluation of Meat

There are several methods available for the assessment of food in general. Roughly, the methods are divided into descriptive

Figure 1 Sensory assessment in a booth with controlled light and air flow.

 doi:10.1016/B978-0-12-384731-7.00253-1

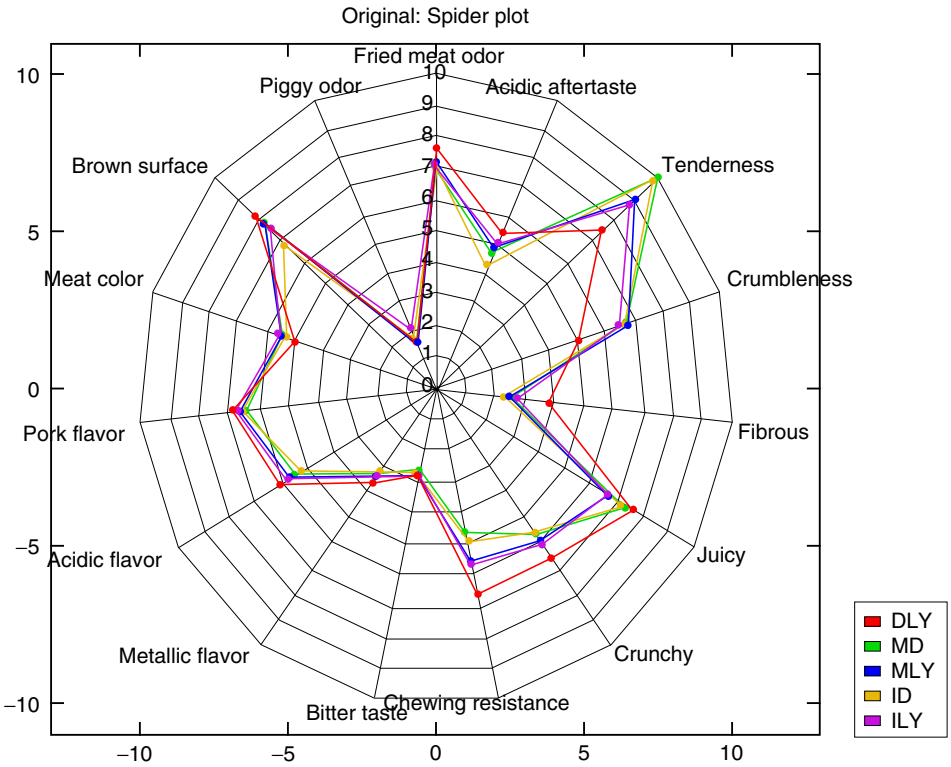

Figure 2 Example of a spider web plot of a sensory profile data of pork loin chops from five different crossbreeds D: Duroc, I: Iberian black foot, L: Landrace, M: Mangalitza, and Y: Yorkshire. It can readily be seen that the difference between loin chops from these pig breeds was especially related to texture attributes.

and discriminating methods. Most descriptive methods are various modified versions of the original QDA® (Quantitative Descriptive Analysis), also known as sensory profiling test. This type of analysis requires a trained panel and standardized settings as described above. The common features of these methods are (1) the initial training sessions, in which the panel agrees on a common vocabulary and (2) the following intensity measures of the selected attributes. The assessment is usually performed by 8–12 trained assessors with replicate assessments of each sample. The panels might be product-specific and thereby perform hundreds of hours of training to create consensus both related to the description of attributes and to the use of the scale (profile panels). The American Meat Science Association Meat Cookery and Sensory Evaluation guidelines involve initial screening of potential panelists by triangle tests, training, and then testing of trained panelists. Only those panelists who have statistically acceptable test scores are used on panels. However, some panels are oriented or trained for only 2–5 sessions before product assessment (descriptive attribute panels). The method is widely used to obtain detailed information about the products as shown in Figure 2. However, as this method is also time consuming and expensive, discrimination tests or rapid sensory methods might be a good alternative depending on the amount of information needed.

The group of discriminating methods is built upon various comparisons, often with a reference, for example, paired comparison test (two samples are compared), triangle test (two similar and one odd sample), duo-trio test (five samples are compared of which two vs. three are similar) and A-not-A test (two samples – are they similar or not). These tests can be used to gain information about differences in one attribute, for example, flavor, or if one needs a general difference between the products to be assessed. There is no training before the assessment.

Rapid Sensory Methods for Comparison with Untrained Assessors

In recent years, the development of rapid sensory methodology has provided several new methods. All these methods use untrained assessors and no replicate samples. With methods like Napping® and Projective mapping, it is possible to compare several samples at the same time. The samples are placed on a piece of paper according to their similarities and differences. The positions of the samples are then measured. This method is applicable in, for example, product development; as it is fast, there is no need for replicates or training, and it visualizes the product space.

Assessment Performed by Consumers

If the consumers opinion is wanted, it is necessary to do consumer studies instead of assessments with trained panels. Most frequently, consumer studies concern liking and preference, as these are subjective. To obtain significant results, it is recommended to include a minimum of 40–50 consumers per

consumer group (segment). If several segments of consumers are targeted such as two genders, different age groups, etc. then 40–50 consumers are needed in each group.

Alternatively, if 'linked' products can be used between consumer panel sessions, it is possible to use as little as 10 consumers, as is used in the Meat Standards Australia (MSA) grading scheme. 'Linked' means that the same product is used across consumer panels, to ensure standardization. The use of 10 consumers in the MSA program was determined after investigating the test accuracy and variation between muscles and balancing this with the physical restriction of the number of samples that can be derived from any one muscle as well as the cost restrictions. In addition, the same descriptions and consumer assessment sheets are used each time a consumer panel is conducted and products are 'linked' between consumer panels. The MSA scheme for assuring beef meat quality has used 10 consumers per product (muscle), linked products, and more than 67 900 consumers to determine the attributes mostly critical to consumer satisfaction of beef. Using the consumer data, a model has been developed to predict the quality of the muscles in beef carcasses and this model has been successfully tested and verified in more than nine countries around the world. This model and scheme is used to assure the quality of meat from 2 million beef carcasses per year and has resulted in increased returns to producers, meat processors, and retailers in Australia.

Questions asked in consumer surveys are often "how much do you like this meat sample?" or "which meat sample do you prefer?" and these two approaches can give slightly different results. As an example, Danish Meat Research Institute (DMRI) developed a healthy Frankfurter sausage with dietary fibers added and with a low fat content. Consumers tasted this sausage with a regular Frankfurter sausage and scored liking, followed by indicating which of the two sausages they preferred. Interestingly, the healthy sausage was equally liked by 66% of the consumers. However, in the preference test, most consumers preferred the regular sausage.

Moreover in the field of consumer science, rapid methods have been developed. One such method is CATA (Check All That Apply), in which the consumers check off all the words presented that they can apply to the meat product at hand. In principle, these words can be any words, but often abstract words are used such as traditional, appetizing, and boring.

Holistic by DMRI™ is a new method using abstract words for the investigation of consumer perception. In this method, a 15 cm unstructured line scale, with anchor points 'very little' and 'very much,' is used to measure the degree of association between the individual abstract words and the given product. In this way, it is possible to gain more insight by knowing how traditional or how appetizing consumers find the product. A close correlation between liking and a word like appetizing has been shown, so liking is also investigated using this method, though not directly asked. This method was used in a consumer survey regarding marinated pork chops. It was evidently shown that the consumers prefer marinates with a clear color and visual herbs and spices (**Figure 3** PCA-bi plot).

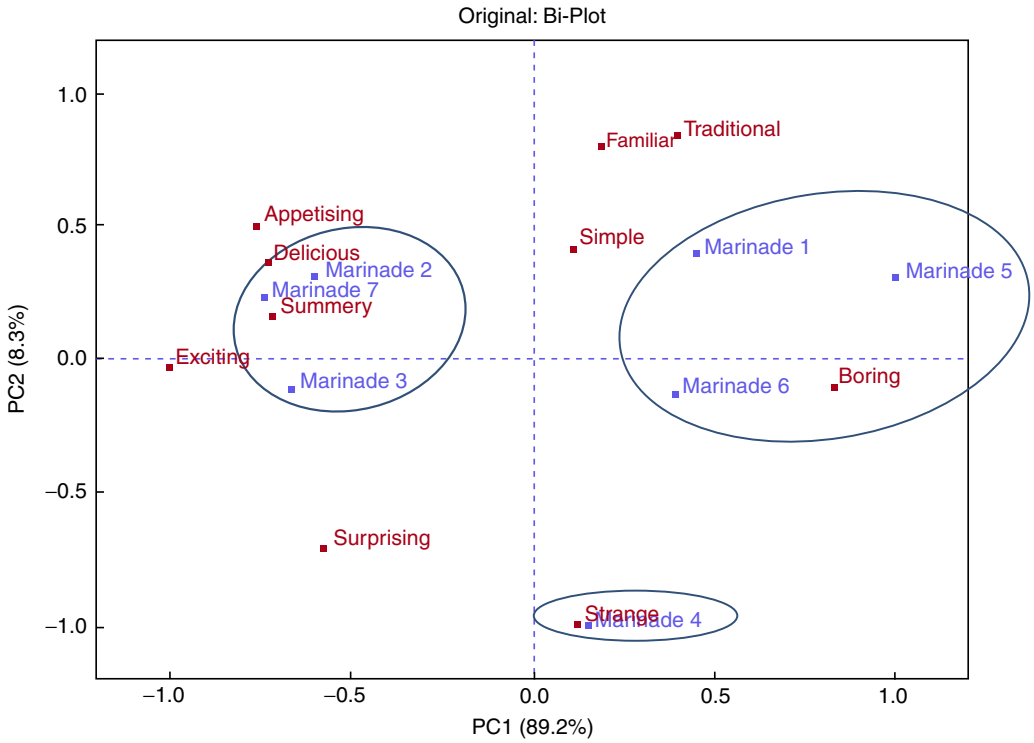

Figure 3 PCA plot of a holistic by DMRI analysis of marinated pork chops Marinades no. 2, 3, and 7 had a clear color and visual herbs and spices, and these marinades were associated with the words: appetizing, delicious, summery, and exciting. Marinades no. 1, 5, and 6 were more common BBQ-like marinades, and these were associated with the words boring, traditional, and familiar. Finally marinade no. 4 was associated with the word strange, probably due to a very pale color.

Factors to Be Considered before Performing a Sensory Analysis of Meat

Several factors have to be considered before starting a sensory analysis of meat. First of all, the cooking procedure, including cooking method, heating rate, and core temperature, is very important. The possibility of detecting differences in raw meat qualities depends on the cooking method used. As an example, the differences in crumbliness of longissimus dorsi and biceps femoris of pork are larger when the meat is cooked in an oven compared with pan frying. Furthermore, the two muscles cooked to a core temperature of 65 °C differ in 'piggy flavor' only when fried on a pan and not when cooked in an oven.

Choosing the Core Temperature

Several structural changes take place in the meat at approximately 65–68 °C. Random variations between samples are therefore relatively large in this temperature range. A slightly higher core temperature such as 70 °C can, therefore, be recommended unless special focus is on juiciness for which a lower core temperature of 60–65 °C will be more suitable. If the aim is to replicate the cooking used by consumers, the core temperature will depend on the cultural habits in the country for the given meat species.

Choosing the Cooking Method

As mentioned in the beginning of this section the cooking method needs to be chosen with care depending on the purpose of the study. For example, if the sensory analysis is going to show differences in fried flavor that might be dependent on the raw meat quality such as the glycogen content, a cooking method like frying or grilling is necessary to increase the amount of Maillard reactions generating fried meat flavors.

Sample Preparation and the Sensory Setup

When the cooking procedure has been decided upon, the assessors need to be trained. This is to ensure a consensus on the understanding of the attributes. During the training, references can be used, especially for the odor, flavor, and taste attributes.

It is very important to cook and present all of the meat in exactly the same way because it is differences in the meat that are being investigated, and not random variations in cooking. The frying pan or oven has to be checked regularly for the uniformity and stability of the temperature. In addition, the core temperature of each piece of meat, at the completion of cooking, needs to be measured to ensure that the desired core temperature is reached (Figure 4). Typically, the core temperature determines when the cooking process is completed.

Before presenting to the panelists, the meat is cut into a reasonable serving size. In most assessments, the meat is cut into a standard cube to mask differences in size of the cuts, but depending on the aim of the study, a whole or half a steak or roast slice is served, and this leads to the opportunity to assess the meat edge, as well as the fat cover.

Figure 4 A handheld thermometer can be used for assessing the core temperature of each pork chop.

To keep the meat warm until assessment, the meat should be placed on preheated plates and covered with a lid. The temperature of the meat should be measured by random sampling to ensure a uniform serving temperature.

The number of replicates within muscles and the number of animals depends on the aims of the study. If the aim is to investigate the effect of, for example, cooking procedure or aging time, a block design can be used in which animal is the block and all treatments are represented within each animal. This can minimize the number of animals required. However, if the study aims to investigate a treatment in the primary production such as breed or feed, more animal replications are needed, taking into account all possible sources of variation such as gender, growth rate, live weight, fat depth, etc. As a rule of thumb, 15–20 animals per treatment are needed to take the animal-to-animal variation into account whereas 5–10 replicates are necessary if the animal can be a block effect. For uniform meat products, as low as three replicates can be performed because the random variation between samples from the same experimental group is low. Furthermore, if consumers are used instead of trained sensory panelists, the variation between consumers in their response can mean that a higher animal replication is required. Thus a replication of >30 would be required.

Sensory Assessment of Pork, Beef, and Lamb

The attributes that the sensory panel is asked to rate for assessments of meat depend on the aim of the study and the cooking method. Fried flavor is only relevant if the meat is fried, whereas assessment of warmed-over flavor is only relevant if the experiment includes handling of the meat that is expected to result in these flavors.

Appearance can be assessed both on the meat surface and in the cutting edge. The surface reflects the meat's ability of obtaining the fried color and is often correlated with fried flavor. Furthermore, it is very sensitive toward small changes in the pan temperature, and the attribute is, therefore, seldom included. Several attributes can be assessed in the cutting edge

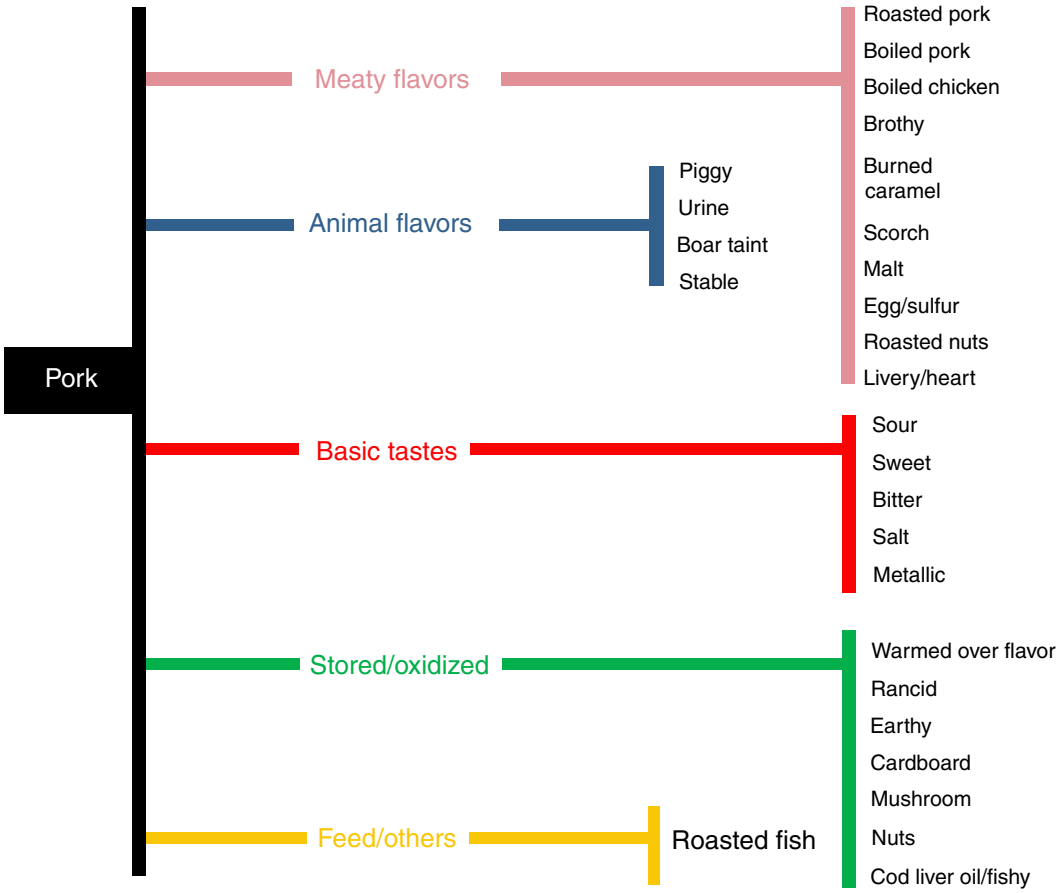

Figure 5 A flavor-tree of pork.

of the meat: degree of cooking (from red to gray) and meat color (from light to dark) represent the color attributes, whereas fibrous (small invisible fibers to large rough fibers) represent the meat structure.

Texture attributes include the group of attributes for which it is easiest to gain consensus among panelists. The attributes vary depending on the meat structure and include among others: bite resistance (hardness at the first bite with the molars), tenderness (easiness of breaking down the meat), springiness (the degree of springiness after a bite), and chewing rest (the amount of product in the mouth when ready to swallow). A comprehensive list of texture attributes is present in the ISO standard 11036. Juiciness is a special texture attribute. Early in the chewing process, the juiciness depends on the amount of loosely bound water in the meat, but later it is more dependent on the intramuscular fat content and on the panelists' ability for saliva production, as the meat at this time has grown up to 40% by absorbing saliva.

Flavor, taste, and odor attributes are the most complex and most difficult to gain consensus among the panelists. Flavors can be divided into several groups as demonstrated in the flavor tree in Figure 5, using pork as an example. Depending on the purpose, the overall descriptor such as stored/oxidized flavor can be used, or the more detailed descriptors such as rancid or earthy can be used.

Although the taste attributes (sweet, sour, acidic, bitter, salt, and umami) often relate to few compounds present in meat, the more complex flavor attributes relates to a cascade of different chemical reactions during cooking such as Maillard reactions, lipid degradation, etc. Using references is, therefore, very important while training the assessors, to ensure the same understanding of the attributes. Table 1 shows a suggestion of reference samples for flavor attributes of meat.

Sensory Assessment of Flavor of Lamb and Beef

Many of the same considerations from sensory assessment of pork are also true for beef and lamb. Differences between species in sensory assessment predominantly derive from the differences in flavor, as the texture and juiciness tend to be similar between species. Flavor is a very complex attribute of meat palatability and refers to the components of food responsible for chemosensory stimulation – volatile aroma and nonvolatile taste compounds. There are literally hundreds of compounds in meat that contribute to flavor and aroma. Many of them are altered through storage and cooking, making meat flavor an incredibly complex topic. Many compounds that contribute to meat smell and flavor are thermal lipid breakdown products.

Owing to the differences in digestive systems between ruminants and nonruminants, deposition of fatty acids is different. Poultry and pork muscle typically have higher levels of polyunsaturated fatty acids than lamb or beef. Furthermore,

Table 1 Examples of references for flavor and odor attributes of pork that can be used for training of panelists

Attribute	*Production of reference*	*Comments*
Meat flavors		
Roasted pork	Loin, pH 5.55–5.65, a boneless chop is dry roasted at 150–160 °C pan temperature, until a core temperature of 65–68 °C	Only the crust is tasted
Boiled pork	Loin, pH 5.55–5.65, a boneless chop simmered for 20 min	
Boiled chicken	Chicken breast simmered for 20 min	
Brothy	MSG powder or the cooking loss from a boiled pork chop	Is a little acidic as well
Burnt caramel	Sucrose melted on a pan for 5 min. Served chilled	
Burnt	Loin, pH 5.55–5.65, a boneless chop dry roasted at 250–280 °C pan temperature, core temperature of 80 °C	
Malt	Malt powder from SFK 5670/550973	
Egg/sulfur	Chopped boiled egg	
Roasted nuts	Fresh hazelnuts, chopped and roasted	
Livery	Pork heart boiled for 30 min or cooked beef liver	Pork liver is sometimes too strong to be used as a reference (therefore the heart is used)
Grassy	Hexanal	Accepted odor standard for 'grassy'
Hay	Sugarcane mulch	
Animal odors		
Piggy	Melted pork fat or a piece of cloth that has been into contact with live pigs	
Urine	Androstenone	
Boar taint	Skatole	
Stable	A piece of cloth from a stable	
Sheep meat	Not defined	
Mutton-like	Not defined	
Barnyard/farmyard	*p*-Cresol	
Basic tastes		
Sour	0.3 g Citric acid in 1 l water or sodium lactate 60 % added to minced meat yoghurt natural	
Sweet	1 g Sucrose in 1 l water or 1 g sucrose in 100 g minced pork	
Bitter	0.09 g l^{-1} Quinine chloride or 0.25 g l^{-1} caffeine	
Salt	0.5 g NaCl in 100 g minced meat	
Metallic	Copper coins or a silver spoon	
Stored/oxidized flavors or odors		
Warmed over flavor	Minced meat cooked as a pattie. Kept refrigerated for 1–3 days at 2 °C. Reheated in an oven	
Rancid	Linseed oil simmered for 10 min	Only odor
Earthy	Earth from a garden or 2, 3, 5-trimethyl pyrazine	Only odor
Cardboard	8 g Cardboard in 250 ml water for 24 h, filtered	Only odor
Mushroom	1-Octen-3-ol	Only odor
Nuts	Nuts at least ½ year old kept in an open bag	
Cod liver oil/fishy	Cod liver oil	
Feed/others		
Roasted fish	Roasted salmon fillet smelled at the skin side	

the feeding systems influence the fatty acid composition in both ruminants and nonruminants. In particular for ruminants, pasture, in comparison to grain, introduces a different flavor to the final product, which is perceptible by both trained and consumer sensory panels. The flavor resulting from pasture feeding is sometimes associated with the species-specific flavor, particularly in sheep meat. Sheep meat from pasture-fed animals is often described as having a 'pastoral' flavor, which is unacceptable to some consumers. The compounds 3-methylindole (skatole) and *p*-cresol have been implicated as the main volatile contributors to the 'pastoral' aroma evident in the cooked meat of pasture-fed animals. Interestingly, skatole is also one of the two compounds associated with 'boar taint' as described in Table 1. Another unacceptable flavor associated with cooked sheep meat is 'mutton' flavor, which is traditionally associated with meat from older sheep. Mutton flavor is derived from branched chain fatty acids. More recently, diet has also been implicated in the formation of 'mutton' flavor in sheep meat.

In beef, the main unacceptable flavors that might arise are 'liver' flavor, which appears to have unknown causes, and metallic flavor.

Sensory Assessment of Meat Products

Meat products differ from fresh meat as they are often served cold or at room temperature. This makes it simpler to standardize the protocol for handling the samples. Before performing a sensory assessment, it is necessary to decide at which temperature the samples should be assessed. As meat products can be spicy and salty, compared with fresh meat, it has to be taken into account while designing the study.

The selected attributes must discriminate between samples, and be relevant to the specific product and the aim of the investigation. It is optimal to have reference samples especially for color, odor, and flavor attributes in order to achieve agreement among panelists.

The texture of meat products is related to mechanical, geometrical, and surface attributes. Mechanical attributes are characterized as hardness, cohesiveness, viscosity, springiness and adhesiveness, whereas the geometrical attributes describe size, shape, and particles within the product during chewing. The surface attributes are related to the sensations produced by moisture or fat content. Similar to sensory assessment of flavor, the terminology for texture can be established using samples representing the full range of textural variation.

Panelists performing color assessment must have normal color vision. A test for color blindness can be performed using 'ISHIHARA's Test for Color Deficiency.' When evaluating color in meat products, a color chart can be used as a reference. Several color chart systems are available on the market like Natural Color System (NCS) and Pantone Color Guide. In some countries, persons must pass the 'Munsell Color Test' before being considered qualified to score color.

Air can influence the color of a product markedly, as observed on sliced products lying in open air before the evaluation, and a standardized time and temperature sequence before the evaluation is, therefore, important to ensure identical evaluation conditions. Moreover, the lighting during assessment must be standardized as well.

The color chart can be used on a number of different products. If products have two colors, for example, a 'meat color' and a 'fat color,' an interval of colors can be defined instead of a single color code (Figure 6).

Figure 6 Example of color chart for an emulsified meat product.

Physical and Chemical Measurements of Sensory Related Properties

Physical Texture Analyses

The texture analyses methods most often used are the Warner Bratzler shear force (WBS) and the texture profile analysis (TPA). The texture is measured as the strength to cut a defined piece of meat; the more force needed, the tougher the meat is. During the years, many researchers have tried to correlate the physical texture measures with the tenderness assessed by a trained panel, and with varying success. It is possible to get indications of tenderness by the physical measures and this is relevant especially if many samples need to be analyzed. However, it has not been possible to translate, for example, a shear force value to a specific score on the sensory scale.

Color Measurements

Color is an important characteristic of meat, and the red color of beef is, by many consumers, related to freshness. Meat color can be measured by various reflectance colorimeters. One widely known and used color scale for meat is the L*, a*, b* color scale. Generally, the instrumental color measures are based on average values. However, measuring meat color is a challenge due to the uneven surface including marbling, and so the new generation of methods is measuring color with a vision camera. By this method, it is possible to measure the color of, for example, a fermented sausage and, subsequently, extract the color of both the fat and the meat parts. With this vision technology, it is possible to generate far more information than before.

Odor Measurements

For the investigation of meat aroma and the presence of specific aroma compounds, gas chromatography (GC) methods are widely used. There are several ways of sampling the aroma compounds (volatiles), though all include initial trapping of the headspace that contains the volatiles. The volatile extracts are subjected to chromatographic separation and instrumental detection by either flame ionization detection (FID) or mass spectrometry (MS), and the gas effluent is simultaneously sniffed by human assessors. The characteristics of each odor is described and the intensity can by quantified by 'present or not' (summing up over the panelists) or the length of time, the given odor can be smelled by the panelist.

In this way, aroma compounds related to a given food can be identified and also quantified. In addition, the trained human assessor evaluates the odors coming into the funnels and adds both a description of the perception of each detected odor as well as intensity. Using GC-O-MS, it is possible to gain knowledge on the individual volatiles constituting the

overall aroma of a given food. For instance, the odor of fried pork is characterized by aldehydes, pyrazines, and sulfur-containing compounds. However, the overall odor attributes of meat or any food are still assessed by the more classical sensory methods.

Glossary

Bleeding/exsanguinations A procedure where the blood vessels in the neck or chest are severed.
Halal slaughter A slaughter procedure that adheres to Islamic teachings where the animal is dispatched by severing the blood vessels of the neck following a prayer.
Kosher The meat produced following Shechita.
Shechita The Jewish method of slaughter carried out by a trained Jewish slaughterman, shochet.
Slaughter The process of exsanguination that ensures the animal cannot recover sensibility.
Soclap Society, Oneself, Customer/client, Legal, Animal, and Profession.
Stunning The procedure where an animal is rendered unconscious before exsanguination or another killing method, pelt removal, and evisceration.

Introduction

Killing animals for food can be a troubling experience or concept. Most of us probably recall our first realization that meat comes from muscle, which in turn is part of a living animal that has feelings. For some, this is a disturbing experience that is difficult to reconcile. The discomfort usually has two facets. First, there is abhorrence at the thought of the physical act of slaughter. Second, there is remorse about the fact that an animal had to be killed for the consumer's enjoyment or benefit. In a survey conducted in the United Kingdom in the early 1990s, it was found that when meat eaters were confronted with the hypothetical prospect of having to kill animals themselves to eat them, the majority said that they would cease eating meat altogether. The connection between slaughter and eating meat can be unnerving.

These concerns depend to some extent on the species being considered and the connection that is conjured up. There is a hierarchy of meats that ranks a meat according to how soon a semivegetarian or reduced meat eater strikes that meat off from her or his food list (Table 1). The reduced meat eater would typically progress toward abstention by first giving up beef, then lamb, pork, poultry, and finally fish. The species of origin, the appearance of blood, and the redness of the meat are thought to be key features that create this hierarchy, but other issues may be involved such as perceived 'lightness' of eating, convenience of preparation, and views about body image. The way a meat is presented may also be pertinent. Some meat eaters dislike confronting a fish with the head, and in particular the animal's eyes, on the plate in front of them. These points demonstrate how ethical concerns can be intertwined with other beliefs and attitudes, and this can make it difficult to rationalize the ethical component when it needs to be considered on its own. A current example is religious slaughter that has received much attention and continuing to be controversial in relation to religious rights, rules, animal welfare, and legislation.

Table 1 Hierarchy of meats among semivegetarian women

Type of meat	*Number of semivegetarians who eat the respective meat for every meat-eater who consumes the same meat*
Beef sausages	0.41
Pork	0.43
Crumbed veal	0.46
Lamb	0.46
Steak	0.47
Bacon	0.47
Roast beef/veal	0.51
Casserole (not chicken)	0.55
Mince meat	0.56
Cold meats	0.65
Processed meats[a]	0.67
Chicken	0.82
Fish	1.05

Applied Ethics and Decision-Making

For some, but by no means all, people, there is an overlap between ethical concerns and squeamishness. Most people manage squeamishness by avoiding a particular thought, by confronting it and overcoming it through familiarization, or, if they are in a position to do so, by modifying the procedure so that it is more aesthetically acceptable. Ethical concerns can be managed or resolved by weighing up responsibilities, and forming a judgment or decision based on careful assessment of all the responsibilities and potential outcomes of a course of action. A useful way of going about this is to use a procedure that has been developed for veterinary practitioners when they are confronted with particularly thorny ethical conflict. It is known as 'soclap:' Society, Oneself, Customer/client, Legal, Animal, and Profession. These elements represent the facets or parties usually involved in any ethical conundrum that involves animals. In the present context it could be used, for example, when trying to decide whether a particular slaughter method is ethically acceptable. In the case of society's expectations, one needs to ask 'What would society expect in this situation?' There will be widely differing views on this, according to race, religion, and tradition, and so limits or a context have to be set. The ethical decision-maker puts him or her in society's position and should adopt a reasonably broad perspective. 'Oneself' covers one's own expectations and sensitivities, and 'customer/client' encompasses, for example, sensitivities of the retail company buying the meat, whether the meat is destined for retail or the catering trade, and any other feature that impacts on the image or reputation of a meat or company in the marketplace. Legal requirements often try to reflect society's expectations, while allowing for fair and honest production or procurement practices. This is included in soclap to ensure that the practice that is being considered is operating within existing law. Responsibilities to the animal can fall into two categories: animal rights and animal welfare. The animal rights outlook considers whether it is fair to the animal to impose on it in a particular way. This could include the right to life, when the ethical issue being considered is whether slaughter is justified. Animal welfare is concerned with how the slaughter is conducted and how to avoid or control animal suffering. Lastly, there is responsibility to the profession; in this case the focus could be on the abattoir industry. How does the industry as a whole view itself in this context, and does it have any position statements?

In regard to killing animals the inevitable question of whether death is a welfare issue or not comes to the fore. Epicurus in ancient past claimed that death should not be a worry but sense-experiences would be more important. This view is still not seriously challenged. However, assumption that death is not a welfare issue for animals creates conflicts for those who deal with animal ethics that an animal's death is ethically significant. One could argue that a meat animal's life has positive attributes, and in this case death becomes a welfare issue. Conversely, if positive states cannot be provided, for example, by changing husbandry methods, then killing an animal may not be a welfare issue provided that it is carried out in a quick and painless way.

This decision-making process may be a personal exercise, or it may be conducted by a company considering the ethical or moral issues of a particular practice, or by an industry as a whole. It does not instruct the parties about what to conclude, but it does direct them in how to arrive at a conclusion.

Stereotypes in Ethical Discussions on Animal Welfare and Slaughter

When a controversial ethical or animal welfare issue is being discussed, particular approaches can usually be identified within each faction. Both sides have a characteristic *modus operandi* in their arguments; these are simplified in Table 2. Assessment of the debate by the public probably works in several ways. People who have strongly developed internal value orientation will consider the arguments in terms of benefits to themselves and the parties concerned. Externally oriented people are more likely to look to state-appointed experts or legislation as controllers of the outcome. These points are relevant, as no single approach to a debate on the ethics of animal practices will satisfy all individuals.

Ethics of Stunning

Preslaughter stunning was probably the first used way of immobilizing animals that were about to be slaughtered. An early wood carving, dating back to mediaeval times, shows an unrestrained pig about to be struck on the head with an axe. This was a practical approach to controlling the animal so that it could be killed, in a convenient manner, by bleeding it out. An added advantage with stunning before slaughter was that it helped satisfy concerns about the pain and distress the animal could experience during the sticking procedure. Cutting the skin in the neck is potentially painful, and many people foster a sense of ethical or moral responsibility for minimizing that pain, as well as subsequent suffering, when animals are being killed for human benefit. Knowing that an animal was stunned when it was slaughtered also helps ease the conscience about taking the animal's life. If one is assured that it was a humane death involving little or no suffering, there is less concern about eating the animal as meat.

When stunning was introduced into law, in some countries there was the added requirement that animals must not

Table 2 Stereotypes in debates over livestock ethical and welfare issues

Approaches used by animal advocates	*Approaches used by livestock trade*
Appeal to public opinion	Consultation with experts
Emphasis on intuition	Emphasis on knowledge
Risks portrayed in broad terms incorporating political and social factors	Narrow framing of the risk analysis, considering only measurable uncertainties
Broad symbolic and political goals	Narrow business goals
Emotion	Rationality
Openness	Secrecy
Suspicion of standards	Trust in standards

be slaughtered within sight of another conscious animal. The reason was to reduce the likelihood of an animal recognizing that it was about to be killed. The basis for this has been questioned, as research has shown that when sheep and pigs have been in a position to watch one of their penmates being stunned and slaughtered, they did not demonstrate any stress response such as a rise in heart rate or plasma cortisol.

Not everyone chooses to eat meat, and part of the reason for this can be ethical (Table 3). Some people become vegetarian, while others are highly selective in the types of meat they eat. Concern is particularly strong among women, and especially among young women. A common view is that they would feel partly responsible for the death of an animal if they ate its meat, and also that knowledge does not rest comfortably with their conscience. Instead, they would prefer to be guilt-free in their eating style. It is not necessarily their purpose to convert the rest of the world into vegetarianism, but they feel the need to dissociate their involvement with animal slaughter. This viewpoint is a personal ethic.

Religious ethics provide another reason for not accepting animal slaughter or meat eating. In the case of Buddhism, there is a belief in reincarnation and that it is inappropriate to take any form of animal life let alone eat it. In other religions, the doctrine requires the believer to avoid eating certain parts of an animal, either because they are defiling or because they hold or represent the soul of the animal. Most religious faiths have one or more sects that ascribe to vegetarianism (e.g., Brahmin, Seventh Day Adventist and Rastafarian sects), and in many instances the reasons for vegetarianism are founded on fundamental precepts connected with metaphysical well-being of the consumer.

In contrast to refraining from eating animals, other religious faiths allow meat consumption and have prescribed methods of slaughtering and processing. Muslim (Halal) and Shechita (Jewish method) are the major religious techniques subject to much debate. There is also the Sikh religious belief that requires slaughter of animals by decapitation. An EC funded project, DIALREL, has recently disseminated information relating to religious slaughter and a recent comprehensive review on religious slaughter has been commissioned by the English Beef and Lamb Executive (EBLEX).

In religious communities that accept the slaughter of animals to eat meat, there are usually rules that govern what species are allowed and how the animals can be killed. Provision and consumption of meat for Muslim and Jewish communities is an essential part of the religious life and certain conditions must be met, so that the meat is lawful. Muslim method, Halal, is based on interpretation of the Koran and the Hadith (the sayings of the prophet Mohammed). The act of slaughter (Al-Dhabh) is carried out by pronouncing the name of God (Tasmiya) and slaughter is carried out by severing the neck to achieve maximum exsanguination as consumption of blood is forbidden.

Jews require their acceptable Kosher meat from animals slaughtered by their prescribed method called Shechita. Slaughter has to be carried out by a trained Shocet who uses a special knife (chalaf). Preslaughter stunning and damage to tissues are not accepted. In addition, a Jewish Inspector examines the carcass and rejects certain parts (treifa) that includes both hind legs.

Although meat production for religious groups is on the rise because of high consumer demand, there are some

Table 3 Summary of reasons given for reduced meat consumption during the 1980s and 1990s

Animal welfare	Moral reasons associated with the view that modern animal production is ethically unacceptable. By reducing consumption of specific meats or all meats, or by eating trusted, welfare-friendly products only, the individual is divorcing himself/herself from those production systems. It is usually a personal expression of rejection rather than a way of trying to change farming systems or society.
Environment	Moral concern that certain features of animal production harm the environment and have undesirable ecological consequences. The individual's conscience is quelled by abstaining from a particular meat or from all meat, and this has an element of long-term self-interest.
Health	Concern about one's own health. This has three features: 1. Avoiding the consumption of products that are normal ingredients in meat but are viewed as harmful (such as cholesterol and saturated fats). 2. Avoiding the consumption of unnatural ingredients that could be hazardous (such as hormones, antibiotics, coccidiostats, and pathogens). 3. Cutting out meat with a view to avoiding specific health problems where the causal agent may not be clearly understood (cancer, hypertension). The decision to reduce meat consumption for health reasons is made out of self-interest or concern for the health of one's family.
Social priorities	Some people reduce their meat consumption to conform or adapt to the lifestyle or standards of friends, relations, or other influential people. One's own body image is an important example.
Displeasure with meat	This takes several forms. Total abstention from meat can be because of revulsion at the sight of meat and in particular any associated blood or blood-like drip. Some people find the sticky texture of meat abhorrent, whereas others dislike the taste and elastic mouth-feel of meat when they eat it.
Metaphysical	The individual abstains from certain meats for spiritual, religious, doctrinal, or ethnic reasons. Eating meat is believed by some to impart negative effects, for example it arouses animal instincts in humans, including greater aggression.
Expense	Poorer communities and households abstain from certain meats because of their cost.
Inconvenience or inappropriate presentation	Some meats may not be presented in a way that fits into 'light,' informal meals. Some meats may be avoided because they are presented in a form that is inappropriate for the take-away trade or are difficult to cook quickly at home.

concerns about religious slaughter. These relate to the following questions:

1. Is there preslaughter stress;
2. Is the neck incision painful; and
3. Is sensibility and consciousness lost quickly enough following exsanguination 'sticking.'

Of all the above questions, the crucial issue is that whether stunning is used or not, while Shechita, in the Jewish method, stunning is completely prohibited; Halal may accept it under certain circumstances. With regard to whether stunning should be acceptable before Halal slaughter there are 3 views: (1) acceptance under certain conditions (e.g., reversible stunning); (2) rejections on grounds that it is against religious rules, painful induction, and causes insufficient blood loss; and (3) some either not sure or require assurances. Certain types of reversible stunning methods have been regularly used for decades in some countries such as New Zealand that exports Halal meat. Poultry slaughter in large numbers also often employs electrical stunning.

Although legislation usually covers conventional methods and requires preslaughter stunning, exemptions for religious slaughter are in place in most countries. However, slaughter without stunning is illegal in several countries (e.g., Sweden, Denmark, Norway, and Switzerland, New Zealand). The religious dispensation is allowed on the basis of human rights, which, with the exception of one or two countries in Europe, takes precedence over animal welfare. In other countries, cultural rights have been embodied in the human rights legislation, and, in the present context, this could complicate interpretation of the scope of the dispensations. One of the reasons for the increase in Halal meat demand is the desire to maintain traditional as well as religious ways of life.

Stunning is considered impractical in most marine fisheries, and so it is not a legal or ethical requirement. Nevertheless, some fish are dispatched by concussion or brain spiking once they are landed on board the boat. This helps control body movement and the risk of surface damage to the fishes' bodies, and it is considered to be a humane death when carried out proficiently.

In general, it is considered impractical to stun an animal that is being hunted. However, some authorities state that it is best to shoot an animal in the head, as this should cause immediate unconsciousness, and death. Some would go so far as to say that if a head shot cannot be achieved, then the animal should not be shot until there is a clearer view or it is close enough to allow a head shot. The concern is that a body shot may not cause concussion of the brain and so the animal may not be rendered unconscious immediately. Some hunters prefer using a neck shot to the less predictable head shot, as this disables the animal immediately and it is likely to experience a quick death. Similarly, some deer hunters use only a chest shot because they consider this leads to fewer cases of maimed animals escaping. There is always the concern that hunting can result in maiming, and that the maimed animal may escape and experience suffering. The risk of this happening will vary considerably according to the type of gun that is used, the accuracy of the marksman, the species, the terrain, and the method of stalking or chasing.

To summarize, in those countries where stunning is a legal requirement, the main reasons for insisting on stunning are to minimize the risk of the animal (1) experiencing pain during slaughter and (2) becoming distressed while it is dying. There are also practical advantages in stunning an animal before cutting its neck, as it helps to immobilize or control its movements. Advocates of preslaughter stunning usually hold that stunning is more humane than not stunning. In contrast, advocates of religious slaughter methods that disallow preslaughter stunning hold that their particular method is humane. In particular, Halal and Kosher meat producers and their consumers believe that their prescribed methods are not only required as ordered, but also in the meantime provide the most humane and painless techniques that protect animal welfare. Their objections to conventional stunning and slaughter methods are based on assumptions that stunning is painful and animals suffer.

SLAUGHTER-LINE OPERATION

Contents

Cattle

DR Woerner, JA Scanga, and KE Belk, Colorado State University, Fort Collins, CO, USA

Introduction

The commercial slaughter process for live cattle generally is uniform across the industry. However, many customizations, innovations, techniques, and practices exist that might not be uniform to all plants. The objective of the slaughter process is to efficiently convert live animals into carcasses, and to harvest dress-off items and offals. Many production processes that precede slaughter have a tremendous impact on the safety and quality of the resulting carcasses and are discussed in detail in other sections of this encyclopedia. Discussion here will focus on those processes that occur between receipt of live cattle and carcass evaluation and grading. The sequence in which these processes are encountered by animals and carcasses as the harvesting proceeds can vary slightly between facilities due to space limitations, slaughter line configuration, and dressing procedures. There also can be numerous modifications and variations to each process as Standard Operating Procedures are tailored within each facility and at each processing step to result in sanitary conversion of live cattle to carcasses.

Cattle Receiving and Animal Handling

Although not technically one of the steps in the conversion of live cattle to carcasses, cattle receiving is often the first step listed on slaughter process flow diagrams. The objective of this step is to take control of incoming live cattle, obtain live weights, and stage animals for entry into the slaughter process. Facility design, maintenance, and employee training are essential elements of this process. Animal handling and animal well-being is paramount to the sustainability of the beef industry, and as a result, beef slaughtering facilities have well-designed animal holding and animal moving facilities to be more efficient and animal friendly (e.g., holding pens with nonslip floors and curved alleyways that eliminate bright lights and shadows). Additionally, slaughtering facilities have implemented strict policies for transportation companies and employees for the transportation and unloading of cattle that are received by the facility. Poor animal handling can result in value reducing defects and impair meat quality.

Antemortem Inspection

Each animal is visually appraised by an inspector (in the United States these are either US Department of Agriculture federal inspectors or state level inspectors) to identify apparent clinical signs of disease or distress. If none are noticed, animals are cleared for slaughter. If the inspector notices any signs of disease or abnormality, an animal can either be identified as 'suspect' and subjected to further evaluation as the slaughter process proceeds, or identified as 'condemned' in which case the animal is not accepted and passed for human consumption. Animals that are nonambulatory at the time of slaughter are 'condemned.' Condemned animals must be appropriately disposed of so that no parts of the animal may enter commerce.

Stunning

Animals cleared for slaughter are presented for stunning, sometimes referred to as 'knocking.' Stunning can be accomplished using several mechanisms, such as captive bolt, electricity, or gas asphyxiation. Regardless of the method utilized, all animals must be stunned and rendered unconscious before starting the dressing process.

To minimize animal stress, proper restraint is required. The most common methods of restraint in large commercial facilities are either 'center-track' restrainers or 'V-Track' restrainers. In smaller plants, a simple 'knocking box' or chute

 doi:10.1016/B978-0-12-384731-7.00157-4

can be utilized. In these situations, the animal is prevented from moving forward or backward and is positioned for subsequent stunning. Automated restraint devices are utilized to immobilize and transport cattle from the lead-up alley to the stunning area so that appropriate stunning can occur without causing undue stress to the animal.

The penetrating captive-bolt device is the most common method for stunning cattle. Captive-bolt stunning devices can be powered with powder charges (similar to firearm blanks) or air pressure (pneumatic, nonair injecting) and are composed of a firing mechanism (trigger) and a 'captive bolt' (a steel rod approximately 1.27 cm in diameter and 10 cm in length). The device should be placed in the center of the animal's forehead and fired. An effective stun results in an animal that is insensible; five key observations necessary to ensure animal insensibility are (1) no blinking of the eyes, (2) no movement of the eyes in response to touch, (3) no rhythmic breathing, (4) no 'righting reflex' (i.e., animals try to stand up), and (5) no response to ear/nose pinching (painful stimuli). If these conditions are met, slaughtering and dressing may then continue. In situations where an animal is not rendered insensible, they must be restunned until the five conditions are met.

Shackling and Hoisting

Animals are shackled as the stunning process proceeds. The shackle is applied to the left hind foot of animals during the brief period when animals are in the restrainer. In some smaller plants, shackles may not be applied until following stunning and removal of the animal from the knocking area. The shackle comprises a heavy chain that is attached to a roller trolley on one end that can move freely on metal rails, and an expanded hook on the other end, which allows for constriction of the chain around the hind foot as animals are hoisted.

Following the application of an effective stun, animals are passed out of the restraint device or rolled out of the knocking box, and hoisted to an overhead rail using the attached shackle. Once animals are suspended, they can be moved forward through the dressing process until they are transferred to rolling hooks (trolleys).

Exsanguination (Sticking/Bleeding)

A common misconception is that stunning 'kills' the animal. The actual point at which death occurs is not finite; brain death and metabolic death do not necessarily coincide with respect to time. Normally, animals maintain cardiac rhythms for several minutes following stunning. Blood loss (exsanguination) usually is the ultimate cause of death in the slaughter process and is commonly referred to as 'sticking.'

Insensible animals are bled by opening the hide from the base of the jaw to the point of the brisket. A clean, sterilized knife is inserted ($\sim$15–20 cm) at an approximate 45° angle at the anterior point of the sternum and a cut is made in the direction of the backbone. When performed correctly, the ascending branch of the aorta and the vena cava are severed, resulting in rapid blood drainage. As both the aorta and vena cava are severed, escaping blood should be a mix of bright red, oxygenated blood (from the aorta) and dark red, deoxygenated blood (from the vena cava). Animals should be allowed to bleed for several minutes, and blood should be collected for either edible or inedible use.

Blood Collection

At the time of blood removal, approximately half of the animal's blood is removed equating to approximately 3.0–3.6% of the animal's live weight in blood (e.g., 13–16 kg of blood from a 450 kg steer). Much of the blood removed from the live animal is captured, dried, and sold as-is for miscellaneous uses including, but not limited to, pet food, nonruminant livestock feed, and fertilizer manufacturing. If a processing facility has the ability to collect blood in an aseptic fashion, then blood can be collected for human consumption and pharmaceutical use. Aseptic blood collection is a much more involved process including the use of specialized devices to capture blood directly from major blood vessels including the carotid artery or the jugular vein during exsanguination. Such devices employ a blade or knife to sever the blood vessel and simultaneously vacuum blood into sanitary collection vessels containing anticoagulants. Some facilities are choosing to aseptically collect edible blood postexsanguination at a point in the dressing procedures when the hide has already been removed. An additional 1–2 kg of blood can be collected immediately following mechanical hide removal, particularly when side pullers and low-voltage electrical stimulation is utilized in the process.

Hide Washing/Dehairing

In an effort to reduce the presence of pathogenic organisms on cattle, many packing plants now have initiated processes to 'wash' the exterior of the hide either immediately before exsanguination or immediately following exsanguination. In some cases, chemical pathogen spray-washing intervention technologies are used to accomplish this objective. Cattle should not proceed to subsequent processing steps until water or chemical solutions no longer drip from the exterior of the hide.

Hide Removal

The process of removing hides from carcasss is the most variable, and most labor- and time-intensive process involved in cattle dressing. The objective of this process is to remove the hide at the intersection of the skin and fat/subcutaneous muscles, leaving all fat and subcutaneous muscles intact and attached to the carcass. All hide removal efforts, along with many corresponding modifications/additions to the slaughtering and dressing process, have focused on keeping dirt, dust, mud, manure, hair, and other foreign materials from the surface of dressed carcasses. Hide removal techniques, in conjunction with the equipment utilized to accomplish this task,

are probably the most variable of the slaughter processes from plant to plant.

First Leg Skinning

Leg skinning is the initial dehiding process; it results in the separation of the hide from the 'free' (right hind) leg. This accomplishes separation of the hide from carcasses from just above the hoof to above the hock joint.

Rump/Butt Skinning

Following hide removal from the free foot, the process is continued by removing the hide from the hock joint over the rump of the free side of carcasses. This involves separation of the hide from the rectum, and it is imperative that the hide is removed so that it can be folded back to prevent contamination of the rump area of the carcass.

Hock Removal

Once the first leg and rump (right) are completely dehided, the free foot is then removed. This is commonly accomplished with a large pneumatic or hydraulic cutter ('hock cutters'). The hind foot and shank are removed at a point distal to the hock joint, at the junction of the tarsal and metatarsal bones, ensuring that the anatomical structure of the gambrel (*Achilles*) tendon is intact and undisturbed.

Leg Steam Vacuuming/Blow-Off

To quickly remove potential microbiological contamination that is transferred from hides to the recently exposed hock, many plants now employ use of a washing/vacuuming system to remove contamination. It is important that such technologies do not result in water that is free to run down the hide or carcass surface.

Leg Hang-Off (Transfer to Trolley)

At this point, the free (right) leg of the carcass is completely dehided and the hind foot and shank are removed. A trolley hook is inserted from the medial side of the shank through the natural gap that exists between the gambrel tendon and the tibia/fibula. The trolley is then placed on the open face of the rail and the carcass is transferred to the trolley, which releases the shackled leg. The shackle is removed and sent back to the knocking area for cleaning and reuse.

Left Leg, Rump/Butt, and Hock Skinning; and Steam Vacuuming/Blow-Off

These processes are identical to first (right) leg skinning.

Left Leg Hang-Off

This process is identical to first leg hang-off, but applied to the opposite leg of carcasses. Following this step, the hind legs and rump are completely dehided and carcasses are suspended by two independent trolleys from the rail. The hind legs are spread apart by chain cogs or rail blocks to aid in further dressing.

Midline Split

Focus now turns to the abdominal region of the carcass. At this step, the hide is opened along the midline axis of the carcass from the stick wound to a point that reaches the already dehided hindquarters. This process, along with the process of splitting the hide on the fore and hind limbs, traditionally is referred to as 'patterning' of the carcasses (creating the 'pattern mark').

Fore-Foot Removal

Equipment (hydraulic or pneumatic cutters) similar to that used for the removal of hind feet also are utilized to separate the front feet from carcasses. The location of removal can vary between plants depending on further utilization of flexor tendons and shank bones. If flexor tendons are to be harvested from carcasses, forefeet are removed just above the hooves at the junction of the metacarpal bones and the proximal phalanx. If tendons are not to be harvested, entire foreshanks may be removed at the junction of the proximal and distal carpal bones.

Belly Skinning

Starting at the midline, the hide is separated from carcasses along the midline outward, from the ventral side to the dorsal side, covering the area from brisket to flank. This process prepares carcasses for subsequent mechanized hide removal, and can be achieved with either a fixed blade skinning knife or a pneumatic skinning/dehiding knife. At this point, loose edges of hides on adjacent carcasses are often hooked together using chains or 'bungee' cords to prevent and minimize carcass contamination from the exterior of the hide.

Side Pullers

Side pullers often are the first mechanical aid used in dehiding. These machines are typically hydraulic and are synchronized with the automated slaughter line to travel with a carcass as it moves. This operation involves inserting the loose midline edges of hide into puller arms that are retracted to pull the hide toward the dorsal edge of the carcass while the back of the carcass is held stationary (commonly using low-voltage electrical stimulation to 'stiffen' the carcass). This accomplishes removal of the hide over the carcass sides, an area typified by attachment to the 'cutaneous trunchi' muscle ('fly shaker' muscle).

Back Skinner

This process is generally completed manually by workers with pneumatic skinning/dehiding knives. The objective is to remove the hide from the back of the animal; from a point posterior to the shoulders, to a point anterior to the lumbosacral junction. This not only removes the hide from an area of the carcass that is prone to fat pulls, but also facilitates removal from the hindquarter.

Up Puller

The 'up puller', also referred to as a 'banana bar', is a smooth cylindrical bar that is inserted between the hide and the dorsal edge of the carcass through the hide/carcass separation created during the previous step. Once the bar is passed through the opening, the mechanism is activated and the bar makes an upward sweeping motion that completes separation of the hide from the hindquarter of the carcass. At this point, the hide is draped downward and remains attached only to the forequarter of the carcass.

Down Puller

The 'down puller' is the final step in the removal of the hide from the carcass. This can be accomplished with several types of equipments, all of which apply downward force on the hide to complete separation from the carcass. The two most popular models are 'clothes pin' and 'track' pullers. Clothes pin down pullers are a steel bar that is shaped like a clothes pin (cylindrical with a channel through the center). The posterior portion of the hide, previously separated from the carcass, is inserted into the channel and the bar is rotated so that the hide is 'wound' around the bar. Simultaneously, the bar will be retracted away from the carcass exerting additional force until the hide is removed from the entire body and head of the carcass. 'Track' pullers work similarly, except that the hide is fed between two sets of rotating rubber tracks that grip the hide and exert a downward force until the hide is freed from the carcass. The removed hide is then conveyed or dropped to an adjacent processing area where fleshing, grading, and further value-adding processes may occur.

Steam Vacuuming Stations

Hand-held steam vacuums (for spots of visible contamination <2.5 cm in diameter) are used to remove visible contamination from beef carcasses. Such systems use steam or hot water to loosen soil and kill bacteria, followed by vacuuming to remove contaminants. When applied correctly (e.g., passing the steam-vacuum system slowly enough over the surface of carcasses so that the temperature of the steam is able to kill bacteria), visible contaminants and bacterial counts are reduced.

Pre-evisceration Washing

Before evisceration, carcasses often are subjected to pre-evisceration washing to decontaminate the surface before bacteria have time to 'attach' adequately. This step generally involves washing of carcasses with large volumes of water at ambient temperatures, often followed by application of organic acid (e.g., 2.5% lactic acid).

Tie and Separation of Weasand

The first step in the removal of the viscera is separating the weasand (esophagus) from the trachea. Care must be taken here to prevent leakage from the rumen and to prevent carcass contamination with ingesta. This step is completed with an instrument referred to as a 'weasand rod.' The rod acts to separate the esophagus from the trachea, to ease the subsequent removal of the viscera. Subsequently, an elastic band or clamp is applied to the weasand (esophagus) to prevent leakage. In some instances, the weasand is tied with a butcher's string at the cranial end before separation from the trachea.

Dentition Check

Following exsanguination and prior to head removal or even prior to the removal of the hide, the age of each animal is routinely checked via dentition. An animal exhibiting a loss of three or more baby (deciduous) incisors and the eruption of three or more permanent incisors above the gum line are designated as 30 months of age or older. Owing to concerns relating to encephalopathic diseases, cattle designated as more than 30 months of age or older are processed separately from 'young' cattle and additional specified risk materials (SRMs) must be removed.

Head Removal

The head is removed at the juncture between the atlas vertebra and the occipital condyles (occipitoatlantal joint) of the skull. Following removal, the oral and sinus cavities of the head are flushed with water to remove debris. Each head must be tagged and identified so that the carcass and the head can be reunited for further inspection if necessary; usually using a four-piece 'gang tag' or 'head tag,' which maintains the sequence and identity of each carcass, head, tongue, and organ.

Tongue Removal

Following head removal, the tongue must be removed from the head for inspection purposes and further processing. This procedure is accomplished by severing the cartilaginous joints of the hyoid bones on either side of the tongue and removing it from the jaw bone. Following removal of the tongue from the head, the tonsils (pharyngeal, tonsil of the soft palate, palatine, tubal, and lingual) are removed from the tongue. Tonsils are an SRM that must be removed from all age classifications of cattle. Each tongue is identified with a portion of the 'gang' tag.

Head and Tongue Washing

Following their removal, heads and tongues must be washed. In large commercial facilities, this generally is accomplished using spray-washing cabinets designed for this purpose. In many cases, microbial intervention cabinets also can be used to apply chemical decontaminates to heads and tongues (e.g., a 2.5% solution of lactic acid). In smaller plants, heads and tongues might be washed manually as they hang on racks by workers. In all cases, care should be taken to insure that the

possible presence of pathogenic bacteria has been adequately addressed.

Head and Tongue Inspection

During head/tongue inspection, mandibular and parotid lymph nodes are excised and examined for abnormalities, and cheeks, lips, and tongues are examined for evidence of sores, abscesses, wounds, or splinters. Signs of abnormalities result in condemnation of either the head or tongue, or both, and in some instances can warrant further investigation of the carcass and viscera to determine carcass wholesomeness.

Brisket Saw

This process results in separation of the sternum along its midline to ease the process of evisceration and to facilitate carcass splitting. A specialized saw, equipped with a short ($\sim$10 cm) blade fitted with a blunt end (typically a steel ball), is used. This prevents the blade from damaging or rupturing the rumen as sawing occurs. Sawing is initiated posterior to the xiphoid cartilage, and extends downward causing complete separation of all sternebrae.

Bung Bagging, Tying, and Separation

This step results in separation and covering/sealing of the 'bung' (anus) so that it cannot contaminate the carcass. Complete separation of the rectum from the exterior carcass surface and pelvic cavity is necessary so that it can be removed during evisceration. This process is commonly referred to as 'bunging' or 'bung dropping.' It is imperative that fecal contamination be prevented; therefore, the bung always should be placed in a plastic bag and sealed with twine to prevent further defecation.

Oxtail Removal

The oxtail is removed by severing the cartilaginous joint between the last sacral and first coccygeal vertebra. Tails are then further processed as an edible by-product.

Evisceration

Evisceration is completed by: (a) removal of viscera (rumen, intestines, liver, esophagus, and spleen) and (b) removal of the 'pluck' (heart, lungs, and trachea). Viscera is removed by opening the peritoneal cavity (abdomen) along the ventral midline of the carcass, locating the bagged and tied bung, and gently pushing the viscera downward, pulling the separated and tied weasand through the thoracic cavity and removing the digestive tract. The liver is removed and presented for inspection. All internal organs are removed, except the kidneys, exposing the diaphragm. The diaphragm is severed where the muscular portion meets the connective tissue portion, and the contents of the thoracic cavity (the 'pluck') can be removed by severing the pericardial sac, pushing the heart and lungs downward, and pulling the trachea upward to complete removal. Both viscera and pluck are identified with a portion of the gang tag and presented for inspection. During inspection, the heart is opened and evaluated for abnormalities, the bile duct of the liver is split and evaluated, the liver is palpated for signs of abscess or sclerosis, and the weasand and intestines are evaluated. Abnormalities result in part or all of the internal organs being condemned and, in some cases, the carcass may be retained for further inspection or condemnation.

Carcass Splitting

Beef carcasses are split laterally down the center of the vertebral column using a hanging band saw. It is critical that the cut be made in the center of the vertebral column to prevent damage to loin and rib cuts of carcasses.

Spinal Cord Removal

Today, due to concerns relating to encephalopathic diseases, spinal cords generally are removed from the exposed vertebral foramen of carcasses and rendered. This process might be performed manually, or via use of an automated vacuum system.

Final Trimming

Carcasses are not considered wholesome if visible contamination is found to be present on the exterior. Knives are routinely used to remove visible contamination as is required by 'zero tolerance' performance standards. A designated area for the 'final trimming' of carcasses, just before final inspection, allows an opportunity to remove any remaining visible contamination on carcass surfaces.

Final Postmortem Inspection

Carcasses are evaluated by inspectors under the guidance of veterinarians to detect conditions resulting in products as unwholesome, or not appropriate for human consumption. Today, such conditions include presence of visible fecal, ingesta, or milk contamination, as well as a long list of pathological conditions. Carcasses can be 'retained' for additional processing or inspection after suitable corrective actions, some carcasses then might be approved (released) for continued processing. Other carcasses that are not salvageable are condemned, and deemed inappropriate for use as a food product; they must be disposed of in a manner ensuring that no carcass parts can enter commerce.

Measurement of Hot Carcass Weight

Carcasses generally are weighed before final washing or additional processing. Hot carcass weights are often subsequently utilized in classification and grading systems.

Hot Fat Trimming

Because it is inefficient to chill fat tissue, many plants now incorporate trimming stations (following the first hot carcass weight scale) designed to allow removal of excessive, trimmable fat from the exterior (i.e., subcutaneous) and interior (i.e., kidney, pelvic, and heart) of carcasses. Following removal of fat, plants generally collect a second hot weight from each carcass; these weights are then used to determine carcass value.

Final Carcass Decontamination Interventions

Just before initiation of chilling procedures, carcasses generally are subjected to a sequence of several 'final intervention' decontamination technologies designed to address the possible presence of pathogens on carcass surfaces ('multiple hurdles' systems). Synergistic or additive effects are obtained when combinations of two or more decontamination systems are used in sequence. As a rule, all carcasses are washed with large volumes of ambient-temperature water. Most plants also incorporate a thermal or steam pasteurization system designed to apply water at temperatures in excess of 82 °C, as well as spray cabinets that apply organic acids (e.g., lactic acid and acetic acid) or other chemical decontaminates to the surfaces of carcasses. Lactic acid and acetic acid are the most commonly applied organic acids in practice, both of which are approved by FDA and the Codex Alimentarius Commission as direct food additives. The Food and Agriculture Organization of the United Nations and the World Health Organization has specifically approved lactic acid and acetic acid as a food additive in all meat products (Codex Alimentarius Commission in 2006). Among the many available chemical decontaminates used as interventions, lactic acid sprays (concentrations ranging from 2.5 to 5% of solution) are one of the most consistently effective interventions against pathogenic microorganisms on the surface of beef carcasses. Until recently, the European Commission has refused to allow the use of chemical applications (e.g., lactic acid) onto carcass surfaces as interventions because of a philosophy that required prevention of contamination of live animals. However, that philosophy has now changed, and beginning in 2013, voluntary use of some interventions will become possible.

Carcass Chilling

Carcasses are generally chilled for 36–48 h in 'hot boxes' that are comp of 'bays' of chilling rails cooled via overhead units and high-velocity forced air. The use of chilled water in 'spray chilling' systems facilitates heat dissipation; usually spray chilling time intervals and the quantity of water applied are reduced as chilling progresses. Hot boxes often contain automated 'walking beams' that minimize human contact with carcasses. Carcass chilling should be initiated within 1 h of exsanguination so that a temperature of 4 °C or less is reached within 24 h. Carcass temperature is usually measured at five randomly spaced locations, 1 mm under the fascia of the inside round (rear leg). Sides of beef should be spaced in hot boxes to minimize carcass-to-carcass contact and to allow efficient air circulation.

Glossary

Abattoir Slaughter plant.
Carcass The dead body of an animal, especially one slaughtered for food.
Carcass contamination Bacterial contamination of the carcass.
Carcass dressing Removal of the hide, feet, head, tail, and internal organs from the carcass.
Electrical stimulation A current is run through the carcass soon after slaughter which makes the muscles contact and therefore speeds up the normal postmortem glycolysis (pH decline). The carcass can be chilled fast without risk of toughening ('cold shortening') and the tenderizing process (proteolysis, and aging) becomes more efficient.

Introduction

The principles for slaughtering and processing nontraditional species are the same as for the main livestock species. The animals have to be handled and slaughtered in a humane manner, and their carcasses dressed, stored, and transported hygienically. The main differences between the species lie in the way they are handled while still alive, in the approach used in skin removal and in the butchery lines used for the dressed carcass. Evisceration before jointing is the usual procedure in abattoirs if the meat is to be sold for meat consumption, but notable exceptions are the camel and the crocodile, where meat is often taken off the uneviscerated skinned body.

When animals are shot in the wild to be sold as game, the carcasses can be trucked to a central processing station. They may or may not be bled where they were shot. In hot climates, if the processing point is at some distance, the carcasses may be fully or partly processed, stored in a refrigerated larder, or chilled in a refrigerated truck before arrival at the processing station. There are many variations on this theme. From a hygiene perspective, there are two important features. First, the carcass or body should be chilled as soon as possible to control bacterial proliferation. Second, opening or dressing the carcass in unhygienic conditions greatly increases the risk of bacterial contamination and growth. In some situations it is advisable to leave the dead animal undressed until it can be taken to a centralized processing area where dressing can be done hygienically. This raises some issues about how bacteria multiply in uneviscerated carcasses, and the effects of delayed evisceration on the quality of the meat. Research studies have shown that when animals have been slaughtered and refrigerated without evisceration, it has not been possible to recover, from the edible carcass, marker bacteria that had previously been introduced into the gut before slaughter. However, the presence or absence of migration of bacteria through the gut wall postmortem may depend on the types of bacteria that are being considered. It is thought that in some circumstances *Clostridia* may be able to pass through the gut wall. This is a particular concern with fish meat, and it is thought that they can occur in terrestrial meat species, especially when the animals are severely stressed or if they have lesions in the gut wall, for example, from enteroparasites. There is no doubt that gases pass from the gut into the edible parts of the carcass. When a carcass is stored uneviscerated, internal tissues are prone to turn green through chemical combination with hydrogen sulfide that is released from the digesta.

Fine-fibred or fur-bearing animals such as kangaroos, rabbits, hares (jack rabbits), and deer can present problems with the transfer of fine hairs to the carcass during removal of the hide or pelt. This issue can be reduced by allowing the skin to cool before starting skin removal, as this encourages the fibers to set more firmly within the skin. If hairs do transfer to the carcass, it is not always possible to remove them with a washdown spray gun. The pressure from the water can cause the hairs to embed into the surface of the carcass, hence making the situation worse. Instead, the hairs should be removed with a knife along with some underlying tissue. In rabbits, the risk of hair transfer can be reduced by pulling the skin as a sock instead of a jacket.

During field slaughter it can be difficult to hoist a carcass to remove its skin, particularly in long-legged or heavy animals. In those situations, the skin may be removed while the carcass is lying horizontally on a cradle, cratch, or pram. An alternative, but less common, arrangement would be to suspend the carcass by four legs for the purpose of skin removal, and then re-suspend it from an Achilles hook or spreader when the legs have been reduced, to drop the guts. Alternatively, an animal killed in a remote area may be dressed while it is resting on its back and side with the partly attached hide serving as a clean apron between the ground and the carcass. The legs, backstrap, and other joints are removed before evisceration, followed by the red offal and fillet. In some birds, three-point suspension (by the neck and both legs) is used to assist vent opening and removal of viscera.

Deer

Both wild and farmed deer are processed in deer abattoirs. Wild deer are shot in the field and their carcasses are sent to

 doi:10.1016/B978-0-12-384731-7.00160-4

the abattoir, sometimes with a holding period in a refrigerated larder. In some countries there is a legal requirement that the carcass must be eviscerated within 3 h of slaughter. To meet this standard, carcasses are gralloched (green offal is removed and discarded) where they are shot, whereas the red offal is usually retained with the carcass, which still carries its hide. Farmed deer and wapiti/elk are processed either in dedicated deer-processing plants or in plants that are registered game premises. It is very important to have pens and stunning facilities that are purpose-built for deer. Deer are versatile jumpers, and high-walled partitions are needed, and the lighting must be adjusted to help control their activity. Deer are usually handled individually between the holding and stunning pens, and some operators use boards to drive the animals in the required direction and to protect themselves from an advancing animal. When the deer is confined in the stunning pen, it is usually shot with a captive bolt gun, and then stuck after shackling and hoisting.

Where inverted dressing is used, consideration needs to be given to health hazards (leptospirosis) for operators, created by hinds that release urine. In some plants the pizzle, as well as the weasand and bung, is bagged and secured with a rubber ring before removal.

New Zealand has pioneered the development of farm-based production systems for deer meat (venison). Consequently, an important component of the research and development for this deer industry has been to define production systems that render distinctive and high-value attributes to venison, together with post mortem processing systems to complement these goals. As a specialist culinary product, venison is processed in specialized facilities licenced by the New Zealand (NZ) Ministry of Agriculture and Forestry. An animal welfare Code of Practice governs the humane treatment of deer before processing to ensure minimum stress and to enhance product quality. Electrical stimulation is standard protocol for the NZ deer carcasses. Venison is processed according to customer requirements. The trend is toward added-value (or further processed) cuts, where the bones and 'silverskin' (i.e., the connective tissue surrounding the muscles) are removed. The most important markets for New Zealand venison are Europe (Germany, Switzerland, Austria, and Scandinavia) and the US. Venison is attractive to the gourmet and to the health-conscious consumer for its unique flavor, low fat content, favorable fat composition, and high mineral content.

Camel

Camels are slaughtered for meat consumption in abattoirs in a number of countries in the Middle East and in Australia. Australia exports live feral and farmed camels for slaughter in Brunei; they kill out at approximately 50%. Most camels are familiar with being handled and this makes the slaughtering procedure a simple business, but feral animals are more difficult as they are prone to sitting down in the yards and refusing to move. When animals are slaughtered individually for local consumption, the tame animal is couched (made to sit in sternal recumbency) in the normal manner or with its hind legs extended backwards, and then shot in the head or slaughtered according to halal regulations. The dressing procedure is unusual in comparison with other species. The hide is opened from the dorsal instead of ventral aspect, and dorsal cuts of the carcass are removed before evisceration. This is done in the following way. While the body is maintained in sternal recumbency, the opening incision is made along the midline of the back, and the hide is freed down the sides. The hide serves as an apron on the ground, which helps reduce contamination of the carcass. The hump is removed at this stage if it is large, or left attached to the carcass if small. The shoulder is separated from the thorax working dorsoventrally, and the ribs are removed, followed by the flank. The carcass is then eviscerated. The camel is not a true ruminant even though it has a rumen. It has three instead of four stomach compartments, the omasum being continuous with the abomasum. In camel abattoirs in Australia, the camels are stunned, slaughtered, and dressed in a similar manner to beef, except that the neck and forelegs are removed before suspension to ensure clearance between the carcass and the floor.

The dromedary carcass is usually less fat than the bactrian. The subcutaneous fat is localized in the hump, and the absence of a continuous subcutaneous fat layer assists body cooling. The fat is usually white and soft, and bactrian fat is valued as a cooking oil in Chinese cuisine. The meat is similar to beef, but it has a lower fat content. Camel hides can flay and flesh easily depending on the level of hydration. They also dehair relatively quickly and are easier to split than cattle hides.

Buffalo

When water buffalo are processed in abattoirs, they are handled and dressed in much the same way as cattle. Difficulties are sometimes encountered in stunning them with a captive bolt gun because of the protection provided by their heavy skulls. Water buffalo in the Indian subcontinent and East Asia have a low dressing percentage in comparison with beef, the normal range being between 38% and 45%. The carcasses have low levels of fat, but the fat is usually white. They have relatively large fore shank, sirloin, and short plate cuts due to well-developed bone, and poorly muscled chuck and ribs, in comparison with beef. The meat is eaten as for beef, but in West Asia and Eastern Europe there are specialist buffalo meat products in the pastrami range of salted dried meats.

North American Bison

North American bison (often called buffalo) production is being tried in a number of countries for curiosity and tourist value. The main centers of production are in the northern parts of North America. Farmed animals are amenable to handling and can be put through processing plants that are designed for beef. There is very little export of the meat.

Horse

Horse and pony meat is exported from a number of countries for human consumption in France, Belgium, and Japan. It is

also sold for human consumption among aboriginal communities in Australia. Horses are slaughtered for the fresh and frozen petfood markets in many countries, but little is used in the canned petfood industry. The horses may be domesticated or mustered from wild populations of brumbies or mustangs. Wild horses and ponies are considered a pest in some regions, and slaughter for meat is a by-product of the culling operation. They are usually killed at dedicated horse export abattoirs, but in Australia there is also some field slaughter in the Northern Territory, and West Australia. Approximately 30% of the horse meat exported from Australia comes from brumbies. In the former USSR, the favored types for meat consumption are the blocky steppe breeds (e.g., Kazakh) and the forest breeds (e.g., Byelorussian Harness and Zhemaichu). Some attention has been given to selecting these types for body and carcass conformation.

On arrival at the abattoir, domesticated horses will sometimes have their shoes removed the day before slaughter to prevent injuries to each other and to staff. They are stunned with either a captive bolt gun or a rifle. Processing and dressing are relatively straightforward in horses, the only peculiarities being that in some countries the head has to be split to allow inspection for the bacterial disease glanders and, as they are hindgut fermenters, they have a large cecum. The dressing percentage varies between breeds, and for a 180 kg live weight harness breed would be approximately 51%. The meat is dark in color, with a strong grain and a sweet odor. Boneless meat yield varies considerably, according to the condition of the animal, and for feral stock it is usually between 125 and 175 kg. The fat can be soft and yellow. In Japan, the meat is used as a manufacturing meat, for example in smoked meats, sausages, and meatballs. In some countries horse meat from feral animals is becoming recognized for being free from veterinary residues. Saleable by-products include horse hide, hair plus, meat, and bone meal. Sound horse hides can command good prices, for example for making the inner soles of fashion shoes. Tail hair is used for making the bows of stringed musical instruments. Hearts and spleens have a market in the pharmaceutical industry.

Various Other Species

Reindeer and Moose

Fennoscandia (Sweden, Norway, and Finland) lead the world in commercial production of reindeer meat. In these countries the traditional Sami reindeer husbandry culture is performed with the reindeer free ranging (i.e., not enclosed in fenced areas) in forests and on the mountain tundra. Traditionally, reindeer were slaughtered at the selection site, i.e., at various locations surrounding the reindeer herding districts of the Sami people. In Sweden, new directives regarding reindeer meat inspection were instituted by the National Food Administration in 1993. The consequences of these new directives were that many of the former outdoor slaughter sites were closed, the numbers of reindeer transported to slaughter increased, and new mobile slaughter facilities were developed and introduced. Reindeer slaughter is seasonal, and almost all slaughter take place in the autumn and winter months, between September and March. The animals are herded on foot, using motorcycles, snowmobiles, or helicopters to gathering corrals where reindeer destined for slaughter are selected. The rules applied for animal transport, veterinary inspection of living animals and carcasses, stunning methods, slaughter hygiene, carcass grading, and chilling conditions for reindeer are similar to those applied for other domestic species, i.e., the specialized reindeer slaughter plants are all EU-approved facilities for slaughter of domestic animals. Reindeer meat is similar to deer venison; however, it is extremely tender and does not require aging before consumption and it has a characteristic wild/gamey flavor reflecting the natural pasture consumed by the reindeer in the forests and on the mountain tundra. Reindeer meat is a very exclusive gourmet product, which is in high demand and always on the menu in the more luxurious Fennoscandian restaurants. The meat is consumed fresh but is also marketed as cold- or hot-smoked and dried meat products.

Several of the dedicated reindeer slaughter plants in Fennoscandia are also approved game handling facilities, which means that they can also process various game carcasses. The processing of game is performed on a separate line from domestic reindeer carcasses and normally kept in a special area within the processing plant. Moose is the most common species processed in the game handling facilities; however, carcasses from various deer species (red deer, fallow deer, and roe deer), wild boar, and brown bear could also be delivered directly by hunters to these processing plants.

Small quantities of reindeer meat are also produced in Alaska, USA, but currently only for domestic/local consumption. Reindeer were introduced to Alaska from Siberia in 1892 to establish a predictable meat source and economic development for Alaskan natives. The extent and management of reindeer in Alaska has changed considerably over time but has recently evolved into a modern animal production system. The current reindeer industry is concentrated in the Seward Peninsula, Alaska, where reindeer are managed over large, rugged, and remote areas with little or no transportation infrastructure. Reindeer meat and velvet antler production generates significant employment and revenue important to the economies of rural Alaskan communities, but lack of slaughtering and transportation infrastructure constrains the development of the industry.

Reindeer and caribou are different. The semidomestic reindeer that inhabit the northern parts of Scandinavia, Russia, Siberia, China, and Mongolia and that have been introduced to Alaska belong to the subspecies of Eurasian tundra reindeer (*Rangifer tarandus tarandus*) and have been domesticated for thousands of years. Alaska caribou (*Rangifer tarandus granti*) and other North American caribou subspecies have never been domesticated, but have been hunted for meat.

Ostrich, Emu, and Rhea

Ostrich, emu, and rhea are often slaughtered in dedicated ratite plants. The birds are led individually to the slaughter point, and either electrically stunned or shot with a captive bolt. Typically, a pair of scissor-type tongs is used for electrical stunning, but a specialized stunner within a box is also used

for ostriches, where the bird's head is shut inside the box and current is then applied. Often, the bird's legs are secured before stunning. This is usually done either with a chain shackle or with a bar applied across the shank while forcing the bird to either sit or stand still within a wedge-shaped restrainer. Leg restraint is used to help control skin damage and to make transfer to the sticking point less hazardous because of flailing legs. Sticking is done with an ear-to-ear ventral throat slit, and this is sometimes followed by an additional thoracic stick once the carcass has stopped convulsing. Ratites do not have a crop, and therefore a chest stick does not usually lead to contamination of the carcass with upper gastrointestinal tract contents. At some plants, ostriches and emus are shorn, using a set of electric sheep shears, before the skin is removed. In the past this has been done on the live animal, but more often it is now done after stunning and sticking. Shearing should be done in a separate dedicated area to help control the spread of dust from the feathers. The skin is removed using a midline ventral incision that deviates around the chest callus over the sternum. The skin is very tight over the back and has to be freed with a knife, whereas at the front and sides it can be punched and pulled by hand. The meat is dark red in color and most is in the thigh and drumstick. There is very little muscle over the keel. The drumstick meat has a lower value than thigh meat because of its higher sinew content. The sinew can be removed with a silver skinner. South Africa exports both frozen and vacuum-packed fresh ostrich meat.

Emus have a well-developed preen gland, which is valued for its oil in medical and health products. It is removed by pulling with one hand while cutting it free from the carcass with the other. It is processed by cutting into small pieces, or grinding with water, then extracting the fat by boiling and pouring it into collecting jars. It may also be skimmed or filtered before despatch to the pharmaceutical company. The skin has a strongly bound layer of subcutaneous fat in well-finished birds, which can be difficult to remove. In addition, the feathers protrude through the skin into the subcutaneous tissues over the back, and it is necessary to remove all these feathers before taking the skin off, otherwise there is a risk of tearing the skin. Manual feather removal can slow the processing considerably. As with ostriches, the shank skin can be valuable in the fancy leather trade. It is removed by pulling after making opening cuts in the sole of the foot and the rear margin of the leg. Rheas have similar feather follicles to emus, and their skins are smaller in overall size. Emus have small caeca in comparison with ostriches and rheas.

Crocodile

Crocodile processing is invariably done at the farms of origin, which also often serve as tourist stops. During slaughter, the animal is snubbed and tied, and carried to the processing area, where it is then shot in the head. The value of the animal is in its skin, and therefore great care is taken to minimize damage during handling. The tail has been the main part of the crocodile used for meat consumption in Africa. It is a pale meat with a characteristic structure, and is usually served as thin slices cut across the length of the tail. In Australia, a standardized jointing procedure has been developed that makes use of the backstrap, leg meat, jowls, neck, flank, and rib covering.

Animals that are killed in the wild are sometimes butchered and eaten where they were shot. The meat can be cooked and eaten immediately, without being unduly tough. In this situation the muscle is cooked and eaten without going into rigor. However, if the meat is cooked slowly, rigor will be accelerated and heat shortening will occur and hence there will be some toughening. The rise in temperature during cooking needs to be rapid to avoid the contraction and thus help ensure acceptable tenderness.

Kangaroo

Kangaroo, wallaby, and euro are usually shot at night time using cross-country vehicles and spot lights. After a shooting run, the carcasses are gathered together and dressed on the spot before loading into refrigerated trucks. African wild ungulates may be treated in the same way, or the uneviscerated carcasses may be trucked to a standing processing depot.

Rabbits

Rabbits are stunned electrically in the larger processing plants. They are handled individually using gloves and the head is pressed into a set of V-shaped wall-mounted electrodes. The stunned animal is then suspended and stuck. In other situations concussion may be used, or the animal may have its neck dislocated manually. There is nothing unusual about the dressing of rabbit carcasses, except that the skin may be removed as a sock, and in some parts of the world the brain is saved for speciality dishes.

Geese and Ducks

Geese and ducks are often processed in automated chicken or turkey plants that can handle birds of larger size than conventional broiler chickens. The plants are often equipped with semiautomated primary feather pullers and baths of molten wax for removing down feathers. Feather removal can be particularly difficult in waterfowl, and it often determines the optimum killing age of the bird; the feathers become more difficult to pull as a bird gets older. Dry salted fermented duck is a traditional product that is popular in China because of its special flavor. The traditional technology of producing dry salted duck is characterized by handcrafted salting and natural drying, which limited the production scale. New processing techniques have been introduced to improve the traditional technology and quality of dry salted duck.

Quail

Quail are sometimes stunned and processed while suspended in shackles from an overhead line. The shackling procedure can be stressful for the birds, and sometimes they attempt to fly out of the shackles. If one leg is removed, the suspended leg may break at the shank. In one system the birds are stunned electrically along the length of the body to simultaneously induce cardiac arrest. They are not bled with a neck cut, but

instead blood is removed at evisceration. At other plants the birds are decapitated either with a cleaver and block, or by a knife or pruning shears, before they are suspended. Both wet and dry plucking methods are used. Dry plucking is done by hand or mechanically, and at some plants the birds are wax dipped in a similar manner to ducks. Gutting can be more difficult in quail because of their small size. Vacuum drawing of the viscera is used in larger plants. Quail products include boneless meat, oven-ready fresh or frozen carcasses, and smoked quail for the delicatessen trade.

Glossary

Audit A systematic examination of a system to determine whether documented procedures are being complied with and that the system achieves its objectives.

Carcass The dead body of a slaughtered animal after removal of the offal.

Codex Alimentarius Commission A joint international committee of the Food and Agriculture Organization and the World Health Organization of the United Nations. Its work includes the development of international food standards, guidelines, and codes of practice to protect consumer health and ensure fair practices in the food trade. In many cases, Codex Alimentarius standards are used as a basis for national legislation.

Critical control point A point, step, or procedure at which control can be applied to a hazard so that it is prevented, eliminated, or reduced to an acceptable level and where loss of control may lead to a food safety problem that could harm the consumer.

Evisceration To remove the viscera from the carcass.

Hazard analysis Identification and assessment of all potential and real hazards that may occur at each step of the carcass dressing process. It includes an assessment of the likelihood that each hazard will occur and the severity of the hazards identified.

Hazard analysis and critical control point (HACCP) A systematic approach to the identification and assessment of hazards and risks associated with the production, processing, distribution, and use of a particular foodstuff and implementing measures which either prevent the hazards occurring or correct the process to maintain control.

Pathogens Bacteria capable of causing disease. Meat items infected with pathogens usually look no different to an uninfected item.

Process A set of activities, usually expressed as a sequence of steps that must be performed to prepare a final product.

Processor A commercial entity responsible for the humane slaughter, dressing, and chilling of pigs and their carcasses.

Risk A measure of the likelihood of a hazard occurring and the severity of a hazard.

Introduction

The slaughter-line operations for pigs can be divided into two major sections. Following stunning and bleeding of pigs, activities on the slaughter floor are concerned with processes to remove hair, including scalding, dehairing, singeing, and polishing of carcasses. Evisceration then occurs, which involves the removal of the intestines and pluck sets (larynx, trachea, lungs, esophagus, heart, liver, and spleen) from carcasses. Carcasses are then washed to primarily remove bone dust and blood. The head, kidneys, kidney fat, flare fat, and foretrotters may also be removed from the carcass before entry into the chiller, depending on customer requirements.

The Codex Alimentarius Commission, the United Nations International Standards Organization for food safety, advocates the implementation of hazard analysis and critical control points (HACCP) systems as effective process controls for managing food safety risks associated with the production of meat. The implementation of quality control systems by pork processors, based on good manufacturing practice and HACCP, is legally mandated in many countries, including the US, Australia, Canada, and throughout the European Union. The requirement to limit microbial contamination to as low as what can be practically achieved may result in additional operations being introduced into a plant. Specific interventions, such as chemical sanitizing, hot-water washing, or steam pasteurization, may therefore be needed to reduce microbial contamination, enhance shelf life, and minimize risks to human health associated with microbial pathogens.

A shortage of labor, the need to reduce costs, customer demands for improved carcass hygiene, and the need to provide good working conditions for employees have resulted in the automation of many pig slaughter operations. Semiautomated, welfare friendly lairage systems are available to divide pigs into groups of approximately 15 and move them toward the stunning point. These groups are then further subdivided into groups of approximately five for automated carbon dioxide group stunning, without requiring the use of electrical prodding devices. Only the shackling, singeing, and gambrelling operations in modern, high-throughput plants need to be manually performed; preevisceration, scalding, singeing, scraping, and polishing can be automated. Automated carcass evisceration systems are available as systems for bung dropping, back finning, and carcass splitting on the slaughter line, with those components that are in contact with the edible product sanitized between each carcass to minimize cross-contamination. The principal slaughter-line operations can be fully automated to form a computer-integrated manufacturing system.

A Description of Current Pig Slaughter Practices

Although current pig slaughter practices may vary slightly from country to country, the core activities remain the same. These are shown in Figure 1.

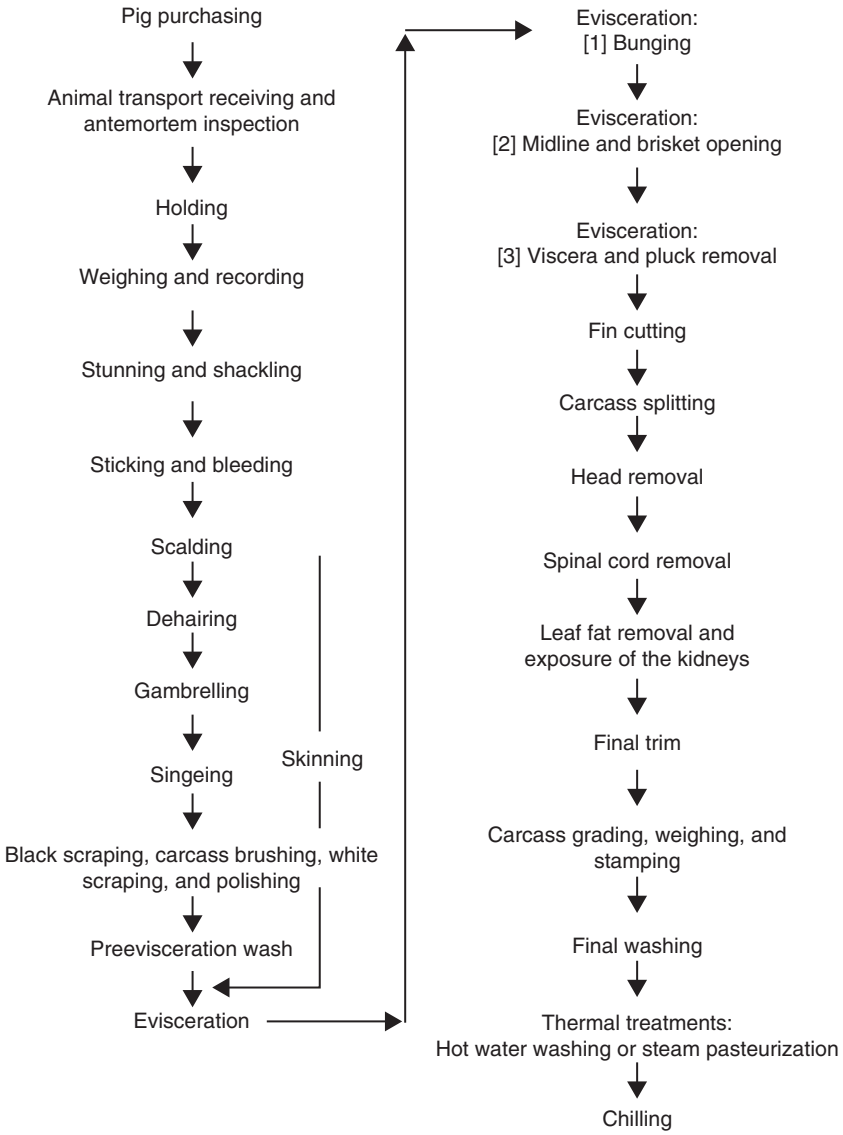

Figure 1 A summary of flow diagram of pig slaughter processes.

On-Farm Pig Quality Assurance Systems

Pigs should be purchased from producers whose production systems meet the standards described in a recognized quality assurance scheme and audited by an independent third party.

Pig quality assurance schemes may include an on-farm *Salmonella* control program (e.g., in Canada and the European Union) based on bacteriological testing. Competent authorities may maintain a central database and each pig producer be issued with a certificate stating the category of the herd. In Denmark, this program also includes serological testing using enzyme-linked immunosorbent assay of meat juice samples at the abattoir to identify previous exposure. A finisher pig *Salmonella* index is calculated based on sample results, and pig herds are assigned on a monthly basis into one of three levels of *Salmonella* infection. The objective of the program is for as many farms as possible to achieve level one status, with fines imposed on producers whose herds fall into levels two and three. The status of each herd is published on a website that details the health status of Denmark's pig breeding herds. Pigs arriving at the abattoir without an up-to-date certificate are usually treated as category three animals. Category three pigs are transported separately, segregated in a lairage, and slaughtered at the end of the day. Unless heat-treated, the head or head meat, gastrointestinal tract, lungs, and liver of these animals are excluded from human consumption. In the US, the Food Safety Inspection Service (FSIS)/United States Department of Agriculture Pathogen Reduction: HACCP Final Rule (61 FR 68806), introduced in 1997, includes *Salmonella* performance standards for slaughter plants to provide incentives for meat processors to reduce *Salmonella* prevalence on their products.

Feed Withdrawal

A feed withdrawal program should be implemented on farm if the time from the farm to slaughter is less than 12 h to reduce the risk of burst viscera during evisceration. Pigs subjected to preslaughter feed withdrawal are less likely to vomit, experience motion sickness, or die during transport compared with pigs transported with a full stomach. Pigs should be slaughtered between 12 and 24 h after they have been removed from feed to minimize *Salmonella* shedding and possible contamination of the carcass.

Animal Transport, Receiving, and Antemortem Inspection

Most countries have guidelines or legislation covering animal transport. Processors may also stipulate that transport companies must be accredited for transporting their livestock. The Australian Standards & Guidelines for the Welfare of Animals Land Transport of Livestock was introduced nationally in July 2012, replacing the Land Transport Standards endorsed in 2009. These standards cover the period before loading when animals are first deprived of feed and water to the period when livestock are unloaded and provided access to water at their destination. Within the EU, regulations on the protection of animals during transport and related operations were amended in December 2004 and are detailed in EU Council Regulation (EC) No 1/2005. In Denmark, requirements for mechanical ventilation, global positioning systems, drinking water, and sprinkler systems on transport vehicles have been introduced by processors.

Antemortem inspection is a requirement of public health legislation as an essential prerequisite to the slaughter of animals intended for human consumption. The antemortem inspection and the judgment of fitness for slaughter are normally restricted to the official veterinarian or other authorized person to whom the inspection is delegated. There is growing evidence that antemortem inspection may be more effective in improving animal welfare and processing efficiency if carried out on farm as part of a quality assurance system by trained personnel familiar with the animals than abattoir antemortem inspection. Adequate facilities should be provided, including appropriate lighting, and the animals should be observed at rest and from both sides while moving.

Holding

Pigs should be rested in lairage pens, with access to clean water, at the abattoir to allow them to settle and overcome any stresses encountered during transport for at least 2 h before slaughter. Pigs should not be mixed with unfamiliar animals during transport and in lairages to minimize fighting and bruising. Apart from the direct loss associated with death during transport, bruising can result in increased carcass trimming or carcass condemnation. Acute stress immediately before slaughter can also result in the development of pale, soft, and exudative pork, negatively affecting its quality, shelf life, and saleability. Lairage facilities should be constructed and maintained so as to prevent physical injuries to the animals and allow for adequate ventilation, light, and shelter from adverse weather conditions. Space allowance in lairages should allow all animals to stand or sit or lie down at the same time. Pigs should be handled calmly and quietly. Pigs have an acute sense of smell, good hearing, poor vision and are curious, but are particularly sensitive to stress. With a poor following instinct, they require firm handling, which can be best achieved using handling aids, such as pig boards, rattles, or flags, to encourage movement through sight or sound. Pigs prefer being handled in small groups of 5–6 pigs and do not like being moved individually or being left alone. The use of electric goads should be avoided as much as possible.

Each batch of pigs should be segregated in a lairage to minimize fighting and the spread of pathogens such as *Salmonella*. Clean drinking water should be available at all times and the pigs should be fed if the delay before slaughter exceeds 24 h. In hot weather, a fine mist or spray of cold water may reduce stress during lairage.

Weighing and Recording

In some plants, live pigs may be weighed using a balanced scale before stunning to allow the calculation of dressing percentage ((carcass weight per live weight)×100). The breed, sex, and ID number may also be recorded.

Stunning and Shackling

To present the pigs for stunning, they must be moved from the lairage. This may be achieved using a series of races and chutes to encourage pigs to move forward. Races should have solid sides and be wide enough for two pigs to walk together. Pig races should never have right-angled bends. Lighting should gradually become brighter toward the stunning point. Chutes may be single or double and include a series of gates to prevent the animals from reversing. In most countries, stunning and exsanguination, or sticking, may only be carried out by accredited persons.

It is a welfare requirement in many countries that pigs are rendered insensible to pain by stunning before slaughter (e.g., EC No 1099/2009 that has repealed Council Directive 93/119/EC and applied from 1 Jan 2013; Australia – Model Code of Practice for the Welfare of Animals: Livestock at Slaughtering Establishments; USA – Humane Methods of Livestock Slaughter Act). All stunning equipment should be maintained and inspected by trained, conscientious employees to ensure that a consistent and effective stun is delivered to each animal. There should always be a backup stunning system within reach of abattoir personnel. Pigs are typically stunned in abattoirs using either a carbon dioxide chamber or by the application of electrical current to the head. Penetrative captive bolt stunning of adult pigs requires accurate placement on the pig's forehead to render the animal insensible to pain in a single shot, as its brain is relatively small and protected by sinuses. This method is not routinely used in abattoirs for pigs as it has a lower efficacy (it is acceptable for 95–98% of animals to be instantly rendered insensible with one shot) compared with electrical or

carbon dioxide stunning. Tonic and clonic movements can also be intense following captive bolt stunning, impacting on worker safety during shackling and hoisting for exsanguination.

Carbon dioxide stunning of pigs is now used in many countries. Pigs should be smoothly moved into gondolas, typically set out in a Ferris wheel-type arrangement. Once appropriately filled, the gondola is lowered into a pit containing a high concentration of carbon dioxide. It is a requirement of the World Organization for Animal Health that the CO_2 concentration used must not be less than 80%. Pigs should be exposed to a maximum concentration of 90% carbon dioxide in air at the bottom of the pit within 30 s, and the total exposure time should be more than 90 s to minimize any chance of recovery. Research has shown that blood oxygen levels fall slightly during stunning, whilst carbon dioxide levels in the blood rise significantly. Carbon dioxide stunning lowers the pH of the blood and brain tissue, leading to analgesia and loss of consciousness. After stunning, the now unconscious, flaccid pigs are tipped onto a shackling table and shackled with a chain by one leg, usually between the dewclaws and the hock, before being hoisted onto an overhead rail and exsanguinated. A semiautomated group carbon dioxide stunning system, developed in Denmark to optimize both animal welfare and meat quality, is now being used in many countries. This system relies on the pigs' natural curious behavior to move forward in small groups toward the stunning unit, with assistance from gates and slowly moving walls. This has removed the need for single file races and use of electric goads. The system allows for stunning of small groups of five pigs at a time and can meet plant line speeds of 830 pigs per hour.

For effective electrical stunning of pigs, a minimum current of 1.3 A at a voltage of at least 240 V must pass through the pig's brain for at least 1 s to reliably induce an epileptic fit. Electrical stunning should only be applied once. Electrical current may be applied by either manual or automatic application of stunning tongs positioned on both sides of the brain between the eye and the base of the ear. Cardiac arrest stunning may also be used either by using head-to-back electrodes (applied either between the ears, on the sides, or top of the head or on the forehead, and on the backbone of the animal behind the heart) or head-to-brisket tongs that are positioned with electrodes placed on the top of the head between the ears and the other electrodes placed between the forelegs on the brisket. Electrical stunning at a frequency of 50 Hz is most commonly used. It is imperative that the electrodes are correctly positioned and the current is applied for a sufficient time so the duration of insensibility persists to ensure that the pig does not recover before it dies from bleeding. A maximum stunning-to-stick interval of 15 s is recommended. For pigs, a minimum time of 37 s to return of rhythmic breathing and recovery from effective electrical stunning has been shown. If the stun is not effective, animals will be merely paralyzed and recover from the stun before brain death following sticking. Electrical stunning of free-standing pigs may result in broken bones, particularly the shoulder blades, as a result of the forelegs hitting the floor when electrical current is applied. Hence, V-shaped restrainers and monorail or double-rail conveyers are often used to hold in position while efficiently moving them toward the point for electrical stunning. High-voltage stunning (up to 1000 V for 1.5–2 s) may also be used, particularly in higher volume plants, and applied in association with the use of a restrainer–conveyer to form an automated system.

Sticking and Bleeding

Sticking should take place within 15 s after stunning to ensure the animal does not regain consciousness and to minimize ecchymosis (blood splashes) in the muscle. Ecchymosis may occur when capillaries restricted by muscle spasm rupture as a result of the build-up in blood pressure when the heart continues beating and is more common in electrically stunned pigs. A knife is used to cut the main blood vessels (anterior vena cava and bicarotid trunk) in the upper chest. This is usually achieved by inserting the knife midline at the base of the neck. Then, with the point of the knife between the sternum and the backbone and directed toward the tail, the operator thrusts the knife toward the anus until it strikes the backbone, cutting the carotid arteries and jugular veins. Blood should flow freely and death should occur within a few minutes. The knife should be sterilized in hot water at a temperature of at least 82 °C between each animal to prevent cross-contamination. Abattoir personnel should ensure that the animal has been effectively stuck by checking for the absence of brain stem reflexes (blinking when cornea is touched and reflexive gasping breaths).

Sticking may push contamination from the skin surface of the pig to the inside of the carcass. Scalding may also contaminate the sticking wound and this should be removed at a later stage and condemned. Bleeding usually takes less than 5 min and death occurs as a result of oxygen deprivation to the brain. Blood may be collected at this stage for later use in the preparation of processed pork products. This can be done using a stainless steel hollow knife, connected to a vacuum pump and storage vessels, which is then sterilized between each carcass in 82 °C hot water. When collected for edible purposes, blood will be batched and held until carcasses have passed inspection. Vision systems for automatic monitoring to ensure that sticking has been performed correctly have been installed in Europe and US abattoirs.

Dehiding

In most countries, skin remains on the carcass. However, in some countries, most notably Japan, China, and Taiwan, skins may be removed from the unscalded pig or immediately after scalding. Leather produced from unscalded pigskins is thicker and has greater tensile strength than that produced from skins that have undergone the scalding process. Skin removal may be performed manually or by machine. Machines capable of skinning the whole carcass are now available.

Scalding

When the pigs are not skinned, the hair must be removed from the carcass. Scalding is the first of the dehairing operations. Scalding facilitates hair removal by denaturing the proteins in

the hair follicles. This can be achieved by immersing the carcasses in a scald tank of hot water. Steam condensation systems are available and are used in countries including Poland, Spain, France, Switzerland, Japan, Australia, and China. The time–temperature combination applied is important, as underscalding does not facilitate hair removal and overscalding causes the skin at the base of the bristles to contract, holding them tighter. Although a typical time–temperature regime may vary from 5–10 min at 60–70 °C, the exact combination applied will depend on the amount of hair and its ease of removal. Factors such as pig breed and seasonal influences should also be taken into account. In the US, for example, there is an easy hair season (February–March) when a scalding combination of 58 °C for 4.5 min is typically used, and a hard-hair season (September–November) when 60 °C for 4.5 min is applied. Throughout the rest of the year, a typical scalding temperature–time combination of 59 °C for 4.5 min is the norm. In Australia, the typical scalding temperature–time combination for immersion systems is 62 °C for 4.5–5 min.

Food safety is also a consideration during scalding as each carcass brings a quantity of dirt, feces, and ingesta to the scald tank and as a result the water quickly becomes polluted and may act as a vehicle for carcass cross-contamination. However, enteric bacteria such as *Salmonella*, *Escherichia coli*, and *Campylobacter* will be destroyed if the temperature is sufficiently high. Studies have found that 1.0×10^6–1.9×10^6 *Campylobacter* per milliliter may be reduced to less than 10 organisms per milliliter after 1–1.25 min in a scald tank water at 56 °C. Similar reductions have been observed for *Salmonella* and *Yersinia* strains at 60 °C after 1.7–2.2 min and 2.5 min, respectively.

Dehairing

Dehairing is usually performed using a dehairing machine. This removes the hairs mechanically by rotating the carcasses using the action of rotating flails while cold or hot water is sprayed over the carcasses. A perforated tray under the machine screens hair and other detritus from the water. The dehairing machine may be an important contributor of *Salmonella*, *E. coli*, *Campylobacter*, *Yersinia*, coagulase-positive *Staphylococcus aureus*, and *Listeria* contamination of pork carcasses during processing. The prevention or reduction of contamination is dependent on effective cleaning of the equipment.

Gambrelling

Pigs are ejected from the dehairing machine onto a stainless steel conveyor belt or gambrelling table. Two parallel incisions are made through the skin on the back of each hind leg to expose the gambrel tendons and the gambrel hook is inserted hooking the hind legs of the animal, which is then hoisted onto an overhead conveyor rail. The toenail may be removed at this stage or after polishing. This is most effectively achieved using a toenail puller. Pruning shears may be used if the toenails are particularly difficult to remove. Carcasses generally remain hung from the Achilles tendon on entry to the chiller, but if split, sides may be transferred from gambrels to individual slides.

Singeing

In the abattoir, singeing is performed to facilitate the removal of any remaining hairs. Intense heat is applied that burns the remaining hairs and tightens the skin, facilitating subsequent polishing or shaving. Singeing may be as simple as using a hand-held gas torch. Larger plants utilize singeing units containing gas jets that are housed in a stainless steel cabinet that is positioned on the line and carcasses pass through it at chain speed. Gas and air are blown into the cabinet, creating a flame that envelops the carcass. The temperature in the chamber may reach up to 1200 °C and is applied for 5–10 s. The surface temperature of the pork carcass may increase to 100 °C during this process. This operation does not eliminate all the bacteria on the carcass, but it significantly reduces contamination. Water is usually sprayed onto the carcasses before and after singeing to remove loose hairs and blood.

Black Scraping, Carcass Brushing, White Scraping, and Polishing

After singeing, a variety of polishing or shaving devices may be applied to remove singed and remaining hairs. The black scraper consists of slowly rotating steel scrapers applied with a cold water spray to remove black singed hairs. Carcass brushers consist of a series of stiff nylon rotating brushes, which contact most parts of the carcass and are usually applied with a spray of cold water to remove loose hairs and other particles. They are particularly useful for reaching areas such as the head, forelegs, and hind legs, which may be unaffected by other dehairing devices. The white scraper is a machine that operates on the same principles as the black scraper. It consists of revolving stainless steel claws, which move up and down the carcass, and is applied dry to give the carcass a polished finish. The polisher consists of horizontal and vertical flails that rotate against the carcass to remove any remaining bristles. The rotating flails are often attached to two or more upright shafts, which typically run at different speeds. For example, the lower shafts may run at 55–60 rpm while the upper shaft rotates at 100 rpm. The whipping action of the flails removes loose hairs, and these machines are particularly effective for carcass cleaning.

Inadequately polished areas may be shaved or scraped by abattoir personnel using a shaver or knife. This includes the removal of eyebrows and hair on the lips and inner ear. If particularly cumbersome, these may be trimmed using a knife. All tools should be immersed in water at temperatures of at least 82 °C between animals to prevent cross-contamination.

Although effective singeing can result in almost complete removal of skin surface contamination, not all singeing is completely effective and bacterial contamination may remain on carcasses postsingeing particularly in skin folds, ears, and hair follicles. Polishing can therefore redistribute those few bacteria that survive the flame treatment across the surface of the carcass, negatively affecting the carcass microbial status.

A second singeing unit after polishing may be used to improve the hygiene status of pork carcasses.

Lean Meat Yield Estimation

Fully automated 3D ultrasound scanning equipment for estimation of lean meat yield of carcasses at a capacity of 1200 carcasses per hour may be installed after dehairing and before evisceration. Alternatively, other systems may be used post-evisceration and be used as a basis of carcass payment to producers. These include automated vision and image-processing systems for lean meat yield estimation. Manual reflectance or ultrasound probes for measurement of carcass fat and muscle depth at a single site are also used. Single-point fat and muscle depth measurements of pig carcasses are generally made over the longissimus muscle at approximately 65 mm from the midline of the carcass between either the third and fourth last thoracic ribs or at the last thoracic rib (referred to as the P2 site). This fat and muscle depth information may then be used in algorithms for the prediction of carcass lean meat yield.

Preevisceration Wash

The polished carcasses then pass through a cold water spray before entering the dressing procedure. This removes any loose hairs from the carcass but it is not a decontamination procedure. Washing may spread localized microorganisms on the skin to other areas of the carcass.

Evisceration

The first stage in evisceration is the removal of the scrotum, testicles, and penis. A cut is made between the hind legs downwards toward the penis and around the preputial pouch. This should expose the penis cord, which is removed along with the penis. Evisceration is then divided into bunging, midline and brisket opening, and viscera and pluck removal. Robots that automate the evisceration process are now available and have been installed in many countries to minimize contamination, improve yields, and optimize labor use. Automated evisceration, using a laser-guided aitchbone saw and belly opener, can reduce contamination and wastage, resulting from the accidental cutting of the stomach and contamination from spilled visceral contents.

Bunging

Bunging or cutting around the rectum and reproductive tract where it enters the pelvic cavity may be done using a knife or bung cutter (consisting of a rectal probe and a sharp rotating cylinder). Some rectal probes use a vacuum to remove fecal material from the rectum during this procedure. All the connective tissue to the bung is then severed, allowing the operator to pull the bung up and out. To prevent cross-contamination between carcasses, the cutting instrument must be immersed in hot water (82 °C or higher) between each carcass. Although the sphincter muscle should prevent leakage of fecal material onto the carcass, this is best prevented by tying off the bung with string or by using a plastic bag to seal the rectum. The operator puts the inverted plastic bag over their left arm (assuming they are right-handed), grasps the rectum with the covered hand and pulls the bag, inside out, over the rectum before sealing it with a plastic band or tying it with a piece of string.

Midline and Brisket Opening

Using a knife, a short incision is made in the inguinal region into the abdomen. The knife is then reversed and the abdomen is opened to the xiphoid cartilage. A cut is then made through the tissue over the sternum to the sticking wound using a brisket saw. Viscera are then lifted out and a cut is made through the esophagus. The pluck is lifted out separately, and this may be done by a separate operator depending on the chain speed.

Viscera and Pluck Removal

The viscera are comprised primarily of the stomach, the small intestine, and the large intestine. In pigs, the pluck set includes the larynx, trachea, lungs, esophagus, heart, liver, and spleen. The liver is released by severing the blood vessel near the top of the organ. The esophagus is cut to free the viscera. Operators must be well trained to ensure that during removal of the intestines the esophagus is cut at the correct distance from the stomach and that accidental cutting into the viscera is minimized. After the pluck set is removed, these organs are usually placed with the viscera on a stainless steel tray to allow for inspection or hung on a moving hook. Either way, the viscera remains linked to the carcass until the completion of inspection. The kidneys may be left in place. The removal of the viscera and pluck is increasingly being performed by robots in larger abattoirs, resulting in reduced levels of microbial contamination on the carcasses. In many countries, including the European Union, USA, Canada, and Australia, evisceration is considered to be a critical control point in HACCP systems. Problems associated with monitoring, critical limits, and corrective actions may be overcome by using an on-line monitoring system.

Fin Cutting

In many countries, long incisions are made exposing both sides of the spinal processes from the tail to the head and the loin is separated from the spine before carcass splitting in a process called fin cutting. This process has also been automated and systems have been commercially installed around the world.

Carcass Splitting

The carcass splitting saw is positioned along the midline between both legs. The carcass is split through the center of the

vertebral column along the midline from the hind to the fore. The glands and any blood clots in the neck and jowl regions may then be removed. The saw should be immersed in water at 82 °C or higher between each carcass to prevent cross-contamination.

Head Removal

Depending on customer requirements, the head may remain on the carcass until after chilling. However, high levels of microbial contamination are associated with the head, particularly tonsils and tongues. Early head removal, including excision of the tonsils and tongue, may be done immediately before evisceration. If not previously done, the eyelids and the inside portion of the ears will be removed immediately before head removal. The head is removed using a knife and trimmed of any residual hair. Head removal is best achieved by cutting directly above each ear before cutting into the seam outlining the jaw on both sides of the head. The atlas joint joining the head to the body may then be cut, followed by the esophagus and trachea. It is important that the esophagus is cut directly above the epiglottis to avoid cutting through the lymph nodes, which will be subsequently inspected. The head may be left attached to the carcass by the remaining skin and muscle or completely severed and washed.

Spinal Cord Removal

The spinal cord is removed using a knife or hook or by suction using a vacuum system.

Leaf Fat Removal and Exposure of the Kidneys

The leaf fat is a heavy layer of fat lining the inside surfaces of the porcine abdominal cavity. This is usually manually pulled away from the carcass to expose the kidneys.

Final Trim

Trimming is performed to remove any excess fat and any visible fecal stains. The knife should be immersed in water at 82 °C or higher to prevent cross-contamination.

Carcass Grading, Weighing, and Stamping

Pork carcass grading is generally based on carcass weight and a measurement of the fat and lean content of the carcass on the slaughter floor before chilling. In Australia, producer payments for pork carcasses are based on hot carcass weight and fat depth at the P2 site, located 65 mm from the midline of the carcass at the last rib. In Canada, the national grading system classifies pork carcasses into indexes based on measurement of fat and muscle depth 7 cm from the midline of the carcass between the third and fourth last thoracic ribs and carcass weight. Within the European Union, carcasses are divided into six classes and assigned a letter (S, E, U, R, O, or P), which indicates estimated lean meat content (S > 60%, E = 55–60%, U = 50–55%, R = 45–50%, O = 40–45%, and P < 40%). In the US, fat depth at the last rib may be measured and the expected yield of four cuts (ham, loin, picnic shoulder, and Boston butt) included in the carcass grading process. Information regarding grade, carcass weight, gambrel identification, and producer's tattoo number may be registered electronically and used in reporting back to producers. In Japan, fat thickness is measured at the narrowest point between the 9th and 13th thoracic vertebrae, carcass weight is obtained, and assessments of carcass appearance, meat, and fat color are then used by the grader to determine the grade of each carcass.

Final Wash

Carcasses are washed with cold (10–15 °C) or warm (15–40 °C) potable water to remove bone dust and blood clots. Washing with cold or warm water should not be considered a decontamination step during slaughter. Its effects are related solely to improving carcass appearance and not to food safety. This wash may also increase subsequent chilling rates (by evaporative cooling) and reduce the moisture loss of the carcasses. Cold water does not reduce the bacterial levels on pork carcasses.

Thermal Treatments

Hot water may be used as a sanitizing procedure to reduce the microbial load on the surface of pork carcasses. The main bactericidal effect of such systems is thermal, although there may also be a physical effect involving the removal of some bacteria as a result of washing. It can be applied either by spraying at high or low pressures, immersion of carcasses, or deluging carcasses with cascading sheets of hot water. In the EU, only the use of potable water is currently allowed in hot-water decontamination units. Recycling of hot water for carcass decontamination may be permitted (e.g., in Canada) to manage environmental considerations and water use and has been shown to be equally effective in reducing bacterial numbers compared with potable water. In Denmark, almost all carcasses from *Salmonella* level three herds and *Salmonella typhimurium* definitive type 104 herds are hot water treated. The FSIS in the US permits the use of specifically designed thermal interventions such as hot-water washing or steam pasteurization for the control of bacterial foodborne pathogens in pork. It may be more cost-effective for *Salmonella* prevalence to be reduced during processing by using thermal carcass decontamination systems rather than through on-farm control strategies, due to the considerable impact of this process on the *Salmonella* status of carcasses.

Steam pasteurization may be applied instead of hot-water washing and kills bacteria by opening pores in the skin. A process of applying pressurized steam to carcasses was approved for use in the USA (Frigoscandia Steam Pasteurization System). In this system, pressurized steam is applied to carcasses inside a chamber to achieve a surface temperature of at least 90 °C for at least 10 s followed by spray cooling of the carcass before chilling. Systems are also available for pork.

Steam treatment at the end of slaughter has been shown to effectively reduce the number of gram-negative bacteria (including *Salmonella*, *Yersinia*, *E. coli*, and *Campylobacter*) by 1.0–2.1 orders of magnitude. The automation of steam vacuuming of pork carcasses is being developed in Denmark. Other interventions, including the use of chemicals (e.g., lactic acid, acetic acid) may require prior approval by regulatory agencies before use.

Chilling

Chilling is the final slaughter-line operation. The duration for processing a pig carcass from stunning point to chiller is approximately 30–45 min in most modern abattoirs. Pork carcasses are usually kept in chillers for approximately 24 h before being sent to the boning room or transported to customers for carcass processing. The rate of chilling of muscles postslaughter is influenced by the size, shape, and fatness of the carcass as well as the chiller temperature, relative humidity, carcass spacing, velocity, and flow pattern of the chiller air. The chilling rate can influence pork quality as it influences the rate of muscle pH and temperature decline of muscles.

Although chilling conditions vary between plants, pork carcasses in Europe are usually chilled rapidly by blast chilling with air in the range of −10 to −30 °C at a fan speed of 0.5–2 ms^{-1} for approximately 2 h (which can result in freezing of the outer surface of the carcass) followed by chilling at 3–5 °C at 0.2–0.5 ms^{-1}. Relative humidity during chilling should be kept high (90–95%) to prevent excessive weight loss; however, relative humidity can be difficult to control. In North America, systems that spray carcasses with water during the first phase of cooling are also used. In other countries, including Australia, batch-chilling systems are used where carcasses are placed into chillers set at approximately 2–4 °C for approximately 24 h postslaughter. Rapid chilling can result in shrinkage losses of less than 1% of hot carcass weight due to a reduction in evaporative weight loss compared to 2–3% when carcasses are conventionally chilled. Chilling carcasses may prevent the proliferation of bacteria on warm carcass surfaces, but it does not always result in a decrease in total bacterial counts.

Glossary

Broiler stunning The process of using either electrical shock or exposure to controlled atmospheres, such as carbon dioxide, to render the broiler unconscious immediately prior to slaughter.

Carcass chilling The process of lowering the broiler carcass temperature to 4 °C within 1–2 h after slaughter. This is commonly done in a counterflow water immersion chiller that is 4 °C at the entrance and 1 °C at the exit.

Carcass prechilling A common practice after the evisceration and washing of broiler carcasses in which the broilers are exposed to temperatures of 7–12 °C in a water chiller for 10–15 min to lower the temperature with the purpose of moisture loss before the carcass is put in the chiller.

Evisceration The process of removing the viscera from the carcass. Viscera generally includes the gastrointestinal tract, reproductive tract, heart, and lungs.

Picking The process of removing feathers immediately after scalding in which flexible ribbed, rubber fingers rotate rapidly and use abrasion to remove feathers from the carcass.

Scalding The process of immersing broiler carcasses in hot water (commonly at 120 or 145 °F) for 30 s to 2 min to loosen feathers from the cuticles that they are attached prior to the picking process.

Poultry

Large-scale poultry processing plants are specifically designed to process poultry (chicken, turkey, and duck) at a rate that meets the growing consumer demand for poultry. The process not only needs to be efficient but also needs to be optimized at every step of the process to maximize yields and quality and insure product safety. The slaughter-line operation includes stunning, bleeding, defeathering, evisceration, inspection, chilling, and packaging operations. In commercial processing, bird uniformity is crucial for efficient processing so that the machines do not need adjustment during processing and lines can operate anywhere between 70 and 180 birds per minute. These production rates allow processors to minimize costs because the fixed costs of facilities and personnel must be paid irrespective of the efficiency of the processing line. The steps involved in a typical poultry plant are shown in Figure 1; modifications of this arrangement might exist, but the basic steps are fairly similar in all plants. The operation can be automated to varying degrees, depending on required output, capital investment, labor cost, etc. Some of the modern plants include automated evisceration, cut up lines, packaging, and labeling that can handle between 4000 and 12 000 birds per hour on a single line.

Receiving and Weighing

Birds are commonly transported to the processing plant either in individual crates stacked on a truck or in cages permanently mounted on a truck. Trucks typically arrive every 10–15 min, so there is more than one truck in the holding area at all times to minimize plant delays and allow the birds to rest for a minimum of 30 min before unloading. This rest results in lower corticosterone levels in the birds, indicating a recovery from any distress of prior handling and transportation. The weight of the birds received, on the truck, is determined and is used as the basis for calculating the payment to the farmer.

Unloading

Unloading the birds from the crates and placing them on the shackle line so that they are hung by their legs can be done manually, which is a common practice for turkeys. Automated unloading systems, also called dumpers, are usually part of a modular crate system, which can be lifted and tilted slowly so that the birds can pass onto a conveyor belt. As carcass damage, such as broken bones and bruising, can result from unloading, proper training is necessary and the distance between the dumper and the conveyer belt should be minimized to prevent such damage. In plants where gas stunning or low atmospheric pressure stunning (LAPS) is employed, the birds can be left in the crates, where they are stunned by carbon dioxide, argon gas, a mixture of gases, or low atmospheric pressure and later removed from the crates (this can assist in reducing bruising of excited birds taken out of a cage); unloading should then be done immediately after stunning so that no time is allowed for the birds to regain consciousness. Excited birds are more active; they flap their wings and are more likely to be hurt during the unloading process.

Stunning

Electrical stunning (ES), controlled atmosphere stunning (CAS), and LAPS are all effective at insuring that broilers are

desensitized before slaughter. Stunning should produce a rapid onset of stress-free insensibility of sufficient duration to allow the animal to remain unconscious until the time of death. ES is the most common method used for poultry; the equipment is relatively inexpensive, simple to use (a fiberglass brine/water bath fitted under the overhead shackle line from which the suspended birds are moved forward), does not require much space, and is compatible with current kill-line speeds. The birds pass through the stunner in a continuous procession (e.g., 140–180 birds per min in a modern processing line).

To insure an irreversible stun, high amperage current (120–150 mA per bird) is utilized in the European Union (EU) so that the birds are stunned to death. No clear relationship exists between stunning amperage and whole-carcass quality attributes, but high stunning amperages have been associated with hemorrhaging in deep breast muscles. Hemorrhaging is due to a sharp increase in intravascular pressure, as a result of which blood capillaries may rupture and cause bleeding. Low-voltage ES is used in the US and is an effective method for immobilizing broilers. Low-voltage (10–25 V) and high-frequency (500 Hz) systems are used in 77% of the US poultry plants. Low-voltage ES can decrease the incidence of carcass quality damage and hemorrhaging that is associated with high-voltage ES. However, a bird will regain consciousness if not bled within approximately 2 min of stunning. In 2004, the European Food Safety Authority published a regulation with minimum currents to be used for ES (Figure 2). This requirement was published with the statement: "Since welfare is poor when the shackling line and water bath electrical stunning method is used, and birds are occasionally not stunned before slaughter, the method should be replaced as soon as possible. At present, the inert gas stun/killing method is the best alternative." This regulation went into effect in 2013.

CAS involves controlled changes in the atmosphere surrounding broilers such that broilers lose consciousness due to lack of oxygen (hypoxia); excess CO_2 (hypercapnic hypoxia); a combination of these two methods (hypercapnic anoxia); use of oxygen with inert gases, such as nitrogen or argon (hypercapnic hyper oxygenation); or atmospheric depressurization. The stunning gas or gas mixture should not be aversive to the broilers, and the induction of unconsciousness should be rapid. Several researchers have indicated that there are advantages to stunning with gases. One particular advantage includes the acceleration of rigor mortis. Stunning and bleeding by gas is effective at improving carcass quality by reducing bloodspots, especially those on the thighs and breasts, when compared with ES (EU electrocution).

Inhalation of elevated concentrations of the inert gases (argon and nitrogen) causes hypoxia, which eventually leads to anoxia (complete absence of oxygen). The commonly used gases are nitrogen and argon with or without CO_2 for broilers and nitrogen with CO_2 for turkeys, which results in anoxic loss of sensibility. In commercial situations, gas stunning minimizes the handling of birds (uncrating/shackling) before stunning, thereby reducing preharvest stress. However, gas stunning can also lead to some distress in birds as exhibited by wing flapping, gasping, and head shakes.

LAPS or atmospheric depressurization reduces atmospheric partial pressure of oxygen by evacuating air from an airtight chamber. Broilers are placed in an airtight decompression chamber and pressures of 0.20–0.29 atm have previously been utilized to stun the broilers. LAPS has been in the development and implementation stages in commercial broiler abattoirs since 2005. This technology controls the atmosphere through anoxia by using a vacuum pump to reduce oxygen tension in the atmosphere. Most tissues of the body can survive without oxygen for several minutes and some for as long as 30 min, during which the cells obtain energy through anaerobic metabolism. The brain is minimally capable of anaerobic metabolism because neurons have only a

minimal reserve of glycogen. Thus, a sudden cessation of blood flow to the brain or a sudden drastic decrease in oxygen in the blood will result in unconsciousness in 5–10 s. As of 2013, a few broiler plants in the US have adopted LAPS as their method of stunning.

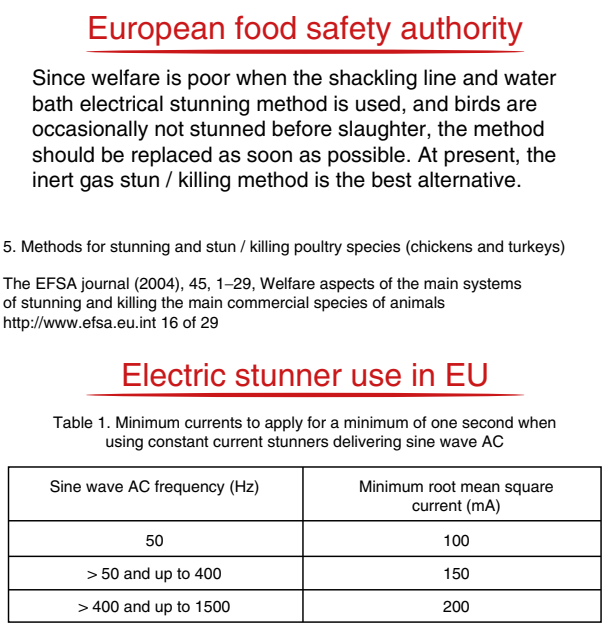
Bleeding

The most common method of bleeding is to cut both carotids just below the jowls to insure fast and efficient bleedout. This method also results in leaving the windpipe and esophagus intact, which is important when automated equipment is later used to pull out the windpipe. When this method is conducted, a cutting machine is used that guides the head so that a circular blade cuts the jugular vein and carotid arteries. Automated high-speed bleeding equipment employs a railing system that positions the neck of the suspended birds in such a way that precise cutting of the blood vessels can be performed. For true kosher slaughter, birds are not stunned and only manual cutting of the blood vessels is permitted. For Halal slaughter, it is dependent on the certifying body on whether or not birds may be stunned before the slaughter process. The bleedout phase takes anywhere between 2 and 5 min, depending on bird size, etc. During the process, approximately 35–50% of the total blood is lost. Other factors affecting blood loss include the stunning method used and the time interval between stunning and bleeding. It is important to note that a poor bleedout can increase the prevalence of carcass downgrading conditions due to bloodspots and, in particular, engorged or hemorrhagic wing veins, which leads to red wing tips and decreased shelf life.

Scalding

In commercial abattoirs, scalding is done in a continuous manner whereby the birds are dipped in a single or multistage scalding bath while suspended from a moving shackle line. There are three commonly employed scalding schemes (Table 1): selection of one over another depends on the degree of difficulty in removing the feathers, the chilling method that is to follow (water and air), and the age of the birds. Soft scalding (50–55 °C) is commonly used for broilers and turkeys. The temperature needs to be closely monitored because a temperature that is less than 50 °C can lead to bacterial contamination or inefficient feather removal. Higher scalding temperatures (60–64 °C) not only are better for loosening feathers from their follicles but are also harshest on the skin (the outer layer of the skin, epidermis, becomes loose and is later removed during the plucking operation). The removal of the epidermis can result in discoloration of the skin if it is dehydrated during subsequent air chilling. In addition, hard scalding can cook the breast meat where the skin is very thin and leads to stripes on the breast meat that has been referred to as tiger striping. However, hard scalding is the only satisfactory way to release the feathers of waterfowl. Generally speaking, hard scalding does not cause as much discoloration in the thick skin of waterfowl as it does in young poultry.

Soft scalding is commonly used for young broilers and turkeys because it does not damage much of the epidermis and allows relatively easy feather removal. Adequate agitation of the scald water and uniform temperature are essential to insure good feather removal. Careful equipment design is required for meat hygiene. Maintaining and controlling the temperature is one of the key features to keep the bacterial load under control. Another means is the use of a counterflow design (clean water introduced at the exit end of the tank, and water flow toward the entrance where the more contaminated birds are introduced). Installing a multistage scalding tank system can further reduce contamination problems; this consists of two to four



European food safety authority

Since welfare is poor when the shackling line and water bath electrical stunning method is used, and birds are occasionally not stunned before slaughter, the method should be replaced as soon as possible. At present, the inert gas stun / killing method is the best alternative.

water tanks, where the carcasses are moved from the initial, more contaminated bath, to the cleanest bath at the end.

Feather Removal

In large processing plants, feather removal is done by mechanical pickers/pluckers equipped with rubber fingers that rub the feathers off the carcass. In a continuous operation, this is done while the carcass is hanging upside down on the shackle line between two and three sets of rotating disks equipped with rubber fingers (Figure 3). The fingers are made out of rubber and contain a certain degree of lubricating agent that controls their hardness and elasticity. The elasticity and length of fingers varies, depending on the task required, the machine speed, etc. The fingers can also be mounted on drums that rotate toward the center. The distance between the two sides is adjusted to accommodate size variations.

Electrical Stimulation

Many commercial plants have adopted electrical stimulation after either the bleeding or the picking steps. Either high- or low-voltage electrical stimulation can be used to speed up rigor mortis so that breast meat can be deboned more quickly than the 4 h postmortem standard deboning time in the industry. Although deboning time can often be decreased, it is still necessary to wait until rigor mortis is complete to insure that the breast meat is tender. Breast meat deboning times for electrically stimulated carcasses are highly variable (30 min–6 h) and depend on the bird size, parameters of the electrical stimulation unit, and many additional factors, such as customer, product application, and company standards.

Feet Removal

During feet removal, the knee joint is positioned by guiding bars on an angle along the shackle line, and the feet are cut off by a circular rotating blade at the hock joint. Cutting through the bone can result in dark/red color in the chilled bird and almost black in the cooked product. Some of the new automated leg cutters first bend the leg and then perform a small incision, which allows further bending before cutting through the joint with a rotating circular blade. Feet are separated into two quality classifications that consist of those with defects including footpad lesions and those with dark color.

Rehanging

After removal of the legs, the carcasses are usually transferred to another line because the broilers need to be hung by the knee joints, and this reduces contamination because the dirty shackles that are used for the live birds are replaced. Broilers are generally hung by their hocks so that they are 6–8 in. apart on shackle lines. An automated rehanging device can consist of a large wheel (carrier) with slots for holding the birds from underneath the knee joints and a device to push them into the evisceration line. The advantages of using automated rehanging equipment include labor savings and better hygiene.

Evisceration

This process refers to opening the body cavity and withdrawing the viscera (the intestines, gizzard, gallbladder, and crop). In semiautomated or fully automated evisceration processes, the first step is to cut around the cloaca, using a circular rotating blade. Some of the new devices are equipped with a vacuum device so that potential fecal contamination is reduced, and the cutting device is usually rinsed after each insertion. The viscera are then scooped out from the body cavity and remain attached to the body for inspection purposes. Some of the new automated equipment allows total viscera separation immediately after withdrawal and placement on a parallel line. This can further improve the hygiene of eviscerated carcasses. Once the viscera pack is exposed or removed, the birds are inspected.

Inspection

Inspection is done at this point because the inspector can see all parts at the same time. The attached or detached viscera can reveal diseases or problems within the internal organs. Inspection requirements differ among countries, but inspection is usually carried out by a government official. This process is essential in insuring that only wholesome birds, free of

disease, reach the market place. In some countries, it is required that each individual bird be inspected by a qualified veterinarian; in other countries, inspection is done on a whole-flock basis and only certain carcasses are inspected by a trained inspector. The suspected birds receive a more thorough inspection and all or parts can be salvaged. In large-scale plants, the viscera are pulled out of the bird using a pack puller that places a clamping device into the abdominal cavity to pull the viscera and esophagus out of the abdominal cavity. Multiple inspectors (two to four) are often on the line to make sure that every carcass is inspected.

Giblet Salvage

The viscera are removed after inspection and giblets (the liver, heart, and gizzard) are salvaged and washed on a separate line. The gizzard (stomach used to grind the food, as birds have no teeth) is first cut open, the contents are removed, and the lining is peeled off. Mechanical equipment used for peeling consists of two rollers that 'catch' the lining and pull it away; this is followed by washing and chilling. The hearts and livers are collected, inspected, washed, and chilled. The chilled giblets can then be collected and sold separately to reduce the risk of *Salmonella* and *Campylobacter* cross contamination.

Lung, Head, and Crop Removal

The crop is removed by placing a spinning probe with barbs through the abdominal opening to push the crop through the opening where the head used to be. The probe is then cleaned and the crop is removed before retracting through the carcass. The lungs can be removed through the use of a vacuum gun that is inserted into the thoracic cavity and suctions the lungs from the dorsal surface of the rib cage. A neck breaker and neck puller is then used to cut the neck at the weakest point between the atlas and the axis vertebrae and separate it from the carcass. The neck is often included as part of the giblets, with the heart, gizzard, and liver.

Inside/Outside Bird Wash

Before entering the chiller, carcasses are washed to remove any material that is present inside and outside of the carcasses. The device usually consists of multiple spray nozzles positioned to cover critical areas in removing debris or blood clots both inside and outside of carcasses. Tilting the carcasses can assist in thorough draining of the water through both the abdominal opening (created during evisceration) and neck opening (formed after pulling the windpipe and the crop). Some designs have spray heads positioned along the moving shackle line, washing first the upper part of the carcasses and subsequently the lower part. Bactericidal rinses, such as chlorine and organic acids, can be used. Chlorine is one of the most commonly used chemicals (where permitted) and is typically used at up to 50 ppm in the rinse. Citric, lactic, and acetic acids have all been used at concentrations of 1.0% or less. Propionic acid, peroxyacetic acid (PAA), chlorine dioxide, and cetylpyridinium chloride (CPC) can also be used in spray washes, as dips or in the chiller to inhibit microbial growth. The washing operation is critical in reducing the number of microorganisms on the carcass and decreasing the incidence of pathogenic bacteria, specifically *Salmonella* and *Campylobacter*.

Chilling

After the washing step, which occurs approximately 15 min after bleeding, the meat is placed in a chiller. The most common methods include water-immersion chilling, air chilling, and spray chilling. For immersion chilling, the carcasses are dumped into a trough-like structure, which usually contains either a large-diameter auger or paddles that move the birds forward (Figure 4). The most common design used today is the counterflow design, in which the product moves counter to the flow of the cold, clean water. This is a more efficient way of cooling the carcasses (the coldest temperature is at the end of the tank), which also assists in improving the hygienic conditions. The microbial quality of birds coming out of a water chiller is often better than before chilling because the water helps to wash off bacteria.

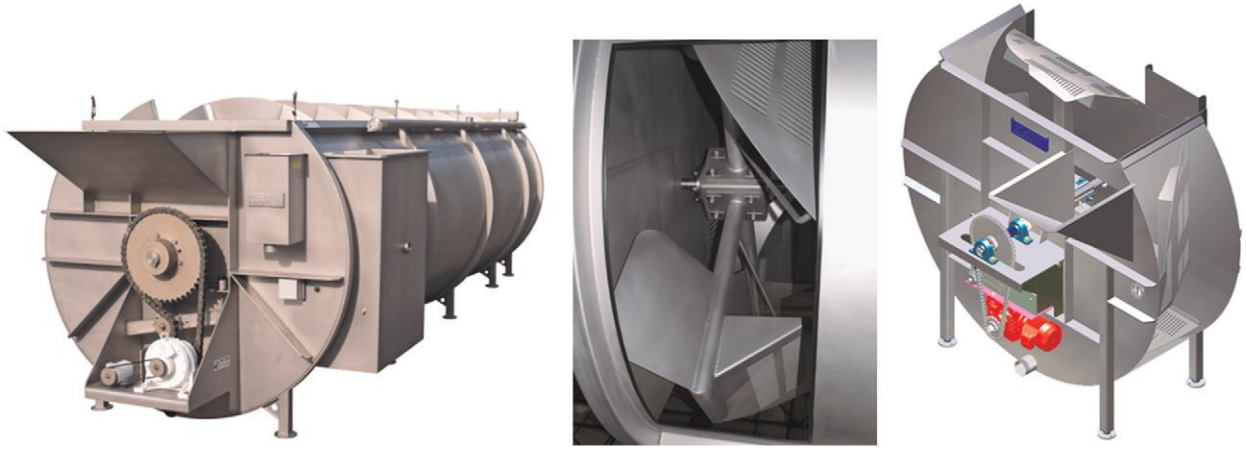

Figure 4 Auger carcass chiller (Left); side view of auger carcass chiller (Center); cross-sectional top view of auger carcass chiller.

A prechiller (7–12 °C) is commonly used in a water-immersion chiller for 10–15 min so that the carcasses have a gradual temperature transition. This is important because the lipids in the skin are liquid when the carcass enters the prechiller. The carcass temperature is generally approximately 30 °C after prechilling, when it enters the main chiller that has a water temperature of approximately 4 °C at the entrance and 1 °C at the exit. This counterflow design is designed to lower carcass temperature to 4 °C within approximately 2 h as well as maximize the heat transfer in the chiller. One problem that can occur in the chiller is thermal layering at the product surface that prevents carcass cooling. Injecting air or using water jets to pump water into chillers at high velocity prevents thermal layering. Chlorine, citric acid, lactic acid, acetic acid, propionic acid, PAA, chlorine dioxide, and CPC all either have been used or have potential for use in chiller systems through either direct addition or use in the pump water. Antimicrobials used in pump water are able to improve contact between the carcasses and the antimicrobials. In addition, a finishing chiller is used, where the carcasses receive a final rinse and antimicrobials to reduce the incidence of *Campylobacter* and *Salmonella*.

Air chillers are commonly used in Europe and are starting to appear in North America and elsewhere. Cold air is used as chilling medium, so care should be taken not to dry the product surface and lose weight. This can be achieved by raising the air humidity or wetting the product at some point (s) along the line; this can reduce weight losses to approximately 1%. A typical setup includes an overhead rail that goes back and forth along a chilling tunnel or room. Depending on the tunnel capacity and the volume of product, chilling can be achieved within 60–150 min. Air chilling generally takes longer than water-immersion chilling because it is less efficient at heat exchange. The air-chilled carcasses are generally exposed to colder temperatures at the beginning of the chiller (−6 to −8 °C) and approximately 1 °C at the end of the chiller. Spray chilling is a hybrid between water and air chilling. Cold water is constantly sprayed over the carcasses while they are moved along the line. Moisture pickup is less during water chilling but higher during air chilling.

Grading, Weighing, and Packaging

Grading is usually not mandatory, but it is done in most large markets to facilitate sales. The grade is based on the relative muscling, bone conformation, presence/absence of tears/bruises/pinfeathers, and missing parts. Each country has its own specifications, but a bird (chicken, turkey, and duck) with adequate muscle deposition and no esthetic defects will generally be classified as Grade A; minor defects will result in Grade B; and more serious defects will result in Grade C. The last two categories will usually not be sold as whole birds but rather as parts (no grade labeling required) or as further-processed products. Grading can be done by a qualified person or with the assistance of a computerized machine-vision system. The final overall grade can be affected by different processing parameters (e.g., stunning and chilling) as well as feeding, growing, and transporting parameters described in other articles.

Weighing of the ready-to-sell birds is usually done by automated weighing equipment connected to a computer network. Alternately, birds/parts can be packaged in bulk and sold to consumers interested in buying only certain parts (wings/drum sticks) or institutions/fast food restaurants interested in large quantities, depending on market demands.

Glossary

Bleeding/exsanguinations The procedure where the carotid arteries, jugular veins, and esophagus are severed – sometimes a knife is inserted to the heart, cutting additional vessels.
Cardiac arrest Cessation of normal circulation. In this case, the passage of an electrical current through the heart causes fibrillation.
Electrical stimulation Application of an electric current through a carcass postmortem that accelerates rigor mortis and enhances tenderization.
Electrical stunning The procedure where a current is passed through the head of the animal, causing a seizure that ensures that the animal is insensible. If only the head is in the electrical pathway, the heart continues to beat and the animal can recover (head-only electrical stunning). If the body of the animal is in the pathway, the heart stops (cardiac arrest) and the animal cannot recover (head-to-body stunning).
Evisceration Removal of the components of the body cavity, such as the heart, lungs, rumen, and the intestines.
GR Thickness of the fat based on measurement of total tissue depth over the 12th rib at a point 11 cm from the midline.
Halal slaughter A slaughter procedure that adheres to Islamic teachings where the animal is dispatched by severing the blood vessels of the neck while the animal is facing Mecca. The knife cut can be preceded by a head-only electrical stun, provided it does not kill the animal and the animal is able to recover if not slaughtered.
Harvest The whole process of production and processing animals.
Inverted dressing A system where the carcass is suspended by the front legs in contrast to systems where the carcass is suspended by the hind legs.
Pelt removal Removing the skin/hide from the carcass – also called depelting.
Slaughter The process of bleeding/exsanguination where the carotid arteries, jugular veins, and esophagus are severed – sometimes a knife is inserted to the heart, cutting additional vessels. The blood loss ensures that the animal cannot recover sensibility.
Stunning The procedure where an animal is rendered insensible before exsanguination, pelt removal, and evisceration.

Introduction

There were approximately 861 million goats and 1078 million sheep in the world in 2008 with most (805 million goats and 739 million sheep) being in Asia and Africa and, additionally, 247 million sheep and 19 million goats in Europe and Oceania, the remainder being mainly in North and Central America and the Caribbean. This means that traditional non-mechanized methods of harvest predominate over mechanized systems. For sheep and goats, the small size means that they have been harvested and eaten by societies ranging from nomadic tribesmen to most western cultures for thousands of years. Not only do they provide meat but also hides and wool (sheep) are important by-products. The small size of sheep and goats are clearly advantageous, when they are slaughtered by individuals away from plants on farms or the steppes of Eurasia, but in commercial processes, the labor and mechanization required per carcass is disproportionately high compared with larger cattle and pigs. The labor required to produce a given weight of dressed carcass is generally less when the carcasses are large. Sheep are relatively small and traditional dressing methods with low levels of mechanization require approximately 80 man-hours per 10 000 kg of carcass. Beef and poultry in contrast require only approximately 22 man-hours to produce the same weight, due to the large carcasses of the former and highly mechanized processing procedures for the latter. Procedures for sheep, the main species in commercial abattoirs, have changed rapidly and procedures for goats are adapted from those used for sheep. The main differences between sheep and goat harvest methods relate to the need to recover wool in sheep – the leanness and the generally lighter weight of goats mean that with rapid chilling, cold shortening and toughening are more likely to occur unless electrical stimulation is used. This article covers the mechanized processes that dominate in Oceania, North and South America, and Europe.

Over the past 20 years, because of the large numbers exported, the New Zealand meat industry in particular has invested heavily in developing slaughter and dressing technology for sheep and lambs to reduce labor costs, to maintain stringent hygiene, and to improve the quality of the pelt and meat quality through all aspects of processing, including boning, cutting, packaging, and retail distribution. The industry in this country is one of the leaders in the field, and the situation is reflected in many other countries with minor changes in details.

Traditional slaughter methods involve a severing of the throat, effectively cutting the carotid arteries, jugular veins, trachea, esophagus (weasand), and various nerves. The animals are usually hung up by their hind legs and then allowed to go through postmortem movements and to bleed out over a period of 5 min or more before depelting and viscera removal.

Such slaughter procedures without stunning have been shown to be humane for sheep, where unconsciousness will occur 6–10 s post the knife cut. In many parts of the world where sheep are slaughtered in this manner, the procedures are also in line with those required for halal and kosher slaughter. A throat cut has been the main sheep and goat slaughter method throughout human history.

When commercial processing operations with high throughputs are required, the sheep need to be transported to the facilities and lairaged before slaughter. Such procedures potentially involve varying degrees of preslaughter stress and consequent meat quality deterioration, so handling procedures to reduce stress should be implemented (including familiarization of animals to some stressors). In most countries of the world, sheep dressing takes place with dry wool surfaces, and the potential risk of contamination by dust, dirt, and fecal contamination does not appear to be a problem. In New Zealand, sheep have been vigorously washed by swimming through a race or have high-velocity water jets spraying the animals to remove visible dirt and feces, but it is unclear whether bacterial loads are reduced overall, because the moist conditions on the warm skin surface during drying would encourage bacterial growth. The stresses imposed can affect meat quality, and the process is being phased out. Goats do not need to be washed.

Stunning

In commercial operations, preslaughter stunning is generally used, and the most common commercial method is electrical stunning. This is achieved by placing tongs spanning the head and passing an electrical current through the brain. With goats some care is needed in placing the electrodes behind the horns. This type of stun, termed a 'head-only' stun, does not stop the heart and the animal can potentially recover. As the slaughterman cuts the throat before the animal recovers, they are effectively taking the life of the animal and this procedure is, therefore, consistent with halal slaughter. Other stunning and slaughter procedures use a modification of the tong system with a pistol grip-like handpiece, which sometimes may be used for head-to-back (or body) stun and cause cardiac arrest (Figure 1). Cardiac arrest arises when a current passes through the heart but because the spinal cord is in the pathway, it additionally reduces the animal's reflexes with significant movement reduction, making it a good option when halal slaughter is not required.

Ideally, the animals are presented to the stunner in a V-restrainer (Figure 1). Additional advantages of the V-restrainer are that it allows precise location of the head of the animal and therefore facilitates automation of application of stunning. Such automated procedures not only reduce costs but also improve worker safety. One system has a series of grids that contact each side of the head. Nozzle electrodes, arranged throughout each grid, then apply an electrical current to the head, concurrently with water to facilitate current flow.

Figure 1 A slaughterman applying a head-to-back stun to a sheep in a restraining conveyor. Inset: A stun gun showing the pointed front electrodes that are applied to the head and the flat rear electrode through which water is also applied to the wool to lower electrical resistance.

Most countries require preslaughter stunning before slaughter. Head-only electrical stunning is consistent with halal, but it is not acceptable for kosher slaughter.

Bleeding

Once the animals are stunned, the throat is cut, and bleeding takes place either by a traditional gash cut as mentioned above or by a thoracic stick that severs the atria and vessels leading to the heart. In some plants, the animals are suspended by hooks on the rail system before they are bled (Figure 2). The blood leaving the carcass is not affected by the stunning procedures. If the heart is still beating, the animal initially bleeds by blood being pumped via the heart from the carotid arteries. At the same time, blood drains into the heart from the jugular–vena cava system. As the heart refills from the venous system draining into it, the amount of blood being lost by cardiac action reduces when the heart cannot fill due to the cut vessels. Eventually, a stage is reached when all the remaining blood must drain by passive means from the severed vessels. With electrical stunning, and in particular head-to-body stunning, there are other types of sticking, for example, a thoracic stick draining blood rapidly via the venous system so that this becomes the main mechanism of bleeding rather than via the carotid artery. It is important to note that from the moment the atrium/vena cava or heart is pierced, bleeding takes place passively (helped by gravity) – this is true for animals shot in the head with a captive bolt as well as electrically stunned animals. Cardiac arrest, therefore, has little or no effect on overall blood loss (providing vessels are severed before clotting occurs). To prevent contamination by ingesta, the weasand (throat or esophagus) is tied or clipped.

Support of the hind legs facilitates good bleeding. However, with increased efficiency on the dressing line, time delays

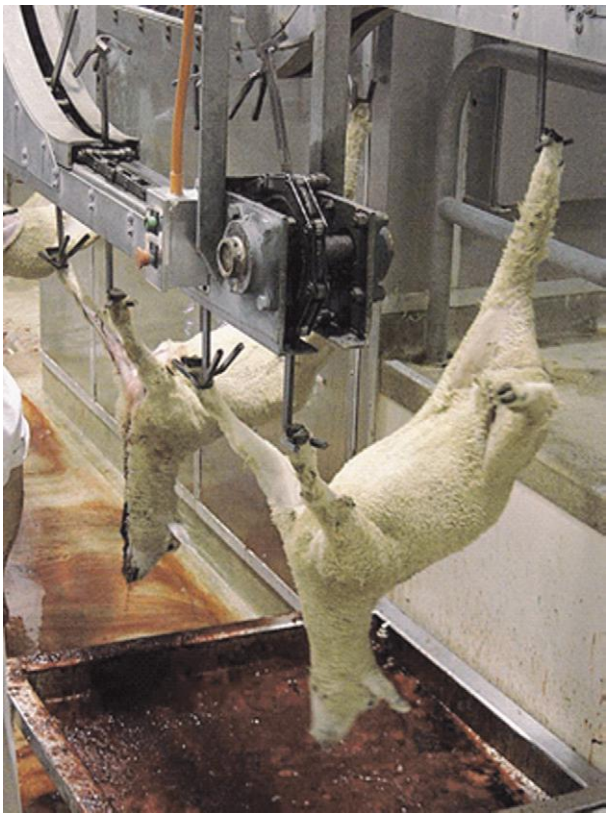

Figure 2 Two sheep carcasses on a processing line. One rear leg is tightly held and the front legs are on a spreader. The nearest animal has just been stunned and not yet bled. The second has just finished bleeding, and knife workup on the neck and fore legs has just commenced. This allows the commencement of head workup and separation of the skin from the brisket area and precedes pelt removal.

are not desired and some procedures are telescoped. For example, carcasses are suspended by both the two rear legs and front legs soon after slaughter commences. This can result in blood pooling in the thoracic area before it bleeds out, if the thorax is lower than fore and hind legs (the correct angle is shown in Figure 2). Clotting occurs because blood that remains in the large vessels, such as the jugular and the vena cava, retains all clotting factors – it, therefore, needs to be rapidly removed. An interesting situation occurs in small vessels (such as those supplying and draining the pelt) where blood leaks out from cut surfaces. This occurs because the biochemical factors that facilitate clotting rapidly diffuse away through the thin vessel walls, so clotting is reduced.

Sometimes there are cosmetic deficiencies with poor bleeding. One type, termed blood splash, results when blood from vessels, torn through muscle spasms (usually, but not always, from an electrical stun), are retained in the muscle. Another cosmetic deficiency, termed speckle bruising, appears as myriads of small red spots lying in the fat over the loin to give a 'salt and pepper effect,' which may coalesce in extreme cases producing a fiery red effect. The defect is particularly visible in sheep, but it can be found in goats, cattle, pigs, and even deer – it is only when it is severe that it is a problem. This defect, essentially the beginning of a bruise, is generally caused by a violent movement just before or during slaughter, for example, a head-to-back electrical stun where there is effectively a shearing action between the fat and muscle fascia initiated by muscle contraction.

Pelt Removal

Traditionally, sheep were depelted while hanging from their hind legs, and this provided the basis for early mechanized systems with various gambrels or hooks placed through the Achilles tendon. By careful knife work, the areas around the rump are cleared, then the legs and the thorax are cleared, and finally the pelt is pulled over the body and head. At all stages, it is desirable to keep the carcass clean; paper is often placed at judicious places to prevent the pelt rolling inward and contaminating the carcass – this is more important for sheep than goats. In the late 1970s, the benefit of depelting the sheep and goats from the shoulder to the hind leg was recognized, and this process was most easily achieved by suspending the animal by front legs. This process, known as the 'inverted' system, formed the basis of many subsequent developments to date with considerable manpower reductions over previous systems. Because the hind legs are at the lowest point, it has the added benefit of reducing fecal contamination and maximizing the return from every part of the carcass, including offal. One of its major attributes is its simplicity and ease of installation as many of the tasks and skills used in the inverted system were used in previous systems.

The inverted manual system requires a mechanical puller to remove the pelt from the rear and then over the front legs. Many variations have been tried in New Zealand and at present at least 10 different designs are being used in meat plants for both sheep and goats. Most of the designs can process at least eight carcasses per min. In one system, the pelt is manually removed around the brisket, cleared from the back area, and the hanging pelt is placed between prongs of the puller shown in Figure 3. The prongs rotate (Figure 4) and trap the pelt, and then the device moves down the carcass, removing the pelt.

Automatic front and rear hock removal machines have also been produced, and machines to assist the transfer of the fore legs from the wide spreader to the narrow hock holder have been developed. Potential contamination from the front trotters onto the carcass is eliminated during the major part of the pelting operation.

Evisceration

After depelting, evisceration and offal handling, such as removal of the intestines, liver, lungs, and heart, are the next biggest users of manpower. Several developments have been undertaken to partly mechanize this area. Brisket cutting and belly opening was the first area studied. A machine not only cuts the brisket but also opens up the belly area. Further developments facilitate viscera removal.

Head Processing

The focus of developments in head skinning and brain and tongue removal has changed, as the European Union (EU)

Figure 3 The four prongs are part of a system to remove the pelt from a sheep carcass. The pelt is freed from much of the carcass, and a hanging portion is placed between the prongs, which can rotate.

Figure 4 The rotating prongs grip the pelt and pull it down over the rear legs in this inverted dressing system.

regulations regarding head inspection required that a totally skinned head had to be presented with the carcass for carcass inspection. A number of head-skinning machines were developed. In one type, a small shaft gripped a flap of skin near the nose and removed the remainder of the skin by a rolling action. The regulation requiring heads to be presented with the carcass was partially relaxed in 1987, so that only those heads from which edible brains and tongues were to be used for human consumption needed to be inspected. Edible brains can still be obtained from sheep in countries without bovine spongiform encephalopathy or scrapie. Small incremental developments include automatic atlas joint severing, automatic head splitting, and automatic brain extraction.

Mechanization

Traditionally, mechanization has focused on direct task replacement. Inverted dressing offered significant advantages in this respect and has generated significant benefits over the past 20 years. With reducing numbers and increased focus on adding value through further processing, the current focus has moved toward more advanced automation and robotics. With the incremental development of mechanized devices, the output from a mechanized sheep dressing system, processing 8 lambs per min, requires 25 butchers plus 11 assistants, the actual labor requirements highly depending on throughput, in contrast with the older systems that needed 44 plus 15 assistants. The recently developed robotic brisket cutting and evisceration robots, combined with a new evisceration inspection protocol, have the potential to remove five evisceration inspection and sorting labor units on a typical eight lambs per min chain. The best-mechanized system is likely to produce carcasses and pelts of a quality equal to or better than any economically viable manual system of a similar throughput. The cost benefit of mechanization has to consider processing quality. Poor hide pulling that impacted on fat over the ribs would have zero impact on value because the fat cap is removed when cutting into French racks; however, an evisceration robot that damaged 1% of runners could be significant.

Modern pelt-pulling equipment senses the force required in removing the pelt. Additional labor units are often deployed to do the necessary workup to ensure product quality as these extra labor units are often doing other part tasks as well; therefore, the combination of mechanization and labor deployment must stack up financially. However, the alternative of a fully manual operation is not viable these days due to throughput requirements and health and safety issues.

Sheep and Lamb Carcass Grading

There is no international carcass grading system for sheep, lambs, and goats, but some generalizations can be made, and

in particular, sex and age are important. Mutton is a female (ewe) or an adult noncastrated male (ram) or a castrated male (wether) with more than two permanent incisors in wear. A hogget is a young male sheep or a maiden ewe having no more than two permanent incisors in wear. Lambs are young sheep less than 12 months of age and without any permanent incisors in wear. New Zealand, Australia, and the EU account for almost 90% of lamb exports, but each country is serving specific markets and therefore the systems are not the same. The greatest sheep meat production is in China, followed by the EU, Australia, New Zealand, and the Middle Eastern countries (where goats are processed as well), all with different grading systems. Links to the various systems can be obtained from web links cited in further reading. VIASCAN systems (video analysis) based on carcass conformation are now being used.

In many systems, grading is based on the overall size and conformation and the fat cover. In New Zealand, the thickness of the fat based on measurement of total tissue depth over the 12th rib at a point 11 cm from the midline, called GR, is used (the fat cover on the longissimus muscle is not such a useful guide as in pigs). The export grades are based on three grades of leanness (A = devoid of external fat, Y = low fat, and P = medium fat). Excessive fat is trimmed and gives rise to another series of grades. There are then, superimposed on this, four weight grades (L = 9–12.5 kg, M = 13–16 kg, X = 16.5–20 kg, and H = 20.5 kg and more). Australia follows a similar, but not identical, system.

Electrical Stimulation, Chilling, and Freezing

Once the pelt and the viscera have been removed from the carcasses, they can be graded and weighed, and they move down the chain to an area where they may be electrically stimulated. There can be either a low- or a mid-voltage system applied early postmortem (Figure 5) or a high-voltage system at the end of processing (Figure 6).

It is ideal for meat to reach temperatures approximately 15 °C at rigor mortis (>12-h postmortem without stimulation) to avoid cold shortening and ensure optimum aging. Compared with beef, the small carcass size of sheep and goats means that excessive rates of chilling or freezing can easily occur with the risk of cold shortening and toughening when temperatures are significantly lower than this. As electrical simulation considerably reduces the time to rigor mortis (3–5-h postmortem, depending on type of stimulation), cold shortening is unlikely to occur. In New Zealand, the accelerated conditioning and aging (AC&A) process was developed and resulted in sheep with a known tenderness specification. The AC&A process consists of high-voltage electrical stimulation using 1130 V peak, 2 A peak, 15.5 sine wave pulses per s for 90 s, which passes from the middle of the back through the legs of many carcasses as they move slowly along the electrode system (Figure 6). Alternative systems utilize a low-voltage system current (80 V peak, 120–300 mA peak, 15 pulses per second) before depelting or a mid-voltage system after depelting (300 V peak 5 ms duration square wave pulses at 15 pulses per s). Chilling or freezing processes together with prior procedures, such as electrical stimulation, have an interdependent effect on optimal processing and on product quality, so a single set of process cannot be put in place.

Figure 5 A low-voltage stimulation unit for sheep that can be used in processing plants with a small throughput. The current (80 V peak, 120–300 mA peak, 15 pulses per s) passes from the front legs to the earthed rail. The duration of stimulation ranges from 30 to 60 s. In this system, the stimulation is applied at the end of dressing but earlier stimulation at the end of stunning may be used and this has the advantage that carcass movement poststun is reduced. Three sheep are connected at a time in this system. The carcasses with the current flowing have the front legs outstretched.

In a typical procedure, the carcasses are aged (tenderized) at air temperatures above 6 °C for 8–12 h before being frozen or packaged for chilled distribution. Sheep carcasses can be further processed into cuts and packaged for distribution. With the best processing hygiene and the use of either vacuum packaging or controlled atmosphere packaging systems, chilled rather than frozen meat can be distributed worldwide for retail distribution for as long as 10–12 weeks postmortem at −1.5 °C.

Future Trends

To date, sheep dressing is based fairly heavily on mechanical principles. In the future, however, rapid developments in the areas of electronic sensing, vision, and robotics are expected to affect carcass dressing. Initially, these new developments will be used to control existing machinery for greater processing accuracy. For significant further manpower reductions in sheep

Figure 6 A typical high-voltage electrical stimulation system for lambs in a meat processing plant. The current (1100 V peak, 2 A peak, 15 pulses per s) passes from the middle of the back through the legs of many carcasses as they move slowly along the electrode system, taking 90 s to complete the process. Reproduced with permission of AgResearch Limited, New Zealand.

and lamb, and even goat, processing, tasks such as opening cuts and clearing cuts, would have to use robotic technologies. To date, the best set of improvements has reduced the labor required for a traditional system by more than 40%, so instead of earlier requiring more than 2.6 times as many man-hours to produce the same weight of carcass as a chicken processing system, it now requires only 1.3 times as many.

Glossary

Carbonyls A class of compounds responsible for the browning reaction contained in smoke.
Condensable and noncondensable gases Condensable gases are those that form a liquid at room temperature; noncondensable gases do not.
Condensed smoke Cooled gaseous smoke.
Genotoxic Agents known to damage DNA.
Liquid smoke preparations These are combinations of condensed smokes.
Polycyclic aromatic hydrocarbons (PAHs) These are the cancer-causing agents.
Rapid thermal pyrolysis A pyrolysis method taking less than 1 s.
Rotary oven A slow pyrolysis reactor; pyrolysis occurs more than 1 min.
Tar fraction The non water-soluble fraction of pyrolysis that is removed from smoke.
Water fraction The gaseous phase of smoke that is condensed in water.

Introduction

Liquid smoke preparations are used extensively in meat processing. The application of liquid smoke (smoke condensates) is steadily displacing the use of traditional smoking. Research conducted in the 1960s and 1970s provided information about the basic aspects of the smoke-generating process and traditional smoking. The work dealt with the thermal degradation of wood, the physical and chemical properties of woodsmoke, the phenomena occurring in the smoking chamber, the diffusion of the smoke components into the products being smoked, and the bactericidal and antioxidative properties of woodsmoke. Studies were aimed at determining the chemical composition of woodsmoke condensate and the mechanisms in the production of polycyclic aromatic hydrocarbons (PAHs); the role of nitrogen oxides generated during thermal degradation of wood was also investigated. Many articles dealt with the species and moisture content of the wood, the degree of disintegration (wood chips or sawdust), and the sensory properties of the smoke preparations or of the smoked products. Attempts were also made to determine the relationship between the chemical composition of the smoke preparation and its sensory properties.

The results of these studies were used in the development of the first generation of liquid smoke preparations. Usually these preparations did not have the required stability and reproducibility from batch to batch. Many preparations produced at that time contained considerable quantities of PAHs. By the mid-1970s, progress in the manufacturing technology had largely eliminated the problems with smoke condensates. The smoke condensates made today are characterized by a high and repeatable quality level. The great increase in the application of smoke condensates is based on numerous factors: the development of new technological methods for producing smoke condensates; the development of technical solutions for application of the smoke condensates; environmental restrictions on the use of traditional smoke; and requirements for health and safety at work.

Methods for Smoke Condensate Production

The predominant raw material for production of smoke condensate is wood, typically of one or more of the following tree types: beech, oak, hickory, maple, eucalyptus, ash, apple, cherry, birch, mesquite, and pecan. Wood to be used for smoke condensate manufacture may be reduced to sawdust or chips, dried to approximately 5% moisture content and thermally decomposed. In some processes batch retorts are still in use. The thermal decomposition of the wood is carried out

under controlled conditions. Usually the process is a slow pyrolysis performed in externally heated retorts or in rotary ovens. In recent years, a so-called rapid thermal pyrolysis has been introduced. This enables the process of wood decomposition to be carried out in less than 1 s. The sawdust is introduced into a reactor in which heated sand is being circulated. When the hot sand comes in contact with the sawdust particle, the sawdust is pyrolyzed, forming the smoke components. The smoke is quickly transferred to a recirculation column where it is condensed. This ensures that a larger portion of the carbonyls is retained, forming a higher-browning capability smoke.

Of primary importance in the pyrolysis process is the temperature of wood decomposition. The temperature of decomposition has a fundamental influence on the quantity of condensate and its chemical composition. Most often the temperature is between 450 and 500 °C. The use of lower temperatures for wood decomposition considerably increases the content of carbonyl compounds and tar in the smoke condensate. The temperature depends on the reaction method used and which fraction is more desirable to the producer. The condensable and noncondensable gases created during the thermal decomposition of wood are contacted with a recirculating water phase of smoke condensate. Noncondensable gaseous components of wood pyrolysis contain carbon monoxide, methane, and hydrogen, resulting in a flammable gas stream that may be burned to generate heat utilized in further manufacturing steps. After cooling, concentration, and normalization, the smoke condensate is separated into a water fraction and a tar fraction. For manufacture of commercial condensed smoke preparations, both fractions may be used individually, although the tar fraction must be further processed to remove the high levels of genotoxic polycyclic aromatic hydrocarbons. The water fraction is subjected to storage for some time to isolate the slowly precipitating fraction of tar that continues to form at decreasing rates over the lifecycle of the condensate. Before further processing, the water fraction is subjected to multiple filtration steps to purify the liquid. The water fraction may then be concentrated by distillation or extraction. To improve its stability when stored, emulsifiers, such as Polysorbate 80, are added.

The filtered water fraction of smoke condensate, while useful in its native form, is best suited as an intermediate product to be used in the manufacture of many commercial forms of condensed smoke preparations. Each manufacturing batch is examined for its content of basic components. Usually, determinations of total organics content, acids (expressed as acetic acid), phenols, and carbonyls are carried out. For the preparations used for coloring of food products, methods that assess the reaction of the condensed smoke product with glycine are usually employed to determine the Maillard reaction potential of the condensed smoke.

Commercial condensed smoke preparations are normally offered in the following forms:

- Concentrated liquids for atomizing, or smoke regeneration, into smoking/cooking chambers, which is done nearly exclusively in batch processes.
- Extracts to be incorporated into food products by injection or mixing.
- Water-miscible solutions for showering products in batch and continuous processes.
- Powder on carriers such as maltodextrin, salt, yeasts, flours, spices, and seasonings to provide smoke flavor.

High-strength liquid smoke preparations are obtained from the tar fraction by distillation and/or extraction. These are highly enriched phenolic products that have far smaller amounts of the water, acids, and carbonyls that are present in seminal woodsmoke. Although smoke preparations of this type have use as is, typically they are more likely to be used commercially on carriers or in emulsions. These preparations possess only the smoke flavor without the coloring ability.

Chemical Composition of Liquid Smoke Preparations

The chemical composition of condensed smoke preparations varies as much as the composition of natural smoke, but the condensed smoke preparations do not contain the gaseous components of traditional smoke. The chemical composition of condensed smoke depends on the raw material used, the method and conditions for wood decomposition, and the methods for purification, condensation, and stabilization. During pyrolysis, the cellulose and hemicelluloses contained in wood generate organic acids, aldehydes, aliphatic and cyclic ketones, furans and pyrans plus derivatives, lactones, aliphatic alcohols, and anhydrous sugars. From the 25% or so lignin fraction of wood, a full range of phenolic compounds is produced. Most of the phenolics fall into the general classes of guaiacols, syringols, dihydroxybenzenes, and methylated phenols.

Condensed smoke preparations to be used for topical application contain the following key components:

Water	40–75% (w/w)
Acetic acid	4–12%
Formic acid	0.5–3.5%
Glycol aldehyde	1.78–5%
Formaldehyde	0.5–1.2%
Glyoxal	up to 1.2%
Acetol	2–5%
Levoglucosan	1.5–5.5%
Water-insoluble tar	up to 7%

The preparations also contain several minor components, which are present at low levels ($1.0\ mg\ g^{-1} = 0.1\%$).

- Furans (furfural, furan, and derivatives): 2–8 $mg\ g^{-1}$.
- Phenols (phenol, cresols, dimethylophenols, and derivatives): 0.4–2 $mg\ g^{-1}$.
- Dihydroxybenzenes (catechol, hydrochinone, and derivatives): 2–7 $mg\ g^{-1}$.
- Guaiacols (guaiacol and derivatives): 1–7 $mg\ g^{-1}$.
- Syringols (syringol and derivatives): 0.8–10 $mg\ g^{-1}$.
- Aromatic aldehydes (vanillin, syringol aldehyde, and derivatives): 0.2–2 $mg\ g^{-1}$.
- Other components (cyclotene, maltol, aliphatic aldehydes and ketones, etc.): 3–25 $mg\ g^{-1}$.

In addition, some preparations contain several hundred components at levels of micrograms per gram.

There is a wide variety of preparations of condensed smoke to be incorporated into food products. They can contain lower levels of the chemical compounds listed above because they are produced either by mixing the water fraction with carriers or extraction of certain components, or they may be converted into dry forms. The levels of phenolic compounds may vary by a factor of ten or more in the different preparations. The ratios between the different groups of compounds can also vary considerably.

Products made from the tar fraction of the smoke condensate have different chemical compositions. These preparations contain much greater quantities of phenolic compounds with considerably lower levels of other constituents. The primary components of these condensed smoke preparations from the tar fraction are syringol, 4-methylsyringol, 4-isopropenylsyringol, 4-ethylsyringol, isoeugenol, eugenol, guiacol, 4-methylguaiacol, phenol, and cresols. The total content of phenolic compounds may be a third of the mass.

The PAH content in condensed smoke preparations depends primarily on the production method and degree of purification. Preparations manufactured by smoldering wood might contain several hundred milligrams of PAHs per kilogram. The method of wood decomposition used today, which utilizes lower and precisely controlled temperatures, has made it possible to reduce the level of PAHs considerably from that of the past.

Thirty-four PAHs have been identified in condensed smoke preparations, and are present in highly varying quantities. Naphthalene and its derivatives are present at the highest level. The total quantity may be as high as 1800 mg kg^{-1} with a total PAH content of 3195 μg kg^{-1}. In Europe, regulation EC 2065/2003 limits benzo[a]pyrene to 10 μg kg^{-1} and benzo[a]anthracene to 20 μg kg^{-1} in smoke condensates that are used in foods. In the water phase of smoke condensates, the level of benzo[a]pyrene may be below 1 μg kg^{-1} when the tar component in the smoke condensate is below 1%.

Smoke Condensate Application Methods

The manufacture of smoke condensates has made it possible to replace traditional smoking and has created new technological possibilities. The application of smoke condensates to meat products may be classified into three basic groups: smoke regeneration (atomization), drenching or showering, and internal addition. The first and second include methods for surface application; the third group covers incorporating the smoke into the products. Applying smoke condensates to the surface of products is most frequently done in normal smoke application chambers used for traditional smoking or in specially designed units. Numerous techniques are used for applying smoke condensates to products in smoke application chambers including pneumatic or hydraulic nozzles, thermal spraying, electrostatic deposition, and ultrasound or centrifugal atomizers to form a regenerated smoke cloud (Figure 1; Table 1).

Color and flavor achieved are dependent on the smoke used, time smoked, meat block formulation, and processing schedule. In general, any color from light tan to very dark brown and very light smoke to heavy smoke flavor can be obtained.

Figure 1 Smoke application in a smoke chamber is carried out with low-velocity circulating air or air movement derived only from the application mechanism itself. The amount of smoke applied is controlled with metering pumps or by air pressure. Optimal smoke regeneration is obtained by sequential steps that include an atomization step followed by a circulation step while the dampers of the smoke house are closed. This also optimizes the use of the smoke. Multiple cycles of smoking and circulating may be utilized to provide the desired flavor and color (see **Table 1** for an example of a frankfurter processing schedule with condensed smoke regeneration).

The volume of smoke used depends on many factors. In most cases the quantity used for a manufacturing cycle is determined by the desired color intensity and flavor of the smoked product. A use of 1.5–3 kg of condensed smoke per ton of product is usually sufficient. Applying smoke condensates via smoke regeneration in smoking chambers provides a result very similar to a traditional smoking process (Figure 2; Table 2).

The color intensity and the degree of smoke flavor can be controlled by the concentration of the smoke condensate and by the contact time between the smoke solution and the product.

Another group of smoke condensates are designed for internal addition. This method is utilized to add flavor to the meat without affecting the color, and for adding a level of antimicrobial and antioxidant protection to meats. The level and type of smoke used are determined by the application method and flavor desired. To ensure a uniform distribution of this type of application in the product, smoke is normally applied in a bowl chopper or added to an injection marinade. Usage rates can be quite low depending on the smoke product used, but usually range from 0.05 to 1 g kg^{-1} of the meat product.

The process of curing meat should not be combined with the addition of a high-acid smoke concentrate. Several smoke condensates, however, are available with higher pH and low acid levels that can be added to brines. The reason is that

Table 1 Example of Frankfurter manufacturing process utilizing smoke regeneration

Chamber conditions	*Time*	*Dry bulb temperature (°C)*	*Humidity*
Reddening	10 min	50	90%
Drying	20 min	55	0%
Smoking	19 min 3 min smoking 4 min circulating 2 min smoking 4 min circulating 2 min smoking 4 min circulating	55	0%
Drying	10 min	60	0%
Cooking		78	100% to core temperature of 71 °C
Dry	5 min	75	0%

Figure 2 Showering or drenching the surface of the meat product or immersion in smoke condensate solutions is widely used. In drenching, a solution of the smoke condensate is showered over the product for a specific amount of time. Normal solution concentrations range from 5% to 50% smoke. The smoke condensate solution is recirculated through a filter system and back over the product to get the highest usage out of the condensate. The meat products are showered for 15–90 s to obtain the desired results (see **Table 2** for an example of a showered frankfurter processing schedule).

Table 2 Example of a showered Frankfurter processing schedule

Chamber conditions	*Time (min)*	*Dry bulb temperature (°C)*	*Humidity*
Reddening	10	55	90%
Drying	15	60	0%
Drying	15	65	0%
Cooking		78	100% to core temperature of 71 °C
Dry	5	75	0%

nitrites used in the curing process may react with the acid in smoke condensates forming nitrogen dioxide if a low-acid smoke is not used. Smoke condensates for brine addition allow for injection into bacon, ham, loins, and other larger meat cuts to allow for even flavor distribution and better end product uniformity.

Use of Smoke Condensates

Generally, smoke condensates can completely replace traditional smoking. Their use is especially common in automated and highly productive manufacturing lines where smoke condensates are widely used for manufacture of popular smoked meat products produced in large quantities. They are especially useful in continuous manufacturing lines using special tunnels and a series of smoking chambers. For smaller-scale production units, equipment has been developed for showering the products with smoke condensates immediately after stuffing of the casings. Smoke condensates are also used in the coextrusion process, in which a collagen dough is extruded around the meat batter. This can provide flavor and structure to the sausage. The following advantages can be achieved by using smoke condensates instead of traditional smoking:

- Eliminating the emission of harmful and undesirable chemical substances to the surrounding atmosphere.
- Avoiding the fire risk associated with traditional smokehouses.
- Reducing the processing time and weight loss of traditional smoking.
- Reducing labor costs.
- Increasing product throughput.
- Reducing smoke chamber clean-up time and expense.
- Producing a healthier finished product with little or no PAH.

In the opinion of many consumers, use of smoke condensates in meat products, even at very low quantities, improves the flavor and aroma of the products. Although according to expert panels, smoke condensates do not usually achieve a smoke flavor identical to that achieved with traditional smoking, testing has shown that consumers do not have a preference for traditional flavor. Use of smoke condensates requires knowledge of their properties and experience and understanding of consumer preferences. The application of smoke condensates for meat products should be preceded by consultation with the smoke condensate manufacturers and

technical tests in the manufacturing facility. Exceeding the optimal level for a given product can result in off-flavors in the treated product, most often in the form of an acid, sharp, acrid, chemical, or medicinal aftertaste.

Properties of Smoke Condensates

Smoke condensates possess, like traditional smoke, coloring, bactericidal, and antioxidant properties. Aldehydes and aliphatic ketones are responsible for the coloring effect. The main aldehyde responsible for the coloring is hydroxyacetaldehyde. The aldehydes react with nitrogen in protein to begin the Maillard reaction. As the reaction progresses, it forms cross-linking of the proteins and color bodies. The color is then set or stabilized in the meat matrix by proper drying. Without proper drying, the color can fade or migrate, leaving a product that is much lighter in color than when first produced. Testing can determine the proper process to use to ensure that the color is properly set.

Acetic acid lowers the pH value on the surface of the product. Acid is important for skin formation on sausages and providing the 'tang' in other meats. Acid level is also used quite extensively as an easy control measure for maintaining showering and drenching systems. Phenols are mainly responsible for the typical flavor of the smoked product. Even with the extensive knowledge about the composition of smoke condensates, it is still not possible to fully predict the quality of the smoke flavor. This places a certain amount of pressure on integrators to achieve the best possible outcome in a given situation. Among the phenolic compounds, syringol and its derivatives are the most desirable for creating a good smoke flavor. Other desirable compounds are guaiacol and its derivatives. Furfural and its derivatives, cyclotene, maltol, and aromatic ketones and aldehydes also play important roles in composing the overall smoke flavor.

Smoke condensates also have bacteriostatic and bactericidal properties. The bactericidal activity is related to the concentration of the smoke condensate in the product. The minimum inhibitory concentration (MIC) has been determined for some smoke condensates. For *Bacillus* spp., *Staphylococcus aureus*, *Listeria* spp., *Lactobacillus* spp., *Escherichia coli*, *Salmonella* spp., *Yersinia* spp., and *Pseudomonas* spp., the MIC is 0.4% for the most active smoke condensates. For less active preparations, the MIC is 1–8%. Published studies indicate that the levels of phenolic compounds and acetic acid in liquid smoke preparations are most important for their bacteriostatic properties. Aldehyde compounds are also very good antibacterial agents in smoke, making all three main groups of smoke compounds important in antimicrobial effects. However, the great variation in the chemical composition of commercial smoke condensates means that their bacteriostatic properties can only be considered a support to the basic preservative concept for a given food product.

The antioxidative property of smoke condensates is related to the content of phenolic compounds. The antioxidative activity of smoke is mainly controlled by the following compounds: *cis*–*trans*-4-propenylsyringol, 4-isopropenylsyringol, 4-propylsyringol, 4-ethylsyringol, 4-methylsyringol, syringol, and the 4-derivatives of guaiacol. It is also assumed that polyphenols in the preparations are active antioxidants and may provide some beneficial health effects.

Health Aspects Relating to the Use of Smoke Condensates

Smoke condensates have been classified by the Food and Drug Administration (FAO) as generally recognized as safe (GRAS) in the US since 1980. In 1987 the FAO/World Health Organization Expert Committee on Food Additives set recommended maximum levels for a number of risk contaminants in smoke condensates including benzo[a]pyrene at 10 $\mu g\,kg^{-1}$ and benzo[a]anthracene at 20 $\mu g\,kg^{-1}$. Subsequently, the Council of Europe followed by the European Union took up the assessment of smoke condensates. As a result, the European Food Safety Authority (EFSA) evaluated dossiers and published opinions on a number of smoke condensates from both water-based and tar-based condensates. The EFSA concluded that there was no genotoxicity concern over the products presently on the market throughout Europe. At the time of writing the European Commission is determining whether limits are advisable on the use of these condensates based on applied safety factors derived from feeding studies.

It is certain that smoke condensates do not contain nitrogen oxides and that the PAH level in the food products with smoke condensates is considerably lower than after traditional smoking. The amount of tar introduced into food products during the process is also much lower than with traditional smoking. In general, the use of smoke condensates allows a controlled application of the smoke organics necessary to achieve the color, flavor, and antioxidant and antimicrobial effects of smoke in smoked food products.

Glossary

Antioxidant activity Decreases the rate of oxidation of meat lipids through smoking. The smoke components that have the highest antioxidant activity are phenols.

Cold smoking The smoke temperature is in the range 12–25 °C.

Health hazards Hazards associated with smoked foods that may be caused by carcinogenic components of wood smoke and toxic effects of pathogenic microflora not eliminated in the whole manufacturing process.

Hot smoking The smoke temperature ranges from approximately 40–90 °C.

Preservative action Decreases the rate of microbial spoilage of meats through smoking that depends on the parameters of processing and the concentration of antimicrobial smoke components in the products.

Sensory properties of smoked products Desirable changes caused through smoking – predominantly in the color, flavor, and texture of meats.

Smoke composition Wood smoke consists of approximately 400 identified organic compounds, mainly phenols, aldehydes and ketones, carboxylic acids, aliphatic and aromatic hydrocarbons, alcohols, and esters.

Smoke phenols A very diversified group of wood smoke constituents, containing monohydroxy- and polyhydroxyphenols, compounds with long side chains, and phenols with additional functional groups.

Warm smoking The smoke temperature is in the range 25–45 °C.

Introduction

Smoking, drying, and salting belong to the oldest methods of food preservation. Meat hung by the fire was preserved by a combination of drying and smoking. Often the raw material was first pickled in brine. In different regions of the world various procedures have been developed, best suited for treating meats and fish for specific purposes. Smoking extended the shelf life and imparted very desirable, new sensory properties to the products. The role of its preservative effect decreased with the advent of canning, modern chilling, and freezing, whereas the aspects of flavoring and safety gained importance. Nowadays smoking is applied in many forms to treat as much as 40–60% of the total amount of meat products.

Traditional smoking involves the exposure of meat or meat products to smoke. The smoke is developed by smoldering wood either directly in the kiln below the hanging meat (Figure 1) or in an external generator. Its flow rate is controlled by natural draft depending on the construction of the smoking oven and on the weather conditions. In modern, automatic smokehouses it is forced by mechanical equipment. The temperature of the smoke is in the range 12–25 °C during cold smoking and 25–45 °C for warm smoking. In hot smoking, which should cause thermal denaturation of the meat proteins, the process may be carried out in different stages, at which the smoke temperature ranges from approximately 40–90 °C.

The progress achieved in traditional smoking of food has focused in the recent several decades on the control of the composition of smoke, application of engineering principles to heat and mass transfer to shorten the processing time and affect the weight loss of the product, rational design of the

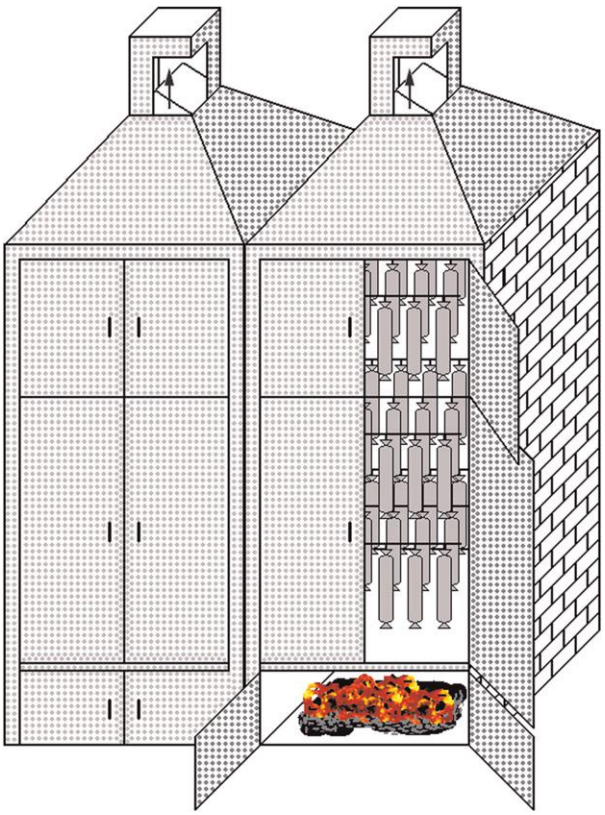

Figure 1 A traditional smoking oven. Courtesy of Łukasz Wiśniewski.

process parameters, assurance of quality including safety of the smoked goods, modernization of equipment, and treatment of the spent smoke to avoid pollution of the environment.

Wood Smoke

Generation and Composition

The curing smoke develops due to partial burning of wood or other suitable material with a controlled oxygen supply. It is composed of air, water vapor, CO_2, CO, nitrogen oxides, and a large number of different organic products of thermal degradation of hemicelluloses, cellulose, and lignin in temperature ranges of 180–300 °C, 260–350 °C, and 300–500 °C, respectively. Some of these products undergo oxidation at temperature reaching up to 900 °C. The yield and chemical composition of smoke depends more on the temperature and oxygen concentration in the zones of degradation and oxidation than on the humidity and kind of wood.

Generally, smoke is made from hardwood, mainly oak and beech. However, for imparting specific color or flavor to some products, wood of other trees that are rich in resins, including coniferous as well as heather, may also be used. According to legal requirements the wood shall be natural, and has not been subjected to any chemical treatment. In some areas, however, even bagasse and coconut husks are used.

From the large number of constituents found in different smoke condensates and extracts, approximately 400 organic compounds have been unequivocally identified. These include approximately 85 phenols, 110 aldehydes and ketones, 65 carboxylic acids, 20 aliphatic hydrocarbons, 80 aromatic hydrocarbons, and a number of alcohols, esters, and other compounds.

The phenol fraction is a very diversified group, containing among others, different compounds with long side chains, polyhydroxyphenols, as well as phenols with additional functional groups. It has been separated into approximately 240 components. The compounds present in the highest concentrations are listed in Table 1.

In the carbonyl fraction of wood smoke, the following compounds have been identified: formaldehyde, acetaldehyde, hydroxyacetaldehyde, acetone, hydroxyacetone, furfural, 5-methylfurfural, furanone, benzaldehyde, methylpropanal, and 3-methyl-2-cyclopenten-1-one. The fraction of acids consists of approximately 80% of acetic acid and includes formic, propionic, valeric, 4-oxovaleric, butyric, oxalic, malonic, maleic, fumaric, succinic acid, as well as various ketocarboxylic acids. In the alcohol fraction, methanol, ethanol, allylalcohol, *n*-amyl alcohol, 2-pentanol, 3-methyl-3-buten-1-ol, 3-methyl-1-butanol, 2-hexanol, 2,4-pentadiol, and 1-heptanol have been identified. The ester fraction of wood smoke contains at least the methyl esters of formic, acetic, butyric, acrylic, propionic, 4-oksovaleric, heptanoic, and pelargonic acids, as well as ethyl and butyl acetates, ethyl butyrate, and ethyl valerate.

The fraction of hydrocarbons contains approximately 20 aliphatic compounds, mainly methane and ethene, and a large group of aromatic hydrocarbons which includes at least 61 identified polycyclic aromatic hydrocarbons (PAH). The contents of PAH can be substantially limited by keeping the temperature of smoke generation below 400 °C.

Wood smoke also contains several O-heterocyclic and N-heterocyclic components.

Table 1 The phenolic compounds present in wood smoke in the highest concentrations

Guaiacol, 4-methylguaiacol, 4-ethylguaiacol, 4-vinylguaiacol, phenol, m-cresol, o-cresol, 3-ethylphenol, 2,5-dimethylphenol, syringol, 4-methylsyringol, 4-vinylsyringol, syringaldehyde, 1-(4-hydroxy-3,5-dimetoxyphenylo)-2-propanon, 1-(4-hydroxy-3,5-dimetoxyphenylo)-1-propanon, 1-(4-hydroxy-3,5-dimetoxyphenylo)-2-etanon, pirocatechin, 3-metoxypirocatechin, 4-methylpirocatechin, resorcinol, pyrogallol, 4-trans-propenylsyringol, hydroquinone.

Deposition on Smoked Goods

The boiling point of most smoke components is higher than the temperature in the smokehouse. Therefore, approximately 90% of the total mass of all constituents is present in the smoke in the form of small liquid droplets, approximately 0.08–0.15 μm in diameter. They are dispersed in the gaseous phase. The concentration of different components in the gaseous and dispersed phases depends on the temperature. The solid particles and liquid droplets disperse light, so that the smoke concentration can be assayed by measuring its optical density. Owing to the Brownian motion the particles and droplets coalesce and settle under the effect of gravitational and centrifugal forces on the walls of the smoking oven, the duct between the generator and the kiln, as well as on the smoked products. The electrostatic charge of the particles and absorption in the wet surface contribute also somewhat to deposition on the meat. High humidity of the smoke increases the rate of smoke deposition. On wet surfaces, the deposition of the components of the vapor phase is more effective than that of the particles and droplets. A rise in temperature of the smoke increases the concentration of some volatile components in the vapor phase and thus accelerates their sorption by the meat that is being smoked.

The quantity of compounds absorbed by the meat depends on the temperature, humidity, agitation, and composition of the smoke, the characteristics of the product's surface, and the duration of smoking. Wet surfaces adsorb approximately 20 times more phenols than dry ones. The published data on the total amount of smoke components absorbed by meat products are incomplete and vary within a broad range. The content of phenols in different smoked sausages ranges from approximately 0.02–200 $\mu g\ g^{-1}$. The composition of the fraction depends more on the conditions of processing, especially the humidity of the surface of the meats than on the concentration of individual phenols in the smoke. The quantity of formaldehyde in cold smoked goods may be as high as 20–40 $\mu g\ g^{-1}$. The amount of formaldehyde in different assortments of sausages may reach 2–50 $\mu g\ g^{-1}$; the surface layers of some products may contain approximately five times more than the inner layer.

Diffusion and Interactions in the Smoked Meats

Some compounds deposited on the humid meat surface stay there, while other diffuse into the deeper layers due to the concentration gradient. The diffusion rate is controlled also by the character of the surface, as well as by the properties of the meat and smoke compounds. Most phenols accumulate on the skin, on the sausage casing, and in the layer of the product several millimeters deep, especially in the fatty tissue. Carbonyl compounds and acids are rather equally distributed throughout the mass of some smoked meat products.

The chemically reactive phenols and carbonyls may be involved in polymerizations and react with amino and thiol groups in proteins and peptides. Furthermore, the phenols absorbed by the meat can be oxidized. The contents of guaiacol and phenol in smoked sausages stored for one month may decrease by approximately 35%. Because of comparatively low concentration of these absorbed components their reactions with meat proteins do not have any significant impact on the nutritive value of the products. However, the carbonyl-amino reactions and oxidation add to the desirable color formation.

The Effect of Smoking on the Shelf Life of Meat Products

Antimicrobial Activity

The shelf life of smoked products depends on the effect of heat pasteurization, level of water activity, as well as on the antibacterial and antioxidant properties of smoke components. Thus the preservative effect is obviously related to the concentration of salt due to presmoking treatment, the time–temperature regime and loss of water during processing, as well as the composition and quantity of smoke deposited on the meat. Cured and heavily smoked products are stable for several months at room temperature. Mild conditions of processing as applied in modern manufacturing of frankfurters do not exert such a high preservative effect. Smoking of frankfurters at internal temperature of 60–76 °C for 30 min reduces the total number of aerobic bacteria by approximately two log cycles, higher temperature and longer processing time being slightly more effective. Smoke components retard the proliferation of bacteria in cold stored frankfurters. Natural smoking can delay the onset of greening of frankfurters caused by *Leuconostoc mesenteroides* during storage.

Various smoke constituents in concentrations similar to those in smoked goods prevent the proliferation of microorganisms. To the most active antimicrobial agents of wood smoke belong guaiacol and its methyl and propyl derivatives, creosol, pyrocatechol, methylpyrocatechol, and pyrogallol and its methyl ether. The presence of an aldehyde group in a phenolic compound increases the antimicrobial activity. Formaldehyde arrests the growth of *Clostridium botulinum* in the concentration of 40 $\mu g\,cm^{-3}$. However, the smoke components present in lightly smoked foods stored under vacuum are not effective enough to inhibit the formation of *C. botulinum* toxin. Adding 8% of liquid smoke containing in 1 cm^3 approximately 1.4–4.0 mg of phenols and 20–70 mg of carbonyl compounds to raw minced beef, may significantly reduce the number of viable cells of *Escherichia coli* O157 H7 after 3 days at 4 °C. Several of the most thermo-tolerant *Staphylococcus epidermis* do not survive commercial hot smoking on inoculated rainbow trout. In cold smoked salmon, the growth of *Listeria monocytogenes* was found to be inhibited proportionally to the smoking time – 12 h of smoking reduced the population by three log cycles. However, well-adapted strains may persist in the smokehouse environment, so that *L. monocytogenes* can often be found in vacuum-packaged cold smoked salmon.

The most sensitive to smoke are generally the vegetative forms of bacteria. Molds are considerably resistant, although their development may be restrained by several phenolic compounds. A large population of molds and yeasts may survive in frankfurters smoked 30 min at an internal temperature of 67 °C. Smoking has little effect on the yeast count in the early stages of manufacturing of fermented sausages. However, in stored products the population of yeasts is lower in smoked sausages than in unsmoked controls.

Antioxidant Activity

The antioxidant effect of smoking was noticed by observing that smoked meats and fish were resistant to oxidative rancidity. Among the smoke components that have the highest antioxidant activity are phenols. The true antioxidants (AH), even in very low concentration, inhibit lipid oxidation by inactivating the radicals ($R^{\bullet}$) capable of initiating the chain reaction

$$R^{\bullet} + AH \rightarrow RH + A^{\bullet}$$

or the secondary radicals produced in the process of lipid oxidation ($LO^{\bullet}$ or $LOO^{\bullet}$)

$$LOO^{\bullet} + AH \rightarrow LOOH + A^{\bullet}$$

AH are able to react with the free radicals faster than the polyenoic fatty acids and thus protect the acids from being pulled into the chain reaction. However, they are ineffective in inactivating the highly reactive $^{\bullet}OH$ radicals. These radicals, because of their reactivity, attack rather the abundant fatty acids instead of the antioxidants present in low concentration. The phenolic AH inactivate the free radicals by donating the hydrogen atom of their OH group (Figure 2). The phenolic radical formed in the reaction has a low reactivity due to resonance delocalization of the radical function. The most active phenolic smoke antioxidants are pyrogallol, resorcinol, 4-methylguaiacol, 4-vinylguaiacol, and 4-trans-propenylsyringol. Less active are guaiacol, syringol, 4-methylsyringol, and 4-vinylsyringol.

The Role of Smoke in Developing Characteristic Sensory Properties of Smoked Goods

The desirable sensory properties of smoked meats result from the concerted action of the components of the meat, salting or curing, predrying, smoking, and heating. The smoke compounds induce smoky color and flavor. They also interact with

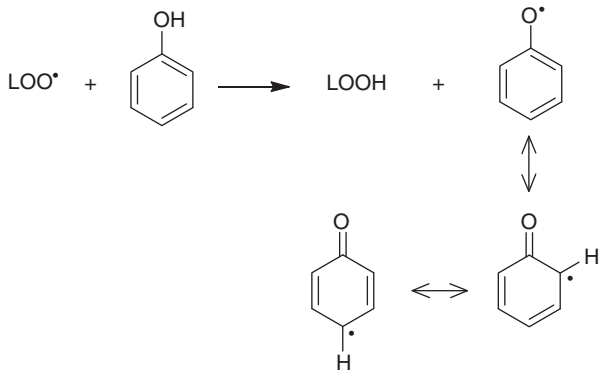

Figure 2 The inactivation of free radicals by phenolic compounds.

the nitrogenous meat constituents thus affecting some texture changes.

The color developed on the surface of the products is caused by colored smoke components and their interactions with the meat. Its intensity is primarily related to the optical density of the smoke and the duration of smoking. It increases at high smoke temperature and velocity. High temperature favors the development of dark color, because the rate of polymerization of the components, mainly phenols and of the carbonyl-amino reactions in the smoke itself and between smoke compounds and amino acid residues in the meat increases with temperature. The higher the temperature and water activity of the surface of small-calibre Brűhwurst, within limits set by other technological requirements, the darker is the color of the sausages. The kind of wood used for smoke generation also affects the color. Smoking with beech, maple, ash, sycamore, or lime tree smoke leads to golden-yellow color; yellow-brownish tint comes from oak, nut, and alder smoke. Products treated with smoke from coniferous wood have a dark coloration.

The dominant factors responsible for the smoky flavor are the smoke compounds themselves, mainly the phenols. The desirable flavor is associated with the presence of a mixture of syringol and 4-methylsyringol, although 4-allylsyringol, guaiacol, 4-methylguaiacol, and trans-isoeugenol also contribute to the typical sensory sensation. However, the multitude of variations of the smoky flavor is probably due to the contribution of different carbonyl compounds, furans, and other constituents not yet identified.

Health Hazards Induced by Smoking of Foods

The health hazards associated with smoked foods are related to the presence of carcinogenic components in wood smoke and smoked meats – PAH, N-nitroso compounds, and possibly heterocyclic aromatic amines, as well as to the toxic effects of pathogenic microflora not eliminated in the whole manufacturing process.

Wood smoke contains different PAH with a wide range of molecular weights (MW). The low-molecular members of this group, below MW 216, are not regarded as carcinogenic, contrary to many heavy MW PAH. Very mutagenic and carcinogenic is benzo(a)pyrene (BaP); until recently it was recognized as an indicator of carcinogenic PAH in wood smoke and smoked products. However, in 2008 the European Food Safety Authority stated that BaP alone is not suitable for use as the only marker of the contents of PAH in foods because, in approximately 30% of a very large number of investigated samples, no BaP could be found, although there were numerous other PAH present. The sum of the concentration of BaP, benz(a)anthracene, benzo(b)fluoranthene, and chrysene (PAH4) serve the purpose better, or else PAH8, i.e. the sum of PAH4 plus the concentration of benzo(k)fluoranthene, benzo(g,h,i)perylene, dibenzo(a,h)anthracene, and indeno(1,2,3-cd)pirene. In the Commission Regulation (EU) of 2011, a maximum concentration of BaP in smoked meat and meat products has been maintained for the present (5 ng g^{-1} until 31 August 2014 and 2 ng g^{-1} after this date). However, additionally the upper limit for PAH4 has been introduced (30 ng g^{-1} from 1 September 2012 until 31 August 2014, and 12 ng g^{-1} after this date). Among PAH isolated from smoked products are mainly compounds with a MW less than 216. In various smoked meat products their total mass may be from approximately 30–250 times larger, whereas that of the heavy PAH approximately 10 times larger than that of BaP.

The contents of BaP in hot smoked sausages is usually below 1 ng g^{-1}, but in some black smoked products it may reach 55 ng g^{-1}. In flame-grilled sausages, BaP has been found in concentrations of approximately 20–40 ng g^{-1}. The contents of BaP in barbecued pork and beef may be in the range 1.5–10.5 ng g^{-1}, and in charcoal-broiled steaks 5–8 ng g^{-1}. In various foods nitropolycyclic aromatic hydrocarbons have also been identified. In smoked sausages the contents of 1-nitropyrene, 2-nitronaphtalene, and 2-nitrofluorene has been found to be approximately 4, 8, and 20 ng g^{-1}. This is comparable to the contents of these compounds in roasted coffee beans of approximately 2, 4, and 30 ng g^{-1}.

Smoked cured meat products contain a number of volatile and nonvolatile N-nitroso compounds, most of which are carcinogenic in laboratory animals. The aldehydes of smoke can react with cysteamine and with cysteine yielding various thiazolidine precursors that can be easily nitrosated. The reaction of formaldehyde with cysteamine and cysteine leads to thiazolidine and thiazolidine-4-carboxylic acid, respectively, which, on nitrosation turn into N-nitrosothiazolidine and N-nitrosothiazolidine-4-carboxylic acid. Minute amounts of these compounds occur in smoked meats. In the presence of glycolaldehyde from smoke 2-(hydroxymethyl)-N-nitrosothiazolidine and 2-(hydroxymethyl)-N-nitrosothiazolidine-4-carboxylic acid (HMNTCA) may be formed. In smoked ham, sausages, salami, pepperoni, and poultry products the contents of HMNTCA may be from approximately 10–260 ng g^{-1}. Generally the concentration of these compounds is higher in meats smoked in traditional ovens than in products processed in modern smokehouses supplied with smoke from external generators. The total amount of various N-nitroso compounds in smoked fried bacon, some of which still unidentified, has been reported to be 430–6800 ng g^{-1}.

Heterocyclic aromatic amines, known to be generated in pyrolytic reactions of amino acids and proteins and in nonenzymatic browning, are present in very heavily smoked foods in amounts lower than 1 ng g^{-1}.

The hazards associated with the effects of pathogenic microflora in smoked foods depend on the initial bacterial contamination of the raw materials, on the bacteriostatic and bacteriocidic action of all processing steps, and on the effectiveness of the applied systems of quality assurance, e.g., the hazard analysis and critical control points.

The Equipment

Smoke Generators

Traditional smoking is carried out in different countries using a variety of smokehouses. The traditional kilns, as shown earlier in Figure 1, are used only in artisan meat processing. In an advanced type of kiln extending over two storeys of a building distinct zones with different temperatures are created. Heat is generated by burning gas, but smoke is still produced in the lower section of the kiln. Modern smokehouses are supplied with smoke produced in conditions that favor the formation of desirable components and minimize the generation of PAH.

In contemporary smoldering-type generators, the wood chips, shavings or sawdust are fed automatically on a grated fire bed or electrically heated plate. The sawdust or chips of wood of standardized water content and mesh size are available commercially. The temperature of the glowing pile is controlled by the humidity of the sawdust and the rate of air flow; by using material of approximately 50% humidity and limiting the air flow, the temperature may be reduced to approximately 600 °C. Because of the relatively high temperature of generation, the smoke is rich in phenols and has fully developed aroma. However, formation of PAH cannot be avoided if the temperature of the process exceeds 400 °C.

In a friction-type apparatus, the heat necessary for thermal degradation of wood is due to pressing of a log against a rotating drum or disk. The temperature at the friction interface can be controlled by varying the pressure exerted on the log or the rotation rate of the rotor. It is generally below 400 °C. In such conditions the thermal degradation of lignin and the oxidation of the reaction products is not as advanced as in a smoldering pile of sawdust, thus the aroma of the smoke may be slightly different. These conditions, however, minimize the development of PAH. Various friction generators are available, especially for rather small smoking chambers.

Wood smoke can be also produced in a hydropyrolytic process by treating sawdust or chips with superheated steam at 250–390 °C. The smoke developed at this temperature is rich in carboxylic acids and carbonyl compounds, but relatively poor in phenols. Its composition can be controlled by adjusting the temperature of the steam, the flow of air, and the rate of feeding the sawdust.

Smokehouses

In a traditional kiln, the operator controls the processing parameters under different weather conditions by appropriate feeding of the fireplace with wood logs, chips, and sawdust, opening or closing the doors and vents, and reversing the rods carrying the smoked sausages. Modern smokehouses are built to utilize the full application of the engineering principles of heat and mass transfer. They are heated by steam, gas or electricity and equipped with devices for forced air and smoke circulation at controlled velocity. The circulation of smoke provides uniform thermal and flow conditions in all parts of the kiln. The temperature, humidity, and density of the air/smoke, as well as the process time are adjusted to requirements depending on the desired properties of the products. Smokehouses used for processing cooked sausages are equipped with a hot water or steam injection systems and a cooling water spray, so that smoking, cooking, and cooling can be carried out in the same kiln. The smoke supplied from a generator is often conditioned by a water spray to control its temperature and humidity, and to separate out some tar fractions and soot. The material to be smoked is usually hung on rods and introduced by trolleys into the kiln or tunnel (Figure 3). Some kilns can be loaded through the front door and unloaded from the back side – this is convenient for a rational organization of the process.

The exhaust gases, after leaving the smokehouse, are cleaned before entering the atmosphere. Some installations comprise three stages – an electrofilter, a fibrous filter, and activated charcoal. Other systems use afterburners to oxidize the components of the spent smoke at 800–1500 °C and some use temperature approximately 600 °C in the presence of a catalyst. Many smokehouses are equipped with installations for automatic cleaning.

Smoking Procedures

Various procedures are used in the industry and in artisan meat processing to produce smoked foods of desired sensory properties and shelf life. Traditional procedures are based on practical experience of generations of meat processors. Skilled, experienced personnel are required to run the processes in a smoking oven at different weather conditions. In mass production of popular items, like frankfurters, the process is carried out in automatic smokehouses; the parameters are based on results of research and are computer-controlled. Some selected examples of different procedures are given below.

Cold smoking is used mainly in manufacturing of raw, fermented sausages, made from cured meats. The smoke at 12–25 °C and controlled humidity is applied for several hours or days, depending on the assortment of produce. When smoking salami, the sausage links are first surface-dried for 1 day at 12 °C in low-density smoke. This is followed by 5 days of smoking in dense smoke at 15–22 °C, and finished within 2 days in a somewhat colder and less dense smoke. For smoked bacon, the cured cuts are soaked for 3–4 h in cold, running water, washed in water at 30–40 °C, hung on hooks for 12–24 h to drip and for surface drying, smoked for 24–48 h at 25–35 °C until the skin and meat surface turns dark brown, and cooled to below 18 °C. The product yield is approximately 90% in relation to the weight of the cured bacon.

When smoking frankfurters, the first phase is tempering at 32–38 °C, which is intended to remove the surface moisture to ensure uniform color development of the product. Smoking properly in dense smoke of controlled humidity brings the

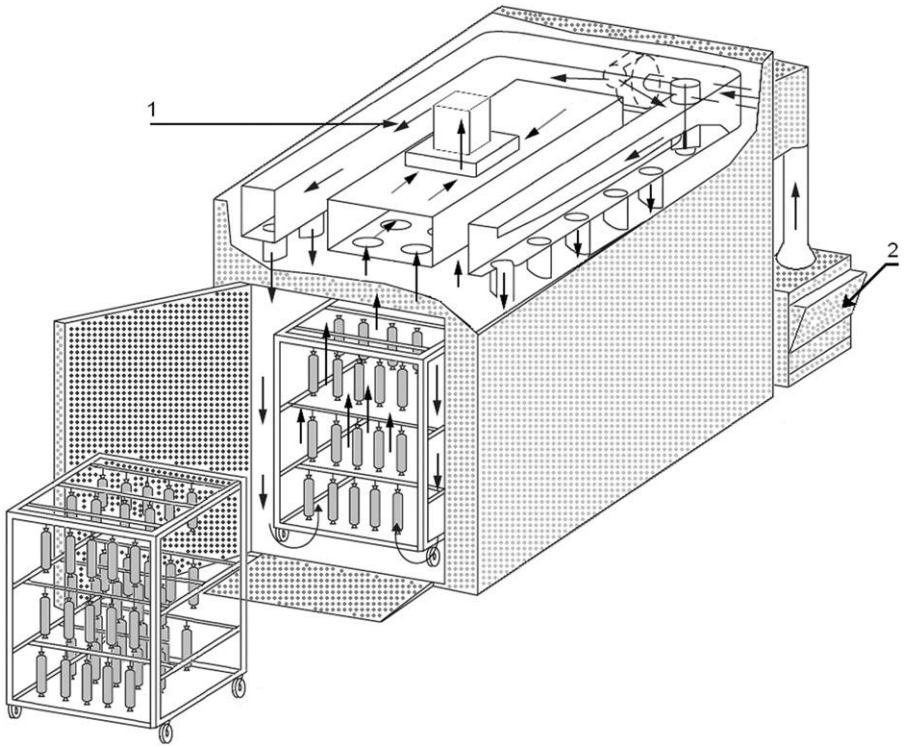

Figure 3 A modern smokehouse: (1) flow direction of the smoke and (2) smoke generator. Courtesy of Łukasz Wiśniewski.

internal temperature of the sausages to 60–68 °C and imparts the desirable smoky color and flavor. It usually lasts for approximately 1–1.5 h. This is followed by cooking in hot water or steam and by chilling. Smoking cooked sausages at a too high temperature may cause excessive fat and weight loss. This may lead to development of creased surfaces of the sausages and loss of uniformity of color.

In manufacturing jagdwurst the sausage batter made of cured pork, beef meat (9:1), and spices is stuffed into natural casings with a diameter of up to 32 mm. The links, 18–20 cm long, are hung for 12 h at 2–6 °C or 2–3 h at room temperature for setting, smoked for 80–90 min at 80 °C, dry-heated at 85 °C during 25 min to reach an internal temperature of 68–70 °C with a brown surface color, chilled to 18 °C, smoked again at 24–32 °C for 12 h to a darker-brown color, dried at 14–18 °C at a relative humidity of 75–80% during 6–8 days to a final water content of 55–57%, exposed to final smoking at 24–32 °C for 2–3 h, and cooled to below 18 °C. The yield of the sausage is approximately 59% in relation to the weight of the cured meat.

Kabanos, a delicatessen-type, spicy sausage, is produced by stuffing the sausage batter made of cured pork and spices into natural casings of 22 mm in diameter, setting the 60–70 cm long links for 12 h at 2–6 °C or for 30–60 min at room temperature, followed by 50–60 min of hot smoking, 20 min of dry heating to a core temperature 69–70 °C and dark brown color, cooling, and drying at 12–18 °C and 75–80% relative humidity for 5–7 days. The yield of the sausage is 55% relative to cured meat.

Traditional Xinjiang smoked horsemeat is made by soaking specially selected parts of the carcass for 1 h in cold water, adding 3% salt, 1% sugar, and 0.04% $NaNO_3$, holding for 3–5 days at 2–4 °C, smoking for 5–6 h at a smoke temperature of 60 °C, and steaming for about 1.5 h at a meat temperature 90–100 °C. The smoked product is packed in cans, sterilized, and cooled. It has a dark brown surface and is dark red inside.

SPECIES OF MEAT ANIMALS

Contents

Cattle

MA Price, University of Alberta, Edmonton, AB, Canada

Glossary

Biological type The commercially important physical characteristics of a beef animal.
Carcass The primary commercial portion of a beef animal after dressing (removal of the blood, head, feet, hide, and internal organs).
Cutability The proportion of saleable meat in the carcass.
Dressing percentage The weight of the carcass expressed as a percentage of the live weight of the animal.
Finishing Feeding to achieve the appropriate level of subcutaneous fat or finish for the target market.
Heterosis The advantage conferred by crossbreeding measured as the difference between the offspring and the midparent mean for the trait; it is also known as hybrid vigor.
Inbreeding Mating of animals that are more closely related than average in the population.
Marbling The fat within the muscles.
Net feed efficiency, also known as residual feed intake The difference between expected feed intake and actual feed intake based on an animal's live weight and growth rate.
Offal All parts of the animal other than the carcass.

Introduction

All types of cattle, irrespective of whether their primary purpose is meat, milk, draft power, or some combination of these, are used ultimately in beef production. Consequently, a wide variety of shapes, sizes, body compositions, and ages of cattle consigned to abattoirs are found around the world. Some of them have been bred and managed specifically for beef production, whereas others, including culled breeding stock, produce beef as a by-product. This article is concerned mainly with the wide variety of breed types of cattle used for beef production in the developed world. In much of the developing world, cattle are not used primarily for beef production, and many different regional types have evolved that are suited to their particular local functions and management systems.

Biological Types of Beef Cattle

Although the word 'breed' is used in common parlance to describe distinct types of cattle, it is not a completely useful or biologically meaningful term. In the past few centuries in particular, livestock (and pet) owners had gathered together groups of their animals with similar phenotypes and kept a formal registry of their progeny. This group of animals was then referred to as a 'breed,' and members of the breed were normally descendants of the original group. A deliberate policy of inbreeding close relatives was often followed to fix the 'type,' i.e., to ensure that the offspring conformed to the distinctive phenotype of the breed. An unavoidable by-product of this process was inbreeding depression whereby the purebred animals were less fit in an evolutionary sense and tended to have poorer reproductive and growth performance than their non-inbred relatives. Crossbreeding nullified this inbreeding depression through heterosis or hybrid vigor, which removed the constraints of inbreeding.

Today, several species of cattle (genus *Bos*), comprising hundreds of major and minor breeds, are owned and used by farmers around the world. Commercial crossbreeding of these cattle can result in a wide variety of sizes and shapes, and the use of four genders (male, female, castrated male, and spayed female) and a broad range of ages and weights at harvest

further exacerbates the complexity of raw material entering the beef chain.

Clearly, in trying to categorize the production traits of cattle, 'breed' is far too unwieldy a descriptor. Instead, the term 'biological type' is preferred and is used here to indicate phenotype in terms of temperament, mature body size, muscularity, and propensity to fatten, which are the most obvious traits of market-ready beef animals. Many other traits, such as libido, fertility, calving ease, and lactation, are of enormous importance to a beef producer, but they are not considered here. A number of very broad 'biological type' descriptors are commonly used in the beef industries of the developed world, including the following:

- 'British' refer to cattle originating in Great Britain, developed specifically for beef production off pasture, and typified as Hereford (Figure 1), Angus (Figure 2), and Shorthorn. Traditionally, they tend to be of medium body size and muscling with a relatively high propensity to fatten and a usually docile temperament.
- 'Continental' or 'European' refer to the multipurpose cattle from the European continent, typified by breeds, such as Simmental (Figure 3), Maine-Anjou (Figure 4), Charolais (Figure 5), and Gelbvieh. They are generally larger than the

Figure 5 A Charolais bull. Reproduced with permission from the Canadian Charolais Association.

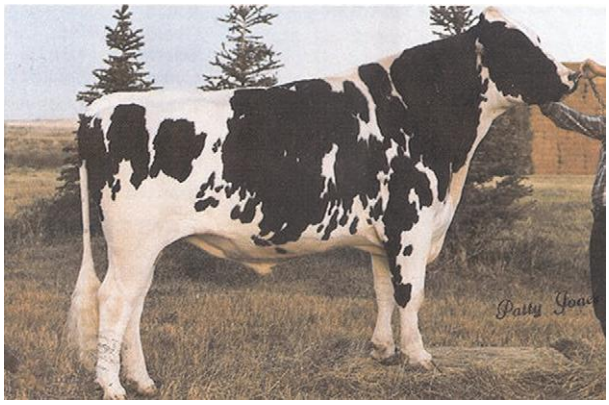

Figure 7 A Holstein bull. Photograph: Patty Jones.

Figure 8 A Zebu bull. Photograph: Mick Price.

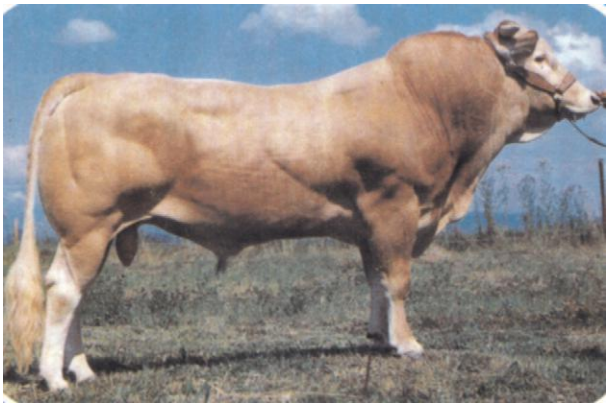

Figure 9 A Blonde d'Aquitaine bull. Photograph: Walt Browarny.

British cattle, with heavier muscling, a lower propensity to fatten, and less docile temperament. A subset of this group, sometimes referred to as the Italian White breeds (e.g., Romagnola, Marchigiana, and Chianina (Figure 6)), consists of very large cattle with a very low propensity to fatten.

- 'Dairy type' refers to cattle that have been bred primarily for milk production. They are characterized by light muscling and a low propensity to deposit subcutaneous fat, but they vary widely in mature body size from small (Jersey) to large (Holstein-Friesian). They are also characterized by a higher propensity than beef-type cattle to deposit intramuscular (marbling) and internal fats, including body cavity and kidney fat. Dairy bulls (Figure 7) are commonly described as having unpredictable and mean temperaments.
- 'Dual purpose' is a term applied to cattle bred to produce both milk and beef. They tend to be of medium to large body size (Brown Swiss, British and Dutch Friesians, Salers, and Normande) with moderate muscling and propensity to fatten. Temperament depends on the biological type of cattle involved.
- 'Zebu' is a general term applied to cattle of the *Bos indicus* species (Figure 8). They vary widely in mature body size and muscling but tend to have a lower propensity to fatten than taurine (*Bos taurus*) cattle and a more volatile disposition than British and Continental cattle. Their strengths include heat and insect tolerance, but their meat is slightly less tender than that from taurine cattle. Maximum heterosis can be obtained by crossing *B. indicus* and *B. taurus* cattle.
- 'Double muscled' (muscularly hypertrophied) is a term used to describe cattle of any breed type exhibiting a particular genetic syndrome characterized by extremely heavy muscling. Although it results from a mutation in a single gene (a deletion in the 'myostatin' gene on bovine chromosome 2), this condition has very wide-reaching effects in terms of body composition and temperament. These cattle might be of any mature body size, depending on their breed type, but always show extremely high muscle-to-bone ratios and a very low propensity to fatten. They also typically exhibit fine bones, thin skin, and a nervous disposition. Some extremely heavily muscled breeds (e.g., Belgian Blue, Blonde d'Aquitaine (Figure 9), and Piedmontese) commonly carry the gene for this condition.

Cattle producers throughout the developed world have been slow to adopt crossbreeding and hybrid breeding systems. Although these are considered essential practices for most other species of livestock and poultry, beef and dairy producers still commonly use purebred or first cross (F1) cattle. However, in recent decades, two- and three-way crosses of cattle breeds have gained in popularity (sometimes resulting in a new 'breed') but hybrids, and particularly the use of hybrid bulls, are still considered a risky venture. Beef producers

have also relied to a greater extent on subjective ('eyeball') assessment to select sires and to cull dams than other livestock breeders.

However, leaders in the beef industry have, over the past half century, increasingly incorporated objective methods of assessment into their genetic selection programs and have adopted crossbreeding to capitalize on heterosis and complementarity of traits. Measurements now include not only live weight and feed consumption but also ultrasonically assessed fat and muscle thickness. The cattle industries have also been quick to adopt the new sciences of genomics and proteomics to help identify and select genes associated with traits, such as fertility, residual (or net) feed efficiency, and carcass and meat quality, that have been difficult to improve using traditional methods.

As technology and computing power have advanced and become more affordable, it has become possible to make comparisons among bulls at very young ages, which would have been impossible a few decades ago. These include the statistical assessment of expected progeny differences (EPDs) and deoxyribonucleic acid (DNA)-based genotyping and quantitative trait loci mapping to discover chromosomal regions and ultimately single-nucleotide polymorphisms associated with traits of interest to the breeder. Modern beef producers are very much aware of the importance of EPDs for a variety of traits in selecting bulls and culling heifers and cows and are increasingly requesting the incorporation of DNA-derived genomic information to assist in sire selection.

Traits of Importance in Finished Beef Cattle

Temperament

Although temperament clearly has an environmental component (even the wildest of cattle can be tamed and the tamest of cattle made wild by the way they are handled), it is in part a genetically determined trait. Cattle handlers are very familiar with the 'typical' temperament of specific breeds of cattle and learn management techniques appropriate to those breed types. It can be generalized that zebu cattle and dairy breeds of bulls are more temperamental than the taurine beef breeds, with British beef breeds being more docile than continental cattle. Cattle exhibiting the 'double-muscled' trait are commonly stress susceptible. In management systems that involve frequent interactions between cattle and people, poor temperament is not likely to be a problem, partly because the animals become tamed through frequent handling and partly because only docile (or at least tamable) cattle are kept. In systems where there is minimal interaction with humans, it is possible for problem temperaments to remain unrecognized until animals are marketed, at which time nervous or aggressive temperaments can have important negative consequences. These cattle can be dangerous to handle and can injure or bruise themselves or other cattle during marketing or processing, resulting in removal and condemnation of the damaged tissue from the dressed carcass and possibly condemnation of the whole carcass. Even if physical damage is avoided, the stresses of marketing and transportation might be severe enough to result in dark, firm, and dry (DFD) or even pale, soft, and exudative meat.

Mature Body Size

Mature body size varies quite widely among the various biological types and genders of cattle. The lower range of sizes among traditional cattle is represented by the Dexter (a taurine breed originating in Ireland), with mature bulls typically less than 450 kg and mature cows approximately 100 kg less than the bulls. Although some specialty miniature cattle have been developed that are considerably smaller than the Dexter; they are not discussed in this article.

At the extreme upper end of mature body size is the Chianina, also a taurine breed, from Italy, with mature bulls sometimes exceeding 1800 kg and cows reaching 1100 kg. It should be noted that the castrated male (steer) of all breed types would typically grow to be larger than the entire male, particularly in linear dimensions (height and length), but only at a very advanced age. Cattle that are raised specifically for beef production are usually marketed at a live weight considerably below their mature size, with each market having a preferred live weight and fatness. When cattle are marketed as culls from the dairy- or beef-breeding herd, they are more likely to have reached their mature body size.

Muscularity

At a common live weight, different biological types of cattle can vary widely in muscularity as a result of genetically determined differences in the muscle-to-bone ratio. In a 'typical' finished beef steer carcass, the ratio of muscle weight to bone weight is approximately 4:1, and almost all steer carcasses fall within the range of 3.5:1 ('dairy type,' e.g., Jersey) to 5:1 ('heavily muscled' type, e.g., Piedmontese). Gender also has an effect on muscle-to-bone ratio; bulls are more heavily muscled than steers, which are, in turn, more heavily muscled than heifers or cows. An extreme of muscle-to-bone ratio is found in cattle with the 'double-muscled' genotype. Bulls with this syndrome have been known to reach a carcass muscle-to-bone ratio as high as 9:1.

The muscle-to-bone ratio is lowest at birth and gradually increases as animals mature. In an animal that is continually gaining weight, no matter how quickly or slowly, environmental effects, including nutrition and management, have little influence on muscle-to-bone ratio, because it is a genetically controlled function of live weight. However, if an animal loses weight, it is lost from muscle and fat in approximately equal amounts, rather than from the skeleton; therefore, weight loss results in a reduction in muscle-to-bone ratio.

Although cattle of some genotypes contain more total muscle than others, biological-type differences in the distribution of muscles, for example, between high- and low-priced cuts of meat, are too small to be of any commercial importance. Traditional livestock judges have placed emphasis on this trait and it is most likely that a great deal of selection pressure, which should have been applied to truly important traits, has been wasted in its pursuit.

Propensity to Fatten

The propensity to fatten is also a genetically determined trait, but its expression is heavily dependent on environmental effects, particularly nutrition. In general, the types of cattle that have been selected strictly for beef production (e.g., the British beef types) have a greater proportion of their fat in the subcutaneous depot, and those that have been selected for dairy production have a greater proportion in the internal fat depots. Dairy types typically deposit more marbling fat than beef types. Some cattle, notably the Wagyu or Japanese Black breeds, have been selected specifically for their propensity to deposit intramuscular (marbling) fat without excessive amounts of fat in the other depots. In most cattle, however, marbling fat is the last to be deposited and reaches high levels only in cattle fed high-energy diets for prolonged periods. These cattle also exhibit high levels of fatness in the other depots.

Traits Determining the Value of Commercial Beef Animals

The value of commercial beef animals depends ultimately on the quantity and quality of meat they contain. In general, biological type has a major influence on meat quantity (size and body composition) but considerably less direct influence on meat quality. Biological type may, however, have a major indirect influence on meat quality through, for example, its effect on temperament leading to DFD beef. Biological type can also influence the thickness of muscle and fat in the carcass, and these together influence the rate of cooling following slaughter. Rapid cooling is a major cause of toughening, through cold shortening, in beef.

Quantity

The quantity of beef in animals is determined by three factors: market weight, dressing percentage, and cutability. Dressing percentage is the weight of the carcass expressed as a percentage of the live weight of the animal and cutability is the weight of saleable meat expressed as a percentage of the weight of the carcass. In general, 'meat' constitutes approximately 35–40% of a beef animal's live weight, but a number of factors can influence this.

Live weight and fatness

The size and fatness of market-ready cattle entering the beef chain is determined by local preference. The challenge for all beef producers is to breed and manage their cattle to meet these demands, as failure to do so results in discounted prices. The biological type of cattle needs to be the one that reaches the optimum subcutaneous fat thickness at the optimum carcass weight in the particular management system. Beef from cattle marketed as culls does not have to meet these standards because it is used mainly in processed meat products. Because of the wide range in size and propensity to fatten among the different biological types of cattle, it is comparatively easy for producers to select types of cattle that quickly and efficiently reach the appropriate live weight and fatness in their particular management system. Unfortunately, this flexibility is sometimes reduced by a producer's loyalty to one particular breed.

The increasing popularity of grain feeding in North America following World War II gives an interesting insight into the ways in which beef producers tailor their product to suit the market. Straight-bred (i.e., purebred, but not registered) British-type beef cattle were the norm in most areas of North America in the early and middle parts of the twentieth century. These cattle had a high propensity to fatten, making them very suitable for grass finishing. Consequently, feeding them on high-energy (grain based) diets led to overfat carcasses at the desired carcass weight or underweight carcasses at the desired fatness. Because producers saw a strong economic advantage in feeding grain, the solution to this problem was to change the biological type of cattle to a larger, later-maturing (lower propensity to fatten) biological type. This led to a wide-scale importation of the larger, leaner, and faster-growing Continental cattle, such as Charolais, Simmental, and Limousin, which could be fed high-energy grain-based diets without becoming excessively fat at the target carcass weight.

Dressing percentage

From the point of view of meat production, live animals consist of two parts: carcass and offal. These are not biological divisions and their definitions vary from time to time and place to place, but the carcass generally consists of the major muscles in the body and their associated bones and fat. In some places the tail, kidneys, and the kidney fat are defined as part of the carcass; in other places they are not. Regardless of how a 'carcass' is defined, 'offal' is always defined as everything in animals other than the carcass. The offal is further subdivided into edible and inedible components.

Many factors affect dressing percentage; they can be conveniently categorized into those that affect the carcass weight and those that affect the liveweight.

$$\text{dressing percentage} = \frac{\text{carcass weight} \times 100}{\text{live weight}} \qquad [1]$$

An important factor affecting the numerator (carcass weight) is the definition of 'carcass.' Clearly, if the tails, kidneys, and kidney fat were defined as part of carcasses, then dressing percentage would be higher than it would be if they were defined as part of the offal. Also, the carcass itself can be weighed 'hot' (immediately after slaughter) or 'cold' (after cooling overnight at 1–3 °C). Before the advent of spray chilling (misting with cold water), a typical carcass used to lose approximately 2% of its weight during cooling; weight loss from spray-chilled carcasses is close to zero.

Other major factors affecting carcass weight are fatness and muscularity (muscle-to-bone ratio): the fatter or more muscular a carcass is (all other things being equal), the higher is its dressing percentage. Both muscularity and propensity to fatten are under genetic control, so biological type influences dressing percentage. In practice, the range in muscularity in market-ready cattle (apart from double-muscled animals) is not nearly as great as the range in fatness, and the majority of body fat is located in the carcass, so it can be further generalized that carcasses with greater dressing percentages are usually fatter.

Factors influencing the proportion of the offal are also direct contributors to dressing percentage. These factors

include gut fill (the amount of undigested feed in the gastrointestinal tract), the weight and condition of the hide (wet/dry, hairy, and mud and manure caked), the proportion of bone, and, in case of females, pregnancy. Gut fill depends more on immediate preslaughter feeding than on biological type, but it might be that some cattle have greater appetites and can be expected to be 'paunchier' given the opportunity. This would tend to include the dairy types. Type of feed, particularly high energy versus low energy (e.g., grain vs. grass), influences gut fill because animals allowed to eat according to appetite consume a greater weight of low-energy feeds in an effort to optimize their daily energy intake. As a consequence, grass-finished cattle typically exhibit lower dressing percentages than grain-finished cattle. The weight of hide is a major contributor to the weight of the offal, and some biological types (e.g., zebu and double muscled) are known to have lighter hides and consequently higher dressing percentages. Geographical area and management system, particularly feedlot versus pasture finishing, might have a major influence on the amount of mud and manure caked on the hide. The presence of large horns, another trait of biological type, influences dressing percentage, but in practice it is common for horned cattle to be dehorned if they are to be finished in feedlots.

The dressing percentage of a 'typical' steer (tail on the carcass, kidneys, and kidney fat in the offal) is in the order of 57–60% or 60–63% when kidneys and kidney fat are left in. Very fat or very muscular cattle could dress as high as 65%, but that would be exceptional. At the other extreme of normal cattle, culled cows typically have dressing percentages of approximately 48–53%, with the lower values being achieved by very lean, sick, or emaciated cattle, particularly of dairy type.

Cutability

Carcass cutability can be defined in a number of ways, but it means the amount of saleable meat in the carcass generally expressed as a percentage of the carcass weight. It is largely determined by the amount of bone and excess fat that are removed from the carcass before retail. The actual value is strongly influenced by the cutting processes used. In some countries, all bones are removed before retail, but in most countries some cuts, for example, T-bone steak and standing rib roast, are marketed bone-in. Similarly, the amount of fat left on retail cuts is a matter of national or regional preference. Thus, to put absolute values on cutability would be misleading because the absolute value varies widely depending on geographical location. It is clear, however, that the influence of biological type on cutability can be profound because a carcass with a higher muscle-to-bone ratio or lower level of fatness has a correspondingly higher cutability. This biological-type effect is further influenced by the effects of age and slaughter weight on muscle-to-bone ratio and nutrition and management effects on carcass fatness. Some carcass grading systems include a 'cutability estimate' as a criterion of carcass merit. This figure is usually based on selected prime cuts, rather than on the whole carcass and therefore cannot be taken to indicate the total amount of meat available for retail sale. In general, 55–60% of the weight of beef carcasses is composed of muscle, with exceptionally muscular or lean carcasses exceeding this range and fat or lightly muscled carcasses falling short.

The term 'conformation' has been widely used in the livestock industries but has no precise and generally accepted definition. It is derived from the concept of conforming to breed type, which was a criterion traditionally used to assess the acceptability of an animal. In modern parlance, it has to do with visually assessed shape, particularly in relation to muscle, but may in fact be greatly influenced by fatness and fat distribution. Muscularity, meatiness, and conformation are all subjective terms that attempt to convey how much 'meat' an animal carries. Unfortunately, meatiness – like beauty – may be in the eye of the beholder, and there is a poor relationship between visual assessments of conformation and actual cutability.

Meat Quality

Although dressing percentage and cutability can be precisely defined (though the definitions vary from market to market), quality is a somewhat ethereal trait and must be subdivided into appearance and eating quality factors. Appearance factors include marbling, color, and texture of the meat and fat, and consumers naturally hope to use these as predictors of wholesomeness and eating quality. Unfortunately, there is little correlation between what can be seen and the ultimate taste and texture of the cooked product. Taste characteristics, particularly tenderness, juiciness, and flavor, are the ultimate measure of meat quality, but, because of their obviously subjective nature, they are very difficult to assess accurately and with repeatability and in any case cannot be known with certainty until the meat is eaten.

Appearance

Many of the components of appearance, such as marbling, thickness, color, and texture of muscle and fat, are known to have little or no relationship to eating quality. Nevertheless, they are considered by consumers, or the retailers who often act in proxy for them, to be important quality traits in their own right, because they influence the perceptions and thus the buying decisions of consumers. A bright red lean color is perceived to be fresh and from young animals.

Marbling – the flecks of fat that appear within meat – is the only appearance trait that gives any repeatable guide to eating quality and hence it has become an important determinant of value. Unfortunately, it is not a very reliable predictor because it accounts for only approximately 10–15% of the variation in tenderness and juiciness. It is also difficult to quantify precisely and is not consistently distributed within the carcass. Marbling is a late-maturing fat depot, meaning that fat is not deposited in this depot in appreciable amounts in very young cattle. The amount of marbling present in a carcass is also related to the total amount of fat: well-marbled carcasses tend to be fatter carcasses. However, there is a discernible breed effect, with the 'dairy-type' cattle having higher levels of marbling at constant total fatness and some specialty breeds, such as the Wagyu or Japanese Black, exhibiting very high levels of marbling. Breeds with consistently lower levels of marbling (Limousin, Piedmontese, and Blonde d'Aquitaine) tend to generally lack fat. Although marbling is not a reliable guide to eating quality, it has been noted that greater amounts of marbling result in less

toughening in meat cooked to higher temperatures, giving rise to the view that well-marbled beef is more forgiving of a poor cook.

Color and texture of muscle tend to be functions of age and immediate preslaughter stress levels, and these dwarf any genetic effects; however, the yellow color in beef fat has a genetic component as well as a nutritional component. The most common cause of yellow fat, other than liver disease, is the presence of β-carotene in solution in the fat. β-carotene is red in color (carrots and tomatoes) but appears yellow in dilute solution. It is found in green forage and is converted into the much paler vitamin A at the intestinal wall during absorption as well as in the liver. Some cattle, notably the 'Channel Island' breeds, Jersey and Guernsey, and the zebus, have yellower fat, probably through a reduced capacity to convert carotenoid pigments in the feed into vitamin A before storing it in the fat. It is notable that the milk of these cattle is also yellower, for the same reason. As both β-carotene and vitamin A are tasteless, their presence or absence has no direct effect on taste, although consumers may subconsciously ascribe superior taste to meat having fat of a preferred color.

The concentration of β-carotene in the fat increases with age, particularly in an animal that has experienced cyclical storage and removal of fat during its life. Consequently, cull cows, which tend to be older and have experienced annual fluctuations in fatness, are associated with yellow fat. Their meat is not preferred, enhancing the myth that yellow fat causes poor eating quality.

Taste

The eating quality of beef is extremely complex. It is sometimes said of taste that 'quality goes in after the hide comes off,' in recognition of the fact that processing and postslaughter handling, including preparation and cooking, are far more important in determining eating quality than the biological type or management of the animal itself. Differences in eating quality among different muscles (retail cuts) and even within a single muscle completely transcend any differences found among live animals, irrespective of whether these differences result from biological type, age, gender, nutrition, or management factors. Eating quality is generally defined as a combination of tenderness, juiciness, and flavor, although each of these is, in turn, a complex of traits.

Tenderness is generally accepted as the most important eating quality trait, and there are documented biological-type effects on certain aspects of tenderness. In particular, the zebu breeds have been shown to produce tougher beef than the taurine breeds, perhaps because of genetic differences in proteolytic enzyme systems that affect the progress of postmortem tenderization. It is known, for example, that zebu cattle have higher concentrations of the inhibitor calpastatin, which is related to toughness. However, it should be clearly recognized that these differences are much smaller than the differences found among muscles in the same animal or between carcasses that have been subjected to different postmortem handling. Rapidly cooled muscles experience cold toughening, whereas aging is a process that progressively tenderizes muscle. The heritability of tenderness is moderately high.

Conclusions

All cattle ultimately produce beef, and cattle come in a wide variety of shapes and sizes. Specialist beef breeders are increasingly moving away from purebreds and are using crossbreeding combined with sophisticated assessments of the genetic determinants of important traits. Breed or biological type can influence carcass and meat quality in a number of ways. Biological types differ in size and body composition (proportions of muscle, fat, and bone), and hence both the absolute and relative (through dressing percentage and cutability effects) amount of meat they produce. However, there is less intrinsic difference in the taste or texture of their meat, and a factor, such as carcass fat covering (insulation) could have a major indirect effect on tenderness through its effect on the rate of postmortem cooling and hence the extent of cold shortening. Fatter carcasses also tend to have more marbling, which might make the (admittedly weak) relationship between marbling and tenderness more of a coincidence rather than a cause-and-effect relationship. However, marbling does tend to ameliorate the deleterious effects of high endpoint temperature on meat tenderness. Feeding and management, which may be breed related, could also have minor influences on taste and texture; for example, in North America, British-type cattle are more likely to be finished extensively on grass, whereas European cattle are more likely to be finished intensively on grain. In general, biological type can have a major influence on the quantity and appearance of meat in bovine carcasses but considerably less direct influence on its taste and texture.

Introduction

Each of four production division groups is identified in a separate table that lists the fish by name (scientific and common), major location, maximum measurement (length, weight, and age), use, production (rank and total), and cooking method.

According to the Food and Agriculture Organization of the United Nations (FAO), the estimated total world production of fishery commodities (e.g., fish and crustaceans) in 1000 metric tones (kt) was 98 627 in 1990; 116 412 in 1995, and 130 434 in 2000. These live weight-based production estimates excluded whales, seals, and other aquatic mammals and plants, but included aquaculture products.

The 2000 world fisheries production (e.g., fish and crustaceans) by capture (wild) and aquaculture revealed that of the total of 130 434 kt, wild harvest accounted for 72.7% and aquaculture contributed 27.3%. In 2000, the top 10 world fisheries production countries, in decreasing order, were China, Peru, Japan, India, USA, Indonesia, Chile, Russian Federation, Thailand, and Norway. During this timeframe, China's total production was 41 568 kt, of which wild harvest and aquaculture accounted for 40.9% and 59.1%, respectively.

An examination of the 2000 international trade in fisheries commodities by principal importers and exporters shows that the top 10 importers, in decreasing order, were Japan, USA, Spain, France, Italy, Germany, UK, Hong Kong, Denmark, and China. The top 10 exporters were Thailand, China, Norway, USA, Canada, Denmark, Chile, Taiwan, Spain, and Indonesia. Interestingly, USA, Spain, Denmark, and China were the numbers 2, 3, 9, and 10 importers, respectively, and they were also the numbers 4, 9, 6, and 2 exporters, respectively.

A comparison of the disposition of the world fishery production indicates that in 1990, 1995, and 2000 the production increased from 98 627 to 116 412 and finally to 130 434 kt, in the respective years. Of the 130 434 kt, human consumption accounted for 74.1% divided by marketed fresh (53.7%), frozen (25.7%), cured (9.6%), and canned (11.0%). The remaining 3726 kt (25.9%) was for other purposes.

Definitions

- Cartilaginous fishes: A classification of approximately 700 fish species (i.e., Class Chondrichthyes) that contains sharks, skates, rays, and chimaeras.
- Finfish: This is a generic term for true fish.
- Fish: The term fish includes finfish, crustaceans, other aquatic animals (e.g., alligators (?), frogs, turtles, and jellyfish) and molluscs.
- Sashimi: Thin slices of fresh (and previously frozen), raw fish that might be served with soy sauce and wasabi (horseradish).
- Surimi: In general terms, this is minced fish tissue from which fat, off-odors, and colors have been eliminated and to which cryoprotectants (e.g., sugars and other additives) have been added before freezing of the meat.
- True fishes: Generally, these fishes are cold-blooded, gill-breathing, aquatic bony vertebrates, usually with fins.

Capture (Wild) Production by Principal Species

FAO's 2000 capture or catch (wild) data revealed production by principal species. Twenty-three of these species by the name (scientific and common), major location, maximum measurement (length, weight, and age), use, production (kt) (rank and total) in 2000, and cooking method are listed in Table 1.

World Aquaculture Production

FAO's 2000 world aquaculture data listed the production for 18 finfish species. The production for these finfish species ranged from 3473 to 137 kt and yielded 19 024 kt; however, the first 6 finfish species' production ranged from 3473 to 1045 kt and produced 13 700 kt. These 18 principal aquaculture finfish species by the name (scientific and common), major location, maximum measurement (length, weight, and age), use, production (kt) (rank and total) in 2000, and cooking method are listed in Table 2.

Nutritional Content of Selected Groups of Finfish

A review of the nutritional content of raw tissue from selected finfish was undertaken, and the finfish were divided into four groups based on their total energy content. Group 1 consisted of Atlantic mackerel, Pacific herring, Greenland halibut, eel (mixed species), and Atlantic salmon. Group 2 contained milkfish, Spanish mackerel, rainbow trout, channel catfish, whitefish (mixed species), European anchovy, carp, and bluefish. Group 3 was made up of yellowfin tuna and skipjack tuna. Group 4 comprised Atlantic cod, walleye pollock, and orange roughy. Subsequently, 11 nutrient values (i.e., water, energy, protein, total fat (lipid), calcium, iron, sodium, ascorbic acid (vitamin C), riboflavin, niacin, and cholesterol) were selected from each group of finfish and the data were averaged and reported in Table 3. A comparison of the total fat and cholesterol as well as the protein and water values was considered to be important because of the high levels of

Table 1 Twenty-three selected finfish species including names, locations, measurements, 2000 catch (wild) production etc.

Names[a,b,c,d] *A. Scientific* *B. Common*	*Major location*[d]	*Maximum measurement* *A. Length*[d] *B. Weight*[d] *C. Age*[d]	*Use*[d]	*Production*[a] *A. Rank*[e] *B. Total*	*Cooking method*[d]
A. *Engraulis ringens* B. Anchoveta (aka Peruvian anchovy)	Subtropical, marine waters off the western coast of South America from Peru to Chile	A. 20.0 cm B. ND C. 3 years	Fish meal (animal feed) fertilizer and oil	A. 1 B. 11 276 kt	ND
A. *Theragra chalcogramma* B. Walleye pollock	Polar, brackish, and marine waters from Alaska to the Sea of Japan and to California, USA, and near Baja California, Mexico	A. 91.0 cm B. 1.4 kg C. 15 years	Roe (egg-laden ovaries of fish) and frozen; further manufactured into surimi, etc	A. 2 B. 3025 kt	Sautéed and steamed, etc.
A. *Clupea harengus* B. Atlantic herring	Brackish and marine waters of moderate temperatures in the North Atlantic (e.g., from the Bay of Biscay to Ireland, Greenland, etc., and from Labrador to South Carolina)	A. 45.0 cm B. 1.0 kg C. 11 years	Fresh or processed (e.g., smoked and canned)	A. 3 B. 2370 kt	Broiled, fried, microwaved, etc.
A. *Katsuwonus pelamis* B. Skipjack tuna	Worldwide (except for the Black and Mediterranean Seas) in marine waters of tropical and moderate temperatures	A. 1.1 m B. 34.5 kg C. 12 years	Fresh or processed (e.g., frozen and dried/salted)	A. 4 B. 1890 kt	ND
A. *Engraulis japonicus* (aka *Engraulis japonica*) B. Japanese anchovy	In big schools near the surface of warm, marine waters of the Western Pacific (e.g., Sakhalin Island and Sea of Japan)	A. 16.0 cm B. ND C. 3 years	Fresh and manufactured (e.g., fish meal)	A. 5 B. 1726 kt	ND
A. *Trachurus murphyi* B. Inca scad (aka Chilean jack mackerel)	Tropical, marine waters of the Pacific Ocean (e.g., off Chile and New Zealand) and Southwest Atlantic (e.g., Argentina)	A. 70.0 cm B. ND C. 16 years	Fresh and processed (e.g., into canned goods and fish meal)	A. 6 B. 1540 kt	ND
A. *Trichiurus lepturus* B. Atlantic cutlassfish (aka largehead hairtail)	Native to subtropical, brackish and marine waters worldwide	A. 2.3 m B. 5.0 kg C. 15 years	Fresh (e.g., for sashimi) and processed (e.g., dried/salted and frozen)	A. 7 B. 1480 kt	Grilled and fried
A. *Scomber japonicus* B. Chub mackerel	Subtropical, marine waters of the Indo-Pacific area	A. 64.0 cm B. 2.9 kg C. 18 years	Fresh and processed (e.g., canned, smoked, and salted), and as a medicine	A. 8 B. 1456 kt	Baked, fried, etc.
A. *Mallotus villosus* B. Capelin	Native to polar, marine waters near the Arctic pole; in the North Atlantic (e.g., in the Norwegian Sea and Gulf of Maine) and North Pacific (e.g., Korea)	A. 25.2 cm B. ND C. 5 years	Roe (egg-laden ovaries of fish) and processed (e.g., canned, dried, frozen, and fish meal)	A. 9 B. 1456 kt	Fried
A. *Micromesistius poutassou* B. Blue whiting (aka poutassou)	Temperate, marine waters in the Atlantic (e.g., the Barents Sea, around Iceland and Africa, and off Greenland and the USA)	A. 50.0 cm B. 0.8 kg C. 20 years	Fresh and manufactured (e.g., into fish oil)	A. 10 B. 1420 kt	ND
A. *Thunnus albacares* B. Yellowfin tuna	Brackish and marine tropical and subtropical seas worldwide except for the Mediterranean Sea	A. 2.4 m B. 200.0 kg C. 8 years	Fresh (including for sashimi) and processed (e.g., canned and smoked)	A. 11 B. 997 kt	ND

Names[a,b,c,d] *A. Scientific* *B. Common*	*Major location*[d]	*Maximum measurement* *A. Length*[d] *B. Weight*[d] *C. Age*[d]	*Use*[d]	*Production*[a] *A. Rank*[e] *B. Total*	*Cooking method*[d]
A. *Gadus morhua* B. Atlantic cod	Native to brackish and marine waters of moderate temperatures of the North Atlantic (e.g., Cape Hatteras to Ungave Bay and off the coasts of Greenland and Iceland)	A. 2.0 m B. 96.0 kg C. 25 years	Fresh and processed (e.g., dried/salted and frozen)	A. 12 B. 945 kt	Baked, broiled, steamed, etc.
A. *Sardina pilchardus* B. European pilchard (aka sardine)	Native to the subtropical, fresh, brackish, and marine waters of the Northeast Atlantic (e.g., North, Adriatic and Black Seas)	A. 25.0 cm B. ND C. 15 years	Fresh and processed (e.g., canned, smoked, and frozen)	A. 13 B. 943 kt	Broiled, fried, and microwaved
A. *Strangomera bentincki* B. Araucanian herring	This species is found in schools (e.g., close to the surface) of subtropical, marine waters of the Southeast Pacific (e.g., near Chile)	A. 28.4 cm B. ND C. ND	Processed (e.g., fish meal for animal feed)	A. 14 B. 723 kt	ND
A. *Scomber scombrus* B. Atlantic mackerel	Temperate, brackish, and marine waters of the Atlantic Ocean (e.g., in the Baltic, Black, and Mediterranean Seas)	A. 60.0 cm B. 3.4 kg C. 17 years	Fresh and processed (e.g., canned, smoked, and frozen).	A. 15 B. 674 kt	Baked, broiled, fried, etc.
A. *Sprattus sprattus* B. European sprat	Native to temperate, brackish, and marine waters of the Adriatic, Black, North, and Mediterranean Seas, etc.	A. 16.0 cm B. ND C. 6 years	Fresh and processed (e.g., frozen, canned, smoked, and fish meal).	A. 16 B. 660 kt	Broiled and fried
A. *Engraulis encrasicolus* B. European anchovy	Native to subtropical, brackish, and marine waters of the Eastern Atlantic (e.g., Norway to South Africa), Mediterranean, and Black Seas, etc.	A. 20.0 cm B. ND C. 3 years	Fresh or processed (e.g., canned, dried, frozen, smoked, and fish meal)	A. 17 B. 605 kt	ND
A. *Brevoortia patronus* B. Gulf menhaden	In dense schools in subtropical, marine waters (e.g., the Gulf of Mexico)	A. 35.0 cm B. ND C. ND	Fresh and processed (e.g., canned, salted, fish meal, and oil)	A. 18 B. 591 kt	ND
A. *Scomberomorus niphonius* B. Japanese seer (aka Japanese Spanish mackerel)	Native to temperate marine waters (e.g., of China, the Yellow Sea and the Sea of Japan)	A. 1.0 m B. 7.1 kg C. ND	Fresh (e.g., raw as sashimi)	A. 19 B. 539 kt	Baked, broiled, and fried
A. *Sardinops caeruleus* (aka *Sardinops sagax caeruleus*) B. California pilchard (aka South American pilchard and Pacific sardine)	Subtropical, marine waters (e.g., Indo-Pacific area) and has three lineages: (1) Southern Africa (ocellatus) and Australia (neopilchardus), (2) Chile (sagax) and California (caeruleus), and (3) Japan (melanostictus)	A. 39.5 cm B. 0.5 kg C. 25 years	Fresh and processed (e.g., canned, frozen, and fish meal)	A. 20 B. 528 kt	Fried and broiled

A. *Clupea pallasi* (aka *Clupea pallasii*) B. Pacific herring	Temperate, fresh, brackish, and marine waters (e.g., of the Arctic Sea and Pacific Ocean)	A. 46.0 cm B. ND C. 19 years	Fresh and processed (e.g., canned, dried/salted, frozen, and smoked). Pacific herring are valued for roe and eggs laid on kelp. (The latter eggs when salted are termed kazunoko-kombu.) This fish is also valued as a Chinese medicine	A. 21 B. 456 kt	Baked, boiled, and fried
A. *Thunnus obesus* B. Bigeye tuna	Originates in subtropical, marine waters of the Atlantic, Indian, and Pacific Oceans	A. 2.5 m B. 210.0 kg C. 11 years	Fresh and processed (canned or frozen). The Japanese value this fish for sashimi	A. 22 B. 433 kt	ND
A. *Euthynnus affinis* B. Kawakawa	This highly migratory species originates in tropical, marine waters (e.g., Indo-West Pacific area)	A. 1.0 m B. 14.0 kg C. ND	Fresh and processed (e.g., canned, dried, frozen, salted, and smoked)	A. 23 B. 428 kt

A. *Carassius carassius* B. Crucian carp	In fresh and brackish waters of moderate temperatures of Europe, Asia and China. The European subpopulation of this species is on the 2002 International Union for Conservation of Nature and Natural Resources (IUCN) Red List of Threatened Species[f]	A. 64.0 cm B. 3.0 kg C. ND	Fresh or processed frozen	A. 5 B. 1379 kt	Baked, fried, etc.
A. *Oreochromis niloticus* (aka *Tilapia nilotica*) B. Nile tilapia	In fairly moderate waters of the Rift Valley lakes, West African Rivers (e.g., Benue), North America (farm raised), etc.	A. 40.0 cm B. ND C. ND	ND	A. 6 B. 1045 kt	ND
A. *Salmo salar* B. Atlantic salmon	Fresh, brackish. and marine waters of moderate temperatures. This species' native habitat is the Western Atlantic (e.g., Quebec, Canada), Eastern Atlantic (e.g., Arctic Circle) and landlocked areas (e.g., Russia and North America). Atlantic salmon are pen raised (e.g., in Canada)	A. 1.5 m B. 46.8 kg C. 13 years	Fresh and processed (e.g., smoked, dried, and salted)	A. 7 B. 884 kt	Broiled, microwaved, etc.
A. *Labeo rohita* B. Rohu	Tropical, fresh and brackish waters of Pakistan, India, Nepal, etc.	A. 2.0 m B. 45.0 kg C. 10 years	Fresh	A. 8 B. 795 kt	ND
A. *Catla catla* B. Catla	Subtropical, fresh and brackish waters of Pakistan, Nepal, Myanmar, etc.	A. 1.8 m B. ND C. ND	ND	A. 9 B. 653 kt	ND
A. *Cirrhinus mrigala* (aka *Cirrhinus cirrhosus*) B. Mrigal	Tropical, fresh and brackish waters of India	A. 1.0 m B. 12.7 kg C. ND	ND	A. 10 B. 573 kt	ND
A. *Parabramis pekinensis* B. White amur bream	Tropical, fresh waters of Sungari, Liao, China, etc.	A. 55.0 cm B. 4.1 kg C. ND	ND	A. 11 B. 512 kt	ND
A. *Chanos chanos* B. Milkfish	Tropical, freshwater, brackish and marine species native to the Indo-Pacific area. Their range includes Asia, Japan, Australia, Red Sea, Africa, etc. They are also found from California to Galapagos	A. 1.8 m B. 14.0 kg C. 15 years	ND	A. 12 B. 462 kt	ND

A. *Oncorhynchus mykiss* B. Rainbow trout	Rainbow trout are native to temperate, fresh, brackish and marine waters from Alaska to Mexico as well as waters of Asia (e.g., Eastern Russia). Rainbow trout have been disseminated worldwide (e.g., Africa, Asia, New Zealand, and South America)	A. 1.2 m B. 25.4 kg C. 11 years	Fresh or processed (e.g., canned, smoked, and frozen)	A. 13 B. 448 kt	Baked, boiled, microwaved, steamed, etc.
A. *Ictalurus punctatus* B. Channel catfish	Fresh waters of moderate temperatures in Canada, Mexico, and USA	A. 1.3 m B. 26.3 kg C. 16 years	Fresh and processed (e.g., smoked and frozen)	A. 14 B. 269 kt	Baked, broiled, fried, etc.
A. *Anguilla japonica* B. Japanese eel	Tropical, fresh, brackish and marine waters of Japan, Taiwan, Korea, China, etc.	A. 1.5 m B. 0.8 kg C. ND	Fresh or further processed (e.g., smoked, canned, and frozen)	A. 15 B. 220 kt	Baked, broiled, and steamed
A. *Cirrhinus molitorella* B. Mud carp	Tropical, fresh waters of Mekong, Chao Phraya, Nanpangjiang, and Red River	A. 55.0 cm B. ND C. ND	Fresh and as prahoc (fish paste)	A. 16 B. 200 kt	ND
A. *Mylopharyngodon piceus* B. Black carp	Subtropical, fresh waters of the Amur River basin and China	A. 1.2 m B. 32.0 kg C. ND	ND	A. 17 B. 171 kt	ND
A. *Serbia quinqueradiata* B. King amberjack (aka Japanese amberjack by some sources)	Subtropical, marine waters of the Northwest Pacific (e.g., from Japan to the Hawaiian Islands)	A. 1.5 m B. 40.0 kg C. ND	Fresh for sashimi	A. 18 B. 137 kt	ND

Table 3 Average nutritional data per 100 g of raw tissue from selected finfish groups[a,b]

Groups[c]	Water (g)	Energy (kJ)	Protein (g)	Total fat (g)	Calcium (mg)	Iron (mg)	Sodium (mg)	Ascorbic acid (mg)	Riboflavin (mg)	Niacin (mg)	Cholesterol (mg)
1	68.50	797.6	17.54	12.82	26.0	0.85	70.8	1.22	0.150	4.757	75.6
2	72.99	562.7	19.19	5.82	44.9	0.86	60.4	0.84	0.110	5.490	60.0
3	70.79	441.5	22.69	0.98	22.5	0.99	37.0	1.00	0.074	12.600	46.0
4	79.56	323.7	16.56	0.72	17.0	0.26	72.0	0.33	0.091	2.118	44.7

[a]The raw data for this table were obtained from the United States Department of Agriculture, Agriculture Research Service, Nutrient Data Laboratory at http://www.nal.usda.gov/fnic/foodcomp

[b]Groups 1, 2, 3, and 4 had energy ranges of 858–766, 619–519, 452–431, and 343–289 kJ, respectively.

[c]Group 1 consisted of Atlantic mackerel, Pacific herring, Greenland halibut, eel (mixed species) and Atlantic salmon (http://www.cfsan.fda.gov/~frf/rfe1at.html); group 2 contained milkfish (http://www.cfsan.fda.gov/~frf/rfe1ml.html), Spanish mackerel, rainbow trout, channel catfish, whitefish (mixed species), European anchovy, carp and bluefish; group 3 was made up of yellowfin tuna (http://www.cfsan.fda.gov/~frf/rfe1yn.html) and skipjack tuna; and group 4 was comprised of Atlantic cod, walleye pollock and orange roughy (http://www.cfsan.fda.gov/~frf/rfe1or.html).

obesity in developed countries such as USA. Further, some individuals may be concerned about consuming enough calcium for bones and iron for blood, whereas others may be interested in maintaining lower sodium intake to help decrease their potential for high blood pressure. The three vitamins were selected to show examples of those components that appeared to be important to consumers or to be significant in some fish flesh.

Processing of Finfish

Finfish products can be processed fresh, frozen, cooked, precooked, smoked, cured, canned, etc. For example, finfish might be caught and immediately transported to the processing plant in tank trucks with water. Fish may be received live at the facility and may then be stunned, headed and gutted, and washed as needed. Afterwards, fish may be cut into fillets (with skin-on or skinless) followed by a liquid cooling step. Next, fillets might be inspected (e.g., for parasites or nematodes), cut and deboned, and evaluated for size or graded. The product can then be put into packing containers and the containers passed over scales to determine the weight and labeled. The last steps might involve chilling and storage at the plant before transporting the product for sale.

Similarly, after fish have been harvested and frozen, fish can be shipped to a processing facility. At the plant, the fish can be received, thawed and examined, sorted, and passed like fresh fish through inspection. The fillets can then be individually quick frozen and glazed with water. The rest of the processing operation is as above, except that the product might be stored frozen before shipment to consumers.

The first steps of smoking fish might approximate the above processes. After the fillet is produced, the tissue might be salted and then rinsed before being placed onto a metal rack for subsequent smoking (hot or cold). After smoking, the product should be cooled before further processing (e.g., coloring and slicing). Smoked product is packaged, frozen, etc. as in the earlier processes. Cured and salted fish might be processed as in the smoked fish operation except that it has a drying step rather than a smoking cycle. These cured and salted products might be stored refrigerated or dry.

Additional fish processing operations (e.g., battered and breaded, precooked or cooked, canned, and modified atmosphere packaged) are not covered here and the reader should refer to other articles in the Encyclopedia and to the Further Reading listed at the end of this article to learn more on these topics.

Potential Health Issues Associated with Finfish

Finfish products are generally safe for human consumption. However, fish are animals and they might have parasites (e.g., anisakid nematodes) that can be killed by freezing or by cooking. In addition, they might contain toxins that are harmful to consumers.

Subjection of scombroid species (e.g., mackerel and tuna) to improper handling and chilling after harvesting can result in histamine formation by bacteria and to consumers being afflicted with scombroid poisoning or histamine toxicity. Reef fish (e.g., barracuda and snapper) might consume toxic dinoflagellates. Subsequently, when humans consume the fish tissue they could become ill from ciguatoxin. Puffer fish might contain a tetrodotoxin, which can be fatal to consumers.

Escolar is a fish that might cause consumers to have diarrhea due to gempylotoxin. Other health concerns include finfish that have been contaminated with chemicals such as heavy metals (e.g., methyl mercury), polychlorinated biphenyls , pesticides, drugs, etc.

Despite the previous comments, it is important to emphasize that finfish products are safe for human consumption in the vast majority of cases and that potential risks can be prevented with adequate processing.

Welfare Issues

Animal welfare has become increasingly important worldwide. A fundamental issue when deciding on moral duties of humans toward animals is whether they are capable of experiencing pain and other forms of suffering such as fear and distress. The welfare of fish has been much less studied than that of mammals and birds, and considerable debate with opposing views still exists on the ability of fish to suffer. The main argument used by those that deny that fish are capable of experiencing negative emotions including pain is that fish lack the extensive cerebral cortex of mammals. This argument,

however, has several problems. First, it has been suggested that emotional responses might not depend on higher forms of consciousness, but on more basic ones. Second, a given function might be served by different brain structures in different animals, and the possibility exists, therefore, that brain structures other than the cortex might support emotional experiences in fish. In this context, it is particularly relevant that the dorsomedial part of the telencephalon of fish seems to be homologous to the mammalian amygdala, which is involved in arousal and emotion, particularly fear.

Several criteria have been proposed to decide whether an animal is capable of experiencing pain. These criteria are as follows:

1. Presence of functional nociceptors.
2. Presence of nervous pathways leading to higher brain structures.
3. Activation of brain structures during potentially harmful or injurious stimulation.
4. Presence of endogenous opioids and opioid receptors.
5. Suppression of responses to noxious stimuli by analgesics.
6. Changes in behavior (including avoidance behavior and inhibition of normal behavior) associated with noxious stimulation.

Current scientific evidence suggests that fish – or at least some fish species – meet all these criteria. For example, studies in rainbow trout (*Oncorhynchus mykiss*) have shown that there are nociceptors on the face of the trout and that they are innervated by the trigeminal nerve, which projects to the thalamus as in mammals. Opioids and opioid receptors equivalent to those found in mammals have been identified in fish brains. Studies in the goldfish (*Carassius auratus*) have shown that brain activity changes during noxious stimulation. Changes in behavior (including an increase in respiration rate, a decrease in feed intake, and a decrease of fear response to a novel stimulus, supporting the idea that pain dominates fish attention) have been described in rainbow trout associated with noxious stimulation, whereas these changes do not appear if fish are given analgesics.

Taking all this evidence together, the Panel on Animal Health and Animal Welfare of the European Food Safety Authority concluded that "The balance of evidence indicates that some fish species have the capacity to experience pain. However research and developments in the area of cognition and brain imaging techniques should be carried out in fish to further our knowledge and understanding of pain perception."

Fear is another negative emotional experience with obvious effects on welfare. Fish show a variety of behavioral responses to threatening stimuli, including escaping and becoming motionless. Additionally, fish can learn to avoid threatening stimuli, suggesting that a cognitive process is involved in their fear response. A cognitive process is further supported by the analogy between the amygdala of mammals and the dorsomedial part of the telencephalon. The conclusion of the Panel on Animal Health and Animal Welfare of the European Food Safety Authority on fear in fish was that "Responses of fish, of some species and under certain situations, suggest that they are able to experience fear."

Stress physiology of fish has been studied over the past decades and has been shown to be similar to that of mammals. Chronic stress in fish, as in mammals, may have negative effects on health, for example, by impairing the immune function. Another similarity between fish and mammals is that both show individual differences in their stress response, some individuals adopting an active strategy and others a more reactive one. The Panel on Animal Health and Animal Welfare of the European Food Safety Authority concluded that "Fish possess a suite of adaptive behavioral and physiological responses that have evolved to cope with stressors. Many of these are homologous with those of other vertebrates…Prolonged exposure to stressors generally leads to maladaptive effects or chronic stress."

Nonfinfish

By definition, sharks, skates, and rays, for example, were not included in the finfish category. Several species of these animals are marketed (e.g., fresh, frozen, dried/salted, and smoked) in interstate/intrastate commerce. Further, some species are utilized to produce fish meal, fish oil, liver oil, shark fin soup, drugs or medicines, leather from hides, etc.

Game and Exotic Animals

LC Hoffman and D Cawthorn, Stellenbosch University, Matieland, South Africa

Glossary

Antelope The term referring to a diverse group of even-toed ungulate species that is indigenous to various regions in Africa and Eurasia.
Bushmeat The meat derived from wild animals that are hunted for subsistence or informal trade, most often illegally.
Dressing percentage The percentage of an animal's live weight that becomes the carcass weight at slaughter, determined by dividing carcass weight by live weight and multiplying by 100.
Farmed game Land animals and birds that are not conventionally regarded as domesticated but are bred and reared in captivity.
Game birds A broad collection of birds, grouped into land fowls and waterfowls that are hunted for sport and food.
Game meat Meat derived from land animals and birds that are legally hunted in the wild.
Ungulate A mammal with hooves.
Venison The term mainly used nowadays to refer to the meat from deer species.
Wild game Free-ranging land animals and birds that are legally hunted in the wild for food.
Zoonotic disease An animal disease that can be transmitted to humans.

Introduction

Species of wildlife or game may be harvested to obtain meat, fur, skins, feathers, antlers, horns, or trophies. In particular, the use of wild animals for food is as old as humankind itself and the meat remains an important food source for many people throughout the world. With the escalating demand for animal protein from domestic animals, coupled with the decreasing supply and the high prices associated with such products, it has become inevitable for many populations to turn to meat from the wild as an alternative, including game and other exotic animals.

The conceptualization of a uniform definition for 'game' has been an issue of ongoing debate over the years and this differs widely in different parts of the world. Some sources define game as only those free-roaming land animals and birds that are hunted for food in their wild environment. According to such a definition, game meat is the result of the process of natural selection, rather than of human 'production.' Other sources, however, use the term to include both those land animals and birds – either wild or farmed – that are not generally considered to be domestic animals. The division of 'large' and 'small' game species is equally confounded, with the legal definitions of these, as well as their range and population levels, also varying from country to country. Since the production, distribution, veterinary inspection protocols, and public health risks differ vastly between wild, extensively farmed, and intensively farmed animals, it is important for concrete distinctions to be made between the latter groups. From a practical viewpoint, it might be preferable to consider 'game' as all animal and bird species that can be legally killed by hunting (recreational or commercial) and that will or may be subsequently used for human consumption. Alternatively, the term 'wild game' may be used for free-range animals/birds legally hunted in the wild, while 'farmed game' might be applied to those not conventionally regarded as domesticated but are bred and reared in captivity.

From a consumer perspective, it is also likely desirable to discriminate the meat of wild, free-roaming game from that of farmed species. Traditionally, the term 'venison' has been loosely applied around the world to describe the meat from any animal considered to be a game species. Although the English word 'venison' originated from the Latin *venari* (to hunt, pursue), today its use is largely restricted to the flesh from various cervid (deer) species, which are being increasingly farmed in the Northern Hemisphere for food. Some argue that these animals are becoming more domesticated in the sense that the farmer often decides which animals will be bred, what feed will be fed, and which animals will be slaughtered. For this reason, it is recommended that the term 'game meat' be exclusively used for the meat derived from animals/birds hunted in the wild (e.g., free-ranging antelope, wild boar, and game birds) and which can essentially be considered 'natural' or 'organic.' However, the term 'venison' should potentially be reserved for the meat from cervids, and perhaps also for that from other 'farmed game' species (in accordance with the aforementioned explanation) (e.g., rabbits and birds reared in captivity). Further, it is essential to define the term 'bushmeat,' which generally refers to the meat from wild animals that are hunted for subsistence or for the informal market, most often illegally. Although originally associated with primates, bushmeat also encompasses hippopotami, elephants, giraffe, zebra, antelope, water buffalo, wild cats, birds, reptiles, and rodents. The bushmeat trade is enormous in Africa and other developing third world countries, mainly as a consequence of rural poverty and the availability of external markets. This has not only resulted in the overexploitation and decline of a large number of wildlife species (many of which are protected by international wildlife legislation and treaties), but also poses a public health risk as these

animals may harbor diseases and would not typically undergo veterinary inspections.

One of the major drivers for the growing acceptability and consumption of game meat can be attributed to increasingly health-conscious modern consumers, as the aforementioned species are known to produce leaner meat compared to domestic livestock species. Another motivator for the increased demand lies with rising consumer concerns about the environment and there is thus the desire for organic products, as well as products produced by natural production (low-input systems) methods. There is also a new generation of younger consumers who wish to try new adventurous foods and many tourists to Africa wish to eat local wild species, ranging from springbok to crocodile as part of the 'Africa experience.' It is common to find game meat or venison on the menu of top-class restaurants throughout the major cities of the world. Furthermore, with the intercontinental immigration of diverse cultures and the fact that the world has become one large global village, many individuals are increasingly seeking access to their own traditional meats even when they are far from home. The farmed game animal industry has experienced unprecedented growth over the last few decades, largely reflecting the aforementioned consumer interests in lean and alternative food products.

Species that are discussed in this article include various ungulates (farmed and wild species) and game birds, emphasizing carcass characteristics, nutritional composition, and palatability attributes. The distribution, population, and hunting methods will not be discussed in detail as this information can be found in various literature sources and is very species-specific. Bushmeat will not be covered in depth as many species that are traded illegally are also traded legally, and are thus covered in that specific section. Since fish are excluded from the term 'game,' these are not discussed further in this section (although some fish caught for sport are termed game fish).

Game Production, Consumption, and Economics

Although it is extremely challenging to obtain reliable data relating to the extent of the global game meat trade, it is accepted that formal game production still constitutes a small share of the word's overall meat production. Africa, the two Americas, Oceania, and Europe are considered to be among the primary game producers. Records from the United Nations Food and Agriculture Organization Statistical Database (FAOSTAT) suggest that the total global game production in 2011 was more than 1 942 500 tons. The African countries that were reported to contribute substantially to the FAOSTAT figures included Nigeria (163 000 tons), Ghana (74 300 tons), South Africa (46 000 tons), and Kenya (25 100 tons). In addition, game production in 2011 in the United States (US) was estimated at 248 000 tons, whereas in the European Union (EU) this was in the order of 130 990 tons. However, it is unlikely that the magnitude of the illicit bushmeat trade was taken into account in the former calculations, neither the value of internal trade or direct sales by hunters to local consumers and establishments. In the Congo Basin alone, for instance, the bushmeat harvest is expected to be upward of one million tons per year.

In South Africa, more than 1 million animals (comprising approximately 35 different species) are harvested a year by recreational game hunters alone and the annual turnover from this industry is around ZAR 3 billion (1 ZAR = 0.095 USD (approx.)). The number of game slaughtered in Canada in 2012 exceeded 668 000 head and more than one million kg of game meat was exported from the country in the same year.

With the exception of poor communities, game meat does not constitute a high proportion of the total meat consumed. The estimated annual per capita consumption of wild and farmed game meat in Austria, France, Germany, Poland, and Switzerland is 0.6–1.0 kg. Ungulates (e.g., deer, moose, and wild boar) contribute approximately 3.3 kg per capita per annum in Norway and 1–4 kg per capita per annum in Italy. Much of the game meat consumed is either from a personal hunt or from value-added products. These range from fermented and processed products adhering to first world standards in Europe to smoked dried meat in Africa.

Birds

The ratites and game birds are among the most important meat-producing birds, being consumed and traded on markets across the globe. Their production systems are not described in this section as this has been done elsewhere.

In terms of the ratites, the raising of ostriches for meat has become well established and has been commercially successful. The birds are generally slaughtered in highly sophisticated abattoirs with strict hygiene controls rather than being hunted in the wild. Attempts have also been made to raise the emu and rhea for commercial purposes, although this has been less effective due to their low yield and the lower market value of their meat and other products. Owing to the morphological structure of ratites – with most of the meat being found on the leg – they have a low lean meat yield (Table 1). Ratites have only small localized subcutaneous fat depots, normally above the legs and then a well-developed fat pad over the belly, posterior to the keel. The low intramuscular fat and favorable fatty acid profile has resulted in an increased global demand for ostrich meat over the past years (Table 1). The fatty acid profile of the birds has been shown to be influenced by the diet.

Table 1 Summary of carcass yields and nutritional values of selected ratites

	Ostrich	*Emu*	*Rhea*
Bodyweight (kg)	85	41	25
Carcass weight (%)	59	53	61

Fat (%)	0.5	1.7–4.5	1.2
Energy (kJ per 100 g)	390	471–531	439
Cholesterol (mg per 100 g)	57	39–48	57

Table 2 The mean weights (±standard deviation (sd)) of the major muscles from ostriches having live weights of 85–95 kg

Muscles	*Mean weights (kg±sd) for muscles (n = 34)*	*Muscles expressed as mean percentage (%±sd) on a leg weight basis*
M. femorotibialis accessorius	0.69±0.10	4.7±0.5
M. fibularis longus	0.29±0.04	2.0±0.3
M. flexor cruris lateralis	0.30±0.04	2.1±0.3
M. gastrocnemius pars externa	0.59±0.08	4.0±0.7
M. gastrocnemius pars interna	0.84±0.13	5.7±0.8
M. iliofemoralis	0.40±0.06	2.8±0.4
M. iliofemoralis externus	0.19±0.03	1.3±0.2
M. femorotibialis internus	0.11±0.02	0.8±0.2
M. iliofibularis	1.41±0.15	9.6±1.1
M. iliotibialis cranialis	0.49±0.07	3.4±0.6
M. iliotibialis lateralis	1.08±0.15	7.5±0.9
M. obturatorius medialis	0.55±0.08	3.8±0.7

The most commonly marketed meat is derived from the posterior limbs and includes whole muscle cuts such as the Musculus iliofibularis (fan fillet), M. iliofemoralis (side strip), M. iliotibialis cranalis, M. femorotibialis accessorius, M. fibularis longus, M. flexor cruris lateralis, M. obturatorius medialis, M. gastrocnemius (big drum), and M. iliotibialis lateralis (Table 2).

Slight differences in the chemical composition and quality characteristics are found between the muscles within the ostrich carcass. Similar to other farmed livestock, the muscle composition is influenced by factors such as genetics, age, and diet. Gender has a smaller influence because most birds are slaughtered as they reach sexual maturity (10–14 months of age).

In spite of the success of the ostrich industry, the international trade in ostrich meat has been negatively influenced by outbreaks of Avian influenza, which has forced large producers in Africa to explore other avenues for meat utilization. These have included promoting consumption locally and in neighboring countries, processing the meat into various value-added products (Table 3), as well as employing a heat treatment to produce *sous vide* products that are exported.

The expression 'game bird' describes a very broad collection of birds grouped into land fowls and waterfowls, including species in the following orders: Galliformes (including guinea fowls, partridges, quails, francolins, and pheasants), Anseriformes (including ducks and geese), Columbiformes (including doves and pigeons), Pterocliformes (including sandgrouse species), and Charadriiformes (including snipes). Game birds have long been hunted for recreational reasons, but their popularity as a food source is growing and these are now obtained from the wild, as well as being farmed. The game bird industry has developed into a multimillion dollar industry, particularly in the United States and European Union, and it is also emerging in South Africa, with its success being accompanied by the ongoing management and conservation of bird populations. In the United States, more than 38 million game birds are shot each year, many of which are destined for restaurants or these are marketed directly to consumers. In the United Kingdom, approximately 19 million game birds were shot in 2004 alone, of which the majority were also incorporated into the country's food chain.

Captive-bred birds are an integral part of the international industry, chiefly in Europe, where large numbers of game birds are bred annually for release into the wild. It is estimated that more than 20 million game birds (80% are pheasant and the rest are mainly red-legged partridge) are reared and released for hunting in the UK each year, with most of the hunted birds being consumed by the hunters, farmers, or beaters. Gray partridge and ducks are also reared for this purpose.

The composition and quality of the meat from different game birds can vary quite substantially and is largely dependent on the diet of the birds. Some game birds closely resemble chicken and comprise mainly white meat, whereas others have a stronger 'gamey' flavor and can contain more dark meat. The proximate composition of selected game birds is shown in Table 4. In general, most game birds have a relatively low fat content, meaning they commonly need to be basted or larded before roasting. Wild birds are normally much leaner than the varieties reared in captivity. Older birds can be tougher and are usually best cooked with slow moist heat, or used in stews or soups.

As wild game birds are normally hunted using shot guns, the possibility of lead residues in the muscle has raised some speculation and has been the subject of considerable research. Lead from ammunition in game meat is more bio-accessible after cooking, especially when using highly acidic recipes that include substances such as vinegar.

Deer

Deer are ruminant mammals of the family Cervidae that can be found in the wild or kept in parks, but which are also increasingly being farmed both extensively and intensively in New Zealand and parts of the northern hemisphere. In particular, New Zealand (having the largest farmed deer population in the world) produced approximately 23 308 tons (carcass-weight equivalent) of venison between 2012 and 2013, of which around 95% was exported after processing. Nonetheless, the hunting of these species in the wild remains popular throughout Europe and North America. Fallow deer (*Dama dama*) and red deer (*Cervus elaphus*) are the most commonly farmed in Europe, whereas the elk or wapiti (*Cervus*

canadensis), fallow deer, sika deer (*Cervus nippon*), axis deer (*Axis axis*), and white-tailed deer (*Odocoileus virginianus*) are mainly farmed in the United States and Canada. The herding of reindeer is mostly carried out in the Nordic countries.

Similar to farmed domestic livestock species (cattle and sheep), various factors can influence the carcass yield and lean yield of deer species (Table 5). Adult animals will have a lower bone yield than subadults due to the fact that bone matures earlier than muscle and fat. The lean yield in mule deer, elk (wapiti), and pronghorn antelope varies from as high as 78% to as low as 57% of the skinned carcass, depending on how the lean yield is calculated. Commercial lean yield percentages vary according to the skill with which the meat is trimmed off the bone and the amount of fat and connective tissue trimmed. The lowest yields are normally obtained from the carcasses of hunted deer, as hunters seldom have the skill to trim efficiently and there is also lean meat lost due to bullet damage, fly strike, and spoilage.

Venison consumption is particularly common in the United States, central Europe, and the United Kingdom. In general, consumers are drawn to its tenderness, low fat content (but favorable lipid composition), and high mineral levels (Table 6). Only very fat carcasses will have a visible subcutaneous fat layer. The same factors that influence the fatty acid composition of ruminants will influence the fatty acid composition of cervids (Table 7).

African Ungulates

The ecosystems of sub-Saharan Africa support a wide range of wild ungulate (hoofed animals) species, including more than 70 antelope species. Antelope not only signify a vital component of the fauna attracting game-viewing tourists and hunters, but they also provide a significant source of protein for human consumption.

South Africa and Namibia are the two countries that have the most developed game meat industries in Africa. In these regions, wild ungulate species are often harvested using modern technologies and are processed according to strict EU regulations utilizing Standard Operating Procedures (SOPs) and Veterinary Procedural Notices (VPNs) to produce meat destined for the formal local and international meat trade. The game species harvested commercially are mainly the springbok (*Antidorcas marsupialis*; >80%), blesbok (*Damaliscus pygargus phillipsi*), and kudu (*Tragelaphus strepsiceros*), while the blue wildebeest (*Connochaetes taurinus*), impala (*Aepyceros melampus*), and gemsbok (*Oryx gazella*) are exported in smaller numbers. The duiker species (subfamily Cephalophinae) are most commonly targeted in the bushmeat harvest and trade throughout Africa.

A major problem faced by both these two countries as pertaining to the export of game meat is the prevalence of zoonotic diseases, particularly foot-and-mouth disease. In South Africa and Namibia, the endemic viral types are the Southern African Territories types of foot-and-mouth virus, SAT 1, 2, and 3.

In contrast to farmed deer that are harvested in commercial abattoirs, the hunted ungulates are normally eviscerated in the field and dressed in informal to formal facilities. Most of the hunted species are hunted for recreational purposes and are consumed by the hunters or landowners and their immediate families. There have been some concerns about the consumption of meat that might contain residual lead (from the bullets) although it would seem as if the levels in the muscle are low.

The dress out percentages of game meat species differ due to the influence of similar factors (age, gender, etc.) that influences the yield in other domestic species (Table 8). However, where males have horns and females have none, the former will have a lower yield.

Most game species have no subcutaneous fat layer with the exception of the zebra, which has a very thick subcutaneous fat cover. Although reliable information on the proximate composition of many African ungulate species is limited in the scientific literature, that which is available indicates that the meat from these species can be considered highly nutritious and a valuable source of protein (Table 9). The meat also has a low fat content (generally <2.5%, with the exception of blesbok), with desirable ratios of polyunsaturated fatty acids (PUFA) to saturated fatty acids (SFA), as well as omega-6 to omega-3 fatty acid ratios. The fatty acid composition of game meat is like most ruminants, influenced to a lesser extent by the diet. Nonetheless, game species can be divided into grazers that only consume grass, mixed feeders that consume both grass and browse, and the browsers. The impala (*Aepyceros melampus*) is a mixed feeder and will consume the more dominant feed type found in the region, which leads to slight differences in the fatty acid profile of muscle (Table 10).

Table 5 Lean, fat, and bone percentages in carcasses of some dissected Cervid species

Species	*Percentage*

Wild boar, belonging to the genus *Sus* and pig family (Suidae), is regarded as the wild ancestor of the domestic pig. The species is native to many parts of Central and Northern Europe, the Mediterranean and Asia, but has also been introduced into some regions (notably Australasia and the Americas). Although long valued for food and recreational hunting, the animals have also come to be regarded as agricultural pests and a threat to the ecosystem. The recent widespread intensifying of wild boar densities has stimulated interest in the animals as meat producers and also as a

potential farmed species. Today, the wild boar is propagated in Canada, Japan, the United States, and the Americas.

Dressed weights (assumed to include the heads) for 3- to 4-year-old hunted wild boar have been reported to be 65–108 kg for males and 50–80 kg for females. The carcass yields of animals hunted in Poland varied from 59% to 74% (the skin contributed ~16–29% of initial weight), and increased with bodyweight. Yields of 81–83% have, however, been reported for adult and medium-sized boars hunted in Croatia and Italy, respectively. In comparison to the domestic pig, wild boar exhibits more carcass fatness and larger loin areas, while having darker, leaner, and less tender meat. The mean proximate composition of wild boar hunted in Italy was described as approximately 70.5% moisture, 25.9% protein, 1.5% fat, and 1.2% ash. Although the flavor and fatty acid composition of the wild boar may be affected by the gender and age of the animals, this is also largely influenced by the diet provided (as with other monogastric animals). The latter is largely evidenced in the depot fat of the wild boar, where unlike ruminants, the double bonds of fatty acids do not become hydrogenated during the process of digestion. An example of the fatty acid profile of hunted wild boar is shown in Table 11. The ratio of PUFA:SFA in wild boar is estimated at 0.52–0.6.

The warthog (*Phacochoerus africanus*) is a further wild member of the Suidae that has a natural distribution in the grasslands, savannah, and woodlands of sub-Saharan Africa. The species is characterized by a high fecundity (having 4–5 piglets per litter, gestation period of 167–175 days) and is frequently regarded as an agricultural pest in many farming regions. The meat has been consumed by locals in South Africa for many years and it is also being increasingly sought by tourists visiting the country's restaurants as part of a novel, uniquely African culinary experience. Recent research has focused on obtaining an enhanced understanding of the chemical composition of the meat, the development of value-added products and the promotion of its consumption based on its health and exotic qualities, with all these activities aimed at providing incentives for better management of growing warthog populations.

Mature warthogs can attain body weights of 100 kg in males and 70 kg in the females. The dressing percentage is in the order of 52%, which is somewhat lower than domestic pigs. However, in contrast to domestic pigs, carcass weight in

warthogs does not normally include the head, skin, and adjacent subcutaneous fat layers, which can largely account for the aforementioned factor. In warthogs, the contribution of the shoulder (37%), hind legs (32%), belly (14%), back (9%), and loin (7%) to the cold carcass weight also differs from that obtained from domestic pigs.

Findings relating to meat quality characteristics suggest that warthogs are prone to develop pale, soft, and exudative (PSE) meat when exposed to ante mortem stress, which is a similar phenomenon seen in domestic pigs under comparable conditions.

Warthog meat is of a high nutritional value and has a favorable fatty acid profile (Table 12), although the latter can be influenced by the diet as with the wild boar. The ratio of PUFA to SFA is approximately 1.33 (compared to 0.46–0.64 in domestic pigs), which is well above the minimum level of 0.4–0.5 recommended to be appropriate for human health.

The bushpig (*Potamochoerus larvatus*) is a nocturnal wild pig species found in woodlands, forests, riverine vegetation, and reed beds in parts of East and Southern Africa. Similar to the warthog, many farmers in these regions consider the bush pig as a problem animal, as it thrives on many agricultural products and unearths root crops in their masses. In spite of this, the meat of the bushpig is still relished as a delicacy. Nonetheless, there is currently little available data on its quality and composition characteristics.

Kangaroos

Kangaroos are marsupial species of family Macropodidae that are endemic to Australia, the meat from which has been consumed by the aboriginal inhabitants of this region for tens of thousands of years. Certain kangaroo species are abundant in rural Australia, being considered pests in some regions. Thus, the commercial harvest of these species from the wild is permitted in a number of Australian states, although this is under regulatory control. The red kangaroo (*Macropus rufus*), western gray kangaroo (*M. fuliginosus*), and eastern gray kangaroo (*M. giganteus*) comprise approximately 90% of the commercial harvest.

Although 70% of the Australian kangaroo harvest is currently exported, the meat also has a niche market in Australia and is sold in both restaurants and retail outlets. Kangaroo meat has a strong flavor, is high in protein, as well as iron and zinc. The total fat content ranges from 0.2 to 1.4%, depending on the species. This consists of approximately 32% SFA, 31% monounsaturated fatty acids (MUFA), and 38% PUFA. The major SFAs in the meat include palmitic and stearic acids, whereas oleic acid is the predominant of the MUFA. The main PUFA include linoleic acid, arachidonic acid, and α-linolenic acid, respectively. The cholesterol levels are low and range from 41.6 to 65.3 mg per 100 g (depending on species, geographical origin, and cut) and the meat has a favorable omega-6:omega-3 fatty acid ratio of 2.5:1.

Rabbits and Hares

Rabbits and hares are plentiful in many regions of the world and these are included in the diets of many populations. More than 60 species are documented within the Leporidae family. All hare species belong to the genus *Lepus* and rabbits belong to eight different genera. Native rabbit and hare species occur throughout Africa, America, Asia, and Europe.

Man has used rabbits as food since 1500 BC. Today, these species can be hunted in the wild for consumption, but they are most commonly bred for meat in many parts of the world, including the United States, several European countries, Africa, and China. Rabbit breeding is particularly recognized to have potential for supplying high-value protein and for improving food security in the developing world. Since rabbits can adapt to diverse environmental conditions, have high reproductive and growth rates, as well as good feed conversion efficiencies, they are considered favorable meat producers. The Californian and New Zealand White are leading commercial breeds, with high ratios of muscle for their size.

Fresh rabbit meat is sold in butcheries and markets in certain countries, while some supermarkets also sell frozen rabbit meat. Recent reviews on rabbit meat composition have confirmed that this is of high nutritional value compared to meat from other domestic animals. Rabbit meat is very palatable and is rich in high-biological value protein (~20–22%) and bioavailable micronutrients. It is generally low in calories, fat (although this varies according to the cut) and cholesterol. The leanest cut is usually the loin (1.8% fat), whilst the foreleg is the fattiest cut (8.8% fat). The meat from wild rabbits is normally leaner than that from their domesticated counterparts, with mean total fat values of 1.05% and 5.55% in the respective animals. As rabbits are monogastric animals, the fatty acid composition of their meat is strongly influenced by the diet consumed, thus the PUFA content could be increased by supplementing diets with vegetable oils, such as linseed and rapeseed oil, or with fish oil. In rabbit meat, unsaturated fatty acids represent approximately 60% of the total fatty acids and the PUFA comprise approximately 32.5% thereof.

Bison

Although bison (*Bison bison*) was previously nearly hunted to extinction, this species is now farmed successfully in Canada and America. The farmed bison population in Alberta, Canada is estimated at >90 000 head, while approximately 500 000 plains bison are said to exist in all of North America. It is calculated that 96% of the animals are selected for anthropogenic commodity production and less than 4% of the herds are managed for conservation purposes. Canada harvests just under 20 000 bison per annum. Factors influencing the carcass characteristics are similar to those observed for cattle, such as the females tend to gain fat earlier than males and there is an increase in meat toughness with age.

In many instances, bison meat has been promoted to a niche market as a product with a strong heritage, unique flavor, dark red color and that is a healthy and nutritious red

meat alternative. Most bison cuts have a protein content that varies from 21.0 to 23.0%. The total fat content of the meat is approximately 1.0–4.6% (depending on the cut), consisting of 0.4–1.3% saturated fat, 0.5–1.5% monounsaturated fat, and 0.1–0.2% polyunsaturated fat. The cholesterol levels found in bison muscles also varies from 25.7 to 48.3 mg per 100 g, values similar to those of other red meat species, when factors such as intrinsic variation between muscle groups, gender as well as analytical methodology is taken into account.

Camelids

Camelids of the family Camelidae comprise the genera *Camelus* (including true camel species), *Lama* (including guanaco and llama), and *Vicugna* (including alpaca and vicuña), although the term 'camel' is normally used broadly to refer to all of these camel-like animals.

Within the true camel species, the one-humped dromedary (*Camelus dromedarius*) accounts for up to 90% of all the camels found, whereas the two-humped Bactrian camel (*Camelus bacterium*) represents the remainder. Approximately 80% of the world's camels are found in Africa, with Northeast Africa having the largest population of dromedaries.

The average slaughter weight of mature, fattened desert camels is around 450 kg. The dromedary (*Camelus dromedarius*) dresses out at approximately 56% of live body and 64% of empty bodyweight, yielding 56% meat, 19% bone, and 13.7% fat. Fat partitioning differs between different body sites of the camel carcass and its distribution is quite unique when compared to other animals. The largest proportion of the camel's fat reserves occur in the hump (~30%), which accounts for up to 5% of live weight and 8% of carcass weight. A significant fat depot also exists on the abdominal floor.

In 2009, the total world camel meat production amounted to over 360 000 ton, with Saudia Arabia, Sudan, Somalia, and Egypt being among the primary producers. Camel meat is often valued in harsh, dry environments where beef is in low supply and is popular throughout the Muslim world, in parts of Africa, Australia, and China. It is, however, noteworthy that some taboos exist with regards to camel meat consumption in certain cultures and religions. For instance, camel meat is seldom eaten in Europe and North America and its consumption is prohibited in the Torah for practicing Jews, for the Raikes or Rabaris of India, and for Ethiopian Christians.

Camel meat is raspberry red to dark brown in color and is considered to be healthy compared to meat from many other animals. Compared to the meat from domestic livestock species, camel meat has a low fat content, higher moisture content, and similar protein content (**Table 13**). The hump frequently forms part of the sirloin cut and can result in the latter having high lipid content. The ratio of essential amino acids to nonessential amino acids is approximately 0.85, similar to the 0.86 reported for beef, 0.83 for lamb, and 0.90 for goat. Camel meat also has a similar mineral profile compared to domestic livestock, although it might have slightly higher sodium levels. The cholesterol content of the meat is believed to increase with the age of the camel (135 mg per 100 g fresh weight for 8 months old compared to 150 mg per 100 g fresh weight for 26-month-old animals).

Of the genera *Lama* and *Vicugna*, the llama (*Lama glama*) and alpaca (*Vicugna pacos*) are domesticated. The guanaco (*Lama guanicoe*) and vicuña (*Vicugna vicugna*), however, are wild, and commercial farming of the latter two remains limited. The llama is produced for both its meat and fiber, while alpaca are primarily farmed for their fiber. Male llamas generally have slightly heavier dressing percentages (approximately 56%) than females (~54%). The meat from llama appears to represent a nutritious food source, providing high levels of protein (>23%) compared with the values derived from most common domesticated animal species and fat content (0.5%) that is generally less than the latter. The fat content of guanaco meat is slightly greater than that of llamas and alpacas, but still less than that in the meat of domesticated species. A comparison of the fatty acid composition of camels and llama is depicted in **Table 14**. Both species have C16:0 as the dominant SFA, whilst llama has nearly twice as much C18:1 (the dominant MUFA) compared to camels.

Buffalo

Water buffalo, belonging to the family Bovidae, are believed to number approximately 158 million in the world, and are important livestock species mainly in tropical and subtropical parts of Asia, as well as in South America, southern Europe, and northern Africa. The classification of water buffalo remains uncertain, with some authorities listing a single species, *Bubalus bubalis*, with three subspecies: the river buffalo (*Bu. Bubalis bubalis*), the swamp buffalo or carabao (*Bu. bubalis carabanesis*), and the wild water buffalo or arni (*Bu. bubalis arnee*). Other authorities believe that these are closely related; however, they are separate species. In 2003, the International Commission on Zoological Nomenclature ruled in favor of classifying wild buffalo as a separate taxon; consequently wild forms are now frequently referred to as *Bu. arnee* and domestic forms as *Bu. bubalis*.

Water buffalo are normally slaughtered as spent animals or for meat production at approximately 18 months of age at 300–360 kg live weight and dress out at approximately 55%. The carcass yields of water buffalo are lower than that of cattle due to a heavier head (from the horns) and skin weights. Buffalo also tend to have a thinner subcutaneous fat layer than cattle, even when reared under comparable feedlot conditions.

The meat accounts for approximately 22% of total meat produced in India, where it is gaining in popularity and there are no taboos against its consumption. There are thus opportunities for the development of the buffalo meat industry to cater for the needs of the domestic markets. Water buffalo meat is also known as carabeef or carabao meat and various value-added products including dried jerky, hamburger patties, bacon, and ham have been made from the meat of this species.

Buffalo exhibit similar meat quality characteristics as cattle as pertaining to extrinsic and intrinsic effects such as age, gender, and muscle type. The meat of the former is darker than the latter, with the myoglobin content varying from 2.7 to 9.4 mg g^{-1} depending on the type of the muscle and age. Water buffalo meat becomes darker with increasing age. It has been suggested that buffalo meat (lean) does not have any peculiar flavors and is organoleptically virtually indistinguishable from beef. Nonetheless, a consumer meat preference survey has indicated that 55.9% of the human subjects involved selected the beef, while 44.1% preferred carabeef. The color and amount of fat on the outside of the beef sample were primary responsible for buyer preference.

Crude protein, ash, fat, cholesterol, myofibrillar, sarcoplasmic and insoluble protein contents of beef and carabeef are similar. Water holding capacity, pH, muscle fiber diameter, tenderness, firmness, and marbling scores in carabeef are also comparable to beef.

Meat Animals, Origin and Domestication

M Konarzewski, Institute of Biology, University of Białystok, Poland

Glossary

Auroch *Bos primigenius*: ancestor of both *Bos taurus* and *Bos indicus*.
Austronesian expansion The process of historic migration and spread of people called Austronesians from Southeast Asia (most likely Taiwan) to the Pacific region.
Holocene The geological epoch which began at the end of the Pleistocene (approximately 12 000 years ago) and continues to the present.
Myostatin A negative regulator of skeletal muscle growth.
Neolithic A period in the development of human civilization, beginning around 10 000 BC in the Middle East.
Order Artiodactyla Two toed mammals, e.g., sheep pigs, and cattle.
Pleistocene The geological epoch which lasted from approximately 2.6 million to 12 000 years ago, spanning the period of repeated glaciations.
Precocial The species in which the young are mobile and feed themselves soon after birth.
Selective sweep The reduction of a local variation of the sequences of nucleotides as a result of positive natural or artificial selection.

Introduction

Domestication of plants and animals was a pivotal moment in human history. It initiated the Neolithic agricultural revolution some 10 000 years ago and underpinned the spread of human civilizations. Domestication originated in only a few areas of the world and gave inhabitants of those areas enormous advantages over other people. This ultimately transformed human demography and gave rise to the modern world.

Domestication of animals most likely had its roots in the ubiquitous habit of all people to capture and tame wild animals, and at first was unintentional. It probably originated as a practice of keeping and raising the young animals captured and spared in hunting. Domestication started at the end of Pleistocene, at the time of increasing unpredictability of climate and rapid reduction of numbers of game animals forced people to seek alternative and reliable food supplies.

The Nature of Domestication

Domesticated animals are those that were ultimately genetically modified from their wild ancestors by artificial selection for use by humans, whose breeding and maintenance is controlled and whose food is provided for the benefit of a community or society. Domestication is thus a different process from mere taming of genetically unmodified representatives of wild species and maintaining them in captivity.

The degree of suitability of wild animals for domestication depends largely on the degree of their genetic variability and the match between husbandry conditions and species-specific behavioral patterns expressed in the wild. Domestication has been restricted to surprisingly few species of mammals and birds. Particularly astonishing is the almost complete lack of domesticated mammals indigenous to subSaharan Africa, which is a homeland of the largest world populations of wild ungulates. Even African cattle probably did not evolve there but were possibly introduced from Southeast Asia. This suggests that there is a very unique suite of physiological and behavioral characteristics defining suitability of a particular species for domestication.

All domesticated mammalian species important for meat production thrive on readily available and renewable plant food that can be harvested and stored as supplies by humans, for later use beyond the main growing period. The ability to digest poor-quality plant food limited the scope of mammalian species available for domestication to large and medium-sized animals weighing 45 kg or more and belonging to the Order Artiodactyla. Most of them (including cattle, sheep, and goats) are capable of fermenting plant material in the voluminous and highly compartmentalized stomach. The domestic pig has a simple stomach and relies on fermentation in the extended morphological structures of the hindgut. The less efficient digestion of fiber-rich plant food is, however, offset by its extremely opportunistic food habits.

All ancestors of major domesticated species were precocial, that is, their offspring became mobile and able to feed themselves soon after birth, which was a prerequisite for pastoralism. Their high growth rates made them easily renewable human food resources and speeded up the process of artificial selection by promoting early sexual maturation and shortening generation time.

Equally important for successful domestication are behavioral traits. All domesticated meat animals live in herds with a well-developed dominance hierarchy. In the process of domestication, humans have essentially taken over the dominant position, which enables them to manage the herds. Many species otherwise suitable for domestication are notoriously aggressive (e.g., African buffalo), have tendency to panic in enclosure (antelopes and gazelles), or are reluctant to breed in captivity (e.g., Andean vicuña). Failure to overcome problems with any of these characteristics is the most plausible reason why only 14 out of 148 mammalian species more than 45 kg body mass, potentially suitable for domestication,

became important as locally or globally distributed domesticated animals. However, only four of them (sheep, goat, pig, and cattle) provide the bulk of world meat production.

Origins of Domesticated Meat Animals

Until recently, documentation of events of domestication in the archeological records has proved to be difficult because of equivocal discrimination of remains of domesticated animals from their wild ancestors. These difficulties have been largely overcome with the advent of analysis of the mitochondrial genome transmitted from generation to generation in maternal lineages and harbored in the egg cells. Sequences of mitochondrial DNA (mtDNA) characteristic of distinct wild populations subject to domestication events have been transmitted throughout millennia, which allow discrimination between single and multiple origins of domesticated breeds. It may also be noted that, across different species, the mutation rate of the most variable regions of mtDNA is constant and high, relative to generation time. This rate of variation constitutes the pacemaker of the so-called molecular clock and has proved to be a useful tool in reconstructing the time depth of domestication. These molecular techniques, along with other archeological evidence, have recently enabled the researchers to reconstruct fascinating histories of domestication and phylogenetic relations of major meat animals. The origins of domestic cattle, sheep, goats, pigs, and fowl, as summarized in Table 1, are briefly reviewed below.

Domestication of Cattle

Among all meat-producing domesticated animals, cattle have had the most economically important role in the evolution of human cultures. There are two major types of cattle: Western cattle (*Bos taurus*) lacking the shoulder hump and the humped Indian zebu cattle (*Bos indicus*). Both types interbreed fully and therefore their status as separate species is questionable. The continued existence of many of the 800 extant cattle breeds (of which, approximately 480 are recognized in Europe) is severely threatened by modern agricultural practices. According to a recent FAO report, 209 cattle breeds have become extinct (141 were of European origin) and more than 200 will be facing extinction in the near future.

There is little doubt that all modern cattle breeds (with the exception of mithan and Bali cattle) were derived from the auroch or wild ox (*Bos primigenius*). Three subspecies of the auroch formerly roamed over vast areas of North Africa (*Bos primigenius opisthonomus*), Asia (*B. primigenius nomadicus*), and Europe (*B. primigenius primigenius*). The auroch became extinct approximately 2000 years ago within most of its geographical range. Small populations survived in the forested parts of Central Europe, but, despite active protection, the last individual succumbed in 1627 in Jaktorowska Forest, near Warsaw, Poland.

A survey of mtDNA variation revealed that the most recent common ancestor of Western and Indian breeds of cattle lived between 330 000 and 1.7–2 million years ago – much earlier than the appearance of modern humans. Separation of African and European cattle ancestors occurred 22 000–26 000 years ago and therefore predates domestication of cattle. This suggests that each continental set of extant breeds originated as a result of separate domestication events in North Africa, the Middle East, and Southwest Asia. However, cattle domestication in Africa remains controversial, as the African mtDNA sequences differ by only few mutations from the taurine founding lineages of Southwest Asia.

The genetic affinity of European cattle breeds is much closer to the breeds from Anatolia and the Middle East (i.e., *B. primigenius nomadicus*) than to now-extinct European populations of the auroch *B. primigenius primigenius*. However, mtDNA sequencing points to the possibility of several, local introgressions from wild aurochs. In any case, the extant European breeds can be mostly considered as derivatives of cattle expanding some 5000 years ago from a center of domestication located in the region of the Fertile Crescent (the area encompassing southern Turkey, northern parts of Jordan, Syria, and Iraq). It is, therefore, unlikely that initial local

Table 1 Wild ancestors of major meat animals and poultry and approximate dates and places of their domestication

Species	*Wild ancestor*	*Date (years ago)*	*Place*
Domestic cattle[a] (*Bos taurus*) (*Bos indicus*)	Auroch (*Bos primigenius nomadicus*)	8 000–10 000	Middle East, India/Pakistan, and North Africa
Sheep[b] (*Ovis aries*)	Eastern Mouflon (*O. orientalis*) Argali (*O. ammon*)? Urial (*Ovis vignei*)?	8 000	Southwest Asia (Turkey and western Iran)
Goat[c] (*Capra hircus*)	Bezoar (*Capra aegagrus*)	9 000–11 000	Euphrates Valley, Zagros Mountains, and Eastern Anatolia
Pig (*Sus scrofa*)[d]	Eurasian wild boar (*Sus scrofa*)	9 000	Near East, China, India, and Southeast Asia
Domestic chicken[e] (*Gallus domesticus*)	Jungle fowl (*Gallus, gallus, G. sonneratii*)	8 000	Southeast Asia

domestication contributed significantly to the establishment of European agriculture, even though separated events might have taken place in Southern Europe (Italy). A genome-wide single nucleotide polymorphism (SNP) analysis suggests that cattle were introduced into Europe sequentially, through Turkey and the Balkans. It then radiated via Central Europe and France, reaching the British Isles. Modern south European cattle breeds also carry genetic signatures of North African origin, most likely imported through the Iberian Peninsula.

Taurine cattle (*B. taurus*) were domesticated from the *B. primigenius nomadicus* 8000–10 000 years ago. The earliest, 7800-year-old, archeological evidence of *B. taurus* has been found in Anatolia (Turkey). Remains of *B. indicus* dated to be at least 4500 years old have been unearthed in Iran, Mesopotamia, and the Indus valley. The analyses of mtDNA suggest that zebu cattle must have been domesticated much earlier, some 8000–10 000 years ago. Archeological evidence of cattle herding from 7000 years ago points to Pakistan as a potential domestication center of zebu cattle.

The oldest (9000 years ago) African *Bos* remains that can be putatively associated with domestication were found in eastern Sahara, although its domestication remains controversial. In contrast to the extant humped African cattle, the earliest cattle were humpless. Although humped African cattle have the distinct morphological characteristics also present in Indian breeds, their mtDNA sequence is much closer to that of *B. taurus*. In contrast, the nuclear DNA of African breeds bears the signature of Indian zebu cattle. The apparent lack of mtDNA of zebu cattle in African breeds along with the presence of zebu cattle sequences in nuclear DNA of African breeds strongly suggests a deliberate breeding of African zebu-type females, bearing *B. taurus* mtDNA sequences, with zebu males of Asian origin. These males were most likely imported into Africa during the Arab invasions of the AD eighth century. Interestingly, as a secondary consequence of the slave trade, North African mtDNA sequences have been found in cattle from southern Portugal.

New World cattle breeds are descendants of cattle brought by Europeans as early as 1493, and bear genetic signatures of the taurine and indicine lineages, including African admixture. The latter may account for the elevated disease resistance of such breeds as Texas Longhorn.

Domestication of Sheep

Recent molecular phylogenies of the wild sheep, based on sequences of cytochrome *b* and Y chromosome (MSY), suggest that *Ovis* species consist of four phylogenetic groups, three of which (Moufloniform, Argaliform I, and Argaliform II) are native to Eurasia. Domestic sheep belongs to the Moufloniforms, along with three wild species: urial (*O. vignei*), eastern mouflon *O. orientalis*, and European mouflon (*O. musimon*). All of them produce fertile and viable offspring when bred in captivity. European mouflon is the only species to share a haplotype with domestic sheep, which agrees with its feral domesticated status, that has undergone male-mediated introgression with domestic breeds.

Eurasian wild sheep – eastern mouflon, urial, and argali (*O. ammon*) – have been suggested as potential progenitors of domestic sheep. Earlier studies indicated that one of the oldest domesticated forms of sheep probably originated some 8000 years ago from urial in the region of the Caspian Sea and was subsequently adopted by the people of the Middle East and later also by early European herders. However, recent mtDNA analysis separated the phylogenetic tree of domestic sheep into five distinct mitochondrial maternal lineages (hyplotype groups A–E), which suggest multiple, independent domestication events. Highly diverged lineages A–D are mainly found in the Caucasus, lineages A–C in Central Asia, whereas A and B in the eastern edge of Europe. Lineage C sequences have also been found in sheep from Portugal, most likely indicating gene flow from the Fertile Crescent to the Iberian Peninsula. The European mouflon is aligned to lineage B. Lineage D has been identified in a single animal sampled from the north Caucasus and therefore awaits further confirmation.

Southern European sheep breeds have higher genetic diversity and are less genetically differentiated compared with breeds from northern Europe. This most likely reflects geographic gradient with highest genetic diversity close to the center of domestication, in the Near East, which still remains a sheep genetic diversity hotspot. According to FAO estimates, 36% of the extant sheep breeds are either extinct or endangered.

Domestication of Goats

Domestication of goats (*Capra hircus*) may have played a key role in the Neolithic agricultural revolution and the spread of agriculture from its earliest homelands. The extreme ability of goats to thrive on poor-quality fodder and to cope with harsh environmental conditions makes them the most geographically widespread, domesticated herbivorous species, ranging from cold Siberian mountains to the driest parts of North Africa.

Archeological evidence suggests that the bezoar (*Capra aegagrus*), the wild progenitor of the domestic goat, was the first wild ungulate to be domesticated. Domestication most likely took place in the region of the Fertile Crescent. Recent analyses of genetic diversity of the domestic goat have revealed six distinct mtDNA lineages, with more than 90% of analyzed individuals belonging to lineage A. This lineage, as well as lineage C, most likely originated in Eastern Anatolia, where they are common in wild populations. This points to Eastern Anatolia as the major center of goat domestication. Lineages B, D, F, and G are found in less than 8% of domestic goats and were most likely integrated to the gene pool following independent, small-scale domestications events in Northern and Central Zagros Mountains. However, recent analyses do not confirm an independent domestication in the Indus Valley.

Goats must often have been human companions, both in commercial trade as well as during migrations and explorations. The geographic distribution of genetic variation of the extant lineages of goats is much less diversified than that in cattle. Intercontinental differences between goat populations account for only 10% of the total mtDNA variation, whereas genetic differences between cattle breeds on different continents explain more than 80% of the variation. This attests to an intensive intercontinental gene flow between goat populations, which resulted from long-distance transportation of goats along ancient trading routes.

Domestication of Pigs

There are two major forms of domestic pigs, European and Asian, whose distinctiveness was recognized by earlier authors including Charles Darwin. Because of marked, morphological differences, both forms were assumed to originate from different species of wild boar. However, recent mtDNA analysis revealed that wild boar originated in western islands of Southeast Asia, and then dispersed to Indian subcontinent. Subsequent radiation of *Sus scrofa* into East Asia was followed by a progressive spread across Eurasia and into Western Europe.

The time since divergence from the common ancestor of European and Asian forms of pig falls well outside the known history of animal domestication and has been estimated at 500 000 years ago. This provides strong evidence for independent domestication of pigs in Europe and Asia, approximately 9000 years ago. However, domestication was predated by a long period of wild boar management that started about the time of the Pleistocene/Holocene transition, as exemplified by the man-made introduction of this species to Cyprus 12 000 years ago. Likewise, phylogeographic structure of pig mitochondrial sequences attests to a significant human contribution to dispersal of this species across Europe (particularly the Mediterranean islands) and the Middle East.

Initially, domestic pigs managed in Europe during the Neolithic Era were of Near Eastern ancestry. By the early fourth millennium BC, local European wild boars were also domesticated. This domestication cannot be, therefore, regarded as truly independent, but rather as a consequence of the introduction of Near Eastern domestic pigs. Once domesticated, European pigs rapidly replaced the introduced Near Eastern pig lineages throughout Europe in a relatively short period of approximately 500 years and later began replacing indigenous Near Eastern pigs.

In Asia, pigs were independently domesticated in at least six locations: China, India, peninsular Southeast Asia (three locations), and off the coast of Taiwan. Some extant European pig breeds (e.g., European Large White) are characterized by high frequency of mtDNA haplotypes of Asian origin. This is most likely a legacy of well-documented European breeding practices of the eighteenth and nineteenth centuries, when Asian sows were used to improve the contemporary breeds.

Domestication of Poultry

Although the meat yield of wild birds was far lower than that of much bigger mammals, attempts to domesticate fowl have a long history and have been independently undertaken on all continents inhabited by humans. Various breeds of duck and geese species were successfully domesticated in Eurasia, turkeys in Mesoamerica, and guinea fowl in Africa, whereas the extant breeds of Muscovy duck originated in South America. The earliest remains of domestic chickens were excavated in numerous archeological sites along the Yellow River in China and dated to be at least 7500 years old. They were also found in the Indus Valley in Pakistan. The 4000-year-old remains unearthed in Spain and Ukraine attest an incredibly rapid spread of the domestic chicken. Approximately 3600 years ago, chickens were introduced to New Guinea and quickly reached Pacific islands during Austronesian expansion. This fast initial dispersion can be attributed primarily to the ease of transportation of the fowl. Another important factor could have been a religious significance attached to the chicken as a divine offering, widespread in different parts of the world.

Earlier analyses of mtDNA sequences pointed to the area of Thailand as a single location of the domestication of chickens. Recent extensive survey of mtDNA sequences from domestic chickens and four red jungle fowl subspecies (*G. g. gallus*, *G. g. bankiva*, *G. g. spadiceus*, and *G. g. jabouillei*) identified nine highly divergent lineages A–I. Seven of them consists of both wild and domestic individuals and are confined to Asia, which strongly suggests that chicken domestication took place independently in different regions of India and China. However, the ubiquitous presence of the E lineage, native to India, suggests that worldwide expansion of domestic chickens took place from there.

Changes in Species under Domestication

Behavioral Changes of Animals under Domestication

Domestic breeds diverged from their wild ancestors in many ways. Because heritabilities of behavioral traits are usually higher than heritabilities of anatomical and physiological traits, one can speculate that the development of domestic phenotypes started with changes of the behavior of animals undergoing domestication. The most obvious change was the loss of fear of humans. Equally important behavioral changes involved increasing of the threshold of within-species and between-species aggression. This has become essential for the successful maintenance of stocks of domesticated animals living under population densities far exceeding maximum densities tolerated under natural conditions, often next to large stocks of unrelated species. Perhaps the most important effect of domestication on behavior was a reduction of the sensitivity to changes in the unfamiliar environment. This stemmed from reduced emotional reactivity to handling by humans and ease of adaptation to novel conditions, which greatly contributed to the high reproductive rates essential for the success of artificial selection.

It is important to note that a successful domestication required the fulfillment of all conditions mentioned above and therefore could have been achieved only with particularly prone individual animals. For example, recent computer simulations revealed that cattle domesticated in the area of modern Iran originated from just 80 female aurochs, which attest to the difficulties of the early stages of cattle herding and breeding.

Morphological and Anatomical Changes of Animals under Domestication

Domestication has also resulted in profound changes in the morphology and anatomy of animals. Primitive breeds of domestic pigs, sheep, goats, and cattle were generally smaller than their wild ancestors, which most likely make them more manageable, as pointed out by Francis Galton in 1865. Chickens, in turn, were selected to be larger. The whole brain volume of domesticated animals is 10% less than in their wild relatives. The decrease of brain sensory centers is particularly

clear cut and corresponds well with the observed behavioral differences between domestic animals and their wild relatives.

An incredible increase of growth rate of modern meat-type strains of domestic fowl is one of the best examples of both the power of intense, directional selection and its negative side effects. During the late 1940s, broilers took approximately 90 days to grow to slaughter body mass of 1800 g. Now it takes less than half of this time to reach the slaughter mass of 2500 g. Surprisingly, most of this progress has arisen through an increase of growth rates during the first two weeks of postembryonic development. However, this impressive selection progress also incurred unavoidable costs associated with increasing incidence of metabolic diseases such as 'heart failure syndrome,' sometimes killing 10% of a broiler flock. In addition, changes in body proportions, such as that resulting from selection for large breast size in domestic turkeys, have severely impaired their mating behavior, and selection for intense egg production resulted in total loss of incubation and brooding behavior in laying hens.

Genetic Footprints of Domestication

Studies on genetics of domestication have been greatly advanced, thanks to the development of the quantitative genetics theory and molecular genetics techniques. Although still in its early stages, identification of quantitative trait loci (QTL) and whole genome sequencing have become powerful approaches that have been recently applied to detect genetic footprints of domestication. For example, one of the most important selective sweeps already identified in poultry occurred at the locus for thyroid-stimulating hormone receptor (TSHR), which underlies hormonal regulation of reproduction, photoperiod, and metabolic rates. Research on the differences in expression of polygenic traits in pigs and wild boars has resulted in the identification of loci, such as insulin-like growth factor 2 (IGF2) associated with muscularity, fat accumulation, and heart size. Domestication has also almost certainly led to near fixation of naturally occurring mutations of gene coding for GDF-8 (myostatin, a negative regulator of skeletal muscle growth) in several cattle breeds such as Belgian Blue. However, high density single nuclear polymorphism (SNP) genotyping has indicated that 50% of ancestral genetic diversity has been already lost in the extant cattle breeds.

Consequences of Domestication for Meat Composition

Ample anthropological and ethnographic evidences indicate that humans are evolutionarily preadapted to a diet that includes meat. There is also little doubt that scavenged or hunted ruminants were the main source of meat throughout early human history. Human dietary lipid requirements are, therefore, more likely to match the lipid composition of wild ruminant tissues. This composition is qualitatively and quantitatively different from the lipid profiles of meat of domesticated cattle, which may have important consequences for the health of modern consumers.

The most significant difference between meat composition of wild and domesticated ruminants is the relative amount of fat per unit mass of muscle tissue. Meat of grain-fed beef (trimmed of all adherent fat) contains 2–3 times more fat (mean 5.6 g per 100 g tissue) than the muscle of wild ungulates such as antelope, deer, or buffalo (mean 2.2 g per 100 g tissue). The high fat content of beef muscle tissues is mainly associated with the formation of intramuscular fat deposits – a phenomenon known as marbling of meat – which is largely absent in wild ruminants. This intramuscular fat is rich in triacylglycerols and resembles subcutaneous fat with respect to the profile of fatty acids.

Another important difference is that muscle tissue of wild ruminants contains a higher proportion of polyunsaturated fatty acids (PUFAs) than muscles of domestic cattle. Up to 30% of all fatty acids contained in game meat are polyunsaturated, whereas PUFAs account for only 10% of FAs in beef. Increased levels of saturated fat in beef (particularly 12:0, 14:0, and 16:0 fatty acids) have substantially contributed to increased dietary fatty acid levels in the modern westernized diet. This, in turn, may be associated with an increased risk of cardiovascular disease if not taken into account in a diet. Moreover, muscles of domesticated cattle are much poorer in long-chain PUFAs (particularly *n*-3 long-chain PUFAs), as compared with muscles of wild ruminants. It is important to note, however, that there are also significant differences in the muscle fat content and composition between pasture-fed and grain-fed cattle. Muscles of grain-fed cattle are particularly rich in saturated and monounsaturated fats, whereas the lipid profiles of pasture-fed cattle resemble those of game meat. Thus, the differences in meat composition between wild and domesticated ungulates can be largely attributed to the practice of feeding cattle grain, rather than to physiological changes incurred by the process of domestication.

The Future of Domestication of Meat Animals

The incredible progress of modern biology has made it possible not only to maintain but also to breed in captivity almost all terrestrial mammals. Some of them such as moose (*Alces alces*), red deer (*Cervus elaphus*), or American bison (*Bison bison*) have been domesticated to some extent in the past century. They are, however, generally still unsuitable for intense meat-producing farming, they cannot be herded for a long time, and it is unlikely that they will soon join a very short list of major meat-producing species. However, together with primitive breeds of already domesticated animals, they can serve as a source of meat of very desirable protein and fat profiles. Growing health concerns of consumers may paradoxically give rise to selection of meat animals: toward emulation of the meat composition of their wild ancestors.

Glossary

Allometric growth The increase in size of different organs or parts of the same animal at differing rates.
Cutability An estimation of boneless closely trimmed retail cuts derived from a carcass.
Iodine value An indication of unsaturation levels in a fat sample. It used to be reported in units of grams of I per 100 g of tissue. In chemistry, it is the mass of iodine in grams that is consumed by 100 g of tissue.
Lairage A period of rest between the time the animal is delivered to the slaughter facility until the animal is actually slaughtered.
Metabolic modifier Compounds that are fed, injected, or implanted in animal to improve production efficiency.

Introduction

The global pork industry produces more than 100 million tons of pork annually and is the most consumed meat animal protein in the world. China is the world's leader in pork production and provides approximately 50% of the global supply. The European Union is estimated to be second at more than 20% and the US is third at a little more than 10% of the worlds pork supply. Together Brazil and Russia account for a little more than 5% of the world's pork production. Recent improvements in the efficiency and volume of pork production are largely related to increases in sow productivity and marketing of pigs at heavier slaughter weights than have been historically reported. Pig production varies greatly around the world. Some production systems, such as Australia and the UK, raise and market entire males, but slaughter them at younger ages before reaching puberty to avoid undesirable boar odor compounds. Other markets, such as the US and Brazil, generally castrate male pigs at a very young age to prevent the development of boar odors. Some parts of the world have very sophisticated vertical integration marketing systems, whereas others still rely on an open market system to buy and sell pigs for food production. Just as there are differences in how pigs are raised and sold around the world, there are differences in how the value of pig carcasses is determined. The objective of this article is to discuss growth rates and composition of pork carcasses, metabolism of early postmortem carcasses and how it influences meat quality, differences in dressing percentage, fabrication techniques, and fat quality.

Growth and Carcass Composition

Body composition changes dramatically as animals grow. Pigs have the greatest proportion of muscle at birth but it slowly declines as they grow and accumulate fat. As a rule, soft tissue comprises more than 50% water and can be as high as 90%. Protein is usually second in terms of weight, except in the cases of very fat animals. Therefore, fat is the most variable tissue in the body and can be second or third in terms of live body weight. After all, fat serves the body as an energy reserve in times of need. Additionally, fat provides insulation, protection of vital organs, and generation of heat. From a chemical element standpoint, greater than 50% of body mass is oxygen, approximately 20% carbon, 10% hydrogen, and approximately 3% nitrogen. These are the elements that make up water, protein, carbohydrate, and fat. As a rule, animals partition nutrients for tissue development in order of skeleton, muscle, and then fat. They tend to deposit fat in the mesenteric regions first followed by perirenal (mesenteric and perirenal depots are sometimes jointly called visceral fat), then subcutaneous (backfat), intermuscular (seam), and finally intramuscular (marbling) fat deposition. Even so, it is important to remember that fat accretion is not a linear process. Pigs simultaneously deposit fat in different anatomical regions of the body throughout development. Subcutaneous fat makes up the largest portion of total fat in pork carcasses and is being deposited at a faster rate than intermuscular fat toward the end of pigs' growth. Intramuscular fat is generally considered the last fat depot to develop and thus makes up the least proportion of total fat. As mentioned, after animals are born, the proportion of muscle in the body begins to decrease and the proportion of fat increases. The rate and magnitude at which fat accumulates and muscle decreases can be breed and sex dependent. Heritage pig breeds, such as Berkshire, tend to grow at a slower rate and finish with a greater proportion of fat than most high-lean, terminal crossbred pigs. Heritage breeds are often referred to as earlier-maturing breeds because of the increased proportion of fat, slower growth rate, and smaller mature body frame size relative to more commercially raised composite breeds. Differences in body composition are more pronounced when pigs of different mature frame sizes are compared at the same weight, rather than at the same age. At equal body weights, barrows will be fatter than gilts and gilts will be fatter than entire males when assessed at the area of the tenth rib. Conversely, entire males will have a greater percentage of fat-free lean than gilts and gilts will have a greater proportion of fat-free lean than barrows. During the growth period, young entire males will have a greater percentage of

lean than fat. Barrows will eventually reach a point that deposition of fat will exceed deposition of muscle. During the last few weeks of the finishing phase, barrows tend to consume more feed than entire males and gilts. Gilts tend to gain less weight per day than barrows and usually require more days on feed to reach a desired body weight than barrows.

Pigs fed a diet that is greater in protein concentration than considered necessary for growth will have a greater lean meat percentage. Additionally, seasonality can play a role in carcass composition. In warm weather, pigs tend to eat less and gain less weight per day than during colder seasons. In production systems where the flow of pigs through the system is tightly managed and feed costs are expensive, it might not be possible to allow pigs to stay on feed to achieve the desired ending live weight. Pigs raised during the hot months of the year tend to be lighter, have less backfat, and greater estimated lean percentages than pigs raised during the cold months.

Metabolic modifiers are compounds that are injected, fed, or implanted to improve growth rate, carcass cutability, or other production enhancing characteristics. There are currently two metabolic modifiers used in pork production in various parts of the world to influence carcass composition. The first is ractopamine hydrochloride (trade name Paylean™) and is commonly used in the US and Brazil pork production operations. Ractopamine is a β-adrenergic agonist that increases growth rate, feed efficiency, and carcass leanness of finishing pigs fed a diet with at least 16% crude protein for the last 20–41 kg before harvest. Feeding ractopamine will slightly reduce tenth rib fat thickness and increase loin muscle area or depth. This translates into a modification of allometric growth rates of various primal pieces and an increase in carcass cutability. The second metabolic modifier is the use of immunological castration as an alternative to physical castration. Immunological castration has been adopted in some parts of the world. It is achieved through a series of two injections that act as an immunological metabolic modifier by changing the natural hormone profile after the second injection. Immunological castration occurs later in life than physical castration and is used to suppress testicular function to reduce boar taint in intact male pigs intended for harvest. The technology was developed in Australia and is now approved for use in more than 60 countries worldwide. Immunologically castrated male pigs also have improved growth rate, feed efficiency, and carcass cutability when compared with physically castrated male pigs.

Carcass Classification

In various parts of the world, a pig's value is determined by carcass weight and an estimation of carcass leanness. In the US, pigs generally are marketed from a single barn over potentially several weeks. The majority of pigs are sold on a matrix type basis that offer premiums for carcasses meeting certain specifications and charges discounts to carcasses that do not comply with the desired carcass weight and lean meat percentage specifications. By doing this, producers are able to better manage carcass weight as well as carcass composition. This can be accomplished by marketing the heaviest pigs within a pen first, and then lighter pigs in subsequent weeks. This increases allotted space per pig in a pen, decreases competition for feeder access, and allows slower growing pigs more time to reach a desired compositional end point. This marketing approach allows producers to be rewarded for marketing pigs that have a desired carcass weight (not too heavy or too light) with minimal carcass weight variation and a desired percentage of lean meat. In many pork slaughter facilities, estimation of carcass leanness is carried out at the very end of the harvest process. Carcass leanness estimations can be accomplished using a variety of technologies. The use and application of these technologies vary greatly around the world. Some examples include: the Fat-o-Meater, Hennessy probe, animal ultrasound system, or a simple ruler to measure fat thickness. Some of these technologies are more invasive than others. So, the method used to determine carcass composition will vary among packers and regions of the world. Other technologies, such as dual energy X-ray absorptiometry, are available to determine carcass leanness, but might be prohibitive in a large-scale fast moving production facility. As fat thickness or fat content is the most variable tissue in carcasses, it plays a very influential role in estimating carcasses lean percentage. Therefore, fat thickness is included in nearly every regression equation, regardless of technology used, to estimate carcass lean percentage. Even though the value of carcasses to the live pig producer is determined by carcass weight and estimation of carcass leanness, the value of carcasses to packers is determined by the cutability of carcasses or the amount of meat products derived from those carcasses. In the US, pork carcasses are fabricated into five primal pieces (Figure 1). Those pieces are the ham (22–25% of the chilled half carcass), loin (20–22% of the chilled half carcass), picnic shoulder (ventral region of the shoulder, which accounts for approximately 9–11% of the chilled half carcass), belly (12–15% of the chilled half carcass), and Boston butt shoulder (dorsal region of the shoulder, which accounts for approximately 8–10% of the chilled half carcass). The Boston butt, picnic, loin, and ham are often referred to as the four lean cuts or lean carcass cutability. When the belly is included, the calculation is referred to as carcass cutability. Lean carcasses generally have a greater cutability than fatter carcasses because there is less fat (also less valuable) to trim away, thereby a greater percentage of carcasses can be sold as lean meat.

In Europe, carcasses are classified based on lean meat percentage using the EUROP classification system that is based on

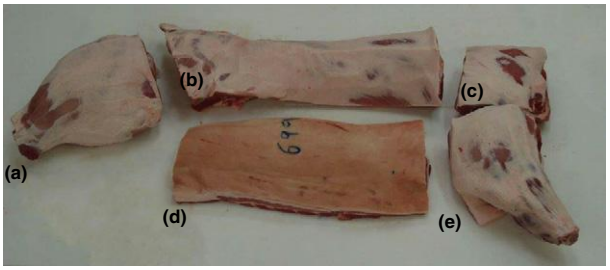

Figure 1 A pork carcass fabricated into the five US primal pieces: (a) ham (22–25% of chilled half carcass), (b) loin (20–22% of chilled half carcass), (c) Boston butt (8–10% of chilled half shoulder), (d) belly (12–15% of chilled half carcass), and (e) picnic shoulder (9–11% of chilled half carcass).

muscle and fat thickness. In that system, E has the greatest lean meat percentage (>55%), U=50–55% lean meat, R=45–50% lean meat, O=40–45% lean meat, and P is the least lean meat percentage (<40%). Similar to the US, European packers also estimate lean meat percentage with objective tools such as a caliper to determine midline fat thickness, Fat-o-Meater and Hennessy optical probes, and various ultrasonic scanners.

Dressing Percentage

Dressing percentage, or carcass yield as it is sometimes referred to, is the proportion of ending live weight yielded after animals have been stunned (desensitized), exsanguinated, skinned or scalded, and eviscerated. The average dressing percentage of pigs in the US is approximately 74%. Average dressing percentages will vary in other parts of the world depending on several factors. Sex of animals is one such factor with entire males usually having a lesser dressing percentage than castrated male or female pigs. This can be partially attributed to the presence of testicles of entire male pigs, which accounts for approximately 0.5–0.7% of ending live weight. Reduced fatness of entire male pigs also decreases dressing percentage. Diet can also impact dressing percentage. Finishing diets that are high in fiber can reduce dressing percentage. It is thought that diets rich in fiber, such as those that contain distillers dried grains (ethanol coproducts), increase intestinal mass, which is approximately 3% of ending live weight, and reduce dressing percentage due to a larger portion of live weight from intestinal mass. In addition to intestinal mass, transport distance, gut fill, and time spent in lairage also will influence dressing percentage. Lairage is the time from when animals arrive at the harvest facility until animals are slaughtered. Pigs are not usually fed during transport and lairage unless they jointly exceed 24 h. Therefore, as transport and lairage time increases, gut fill generally decreases and thereby increasing the dressing percentage. Gut fill, even after a 15-h lairage period can be as much as 5% of ending live weight. Not only can things such as sex, diet, composition, and transportation/lairage loss influence dressing percentage, but the actual dressing process itself can also greatly impact dressing percentage. Some parts of the world leave the head attached to carcasses or leave the front feet intact. The head can account for 5–7% of ending live weight and the front feet, depending on the anatomical removal location, can account for approximately 1% of ending live weight. Skin can account for approximately 4–6% of ending live weight when carcasses are skinned rather than scalded and can be much greater depending on the skill level of persons skinning the carcasses. Other visceral organs that can influence dressing percentage are the heart (~0.4%), liver (~1.7%), and the kidneys (~0.5%) and can be influenced by a variety of management practices.

Time of harvest in relation to the biological growth curve will also influence dressing percentage. Live animals that are destined for harvest can be divided into a carcass component and a noncarcass component. Early in life, noncarcass components, such as blood, viscera, and skin in some cases will make up a greater proportion of live weight than later in life. As animals reach maturity, visceral growth is completed and animals begin to accumulate fat at a more rapid rate. Carcass components begin to increase in proportion to live weight relative to noncarcass components, thereby increasing the dressing percentage. Therefore, larger, heavier, and older animals usually have a greater dressing percentage than young, growing animals. Even though noncarcass components are considered byproducts, they represent a great deal of value to the pork industry in the US and other countries. Drop value, or the value of ears, hearts, livers, tongues, snouts, salivary glands, and other noncarcass component byproducts can be worth approximately US$5 per cwt per pig or in some cases even more.

Meat Quality

Shortly after animals are stunned, they are exsanguinated. When animals are exsanguinated, the circulatory system is disrupted and homeostasis is lost. A series of metabolic and biochemical reactions take place in an attempt to regain homeostasis. Thus, exsanguination begins the conversion of muscle to meat. During the conversion of muscle to meat, tissue pH declines from approximately 7.2 in living muscle to an ultimate pH of approximately 5.7 but can range from 5.2 to 6.5 in very extreme cases. In rare cases, the magnitude may be even greater. Ultimate pH, or the pH after postmortem metabolism has concluded, usually between 12 and 24 postmortem, is often the first topic of discussion when evaluating meat quality because it shares the greatest relationship with other meat quality parameters such as color, water-holding capacity, and texture or firmness. Ultimate pH is measured as the inverse log of the $[H^+]$ ion concentration. In living animals, the circulatory system transports oxygen, dissipates heat, and removes waste from various tissues. As blood is removed during the conversion of muscle to meat, carcasses undergo transition from aerobic postmortem metabolism to anaerobic postmortem metabolism. In an anaerobic environment, the carbohydrate source used to produce adenosine triphosphate is converted from pyruvate into lactic acid rather than from pyruvate to acetyl CoA as is the case in living muscle. As there is no blood available to remove lactic acid, it begins to accumulate and results in postmortem muscle pH decline. The rate and magnitude of pH decline will have noticeable effects on meat quality. When little carbohydrate is available at the time of death, usually due to chronic stress, very little pH decline occurs. This condition is referred to as dark, firm, and dry (DFD). Water-holding capacity is inversely related to ultimate pH. So, in DFD conditions, water-holding capacity is at its greatest. Water is bound tightly within the muscle cells and makes the surface of the meat appear very dry. When the surface of the meat is dry, light is absorbed into the tissue rather than reflected or scattered from the surface. This causes the surface of the meat to appear dark (similar to a color score of 6; Figure 2). A condition opposite to DFD is known as pale, soft, and exudative (PSE). This condition occurs in part due to acute stress shortly before the animals are harvested. Excessive available glycogen at the time of death can result in a rapid rate of pH decline when carcass temperatures are relatively warm. The combination of low pH and high temperatures denatures sarcoplasmic and myofibrillar proteins. When this happens, water becomes loosely associated with muscle cells

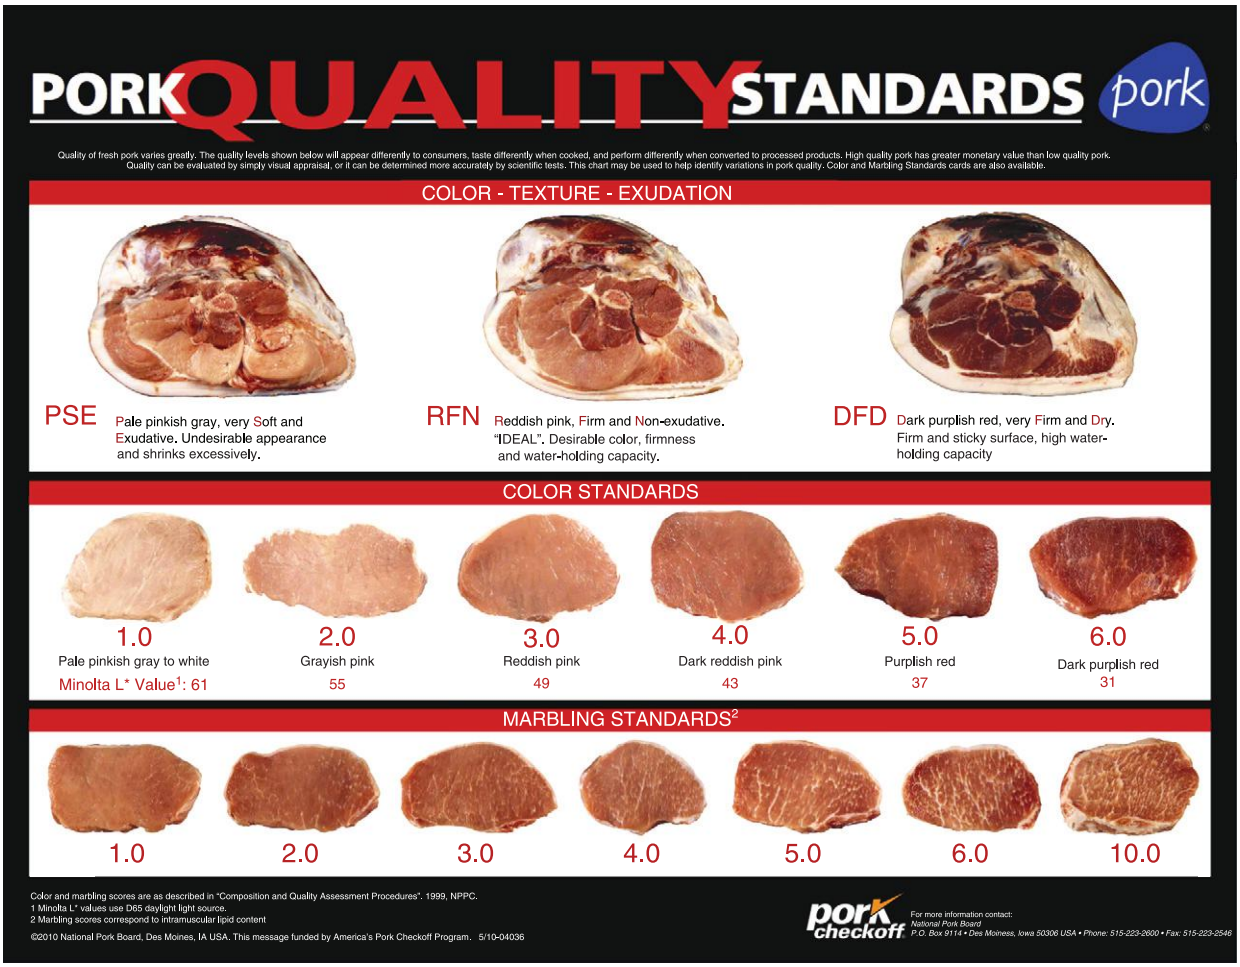

Figure 2 Pork quality standards for color–texture–exudation of hams (top), color standards of loins (middle) and marbling (bottom). Provided courtesy of the National Pork Board and Pork Checkoff.

and tends to pool on the surface. This is what is referred to as exudative. Moisture on the cut surface of meat tends to reflect rather than absorb light making the color appear light (similar to a color score of 1; Figure 2). Proper environmental conditions and handling practices can aid in preventing PSE and DFD from occurring. Another metabolic condition is referred to as acid meat. Acid meat is a condition sometimes found in the Hampshire breed where excess glycogen is stored in the muscle and results in very low ultimate pH values when animals are harvested. This condition is different from PSE, however, in that the rate of pH decline is normal but the magnitude of pH decline is greater. Pigs that store excessive amounts of glycogen in their muscles are suspect for extended postmortem pH decline and a greater concentration of lactic acid in the postmortem tissue. These pigs are referred to as having a high glycolytic potential. This phenomenon is often referred to as the 'Hampshire effect' caused by the Rendement Napole gene. The dominant allele (RN^-) is responsible for the increased muscle glycogen levels. The RN^- mutation is a single-nucleotide polymorphism of a gene that encodes for a regulatory subunit of adenosine monophosphate-activated protein kinase. New literature available now indicates that postmortem pH decline may be more complex than originally thought.

All three of these metabolic conditions are a concern for the pork industry because they negatively influence palatability. Palatability is generally referred to as the combination of tenderness, juiciness, and flavor of cooked meat. These three things together will largely impact consumers eating experiences. However, color is often cited as the primary parameter involved in consumers intent to purchase. Myoglobin is the sarcoplasmic protein that gives meat its color. Myoglobin concentration tends to increase as animals age due to a loss of affinity to oxygen. As a rule, however, pigs have approximately 2 mg of myoglobin per gram of muscle. Entire males tend to have a slightly greater myoglobin concentration than castrates or gilts.

Producers are not often directly compensated for lean muscle quality. In some cases, such as product meeting export specifications, a premium may be offered but, in general, there are no value-based premiums for meat quality parameters. This is largely because quality is subjective in nature and can be difficult to measure in real time. Tenderness is often the most influential parameter in determining the eating experiences of the consumers. A new technology is being developed to classify pork loins based on tenderness levels. Pork is generally considered tender, but the genetic selection of lean fast

growing pigs may negatively influence tenderness. Visible and near-infrared reflectance spectroscopy can allow packers to noninvasively predict tenderness on the fabrication line of plants.

Eating meat provides several important dietary nutrients. Meat consumption directly contributes to a low glycemic index because meat is low in carbohydrates. Dietary protein from meat provides necessary amino acids needed for muscle growth and maintenance of tissue. Meat consumption is an excellent source of minerals such as iron, calcium, and zinc. Meat is also a good source of all four fat soluble vitamins (A, D, E, and K). Pork, in particular, is a good source of B vitamins. Pork consumption also provides selenium, which is a natural antioxidant via glutathione peroxidase.

Fat Quality

Over the past couple of decades, pigs have become leaner. Leaner pigs tend to have greater concentration of polyunsaturated fatty acids (PUFA) than fat pigs. The type of fat (saturated or unsaturated) in various fat depots can impact consumers perceptions, shelf-life, processing capabilities, and bacon characteristics of pork products derived from those fats. Fat quality can be described using a variety of parameters, but is most commonly discussed in terms of iodine values. An iodine value is an indication of the level of unsaturation in fat samples. Iodine values are most commonly calculated using a regression equation based on fatty acid concentrations: iodine value (IV) = 16:1 (0.95)+18:1 (0.86)+18:2 (1.732)+18:3 (2.616)+20:1 (0.785)+22:1 (0.723). More recently, a similar equation has been offered that includes most of the previous coefficients, but also includes some longer chained fatty acids. A newer equation for iodine value is as follows: IV = 16:1 (0.95)+18:1 (0.86)+18:2 (1.732)+18:3 (2.616)+20:1 (0.795) +20:2 (1.57)+20:3 (2.38)+20:4 (3.19)+20:5 (4.01)+22:4 (2.93) +22:5 (3.68)+22:6 (4.64). As IV increases, fat firmness decreases and shelf-life of products becomes shorter. Lipid oxidation is one of the primary processes involved in quality losses of pork products. The oxidative breakdown of PUFA leads to rancidity and development of undesirable odors and flavors. Fat quality can also be assessed by measuring the thickness of the belly. Generally speaking, fatter pigs have thicker bellies and a greater proportion of saturated fatty acids than lean pigs. This means the bellies are firmer and easier to slice into bacon. Pork fat can range from less than 25% PUFA to greater than 35% PUFA and is dependent on things such as diet, sex, season, fat depot, and a variety of other factors. Generally, pork fat is less saturated than lamb or beef, but more saturated than fish or poultry. As mentioned above in the Section Growth and Carcass Composition, gilts tend to be leaner than barrows and thus usually have greater iodine values. It is also well known that fatty acid profiles of pigs are directly influenced by diet. Feed ingredients that are high in polyunsaturated fat will increase the polyunsaturated fatty acid concentration of pork fat and increase the iodine value of various depots. Increasing the dietary consumption of linoleic acid (an unsaturated fatty acid) during the last 6–8 weeks before harvest increases the calculated iodine value of backfat in finishing pigs. Finally, pigs tend to deposit fat anatomically from the head and tail end toward the visceral cavity. So, as pigs reach physiological maturity, they begin to deposit fat in the jowl and shoulder region earlier in their growth curve than they deposit fat in the loin and belly area.

In some parts of the world, the belly is the most valuable primal component of pork carcasses. Pigs bellies can be as much as 40% fat. So, it is important for packers to understand how diet and sex can influence fat quality and quantity. Soft, oily bellies are more difficult to slice and ultimately reduce the yields of salable products that can directly influence profits. Fat quality at all stages of pork production is quickly becoming of major interest to scientists because of its direct link to bacon processing. Leaner pigs have a greater percentage of lean, greater percentage of moisture, and a greater proportion of PUFA relative to fatter pigs. All of these things can lead to soft, oily bellies and reductions in bacon yield. Allowing pigs to become adequately fat (in markets that value bacon) will reduce slice yield variation and increase total bacon yield.

Introduction

Poultry refers to birds such as chickens, turkeys, ducks, pheasants, geese, ostrich, emu, quail, and related species that are used for commercial production of meat. Many breeds of these species exist in the wild, but in commercial production many different breeds have been replaced by crossing several breeds with different desirable characteristics to produce a single breed or to develop hybrid lines with optimal meat yield and production efficiency. The focus of this article will be to review the classic and current species of poultry possessing desirable eating characteristics, and the nutritive value of poultry meat. The meat from almost all birds is commercially available. This review focuses not only on chickens, turkeys, ducks, geese, but includes ratites, which are flightless birds with rudimentary wings and without a sternum.

Chickens

Domestication of chickens began with red jungle fowl, which were raised in different regions of India and China approximately 1000 BC. However, the birth of the modern chicken industry in the US began in the early 1900s, when chicken production was characterized by small backyard flocks that were maintained to produce eggs for food or sold locally. The aged hens or roosters from the home flocks were cooked in pressure cookers and eaten only for a Sunday dinner or holiday meal. In the early to mid-1900s, there was no organized system for processing poultry, which made it impossible for poultry meat to be available for retail sale at grocery stores, but live birds could be purchased and processed at home. As the twentieth century progressed, large markets for poultry meat developed in the northeast and the poultry industry became a year-round enterprise with broiler (i.e., young meat-type chicken) production becoming concentrated in the southeast because of its warm climate, economical labor, and access to grain via rail and barge transportation. As the demand for white/breast meat increased in the 1950s, the chicken industry began to undergo vertical integration to bring control of the hatcheries, feed mills, growth facilities, and processing plants under a single corporate structure. Concurrently, the poultry companies ceased using dual-purpose (meat and eggs) breeds of chickens, and they began to breed and produce chickens specifically for meat production.

In the early days of the meat chicken production industry, it was common to grow dual-purpose breeds or to mate a dual-purpose rooster such as a Rhode Island Red with a Barred Plymouth Rock (Figure 1) hen to produce male progeny that were barred like their mothers and female progeny that were nonbarred like their fathers. The cockerel (young male chickens) could then be separated and raised for meat production and the pullets (young female chickens) could be kept as egg producers. However, to improve production, companies stopped using dual-purpose birds and developed separate lines of chickens to produce either meat or eggs. The meat chicken or broiler industry has traditionally used crosses between White Plymouth Rock and Cornish birds. Both breeds have a large body size, but Cornish birds tend to grow faster than White Plymouth Rocks. Although most commercial broilers originated from crosses between White Plymouth Rock and Cornish chickens, the broilers of the 1950s are very different from modern day broilers.

A commercial broiler chicken from a 2001 genetic background takes approximately 42 days to reach a bodyweight of 2.6 kg, a carcass weight of 2 kg, and a *Pectoralis thoracicus* (breast muscle) percentage of bodyweight of approximately 15.8%. In comparison, a commercial broiler from a 1957 genetic stock reaches a bodyweight of 1.8 kg, a carcass weight of 1.2 kg, and a *Pectoralis thoracicus* percentage of bodyweight of approximately 8.6% at 84 days of age. The most economically important chicken and turkey muscle is the *Pectoralis thoracicus*, which is composed of predominantly white (or fast twitch) muscle cells. Modern selection has decreased the time to market weight, increased the total size of the chicken, and increased the size of the *Pectoralis thoracicus* relative to bodyweight. Overall, modern selection techniques have profoundly changed the size of the chicken breast muscle (Figure 2).

Chicken has grown to be a popular meat product because the increases in production efficiency have led chicken to become a low cost, tasty alternative to traditional red meats, such

as beef and pork. Chicken has become a low cost product because modern selection and production techniques have reduced the time to produce a broiler chicken to approximately 6 weeks. More importantly, it is possible to manage large numbers of chickens on a single farm (Figure 3), lending poultry production to be very efficient and making it possible for the poultry industry to easily become vertically integrated. Almost every chicken produced in the US comes from contract growers who enter into partnerships with major poultry companies and who may supply the chicks that are grown on the farm. Therefore, the large corporation can determine the type and number of chickens grown, the feed provided to the animals, and all aspects of production. Subsequently, the same company buys the chickens from the growers, processes the chickens, and distributes the final product to the retailers. The vertical integration of chicken production almost eliminates the costly possibility of either an oversupply or shortage of chickens for the processor, and provides the opportunity for an efficient operation.

Chicken consumption in the US was approximately 9.9 kg per person (carcass weight) in 1955, whereas in 2009 it was approximately 42 kg per person (carcass weight). The increase in chicken consumption has not only occurred because of its relatively low cost but also because chicken meat tends to have consistent quality. Chicken tends to have few inherent tenderness issues because the vast majority of chickens grown in the US and other countries for fresh consumption are harvested at a young age (approximately 6 weeks) when the animals have low connective tissue levels. Furthermore, the normal rapid pH decline and rapid onset of rigor mortis (approximately 4 h) and subsequent ageing in poultry has made meat quality defects, such as cold-shortening or thaw rigor negligible issues. In particular onset of cold shortening occurs at a much lower temperature (approximately 2 °C) than for red meats, but rigor at elevated temperatures (if there is no stimulation) can still toughen meat. Electrical stimulation can be used and in fact can both enable early portioning without shortening and toughening thus enhancing tenderness, but is not commonly used. Meat quality problems in poultry tend to be related to a pink color in the normally white breast muscle or a pink color in processed meat products. Similarly, hemorrhaging during slaughter and bruising during processing also tend to be a quality problem. A pale soft exudative (PSE) condition has been described in chicken and turkey meat, but the biological basis for the PSE condition in poultry is not as well understood as PSE condition in pork.

The advent of new chicken products (chicken bologna, chicken nuggets, chicken hotdogs, and chicken wings) throughout the 1980s and the 1990s that are not only tasty but also convenient to prepare has fueled an increase in poultry consumption. The new chicken convenience foods have been successfully marketed for consumption at home and in the growing fast-food industry. However, one of the greatest reasons for the growth in chicken consumption may be the perception by health conscious consumers that chicken is a low-fat high protein source of healthy nutrition (Table 1).

Turkeys

Domestication of the turkey may have begun with the Mayas in Mexico and Central America, and there are two different subspecies of turkeys found in the wild. One subspecies is found in Mexico/Central America, whereas the other is found native to the US. The variety found in the US is large, has a characteristic bronze plumage, and it is likely that the commercial lineage of domestic turkeys arose from the turkeys native to the US. The current standard breeds of turkeys are the Broad Breasted Bronze, White Holland, Naragansett, Black, Bourban, Royal Palm, and Slate. The White Holland was the only commercial white turkey during the early twentieth century. Much of the success of the modern turkey industry lies with the Broad Breasted Bronze whose rapid growth rate made it an exceptional animal for turkey meat production. Modern turkey production uses a large white breed (Figures 4 and 5), which was likely developed from the Broad Breasted Bronze and the White Holland breeds.

Modern turkey production/consumption has undergone as great or greater increase than chicken production over the past 50 years, and the turkey industry has also undergone vertical integration. Similar to chickens, modern selection techniques have greatly changed the turkey over the last half of the twentieth century. In the late 1950s, tom turkeys were marketed at approximately 10.5–11.3 kg live weight. However, it took nearly 25 weeks for a tom turkey to reach approximately 11.3 kg in 1960, approximately 21 weeks to reach the same weight in 1974, and only approximately 28 weeks to reach 15.8 kg. In 2011, an achievable performance goal for a tom

Table 1 Nutrient composition of various poultry meats data for beef and pork are provided for comparison

turkey to reach 11.3 kg of live weight was 13 weeks of age, and a 22 week-old tom turkey to reach 22 kg of live weight. Therefore, modern selection has significantly altered the quantity, proportionality, and muscularity of turkeys, and rate of turkey muscle development. Overall, turkey carcasses have a high muscle to bone ratio, the breast meat accounts for approximately 29% of the carcass weight, and there is a high dressing percentage (>75% live weight). However, selection for rapid growth has caused some problems for modern turkeys because the size of the breast muscle precludes mating and focal myopathy, which is a pathological muscle condition characterized by enlarged muscle cells, in the breast muscle has been reported to be associated with the rapid growth of these fascinating birds.

In concert with the improvement in the turkey production efficiency were also increases in turkey meat consumption. Till the late 1970s, turkey consumption was heavily concentrated at holiday festivals with very little consumption during the remainder of the year. However, because of aggressive marketing programs and the advent of new products, turkey has become a year-round meat product that American consumers enjoy on a daily basis. Per capita US turkey consumption was approximately 2.25 kg in 1955, but it rose to nearly 8 kg in the late 1990s, and the 2008 per capita consumption was approximately 8 kg and consumption has remained flat. The growth of the turkey industry can be tied to the relatively low cost of turkey meat, the advent of new turkey products (turkey bacon, turkey bologna, turkey hotdogs, sliced turkey breast,

and turkey ham), and the perception by health conscious consumers that turkey is a healthy food. Furthermore, turkey meat is low in fat, high in protein (Table 1) and versatile.

Ducks

Wild Mallard ducks are generally regarded as the ancestor of all breeds of domestic ducks. The Pekin is likely the most popular breed of duck that is used in commercial production. The Pekin undergoes early maturity, is hardy, and develops a good carcass. Pekin ducks originated in China during ancient times, and they were first imported to America after a lengthy sea voyage from Peking China in 1874. A young duck or duckling (usually under 8 weeks of age) has dark, tender meat, and weighs approximately 1.6–2.25 kg. The duck industry in the US was initially concentrated on Long Island, New York to supply the New York City market. However, the duck production industry in the US has shifted from its original Long Island base to be concentrated in the mid-western US, and the duck industry now enjoys a nation-wide market in the US. The single largest company producing ducks in the US has facilities in California, Wisconsin, Indiana, and Michigan producing 14 million ducks per year. Overall, the duck industry in the US is still much smaller than the chicken or turkey industries. It produces approximately 24 million ducks annually compared to approximately 8 billion chicken, and approximately 275 million turkeys. Similarly, the average American only consumes approximately 0.15 kg of duck per year making duck much less popular with American consumers than other poultry meat species. The largest duck producing nation is China (approximately 2.6 million metric tons), followed by France, Thailand, Vietnam, and the US (approximately 50 000 metric tons). Although it appears that duck meat is consumed on a world-wide basis, it tends to be less popular world-wide than chicken or turkey meat.

The appeal of duck meat to American consumers tends to be in affluent specialty markets for people who prefer the taste of duck to turkey or chicken. Duckling is an international mealtime favorite, and it is best known for the elegant dishes prepared in elite restaurants, such as Peking Duck and Duck al' Orange. However, there are a number of delicious duck recipes that are easy to prepare at home, such as Bar-B-Q duckling, roast duckling, and duckling pasta. Duck breast meat does not appear as white as turkey or chicken meat, and it is marketed as a 'red' meat. Duck meat is nutritionally similar to other poultry meats, except it appears that skinless duck meat has a higher fat content than skinless chicken or turkey meat (Table 1). A potential reason for the limited growth of the duck industry may be that duck tends to be much more expensive than chicken or turkey, or it may simply be related to the high cost of duck compared to all other food. Similarly, the convenience food, such as chicken nuggets, sliced turkey breast, chicken hotdogs, and turkey burgers, have not been produced or successfully marketed by the duck industry.

Geese

The popular geese breeds are the Embden, Toulouse, African, Chinese, Pilgrim, Egyptian, and Diepholz. The development of modern geese breeds has not followed the same path as modern chickens or turkeys, because goose production has not achieved the same corporate scale as the chicken or the turkey industry. Therefore, few industrialized breeding programs have been implemented for geese. The number of geese in Europe has dropped steadily since the introduction of modern poultry production techniques during the early twentieth century. An increases in geese production have occurred in less developed countries where geese can free range, live independently, and produce culturally acceptable, tasty meat. A major country producing goose meat is China. The barriers to geese playing a role in large-scale agriculture are the relatively poor reproduction rate, their slow growth rate compared to chickens and turkeys, and the lack of corporate marketing. Nutritionally, skinless goose meat is similar to other poultry meat species, but it contains a higher caloric fat and iron content than skinless chicken or turkey meat (Table 1). Overall, goose meat is a highly nutritious product that is an excellent source of protein for people in developing countries or consumers in more developed countries who enjoy its taste.

Ratite

The US ratite (ostrich, emu, and rhea) industry began in the early 1980s as an almost totally breeder-production system. Bird prices were very high and the ratite market quickly reached a saturation point. The present ratite industry has shifted from a breeder-based industry to be a product-based industry (meat, hide, oil, and feathers), but the limited infrastructure of ratite-processing facilities has been a major barrier to the development of the industry. There are limited statistics available for ratite production, but there are likely between 50 000 and 100 000 ostriches and between 50 000 and 100 000 emus in the US. In Canada, there were only 11 ostrich, emus, or rhea harvested in 1993, whereas in 1997, there were 13 000 birds harvested. Therefore, some growth has occurred in the North American ratite industry during the 1990s, but there has not been a strong demand for ratite meat by North American consumers. Subsequently, there has been a steady decline in the number of Canadian farms producing ostrich and emus as well as a steady decline in total Canadian ostrich/emu numbers between 1996 and 2006 suggesting that the ratite industry has failed to develop in North America.

The ostrich is indigenous to Africa, and it has been raised domestically in Africa since the 1800s. Ostriches stand up to 3 m high and can weigh 180 kg. Normally, ostriches are processed at approximately 10–14 months of age. Emus originated in Australia, and they are smaller than ostriches standing approximately 1.5 m high and weighing approximately 54 kg. Lastly, rheas are indigenous to South America, and they stand approximately 1.5 m high and weigh approximately 27–36 kg at maturity. All three species have organized associations to support the marketing of their products. The current market for ratite has been primarily for specialty meats, focusing on customers who wish to enjoy a tasty, low fat alternative to traditional red meat products.

Consumer taste panels have only found slight differences in palatability attributes between ostrich steaks and Choice beef top loin steaks; however, the slight differences in palatability

did not significantly affect overall acceptability of ostrich steaks. Ostrich meat is very high in protein, but low in lipid content (Table 1). The nutrient composition of ostrich meat is similar to other poultry meats, but the sensory attributes are similar to traditional red meat. Overall, it has been difficult to introduce new meat products to American consumers, and demand for ratite meat failed to be firmly established. Any future success of the ratite meat industry in the US may depend on an effective distribution, marketing, and promotion strategy that have been characteristic of the broiler and turkey industries.

Game Birds

The US game bird industry raises millions of birds to stock land for recreational hunting, sale to restaurants, and sale directly to consumers. Wild game legally hunted in the US cannot be sold to consumers, but the game can be harvested for personal consumption. Wild game that is raised on farms and processed under appropriate regulations can be sold to the consumers. In general, a large portion of the game bird industry is focused on hobbyists raising home flocks, and also on raising game birds to stock hunting grounds. Therefore, game birds, such as pheasants and Bobwhite quail, can be marketed as day-old-chicks for the small flock hobbyist, as young mature birds to stock hunting lands, and as meat for restaurants or the home consumer. In the US, up to 10 million pheasants, and 37 million quail are raised for consumption. Pheasants reach approximately 1.2 kg by approximately 16 weeks of age. A major obstacle to pheasant production is cannibalism, which is prevented by beak trimming, and the pheasants need their wings clipped to prevent flight. Quail are raised in similar conditions to broiler chickens, but they are very small birds making each require little floor space, and they reach market age by approximately 7 weeks of age with a carcass of 0.2 kg.

Overall, the poultry industry provides a variety of tasty products, such as ratite, duck, quail, and pheasant for consumers who wish to explore the exotic meats, but these speciality products are vastly overshadowed by the larger scale production and consumption of lower cost broiler and turkey meat.

Sheep and Goats

EL Walker and MD Hudson, Missouri State University, Springfield, MO, USA

This article is a revision of the previous edition article by EP Berg, EL McFadin Walker, volume 3, pp 1291–1295, © 2004, Elsevier Ltd.

Glossary

Average daily gain (ADG) A measure used to compare growth rates of animals.
Cabrito A name given to meat from milk-fed kids. It is similar in meaning to veal in cattle.
Callipyge 'Beautiful buttocks.' A genetic mutation found in sheep associated with muscle hypertrophy, typically seen in the leg.
Carcass composition The combination of, and relationship between, lean, fat, and bone present in the carcass.
Carcass quality Meat tenderness, juiciness, color, and flavor.
Chevon Generic name for goat meat.
Cold shortening A phenomenon that results in decreased tenderness of meat due to rapid heat dissipation from carcasses in the hours following slaughter.
Small ruminant A term that denotes both sheep and/or goats. Small ruminants have a multicompartment pregastric digestive system similar to that of cattle and buffalo.

Introduction

Small ruminants, such as sheep (*Ovis aries*) and goats (*Capra hircus*), were among the first animals to be domesticated, with historical evidence linking them to western Asia approximately 9000–12 000 years ago. Domesticated sheep and goats provided early humans with a supply of fiber, pelt, meat, and milk. Owing to their small stature and versatility, small ruminants were, and still are, an important food source in dry, remote regions of the world that lack electricity and have limited grain or roughage. Small ruminants are also efficient convertors of low-quality feed materials to high-quality protein. Furthermore, a small ruminant carcass can be consumed in a few days, which allows only limited time for spoilage.

Unlike sheep, which descended from four distinct types of wild sheep, including the Urial, Argali, Mouflon, and Aoudad, most goat breeds can be traced back to only one wild type, the Benzoar of Asia Minor and the Middle East. There are more than 850 breeds of sheep and more than 500 different breeds of goats worldwide. Although many believe that sheep and goats are similar in their physiological traits and behavior, they are quite dissimilar and should be treated separately. As large ruminants, such as cattle, and small ruminants are researched and managed differently, the sheep and goat should also be evaluated independently.

Since the 1960s, meat consumption has increased worldwide following the increase in human population and greater disposable income in developing countries. Production of small ruminants could be increased in developing countries, if it were not for limited feed, lack of veterinary assistance and educational resources, and climatic challenges. In many areas of the world, including the USA, sheep and goat production tends to be thought of as low-investment, low-output enterprises. However, in many countries, these animals could generate greater income for producers, if it were not for a complicated system of government subsidies and regulations.

World Sheep and Goat Inventory

Between 2004 and 2007, the areas of the world most noted for sheep and goat production included China (143.8 million; home to one-third of all small ruminants), India (182 million), Australia (99.3 million), Iran (54 million), the Sudan (47 million), and New Zealand (40 million). Total worldwide production of small ruminants was approximately 2 billion head (1.25 sheep for every 1 goat), yielding more than 11.8 million metric tons of product. More than 90% of the world's goats and almost 70% of the world's sheep are in Asia and Africa. Australia produces more than 50% of the world's exported goat meat. The total number of goats worldwide has increased 146%, whereas production has doubled since 1990; in contrast, sheep numbers have decreased 10% since 1990. Although sheep meat has increased in value, the consumption of sheep meat has increased 36% from 2010 to 2011, which is greater than both beef (18%) and poultry (16%).

The number of small ruminants worldwide has increased due to high fertility rates, frequency of multiple births, short generation interval, low-cost management, and opportunity for short-term return on investment. People living in rural areas with marginal land and poor economic opportunities can raise small ruminants, which improves income potential and the opportunity for consumption of quality protein. Since 2006, government restrictions in China and adverse weather conditions worldwide have slowed the population growth of small ruminants. Some countries, such as Australia, are trying to restock their breeding inventories, but elevated sheep and goat meat prices have encouraged the sale of live animals into the slaughter market.

Small ruminants do well in a variety of climates. In general, sheep do better than goats in colder climate, whereas goats do better in rugged areas where brush and shrubs are the predominant forage types. Both can thrive on marginal lands and in areas that are unsuitable for cattle or buffalo and are more

 doi:10.1016/B978-0-12-384731-7.00078-7

efficient than larger ruminants at converting forage into useable product. Except for dairy animals, sheep and goats have lower dietary requirements than larger livestock.

Biological Types of Sheep

Domestic sheep are found in nearly every country throughout the world and are highly sought after for their wool, hides, and carcasses. Breeds, or biological types, of sheep can be broadly classified into five general types: ewe/wool, ram/carcass, dual purpose, milk, and hair breeds. Ewe/wool breeds, such as Rambouillet, Merino, and Finn, are noted for their maternal characteristics and/or high-quality wool. Ram breeds (e.g., include Suffolk, Hampshire, and Dorset) tend to excel at growth and carcass traits. Dual-purpose breeds, such as the Targhee and Columbia, are productive at two or more traits (e.g., wool and meat). The East Friesian is the world's highest-producing dairy breed, producing 500–700 kg of milk per lactation with 6–7% milk fat. Hair breeds shed, and thus do not have to be shorn, and are noted for their maternal or carcass qualities. Some hair breeds are also noted for their tolerance to parasites and overall vigor, making them popular in both tropical and temperate climates. Popular hair breeds include the St. Croix, Dorper, Barbados Blackbelly, and Katahdin.

Selection of a particular breed depends on the breed's suitability to the production environment and its ability to meet the social and economic needs of the community. In areas of the world possessing a moderate climate, sheep breeds are often medium framed, of a compact conformation, with short legs and thicker wool. The average breed type in tropical regions has longer body and legs, longer ears and tails, and possesses short hair, as opposed to wool. The biological type chosen in arid regions that have a limited or seasonal supply of forage are often described as 'fat-tailed' breeds. Fat-tailed sheep, such as the Karakul, utilize the large stores of fat in their tail and hind-saddle region to sustain them through periods when food and water are limited.

Biological Types of Goats

Goats can be sorted into fiber, milk, meat, or feral/brush types. The two most popular fiber breeds or breed types are the Angora and Cashmere (the latter of which is a breed type, not a particular breed). Although any goat can be used for milk production, popular milk breeds include the Alpine, Nubian, and Majorera. Meat breeds vary in type and kind and can include small breeds such as the Pygmy and large breeds such as the Boer. Feral/brush types include the Spanish (breed type) found in West Texas and the Kiko of New Zealand (before genetic improvements). In many areas of the world, breeds of goats are indiscernible and often exist in a feral state. Like sheep, selection of a goat breed for any one particular region of the world is based on the inherent traits of that animal in conjunction with the environment and the specialized needs of the populace.

Of particular note is the Boer, which was developed in South Africa and is being used in countries such as China, Australia, and the USA to improve meat quality of feral goats. Boer goats have superior growth and carcass quality compared with many other breeds; however, research indicates that Kikos can wean more and heavier kids than Boers.

Factors Affecting Growth, Carcass Composition, and Carcass Quality

Growth Effects of Breeds and Genetics on Growth

Growth traits such as weaning (20% heritable) and postweaning (40% heritable) weights are used for selecting carcass quality and quantity. Carcass traits are moderately to highly heritable (30–60%), thus selection for superior growth and carcass traits can be used for increasing meat production. However, in the quest for increasing growth, it is important not to overlook fertility and efficiency traits. In addition, some genetic traits, such as growth rate and wool/hair production, are negatively correlated, and as more emphasis is placed on growth, fiber production and/or quality declines. If feed or capital resources are limited, it is not economically feasible to select for maximal growth.

Sheep

Traditionally, ram breeds have been primarily used to increase growth in wool breeds. However, as wool becomes less valuable, hair breeds become more popular. Most hair breeds have decreased growth rates and average daily gain (ADG) compared with ram breeds. However, the Dorper, a hair breed originating from South Africa and comprised of the Black-Headed Persian and the Horned Dorset, offers advantages in growth as compared with other hair breed types. More research is needed to understand differences in growth between hair, wool, and ram breeds.

Goats

Goats typically produce smaller carcasses, even when slaughtered at similar ages or weights as sheep. Meat-type goats, such as the Boer, have greater ADG and yield heavier, meatier carcasses when compared with milk or feral breed types; however, Boers are not noted, at least in the USA, for possessing superior mothering or hardiness traits. Crossbreeding Boers with other breeds creates hybrid vigor, making the offspring superior than both parents in economically important traits.

Effects of management on growth

Diet can significantly affect ADG, live and carcass weights, fat quantity and composition, and meat flavor. Animals on a high-energy diet grow faster and produce fatter carcasses than those on a forage diet. Animals on high-protein diets yield carcasses that consumers perceive as having 'off'-flavors compared with animals fed high-energy diets.

Castrated sheep tend to grow slower than intact males, which is similar to results demonstrated in cattle and hogs. Studies with goats indicate that there is both a breed and time of castration effect on ADG; however, the results are conflicting with respect to age of castration. Some studies recommend early castration (less than 1 week of age), whereas others

recommend delayed castration (after 6 months) for achieving most efficient growth in goats.

Carcass Composition

Effects of breeds and genetics on carcass composition

On an average, approximately 50% of live sheep/goat weight is retained as carcass weight. The carcass dressing percentage increases with increasing levels of fatness and/or muscularity. Dressing percentages typically range from 40% to 60%; however, extreme, heavily muscled animals may yield greater than 60% of their live weight as carcass weight. The weight of muscle tissue comprises 46–65% of the total dressed carcass weight. Sheep are intermediate to pigs and cattle for the propensity to deposit subcutaneous fat. Sheep produce carcasses with more dissectible fat and lean but with less bone than goats raised under similar management and slaughtered at similar ages and weight. Hair sheep may differ in the muscle–fat ratio; however, sufficient research has not been conducted to fully understand possible breed or type differences. Generally, it is thought that hair sheep deposit fat more like goats rather than like other sheep breeds.

Small ruminants are sold for harvest as intact males, intact females, and wethers (castrated males). In some countries/cultures, castration is either not permitted or consumers prefer meat from intact males. Carcasses from intact males typically have a thicker, more muscular neck and shoulders (adding weight to low-value cuts) compared with carcasses from females or castrated males. Depending on culture, these characteristics may be considered undesirable. The pelt of intact males is also more difficult to remove and may result in tearing of the external fat cover and a reduction in carcass appeal. Overall, breed and weight at the time of slaughter may have a greater effect on dressing percentage than gender.

Goats deposit greater amounts of internal fat rather than subcutaneous fat when compared with sheep or cattle. Goat meat tends to be leaner than sheep meat and therefore has higher proportions of protein and minerals. Not much is known regarding growth or body composition of goats or hair sheep, especially when compared with wool and ram breeds of sheep, beef cattle, and swine.

Chemical profiles of sheep and goat meat

Meat from lamb and goats is frequently touted as healthy. On an average, lamb contains 22% protein, 16% fat, and 78 mg of cholesterol per g of meat. Chevon contains, on average, 23% protein, 12% fat, and 94 mg of cholesterol per gram of meat. However, all of these values differ depending on preslaughter management and the particular cut of meat from which the sample was obtained. Animals slaughtered before six months of age tend to have lesser amounts of cholesterol than older animals. Also, breed may influence cholesterol content, as meat from St. Croix lambs may contain greater amounts of cholesterol compared with other breeds and breed crosses.

Although there are species and breed differences, in general, meat from sheep and goats has a high monounsaturated to polyunsaturated fatty acid ratio. However, feeding diets with a ruminally protected source of fat can produce a more favorable polyunsaturated to saturated ratio. Also, as animals become fatter, the composition of fatty acids changes because the triglycerides, which increase with fatness, are more saturated. Diet can also affect the ratio of oleic, palmitic, and linoleic acids. In addition, some have reported that there is a difference in fatty acid profile between genders, with males having a greater proportion of palmitic acid. The predominant fatty acids isolated from lamb and goat meats are oleic (28–44%), stearic (12–25%), and palmitic (16–23%) and are roughly in the same proportions as found in beef and pork. Proportions can differ depending on diet (milk fed vs. concentrate vs. forage), age, and breed.

Effects of Management on Carcass Composition

Sheep

Across all breeds and weights, carcasses from rams are the leanest and ewes are the fattest. Ram lambs tend to have the largest and the longest carcasses and possess larger loin muscles compared with ewes. Wether lambs are intermediate. Delaying castration or slaughtering ram lambs before puberty can increase the carcass lean to fat ratio.

Goats

Few studies have evaluated the effects of gender on carcass composition in goats. Time of castration affects dressing percentage, and variations in timing may explain why there is limited agreement between the published studies. In most cases, goats are slaughtered either before or soon after puberty (4–8 months); therefore, the effects of the male sex steroids may not have had sufficient time to affect dressing percentage. The proportion of retail carcass cuts is also affected by gender; however, breed and age have greater effects on carcass composition.

Carcass Quality

Carcass quality is commonly assessed for carcass conformation and indicators of potential eating satisfaction (palatability). It should be noted that carcass conformation has little relationship with palatability. Furthermore, the definition of quality in the eye of the consumer is much broader and includes not only palatability but also product appearance, nutrient density, and wholesomeness (freedom from pathogens). Sensory characteristics, such as flavor, aroma, juiciness, and tenderness, are influenced by breed, diet, gender, and pre- and postslaughter management. Small ruminants are consumed all over the world; one should, therefore, expect the perception of quality to be extremely diverse. Factors that influence the perception of quality include (but are not limited to) muscle texture, tenderness, flavor, fat content, fatty acid profile, water content, preslaughter nutrition, postslaughter handling, processing practices, level of sanitation, meat aging, refrigeration (or absence of refrigeration), and cooking methods.

Factors affecting meat flavor

Components of meat flavor are both fat and water soluble, but the water-soluble components are relatively similar across species and are the main reason why fat-free products taste similar across species. It is the fat component of meat that primarily

contributes to species differences in flavor. The total and ratios of fatty acids present (often referred to as the fatty acid profile) in the adipose tissue of lamb and chevon influence flavor perception by consumers. Forages contain a variety of odoriferous and reactive fat-soluble components that ultimately are deposited as flavor precursors in the muscle. These compounds can accumulate within adipose tissue over time and are perceived as either positive or negative meat flavors (depending on culture or geographical origin of consumers). These flavor-influencing compounds are more prevalent in chronologically older animals and can contribute to the distinct flavor differences between young and old animals. Generally, as animal's age, flavor intensity increases, often to the point of undesirability for many consumers. In some areas of the world it is common to harvest and consume intact males, the meat from which may be perceived as less tender with stronger flavor.

In the USA, more than 80% of lambs marketed are finished on high-concentrate (predominantly corn) diets, yet, in many countries, lambs are fed 100% forage diets. Lamb consumers accustomed to corn-finished lamb perceive forage-finished lambs to have 'lamby' or 'grassy' flavors. Those accustomed to the more common worldwide production practice of pasture- or forage-finished lambs find the corn-finished lamb to be mild, lacking in traditional lamb flavor, and too fat. Little research has been conducted regarding the effects of diet on sensory characteristics of goat meat.

Effects of breeds and genetics on carcass quality

There are some notable differences between lamb and chevon with respect to the role of breed on carcass quality. Although lamb is rarely perceived as tough, biological (breed) type can influence tenderness. Hair breeds are generally regarded as yielding tougher meat compared with ewe breeds. Although it has not been evaluated, differences may exist between hair breeds. Furthermore, meat from lambs expressing the callipyge (double muscling) genotype is distinctly less tender compared with lamb from 'normal' carcasses, irrespective of whether it is from wool or hair breeds. Lambs of St. Croix breeding have been shown to produce a more palatable carcass when compared with wool or callipyge sheep. However, little research has been conducted comparing hair breeds with the other breed types in terms of overall carcass palatability.

Sheep carcasses tend to be perceived as higher quality than goat carcasses, and meat breeds of goats, such as the Boer, tend to be perceived as having higher quality carcasses, based on hindleg circumference, than indigenous or feral- and milk-type goats. However, assessment of carcass quality is influenced by local custom and preference, so it is hard to define a universal standard for carcass quality in the goat.

When similarly prepared, consumers generally prefer lamb over goat in terms of tenderness, juiciness, and overall palatability. Unfortunately, less is known concerning the effects of breed or breed type on carcass quality in goats. There are conflicting results regarding the effect of breed on carcass quality, with some reports showing small or no effects, whereas others report breed to be a significant factor in carcass quality traits. This represents another area in which additional research efforts are needed.

Goat carcasses have greater collagen content compared with lamb carcasses, which results in greater toughness. However, because chevon is leaner than lamb, mutton, or beef, consumers may overlook some of the negative palatability traits as a trade-off for a leaner protein source.

Additionally, sheep and goats have less subcutaneous fat cover than pigs and cattle have; moreover, goats deposit less subcutaneous fat than sheep and yield leaner carcasses. Lean carcasses chill faster than ones with more fat cover, which may lead to cold shortening of muscle fibers and increased meat toughness. Rapid chilling of prerigor carcasses can also induce cold shortening of the muscle fibers and thus should be avoided. Cold shortening can be reversed by applying electrical stimulation to the carcass or by increasing the postmortem aging process, which may increase tenderness. This procedure shortens the time necessary for the onset of rigor mortis by accelerating postmortem glycolysis so that carcasses may be rapidly chilled without the risk of inducing cold shortening.

Effects of management on carcass quality

Worldwide management practices favor production of small ruminants on a pastoral diet. Pasture-raised animals rarely become excessively fat. However, in countries where it is economically feasible to feed high-energy, corn-based diets, the potential for overfattening exists if animals are not properly managed. Those raised on high-energy diets tend to be tenderer, but fatter, than animals fed with low-energy diets. Little research has been conducted in goats to determine how diet affects overall carcass quality, including tenderness.

In other meat animals, age at harvest affects tenderness; however, there is no consensus as to the effect of chronological age on lamb tenderness (lamb vs. mutton). The accumulation of connective tissue and the increased maturation of muscle of older lambs increase the potential for tougher meat. Early maturing, small-framed sheep (such as the hair breeds) reach an ideal lean to fat ratio earlier, and if fed to a harvest weight similar to large-framed breeds, they will possess too much fat. Later maturing, fast-growing sheep (often black-faced breed types) and goats (Boer or Boer type) tend to be more heavily muscled and should be marketed at an earlier chronological age to increase the lean to fat ratio.

The age at which small ruminants are harvested depends on the demands of consumers. If consumers prefer larger cuts of lamb/goat, age at slaughter will increase to allow more time for increased muscle growth. However, without proper management, lambs/kids fed to heavier market weights reach a point of physiological maturity, at which increases in muscle mass slow or cease causing the animal to become excessively fat. Consumers usually avoid excess fat when purchasing lamb/goat. Animals slaughtered at an older age may also be perceived as less desirable by the consumer, in part due to darker meat color. In addition, due to enhanced proteolysis, older animals yield meat with flavor differences, which are often characterized as bitter tasting.

An additional benefit of castration is to prevent taint of the meat, which is caused by androstenone, a steroid produced by the testes. Androstenone accumulates in the fat and is released when the meat is cooked. However, the perception of an undesirable sexual odor in meat is not consistent or well understood. Factors such as breed, season of rearing, age at castration, and age at slaughter all affect palatability traits of meat from

intact males. Regardless of gender, lamb meat tends to be perceived as tender. In goats, does yield tenderer carcasses with greater marbling than intact males. Color is also affected by gender, with males generally yielding lighter lean tissue. In goats, differences between intact and castrated males have not been evaluated. However, gender does not influence muscling indicators, such as carcass or leg conformation scores, which are commonly used to assess carcass quality in goats.

Effects of postslaughter management on carcass quality

Breed, genetic type (e.g., callipyge genetic condition), subcutaneous fat cover, and pre- and postslaughter handling may be more important factors affecting tenderness than chronological age in sheep or goats. Most sheep and goats are killed before 1 year of age, which decreases the amount of connective tissue growth, thus decreasing the chance of toughness. Consumers first assess leanness when determining their intent to purchase lamb. However, the evaluation of retail cuts of lamb for freshness, as perceived by color, is an important factor for consumers. There are contradictory assessments of meat color and presumed freshness; some consumers equate a bright red color with greater quality and freshness of the product, whereas others deem a darker red color as more acceptable. Like flavor, color preference is culturally and geographically specific. Potential consumers also perceive lamb meat color differently based on the manner of packaging.

Meat color can also be influenced by factors that have little to do with the overall quality of the product, such as preslaughter management of live animals. Sheep exposed to prolonged periods of preslaughter stress, such as illness, poor nutrition, or prolonged transportation, often produce meat that is darker in color. Furthermore, these animals often yield carcasses with greater intramuscular pH that leads to an increased risk of premature spoilage.

Summary

Small ruminants have been economically important to humans for thousands of years; because of this, more than 1000 breed types have been developed to fit various management practices and environmental conditions worldwide. Meat quality (palatability, nutrient density, wholesomeness, appearance) can be influenced by various factors, such as breed, gender, feeding regimen, and chronological age. There is no universally accepted method of assessing carcass composition and quality, because of worldwide differences in perception of what constitutes acceptable lamb/goat. Generally speaking, consumers of lamb and goat prefer a lean, low-fat product, but they disagree with regard to what is considered desirable palatability or flavor. Sheep and goats are inherently different animals, and thus they should be treated and researched as such.

Shellfish

XM Vilanova, Universitat Autònoma de Barcelona, Barcelona, Spain

This article is a revision of the previous edition article by LS Andrews, volume 3, pp 1317–1324, © 2004, Elsevier Ltd.

Introduction

Shellfish are edible aquatic invertebrate animals, usually with a shell, including molluscs such as oysters, clams, mussels, and cephalopods and crustaceans such as shrimp or lobsters. This article presents the major species of shellfish consumed worldwide. It is divided by scientific classification and presented with the market and scientific names as well as a brief description of each. Those species of major economic importance and those of popular or regional consumption such as, 'Louisiana crawfish,' are described in more detail.

Nutritionists value shellfish as a quality protein source. Seafood contains all of the essential amino acids, and with 17–25% protein is an excellent source to meet our daily protein needs. Although shellfish tend to contain slightly higher amounts of cholesterol than finfish, the amounts for crab and lobster are similar to that in the dark meat of chicken. Cholesterol levels vary with shrimp species, but are generally 1.5–2 times higher than in other shellfish. Previously, shellfish were excluded from low-cholesterol diets because they were believed to be high in cholesterol. Today, with modern sophisticated measuring, it is known that cholesterol levels are lower than previously reported. Molluscs, such as clams, oysters, scallops, and mussels, have been found to have a large percentage of noncholesterol sterols that appear to have a positive effect on cholesterol levels. Shellfish are a rich source of essential minerals. Oysters and crustaceans are rich in zinc, iron, and copper; mussels, scallops, and clams are rich in potassium. All shellfish are good sources of iodine, phosphorus, and selenium. Shellfish eaten raw or cooked without added fat are low in fat ($<5\%$) and calorie content.

Crustaceans or Crayfish

Crustacea, a Subphylum of Arthropoda, contains mostly marine arthropods, though many of its members, like crayfish, have invaded fresh water. In the sea, large crustaceans such as crabs and shrimp are common bottom-dwellers. Many minute species of crustaceans are important components of the zooplankton (floating or weakly swimming animals) and serve as food for other invertebrates, fishes, and even whales.

Shrimp/Prawn

One of the world's most abundant and popular seafoods, shrimp contribute to the diets of cultures around the world. Shrimp and prawn are vernacular or colloquial terms and are terms of convenience, but one should not confuse them with the names or relationships of actual taxa (Figure 1). Shrimp are caught or cultured in temperate and tropical salt waters and fresh waters, especially in China, Thailand, Ecuador, Indonesia, India, Bangladesh, and the Gulf of Mexico. World shrimp consumption has increased steadily since 1970. Wild-caught shrimp provided most of the world supply until the mid-1980s. The world catch is now more than 2 million tones, with 30% supplied from aquaculture. Common edible shrimp are presented in Table 1.

Lobster and Spiny Lobster

Lobster is the common name for marine decapod crustaceans. The American and European lobsters are characterized by an enlarged pair of pincers or claws. Spiny lobsters (Figure 2) are not closely related to true lobsters and are distinguished from American and European lobsters by their long antennae and hard shell and are clawless. Spiny lobsters are also, especially in Australia, New Zealand, and South Africa, are sometimes called crayfish, sea crayfish, or crawfish, terms which elsewhere are reserved for freshwater crayfish. Lobster is considered a luxury seafood. Species of the common lobster are included in Table 2.

Crab

Crab meat and claws are among seafood lover's favorite seafood. Crabs are found both on the Atlantic and Pacific coasts of North and South America and the western coasts of north and central Europe, with each region having a local favorite. Several of the world's favorite crab species are presented in Table 3 (Figure 3).

 doi:10.1016/B978-0-12-384731-7.00082-9

Table 1 Common edible shrimp

Zoological name	*Common name*	*Location*	*Properties/uses*	*Culinary attributes*
Penaeus monodon	Black tiger	Central and SE Asia	Black with yellow striped tails	Mild flavor
Penaeus stylirostris	Blues or Mexican whites	Pacific coast of Mexico	Similar to Gulf of Mexico Whites	Firm texture and full, nutty flavor
Penaeus aztecus	Browns	SE USA; Gulf of Mexico	Abundant, low cost	Softer texture than others
Pandalus borealis	Deep sea shrimp	Coast of northern Europe	Most are sold at local markets	Firm texture
Hymenopenaeus robustus	Gulf shrimp	Gulf of Mexico	Large shrimp weighing ≤40 g	Firm texture
Penaeus japonicus	Kuruma or Japanese prawn	Indo-Pacific area; Red and Mediterranean Seas	Large prawns	Firm texture
Aristeus antennatus	Mediterranean prawn	Mediterranean Sea	Blue or red varieties	Sold as appetizer or 'starter' in local markets
Penaeus duorarum	Pink shrimp	Coastal USA in wide bottom sand or mud shelves	Premium domestic US shrimp	Firm texture and mild sweet flavor
Palaemon serratus	Prawn/pink shrimp; sword shrimp; crevette rose; camaron or gamberellon	Deep water Atlantic Ocean and Mediterranean Sea	Premium shrimp of France and Italy	Firm texture and mild sweet flavor
Sicyonia brevirostris	Rock shrimp	Tropical variety found off the coast of Florida	Small with a thick shell	Texture and flavor similar to lobster
Crangon crangon	Sand shrimp	Coastal Europe	Often served with oysters	Cooked whole
Panaeus setiferus	Whites	Gulf of Mexico and SE USA	30% of total US harvest	Firm texture with nutty flavor

Figure 2 Spiny lobster. © Avril Bourquin.

Crayfish/Crawfish

More than 400 species of crayfish are found worldwide. Only 3 of the 250 edible species are available commercially in North America. Crayfish live in freshwater rivers and streams, mostly in temperate climates. In North America, the crayfish is commonly called 'crawfish.' Most crawfish processing occurs in Louisiana, where they are caught wild and pond-raised. Crawfish are sold live for 'crawfish boils' or processed for frozen tail meat. Crawfish, like crabs, replace their hard shell during growth. During the 'softshell' period, the whole crawfish can be eaten and is considered a delicacy.

Procambarus clarkia (Red Swamp Crawfish)

Louisiana red swamp crawfish are harvested in the delta region. They are the most popular because of their larger size than other commercial species and they turn a beautiful bright red when cooked. The meat has a firm texture and is generally considered more flavorful than shrimp. The hepatopancreas (called 'fat' by local consumers) is often consumed along with the meat and is used as a flavor ingredient in a variety of local recipes.

Procambarus zonangulu (White River Crawfish)

White river crawfish are primarily harvested from northern and central Louisiana.

Pacifastacus leniusculus (Pacific Crayfish)

Harvested in California and Oregon, they are consumed by local markets.

Krill (*Euphausia superba*)

Krill is a tiny shrimp-like crustacean and is considered the most important zooplankton species associated with sea ice, playing a key role in the Antarctic food web. Krill travel in large swarms. Commercial fishermen harvest krill as a high-protein ingredient for value-added products and krill has recently been featured at various seafood shows throughout the world.

Molluscs

Any member of the Phylum Mollusca, an invertebrate with a soft unsegmented body, usually protected by a shell in one, two, or three pieces. The molluscs include oysters, clams,

Table 2 Common edible lobster

Zoological name	*Common name*	*Location*	*Properties/uses*	*Culinary attributes*
Jasus edwardsii and jverreauxi	Australian rock lobster	Coastal Australia and New Zealand	Major import to the USA	Marketed frozen for broiling
Panulirus llaevicauda	Brazilian spiny lobster	Caribbean Sea; East coast of S America	Harvested for tail meat	Marketed frozen for broiling
Palinurus interruptus	California spiny lobster	Southern coast of California	Mainly supplied local markets	Boiled whole
Homarus americanus	Canadian/American lobster	Western Atlantic Ocean from Labrador to North Carolina	Weight range 0.9–2.2 kg; bright red shell	Considered a delicacy in American and European markets; boiled live
Homarus gammarus	European lobster	Coasts of Great Britain, Norway and Brittany	Darker, bluish shell compare to American	Flavor and texture same as American
Palinurus mauritanicus	European spiny lobster	Mediterranean and E Atlantic	Thorny shell	European delicacy
Palimurus argus	Florida spiny lobster, Caribbean lobster, rock lobster, or langouste	Western tropical Atlantic from Florida to S America	Rough, hard shell. Sold for local markets only	Flavor and texture similar to American and European lobster
Panulirus marginatus	Hawaiian spiny lobster	NW Hawaiian Islands	Season limited by supply	Firm texture and sweet flavor
Nephrops norvegicus	Langoustines, Dublin Bay prawns, scampi	Norway, E Atlantic coast of Europe and Adriatic and western Mediterranean Sea	Smaller than lobsters, with long, smooth bodies	Boiled whole
Scyllarus arctus	Slipper/squat lobster, or Australian 'bug' lobster	Tropical seas	Small	Boiled whole
Jasus lalandii	South African rock lobster	South Africa	Cape crayfish	Premium lobster

Table 3 Common edible crab

Zoological name	*Common name*	*Location*	*Properties/uses*	*Culinary attributes*
Callinectes sapidus	Blue crab	East Coast USA and S America, Gulf of Mexico, France, Holland, and Denmark	Largest commercial crab fishery in the USA	Cooked and eaten whole or processed for meat and claws. Strong distinct flavor
Cancer magister	Dungeness crab	Oregon and Washington states	Niche market	Cooked for local markets
Paralithodes camtschaticus	King crab or 'red' king crab	Alaska	Coldwater crabs. Have 6 legs and 2 claws, unlike other crabs with 8 legs and 2 claws	Firm texture; meat like lobster; legs are meatier and are preferred over the claws
P. brevipes	Brown or deep water king crab	Deep water Alaska		
Lithodes antarcticus	Southern king crab	Chile to Antarctica		
Chionoecetes oplio, C. bairdi, and *C. tanneri*	Snow crab	Alaska	Smaller and less expensive than king crab	Legs are steamed or boiled
Maia squinado	Spider crab, thomback crab	Europe and Japan	Giant crab may reach 40 cm	Steamed or broiled
Menippe mercenaria	Stone crab	Florida west coast	Stone crab claws are snipped off the live crab and will regenerate	Claws are steamed and served cold
Portunidae spp.	Swimming crab, mud crab, shore crab, velvet crab	Italy, Portugal, Australia, and SE Asia	Distinguished by their extra pair of 'paddlelike' appendages	Soft shell are a delicacy in China; used for Thai crab cakes and Scottish crab soup

snails, slugs, squid, and octopuses. Most molluscs are aquatic but some land snails like *Helix aspersa* are also eaten. It is the snail most cultivated for gourmet food and is known as petit gris.

Bivalves (Two Piece Shells)

Oysters

Oysters have a rough, irregularly shaped shell and live mainly in temperate or warm coastal or estuarine waters. Oysters (often eaten raw) are considered a seafood delicacy. Raw oyster consumption is occasionally associated with gastrointestinal disease. Oyster beds, often located adjacent to rural communities, must be carefully monitored to ensure that they have not been contaminated with polluted water, especially during periods of heavy rain. Many species of oysters are harvested in small numbers and marketed for retail as exotic speciality oysters. The more important edible species are presented in Table 4 (Figure 4).

Clams

These burrowing shellfish are freshwater or marine molluscs having a muscular foot with which they can burrow into sand. More than 20 000 species are edible, but only approximately 50 species are harvested commercially. A few of these commercially available clams are presented in Table 5 (Figure 5).

Table 4 Edible oysters

Zoological name	*Common name*	*Location*	*Properties/uses*	*Culinary attributes*
Crassostrea virginicus	Eastern Atlantic or American oyster	Eastern USA, Southern Canada, Gulf of Mexico	Thick rough shells; the most popular and plentiful oyster in the USA	Mild delicate flavor; often consumed raw
Ostrea edulis	Native or 'flat' oyster; French Belon, the English Whitstable, Colchester and Helford, the Irish Galway and the Belgian Ostendes	Europe		Fine texture and rich flavor. The Belons, grown in cold water, have a briny, metallic flavor
Crassostrea gigas	Pacific or Japanese oyster	Pacific coasts of USA and Japan	Most widely farmed oyster in the world	Very large size makes them highly suitable for cooking
Crassostrea angulata	Portuguese cupped oyster	France and Portugal	Farm raised	Considered a delicacy, spéciales claires
Crassostrea commercialis	Sydney rock oyster	New South Wales	Farm raised	Rich, fresh flavor
Ostrea lurida	Western Olympia oyster; American native	Pacific coast USA	Small oyster less than 5 cm in length	Sold at local markets
Ostrea chilensis	Bluff oyster	Native to Chile and New Zealand	Dredged	Sold at local markets
Saccostrea commercialis	Rock oyster	New Zealand	Commercially grown originally but now supplanted by Pacific oyster	Exported

Table 5 Common edible clams

Zoological name	*Common name*	*Location*	*Properties/uses*	*Culinary attributes*
Panopea generosa	Geoduck clam	Pacific coast USA	Large clam attaining an in-shell weight of 4 kg	Steamed for delicate texture and flavor
Mercenaria mercenaria and *Mercenaria campechiensis*	Hard clam; quahog	New England shores of USA	Popular recreational fishery	Marketed for steaming as chowder clams (large), cherrystone (medium), and 'little neck' (small)
Tapes philippinarium	Manila clam	Philippines	Exotic species to USA	Satisfy a 'niche' market
Arctica islandica	Ocean quahog or 'black clam'	N Atlantic Coasts from Europe to USA and Canada	Harvest estimates are 46 million annually	Comprise 38% of US clam market; light flavor with crisp texture
Venerupis decussate	Palourde/carpet shell clam	Southern Europe	Small clam	Consumed raw in local markets
Venus verrucosa	Praire/warty Venus clam	Europe to Africa	Small clam	Consumed raw in local markets
Ensis directus, Solen marginatus and *Siliqua patula*	Razor or jackknife clam	Europe, California, Aleutian Islands	Long shape up to 25 cm	Popular for 'clam diggers;' steamed in sandy pits
Mya arenaria	Soft-shell clam	North America, Europe, and Pacific coast of the USA	A soft-shell clam with a long neck	Usually steamed
Spisula solidissima	Surf clam	Atlantic coast of N America from S Carolina north to the St Lawrence Gulf	A larger clam species	Processed as clams strips for breading and frying

Figure 5 Quahog clam. © Avril Bourquin.

Scallops

Marine bivalve molluscs have a distinctive fanshaped shell with radial ribs and wavy edges. Scallops move by opening and closing their valves. Near the hinge where the two valves (shells) meet is the eye, or adductor muscle, which is the part of the scallop eaten in North America. In Europe, the entire scallop is eaten. More than 300 species of scallop occur worldwide, with varying shell color including beige, pink, salmon, and yellow. The more commonly consumed scallops are presented in Table 6 (Figure 6).

Mussels

Mussels are distinguished by a blue–black shell and live attached to objects in the sea. The many varieties of mussels are harvested from cold Atlantic waters in both Europe and the US and off the coast of New Zealand.

Mytilus edulis *(blue mussel)*

The blue mussel represents the dominant mussel species in North America. They are found in Atlantic waters from Canada to North Carolina. They have a smooth, bluish-black elongated shell. The inside of the shell is pearly violet or white. Between the shells on one side is a bundle of tough, brown fibers called the byssal threads or 'beard.' These fibers are used to anchor the mussel to rocks, pilings, and other mussels. As demand for consumption increases, wild populations are being supplemented by aquaculture to prevent depletion of natural beds. In Europe, blue mussels have been cultured for over 300 years. Mussels are efficient feeders compared to other shellfish. They have a third more protein than oysters. Orange-tinted meats represent mature female mussels, whereas the ivory meats are males and immature females. Connoisseurs maintain that mature females have the best flavor.

Perna canaliculus *(greenshell mussel)*

Greenshell mussels are harvested off the coast of New Zealand and may grow up to 23 cm.

*Cockles (*Cardium edule*)*

Cockles are found worldwide but are traditionally thought of as a British speciality. In North America, they are known as 'heart clams.'

Table 6 Common edible scallops

Zoological name	*Common name*	*Location*	*Properties/uses*	*Culinary attribute*
Argopecten irradians	Bay scallop	N America: New England to Gulf of Mexico	Small scallop only 2 cm	Firm, white meat
Argopecten gibbus	Calico scallop	Tropical and subtropical Atlantic from N Carolina to Brazil	Important commercial species; 465 t annually	Firm, white meat
Chlamys opercularis	Queen scallop	SE Asia	Small scallop	Firm, white meat used in soups
Placopecten magellanicus	Sea scallop	Atlantic coast of N and S America	Largest species, market size is 1.5–8 cm	Distinct sweet odor when fresh
Patinopecten cauimus	Weathervane scallop	Alaska	Short harvest season; 2–3 weeks in late summer	Sweet, crisp flavor and texture
Pecten novaezelandiae	Scallop	New Zealand	Important commercial species; 747 t annually in 2004. Seeded from spat	Firm, white meat

Single-Shell Molluscs

Gastropods

Gastropods have a head with eyes, a large flattened foot, and often a single shell. Gastropods are the largest class in the Phylum Mollusca and are the most diverse. Nearly 35 000 living species and 15 000 fossil species have been identified, including spirally coiled snails, flat-shelled limpets, shell-less nudibranchs, whelks, abalones, pteropods, and terrestrial snails and slugs.

There are several varieties of Abalone (*Haliotis cracherodii* (black), *Haliotis rufescens* (red), and *Haliotis iris* (white)).

Of all the gastropods, abalone is the most popular for human consumption. The red and black abalone are found along the coastlines of California, Mexico, and Japan. Approximately 100 species exist worldwide. The edible portion is the adductor muscle, by which it clings to rocks. Abalone, used widely in Chinese and Japanese cooking, can be purchased fresh, canned, dried, or salted. The iridescent shell is a source of mother-of-pearl. The wild fishery is carefully managed and abalone farms have been established to meet consumer demand.

Conches (Strombidae *sp.*)

Of the numerous species of conches, the queen conch is the most popular edible species. They are mostly found near the breaking surf of barrier reefs because of their high oxygen requirement. Conches are harvested from Belize, Turks, and Caicos and the Bahamas for restaurant trade. The meat is white with a tough rubbery texture and is pounded to tenderize it. Because of their rarity, conches bring a good price in restaurants.

Whelks (Subclass Prosobranchia, Buccinum undatum*)*

Prosobranchia (limpets, winkles, whelks, etc.) are familiar creatures, often found in rockpools on the seashore. The common whelk is distributed along Atlantic coasts, the English Channel, the North Sea, and the Baltic Sea. They inhabit sand and mud from shallow water to a depth of 100 m. Fully grown, whelks have a shell up to 10–15 cm high with a pointed spire and well-defined ribbed whorls. They are usually pale brown in color. The largest whelks (like *Busycon carica)* are found on the American side of the Atlantic and may grow up to 30–35 cm.

*Periwinkles or sea snails (*Littorina littorea*)*

Nearly 300 species are known throughout the world, but few reach edible size. Periwinkles are found among seaweed on the rocky shores of the eastern coast of North America from Canada to lDelaware. Usually dark brown in color, the shell is rounded with concentric ridges and dark lines. Periwinkles are a common food in Europe but are not harvested in large numbers.

Cephalopods

Cephalopods are molluscs closely related to snails and include squid, nautilus, cuttlefish, and octopus. Cephalopods are found in most of the world's oceans in plentiful supply.

Squid (Loligo pealei, Illex illecegrosus, *and* Loligo opalescens)

Squid, commonly called calamari, are found in the northwest Atlantic Ocean and on the Pacific coast. There are marine cephalopods with two long tentacles and eight shorter arms, a long tapered body, two triangular fins, and an internal shell (Figure 7). Squid sizes range from 7.5 cm to as large as 17 m for the giant squid. Squid landings for edible food have greatly increased over the past 25 years; most are from Pacific harvest and more than half are exported to Asian markets, especially Japan. *Loligo vulgaris*, found throughout Europe, weigh up to 2 kg and are noted to propel themselves out of the water, like a missile.

Octopus (Octopus spp.)

Unlike the cuttlefish and squid, the octopus has no internal shell. There are several species of edible octopus. The giant octopus ranges the coastal waters off northern California through the Gulf of Alaska and around the Pacific Rim to Japan and Korea. Typically they are found in waters shallower than 180 m. The octopus has a large head, a soft oval body, well-developed eyes, and eight arms containing rows of suckers (Figure 8). Edible species range in size from 1 to 3 m in length. Octopus is available live, fresh, frozen, and cooked. Spiced and boiled octopuses are prepared with the viscera and eyes removed. Pickled octopuses are primarily available in Mediterranean and Asian fish markets.

Figure 7 Squid. © Avril Bourquin.

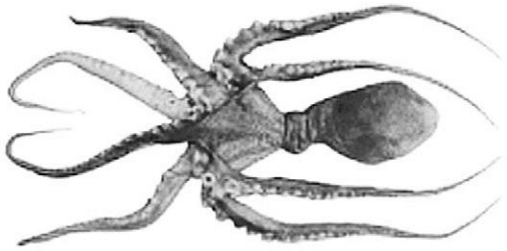

Figure 8 Octopus. © Avril Bourquin.

Cuttlefish (Sepia spp.)

Cuttlefish are caught for food in the Mediterranean, East Asia, the English Channel, and elsewhere. Squid is more popular as a restaurant dish all over the world. Cuttlefish ink was formerly an important dye, called sepia.

Welfare Issues

Animal welfare has become increasingly important worldwide. A fundamental issue when deciding on our moral duties toward animals is whether they are capable of experiencing pain and other forms of suffering. The welfare of shellfish has been much less studied than that of mammals, birds, and even finfish. A summary of findings relevant to the welfare of cephalopods and decapods follows.

There is evidence that cephalopods have a nervous system and relatively complex brain similar to many vertebrates, with good learning ability, and memory retention. They release adrenal hormones in response to situations that would elicit pain and distress in humans, can learn to avoid painful stimuli and have nociceptors in their skin.

Research has found the presence of opioids and opioid receptors in crabs. Also, in an avoidance learning experiment, crabs showed memory of aversive stimuli and learned to avoid them. In another experiment, noxious stimuli (irritating chemical solutions and physical pinching) applied to antennae caused prawns to display immediate reflex tail-flicking responses and also two prolonged activities, grooming of the antenna, and rubbing of the antenna against the side of their enclosure. These responses were blocked with the application of a local anesthetic.

According to some authors, the previous findings suggest that at least some groups of shellfish (in particular, cephalopods and decapods) are capable of experiencing pain and suffering. This would have obvious implications for the industry, as some of the methods used to catch and kill these animals would then be questionable on ethical grounds. Others, however, think that one does not know enough yet to decide whether shellfish are sentient, i.e., capable of experiencing emotions such as pain. Even in this case, however, whether they should be given the benefit of doubt is still an open question so one should aim for procedures that ensure humaneness.

Glossary

Catabolite repression The quick adaptation of bacteria to a preferred carbon and energy source through inhibition of synthesis of enzymes involved in catabolism of carbon sources other than the preferred one.
Gram-negative bacteria Bacteria that are decolorized when stained with crystal violet dye after treatment with ethanol according to Gram's procedure.
Gram-positive bacteria Bacteria that retain the crystal violet dye on treatment with ethanol according to Gram's procedure.
Partial pressure The pressure due to an individual gas in a mixture of gases.
Spoilage flora (plural flora) A group of microorganisms that grow on food with ultimately deleterious effects.
Water activity (a_w) The ratio of vapor pressure of water in a food or substance to that of pure water at the same temperature.
Wiltshire bacon The pork cured by immersion in brine.

Introduction

Meats are spoiled by microorganisms when microbes on or in the product cause changes to meat qualities that consumers perceive as being undesirable or frankly offensive. Undesirable or offensive changes can involve the appearance, odor, and/or flavor of the meat. Visible changes include the appearance of visible colonies or a layer of slime on the product surface; or changes in the color of meat, from red to brown, gray, or green. Changes in the odor of meat can range from strong, putrid, or sulfurous odors to mild, stale, aromatic, or acid odors. Flavor changes can be similarly variable, but during the development of microbial spoilage flavor changes can often be detected before spoilage odors are apparent.

The spoilage conditions that develop will depend on the types of organisms that are present in the spoilage microflora. The composition of the spoilage flora will be affected by intrinsic properties of the meat, such as the pH and the water activity (a_w) of the product; and by extrinsic factors, such as the atmosphere around the product and the temperature at which it is held. In addition, the form of spoilage that is manifest can be affected by the amounts of specific nutrients for some elements of the microflora that are present in the product. As meats are not necessarily homogeneous products, spoilage need not be uniform over all parts of an item of meat. For example, spoilage of moist fat tissue of a meat cut may precede spoilage of the muscle tissue. Moreover, the environment around an item of meat need not be homogenous. For example, meat in clipped chub packs may be exposed to an aerobic environment in the regions of the clips but be anaerobic elsewhere. However, spoilage of one part of an item will usually render the whole item unacceptable.

Aerobic Spoilage of Raw Muscle Tissue

Muscle tissue in the carcass immediately after slaughter is essentially sterile. The tissue is contaminated with bacteria from the hide and from the packing plant equipment and environment during the dressing and breaking of carcasses. Consequently, meat surfaces are contaminated with a variety of organisms that include psychrotrophs from environmental sources, which can grow at chiller temperatures, as well as mesophiles derived from flora associated with animals, which cannot grow on chilled meat. Initial numbers of bacteria on the surfaces of meat can exceed 10^4 cfu cm^{-2}. However, improvement of processing hygiene at packing plants in recent

 doi:10.1016/B978-0-12-384731-7.00090-8

years has resulted in some plants at least routinely producing carcasses and cuts with initial numbers of $< 10^2$ cfu cm^{-2}.

Postrigor muscle tissue provides a rich medium for the support of bacterial growth. Although the major potential nutrient for bacteria is protein, most bacteria do not elaborate enzymes to attack complex compounds when simple compounds are readily available to support their growth. As lactic acid, amino acids, and glucose are readily utilized by most bacteria, and are generally abundant in muscle tissue, such simple substances, not proteins, are the initial nutrients for the spoilage flora (Table 1).

The accumulation of lactic acid in the muscle tissue during the development of rigor can reduce the tissue pH to 5.5 or a little lower. The aerobic growth of many bacteria is not affected by such pH values, and the concentrations of solutes do not reduce the water activity to values that inhibit bacteria growth. Thus, aerobic growth of many bacteria on muscle tissue is initially constrained by temperature alone. In these circumstances, the organisms that can grow most rapidly at the prevailing temperatures will tend to overgrow competitors, to predominate in the spoilage flora.

The extent to which the fastest-growing species dominate the flora will depend not only on the extent to which their rates of growth exceed those of competitors, but also on the absolute numbers of the initial flora and the initial fraction of the potentially dominant organisms. If the initial numbers of the flora are low, then the relatively large number of generations required before maximum numbers are attained will allow extensive expression of a growth rate advantage. However, if the initial numbers are high, but the numbers of the faster-growing organisms are relatively low, then the final flora may contain relatively large fractions of slower-growing organisms.

Under aerobic conditions, the organisms that grow best on muscle tissue at chiller temperatures are Gram-negative, strictly aerobic pseudomonads and moraxellaceae (Table 2). The latter group includes acinetobacteria, moraxellae, and psychrobacteria. Although organisms of the latter groups are usually found in aerobic spoilage flora, they generally do not produce offensive metabolic by-products; pseudomonads, which do produce offensive by-products, are generally major components of the flora at spoilage onset, and often predominant. Consequently, aerobic spoilage at chiller temperatures is largely the result of the activities of pseudomonads.

The pseudomonads are nutritionally versatile but generally exhibit strong catabolite repression during the utilization of substrates from complex media. Catabolite repression ensures that while a preferred substrate is available, metabolic pathways for the utilization of other substrates are suppressed. For pseudomonads, glucose and related substances are the preferred substrates. When these are metabolized, no by-products that impart objectionable odors or flavors to meat are produced. However, when such substrates are exhausted amino acids are utilized, with the production of ammonia and other by-products, such as organic sulfides, esters, and acids, which impart strong, putrid odors and flavors to meat.

The amounts of glucose present in muscle tissues are limited. When glucose diffusing from within a piece of muscle can no longer meet the demand of bacteria proliferating at the surface, then pseudomonads in the flora will attack amino acids. When glucose is at concentrations in the tissue of approximately 0.1 mg g^{-1}, as is typical for beef from pasture-fed animals, this will occur when the aerobic flora numbers approach 10^8 cm^{-2}. With meat from feed-lotted cattle, glucose concentrations may exceed 1 mg g^{-1} and overt spoilage may not occur until numbers are $> 10^8$ cm^{-2}. At these high numbers, offensive by-products are rapidly generated in organoleptically detectable quantities from amino acids. Thus, in these circumstances the onset of spoilage is abrupt, with the tissue being wholly unspoiled when glucose is available at the surface even though bacterial numbers are high.

The abundance of nutrients other than glucose precludes growth of the aerobic spoilage flora being limited by the availability of nutrients. Instead, numbers increase to exceed 10^9 cm^{-2}. At these numbers, putrid spoilage is visibly augmented by a layer of slime on the tissue surface. Growth of the aerobic flora is then limited by the rate at which oxygen can diffuse from the atmosphere into the slime layer. As catabolic activities decline because of the increasingly limited availability of oxygen, catabolite repression is relieved, and exoenzymes that degrade proteins and other complex substrates are synthesized. Such enzymes degrade structural elements of muscle tissue, which allows bacteria to move from the surface into the deeper tissues, between muscle fibers.

If muscle tissue is deficient in glycogen at the time an animal is slaughtered, then the amount of lactic acid formed will be lower than usual, the pH of the tissue will remain high, and little or no glucose will be present in the postrigor muscle. The high pH does not affect the composition of the spoilage

Table 1 Typical concentrations of low-molecular weight soluble components of beef muscle tissue of normal pH from pasture-fed animals

Substance	*Concentration (mg g^{-1})*
Lactic acid	9.0
Creatine	5.5
Amino acids	3.5
Dipeptides	3.0
Inosine monophosphate	3.0
Nucleotides	1.0
Glycogen	1.0
Glucose 6-phosphate	0.2
Glucose	0.1

Table 2 Rates of growth of Gram-negative bacteria from aerobic spoilage flora on muscle tissues of normal and high pH stored in air at 2 °C

Organisms	*Growth rate (generations/day)*	
	pH 5.6	*pH 6.4*
Pseudomonas spp.	2.03	2.11
Moraxella spp.	1.85	1.82
Acinetobacter spp.	1.58	1.55
Flavobacterium spp.	1.18	1.14
Enterobacteriaceae	1.13	1.20
Aeromonas spp.	0.96	1.36

flora. However, in the near or total absence of glucose, the pseudomonads will degrade amino acids at an early stage of spoilage flora development. At first, the amounts of offensive by-products produced by the relatively few bacteria are undetectable organoleptically. However, as the flora increases, offensive by-products accumulate until putrid spoilage is apparent when numbers are approximately 10^6 cm^{-2}. Therefore, the deficiency of glucose in muscle tissue of high pH results in the meat being prone to early spoilage.

Psychotrophic pseudomonads usually dominate aerobic spoilage flora when meat is held at temperatures $\leq$20 °C. At higher temperatures, mesophilic enterobacteria will predominate on moist meat surfaces. However, the enterobacteria also utilize glucose preferentially, and thus the course of spoilage with these organisms is similar to that resulting from the activities of pseudomonads.

Aerobic Spoilage of Fat and Organ Tissues and Minced Meats

As moisture that evaporates from fat tissue surfaces cannot be replenished from within the tissue, fat tissue surfaces can dry and hence preclude the growth of bacteria. However, if fat tissues remain moist because the meat is held in a humid environment, then an aerobic flora will develop on the fat as on muscle tissue. Fat tissue surfaces are contaminated with exudate, from cut blood vessels and/or muscle tissues, that contains bacterial nutrients. However, the concentrations of bacterial nutrients on fat surfaces are generally low and the nutrients cannot be replenished from the underlying tissues. Thus, glucose is rapidly exhausted, and growth continues with the utilization of amino acids, and then lactic acid when preferred amino acids are depleted. Consequently, putrid spoilage becomes evident when numbers approach 10^6 cm^{-2}, as with high-pH meat. However, the total amount of nutrients available may be inadequate for the flora to grow to numbers at which a visible slime layer is formed. That is, growth may be nutrient-limited rather than oxygen-limited.

Organ tissues are generally of pH$>$6 but can contain substantial concentrations of glucose. For example, liver can contain glucose at concentrations up to several milligrams per gram. Unlike muscle tissue, the tissue structures of liver and other organs allow bacteria from the surface to invade the deep tissues. However, the deep tissues are anaerobic, and thus growth of bacteria within the tissues is slower, and the bacteria growing these do not include the strictly aerobic organisms that predominate in the flora on the surface. Spoilage at surfaces exposed to air will then precede spoilage of deep tissues. Aerobic spoilage will proceed as with muscle tissue, but the formation of visible colonies or slime may precede or be contemporaneous with the development of spoilage odors when glucose concentrations are high. In addition, the tissues may be acidified, because when glucose is abundant it is converted extracellularly by pseudomonads to gluconic and 2-oxogluconic acids.

For minced meat products that are not preserved by high concentrations of solutes or acidification, spoilage at surfaces exposed to air will also precede deep spoilage, and proceed as for muscle tissue. Again, colony or slime formation may be among the first symptoms of spoilage, if carbohydrates preferentially utilized by pseudomonads have been added to a product.

Anaerobic Spoilage

The pigments in muscle and organ tissues – myoglobin and hemoglobin – react readily with oxygen at all partial pressures. Thus, when meats are sealed, with little or no headspace, in packs composed of materials that are nearly or wholly impermeable to oxygen, the residual oxygen will be removed from the meat environment quite rapidly. With raw tissues packaged in an essentially gas-impermeable material, such as laminated plastic films that include two layers of metalized film, anaerobic conditions will develop and be maintained. However, vacuum packages for meats are usually composed of plastic films with various low, but measurable, oxygen transmission rates at temperatures above 0 °C. In addition, some raw tissues, such as fat, and some meat products have only limited oxygen-scavenging capabilities. Thus, in many circumstances, the environment at the surface of vacuum-packed product can be microaerobic rather than anaerobic. In either environment, growth of the strictly aerobic organisms that predominate in aerobic spoilage flora will usually be suppressed. Instead, spoilage flora dominated by anaerobic or facultatively anaerobic organisms develop. Unlike with aerobic spoilage, the types of organisms that contribute to the spoilage flora are determined by the pH of the meat as well as the storage temperature.

Many spoilage organisms are unable to grow under anaerobic conditions on muscle tissue of normal pH (5.5) held at chiller temperatures. Under these conditions, the flora that develops is composed of Gram-positive lactic acid bacteria such as lactobacilli, carnobacteria, and leuconostocs, with organisms of the last group tending to predominate. The lactic acid bacteria are metabolically anaerobic, although they are aerotolerant. The substrates they can ferment to support growth on muscle tissue are limited to glucose and some other carbohydrates available in lower amounts. Thus, growth of the lactic flora ceases when the concentration of glucose at the tissue surface is depleted. This substrate limitation of the flora growth typically occurs when numbers are approximately 10^8 cm^{-2}.

When fermenting glucose, the lactic acid bacteria do not produce offensive by-products. Although most lactic acid bacteria cannot utilize amino acids to support growth, some amino acids, notably valine and leucine, may be metabolized with the production of volatile fatty acids as byproducts. The slow accumulation of such substances can impart acid/dairy flavors and, ultimately, odors to meat. Such flavors and odors are unusual for meat rather than grossly offensive, but they finally render the meat unacceptable to consumers some time after the flora has reached maximum numbers. Some strains of lactic acid bacteria can metabolize sulfur-containing amino acids, with slow production of hydrogen sulfide. Hydrogen sulfide can react with muscle or blood pigments to spoil the meat by green discoloration. Hydrogen peroxide produced by some lactic acid bacteria under microaerobic conditions can also cause the green discoloration of fresh and cured meats.

If the pH of the meat is above 5.8, facultative anaerobes of high spoilage potential can grow on products held under

anaerobic conditions at chiller temperatures. Such organisms include psychrotophic enterobacteria, *Shewanella putrefaciens*, and *Brochothrix thermosphacta*.

Under anaerobic conditions, the enterobacteria will ferment glucose while it is available, and then utilize amino acids when glucose is exhausted. Some amino acids are decarboxylated to give malodorous amines, while hydrogen sulfide as well as organic sulfides may be produced from others. All such by-products grossly affect the odor and flavor of meat, and hydrogen sulfide can cause green discoloration.

Shewanella putrefaciens can form part of an aerobic spoilage flora, in which its behavior is similar to that of the pseudomonads. However, unlike the pseudomonads, it utilizes the amino acids serine and cysteine even when glucose is available. Hydrogen sulfide and organic sulfides derived from the latter substrate contribute to spoilage odors and flavors. The organism is not fermentative, but under anaerobic conditions it can utilize a variety of terminal electron acceptors other than oxygen to maintain respiratory metabolism. Under anaerobic conditions, hydrogen sulfide is produced in abundance, with consequent degradation of the color, odor, and flavor of product.

Brochothrix thermosphacta ferments glucose to lactic acid, and therefore under strictly anaerobic conditions its spoilage potential is limited. Under aerobic conditions, glucose is metabolized to acetoin, diacetyl, and a variety of fatty acids and alcohols. These products of aerobic metabolism impart strong, stale, and sour odors and flavors to meat. Thus, under conditions where some aerobic metabolism is maintained, these by-products can spoil meat.

Unlike pseudomonads, enterobacteria, and lactic acid bacteria, which produce offensive by-products only when preferred carbohydrate substrates are unavailable, *B. thermosphacta* and *S. putreficiens* can produce offensive by-products at all times during their growth on meat. Therefore, even when the numbers of these organisms are less than $10^6\,cm^{-2}$, offensive by-products may be produced in detectable quantities to spoil the meat, irrespective of the state of growth of the spoilage flora as a whole.

However, the maximum numbers of the potent spoilage organisms in an anaerobic flora are usually constrained by the lactic acid bacteria, which sequester nutrients and produce inhibitory bacteriocins. The inhibition of other organisms by lactic acid bacteria occurs only as the flora approaches its maximum numbers. Before that, the various types of bacteria grow at rates that are determined by the temperature and the environment provided by the meat, without any obvious interactions between types of bacteria. Thus, whether or not the potent spoilage organisms contribute to the spoilage of anaerobically stored meat, when pH does not inhibit their growth, will depend on their numbers in the initial flora. If their numbers are low relative to the numbers of lactic acid bacteria, growth of the potent spoilage organisms can be suppressed before they reach numbers sufficient to elaborate offensive by-products in detectable quantities; but if their numbers are relatively high, they will reach numbers sufficient to cause spoilage before growth ceases.

Although lactic acid bacteria, particularly leuconostocs, have a growth rate advantage at chiller temperatures, that advantage reduces at increasing temperatures (Table 3). At abusive temperatures, enterobacteria and *B. thermosphacta* can compete effectively with the lactic acid bacteria; and at warm temperatures, anaerobic flora can be dominated by enterobacteria.

Table 3 Rates of anaerobic growth of bacteria from anaerobic spoilage flora at abusive and warm temperatures

Organism(s)	*Growth rate (generations/day)*		
	10 °C	*20 °C*	*30 °C*
Leuconostoc spp.	3.9	10.4	15.0
Enterobacter spp.	2.8	10.9	12.6
Brochrothrix thermosphacta	2.5	14.1	15.7
Escherichia coli	1.9	11.4	17.1

In addition to the usual microbial spoilage conditions of vacuum-packed meats, both raw and cooked meats may be spoiled by psychrotrophic clostridia. A number of species can apparently be involved in such spoilage, which often involves some swelling (blowing) of packs. However, gross swelling of vacuum-packed chilled meats stored for short times at non-abusive temperatures appears to be due largely to the fermentation of lactic acid by *Clostridium estertheticum*. Other clostridia can cause softening of meat, with the release of large volumes of exudate and the development of putrid and sulfurous odors. The organisms responsible for the production of the large volumes of gas and the proteolytic degradation of the muscle tissue are often difficult to recover. Usual methods for enumerating and isolating bacteria from meat generally recover a flora of mainly lactic acid bacteria from meat spoiled by psychrotrophic clostridia. In view of the difficulties with their recovery and the limited understanding of the circumstances under which they appear in meat spoilage flora, it is possible that psychrotrophic clostridia are involved in meat spoilage more often than is now recognized. Studies aimed at characterizing meat spoilage flora by molecular methods, and identifying the metabolic activities of psychrotolerant clostridia growing on meat, may resolve the current uncertainties about their roles in meat spoilage.

Spoilage in Modified and Controlled-Atmosphere Packagings

Modified-atmosphere packagings are filled with aerobic atmospheres that are usually rich in oxygen, and which have concentrations of carbon dioxide (CO_2) sufficient to inhibit growth of pseudomonads. As large volumes of CO_2 can dissolve in meat, and CO_2 and oxygen can exchange across packaging films, the atmosphere can change during storage. Controlled-atmosphere packagings are those in which a stable atmosphere is maintained throughout storage of the product. The only packagings of this type used with meats employ pouches made of gas-impermeable films that are filled with an atmosphere of CO_2 to obtain an anaerobic atmosphere.

The growth rates of pseudomonads decrease with increasing CO_2 concentrations up to approximately 20%. Increases in CO_2 concentrations beyond that do not greatly reduce the rate of growth provided the atmosphere is aerobic. The maximum reduction in the rate of growth of pseudomonads is

Table 4 Examples of conditions tolerated by spoilage organisms growing on meats

Organisms	*Conditions*			
	Minimum a_w	*Minimum pH*	*Maximum salt concentration (%)*	*Maximum sorbate concentration (ppm)*
Gram-negative bacteria	0.95	4.4	10	100
Gram-positive bacteria	0.90	3.8	15	700
Yeasts	0.80	2.0	20	400
Molds	0.75	1.7	<20	1000

approximately 50%. A reduction of that order is sufficient to allow lactic acid bacteria, which are not affected by CO_2 at such concentrations, to outgrow pseudomonads and dominate the spoilage flora. However, *B. thermosphacta* and enterobacteria are also unaffected by the CO_2, and thus can form large fractions of the spoilage flora. In such circumstances, *B. thermosphacta* can cause early spoilage of a product as the flora develops. Enterobacteria cause spoilage as glucose is exhausted by the activities of the total flora.

As a controlled atmosphere of carbon dioxide is anaerobic, growth of pseudomonads is totally inhibited. Such an atmosphere also inhibits the growth of enterobacteria, raises the minimum temperature for growth of *B. thermosphacta*, and probably affects some elements of the lactic flora. Consequently, meat in a carbon dioxide atmosphere generally supports a lactic flora and develops acid/dairy flavors only well after the flora attains maximum numbers.

Bacterial Spoilage of Preserved Meats

Meats are preserved by drying; by the addition of salt or other solutes in quantities sufficient to reduce the water activity to levels at which growth of spoilage bacteria is affected; by fermentation of added carbohydrates or addition of acidulants, to reduce the pH; or/and by addition of antimicrobial agents, such as curing salts (nitrate/nitrite), sulfite, and benzoate. The Gram-negative organisms that spoil products rapidly are mostly susceptible to relatively mild preservative treatments (Table 4). Inclusion of preferentially utilized carbohydrates in preserved meats also tends to inhibit the production of ill-tasting and malodorous byproducts. Bacterial flora of preserved meats is then commonly dominated by Gram-positive organisms of low spoilage potential, with microbial spoilage being first manifest as slime or visible colonies, or discoloration of cured products. However, certain preserved meats tend to develop a flora enriched for specific spoilage organisms and thus undergo spoilage in a product-typical fashion. Examples of such products are raw sausages preserved with sulfite, which are usually spoiled by *B. thermosphacta*, as that organism is tolerant of the preservative, and Wiltshire bacons, which can be spoiled by the activities of salt-requiring vibrios.

Spoilage by Yeast and Molds

Yeast and molds grow far more slowly than the spoilage bacteria and thus will cause meat spoilage only when conditions prevent bacterial growth. Most yeasts and molds can grow only aerobically and are inhibited by relatively low concentrations of carbon dioxide, and therefore atmospheres other than air do not favor their growth. However, yeasts and molds can commonly tolerate lower water activities and more acidic conditions than spoilage bacteria, and some can grow at lower temperatures or are less affected by preservatives than the bacteria. Yeasts generally grow more rapidly than molds, and hence when conditions allow the growth of both, but prevent the growth of bacteria, spoilage will likely be caused by yeasts. Spoilage by molds or yeasts is usually due to the development of visible colonies on product surfaces.

Table 5 Growth rates of bacteria, yeasts, and molds at 0 °C and subzero temperatures

Type of organism(s)	*Name of organism(s)*	*Growth rate (per day)*[a]		
		0 °C	*−2 °C*	*−5 °C*
Bacteria	*Pseudomonas* spp.	1.75	1.00	–
	Leuconostoc spp.	0.48	0.19	–
Yeasts	*Cryptococcus infirmo-miniatus*	1.03	0.57	0.11
	Cryptococcus laurentii	0.60	0.43	0.09
Molds	*Thamniduim elegans*	0.67	0.50	0.03
	Cladosporium herbarum	0.31	0.18	0.03
	Penicillium hirsutum	0.35	0.17	–
	Penicillium corylophilum	0.19	–	–

[a]Growth rates of bacteria and yeasts are generations/day. Growth rates of molds are increase in length per unit length per day of hyphae from newly germinated spores.

On raw meats, mold spoilage occurs when desiccation of the surface prevents the growth of spoilage bacteria. The surfaces of chilled carcasses can become desiccated and develop mold colonies when circulating air of low humidity prevents the dry surfaces of muscle tissues being rehydrated by the water that moves from within the muscle. Fat surfaces will obviously remain dry under such conditions and may also support mold growth.

Mold spoilage also occurs on frozen raw meats that experience prolonged periods of temperature abuse. The minimum temperature for growth of spoilage bacteria is approximately −3 °C, whereas that for molds and yeast is approximately −5 °C. It has therefore been assumed that temperature alone can dictate mold instead of bacterial spoilage. In fact, molds grow very slowly at −5 °C compared with yeasts (Table 5), so when only temperature and the depression of water activity associated with freezing affect microbial growth, visible yeast colonies can be formed long before mold colonies appear. Mold colonies are the main

manifestation of spoilage when substrate limitation precludes the formation of yeast colonies, or when surfaces desiccate to give water activities below those tolerated by yeasts. Such desiccation can occur by sublimation of ice from frozen tissues, but in practice the appropriate conditions for mold spoilage of frozen meat seem to arise when surfaces thaw, perhaps cyclically, and water evaporates into the dry, refrigerated air.

Yeasts and mold colonies can also cause spoilage of cured and preserved meats of low water activity, whereas raw meats preserved by the addition of sulfite can be spoiled by fermentative yeasts.

Glossary

Anserine An imidazole dipeptide of the amino acids *β*-alanine and *N*-methylhistidine, found in skeletal muscle, which acts as an antioxidant due to its chemical structure.
Carnosine An imidazole dipeptide of the amino acids *β*-alanine and L-histidine, found in skeletal muscle, which acts as an antioxidant due to its chemical structure.
Ferrylmyoglobin Metmyoglobin (Fe^{3+}) activated with hydrogen peroxide to yield a relatively stable hypervalent (Fe^{4+}) heme protein (without a protein-based radical) with prooxidant activity.
Free radical An atom or group of atoms that has at least one unpaired electron and is therefore unstable and highly reactive.
Glutathione peroxidise An enzyme family found in muscle, whose preferred substrate is hydrogen peroxide and main biological role is to protect the organism from oxidative damage.
Malondialdehyde A compound produced by oxidation of unsaturated fatty acids.
Metmyoglobin A brown-colored pigment found in meat, formed from myoglobin by oxidation of iron from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state.
Myoglobin An iron-containing protein (pigment) found in meat, consisting of heme (iron) connected to a single peptide chain. Myoglobin's role in muscle is to transport oxygen released by red blood cells to the mitochondria, where the oxygen is used to produce energy.
Oxymyoglobin The form of myoglobin that is complexed with an oxygen molecule – the color of meat most acceptable to consumers.
Perferrylmyoglobin Metmyoglobin (Fe^{3+}) activated with hydrogen peroxide to yield a transient hypervalent (Fe^{4+}) heme protein (with a protein-based radical) with prooxidant activity.
Reductase Any enzyme that catalyzes a biochemical reduction reaction.
Superoxide dismutase An enzyme that catalyzes the conversion of superoxide into hydrogen peroxide and oxygen.
Thiobarbituric acid (TBA) A widely used test for determining the extent of lipid oxidation by measuring the concentration of relatively polar secondary reaction products such as aldehydes.
Warmed-over flavor (WOF) An unpleasant flavor (rancid, stale) arising from heme-mediated lipid oxidation that develops in cooked meat that is subsequently refrigerated before reheating.

Introduction

Spoilage of meat occurs when there is deterioration of its odor, flavor, color, texture, and/or nutritive properties. These changes may result from chemical, physical, enzymatic, or microbiological processes. Oxidation, or the process of loss of electrons, hydrogen abstraction, or flow of unpaired electrons, may occur in all the chemical constituents of muscle foods. Peroxidation of lipids will become apparent to consumers by the development of rancid odors or flavors, and 'warmed-over' flavor (WOF) in previously cooked meats. Oxidation of meat pigments is recognizable by the development of brown discoloration replacing the normally acceptable bright red meat color. Oxidation of meat proteins leads to the loss of functional properties such as gel-forming ability, meat-binding ability, emulsification capacity, solubility, viscosity, water-holding capacity, and nutritive value. Changes to functional properties may result in a loss of texture in further processed meats or, in some cases, an increase in toughness/hardness and decrease in juiciness in whole muscle foods. Because of these deleterious changes associated with oxidation, much of the applied research in the meat industry is directed toward slowing the rate of oxidative reactions. Endogenous catalysts, antioxidants, and enzymes can all affect oxidation rates. In addition, oxidation rates can be affected by numerous interventions throughout the production chain, such as incorporation of antioxidants into animal feed, packaging systems, temperature control, exposure to light, or direct addition of antioxidants, metal chelators, dipeptides, etc. during processing. In the context of the present review, only enzymes that affect rates of lipid oxidation are considered. In addition, recent research on the oxidation of enzymes associated with changes in texture (proteolysis), which can contribute to decreased tenderization postmortem, will be overviewed. However, the mechanism of action of these enzyme systems and their postmortem activity, which may result in spoilage due to overtenderization, are discussed elsewhere.

Peroxidation of Lipids

Lipid peroxidation is the major form of quality deterioration, including flavor, odor, taste, color, texture, and appearance, leading to spoilage in meat and fish products, even when lipid content is fairly low. In lean beef, triacyglycerols and phospholipids comprise 2–4% and 0.8–1% of the meat weight,

 doi:10.1016/B978-0-12-384731-7.00091-X

respectively. Only oleic, palmitic, and stearic fatty acids are present in substantial amounts in the fat of meat animals, combined with glycerol to form the triacylglycerols. The phospholipids, the so-called 'structural lipids,' are located in the membranes and contain over 40% polyunsaturated fatty acids (PUFA; 22% 18:2n−6, linoleic acid; 2% 18:3n−3, linolenic acid; 15% 20:4n−6, arachidonic acid; 1% 20:5n−3, eicosapentaenoic acid (EPA); and 2% 22:6n−3, docosahexaenoic acid (DHA)). Owing to their high level of unsaturation and their proximity to the heme catalysts of the mitochondria and microsomes, the initial oxidation reactions in meat generally involve the phospholipids. Chicken and turkey muscle are more susceptible to oxidation than beef due both to the higher levels of polyunsaturated phospholipids and lower levels of antioxidants in the poultry meats. Fish muscle is even more susceptible to oxidation due to the high degree of unsaturation, including enrichment with the characteristic omega-3 fatty acids, EPA, and DHA. Recent applied research efforts to shift the fatty acid composition of meat animals (e.g., beef and pork) toward increased long chain omega-3 PUFA to improve human dietary health may result in increased rates of oxidation, particularly in high-fat muscles and meat products. In this context, Australia has recently recognized the potentially important contribution to human dietary health of the long chain omega-3 PUFA, docosapentaenoic acid (DPA), which is present in quite high levels in ruminant animals (e.g., beef and lamb).

Refrigerated, whole, raw meat is relatively resistant to lipid peroxidation. Under the appropriate conditions, frozen beef has been found to maintain an acceptable quality for 10 years or more, provided desiccation (freezer burn) is avoided. However, oxidation of the tryacylglycerol fraction does proceed slowly and is referred to as 'normal oxidation,' as opposed to WOF, which is a rapid, heat-activated oxidation affecting mainly the phospholipids.

Normal Lipid Peroxidation

In whole meat, fats are compartmentalized away from propagators of oxidation. However, prolonged storage under unfavorable conditions can create rancid odors described as tallowy for beef; muttony for mutton; stale, cheesy, acrylic, fishy, or oily for pork; and rancid, painty, fishy, and cod-liver oil-like for fish. These odors develop from the products of autoxidation of unsaturated fatty acids, such as oleic, linoleic, linolenic, and arachidonic. Three stages have been proposed to describe the autoxidation process, namely, initiation, propagation, and termination (Figure 1). Initiation occurs when an unsaturated fatty acid reacts with O_2 to produce a free radical. The actual formation of the free radical occurs when a labile hydrogen is abstracted from the carbon atom adjacent to the double bond. The free radical then reacts with oxygen to form a peroxyl radical, which in turn can abstract another hydrogen from a different fatty acid, resulting in the propagation of a chain reaction. Termination occurs when two free radicals react together, when a peroxyl radical reacts with a free radical, when two peroxyl radicals react, or when radicals react with other meat constituents (e.g., vitamins, amino acids, dipeptides, etc.). The hydroperoxides formed during

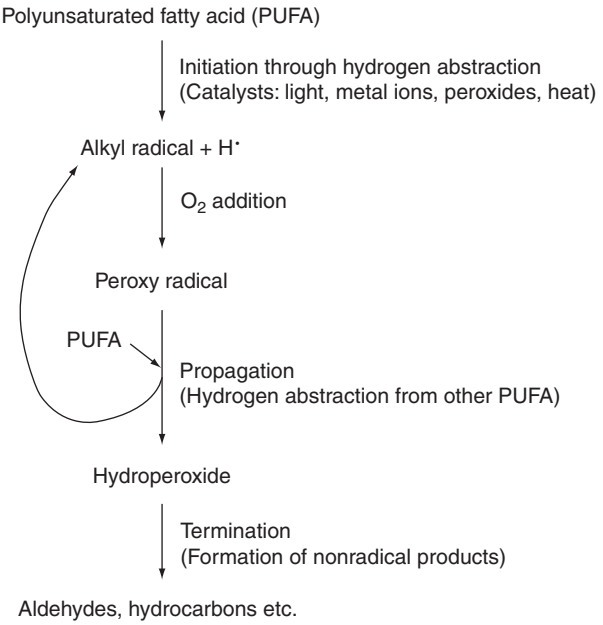

Figure 1 Fatty acid oxidation showing initiation, propagation, and termination steps.

propagation decompose and form secondary products that include aldehydes generated from the methyl ends of the fatty acids. Aldehydes, the types of which depend on the structure of the parent fatty acids, are largely responsible for rancid flavor development in meats. The degree of rancidity in fats has been traditionally measured using an assay for the determination of malondialdehyde by its reaction with thiobarbituric acid (TBA). However, the TBA assay is not specific to malondialdehyde and in some cases has been found to overestimate malondialdehyde content up to ninefold. Hence, assays specific to malondialdehyde or other specific aldehydes may be preferable for determining the development of rancidity in meats.

Rancidity in refrigerated and frozen whole meat products can be prevented through appropriate handling and packaging. Although some inherent factors (Vitamin E levels and animal age) can be controlled through management practices, others can be implemented in the postmortem period. Packaging under atmospheres of low-oxygen partial pressure and vacuum packaging are useful means of prolonging the oxidative stability of meat products. Packaging under oxygen-free atmospheres of nitrogen or carbon dioxide is an even more effective means of increasing the stability of meat products. The use of opaque packagings reduces exposure to light and this can further reduce the rate of oxidation. Grinding of meat, as in hamburger manufacture, disrupts membrane integrity and exposes the lipids to metal catalysts, and thus accelerates oxidation. Appropriate temperature control will minimize oxidation. Fish is particularly susceptible to temperature abuse as lipid peroxidation can continue even in the frozen muscle. At −4 °C, rancidity in fish is accelerated because freezing of a large fraction of free water as pure ice causes concentration of the catalytic metals in the unfrozen fraction. Frozen storage of meat at steady temperatures (−18 °C or lower) in tight-fitting, moisture-proof packaging is required to minimize lipid

peroxidation and prevent freezer burn. Unfortunately, consumers' need to assess the appearance of fresh meat products leads to nonoptimum conditions for preserving oxidative stability during retail display and home storage.

Warmed-Over Flavor (WOF)

WOF is one of the major causes of quality deterioration in cooked, refrigerated, and precooked meat products. WOF includes both the development of undesirable flavors and the loss of desirable meat flavor characteristics. The odors and flavors associated with WOF are commonly described as painty, rancid, stale, and cardboard-like. WOF can develop rapidly: in 48 h or less in reheated, refrigerated meat, and within a matter of days in precooked, frozen meats.

WOF results from the oxidation of PUFA located mainly in the cell membrane as phospholipids. The highly reactive sites next to the double bonds readily lose hydrogen atoms, resulting in the formation of lipid free radicals. Free radicals rapidly react with oxygen, to yield aldehydes such as pentanal, pentenal, hexanal, hexenal, and 2,4-decadienal. These compounds are volatile and perceptible as WOF at low concentrations (ppb). Unsaturated aldehydes are perceptible at lower concentrations than saturated aldehydes. Hence, muscles that are high in PUFA content are also the most susceptible to WOF development. This translates into a species difference in WOF development, with the problem for meats in the order fish > poultry > pork > beef > lamb. With the addition of advanced analytical technologies (e.g., gas chromatography–mass spectrophotometry with an olfactory port (GC–MS-O) and the electronic nose), progress in identification of the compounds directly related to the sensory perception of WOF continues to be made for different species, muscles, and types of muscle foods.

The rate of oxidation of PUFA can be influenced by catalysts that reduce the energy required for oxidation (metals, high-energy oxygen, or enzymes) or that add energy to drive the reaction (heat, light, oxidizing enzymes). During cooking, heat causes extensive protein coagulation and loss of functional properties. Of particular importance for lipid stability is the loss of iron-binding capacity in hemoglobin and myoglobin. On heating, free iron released from the globin proteins can come into contact with oxidizable substances such as PUFA. Free iron in the reduced, ferrous (Fe^{2+}) state readily converts into its oxidized, ferric (Fe^{3+}) state, assisting in the generation of lipid free radicals that then propagate a lipid peroxidation chain reaction. Hence, once heating occurs, oxidation proceeds very rapidly. Salt has been shown to enhance iron-catalyzed oxidation. Transition metals other than iron can also play a role in lipid peroxidation and are often added during processing through the addition of water and spices. Similar to iron, they undergo the loss of a single electron (e.g., Cu^{2+} to Cu^{3+}) during oxidation, and catalyze the formation of free radicals from PUFA.

Certain wavelengths of light (particularly blue-purple fluorescent and ultraviolet) are able to promote the oxidation reaction. Light energy elevates the energy states of oxygen and meat pigments, increasing their ability to participate in oxidation. Hence, the quality of light used during retail display of meat products and precooked frozen items is of concern.

Because oxygen is integral to the formation of WOF, any process that increases oxygen content in the muscle increases the problem. Mechanical manipulation through grinding, chopping, deboning, mixing, and tumbling introduces air into the normally anoxic interior of whole muscle cuts.

Although a number of factors can trigger oxidation and add to the development of WOF, there are also a number of ways of preventing or delaying its development. In the raw product, it is important to use fresh materials that have had little time to undergo extensive enzymatic oxidation preventing the production of autocatalytic substances that can cause oxidation even after the enzymes themselves have been inactivated by heat.

Antioxidants protect PUFA from oxidation by undergoing oxidation themselves, thus delaying the development of WOF. However, the protective effect of an antioxidant is dependent on its concentration and fat solubility, and on the number of antioxidative sites on the molecule. Dietary supplementation of the naturally occurring vitamin E (α-tocopherol) has been shown to reduce the susceptibility of meat to oxidation. α-Tocopherol is readily stored in the cell membrane, preventing the oxidation of nearby PUFA. Carotenoids are another group of fat-soluble antioxidants that can be obtained from the diet and can react with singlet oxygen to block the formation of lipid peroxides. However, their inclusion at high concentrations can lead to discoloration of fats, skeletal muscle, and associated skin. Although this can be detrimental in some muscle foods, carotenoids are purposefully added to both salmon and poultry diets to enhance the color of the final product.

Various synthetic phenolic substances, including butylated hydroxyanisol (BHA), butylated hydroxytoluene (BHT), tertiary butylhydroxyquinone (TBHQ), and propyl gallate (PG), can be used as antioxidants in muscle food systems. In addition, some common herbs and spices such as rosemary, marjoram, sage, thyme, mace, allspice, and clove have antioxidant properties. In cured meats, nitrite is known to have a powerful antioxidative effect, although the mechanisms are not clearly understood. Mechanisms that may be involved include prevention of ferrous iron release via complex formation with heme pigments, stabilization of PUFA in cell membranes, and chelation of metal ions.

The histidine-containing dipeptides found in muscle tissue, carnosine, and anserine have been found to have antioxidant activity in addition to their pH-buffering capacity. Species differences exist, with pigs, beef, and turkey having higher concentrations of carnosine than anserine, and the reverse being the case for salmon, rabbit, and chicken. Primarily anaerobic muscles have higher carnosine and anserine concentrations than aerobic muscles. The antioxidant mechanism of carnosine and anserine may be due to metal chelation or free radical scavenging. Many of the lipid peroxidation catalysts and free radicals are found in the cytosol, and hence the hydrophilic nature of carnosine and anserine is probably significant for their antioxidative activity.

Chelating agents such as citric acid, ethylenediaminetetracetic acid (EDTA), sodium tripolyphosphate, pyrophosphate, or hexametaphosphate are effective in reducing

oxidation that is initiated or propagated by metal ions. These agents form stable complexes with metals, thereby preventing their involvement in the oxidation of PUFA.

Oxygen scavengers such as ascorbic acid and erythorbic acid are added to cured meats to prevent nitrosamine formation, but also to prevent lipid oxidation. They act alone as reducing agents in low concentrations, and synergistically with other antioxidants. Ascorbic acid can form a stable complex with metals, thereby raising the energy required to initiate oxidation.

Exclusion of oxygen through physical means such as vacuum tumbling, vacuum stuffing, and vacuum packaging can delay the onset of WOF. Oxygen can also be excluded by covering precooked products with liquids or sauces. Owing to the antioxidant nature of Maillard (browning) reaction products (particularly histidine-glucose reaction products), covering pork with drippings or gravy made from the drippings can also increase the acceptable frozen storage life in precooked products. The use of red-orange tungsten halogen lights for illumination may also be beneficial, and the complete exclusion of light may be a necessity for some products.

Oxidation of Pigments

Muscle color is a major factor in consumer selection of meat on retail display and is, in some cases, mistakenly relied on as an indicator of freshness. Hence, consumers have firm expectations about fresh meat color, and deviations, particularly browning, are thought to indicate spoilage.

The pigment primarily associated with meat color is myoglobin, which in the living animal functions in the transfer of oxygen from hemoglobin in the blood to the mitochondrial cytochromes. Myoglobin constitutes 50–80% of the meat pigments, depending on the species, age of the animal, and muscle type. Higher concentrations of myoglobin are found in beef than in pork, in older than in younger animals, and in muscles responsible for sustained activity than in muscles that are used sporadically, and less intensively. Hence, in bright, cherry-red beef, the myoglobin concentration ranges from 4 to 10 mg g^{-1} (wet matter basis) compared to 1–3 mg g^{-1} for grayish-pink pork. In dark-colored beef the range is from 16 to 20 mg g^{-1} compared to light-colored veal at 1–3 mg g^{-1}. The extensor carpi radialis, a locomotory muscle located in the forelimb, has twice the myoglobin concentration of the longissimus thoracis et lumborum, the major support muscle along the vertebrae (12 vs. 6 mg g^{-1}, wet matter basis). These differences in intensity of color are familiar to and, for the most part, accepted by consumers.

In the native deoxymyoglobin state (Mb), before exposure to oxygen, meat pigments are purplish-red (Figure 2). This can be seen when the interior of meat is first exposed during cutting or when fresh meats are vacuum packaged in oxygen-impermeable film. On exposure to atmospheric oxygen, the pigments are rapidly oxygenated, producing oxymyoglobin (MbO_2) and the bright red, 'bloomed' color of fresh meat. Brown metmyoglobin (MMb) is formed by oxidation of the pigment from its ferrous (Fe^{2+}) to its ferric (Fe^{3+}) iron state under conditions of low-oxygen partial pressure. Hence, in intact meat, the depth of oxygen penetration into the interior of the meat is marked by a layer of brown MMb.

In muscle, the three states of myoglobin exist simultaneously; *in vivo* MMb exists at a steady state of approximately 2–3%, whereas in meat color deterioration is not perceptible until greater than 30% of the pigments are in the oxidized

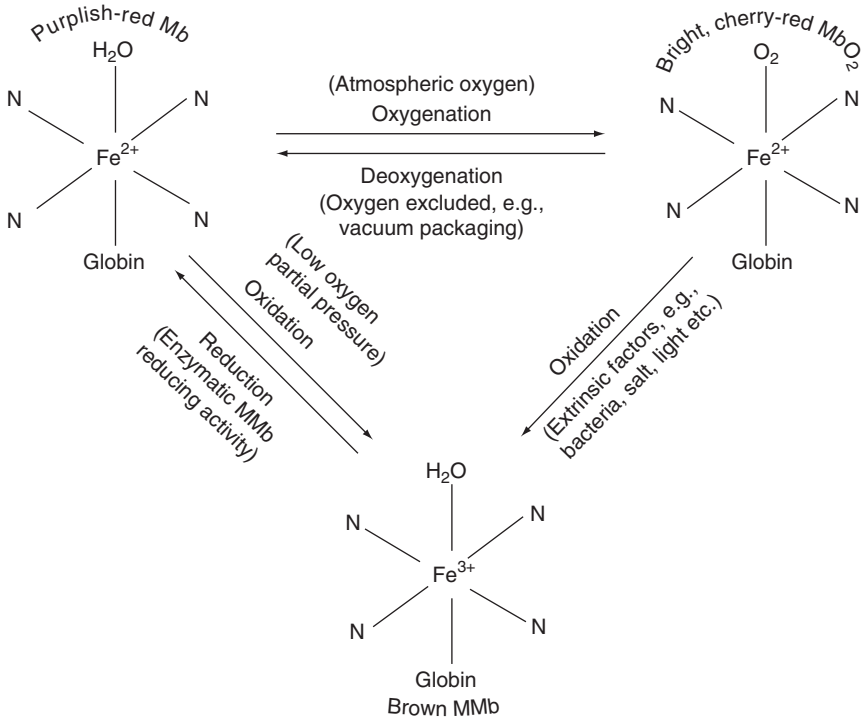

Figure 2 The normal cycle of myoglobin (Mb) pigment changes in fresh meat.

MMb state. Fresh beef is considered to have an unacceptable color when over 60% of the myoglobin is in the MMb form. Discoloration discounts at retail have a significant economic impact, calculated to be in excess of US$700 million per year in the US beef industry alone.

Though the conversion of MbO_2 to MMb is thermodynamically favored, reduction of MMb to ferrous myoglobin may also occur. The MMb is reduced nonenzymatically by reduced cytochrome b_5. In turn, cytochrome b_5 is regenerated to its active reducing form by cytochrome b_5 reductase (MMb reductase), which utilizes the reduced form of nicotinamide adenine dinucleotide (NADH). Once the reducing capacity of the meat is exhausted, complete MMb formation will occur. MMb reductase activity has been shown to differ among muscles, with, for example, the *longissimus* muscle having greater activity than the *psoas* major muscle.

In addition to loss of MMb reductase activity, color stability is reduced by any factors that cause denaturation of the globin (e.g., heat, salts, low pH, and ultraviolet light) and by low-oxygen tension. The formation of MMb is maximal at an oxygen pressure of approximately 4 mm Hg, and increasing oxygen pressure improves fresh meat color stability. The packaging environment can substantially affect the oxygen pressure to which meat is exposed, and can thus profoundly affect the color stability of fresh meat. Packaging systems with atmospheres of high-oxygen partial pressure extend fresh meat color shelf life. Vacuum-packaged meats retain the ability to oxygenate when exposed to oxygen. An anoxic atmosphere in master packs, with subsequent display in oxygen-permeable packaging at retail, has allowed the development of central packaging. However, failure to completely remove oxygen ($<1\%$) from these packages can result in pro-oxidative conditions and subsequent loss in color stability. The use of oxygen scavengers in which oxygen reacts with iron or low-molecular weight organic compounds such as ascorbate has proven efficacious for maintaining the color shelf life in meats that are stored under oxygen-depleted atmospheres during subsequent retail display.

Research into the biochemical mechanisms involved in heme pigment catalysis of lipid oxidation has shown that, during oxidation of MbO_2, both superoxide anion and hydrogen peroxide are produced, which can further react with iron to form hydroxyl radicals that facilitate lipid oxidation. Generally, MbO_2 shows higher prooxidant activity than MMb. However, MMb has been shown to react with hydrogen peroxide to form unstable hypervalent (Fe^{4+}) myoglobin species, perferrylmyoglobin and ferrylmyoglobin. Perferrylmyoglobin is a transient species that autoreduces rapidly to the more stable ferrylmyoglobin. Under conditions found in fresh meat of usual pH values (5.5–5.8) ferrlymyoglobin also autoreduces rapidly to MMb. Both of these hypervalent myoglobin species have been shown to initiate lipid oxidation through abstraction of a hydrogen atom from fatty acids. In turn, the aldehydes arising from lipid oxidation can induce myoglobin pigment oxidation to MMb. Hence, many of the lipid (α-tocopherol)- and water-soluble (ascorbic acid, dipeptides) antioxidants used to reduce rancidity will also be efficacious for preserving meat color. Many of these antioxidants, rather than having a direct effect on the myoglobin, act to delay the production of lipid peroxidation breakdown products such as peroxides, which can accelerate MbO_2 oxidation.

Oxidation of Proteins

Until recently, most research on oxidation and its effects in muscle foods concentrated on the lipid fraction, with limited study of protein oxidation (Pox). This may have been due to the greater susceptibility of lipids to oxidation, the generally later postmortem onset of Pox, and the challenges associated with measuring Pox in a complex meat matrix. However, the focus on Pox in relation to age-related disease in humans has provided methodologies and impetus to investigate Pox in the context of muscle foods.

Although the basic mechanisms underlying Pox are still under investigation, both the amino acid side chains and peptide linkages of the protein backbone have been shown to be susceptible to reaction with free radicals in the presence of oxygen. Hence, oxidative changes to proteins include protein cross-linking, amino acid side chain modification, and protein fragmentation. The chemical mechanisms are similar to those that occur in lipid oxidation but are less complex, and fewer oxidation products have been reported to date. In general, unsaturated double bonds susceptible to oxidation occur infrequently in proteins as they are found in only the aromatic amino acids tryptophan, tyrosine, and phenylalanine, and in the heterocyclic amino acid histidine. Amino acids most susceptible to metal-catalyzed oxidation include those with nitrogen-containing functional groups (arginine, lysine, proline) that yield carbonyl residues, and sulphur-containing amino acids (methionine and cysteine) that form cross-links and yield sulphur-containing residues. The extent of Pox has been generally estimated by measuring the appearance of protein carbonyl compounds in muscle foods using the dinitrophenylhydrazine method. The loss of thiol groups in proteins from muscle foods, which is also a good indicator of oxidation, has been determined spectrophotometrically using Ellman's reagent and, recently, with greater sensitivity, using a fluorescent reagent (ThioGlo®1).

Theoretically, amino acids with reactive side chains that include an imidazole ring, indole ring, suflhydryl, thioesther, or amino group (tryptophan, histidine, lysine, cysteine, and arginine) are most susceptible to reaction with lipid peroxidation products. However, the role of lipid peroxidation products in the initiation of Pox is still a matter of debate. In a complex matrix such as meat there seems to be little doubt these processes are not entirely independent; and due to the earlier onset of lipid oxidation, it would seem that lipid peroxide products must have a role in promoting Pox. In addition, the interaction between lipid and Pox must be highly dependent on the species, muscle type, type of muscle food, and a host of other environmental moderators. Of interest is the suggestion that proteins, particularly the myofibrillar proteins, may themselves act as an antioxidant within muscle foods. Their ability to scavenge free radicals and chelate metal ions may provide protection to other susceptible compounds, including lipids and proteins.

Research on the effect of Pox in muscle foods focused initially on changes to protein functionality during further

processing that results in alterations of the gel-forming ability, meat-binding ability, emulsification capacity, solubility, viscosity, or water-holding capacity of meat preparations. These changes in protein functionality can result in textural changes to meat products. However, the oxidative processes are complex and, depending on various intrinsic and extrinsic factors, may result in either improved or reduced functionalities. The intrinsic and extrinsic factors include the types of pro-oxidants or antioxidants, types of muscle or protein, specific protein side chains or amino acid residues located on the surfaces of protein molecules, the extent of oxidative modification, and the storage time. It has been suggested that mild-to-moderate protein modification results in improved protein functionality, whereas extensive alteration results in decreased functionality due to excessive aggregation and precipitation of the proteins.

In the past decade, attention has been directed toward the consequences of Pox in fresh, whole muscle during processing, fabrication, and storage. The findings indicate that Pox may have a negative effect on juiciness, tenderness, and nutritional quality. Pox-induced increases in cross-linking of the myofibrillar proteins is thought to contribute to reduced juiciness and tenderness, although Pox-based inactivation of μ-calpain may also be involved (see Section Enzymatic Factors). Increased cross-linking of the myosin tail region can stabilize the myofibrillar structure and constrain myofibrillar swelling, resulting in decreased tenderness and juiciness of fresh meat stored under high-oxygen packaging. Conversely, increased Pox during drying and salting may contribute to the unique and preferred textural characteristics of dry-cured meats and salted fish. Increased hardness of pâtés and cooked sausages during refrigerated storage has also been ascribed to Pox-induced cross-linking. Pox may decrease the nutritional value of muscle foods through both depletion of essential amino acids and decreased digestibility of oxidized muscle proteins, although the science is not yet conclusive. Through modification of the oxidation state of the heme iron, Pox can also contribute to negative effects on meat color. In addition, the formation of carbonyls during Pox may impact odor and flavor, and may contribute significantly to the unique flavor of dry-aged meats.

Enzymatic Factors

Enzymes, including lipoxygenases, peroxidases, and microsomal enzymes, which catalyze insertion of oxygen into polyunsaturated fatty acids with methylene interrupted dienes, have been identified in various animal tissues and contribute to enzyme-mediated oxidation of lipids. In contrast, phospholipases have been shown to inhibit lipid peroxidation by forming iron complexes with the free fatty acids liberated by hydrolysis of phospholipids in the membrane.

Several cytosolic enzymes, including superoxide dismutase, catalase, and glutathione peroxidase, are active antioxidant enzymes in muscle. Superoxide dismutase controls the reactivity of superoxide anions and perhydroxyl radicals, both of which are involved in promotion of lipid oxidation. It also catalyzes the conversion of the superoxide anion to hydrogen peroxide. Hydrogen peroxide can be rapidly decomposed by transition metals to an extremely reactive hydroxyl-free radical, which can propagate oxidation. However, both catalase and glutathione peroxidase are active in converting peroxides into inactive derivatives, thereby preventing oxidative damage. In addition, glutathione peroxidase is capable of reacting directly with lipid peroxides, limiting oxidation.

Species differences in antioxidant enzymes have been reported with higher activities of superoxide dismutase and glutathione peroxidase in beef > turkey > pork, whereas activities of catalase are higher in pork > beef > turkey. Some evidence exists that the inactivation of antioxidant enzymes through heating contributes to the development of WOF. However, when catalase and glutathione peroxidase were added back into cooked muscle, only 15% of the lipid peroxidation was inhibited.

Because most enzymes are proteins, Pox may affect numerous enzyme-mediated processes in muscle foods. Perhaps the most attention to date has been given to the calpain enzyme system that plays a key role in postmortem tenderization. Irradiation of meat decreased tenderness and increased Pox in both the sarcoplasmic and myofibrillar fragments of meat, but the direct effect on μ-calpain was not measured. In contrast, storage under high oxygen also decreased tenderness but showed no inactivation of μ-calpain. Thus, although conclusive evidence that the μ-calpain enzyme undergoes Pox has not been obtained to date, this remains an active research area. There is also need for further understanding of the potential impact of Pox on other sarcoplasmic proteins.

Glossary

Anoxia Severely reduced levels or complete lack of oxygen.
Breathlessness A sense or feeling of unable to breath.
Bronchoconstriction Narrowing of bronchi/respiratory tract.
Dyspnea Difficulty in breathing.
Hypercapnea Elevated levels of carbon dioxide.
Hyperventilation Increased rate and/or depth of breathing.
Hypoxia Reduced oxygen levels.

Introduction

In most of the developed countries, it is a statutory requirement that all animals, including poultry, slaughtered for human consumption are rendered immediately unconscious and that they remain so until death supervenes through loss of blood. Because the effect of a stunning method is momentary, the onus of preventing resumption of consciousness following stunning relies on the efficiency of the slaughter procedure, i.e., the prompt and accurate severance of blood vessels supplying oxygenated blood to the brain. By contrast, killing animals with gases can eliminate the chances of recovery of consciousness. Regulations governing the welfare of animals (during stunning or killing) in many countries, including the UK, prescribe certain gas mixtures for stunning/killing of pigs and domestic poultry. The relative merits of various gas mixtures used for stunning pigs and poultry are addressed in this article. Stunning of farmed fish using gas mixtures is also considered.

Reason for Use of Gas Stunning

Among the farm animals slaughtered for human consumption, pigs are arguably the most susceptible to stress during preslaughter handling and stunning. Electrical stunning is commonly used for rendering pigs unconscious before slaughter. With electrical stunning, some form of restraint (lifting or squeezing) is necessary to facilitate ideal placement of the stunning tongs and to achieve an effective stunning. Research has shown that isolation of individual animals from their pen mates and the application of any form of restraint can be distressing to pigs. By contrast, stunning of pigs with gases does not require a restraint and modern gas stunning devices involve killing in small groups. For example, pigs are loaded into a cage or cradle and lowered into a well, or passed through a purpose-built tunnel containing gas mixtures.

Multiple-bird electrical water bath stunning is the most common and cheapest method of rendering poultry unconscious before slaughter under commercial conditions, where high throughput rates (up to 220 birds per minute) are required. Under this system, conscious birds are hung upside down on a moving metal shackle line (process known as shackling) and passed through an electrified water bath, such that the current flows through the whole body toward the earthed shackle. There are many welfare concerns associated with the commercial electrical water bath stunning systems, such as unnecessary pain and suffering caused by uncrating, shackling, prestunning electric shocks, inadequate stunning, and recovery of consciousness leading to live birds entering the scald tanks. Owing to the complexity of multiple-bird electrical water bath stunning systems, it will be difficult to resolve the bird welfare problems. However, killing of poultry using gases, while the birds are still in their transport containers, will eliminate the problems associated with handling of live birds at the primary processing plant and electrical water bath

stunning systems. This concept was originally proposed in 1982 by the Farm Animal Welfare Council in the UK. All the gas stunning systems now operating in Great Britain involve killing in transport crates. Some gas stunning systems operating in Europe, however, involve tipping of live birds from transport modules on to a conveyor belt that passes through a gas stunning tunnel. There are gas stunning systems operating in North America that involve shackling of conscious poultry before stunning. Needless to say, the latter systems have failed to fully utilize the welfare benefits of gas stunning.

Gas Mixtures Evaluated for Stunning/Killing

Although a number of scientific and commercial establishments evaluated the commercial feasibility of stunning pigs and poultry with gases as early as 1950, the animal welfare and carcass and meat quality issues were addressed only during the latter part of the twentieth century. In this regard, most of the research and development was carried out in Scandinavian countries, Spain, and the UK.

Gas mixtures investigated so far have included:

- 40–90% by volume of carbon dioxide in air (hypercapnia).
- Mixtures containing a minimum of 30% by volume of carbon dioxide and 20–30% by volume of added oxygen in air (hypercapnic hyperoxia).
- Mixtures of argon and nitrogen with 2% by volume of residual oxygen in air (anoxia).
- A mixture of less than 30% by volume of carbon dioxide in argon or nitrogen or both with up to 5% by volume of residual oxygen (hypercapnic anoxia).

The normal atmospheric concentration of carbon dioxide is 0.003% by volume; however, the gas is cheaply and readily available as a by-product of the chemical/fertilizer industries. Argon and nitrogen occur naturally and can be separated from atmospheric air. The atmospheric concentration of argon is 0.94% by volume and that of nitrogen is 79% by volume, and thus nitrogen is cheaper than argon. Another advantage of using nitrogen is that it can be separated from atmospheric air in any part of the world with the minimum of cost and impact on the environment. Nitrous oxide has been used experimentally to stun pigs, but owing to toxicity on chronic exposure in humans, it is not used commercially.

Mechanisms of Induction of Unconsciousness

Carbon dioxide induces unconsciousness through inhibition of neurons. This mechanism is closely related to the fall in pH of the cerebrospinal fluid (CSF), which bathes the brain and spinal cord. It has been reported that unconsciousness begins when the CSF pH falls below 7.1 and reaches a maximum at pH 6.8. The level of γ-aminobutyric acid (GABA), which is the major inhibitory amino acid neurotransmitter, has been known to increase during distress and anxiety; it is not certain whether the increase in GABA level is due to the stress of induction of unconsciousness with this gas or a physiological mechanism involved in carbon dioxide-induced neuronal inhibition.

Inhalation of carbon dioxide does not lead to a reduction in the blood oxygen level and, therefore, anoxia does not accompany the inhalation of carbon dioxide at concentrations required for stunning animals. In addition, the anesthetic effect of carbon dioxide is independent of residual oxygen in the breathing mixture. For example, a mixture of 40% carbon dioxide and 30% oxygen will also render animals unconscious. The time to onset of unconsciousness in pigs is related to concentrations of carbon dioxide between 40% and 70% by volume in air. Increasing the concentration of carbon dioxide in an air mixture above 70% by volume does not reduce the time to loss of consciousness greatly. However, the times to loss of consciousness in terrestrial poultry species seem to be very similar during exposure to 40% by volume or more of carbon dioxide in air and are rather prolonged when 20% by volume or more of oxygen is added to the mixture. The time to onset of death in both species is related to the concentration of carbon dioxide and the duration of exposure to the gas. Gas mixtures containing carbon dioxide and 30% by volume or more of oxygen do not induce death and therefore require a killing procedure (e.g., further exposure to a high concentration of carbon dioxide in air).

In general, hypoxia or anoxia occurring as a result of the inhalation of argon or nitrogen induces unconsciousness by depriving the brain of oxygen. For example, it has been established that cerebral dysfunction occurs in mammals when the partial pressure of oxygen in cerebral venous blood falls below 19 mmHg. Brain oxygen deprivation leads to accumulation of extracellular potassium and a metabolic crisis as indicated by the depletion of energy substrates and accumulation of lactic acid in the neurons. These effects can occur within a matter of few seconds of inhalation of an anoxic agent. However, it is worthy of note that the survival times of various parts of the brain may differ according to the regional oxygen consumption rate. For example, the survival time of the cerebral cortex is considerably shorter than that of the medulla, in which the respiratory center is located. Normal brain activity may be restored in anoxia-stunned animals if oxygen is administered or they are allowed to breathe atmospheric air. Inevitably, the recovery of consciousness in these animals is rapid. It is therefore a statutory requirement in the UK that animals must be held within the gaseous atmosphere until they are dead.

Argon and nitrogen, along with xenon, are frequently referred to as inert gases. However, in contrast to argon or nitrogen having anesthetic properties under hyperbaric conditions, xenon is an anesthetic gas under normobaric conditions. It has been reported that inhalation of 80% xenon and 20% oxygen induced unconsciousness in humans via the inhibition of *N*-methyl-D-aspartate (NMDA) receptor channels, which are essential for maintaining neuronal excitation during the conscious state. Interestingly, induction of unconsciousness with xenon, argon, nitrogen, and nitrous oxide ('laughing gas') has frequently been described by humans as a euphoric or very pleasant way of losing consciousness, and this may be due to the effects of those gases on NMDA receptor channels. It is worth noting that the effects of a number of modern analgesics, sedatives, and anesthetics are also mediated via NMDA receptor channels in the brain.

Time to Onset of Unconsciousness during Exposure to Gas Mixtures

Although 'unconsciousness' has different interpretations, from the stunning and slaughter point of view it can be suggested to be 'a state in which the ability of the brain to process sensory stimuli, including pain, is lost.' In this regard, the time to loss of somatosensory-evoked potentials (SEPs) in the brain, induced by electrically stimulating a peripheral nerve, has been determined during exposure of pigs and poultry species to various gas mixtures. The time to loss of SEPs is found to be rapid with argon-induced anoxia. By contrast, the time to loss of brain responsiveness during exposure to carbon dioxide in air can be relatively long and highly variable. Inhalation of a mixture of 30% by volume of carbon dioxide in argon or nitrogen seems to have an additive effect on the brain in species that are known to be resilient to the effects of carbon dioxide or anoxia alone (e.g., waterfowl).

Welfare Concerns of Gas Stunning

The induction of unconsciousness with gas mixtures should be differentiated from asphyxia. The physiological definition of asphyxia implies a physical separation of the upper respiratory tract from the atmosphere. For example, drowning involves water as a separating medium, strangulation leads to constriction of the trachea, and choking is due to obstruction in the respiratory tract. Suffocation is frequently used as a synonym for asphyxia.

Unlike other established stunning methods, exposure of animals to gas mixtures does not produce an immediate loss of consciousness. It is therefore important to ensure that the induction of unconsciousness with gas mixtures does not compromise animal welfare.

It is known that breathlessness (dyspnea) can occur as a result of changes in the blood oxygen or carbon dioxide levels. For example, exercise induces breathlessness through the gradual increase in blood carbon dioxide concentration. However, inhalation of high concentrations of carbon dioxide results in rapid increases in blood carbon dioxide concentration, and this is more effective in producing dyspnea. It is also worth noting that the severity of breathlessness depends upon the rate at which the blood carbon dioxide increases. It has been reported that, in humans, an increase in blood carbon dioxide tension of 5 mmHg above normal will stimulate respiration, whereas the blood oxygen tension has to decrease by approximately 60 mmHg from the normal level before hypoxia stimulates the respiratory centers in the brain. It is therefore apparent that hypercapnia is a more potent respiratory stimulant than is hypoxia. Further evidence to support these concerns also emerges from studies involving pigs and poultry.

Aversion to the initial exposure to argon-induced anoxia or carbon dioxide has been used (e.g., passive avoidance tests in the presence of a reward) to determine the relative merits of gas mixtures. The results of this study clearly indicated that pigs do not show any aversion to 90% argon in air; the majority (75%) of pigs did not show aversion to 30% carbon dioxide in air, whereas the majority (88%) of pigs avoided an atmosphere containing a high (>80%) concentration of carbon dioxide in air. In this study, pigs that found carbon dioxide aversive withdrew their heads immediately on exposure and did not attempt again to obtain the reward offered. However, a minority of pigs made repeated efforts to obtain the reward.

It has been reported that human volunteers also find inhalation of 40% by volume of carbon dioxide extremely unpleasant. It is therefore not surprising to note that pigs, being phylogenetically close to humans, also experience the same aversion. Fasting pigs for up to 24 h before exposure to 90% carbon dioxide in air did not overcome the aversion. Similarly, a considerable proportion of chickens and turkeys have been reported to avoid atmospheres containing high concentrations (40% by volume or more) of carbon dioxide in air.

Passive avoidance tests also showed that pigs spent similar times feeding in air and under anoxia (Figure 1) and, as would be expected, several of them lost consciousness (as determined from the occurrence of loss of posture) while eating apples presented in the anoxic atmosphere.

Recent research carried out in an experimental slaughterhouse in Spain demonstrated that pigs show more aversion to gas mixtures containing nitrogen and either 15% or 30% carbon dioxide by volume than 90% argon by volume in air.

It is thus evident that the initial exposure to a high concentration of carbon dioxide is extremely aversive and, given a free choice, animals will avoid such an atmosphere. This is probably because carbon dioxide is an acidic gas and is pungent to inhale in high concentrations. Indeed, carbon dioxide gas has been used to stimulate the nasal mucous membrane in order to induce pain-evoked responses in the brain.

In addition, the severity of respiratory sounds occurring during the induction of unconsciousness in pigs (until they

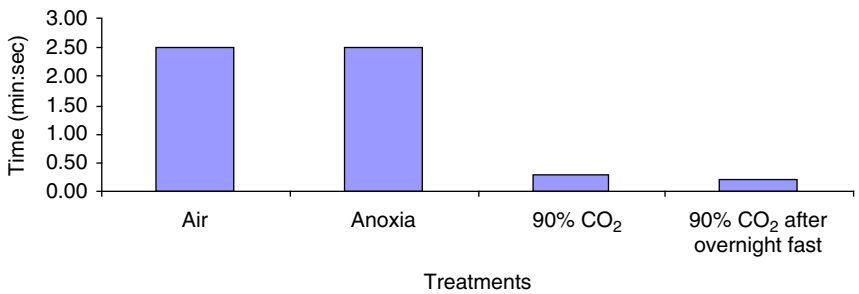

Figure 1 The average time (maximum 3 min) spent by pigs on feeding apples in various atmospheres.

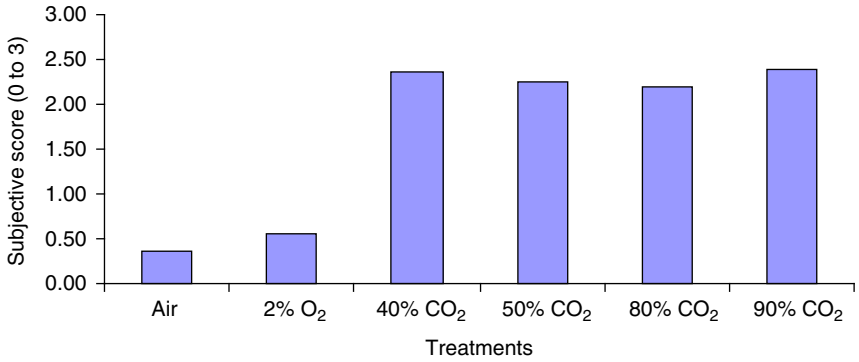

Figure 2 The severity of respiratory distress occurring in pigs during the induction of unconsciousness with gas mixtures.

lose posture) with gas mixtures has been subjectively rated and used to ascertain respiratory distress. It has been reported that exposure to 90% argon induced minimal respiratory distress, whereas, exposure to 40–90% by volume of carbon dioxide in air induced severe respiratory distress. Exposure to 30% by volume of carbon dioxide in an argon mixture induced moderate distress. Some pigs that were exposed to less than 70% carbon dioxide in air showed escape attempts. By contrast, during exposure to argon-induced anoxia, pigs lost posture without any evidence of behavioral arousal or escape attempts. See Figure 2.

Research carried out in an experimental slaughterhouse using a dip-lift system indicated that the incidence of pigs showing retreat and escape attempts was lower in 90% argon by volume in air than in the gas mixtures containing nitrogen and 15% or 30% by volume of carbon dioxide.

In poultry species, however, high concentrations of carbon dioxide induce severe head shaking, gasping, sneezing, and vocalizations, which can be considered as indicators of distress. This interpretation is based on the fact that these behaviors also occur during respiratory disease.

On the basis of the above evidence, it is suggested that anoxia is the best option on animal welfare grounds. The use of a mixture containing low concentrations (<30% by volume) of carbon dioxide in argon or nitrogen or both would appear to be better than using a high concentration of carbon dioxide in air.

However, those who wish to promote carbon dioxide for stunning argue that the cumulative stress associated with conventional electrical stunning methods can be greater than the stress of induction of unconsciousness with this gas. It is also claimed that the increased rate and depth of breathing occurring during carbon dioxide stunning of pigs enable them to breathe more of this gas and lose consciousness rapidly. It could also be argued that the cumulative stress caused to poultry during electrical water bath stunning is more than that would occur during stunning with carbon dioxide. On the basis of these arguments, carbon dioxide is widely used for stunning pigs and poultry.

Control of the temperature and humidity of the carbon dioxide in the stunning atmosphere could improve the welfare of animals. For example, in humans, nasal breathing of air increases the respiratory system's ability to warm and humidify the inspired air compared to oral breathing. By contrast, oral breathing, in particular during exercise-induced hyperventilation, results in drying and cooling of the upper respiratory tract, and this is one of the causes of exercise-induced asthma or bronchoconstriction. Under these circumstances, inhalation of warm and humidified air helps to alleviate distress, and this concept is widely used in human artificial respirators. Because animals exposed to carbon dioxide gas also show gasping (oral breathing), it is thought that administration of a warm and humidified gas mixture will help to reduce the severity of distress.

Commercial farming of several species of fish for human food has become popular in recent years. Traditionally, fish would be taken out of the water manually using nets or mechanically using pumps and placed in air or on ice, which is considered to be equivalent to asphyxiation in terrestrial vertebrates. Owing to the concern for their welfare at slaughter, the use of gas mixtures, especially carbon dioxide, for stunning salmon, trout, seabream, and seabass under commercial farming conditions has also been developed, at least in Europe. Carbon dioxide is highly soluble in water. Under commercial conditions, carbon dioxide is bubbled into water (sea or fresh water, depending upon the species of fish) contained in tanks until the water becomes saturated with the gas. Batches of fish are then placed in the CO_2-saturated water and held until they become completely sedated or motionless. However, research has shown that fish find immersion into CO_2-saturated water aversive, as indicated by rapid swimming and making escape attempts.

Commercial Implications

Experiments with the carbon dioxide stunning of pigs have shown that exposure to a minimum of 70% carbon dioxide for 90 s results in stunning; therefore sticking (bleeding or exsanguination) should be performed as soon as possible (e.g., ideally within 15 s of exiting the gas) to prevent resumption of consciousness. When the duration of exposure to this level of carbon dioxide is increased, the incidence of death also increases. Under high-throughput conditions, exposure of pigs to a minimum of 90% by volume of carbon dioxide in air for 3–5 min results in death in the majority of pigs, which can be recognized from the presence of dilated pupils and absence of gagging (rudimentary respiratory activity) at the exit from the gas.

In Denmark, where almost all pigs are stunned using carbon dioxide, a comprehensive automatic system for driving

large groups of pigs (15–16 pigs) from the lairage to the point of stunning, dividing them into small groups (e.g., 5–6 pigs) and loading them onto a lift, which is lowered into a carbon dioxide stunning unit, has been developed. In comparison with the conventional pig handling and loading systems and carbon dioxide stunning units, this group handling and stunning system is far better on animal welfare grounds.

It has been reported that exposure of pigs to either argon-induced anoxia or the carbon dioxide–argon mixture for 3 min resulted in satisfactory stunning; however, bleeding should commence within 15 s to avoid resumption of consciousness. A 5 min exposure to these gas mixtures followed by bleeding within 45 s prevented carcass convulsions during bleeding. The results also showed that exposure of pigs to argon-induced anoxia or the carbon dioxide–argon mixture for 7 min resulted in death in the majority of pigs. Owing to the prolonged exposure time required to kill pigs with anoxia, it is not used under commercial conditions. However, further research and development is needed to evaluate the feasibility of inducing unconsciousness with anoxia and then killing pigs by other means (e.g., induction of cardiac arrest in unconscious pigs using an electric current).

Chickens and turkeys can be killed with a minimum of a 2 min exposure to 50% by volume carbon dioxide in air, 90% by volume of argon or nitrogen in air, and a mixture containing less than 30% by volume of carbon dioxide in argon or nitrogen.

The Welfare of Animals (Slaughter or Killing) Regulations in the UK approved the use of a minimum of 70% by volume of carbon dioxide in air for killing pigs. However, on bird welfare grounds, this regulation does not allow the use of carbon dioxide for killing domestic poultry, except for disease-control purposes. Instead, two other gas mixtures have been approved for killing domestic poultry intended for human consumption:

- Argon, nitrogen, or other inert gases, or any mixture of these gases, in atmospheric air with a maximum of 2% oxygen by volume.
- Any mixture of argon, nitrogen, or other inert gases with atmospheric air and carbon dioxide provided that the carbon dioxide concentration does not exceed 30% by volume and the oxygen concentration does not exceed by 2% by volume.

However, the European Slaughter Regulation 1099/2009, which comes into force from January 2013, permits the use of:

1. Direct or progressive exposure of conscious pigs to a gas mixture containing more than 40% carbon dioxide for pigs.
2. Direct or progressive exposure of conscious pigs and poultry to an inert gas mixture such as argon or nitrogen leading to anoxia.
3. Direct or progressive exposure of conscious pigs and poultry to a gas mixture containing up to 40% of carbon dioxide associated with inert gases leading to anoxia.
4. Successive exposure of conscious birds to a gas mixture containing up to 40% of carbon dioxide, followed when they have lost consciousness, by a higher concentration of carbon dioxide.

In general, gas stunning/killing of pigs and poultry results in better carcass and meat quality than other established stunning methods. In comparison with electrical stunning, gas stunning or killing can reduce the incidence of broken bones in carcass and hemorrhaging in muscles. However, stunning with gas mixtures containing 40% by volume or more of carbon dioxide tends to retard the rate of rigor development and, hence, tenderness development. By contrast, stunning of pigs and poultry with argon and nitrogen mixtures or a mixture containing less than 30% by volume of carbon dioxide in argon or nitrogen mixture accelerates the rate of postmortem rigor development and tenderization of meat. This is found to be at least as effective as electrical stimulation of carcasses, especially in poultry. Therefore, these gas mixtures provide an opportunity for poultry processors to portion or separate breast muscles soon after chilling (in less than 2 h postmortem) without inducing toughness, provided the muscle temperature is also reduced rapidly by the use of an appropriate chilling method.

However, convulsions occurring as wing flapping after the loss of consciousness in poultry can increase the incidence of dislocated or broken wing bones. Owing to this and the cost of argon, the poultry industry would prefer to use gas mixtures causing less of this quality problem, especially methods involving exposure to low or gradually increasing concentrations of carbon dioxide in air as these methods have been known to cause very little or no wing damage in the carcasses.

Irrespective of the species of animals involved, the ever-decreasing competition in the fields of stunning equipment manufacturing and gas distillation and distribution are disconcerting on economic grounds.

Conclusions

In general, gas stunning of pigs in small groups and of poultry in transport crates can benefit animal welfare and improve carcass and meat quality. Anoxia induced with argon, nitrogen, and any mixtures of inert gases would appear to be the best option on animal welfare and carcass and meat quality grounds. By contrast, the induction of unconsciousness with carbon dioxide could be distressing to animals, and therefore the meat industry should be encouraged to seek potential alternatives.

Electrical Stunning

E Lambooij, Wageningen UR Livestock Research, The Netherlands

This article is a revision of the previous edition article by E Lambooij, volume 3, pp 1342–1348, © 2004 Elsevier Ltd.

Glossary

Cardiac arrest A process that occurs when the heart ceases to function. It can occur, for example, through ventricular fibrillation.

Clonic muscle spasms A series of alternating muscular contractions and relaxations.

Consciousness A state of the mind that includes subjectivity, awareness, the ability to experience or to feel, wakefulness, and the executive control system of the mind.

Electroencephalogram (EEG) A measure of the electrical activity of the brain.

Electronarcosis or electroanesthesia A state of unconsciousness achieved by application of an electric current.

Generalized epileptiform activity The seizure of grand mal epilepsy, consisting of a loss of consciousness and generalized tonic convulsions followed by clonic convulsions.

Neurotransmitters A group of chemicals in the brain responsible for brain/nerve function. They include gamma amino-4-butyric acid (GABA), vasopressin, oxytocin, glutamate, and aspartate.

Slaughter The process of exsanguination or bleeding that involves sticking (severance of the brachiocephalic trunk at the thoracic inlet in cattle and pigs) and cutting both the carotid arteries in the upper neck (sheep, goat, and poultry).

Tonic muscle spasm A sudden, abnormal, involuntary muscular contraction consisting of a continued muscular contraction.

Introduction

Stunning Process

All animals, including poultry and fish, should be protected from anthropogenic excitement, and pain or suffering during transport, lairage, restraint, stunning, slaughter, or killing. Research in bird-, mammal-, and fish-slaughtering industries has linked improvements in animal welfare to improvements in meat quality.

Stunning of animals is applied to induce a state of unconsciousness and insensibility of sufficient duration to ensure that the animal does not recover before exsanguination results in death. It is accepted that unconsciousness and insensibility should be induced immediately during stunning to minimize detrimental effects on animal welfare and meat quality.

Electrical stunning, also referred to as electronarcosis or electroanesthesia, is widely used all over the world in slaughterhouses on farmed animals such as cattle, sheep, pigs, poultry, and fish. Electrical stunning involves passing of an electric current of sufficient magnitude through the head of an animal such that a generalized epileptiform activity is induced in the brain (grand mal seizure-like state). In humans, generalized epileptiform activity involving both the cerebral hemispheres is always accompanied with unconsciousness, and therefore sentient animals are also considered to be unconscious and insensitive following electrical stunning.

The epileptic process is characterized by rapid and extreme depolarization of the resting membrane potential of neurons in the brain. Nevertheless, behavioral and clinical signs of recovery are not always sufficient for the assessment of the effectiveness of electrical stunning. Therefore, the use of electroencephalogram (EEG) recordings alongside responses to stimuli (visually evoked and somatosensory evoked responses) to assess unconsciousness and insensitivity are recommended.

History

Early in the nineteenth century scientists experimented with electricity in order to produce a state of anesthesia in animals and man, and later in the twentieth century, on animals to render them unconscious and insensible before slaughter. Most of the work in this connection was done in Germany, France, The Netherlands, and the USA. Leduc found that a constant current, which was rhythmically interrupted 90 times per second using a voltage of 5–20 V, was able to produce a comatose-like narcosis in rabbits. In other experiments on himself, his motor functions were paralyzed, whilst higher cerebral functions were not disrupted, but analgesia was present. Small animals showed tonic spasms before clonic contractions, which were often followed by convulsions when applying 300 mA on the head.

Many meat hygienists came to the conclusion that the animals were unconscious because of the absence of the corneal reflex. It is clear that the conjunctival reflex, i.e., shutting of the eyelids after the conjunctiva was touched, was only possible provided that the eyelids were free to react. Because the eyelids were brought into tonic spasms as soon as the circuit was closed, the reflex was prevented. In this condition, absence of the reflex did not mean anything as regards the condition of the central nervous system, i.e., the brain.

It was claimed that the 'electrolethaler,' which was designed for slaughter animals, was humane, instantaneous in action, economic in use, causing no blood splashing in the meat, safe, and ensured complete bleeding. The electrodes were placed behind the ears for a few seconds, and it was recommended to

place the electrodes as a second application on the head and back of the animal for 15–30 s. The voltage applied was 30–70 V. It was claimed that farm animals such as pigs, sheep, and calves were unconscious after the application of current. Fractures in the vertebrae of the carcasses were found and believed to be due to the sudden contraction of muscles.

Brain Stimulation

Anesthesia

Since the end of the past century, many investigations have been performed on electroanesthesia in animals and man. The anesthetic effect is brought about immediately with the onset of the flow of sufficient electric current through the brain, and the recovery is also very rapid after the end of electrical stimulation. In veterinary medicine, electroanesthesia might be used because it represents a simple, completely controllable, and low-cost method of anesthesia. During electroanesthesia, unconsciousness may be present but without a general epileptiform insult. It has been suggested that the ascending activating influence of the reticular formation of the brain stem suppress responses of the telencephalon or cortex (the seat of consciousness) during current delivery. Another suggestion is that the administered current interferes sufficiently with neuronal function at the thalamic (midbrain) level to cause anesthesia. It has also been observed that overt behavioral unconsciousness or loss of somatosensory potentials can occur without the development of polyspike activity in the EEG in sheep and poultry, respectively, when extremely high currents (almost 10 times than that is necessary to achieve effective stunning) are applied during stunning.

Stunning

Electroanesthesia is widely used for the stunning of slaughter animals. The amounts of current necessary to stun various species of farmed animals are presented in Table 1.

Effective electrical stunning can be ascertained from the occurrence of generalized epileptiform activity in the brain by using EEG. Generalized epileptiform EEG consists of relatively small waves increasing in amplitude in the tonic phase and decreasing in frequency in the clonic phase to result ultimately in a period of strong depression of electrical activity in pigs, sheep, calves, and poultry (Figure 1). Several studies involving sheep, in which neurotransmitters have been measured, coupled with pharmacological experiments, suggest the general epileptiform insult induced by an electrical stun is dependent on the release of vasopressin, oxytocin, glutamate, aspartate, and gamma amino-4-butyric acid (GABA). The first phase induced by the stun produces the tonic phase through the release of the excitatory neurotransmitter glutamate. This is followed by the release of GABA that provides a period of analgesia and also assists in the recovery if the animal is not slaughtered. The observed behavior of a general epileptiform insult is characterized by a phase of tonic muscle spasm followed by a phase of clonic muscle spasms and ultimately an exhaustion phase with muscle flaccidity. An eye reflex cannot be used as an indicator, because the reflex is blocked during the tonic phase and may occur spontaneously during the clonic phase. In sheep as well as in other mammals the extensors are stronger than the flexors that caused the extension. During head-only stunning, broilers may display wing flapping during and after stunning, which is sometimes intensive. Fish, which were able to move freely, initially showed limited tonic/clonic cramps, followed by heavy clonic contractions combined with uncoordinated movements or turning aside. The flexors and extensors in fish are considered to be equal in strength, which may explain the observation of limited tonic and clonic cramps.

Table 1 Recommended minimal current for electrical stunning of poultry, ruminants, pigs, and fish

Species	*Head-only*	*Water-bath/water tank*	*Head to body*
Broiler	240 mA	100 mA < 200 Hz^{-1}	
Turkey	400 mA	250 mA < 200 Hz^{-1}	
Ostrich		500 mA	
Duck and geese		130 mA < 200 Hz^{-1}	
Quails		45 mA < 45 Hz^{-1}	
Cow	1.28 A		
Calf	1.25 A		
Sheep and goat	1.0 A		1.0 A
Pigs	1.3 A		1.0 A
Eel	600 mA	0.64 A dm^{-2}	
Trout	500 mA		
African catfish	630 mA	1.6 A dm^{-2}	570 mA
Carp	240 mA	0.14 A dm^{-2}	
Salmon			670 mA
Cod		2.5 A dm^{-2}	
Turbot		3.2 A dm^{-2}	
Tilapia		1.0 A dm^{-2}	
Sea bass		4.3 A dm^{-2}	

The most common electrical stunning method for livestock uses a frequency of 50 Hz alternating current (AC) with sinusoidal waveform. The frequency can be as high as 1800 Hz, and the waveform can be square or rectangular. High-frequency electrical stunning can induce epileptiform activity in the brain; however, relatively higher amounts of current are necessary to induce epileptiform activity and the duration of unconsciousness also shorter than those with 50 Hz. A sufficiently prolonged period of unconsciousness and insensibility (e.g., 40 s) is necessary to facilitate exsanguination (bleeding out) and onset of death in unconscious animals. In this regard, a bipolar sine or square wave is found to be more effective than monopolar-pulsed direct currents. In 'head to body' stunning involving passage of a 50 Hz sine wave alternating current simultaneously through the brain and heart, the animal may die due to a heart failure, which is recordable on an electrocardiogram (ECG). The heart failure results in loss of blood pressure and lack of oxygen to the brain and affects the characteristics of general epileptiform insult.

Transcranial magnetic stimulation (TMS) is a recently developed noninvasive technique used in human psychiatry to treat depression with slowly repeated pulses to the frontal lobe or to induce seizures. A study was done to determine whether or not TMS with an adapted coil has potential for further development as a noninvasive stunning method for broilers and

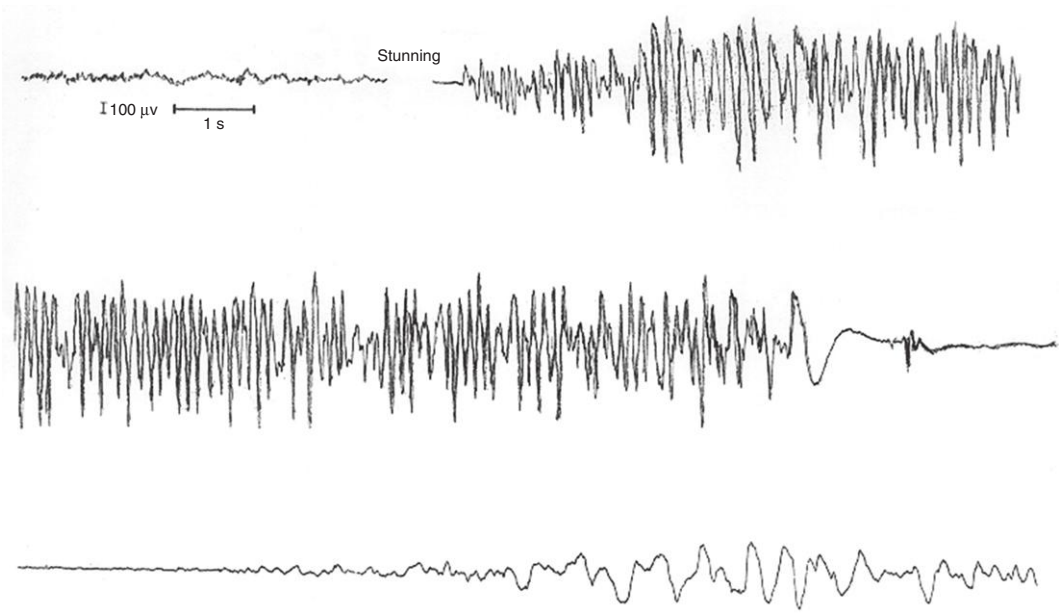

Figure 1 Trace of the EEG before and during a general epileptiform insult. The relatively small waves (initial phase) became larger (tonic phase) with an increase in amplitude and a decrease in frequency, followed by a period of strong depression of electrical activity (exhaustion phase) and recovery.

rabbits but further research and development is needed to optimize parameters.

Ethics

First, stunning of animals is applied to induce a state of unconsciousness and insensibility of sufficient duration to ensure that the animal does not recover before death occurs via exsanguination. Second, stunning should produce sufficient immobility to facilitate safe shackling, hoisting, and exsanguination of animals. It is generally stated that unconsciousness should be induced, as soon as possible without imposing a detrimental effect on the welfare of the animal and the meat quality. For the application of stunning methods, it is necessary to confine or restrain the animal and to position it for stunning. The effectiveness of any method of preslaughter stunning can be seriously impaired by improper use of the restraining device on the animal and by preslaughter stress.

Stress before slaughter increases some neurotransmitters, which may affect the poststun reflexes and unconsciousness. Combining head-only stunning with exsanguination has a synergistic effect on the release of glutamate and aspartate, which increases the duration of unconsciousness and insensibility. Sticking (also referred to as slaughter, exsanguination, or bleeding) following a stun should be carried out as promptly as possible when using head-only stunning as it takes time depending on the species before brain responsiveness is lost following sticking. It is widely recognized that inducing a cardiac arrest at stunning has distinct welfare advantages: (1) it results in a rapid loss of brain function, (2) it ensures that the animal will not regain consciousness, and (3) it does not depend on the slaughter man performing an accurate stick. Sticking should involve severance of blood vessels supplying oxygenated blood to the brain. For example, sticking in cattle and pigs involves severance of the brachiocephalic trunk at the thoracic inlet and cutting both the carotid arteries in the upper neck of sheep, goat, and poultry.

Meat Quality

Various stunning methods and electrical parameters have been reported to have a different effect on postmortem rigor development and subsequent meat quality. The postmortem metabolism is largely a consequence of indirect stimulation through nervous pathways. Electrical stunning of lambs for 3–4 s can influence the pH measured in the loin and some other muscles. This is also the case in pork, and it may result in pale soft exudative meat, which is not necessarily related to genotype. In chickens, high-current electrical whole-body stunning at 100 mA and above resulted in higher initial muscle pH than nonelectrically stunned birds or birds stunned with 50 mA or less. Breast muscle shear values of birds whole-body stunned with currents lower than 100 mA were lower than or similar to, depending on the deboning time, stunning with currents higher than 100 mA.

Broken vertebrae can occur in pigs stunned with head-to-back electrode positioning if the voltage and the current are too high. A satisfactory stun with a minimum of fractures is obtainable when using 1.3 A with head-to-back stunning systems. Sinusoidal alternating currents of 50 Hz have a large stimulatory effect on skeletal muscles, which can be reduced by increasing the current frequency to an extent that prevents the occurrence of broken backs. The prevalence of broken vertebrae and pelvises could be reduced to zero by increasing the frequency from 50 to 1500 Hz when stunning head-to-back with 300 V for 3 s. The drawback of this approach is that

Figure 2 Hemorrhages in the muscles of the ham.

the effect on fibrillating the heart is also reduced. However, it might be possible to find an optimum combination of frequencies and current, and electrode position that stuns the pig and fibrillates the heart with minimum of damage to the carcass and meat.

Hemorrhaging in major muscles and surrounding tissues results in a decrease in the quantity (trimming) and quality of meat products, and hence causes economic losses to the meat industry. Hemorrhages can be induced by stunning; however, the underlying mechanism is considered to be multifactorial. The morphology of hemorrhages investigated was dependent on the tissue in which they occurred. In the pectoral muscles, extravasating blood was found to follow the direction of the muscle fibers. In fat tissue, the majority of the hemorrhages had a petechial appearance. More diffuse hemorrhages were found in loose connective tissue (Figure 2). The histological study of hemorrhages in different types of muscles showed that the morphological appearance of the blood extravasation is determined by the structure of the tissue as well as by the amount of blood leaving the circulation. Some hemorrhages were associated with hypercontracted and disrupted muscle fibers, indicating that they were caused by severe muscular strain. Many hemorrhages were found near venules or veins and were packed with erythrocytes, surrounded by intact adipocytes and connective tissue. Rupture was observed only in venous structures, such as postcapillary venules and small veins, not in arterial vessels. This strongly indicates that a local rise in venous blood pressure can cause rupture of venules and small veins.

The force experienced during electrical stunning probably depends on the posture or restraining method of the slaughter animals. For instance, shackling involves hanging live birds upside down, whilst suspended by their feet. The restrained legs carry the body weight of the birds. Electrical water bath stunning of broilers has the most detrimental effect with respect to muscle hemorrhaging. A poor bleed out can significantly increase hemorrhage conditions in broilers. Electrical stunning with currents that induce cardiac arrest in the majority of the broilers is associated with a high incidence of red wing tips. This is explained by inadequate bleeding of the birds after cardiac arrest. The wings of killed instead of stunned birds hang low resulting in stagnation of blood in the wing veins. The use of high frequency (500 and 1500 Hz) stunning currents resulted in a decrease in carcass downgrading and a marked reduction in the occurrence of breast muscle hemorrhages, which represent significant commercial benefits.

In lambs subjected to head-to-back stunning, higher currents and longer-stunning durations increased the severity and incidence of speckle in the legs but not in the loin. The reason for this is that its electrode placement ensures a maximal tetanic effect over the whole musculature of the loin. There are effects on speckle in the leg due to stimulation through the nervous system.

It is well known that ac currents between 50 and 100 Hz cause substantial injuries in salmon, but an older study indicates that dc currents although tending to improve the quality do not guarantee efficient stunning. The combined ac/dc supply used in the experiment was not only efficient for stunning but also did not provoke internal injuries such as spinal deformities or rupturing the aorta dorsalis in fish.

Practical Application

Ruminants

Sheep and calves are regularly stunned using head-only or head-to-back electrical methods. For head-only stunning, the current is either delivered via scissor-model stunning tongs with pointed steel electrodes placed on either side of the head or a pistol grip-like handpiece holding the electrodes. The head of animal may be wetted with a water jet in order to improve electrical conductivity between the head and stunning electrodes. The electrodes should be positioned on both sides of the head between the eye and ear such that they span the brain during head-only stunning. This type of stunning is termed 'head-only' stun that does not stop the heart. As the animal can potentially recover and the slaughterman cuts the throat before the animal recovers (i.e., effectively taking the life of the animal), this procedure is therefore consistent with halal slaughter.

During head-to-back or body stunning, one electrode should be positioned on the head and the other one on the withers or loin back such that the two electrodes span the brain and heart. The duration of insensibility associated with a head-only electrical stunning in sheep is 34–45 s, and recovery can be prevented by rapid exsanguination. Head-to-body stunning can cause cardiac arrest and as the spinal cord is also in the pathway, it additionally reduces the animal's reflexes with significant movement reduction, making it a good option when halal slaughter is not required.

In cattle, the head of the animal is usually restrained by two parallel bars, which also serve as stunning electrodes. After head-only stunning for 4 s with 1.5–2.5 A, the animal is rolled out of the stun box on to a conveyor and bled out by a throat cut within 10 s from the end of stun. While bleeding, a low voltage pulsed direct current is applied from nose to rump of the animal for a minimum of 30 s (80 V, 15 Hz). This results in a still carcass, enhancing worker safety and producing a degree of electrical stimulation that protects meat tenderness. Alternatively, head-only electrical stunning in cattle is swiftly followed by the application of a second current cycle from the

Figure 3 Correct placement of the stunning tongs on the head.

muzzle to brisket of the animal to induce cardiac ventricular fibrillation.

A double-rail conveyor restrainer for cattle or sheep in an upright position with the legs straddling and the body supported by the belly has been developed. The animals experienced less stress in this system. It is recommended to use a double-rail restrainer and stun the animal in an upright position.

Pigs

Most slaughter pigs are stunned electrically. The current is delivered via scissor-type stunning tongs positioned on both sides of the head between the eye and ear such that the electrodes span the brain for head-only electrical stunning (Figure 3). During head-to-back or -body stunning, one electrode is on the head and the other on withers, loin back, fore- or hindleg such that the current flows through the head as well as heart. In the case of the head-body position, a cardiac arrest may occur. It is considered that the pig skin has a high resistivity and penetrating this layer would improve current flow.

Several automatic electric stunning methods are available. One device consists of two V-type restrainers running at a different speed in order to separate the successive animals. At the end of the second restrainer, each pig touches the electrodes and the current is passed. In another method, pigs make automatic contact on the head with two electrodes at the end of one V-type restrainer. After stunning, the animals are turned out and fall onto a table. A third method is automatic electric stunning at a band restrainer. At the end of the restrainer, the nose of the pigs interrupts a beam of light that initiates the electrodes. The electrodes are positioned between the eye and ear. After 1 s of stunning a heart electrode is positioned behind the left shoulder for 1.5 s. As a result of the body current, the animals do not show muscle contractions.

Poultry

Water-bath electrical stunning is commonly used under commercial conditions where large throughput rates are required. In this system, birds are hung upside down on a moving, metal-shackle line (shackling), and passed through an electrified water bath, such that the current flows through the whole body toward the shackle, which serves as the earth. In water-bath systems, the electrical current is applied to the whole body, and the minimum current necessary to induce unconsciousness and insensibility depends upon the waveform and frequency of current used. However, the minimum currents recommended for broilers increase quality defects (hemorrhages, broken bones) of carcasses and meat. An alternative to whole-body electrical stunning is head-only stunning, where the stunning current only passes through the head of the birds. Head-only electrical stunning has been evaluated using a cone-shaped restrainer in which the broilers were suspended by their feet. Broilers may be insensible and unconscious after head-only electrical stunning with pin-electrodes using a current of 190±30 mA for 0.5 s. For practical implementation, a set current of 250 mA is recommended to overcome individual differences in resistance. To prevent recovery the stun should be followed by an immediate neck cut.

Fishes

Electronarcosis is used to immobilize fish for routine laboratory or farming practices. In general, 50–70 V depending on the length of the fish is used. Assessment of narcosis in fish by several researchers has been based on behavioral observations and clinical signs of recovery. It is assumed that narcosis lasts until the onset of opercular movement, the first response to a stimulus, and the commencement of swimming.

Electricity has been used in various studies to stun farmed fish species. It is known that the specifications for electrical stunning are not only dependent on fish species but also are partly determined by waveform, field strength of the current applied, and water conductivity. There are two approaches of electrical stunning applicable for use in practice. The fish species can be either stunned in water or after withdrawal from the water. Stunning in water involves exposing the fish to an electrical current administered via two plate electrodes in a tank. For stunning after dewatering, the fish is placed in a device that consists of rows of steel flaps as positive electrodes and conveyer belts or steel plates as negative electrodes. In principle, electrical stunning in water reduces stress in the fish, whereas applying stunning after dewatering the fish may result in exposing the fish to air longer.

Other Species

Ostriches are stunned by electrical means (head-only and 80/90 V) or by captive bolt and suspended by both legs by chains hanging from the ends of an upturned horizontal bar. The animal is then lifted and bled. Based on clinical parameters, it was recommended that the current to stun ostriches is 500 mA.

Preslaughter stunning of rabbits is now usually carried out by the preferred method of employing electrical currents. A wall mounted V-shaped metal electrode, with serrated edges for optimum contact, can be used as the stunning electrode. The head of the rabbit is placed into the V of the electrodes, which makes firm contact with the back of the eyes and the base of the ears to span the brain. Electrical stunning can be achieved using currents in excess of 140 mA.

Glossary

Corneal reflex Blinking (fast or slow) in response to stimulus of the cornea.

Eye movements A correctly stunned animals will show fixed eyes: They are wide open and glassy, and no nystagmus (spontaneous rapid side to side (twitching) movements of the eyeballs). They will also not show eyeball rotation, in which the eyeball rolls so mostly pink sclera can be seen and little or no iris.

Spontaneous blinking Animal opens/closes eyelid on its own (fast or slow) without a stimulation.

Introduction

The Physiology of Mechanical Stunning

The main method for stunning cattle is the penetrative captive bolt.

It is intended to produce immediate unconsciousness and insensibility that lasts until death occurs from exsanguination. Well-serviced and -maintained weapons should consistently achieve proper stunning in cattle. The stun effectiveness (stun quality) can be influenced by variations in cattle breed, size and maturity, as well as differences in mechanical properties of commercially available guns.

There are two types of captive bolt guns: penetrating and nonpenetrating. In penetrating captive bolt guns, a metal rod is propelled from the muzzle of the gun by the discharge of a blank cartridge inserted in a chamber behind the proximal end of the bolt. In nonpenetrating captive bolt guns, a mushroom head-shaped bolt is propelled from the muzzle of the gun by the discharge of a blank cartridge inserted in a chamber behind the proximal end of the bolt. The use of the penetrating captive bolt is also referred to as concussion stunning and the nonpenetrating bolt as percussion stunning. The impact of the bolts on the head of an animal causes concussion of the brain and rupture of brain blood vessels, leading to unconsciousness.

The bolt velocity varies according to the gun powder content within a selected cartridge, which is usually color coded by the manufacturer. When a penetrating captive bolt gun is fired on the head, the sharp-rimmed bolt enters the skull and brain and then recoils automatically back into the barrel of the gun. The depth of penetration into the skull varies according to the length of the bolt and the power of the weapon. The captive bolt should create a large, deep, penetrating, and well-defined hemorrhagic track which traverses almost the full thickness of the brain. It should cause severe damage to the cerebellum, brainstem, and caudal aspect of the cerebral hemispheres with marked subarachnoid and intraventricular hemorrhages, especially adjacent to the entry wound and around the base of the brain. The rupture of arteries entering the brain ensures a lasting unconsciousness and insensibility during shackling, hoisting, and sticking (exsanguination or bleeding) procedures until death of the animal (Figure 1).

The bolt velocity and angle of firing determine the effectiveness of stunning, and the kinetic energy impacted on the skull travels to the basal area of the brain. Exsanguination should be carried out without undue delay following captive bolt stunning. In cattle, exsanguination is normally performed by inserting a knife at the base of the neck pointing toward the chest and severing the brachiocephalic trunk and anterior vena cava.

The effects of different bolt velocities at stunning on brain function may be investigated by looking at visual evoked responses (VERs) as an index of brain damage. VERs, induced by flashing a strobe light in front of the animal, are recorded along with the spontaneous brain activity by way of electroencephalograms (EEGs) recorded using electrodes attached to the head or electrocorticograms (ECoGs) recorded using electrodes implanted (under anesthesia) on the surface of the

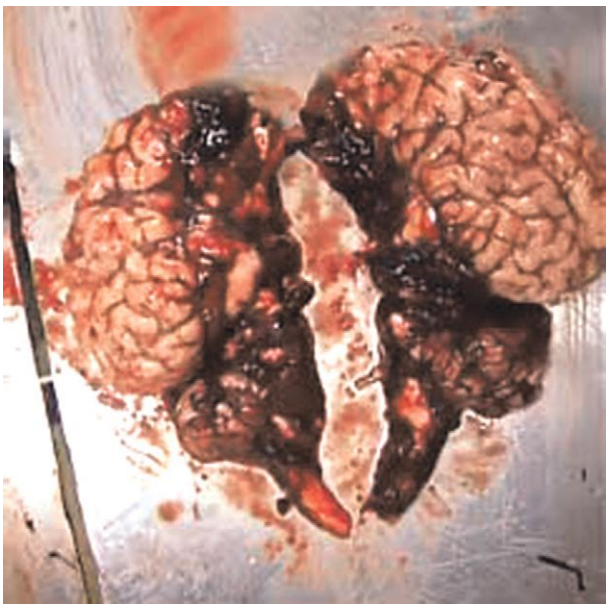

Figure 1 Typical brain hemorrhage in a well-stunned animal (notice heavy bleeding track down the central part of the brain).

brain area responsible for normal vision (known as visual cortex). The electrical activity evoked by the flashing light indicates the brain's ability to respond to external stimulus. VERs are present in conscious as well as unconscious animals, but their loss indicates an insult to the brain sufficient to cause failure of a primary sensory pathway, and are therefore used as an indicator of profound brain failure, and hence unconsciousness and insensibility.

The capability of penetrating captive bolt guns to obliterate VERs depends on bolt velocity and the shot accuracy. In an experiment conducted by Daly in 1987 on the effect of bolt velocity and diameter on abolition or retention of VERs, it was found that visual-evoked responses are abolished or significantly reduced in amplitude as energy transfer increases and that energy transfer increases with bolt diameter (**Table 1**).

The application of the shot should be at a point derived by the two lines between the ear base and the opposite eye (A, **Figure 2**).

Bolt velocity is reduced if (a) incorrect cartridges for the species and size of animal are used, (b) the cartridges are damp (kept in humid environments), and (c) the gun is dirty or has worn out or damaged parts. The impact of a captive bolt can also be seriously hindered if the operator applies the gun at an incorrect angle or too far away from the animal's forehead. In principle, the gun should be placed flat on the animal's forehead at a 90 degree angle to achieve the maximum impact. If animals are moving within the stun box, obtaining the correct shooting angle, location, and closeness on the forehead can be difficult. This can be especially a problem when shooting relatively small animals such as calves in a large stun box designed for adult cattle.

It is worth noting that sheep and cattle stunned in the poll position are less likely to lose VERs than those shot frontally. Also, increasing bolt velocity when stunning cattle increases the likelihood of them losing VERs, but even very high velocities are not invariably successful in this species. The impact of the bolt with the cranium is the principal determinant of effective stunning rather than the penetration of the bolt into the brain tissues. Furthermore, the tissue damage produced by the passage of the bolt through the brain tissue does not necessarily contribute to loss of VERs.

Table 1 Effect of bolt speed and bolt diameter of a captive bolt gun on energy transfer (joules), to the head of the animal and the prevalence of visual-evoked responses in the cortex of the brain

Bolt speed ($m\ sec^{-1}$)				
	47		*55*	
Bolt diameter (mm)	*Energy transfer*	*Evoked responses*	*Energy transfer*	*Evoked responses*
12	97 + 17	3/6	124 + 25	1/8
14	125 + 18	2/8	139 + 25	1/8
16	158 + 20	1/7	186 + 30	0/7

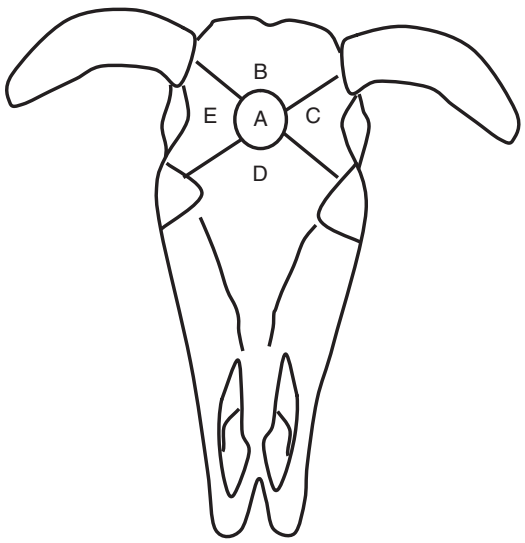

Figure 2 Accurate shot application.

Assessment of Stun Quality

The following criteria may be used to determine an effective stun:

1. Immediate collapse of the animal
2. Brief tetanic spasms that might be followed by uncoordinated hind limb movements
3. Immediate and sustained cessation of rhythmic respiration
4. Absence of coordinated attempts to rise
5. Absence of vocalization
6. Glazed "glassy" appearance of the eyes
7. Absence of eye movements and reflexes

Ineffective stunning is considered to occur if animals show any of the following symptoms: nystagmus, eyeball rotation, vocalization, rhythmic breathing, righting reflex, spontaneous blinking, or corneal reflex. Other symptoms may be failure to collapse properly, excessive ear or tail tonus, or excessive kicking.

Animals can show signs outside of these criteria due to neural reactivity occurring from various levels of physical injury to different parts of the brain. Despite the instantaneous brain trauma caused by penetrating captive bolt stunning, the physical manifestation of its effect can occur in stages. For example, kicking movements can occur at various times after the stun. The actual sticking process can also cause a further bout of kicking or front leg and head movements that are not necessarily associated with ineffective stunning. To be sure that there is no risk of recovery, eye reflexes must be absent. Bulls tend to display eye rotations and nystagmus more often than other cattle classes, and if seen in isolation, these symptoms represent a risk of recovery rather than a symptom of sensibility. Eye rotation can also sometimes occur for a short period immediately after stunning and persist for up to 15 s, then the eyeball centers in the socket and the glazed appearance of proper stunning occurs as the animal falls into a state of coma or death ensues. However, to prevent any risk of

recovery, and especially if seen with other symptoms, the animal should be restunned when these symptoms appear and remain for more than 15 s.

It is important when assessing stun quality that animals are inspected during the whole stun to stick period and during bleeding. A judgment should be based on the absence or presence of certain symptoms, and further inspection is warranted when symptoms outside of the deep stun criteria appear. For example, symptoms that indicate that the animal should be checked more closely for further signs include stiff ears usually held upright, gasping, stiffness in the jaw, absence of a protruding tongue while on the shackle or during sticking procedures, and excessive head or paddling movements that hinder the sticking process. An immobile tongue hanging out of the mouth is a valuable sign of an effective stun but is not a requirement for the diagnosis of effective stunning. If at any time animals show a positive corneal reflex or spontaneous blinking, the animal must be restunned immediately.

If an appropriate captive bolt gun is fired with the correct cartridge and positioned in the appropriate angle, captive bolt stunning should achieve a close to 100% success rate. The risk for inadequate stunning can be reduced in larger cattle (i.e., bulls) by using well-serviced, commercially available, pneumatically operated bolt guns because of the higher power and bolt velocity compared to conventional captive bolt guns. Brain damages seen in pneumatically operated bolt guns have been shown to be larger, with more severe hemorrhaging at the base of the brain, suggesting that the brain is shaken more vigorously within the cranium due to the impact of shooting cattle with these guns, contributing to higher stun quality. Problems with animal welfare can be minimized by designing handling facilities in abattoirs that consider natural species-specific behavioral principles. The effectiveness of the stun also depends on the skill of the abattoir staff, who should be adequately trained and certified. It is important to assess each situation separately when deciding whether standards at a given abattoir are satisfactory from an animal welfare perspective. However, by implementing quality assurance schemes in abattoirs including external stun quality auditing by appropriately trained personnel, animal welfare can be safeguarded.

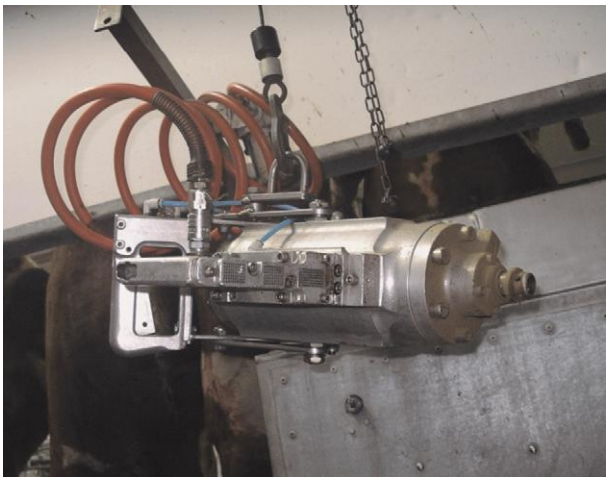

Figure 3 Pneumatic stunner.

Figure 4 A bull in a stun box with a neck restraint ready for stunning.

Practical Considerations

Bulls tend to be more difficult to stun than other cattle classes due to their thicker skull and greater hair mass on the forehead, which reduce bolt velocity as well as the transfer of energy to the brain. For consistent, effective stunning of bulls, it is therefore pertinent to use well-maintained, clean, and high-performance captive bolt guns. Bolt velocity (and stun effectiveness) can also be reduced in the event any part of the gun is damaged, worn, or dirty. In high-throughput abattoirs, the repeated use of the same captive bolt gun may cause overheating, reducing its efficacy. Changing guns frequently, e.g., after every 20 animals or so, may prevent this problem. It is also advisable to use a separate gun appropriate for the size of cattle, e.g., cows, steers and smaller cattle, and bulls. The use of a well-maintained pneumatically operated captive bolt gun and properly designed, constructed, and maintained neck restraints help to achieve effective stunning in bulls (Figures 3 and 4).

Free bullets can also be used in field conditions (e.g., during disease outbreaks) fired using either a conventional or modified rifle, with a high velocity bullet (9 mm) (Figure 5). In many abattoirs, however, due to the associated risk to human safety from possible ricochet, captive bolt guns are more often used.

Stun quality not only impacts on animal welfare but also greatly influences meat quality.

In small and older abattoirs, cattle are manually driven by a stock person from single line laneways into a final enclosed pen or 'stun box.' The stunning process involves a shooter leaning over the animal from an elevated platform and

Figure 5 Two modified weapons used for stunning bulls and cows. The original weapon is shown above and the two weapons below have been modified to activate the firing of the bullet only when the trigger is pressed and the rod under the muzzle is pushed in when placed on the animal's forehead.

Figure 6 A typical type of stunning system with captive bolt.

shooting the unrestrained animal in the forehead with a cartridge-fired captive bolt gun (Figure 6).

Recently, new automated designs have been developed to improve cattle handling and stunning. Cattle are loaded into the stun box with the help of a hydraulically operated moving gate, which pushes the animal forward into the stun box. The stun box is partly open in front, reducing the perception by the animal of 'dead end,' and facilitates voluntary forward movement of the animal. The animal can place its head through an opening where it is restrained by hydraulically closing metal bars on the side of the neck. A shelf can also be used to lift the head up by pushing under the animals chin (chin-lift) (Figure 7).

If cattle are stressed and frightened, they can attempt to escape the stun box or move the head out of reach of the operator making it difficult for the shooter to position the gun in the optimal area to achieve an appropriate stun. The purpose of restraint devices is therefore to hold the animal still and the chin-lift presents the forehead to make shooting easier and more accurate. It is important that push gates, neck

Figure 7 A restraint device for pneumatic stunning of cattle using both neck restraints and a chin-lift.

restraints and chin lifts, are operated slowly and smoothly to reduce fear reactions in the cattle. Operating these devices too quickly can startle the animals and set them into a panic response at the time of shooting.

Abattoir Audits

The guns and their maintenance records should be inspected and the type of cartridge should be appropriate for the type of cattle. A decent sample size needs to be inspected during stunning, and this probably requires spending a day making observations during the slaughter process. The system for loading the stun box, the restraint devices used, and observations of the animals' reactions in the stun box should be noted. If many animals ($>20\%$) are showing severe retreat or struggle and escape attempts during loading the stun box and at stunning, the facilities and the staff should be reviewed to identify the problem areas. A sample of the stun to stick times should also be noted (at least 10%). Prolonged sticking times can increase the recovery risk.

Glossary

Avoidable pain and suffering Any additional pain and/or suffering of a food animal caused by how the animal is handled, restrained, slaughtered, or otherwise manipulated.
Head gate A mechanical restraining device placed in the path of an animal, commonly used for bovine animals, that, when closed, provides a narrow opening large enough to contain the neck of the animal, but too small for either the head or shoulders of the animal to pass through.
Immobilization Implicates measures that interfere with the animal's motor control, such as electric depolarization of the nervous system, to prevent directed movement, flight or attack.
Religious or ritual slaughter Slaughter of a food animal while observing religious rites, traditions, or requirements. Common examples are Halal and Kosher slaughter.
Restraint Restricting the space in which the animal can move about, usually by erecting physical barriers, such as a stun box, a cattle head gate, ropes, or manual force.

Humane slaughter involves methods that meet the dual objective of minimizing the risk of injury to the slaughter person and not inflicting avoidable pain and suffering onto the animal – critical for avoiding ethical (animal welfare) and meat quality problems.

Restricting an animal's movement such that the desired method of slaughter can be reliably employed requires much more than only the physical restraint. It is important to understand that the experience an animal had during an earlier part of the process, between being on a farm and being delivered to slaughter, which will affect later stages of the process.

At the time of slaughter, animals find themselves in unfamiliar environments, experiencing loud noises, strange odors, sometimes poorly designed facilities, are separated from their herd, and forced to interact with strangers – both animal and human. Most of our food animals are aware of their surroundings and are capable of directed movement to defend themselves, attack a threat, or get away from frightening situations.

The desired outcome of a functional and humane slaughter setup is restrained, nonstressed animals that are calmly and reliably slaughtered on a consistent basis. The animals' preslaughter and slaughter experience each play significant roles in achieving the desired outcome of safe and humane slaughter. It is imperative that the individuals involved have an understanding of animal behavior, handle animals appropriately and employ transport, preslaughter and slaughter facilities and equipment that are appropriate for the species, sex, age and number of animals being slaughtered.

The more rigid a method of restraint, the more risk it generally poses for the welfare of the animal and the more important it becomes to apply the restraint correctly and keep the time the animal has to cope with the restraint to a minimum.

The type and duration of preslaughter and slaughter handling and restraint vary greatly, depending on the economic circumstances, the part of the world in which it occurs, local customs and knowledge base, the species, size, and number of animals involved and the type of market that the end product is sold to and consumed in.

Western World

'Immobilization' is distinct from 'restraint.' Immobilization implicates measures that interfere with the animal's motor control, whereas 'restraint' refers to restricting the space in which the animal can move about. Immobilization before slaughter is generally not considered necessary where preslaughter stunning methods are used and not acceptable in the western world. Rather, the ability of the animal to move is greatly restricted by confining the animal in a small enclosure (e.g., 'knock box,' 'stun box') for the brief period of time it takes to stun the animal and/or initiate the bleeding process. A conveyor belt may be used that supports the animals' body but leaves the legs unsupported. Design features of the belt prevent struggling or escape. In bovine animals and pigs, such conveyor belt restrainers have a calming effect on the animals. The automated system presents an animal to the stunner at easily controllable intervals.

When a bovine animal moves to the slaughter area under its own power, a head gate that, when closed, creates a narrowing of the space to both sides of the animal's neck that, without applying painful pressure to the neck, is too narrow for the head to be pulled back or for the shoulders to push forward is most commonly used. Some forms of religious or ritual slaughter require even tighter restraint or a specific presentation of the animal. Examples are a head restraint that securely holds the head and extends the neck, or placing the animal into a rotating drum fixating the entire animal and intended to roll the animal on its back before the neck vessels being cut with a knife. For small ruminants, manual restraint during ritual slaughter is often sufficient.

Poultry are unable to see in low levels of light or areas that are lit with blue light. This can be used to ensure that they remain calm during slaughter, as well as employing handling practices that avoid sudden movements and loud noises, similar to what is recommended for other animal species.

When poultry are shackled (hung upside down on a conveyor in brackets that grasp the birds' legs) to restrain and

 doi:10.1016/B978-0-12-384731-7.00152-5

transport them through the process of slaughter, the moving conveyor line brings the birds' breasts into contact with and moves them along a smooth breast bar to soothe or pacify the birds. This helps to ensure they remain calm as they approach and enter the automatic stunner and avoids wing flapping.

In gas stunning, the birds sometimes find immersion into the gas pit noxious and stressful. This is especially true if the gas concentration gradient is too steep or the descent into the gas pit is too rapid. Calm and relaxed birds that have been handled well before their entry into the gas stunning device are less likely to struggle to escape. Some gas stunning poultry plants attempt to restrain stressed birds and prevent them from escaping by placing a physical barrier over the crate as it descends into the pit.

In countries such as Australia, where night hunting of game animals is legal and common practice, bright spotlights trained onto the animals are used to temporarily immobilize animals while they are being shot with a firearm.

Fish

Crustaceans, such as lobsters, are restrained with an elastic band placed around their claws, minimizing the harm that they can do to each other and the people that remove them from the lobster tank and submerge them in a boiling pot of water (slaughter) for consumption.

Emerging Economies

In much of the world, slaughter, often of a single animal, provides for the family meal, a religious event or the local market. Slaughter may be carried out at home or at the farm. This is especially true for larger animals. Slaughter sometimes occurs at the local market only a short time before the meat being offered for purchase. In other circumstances – especially those involving fish and poultry – slaughter and evisceration may be carried out while the customer waits.

Immobilization and restraint in emerging economies are often different from methods seen in the western world. Some of these, often traditional, methods are not acceptable when assessed toward current animal welfare criteria and their inclusion in this article does not constitute an endorsement of their use.

Small ruminants, pigs and birds are held to the ground and their legs are then tied together so that they remain restrained up to and during slaughter.

Standing animals are sometimes tied (tethered) together in groups pending sale or slaughter. There is usually a rope attached to a post or building. However, much of the restriction to movement is supplied by the other animals in the group.

A method of restraining small ruminants is to have a person stand over the animal with their legs straddling the animal. The person's legs are pressed firmly against the shoulder and rib cage on each side of the animal's body. One hand (usually the left) is used to lift the animal's head and pull it firmly against the body of the person while the right hand holding a knife is used to cut the animal's throat.

A small ruminant may also be on its back and held to the ground by several helpers that also stretch the neck, allowing the slaughter person access to the neck with a knife.

Tying the small ruminant's head to a fixed object (e.g., pole) or having a helper hold the head while stretching the hind legs firmly allows rapid decapitation with a sharp saber or cutlass.

Confinement of animals up to the size of a pig in very small cages (metal, wooden, wicker, cardboard) is used during transport and sometimes even slaughter. For example, pigs may remain immobilized in a small form-fitting, basket-like cage for transport to the slaughter facility, while awaiting slaughter and may be bled out inside this cage by an operator using a knife on a long handle.

Akin to low levels of lighting used calm birds during catching, preslaughter handling and slaughter, in some parts of the world a fabric bag or hood is sometimes placed over the head and eyes of animals so that they cannot see. These animals remain quite calm, even if there are high levels of activity and noise around them.

Bags are sometimes used to hold and restrain poultry for transport and while they await slaughter. When this method of restraint is used, chickens are enclosed entirely in the bag. Larger birds, such as waterfowl, are often restrained with their body enclosed by the bag and their head and neck protruding.

In some places, poultry are picked up by their legs (restraint) and their breasts lie against a block of wood until the birds become quiet and do not move (similar to 'breast bars' in western-style poultry slaughter). Then the birds are decapitated with an axe. The birds are held (restrained) by their feet until the bleeding and involuntary movement have stopped.

A practice of immobilization of larger animals involving severing the spinal cord between the skull and the neck with a sharp, pointed knife ('puntilla') inserted into the foramen magnum is in use in some places. As soon as the knife severs the spinal cord, the animal collapses and can no longer move. The animal remains conscious throughout the bleeding process, until death through blood loss occurs, making this practice inhumane.

Immobilization of large animals by severing tendons on the extremities is used in some countries. The practice leads to the collapse of the animal and makes it impossible for the animal to move its extremities. Immobilizing animals by flexing the joints of the extremities and tying them in this position is used for smaller species.

Fish are held in tanks at markets pending slaughter. Fish placed in smaller containers are easier to grasp, especially if the water is warm and low in oxygen. Some individuals use their hands; others use small nets to catch the fish. The fish are held and immobilized by one hand while they are rendered (semi) unconscious with a blow to their head and eviscerated with the other hand.

Postslaughter Considerations

The slaughter process includes the transition from a live, conscious animal to a dead carcass. Inevitably, there is an intermediate state, where the animal is no longer aware of its

surroundings, but many organ systems are still functional. Voluntary, directed movement is replaced by involuntary kicking or paddling of extremities or flexing of the back. While this type of uncoordinated movement is a normal observation on a dying animal, it creates a hazard for workers, may slow the processing speed and can negatively affect meat quality. Immobilization of an irreversibly unconscious animal is acceptable and no animal welfare concerns exist at this point.

Where penetrating stunning devices are used, mechanical disruption of the brain stem and spinal cord ('pithing') is achieved by inserting a metal or plastic rod through the hole left by the stunning device and advancing it toward the foramen magnum. Vigorous manipulation of the rod destroys vital brain stem and spinal cord structures and will successfully prevent convulsions or kicking. The penetrating stunning device and the pithing rod must be matched in order to avoid a hole too small for the pithing rod, making enlargement of the hole necessary. There are downsides of the procedure associated with the potential for introducing pathogens into the carcass by means of a contaminated rod or brushing bacteria off the forehead onto the rod or into the skull cavity or causing proteins implicated in prion diseases, such as bovine spongiform encephalopathy (BSE), to cross from nervous tissue into the bloodstream resulting from the mechanical damage to brain tissue and blood vessels. Dissemination of pathogens throughout the carcass is possible at this stage, because the animal has not yet bled out and some blood circulation still occurs. These concerns led to pithing no longer being accepted practice in many countries. Some countries may allow pithing after the animal has been bled.

The use of electric current to immobilize animal carcasses is of increasing interest in slaughter practice, because it appears to avoid most of the pitfalls associated with mechanical methods of immobilization.

Electrical immobilization (EI) is the application of electric current to the carcass to temporarily disrupt the nervous system. In general the peak voltage is usually relatively low (80 V) with a pulsed waveform approximately 15 pulses per second and is not regarded as dangerous (higher frequencies have been used) and is widely used for cattle. The animals are not only immobilized while the current is applied (e.g., from head to legs), and workers are protected from movement, but the lack of movement continues after the current is switched off. There is an additional advantage of using these voltage waveforms in that immobilization effectively becomes low voltage electrical stimulation if the duration is long enough.

Nerve deactivation (ND) begins before carcass dressing will permanently disable nerve function and eliminates risk of injury to workers. If the voltage is higher than for EI, it can be applied for a shorter duration for a lasting effect. In the case of cattle that have been restrained and electrically stunned, they are already in an area where issues of electrical safety do not arise.

Electrical back stiffening (EBS) is used at the hide pulling stage to contract the carcass back muscles while the hide is being removed. This reduces the incidence of spinal fracture.

Electricity from the power grid must be modulated and transformed in order to have the desired effect. Technical applications exist that tailor the current to suit the characteristics of the particular carcass being dressed at the time, taking into account parameters such as carcass electrical response, carcass biochemical parameters, muscle glycogen levels, type of carcass, and carcass weight.

The EI, activation and deactivation methods listed above can be used individually or combined, at different stations in the process flow.

STUNNING AND KILLING OF FARMED FISH: HOW TO PUT IT INTO PRACTICE?

H van de Vis and W Abbink, IMARES – Wageningen UR, Yerseke, The Netherlands
B Lambooij and M Bracke, Livestock Research – Wageningen UR, Lelystad, The Netherlands

Glossary

Electrical stunning The immediate induction of unconsciousness and insensibility in an animal or fish caused by the passage of an electrical current of sufficient strength through the brain.
Electrocardiogram Recording of the electrical activity of the heart muscles by using electrodes implanted or applied to the skin.
Electroencephalogram Recording of electrical activity of the brain, using implanted or surface electrodes.
Generalized epileptiform insult A state of brain characterized by abnormal, excessive or hypersynchronous neuronal activity throughout the brain, generally considered to lead to unconsciousness and insensibility.
Insensible Inability to perceive (and as a consequence respond to) stimuli.
Slaughter The killing of animals, especially farmed ones, for the production of food.
Stunning The process that renders an animal unconscious and insensible without causing avoidable stress and discomfort prior to death for a sufficient period of time to allow killing.
Stunning/killing The process that renders an animal unconscious and insensible without causing avoidable stress and discomfort that subsequently induces death.
Unconsciousness A state of unawareness (loss of consciousness) in which the brain is unable to process sensory input (e.g., during (deep) sleep, anesthesia or due to temporary or permanent damage to brain function).
Vestibulo-ocular reflex A reflex where eye movement occurs when a fish's body is moved/tilted along a longitudinal axis (also referred to as eye roll). The absence of this reflex is not an evidence of unconsciousness in fish.

Introduction

World aquaculture production of food from finfish comprised 36 million tons in 2010 and is increasing yearly up to 7–10%. The authors estimate that this production volume boils down to 7–120 billion of farmed fish slaughtered in 2010 (with an average weight of 5–0.3 kg, respectively). Asia accounted for 92% of world aquaculture finfish production by volume in 2010, whereas for Europe this was 5.2%.

Several types of aquaculture are used for the production of food fish: ponds, land-based intensive flow-through systems, cage farming and recirculation aquaculture systems. In Europe, the production of Atlantic salmon (*Salmo salar*), European sea bass (*Dicentrarchus labrax*), and gilt-head seabream (*Sparus auratus*) rely mainly on cage culture at sea. For rainbow trout (*Oncorhynchus mykiss*), the ongrowing stage is done in different systems across Europe (for instance ponds and flow-through systems). In Asia, dominant fish are freshwater species such as various carp species and tilapia subspecies. Asian farmers perform ongrowing of these species predominantly in ponds.

Owing to increasing societal awareness, especially in Europe, Canada, Australia, and New Zealand, attention has been drawn to fish welfare in aquaculture, which is still growing. In view of the fact that mammals and birds should be spared of unnecessary stress and discomfort at slaughter, the question is raised whether this concern is also relevant for farmed fish. In humans, awareness of pain and fear apparently depends on proper functioning of specific regions of the cerebral cortex. Because fish lack a cerebral cortex, it might be argued that fish do not have a capacity to experience pain and fear (sentience). However, Braithwaite *et al.*'s recently reviewed studies showing that teleost fish species have the relevant functional areas in the telencephalon for cognition and emotion. The reported studies show that it is possible that teleost fish perceive pain and fear when they are not stunned before killing or slaughter. The number of fish species studied for behavioral and brain function with respect to cognition and emotion is, however, limited. Within the class of fish there is a diversity with respect to phylogeny, behaviors and habitats, consequently, a variability is found in brain structure and functions among fish. Hence, detailed studies on a wider range of fish species are needed to characterize further the taxonomic distribution of such capacities.

Commercially used methods, such as chilling of live fish by asphyxiation on ice or ice water slurry or killing by decapitation without prior stunning, might cause considerable pain and distress in these animals. These killing methods have been developed not to minimize stress but to achieve product quality control, efficiency, and processor safety. Therefore,

there is a need to develop methods for stunning or stunning/killing of farmed fish and implement them under commercial conditions and control the methods in that setting.

In this article, therefore, the focus is on:

Assessment of stunning and killing or stunning/killing of fish in a laboratory setting to establish ideal conditions for stunning or stunning/killing of fish without causing avoidable stress and discomfort and how the stunned fish can be killed without recovery of consciousness. Assessment of product quality parameters is also of interest as stunning or stunning/killing may affect its properties. A method such as percussion can be suitable for stunning/killing, whereas fish recover from an electrical stun.

In implementation of assessed stunning and killing or stunning/killing in a commercial setting, methods that are suitable for assessment are limited; it is likely that only observation of behavior and physical measurements to assess the equipment installed can be used.

Control of the process for stunning and killing or stunning/killing in a commercial setting can be achieved by using an effective management system. In a commercial setting, an approach that is process-oriented and focused on prevention rather than inspection only is needed, i.e., a quality assurance system.

Slaughter of Farmed Fish

Slaughter is the process for killing of animals intended for human consumption. The term slaughter is also used to depict killing of animals by bleeding. Most farm animals are killed by bleeding. In general, the following steps for slaughtering can be distinguished:

1. Transport from the rearing enclosure to the slaughterhouse or facility for slaughter at the farm.
2. Restraint (fixation of an animal for a proper application of a stunning method).
3. Stunning, i.e., rendering the animal unconscious and insensible so as to reduce avoidable stress and discomfort before killing. The application of a method like percussion can be suitable to achieve both stunning and killing; in this case, step 4 is not performed.
4. Killing of the stunned animals.

Figure 1 gives an impression of the four steps used in the slaughter process of Atlantic salmon, i.e., lairage, pumping, stunning, and killing.

The percussive stunner in Figure 1(d) is used, as this machine has the ability to bleed the electrically stunned salmon automatically.

Before transportation of live, farmed fish from a farm to harvest facilities for slaughter at the farm, the following process is normally carried out: fasting (withholding feed), crowding to facilitate capture of fish for loading into a transport vehicle, unloading of the fish and releasing them (e.g., in holding pen/tank for lairage) before commencing slaughter at the harvest facility or at the facilities for slaughter on the farm. The welfare of farmed fish could be at risk at each of these steps in the process. However, in this article the authors focus on the methods of stunning and killing of farmed fish. For assessment of welfare aspects of stunning methods, the general provision in the European Union (EU) legislation for warm-blooded slaughter animals can be used as a general term of reference. The general term of reference is met when stunning induces immediate loss of consciousness and sensibility in fish, which lasts until death or, when an instantaneous induction is not possible, the animal should be rendered unconscious and insensible, without causing avoidable pain and distress.

Stunning and Killing

For stunning and killing of farmed fish, a wide range of methods are used. Killing methods used at present for farmed fish include asphyxia by chilling on ice in air, live chilling in ice water slurry, exposure of live fish to a salt bath or ammonia, freezing, bleeding (exsanguination) by cutting blood vessels through the gills, and the transfer of fish to water saturated with carbon dioxide gas. Most of these methods do not induce unconsciousness and insensibility immediately, nor do they prevent avoidable stress and discomfort.

Only a limited number of methods have been shown to be able to result in immediate loss of consciousness and sensibility. The authors demonstrated that percussive stunning (a blow to the head) of Atlantic salmon resulted in an immediate onset of irreversible stunning, as judged from electroencephalogram (EEG) and electrocardiogram (ECG) recordings. However, this stunning/killing method, when delivered using a pneumatically operated bolt, required such a high pressure driving the percussive bolt that carcass damage of Atlantic salmon occurred, under the conditions used.

Electrical stunning can induce immediate loss of consciousness and sensibility in fish. However, reported data show that fish cannot be killed by the use of electricity, as the fibrillation of the heart is not permanent. This implies that electrical stunning should be followed by a killing method to avoid recovery of the stunned fish. Because stunning and killing are procedures that take some time, it is normally necessary to apply the electrical current not only at a certain voltage, but also for a certain duration of time, so as to allow subsequent killing before the fish have recovered. For example, Nile tilapia can be stunned using an electrical stun lasting for 5 s and the unconscious fish can be killed subsequently by chilling in ice water slurry.

A problem of electrical stunning, especially when fish are immersed in water during stunning, is that carcass damage might occur, such as muscle hemorrhages or a broken vertebral column. Roth *et al.* found that this problem could be overcome by exposing fish to the electricity after draining the water, so called 'dry stunning.' In this method, the fish are exposed to an electrical current via a series of rows of positive-plate electrodes and a conveyor belt acting as the negative electrode. Evidence shows a positive effect on the quality with a very low incidence of injuries in Atlantic salmon.

In Australia, Chili, Korea, and New Zealand, and some other countries outside of Europe, it is allowed to add the chemical compound Aqui-S^{TM} (with isoeugenol as the active ingredient) to the water in order to stun and kill fish. Using EEGs and ECGs isoeugenol can result in an effective and irrecoverable stun in cod. Isoeugenol is a food grade substance

Figure 1 (a) Stunning and killing of Atlantic salmon: lairage, (b) pumping of fish to the slaughter facilities, (c) electrical stunning after draining the water, and (d) killing the stunned fish by percussion and gill-cutting.

based on clove oil. Barriers to its use in the EU include the cost of overcoming the legislative requirements to introducing isoeugenol as anesthetic for food fish.

In Norway, live chilling of Atlantic salmon with controlled addition of low to moderate levels carbon dioxide (65–257 mg l^{-1}) and oxygen has been widely used to stun the fish. This method, however, has not yet been assessed with EEG and ECGs recordings.

How to Assess Stunning and Killing

Welfare Aspects

To establish whether the general term of reference is met after the application of a stunning method, the onset and duration of unconsciousness and insensibility in fish has to be assessed in a laboratory setting. Behavioral measures only are insufficient to assess the level of brain function of fish unequivocally. On the EEG, the electrical activity in the brain is monitored. In addition, nociceptive stimuli are administered to determine whether the stunned fish can be aroused, both on the EEG and behaviorally. When the fish do not respond, this implies that the fish remain unconscious and insensible until death occurs. The electrical activity of the heart (as determined using ECG) should also be recorded to assess stunning methods. The ECG can be used to determine, for example, whether fibrillation occurs or when the heart rate changes. In case of fibrillation, the circulation of blood in the body is reduced, including the supply of oxygen to the brain. Changes in heart rate might occur in fish that are subjected to live chilling on ice in air or using ice water slurry, carbon dioxide gas or chemical stunning. When these changes are observed before loss of consciousness, they can be signs of stress in fish.

Owing to the highly technical nature of recording the electrical activity in the brains and hearts of fish, conditions to achieve an effective stun in fish without causing avoidable stress and discomfort until death occurs need to be established in a laboratory.

For an instantaneous electrical stun, sufficient current should be passed through the brains of animals to induce a general epileptiform insult (where all brain parts are stimulated). The epileptic process is characterized by rapid and extreme depolarization of the membrane potential, but there is

heterogeneity of findings. It is generally assumed that animals are unconscious and insensible during a general epileptiform insult. Generalized epileptiform insults was observed in various fish species following electrical stunning. For percussive stunning, the patterns on the EEG, characteristic for an instantaneous stun, differ from those recorded in fish that are stunned using electricity. Percussive stunning of Atlantic salmon resulted in the appearance of theta and delta waves and spikes, which were followed by an isoelectric line. Exposure of cod to Aqui-S™ resulted in a slow increase in theta and delta waves and a decrease in the alpha and beta waves, which is indicative for loss of consciousness and sensibility.

For field observations (i.e., during slaughter on a commercial farm or in a harvest facility), registration of EEGs and ECGs might not be feasible. In this case, observation of behavior can be used. Spontaneous behavior (e.g., righting response and escape behavior), responses to stimuli, and physical reflexes (vestibulo-ocular reflex) can be used as preliminary behavioral observations to evaluate loss of consciousness and sensibility in fish. To scale the observations, a three-point scoring system can be used, where 0 designates no response, 1 refers to an attenuated or abnormal response or behavior, and 2 indicates a normal and clear response or behavior. Immediately after an effective electrical or percussive stun, rhythmic breathing as evidenced from the rhythmic gill movements should be absent, and the capacity of the fish to swim in a coordinated way lost. In an experiment with electrical stunning of Atlantic salmon followed by gill-cutting, we observed on the EEGs that one out of three fish recovered. The vestibulo-ocular reflex (eye roll) in the recovered fish was still absent. In properly stunned fish, the capacity to right themselves is also lost. When live chilling or gas stunning results in escape attempts, it is likely that the fish are conscious and stressed.

Fish can be motionless for a number of reasons, such as paralysis, exhaustion, chilling, or tonic immobility (feigning death). In such cases, motionless fish might well be conscious. Caution is therefore needed when using behavior and physical reflexes to determine the effectiveness of stunning methods in practice. Therefore, the use of EEG recordings, including evoked responses on the EEG by administering nociceptive stimuli to the fish, are necessary for an unequivocal assessment of the level of brain function in fish to determine whether or not the fish are effectively stunned.

Chemical stunning (i.e., the use of a gas and a combination of gases or a chemical such as Aqui-S™) or chilling of fish by exposing them to a drop in temperature do not result in an instantaneous stun. In such cases, the observation of behavior and the registration of EEGs and ECGs should be supplemented with stress-physiological measurements. Owing to their complexity, stress-physiological measurements might only be feasible in a laboratory setting.

Analysis of plasma cortisol, glucose and lactate, as indicators for stress in fish, might not be sufficient when Nile tilapia (*Oreochromis niloticus*) are exposed to a noxious stimulus as exposure of a fish to ice or ice water may be noxious. These stress parameters did not allow discrimination between a tailfin clip as noxious stimulus and the handling stress. However, the following parameters indicated a strong differential response in the clipped Nile tilapia: (1) a remarkable migration of chloride cells into the lamellar epithelium of the gills; the chloride cells in the gills are involved in the osmoregulatory performance of fish, (2) swimming activity of the Nile tilapia increased and the clipped fish spent more time in the light than in a dark region in the tank, and (3) the gill's mucus cells released their content.

Regarding exposing a fish's to rapid temperature drop, it is important to note that fish's homeostasis might be fine-tuned to a particular temperature. To understand the possibilities of analyzing the stress response in fish exposed to live chilling on ice or in ice water slurry, some information on the time course of physiological stress response is presented. It is known that changes in cortisol, glucose, and lactate levels in the blood of fish normally occur within a time frame of minutes. Hence, it is possible that due to rapid chilling of fish, no changes in these blood parameters can be detected, due to a fast decrease in metabolism in fish caused by the temperature drop in fish. Therefore, caution is needed to interpret stress-physiological parameters such as cortisol, glucose and lactate when analyzing fish exposed to rapid drop in temperature.

Physical Measurements

To assess whether equipment for stunning and killing of fish in practice meet the established criteria for stunning and killing or stunning/killing, physical measurements are needed. For electrical stunning, the strength of the electrical current (in water it is the height of the current density), its waveform, the applied voltage (in water it is the field strength) and duration of exposure of fish to the electricity need to be established, as well as the time interval between fish leaving the stunner and the application of a killing method. When percussion is applied, it should be measured whether the air pressure, which drives the bolt, is sufficiently high. For chemical stunning (gas and a combination of gases or in countries which allow Aqui-S™ for slaughter) the dosage and duration of exposure of the fish need to be assessed.

Product Quality

The assessment of product quality is relevant for the industry, as stunning and stunning/killing of fish can affect product quality parameters. In addition, a reduction of stress during slaughter might delay the onset of rigor mortis (i.e., the stiffening of the body after death), which is relevant for prerigor filleting of, for example, Atlantic salmon.

Analysis of product quality might not be feasible in a commercial setting and, therefore, these experiments should be performed in a laboratory. However, collection of stunned and killed fish in practice for analysis in a laboratory is doable.

To assess the effects of stunning and killing on product quality, a range of indicators can be used:

1. Appearance of the fish and fillet, for example, residual blood, fillet gaping, and color.
2. Technological properties of fish and fillet, such as texture, water holding capacity, drip loss, and fillet shrinkage (in relation to prerigor processing).

3. Freshness indicators: analysis of freshness, using K-value (calculated from adenosine triphosphate-degradation products).
4. Sensory properties and shelf-life; sensory traits of cooked fillets as texture, taste, flavor and odor, and microbial counts.

How to Control the Process of Stunning and Killing in Practice?

Current ethical concerns about aquaculture, which are broader than welfare of fish alone (for instance ecological aspects of aquaculture), drive the preparation of certification schemes that may include consideration of fish welfare, as for instance in the Freedom Food concept for Atlantic salmon. Increasing calls from nongovernmental organizations and supermarkets in Europe also promote optimization of fish welfare using a certification scheme with appropriate standards. Furthermore, embedding in auditing procedures for accreditation is required to ensure that labeled products comply with the established standards for optimized fish welfare.

Monitoring and auditing procedures, generally, do not focus on preventive measures and they might not control the entire process. To supplement existing procedures, a strategy is needed based on a thorough analysis of the conditions used during the whole process of stunning and killing, considering the specific requirements of a fish species. For this purpose, Quality Assurance appears to be a suitable approach, as it is process-oriented, efficient, focused on preventing hazards, and it involves establishing critical points/steps and standards for all steps in the production process. Previously, the authors developed a Quality Assurance system for safeguarding the welfare of fish at the fish farm – Fish Welfare Assurance System (FWAS). FWAS is based on the hazard analysis critical control points (HACCP) system. HACCP is an internationally acknowledged quality assurance system that is mandatory for the food industry in the EU and other countries outside of Europe. HACCP provides a management tool for food safety based on scientific principles while still being practicable, for example, small specialty shops that might be run by a single person, for example, a butcher.

Briefly, the FWAS consists of the following seven principles: (1) perform a hazard analysis and risk assessment, (2) determine Critical Control Points (CCPs), (3) establish target levels and critical limits for each CCP, (4) establish monitoring procedures at each CCP, (5) establish corrective actions, (6) establish verification procedures, and (7) establish a record keeping system.

The FWAS's structured approach is suitable to control proper stunning and killing of farmed fish in practice, as the basic premise is prevention rather than inspection.

Conclusion

In the authors' view, the following approach is needed to put stunning and killing of farmed fish into practice. The first step is to establish the specifications needed for stunning and killing by registration of EEG and ECGs, behavioral observations and, when a stunning method is not instantaneous, supplementary stress-physiological analysis. Owing to the complexity of these methods, they can best be performed in a laboratory setting. Product quality analysis, which may be only feasible in a laboratory setting, needs to be taken into account, as for example, electrical and percussive stunning can lead to carcass damage. This might have adverse economic consequences and these should be prevented or minimized. For the assessment of the welfare aspects of stunning and killing in a commercial setting, it is likely that behavourial measurements supplemented with physical measures (e.g., voltage, amperage, dosage, and percussion forces depending on equipment used) might suffice. To control the subsequent implementation of stunning and killing of farmed fish in practice, the authors foresee that development of a process-oriented assurance system is needed to safeguard and monitor fish welfare during stunning and killing.

SUSTAINABLE MUSCLE FOODS INDUSTRY

E Kurt, Istanbul, Turkey
R Klont, Vion Food, Boxtel, The Netherlands

Glossary

Distiller's Grains with Solubles (DGS) These are cereal by-products of the distillation process used for biofuel production.

Feed Conversion Rate (FCR) It is a measure of an animal's efficiency in converting feed mass into increased body mass.

Life cycle analysis (LCA) It is a technique to assess environmental impacts associated with all the stages of a product's life from conception to consumption.

Polylactic acid (PLA) Biobased material from corn or sugarcane by-products that can be used in biorenewable packaging.

Sustainability Defined as the effective use of agricultural crops with reduced use of energy and water, and a minimization of losses within the food chain and is still profitable.

Background

Food production in general puts a lot of pressure on the environment. A growing global population to more than 9 billion people by 2050 will require approximately twice as much food, whereas high-quality proteins will become the limiting factor in a healthy diet according to the Food and Agriculture Organization (FAO). The demand for animal protein will continue to grow, especially in developing countries as they become more affluent. Production of meat requires substantial amounts of feed grains, which, in turn, uses vast amounts of arable land. Currently, 40% of the land on the earth is used for food production. On the one hand, it is important to produce enough food of high quality, but on the other hand, food production has not been optimized in the past with respect to sustainability issues. For every 1 kg of high-quality animal protein produced, livestock are fed between 3 and 10 kg of feed grain.

Sustainability can be defined in many different ways, but in this article, it is interpreted as making more effective use of crops with reduced use of energy, reduced use of water, and minimization of losses through better chain management and logistics and optimal valorization of by-products and residues within the whole of the food chain. The standard methodology that is used to assess sustainability of any product or process is life cycle analysis (LCA). The total impact is often expressed in terms of the 'carbon footprint,' which gives an overall indication of the environmental impact of the product and its use. Although LCA is useful for the analysis of complete chains, it does not give insight into where inefficiencies are located and how these can be reduced. Profitability must be a component of 'sustainability' because no enterprise can continue unless it is profitable.

LCA studies on meat production seldom extend beyond the agricultural production stage. Food production, preservation, and distribution consume a considerable amount of energy, which contributes to the total CO_2 emission. LCA studies that cover more of the life cycle indicate that the agricultural production part is the main source for greenhouse gas emission in the life cycle of meat products. A recent study from the National Pork Board in the USA revealed that crop production, manure management, and retail distribution and consumption had the most impact on CO_2 production in the pork production chain. Pig production from nursery to finishing accounted for 60% of emissions, whereas retail and consumer parts of the chain accounted for less than 10% each. This paper will focus on the entire production chain for meat and the opportunities that are available to optimize the efficiency and sustainability of meat production chains.

Livestock Production

It is estimated that more than 60% of the arable land is used for the production of animal feeds. One of the approaches to reduce the environmental impacts of food is to optimize both the livestock and systems in which meat is produced. Animals need feed to grow and Table 1 shows that different types of animals require different energy input levels to produce 1 kcal of protein. Lamb and beef are the least efficient forms of animal protein production, but one has to keep in mind that these can also be grown on land that is less suitable for other types of agricultural production. Furthermore, both species can also be a by-product of wool or dairy production. The biological differences will remain as pigs will never be able to eat grass and the higher yields of broilers are due to their relative small size in comparison with pigs and beef cattle. In organic agricultural systems, livestock have more freedom of activity resulting in a higher feed-to-gain ratio.

Other important traits in livestock production that can be optimized are growth rate and feed conversion of animals. The animal breeding industry has been focusing on increasing lean

Table 1 Ratio of fossil energy input required to produce 1 kcal of animal protein

Livestock and animal products	*Ratio of energy input to protein output (kcal)*
Lamb	57:1
Beef cattle	40:1
Eggs	39:1
Swine	14:1
Dairy (milk)	14:1
Turkey	10:1
Broilers	4:1

Source: Reproduced from Pimentel, D., Pimentel, M., 2003. Sustainability of meat-based and plant-based diets and the environment. American Journal of Clinical Nutrition 78 (Suppl.), 660S–663S.

growth rate and improving feed conversion rates (FCR) in the past decades. This has reduced the total feed intake and age at slaughter in most species. Improvements in broiler genetics, nutrition, and other management changes in the period of 1957–2001 have resulted in 2001 broilers that reached processing time in one-third of the time required for a 1957 bird with more than threefold decrease in the amount of feed consumed. Similar improvements in productivity over the past 40 to 50 years can be shown for pigs. Genetic improvement has led to a reduction in greenhouse gas emission for broilers and pigs and global warming potential per kg of animal product in the past 20 years of up to 30%.

Optimization of feed composition is a major tool toward more sustainable meat production systems. Livestock feed is produced out of different feed ingredients. These feed ingredients can be whole crops (e.g., grains, rapeseed, peas, and soybeans) or by-products (e.g., pulp and milling products). Animals are very well able to digest low-quality vegetable by-product sources to produce high-quality meat proteins. Future research should focus on increased utilization of these types of lower quality by-products. Examples of alternative proteins for animal feed would not only be insect or algae proteins but also safe reintroduction of animal by-products. Concerns about food safety and the BSE crisis have understandably inhibited previous procedures of recycling animal and food waste, such as supplementing animal feed with rendered animal material. Beyond changes in behavior of the food industry, retailers, and the general public to reduce food wastage, imaginative yet safe systems are required to recycle biological material discarded throughout the meat production chain. Traditional protein sources for animal feed as soybean and rapeseed in the future will be replaced by distiller's grains with solubles (DGS). DGS are by-products of the production of bioethanol. Different developments, like the responsible soy initiative, aim at global solutions to improve the sustainability of agricultural food production.

Processing Optimization

The meat industry is continuously optimizing carcass and meat product processing conditions by using operational excellence projects to reduce costs of production and make better use of all the by-product streams. Water is primarily used to ensure food safety and hygiene during operation. Overall water consumption has been reduced by recycling and reuse under stringent food safety restrictions. Refrigeration and production of hot water are the major energy-consuming activities in meat processing with lesser amounts used for lighting, motors, and the like. The Australian red meat industry recently published an industry environmental sustainability review in which they monitored the changes in water and energy usage between 2003 and 2008–09. Overall, there was a reduction in raw water usage by 11% and a reduction in waste water generation by 13% compared with 2003. Energy usage levels had increased by approximately 18% since 2003 because additional energy sources were included compared with 2003 and some of the companies had started value-added processes, which are more energy intensive. Similar results were found by Ramirez *et al*. for a 10-year period in which they analyzed energy use and energy efficiency developments for the meat industry in four different European countries. They concluded that energy consumption increased between 14% and 32%, partly due to a shift from beef to broiler and pork processing and due to an increased demand for value-added meat products. However, strong hygiene regulations could explain between one- and two-thirds of the increase, whereas the role of increasing shares of frozen and cut fresh meat was found not to be of significance.

Energy-related issues will become even more important in food processing plants as increasing sales of ready-to-eat meals and a greater demand for different and flexible range of products by consumers will lead to a larger energy demand. These changes in consumer behavior, together with raised energy prices, hardened price competition, and potential policy instruments such as CO_2 taxation will stimulate the meat industry to continue their focus on reduction in water and energy usage. Reduction in water and energy usage currently is an integrated part of the corporate social responsibility agenda of all global meat companies. In a case study, it was shown that, even in a modern meat plant where many energy-saving measures have taken place, there is still a technical potential for saving 30% of the external heat demand and more than 10% of the mechanical shaft work used in the plant.

It should be kept in mind, depending on the species, that between 40% and 60% of the processed animal is directly suitable for human consumption, whereas the rest are useful by-products. Head, bones, skin, heart, lungs, intestines, and blood are removed in the slaughter process. None of these by-products are wasted and are used for a wide variety of food, feed, and nonfood applications like gelatin, different protein hydrolysates, fats, bone powder, etc. A comprehensive overview of all the products that can be made from pigs include medicine, heart valves, brakes, chewing gum, porcelain, soap, toothpaste, cosmetics, conditioner, and biofuel.

New Product Development

Meat fulfils some key important nutritional requirements and is part of a healthy diet. Both a meat-based and a lacto-ovo vegetarian diet require significant quantities of

nonrenewable fossil energy to produce and are not sustainable in the long term according to Pimentel and Pimental. However, approximately 1.3 billion people are employed, either directly or indirectly, in livestock production and processing and provide economic livelihood for societies in addition to the dietary contributions they provide. However, the meat-based diet requires more energy, land, and water resources than the lacto-ovo vegetarian diet. Except for Japan (with its high fish intake), meat is now the single largest source of animal protein in all affluent nations, and it remains among the most desirable, high-status foodstuffs in all countries. In some of the developed countries, there have been recommendations to reduce the average meat consumption without negatively affecting the healthy diet requirements. Consumers do not easily reduce or replace meat for more sustainable alternatives. Nonvegetarian households are reluctant to decrease meat consumption just for environmental reasons, specifically reduced carbon footprint. Furthermore, current meat substitutes are not comparable in sensory perception to real meat products, and there is a low level of repetitive purchase by nonvegetarian consumers. Meat was judged more positively overall, which explains the choice for meat. Substantial voluntary reductions of meat consumption are not very likely. Because a large part of the meat production is sold as minced or further processed products, it should be possible to incorporate varying shares of plant-derived proteins and fibers into meat products and thus increase their sustainability. Development of hybrid products with a similar sensory profile would be an option to reduce current meat consumption levels. A commercial example of such a hybrid product development can be found where minced meat has been mixed with 30% plant protein and fibers and reducing the fat content of the product as well.

Another area of product development for the meat industry will be packaging. Even though packaging material represents a relatively small part of the carbon footprint from the meat production chain, it is perceived by consumers as having a negative impact on sustainability and being environmentally unfriendly. An increasing part of total meat production is sold as case-ready products using modified atmosphere conditions to increase shelf life of the products. The need for convenience and ease of preparation will increase the demand for different types of meat-packaging options. The purpose of food packaging is to preserve the quality and safety of the food it contains from time of production to time of consumption. The majority of the current meat-packaging materials are based on petroleum derivates. As petroleum costs are increasing, renewable packaging for meat, such as materials based on Polylactic acid (PLA) from corn or sugar cane by-products, will become more feasible in the future. Different bio-based materials have become available made from a variety of renewable and sustainable agricultural commodities that can be applied for meat products and that have been tested for retention of product quality characteristics, handling properties, and microbiological stability of muscle foods. With consumer demanding more environmentally friendly packaging, new and novel food grade packaging materials or technologies have been and continue to be developed.

Conclusions

The challenge for the next 50 years in meat production is to increase the productivity of major livestock species in order to address the food needs of the world, but at the same time minimizing the environmental impact. A number of technologies and techniques are available to continuously improve feed conversion, reproduction, and overall production efficiency in beef and dairy cattle, pigs, and poultry. New processing technologies will reduce the water and energy usage in animal processing and further processed meat production. Although a voluntary reduction in meat consumption is not very likely, it is possible to develop new minced-based meat products that are enhanced with plant and/or by-product proteins and that taste and present nutritional value that is as good as found in the original products.

Glossary

Ageing It is the process of meat tenderization that occurs over time – it commences after rigor mortis.
Contractile proteins It includes actin and myosin, which form the thin and thick filaments of skeletal muscle. These two proteins interact chemically (to form actomyosin), which gives muscle the ability to contract and relax. Associated with actin are the proteins troponin and tropomyosin.
Costameres It connects Z-disks to the sarcolemma and are made up of proteins such as talin, vinculin, desmin, and dystrophin.
Cytoskeletal proteins These are a set of filamentous structural proteins (includes actin, titin, nebulin, and desmin).
Electrical stimulation Application of an electric current through a carcass postmortem that accelerates the rigor process.
Myofibril It is comprised of contractile, structural, and regulatory proteins. The contractile protein is composed of myofilaments, which are in turn made up of thin and thick filaments. Structural proteins include titin and nebulin. Titin is the largest protein in skeletal muscle (approximately 3700 kDa) and it provides elasticity to the sarcomere. The regulatory proteins include troponin and tropomyosin.
Proteolysis It is the degradation of proteins into smaller subunits that occurs with ageing and also during turnover of living muscle.
Rigor It is a term for individual muscle fibres that have been depleted of adenosine triphosphate and the actomyosin bond has formed.
Rigor mortis It is a term used when muscles stiffen after all muscle fibres enter rigor.
Sarcomere The basic unit of skeletal muscle defined by the distance between two Z-disks. Z-disks are dense protein structures into which the contractile protein actin is attached along with proteins such as titin and nebulin. Z-disks are the anchor points for the contractile proteins that allow contraction and relaxation.
Shear force It is the force (N) applied to a standardized piece of cooked meat to shear it.
Shortening It is a process that occurs when prerigor muscle is cooled below 10 °C when the pH is still above 6.0. Additionally it also occurs as muscles enter rigor at high temperatures (rigor shortening).
Tenderization It is the enzymatic process that takes place after rigor mortis that makes meat tender.
Ultimate pH It is the pH attained when muscles reach rigor mortis.

Introduction

The process that leads to an improvement in tenderness can be termed 'tenderization' and this is driven by proteolysis of myofibrillar, cytoskeletal, and costameric proteins. Proteolysis of some of the myofibrillar proteins can precede tenderization (i.e. before rigor mortis) and the degree of disruption of these proteins (such as titin and nebulin) will influence the final stage of meat tenderness. Other proteins, like actin and myosin, are not generally degraded under normal storage temperatures. The introduction of exogenous solutions containing ions such as Ca^{2+} or Na^{+} has been shown to impact the tenderization of meat. The action of Ca^{2+} is strongly linked to the activation of the calpains as opposed to altering protein structure *per se*, whereas Na^{+} based solutions can lead to solublisation of proteins and thus improve tenderness. Connective tissue provides support in muscle at a number of levels via the endomysium, perimysium, or epimysium and maintains the integrity of the contractile apparatus. This connective tissue is not significantly degraded during 'normal' tenderization. However chemical mechanisms have been implicated in the solubility of connective tissue, particularly based on the use of organic acids. Commercial application of systems to introduce chemical-based solutions to meat have been restricted to vascular infusion, but the efficacy of this approach for improving tenderness is debatable.

Rigor Bonding

After death, muscle filaments are in a continual state of contraction and relaxation. As adenosine triphosphate (ATP) is depleted, the filaments enter rigor and a contracted state, but this process does not occur uniformly throughout a muscle fiber. As a consequence of the interaction between the contractile proteins actin and myosin, and other associated filament proteins, the overlap between thick and thin filaments increases, leading to an increase in toughness and a decrease in the width of the A band within the sarcomere. The degree of overlap will be influenced by temperature, with extreme contraction (increased overlap) occurring under low temperatures, known as 'cold shortening.'

Based on theoretical studies of muscle biochemistry, several workers have proposed that the binding 'state' of actin and myosin can be manipulated as fibres enter rigor. These binding states are proposed to arise through a change in contact between myosin heads (S1) and specific regions of actin monomers reflected by the sequences of amino acids in different regions. The relative proportion of different states of actin–myosin interactions is proposed to vary in relative proportions as muscle enters rigor. The hypothesis is that this would affect subsequent toughness, and so changes in conformational states of actomyosin at rigor could explain the toughening of muscle at this stage.

Several studies have linked changes in the ease with which actomyosin can be dissociated (as an indicator of binding strength) and tenderization, but these studies did not provide definite evidence to support the hypothesis. Indeed, when the potential confounding effects of proteolysis (due to endogenous enzymes) have been taken into account, the hypothesis is not supported.

Infusion/injection of meat with ionic compounds in solution termed 'meat enhancement' can manipulate several biochemical processes, depending on the postmortem time of injection. For example, prerigor infusion can have a dramatic effect on the rate of glycolysis, the rate and state of contraction, the oxidative processes and rate of the proteolysis whereas postrigor injection will affect mainly proteolysis and oxidative processes. Early prerigor enhancement can result in dramatic toughening. The impact of the infused compounds on meat quality will be greatly dependent on the postmortem time of the treatment (reflecting the pH and the temperature of the meat), the concentration of the infused compounds (level of activation or modification) and the method of infusion (the distribution of the compounds in the meat). Each combination of the above factors can lead to unique outcomes for different species and within these combinations a set of factors can be optimized for the best outcome.

Injection of Metal Ions and Ionic Strength

Metal ions such as Ca^{2+} and Mg^{2+} have many functions in regulating muscle contraction and enzyme activity, and for this reason extensive research has been conducted to examine the effect on tenderization when such ions are injected into muscle. There is a significant rise in ionic strength as muscle enters rigor, without any exogenous introduction of ions, and this has been proposed to contribute to tenderization. The rise in ionic strength mirrors the decline in pH (Figure 1) and is attributed to an alteration of protein structure and the release of bound ions and metabolites. A rise in osmolality has been shown to increase the solubility of proteins, which could make them more liable to enzymatic degradation and thus be part of a synergistic mechanism. The extent of the increase in ionic strength is muscle specific, with higher osmolalities in fast-twitch glycolytic muscles.

The introduction of metal ions into muscle has been studied extensively as a means of understanding the potential synergy between a rise in ionic strength and enzyme activity. Prerigor injection of high ionic solutions creates an atypical

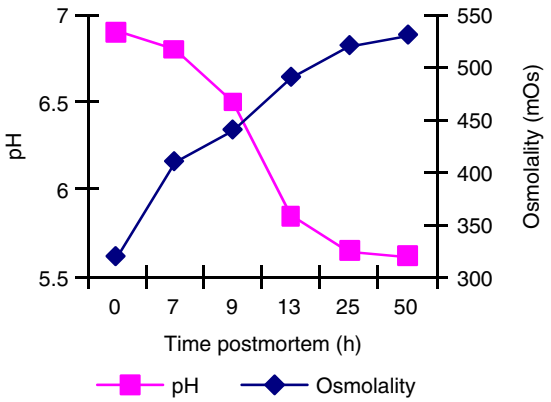

Figure 1 Postmortem decrease in muscle pH (—■—) and increase in osmolality (—◆—) in bovine Musculus longissimus. Adapted from Ouali, A., Vigon, X., Bonnet, M., 1991. Osmotic pressure changes in postmortem bovine muscles: Factors of variation and possible causative agents. Proceedings 37th International Congress of Meat Science and Technology, Kulmbach, pp. 452–455.

environment within the muscle, and this may by itself result in premature membrane rupturing and the release of endogenous enzymes. Isolating the mode of action of ion injection on tenderization has been a major challenge since ions such as Ca^{2+} can cause shortening when injected prerigor as well as activate endogenous enzymes. One approach that has been used to speed up the onset of rigor is electrical stimulation, so that earlier postmortem injection of ions could occur. Infusion with 0.3 mol l^{-1} $CaCl_2$ has been shown to accelerate tenderization and lower shear force values compared with control samples and the reduction in shear force has been attributed to an increased level of activity of μ-calpain and also m-calpain at the highest concentration of $CaCl_2$. The requirement for such high levels of $CaCl_2$ may reflect the barriers that exist to the translocation of ions into the cell; a high level could ensure that some of the ions reach the target enzymes, by effectively swamping the cells. Injection of hot-boned muscle (prerigor) with 0.3 mol l^{-1} $CaCl_2$ does elicit significant shortening, but the muscle is still significantly more tender than control muscle, or muscle injected with 0.15 mol l^{-1} NaCl. In this case the effective Ca^{2+} concentration would be much higher than would occur intrinsically because it has been clearly shown that maximum Ca^{2+} concentration is not reached until the postrigor period. A summary of the reported effects of Ca^{2+} on tenderness is given in Table 1. Injection of sodium chloride (NaCl), combined with phosphates, will enhance the ability of muscle proteins to bind with water and could reflect increased solubility of these proteins and this is the principle applied for the brine treatment of pork. Sodium chloride and polyphosphates accelerate the degradation rates of titin and troponin-T as well as the appearance of 95 and 30 kDa degradation products, which leads to higher tenderization rates and these effects have been attributed to an increased pH due to the high buffering capacity of polyphosphates.

In some instances, sodium pyrophosphate has been injected into muscle in combination with NaCl. Although this has been observed to cause increased calpain activity leading to a reduction in shear force, the ability of pyrophosphate to compete with ATP binding sites on myosin, and thus reduce the extent of muscle contraction, is also a possible explanation for the reduction in toughness. When myofibrils that have been treated to remove endogenous proteolytic enzymes (i.e. calpains), are incubated with 0.3 mol l^{-1} $CaCl_2$, some key myofibrillar proteins show no degradation with time, indicating that protein solubility alone cannot explain tenderization. Equally, this is consistent with activation of the calpains as the major contender for the mechanism that drives tenderization. A major drawback of injection with $CaCl_2$ is that the meat tends to be regarded as having a bitter flavour and to be less acceptable to consumers, due to the fact that Ca^{2+} can stimulate lipoxygenase activity and the mitochondrial respiration process leading to higher rate of oxidative processes. For this reason, commercial adoption of $CaCl_2$ infusion into meat has been limited. The extent of the synergy between enzyme activity and changes in ionic strength is yet to be fully clarified.

Injection of Acids and Other Compounds

A number of organic acids such as acetic, citric, and lactic have been used to tenderize meat. Administration is often by marination, but this requires extended storage periods for penetration into the meat. A number of studies have investigated the efficacy of these acids after injection into meat. These acids cause a significant decrease in pH, creating an environment that is optimal for cathepsin activity (these are lysosomal proteases), which is confirmed by the degradation of proteins such as myosin, a protein that is not degraded under normal (control) postmortem conditions. A drop in pH leads to swelling of the meat. Another effect of this treatment is the weakening/solubilization of perimysial collagen and lowering of the temperatures required for denaturation of connective tissue. On the whole, organic acids lead to an increase in meat tenderness (Table 2). Since the effect of acid injection is largely dependent on the buffering capacity and overall pH reduction in meat, the type of acid used is very important to achieve desired quality attributes. Lactic acid lowers the pH compared with citric and acetic acids, and illicits more dramatic changes in the meat. Combinations of ions and organic acids have also been used to enhance tenderization.

Vascular Infusion

Another approach that has been developed commercially is the vascular infusion of a chemical mix into carcasses via the arteries immediately after death at a rate of 10% of live weight. The chemicals include sugars, phosphates, and sometimes salts. A reduction in toughness has been reported in a couple of studies using this methodology (Figure 2), although other studies have reported no difference in either objective tenderness (shear force) or consumer assessments of tenderness. One of the reports of increased tenderization was associated with increased fragmentation of myofibrils and increased degradation of myofibrillar proteins such as troponin. Unfortunately, the methodology does cause paler meat colour, with higher weep, and thus tends to be less acceptable to retailers, wholesalers and consumers. The main advantage is the increase in carcass weight resulting in increased returns per kilogram of carcass weight. The mode of action that occurs through use of the chemicals has not been confirmed, but could include disruption of muscle cells and increased proteolysis or changes in osmolality. The rate of glycolysis increases with infusion and this may in turn accelerate the activity of the calpains. More recently, this same approach has been investigated, but with the infusion of an ice-slurry throughout the carcase, which has been shown to reduce shear force, but the mechanism was not quantified. Infusion of plant extracted enzymes has also been effective at reducing shear force.

Related to this concept is the prerigor injection or infusion of carcases to manipulate the rate of glycolysis and thus pH fall. It has been reported that prerigor injection of either sodium fluoride or sodium citrate can increase the level of muscle glycogen and thus reduce the absolute decline in pH. Given the link between pH and the activity of the calpains, this could presumably enhance the rate of tenderization. These compounds have resulted in a higher ultimate pH, a reduction in sarcomere length, and in case of sodium citrate a reduction in shear force (Figure 3). For the immediate postmortem period when the citric acid cycle is still operative, citrate is produced, which has an inhibitory effect on

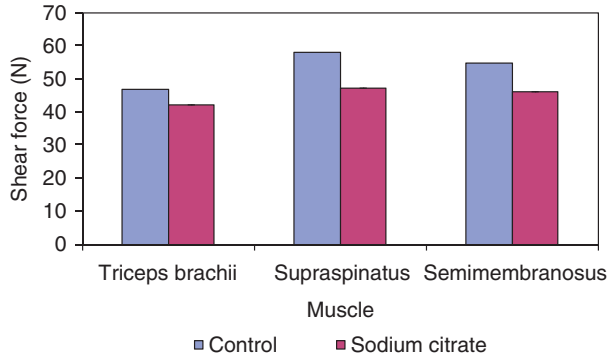

Figure 3 Effect on the shear force of bovine muscles (72 h post mortem) after prerigor injection with a solution of 200 mmol l^{-1} sodium citrate compared with noninjected muscle. A significant difference ($P < 0.05$) in shear force between treatments was found for the supraspinatus muscle. Adapted from Jerez, N.C., Calkins, C.R., Velazco, J., 2003. Prerigor injection using glycolytic inhibitors in low-quality beef muscles. Journal of Animal Science 81, 997–1003.

phosphofructokinase. Because this enzyme is an important regulatory enzyme in glycolysis, this may partially explain the apparent reduction in glycolysis reported by the injection of sodium citrate.

Similarly, injection of sodium bicarbonate has been found to slow the rate of pH decline in porcine muscle, decrease drip loss and darken meat, but again no mode of action has been proposed. It is probable that the response was mediated through a buffering effect whereby the free hydrogen ions produced as a result of glycolysis become complexed with the bicarbonate.

Selection of compounds that can inhibit critical steps in the glycolytic pathway will control the decline in pH. Another approach would be to increase the concentration of creatine phosphate to buffer ATP levels and thus prolong the postmortem time period before ATP is utilised and, therefore, prevent an immediate fall in pH. The inhibition of AMP-activated protein kinase (AMPK) would also presumably lead to a reduction in the rate of pH fall postmortem, as would regulation of the activity of glycogen debranching enzyme (GDE), by a reduction in glycogenolysis. A delay in activity of GDE until the carcase temperature dropped below 39 °C would result in a reduction in the rate of pH decline. Whichever mechanism was applied, the critical concentration of the inhibitor would have to be determined, for high concentrations would potentially lead to a reduction in glycolysis to the extent that the final pH was too high creating other quality issues.

Nonenzymatic Tenderization Meditated by Calcium Ions

There is a hypothesis that Ca^{2+} ions cause nonenzymatic weakening of the myofibrillar structure, and thus tenderization. It is suggested that the significant rise in the concentration of free calcium as rigor develops leads to fragmentation of proteins such as nebulin, desmin, and titin and the weakening of Z-disk proteins through the liberation of phospholipids. Several facts bring into question the validity of this theory: (1) when myofibrils, which have been treated to remove endogenous proteolytic enzymes (i.e., calpains), are incubated with 0.3 mol l^{-1} $CaCl_2$, some key myofibrillar proteins show no degradation with time; (2) troponin T is readily degraded in postmortem muscle, but there is no claim that it is directly affected by calcium; (3) when Triton X-100, which causes a release of Ca^{2+} ions, is combined with a calpain inhibitor, toughness is not reduced; (4) inhibition of specific proteases has been found to prevent tenderization in the presence of an increasing concentration of free calcium; and (5) there is clear evidence for protein degradation/deposition in living muscle as a result of calpain activity, so there is no reason to suggest activity to cease in postmortem muscle, particularly in the early period of rigor development.

It has been shown using autoradiography that Ca^{2+} ions bind to titin, and more specifically by using fluorescence detection they bind to the major sub fragment of this degraded protein. Since calpains bind to Ca^{2+} ions for activation and titin has been shown to be a good substrate for these enzymes, these results are not inconsistent with the proposed role of the calpains in tenderization. Also, this partially reconciles some of the results to emerge from the theory that Ca^{2+} ions cause nonenzymatic weakening of the myofibrillar structure.

Glossary

Calpains A group of enzymes, including μ-calpain and m-calpain, that when activated by calcium degrade the cytoskeletal proteins.
Calpastatins Endogenous inhibitor of μ- and m-calpains.
Cathepsins Cysteine proteases that degrade many different types of proteins.
Contractile proteins Muscle proteins, such as actin and myosin, that are directly involved in the contractile process and minimally involved in tenderization.
Cytoskeletal proteins A set of structural proteins (includes titin, nebulin, and desmin) are denatured by calpains during tenderization.
Endogenous proteases Proteases involved in muscle remodeling in life that take on the role of degrading cytoskeletal proteins postmortem.
Exogenous enzymes Protease enzymes usually of plant material that when applied to meat degrade myofibrillar and connective tissue proteins.

Introduction

The process of meat tenderization is a complex phenomenon. It is accomplished naturally by the presence of endogenous enzymes and it can be augmented by the application of exogenous enzymes, typically purified from plant sources. In postmortem muscle, natural tenderization begins at slaughter and continues to occur while the meat is held at refrigerated temperatures over the next 2–3 weeks. This natural tenderizing process is often referred to as 'aging' the product.

Tenderization via natural aging is done by the actions of enzymes in the muscle that function to regulate the growth and repair of living muscle, often by serving a role in the initiation of the removal of damaged proteins so that new proteins can be inserted into the appropriate muscle structure. The majority of these endogenous enzymes act on the structures of the myofibril, the main contractile organelle of the muscle cell. The tenderization that occurs via these endogenous enzymes starts at death and is essentially slowed or has ceased by 7 days postmortem in most species.

Tenderization via the application of exogenous enzymes is generally less specific than endogenous enzymes. These enzymes target not only myofibrillar proteins but also the connective tissue proteins of the muscle. Most plant enzymes have the capacity to tenderize the product to a greater degree than is possible with endogenous enzymes, leading to the need for the processor to carefully monitor the process to avoid 'over-tenderizing' the product and creating an overly soft, or even 'mushy' texture to the meat.

Both types of enzymes are important in the production of tender meat products. An appropriate understanding of the enzyme systems being relied on for tenderization is important to allow maximal tenderness development in a given product.

Enzymatic Tenderization

Role of Endogenous Proteases

During aging of meat, major structural changes occur in the muscle tissue. Many of these changes are associated with myofibrils, the contractile elements of muscle cells, and their linkages to the cell membrane (sarcolemma) through the cytoskeletal network. As myofibrils make up approximately 80% of the volume of the muscle cell, disruption of myofibrillar structure and, in particular, the cytoskeletal network has the greatest influence on meat tenderness during aging. Changes in the connective tissue are minimal during aging, although the amount of connective tissue that varies between different cuts influences the basic tenderness. Degradation of some proteins linking myofibrils to the sarcolemma and to each other has been observed during the early postmortem period. Other changes that are correlated with increased tenderness include breakages within the myofibrils themselves, particularly within the I-band. These breakages lead to increased fragility and fragmentation of the myofibrils.

The histochemical and biochemical evidence indicates that much of the tenderization associated with postmortem aging is due to the action of the enzymes, which are known to be endogenous to the muscle. Some of the major myofibrillar and cytoskeletal proteins that are known to be degraded early during postmortem aging include (but are not limited to) titin, nebulin, desmin, and troponin-T. Interestingly, the most abundant proteins of the myofibril, actin and myosin, are not significantly degraded during postmortem aging.

Cathepsins

Early research on the mechanism responsible for the development of meat tenderness during aging focused on the cathepsins. The cathepsins are endogenous proteases found in

 doi:10.1016/B978-0-12-384731-7.00248-8

lysosomes in living muscles. The most frequently studied cathepsins with respect to meat tenderness include cathepsins B, D, L, and H. The majority of the cathepsins are active at acidic pH values (usually between pH 5 and 6). These proteases were originally of interest because in living tissue lysosomes are one of the major sites of protein degradation. Additionally, these enzymes are active at acidic pH values, near the pH values found in postrigor meat.

Characteristics of the cathepsins

Cathepsin B (EC 3.4.22.1) is a glycoprotein that has a molecular weight of approximately 25 000. It is a cysteine protease and has been shown to have activity over the pH range of 4–6.5. Cathepsin B degrades many proteins in the muscle, including myosin and actin. Cathepsin D (EC 3.4.23.5) is an aspartyl protease with an approximate molecular weight of 42 000. This glycoprotein has been shown to have activity over the pH range 2.5–5.0. Like cathepsin B, cathepsins D and L (EC 3.4.22.15) will degrade myosin and actin. Cathepsin L has also been shown to have activity against α-actinin, troponin-T, and troponin-I and is active over the pH range 3.0–6.5. Cathepsin H (EC 3.4.22.16) is a cysteine protease with a molecular weight of approximately 25 000 and is active from pH 5.5 to 6.5. Like all of the cathepsins mentioned in this article, cathepsin H has a high specific activity against myosin.

In addition to degrading many myofibrillar proteins, several of the cathepsins have the ability to hydrolyze connective tissues, especially cathepsins B and L. Cathepsin B has been shown to have activity against collagen and proteoglycans. Cathepsin L has been shown to have activity against collagen, proteoglycans, and elastin. Some studies have indicated that limited proteolytic alteration of collagen occurs especially after long periods of aging.

Cystatin

Muscle also contains a family of potent cysteine-type protease inhibitors collectively known as cystatins. These cystatins are found distributed throughout the muscle cell and in the living muscle are thought to modulate the activity of cysteine proteases. In postmortem muscle, the pH should favor the activity of many of the cathepsins and because of this it might be expected that myosin and possibly actin would be among the proteins degraded. However, there is little evidence of either myosin or actin degradation in postmortem muscle. The presence of cystatins may help explain why there is little evidence of cathepsin activity in postmortem muscle.

Although there is some evidence that proteins like myosin and actin can be degraded when meat is stored at relatively high temperatures or for extremely long periods of time, myosin and actin are not degraded in the first week after slaughter under normal storage conditions. Therefore, the current evidence implicating the cathepsins in the tenderization of meat during the early stages of normal postmortem aging (when most tenderization occurs) is somewhat limited. Owing to this, in recent years, a much larger effort has been focused on the calpain enzyme system, a system that seems to degrade the same proteins that are degraded in postmortem muscle under normal meat storage conditions. Unlike the cathepsins, calpains degrade the majority of proteins into relatively few fragments, which is similar to what is seen in meat. It should be stressed that other enzyme systems like the serine proteases and the proteasomes may have a role in postmortem proteolysis. Recent studies on the proteasome endopeptidase complex (EC 3.4.25.1) in bovine skeletal muscle have suggested that it could play a role in protein degradation late in the aging process. At this stage, however, there is insufficient evidence to substantiate involvement of these other enzyme systems.

Calpain System

The endogenous calpain system has been implicated as playing a major role in the proteolysis of muscle proteins under postmortem conditions. Some of the proteins that have been shown to be substrates of calpains include titin, nebulin, troponin-T, desmin, synemin, talin, and vinculin. Most of these proteins have structural roles within the muscle cell. Degradation of these proteins has been associated with a weakening of the muscle cell and the myofibrillar structure and with tenderness.

Calpain enzymes

The calpain system is composed of several isoforms of tissue-specific and ubiquitous calcium-dependent cysteine proteases (calpains, EC 3.4.22.17), and their specific competitive inhibitor, calpastatin. The two best-characterized isoforms of calpains are the so-called ubiquitous forms μ-calpain and m-calpain. They are referred to as ubiquitous because they are found in most tissues. These proteases are named μ-calpain and m-calpain in reference to the amount of calcium they require for activation *in vitro*. μ-Calpain requires between 3 and 50-μM calcium for half-maximal activity, whereas m-calpain requires between 0.4 and 0.8-mM calcium for half-maximal activity. Both μ- and m-calpain are heterodimers composed of an 80- and a 28-kDa subunit. The 28-kDa subunit is identical in both μ-calpain and m-calpain. The *C*-terminus of this subunit has four sets of amino acid sequences that predict calcium-binding EF hand structures; however, the exact function of this subunit is not known. The 80-kDa subunits of μ- and m-calpains are similar, but are encoded for by different genes. The 80-kDa subunit is composed of four domains. Domain I, the *N*-terminal domain, has no sequence homology to any known polypeptide. Domain II is the catalytic domain and contains a cysteine residue as well as a histidine and asparagine residue that form a catalytic triad similar to that seen in other cysteine proteinases (including papain). Recent determination of the crystal structure of m-calpain has shown that in the absence of calcium, critical regions of the catalytic domain, domain II may be misaligned. The region of domain II (referred to as domain IIa) that contains the cysteine residue and the region of domain II that contains the critical histidine and aspargine residues (domain IIb) appear to be held slightly apart and rotated, potentially rendering the protease inactive. Release of specific structural constraints, possibly triggered by calcium, may play an important role in conferring activity to the enzyme. It has been speculated that conformational changes in domain I and III may play critical roles in calpain activation by their potential influence on the active site conformation in domain II. The

amino acid sequence of domain III is not homologous to any other known protein, but has two sets of sequences that predict EF hand Ca^{2+}-binding sites. The crystal structure of m-calpain suggests that this domain resembles the C2-domain found in several Ca^{2+}-regulated proteins like protein kinase C. Domain IV is a calmodulin-like domain that has four sets of sequences that predict EF hand Ca^{2+}-binding sites.

The protease μ-calpain is active under *in vitro* conditions mimicking postmortem muscle pH, ionic strength, and temperature. Although the calpain enzymes are active under postmortem conditions, their level of activity is somewhat compromised by the low pH and high ionic strength conditions that develop within the meat during storage. During postmortem storage in beef and pork, μ-calpain has been shown to become increasingly associated with the myofibril. It has been suggested that this myofibril-associated μ-calpain may indeed be active.

Although calcium is necessary for their activation, both μ- and m-calpain will also autolyze (selfdegrade) when incubated with calcium. Autolysis reduces the mass of the 80-kDa subunit of μ-calpain to 76 kDa, and the mass of the 80-kDa subunit of m-calpain is reduced to 78 kDa. The 28-kDa subunit of both enzymes is reduced to 18 kDa. Brief autolysis also reduces the Ca^{2+} concentration required for half-maximal activity of either enzyme. Extended autolysis leads to inactivation of the enzyme. Autolysis occurs under situations that allow activity, both in living cells and in postmortem muscle, but the significance of this is not clear. Both autolyzed and unautolyzed forms of the enzymes have been shown to have activity. However, the autolyzed form of μ-calpain appears to be more hydrophobic and binds tightly to subcellular organelles, including myofibrils. The presence of the autolyzed form of μ-calpain in postmortem tissue has been suggested to indicate that activity has occurred.

One of the tissue-specific forms of calpain, often referred to as p94 or novel calpain-1, deserves mention. This muscle-specific calpain isoform was the first tissue-specific calpain identified. The messenger ribonucleic acid for p94 in muscle has been reported to be as much as 10 times that of either μ- or m-calpain. The p94 peptide appears to be a single polypeptide that has a structure similar to the large catalytic subunit of μ- and m-calpain. It has a predicted molecular weight of 94 000 – slightly larger than the catalytic subunit of the ubiquitous calpains. This larger size is due to three unique regions: one in the *N*-terminus, one in the catalytic domain, and one at the interface of domains III and IV. Unlike μ- and m-calpain, which are sarcoplasmic proteins, p94 is associated with the myofibrillar fraction. More specifically, p94 appears to be closely localized if not bound to the large myofibrillar protein titin. This calpain has proven to be very difficult to study as it autolyzes rapidly during conventional extraction procedures and so it has been very difficult to ascertain its role, if any, in proteolysis/tenderization.

Calpastatin

Calpastatin, the endogenous inhibitor of μ- and m-calpain, has been found in all the tissues that contain calpains. Calpastatin in the skeletal muscle is a single polypeptide that contains within its structure four repeating domains that each has calpain inhibitory activity. Theoretically, then one calpastatin molecule may inhibit at least four calpain molecules. Calpastatin plays a major role in the regulation of the expression of calpain proteolytic activity. The amount of calcium required to allow half-maximal binding of calpastatin to calpains is generally lower than that required for half-maximal activity of the unautolyzed and autolyzed forms of m-calpain and for half-maximal activity of autolyzed μ-calpain. Calpastatin binding is reversible as calcium chelators can cause calpastatin to dissociate from calpain.

The level of inhibitory activity of calpastatin declines during postmortem aging (Figure 1). The level of inhibitory activity of calpastatin that remains at approximately 24 h after slaughter is associated with tenderness. Calpastatin is actually degraded in postmortem muscle and this rate of degradation is related to the rate at which it loses its ability to inhibit calpain. Both degradation of calpastatin and its loss of inhibitory activity are related to the rate of proteolysis and tenderization observed in meat. There is good evidence that calpains are at least partially responsible for the degradation of calpastatin. Currently, the conditions that promote calpain degradation of calpastatin in postmortem muscle have not been defined.

Even though there has been much research done on the calpain system over the years, relatively little is known about its regulation. Certainly, the endogenous inhibitor of the calpains, calpastatin, is involved, but there is evidence to suggest that other mechanisms may also be important, particularly in meat. Environmental factors in the early postmortem muscle cell can influence calpain activity and inhibition of calpain by calpastatin. These can include factors like pH and ionic strength. Therefore, it is important to examine other mechanisms that may affect calpain activity to fully explain how calpain activity is regulated in meat. Alterations in pH or ionic strengths in early postmortem meat have the potential to cause conformational changes allowing for increased hydrophobicity. This increased hydrophobicity has been hypothesized to lead to aggregation of the enzyme. Likewise, pH/ionic

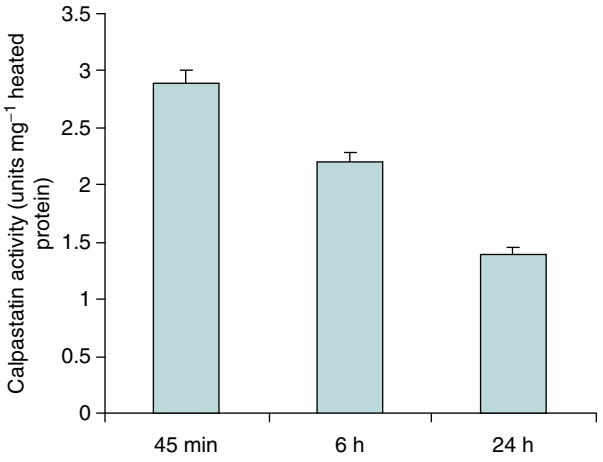

Figure 1 Effect of aging time on calpastatin activity from porcine longissimus muscle. Data taken from Melody, J.L., Lonergan, S.M., Rowe, L.J., *et al.*, 2004. Early postmortem biochemical factors influence tenderness and water-holding capacity of three porcine muscles. Journal of Animal Science 82, 1195–1205.

strength changes may alter the conformation of substrate proteins and render them less susceptible to cleavage by μ-calpain. A slightly accelerated pH decline has been shown to be associated with more rapid attainment of ultimate tenderness and more rapid proteolysis. However, a greatly exaggerated rate of pH decline, like the rapid pH decline that results in pale, soft, and exudative pork, seems to result in very limited aging potential. Hypothetically, a rapid pH decline would lead to an increased level of activity of catheptic enzymes and increased proteolysis; however, in most cases, this does not seem to occur. The product that has an exceptionally rapid pH decline has often been shown to also exhibit limited proteolysis of muscle proteins associated with tenderization. Low pH values have been shown to destabilize μ-calpain and to promote more rapid autolysis and/or activation and subsequent inactivation in *in vitro* studies and may do the same in muscle tissue. Therefore, the rate of pH decline may play a very pivotal role in the attainment of ultimate tenderness.

Caspase Enzyme System

Caspases are a family of enzymes that are involved in apoptosis, or programmed cells death. Cell death by apoptosis is characterized by a systematic and organized dismantling of a cell. Common hallmarks of apoptosis include shrinkage of the cell, cell membrane blebbing, chromatin condensation, damage to deoxyribonucleic acid, and the formation of apoptotic bodies without causing a generalized inflammatory response. Apoptosis is adenosine triphosphate (ATP) dependent, which may seem to be incongruous with postmortem tissue; however, in most postmortem muscle ATP can be produced for a period of time via anaerobic glycolysis, which may be different from the classical necrotic state. Necrosis is typically caused by a catastrophic loss of energy and is a passive process. It is accompanied by a loss of membrane integrity and swelling of organelles. Thus, in reality, as the loss of energy in the early postmortem cell is a gradual process, the argument could be made that early postmortem tissue resides in a 'nether region' between the two states of apoptosis and necrosis.

The apoptotic process is choreographed by the caspases. Caspases are cysteine proteases that require their substrates to have aspartate residues. There are more than a 1000 substrates that have been identified for the caspases, and they include myofibrillar and cytoskeltetal proteins. Activation of caspases can be initiated by pathological events including ischemic/hypoxic conditions.

There are two general classes of caspases, initiatior caspases (caspases 8, 9, 10, and 12) and effector or executioner caspases (caspases 3, 6, and 7). Initiator caspases are activated when a stimulus for apoptotic events is received. Once they have been stimulated, these initiator caspases activate the executioner caspases by cleaving a linker that separates the small and large subunits of the catalytic domain. Once activated, the executioner caspases are responsible for the enzymatic cleavage of substrates that are ascribed to the caspase system.

Since the early 2000s, caspases have been suggested to play a role in postomortem proteolysis related to tenderness. Many of the caspase substrates are proteins that have been shown to be at least partially degraded during the early postmortem period. These include (but are not limited to) actin, troponin-T, desmin, and myosin light chains.

The question of whether or not caspase enzymes or calpain enzymes are the predominant systems involved in early postmortem proteolysis has been hotly debated. It has proven difficult to rule out either system. Indeed, there is evidence that the two systems work together in the cell. For example, it has been shown that the calpain inhibitor, calpastatin, can be cleaved by caspases 1, 3, and 7, thereby directly influencing the activity of the calpain system. Thus, it may not be a question of which enzyme system is responsible for postmortem proteolysis, but rather, how do the two systems work together. For a more detailed discussion of relevant research on this topic, the reader is referred to the Further Reading section of this article.

Exogenous Enzymes

In addition to allowing the endogenous enzymes to tenderize meat, exogenous enzymes, mostly of plant origin, have been used to augment the tenderization process. The most commonly used plant enzymes are papain (from papaya), bromelain (from pineapple), and ficin (from figs/ficus). More recently, actinidin (from kiwi) has been investigated, as has been zingibain (from ginger).

Papain, bromelain, and ficin are all cysteine proteases and have a broad spectrum activity, cleaving a wide variety of bonds, thus degrading a large number of muscle proteins. These proteases are active in the pH range found in meat (papain, pH range 5.8–7; bromelian, pH range 5–7; and ficin, pH range 5–8). The ideal temperature range for these proteins is approximately 50–60 °C, making them maximally active on heating. Actinidin has a higher pH range than the aforementioned enzymes (ideal range is 7–10, but can have activity at pH 5–7) but the temperature range is similar. Zingibain is obtained from a crude extract of ginger. It has a maximum activity at pH 6–7 and a temperature of 60 °C.

These plant-derived enzymes are very effective tenderizers. In addition to acting on myofibrillar proteins, most will also act very effectively on connective tissue proteins as well. In fact, one of the major challenges of using these enzymes is countering the effect of overtenderizing. However, continued research in the application of these enzymes is yielding better ways to utilize them. For further detailed information, the reader is referred to a review by Bekhit *et al.* (2013).

Conclusions

On the basis of available data the major candidate to explain proteolysis of myofibrillar proteins and thus tenderization postrigor is the calpain protease system. The mode of action of the calpains is not yet fully defined and questions remain as to the role of m-calpain given the *in vitro* requirement for a Ca^{2+} ion concentration exceeding that observed in postmortem muscle. The existence of the calpains in living muscle and other tissues is consistent with the involvement of these enzymes in tenderization (which reflects protein degradation) but suggests a mode of action more intricate than previously thought.

An increase in ionic strength postmortem may assist degradation of proteins by enzymes and also lead to solubilization of proteins, but in itself is not the sole mechanism causing tenderization. Equally, changes in the binding of actomyosin (the complex of contractile proteins formed at rigor) or cleavage of myofibrillar proteins due to Ca^{2+} ions do not offer plausible explanations for the mechanism that results in tenderization. It also appears that the cathepsin proteases are unlikely to have a role in early postmortem cleavage of proteins (proteolysis) and thus tenderization and this also applies to other enzyme groups such as the serine proteases, proteasomes and matrix metallopeptidases. Recent work on caspases has indicated that they may be worthy of further investigation, especially with respect to their interaction with the calpain system.

The use of exogenous plant enzymes is a useful method to tenderize meat cuts beyond what can be achieved via postmortem aging alone and is a viable method to use particularly for cuts that have high amounts of connnective tissue.

Glossary

Aging The process of meat tenderization that occurs over time – it commences after rigor mortis.
Contractile proteins Actin and myosin, which form the thin and thick filaments of skeletal muscle. These two proteins interact chemically (to form actomyosin), which gives muscle the ability to contract and relax. Associated with actin are the proteins troponin and tropomyosin.
Costameres Connect Z-disks to the sarcolemma and are made up of proteins such as talin, vinculin, desmin, and dystrophin.
Cytoskeletal proteins A set of filamentous structural proteins (includes actin, titin, nebulin, and desmin).
Electrical stimulation The application of an electric current through a carcass postmortem that accelerates the rigor process.
Myofibril Comprises contractile structural and regulatory proteins. The contractile protein is composed of myofilaments that are in turn made up of thin and thick filaments. Structural proteins include titin and nebulin. Titin is the largest protein in skeletal muscle (up to 3700 kDa) and provides the elasticity to the sarcomere. The regulatory proteins include troponin and tropomyosin.
Proteolysis The degradation of proteins into smaller subunits that occurs with aging, but also in turnover of living muscle.
Rigor A term for individual muscle fibers that have been depleted of adenosine triphosphate and in which the actomyosin bond has formed.
Rigor mortis A term describing muscle stiffening after all muscle fibers enter rigor.
Sarcomere The basic unit of skeletal muscle defined by the distance between two Z-disks. Z-disks are dense protein structures to which the contractile protein actin is attached along with proteins such as titin and nebulin. Z-disks are the anchor points for the contractile proteins that allow contraction and relaxation.
Shear force The force (N) applied to a standardized piece of cooked meat to shear it.
Shortening A process that occurs when prerigor muscle is cooled below 10 °C. It also occurs as muscles enter rigor at high temperatures (rigor shortening).

Introduction

Methods to reduce meat toughness by mechanical or physical means can be employed during either the prerigor or postrigor phase as muscle is converted to meat. The methods fall into two broad categories: those that prevent shortening during rigor or those that disrupt the meat structure either by physical or enzymatic means when applied some time after slaughter. In the former category, carcass-hanging methods, or excision of cuts combined with devices to restrict shortening, have been found to impact on tenderness levels. The mechanism behind these methods is essentially a restriction of the degree of actin and myosin overlap as muscle enters rigor and a reduction in fiber cross-sectional area. For the latter category of meat disruption, electrical stimulation, ultrasonic waves, blade tenderization, pressure treatment, and freeze–thawing have been investigated. These methods depend on one or more mechanisms: decreased actin and myosin overlap, physical damage to sarcomere and connective tissue structure, or altered rates of proteolysis.

Although carcass-hanging methods have been found very effective for reducing the toughness of loin and hindquarter cuts and are generally cost-effective, they provide no benefit to forequarter cuts. The other methods provide the opportunity for more cuts to be improved, but the practicality and effectiveness is in some cases questionable. Inevitably, any method that reduces the density of muscle fibers in a unit area or causes disruption of sarcomere structure will lead to a reduction in the toughness of cooked meat.

Shear force is an objective instrumental measure of tenderness, where high shear values indicate increasingly unacceptable meat (tougher). Tenderness can also be assessed by sensory evaluation, where high numbers indicate greater levels of satisfaction (less tough).

Carcass Methods

Tenderstretching

The decline postrigor in shear force from a peak attained during rigor is illustrated in Figure 1. Numerous studies have shown that temperature conditions prerigor dramatically influence the level which the peak reaches. Prerigor methods that physically prevent a large rise in the peak shear force (indicated by arrows) will confer an immediate postrigor advantage in tenderness.

Suspension of carcasses by the obturator foramen or aitchbone so that the back leg falls into the walking position (Figure 2) was given the name tenderstretch. Researchers in the US first investigated this method and Australian researchers conducted extensive follow-up research. The technique places tension on the hind leg and loin muscles and physically prevents them shortening (i.e., reduces the overlap of actin and myosin).

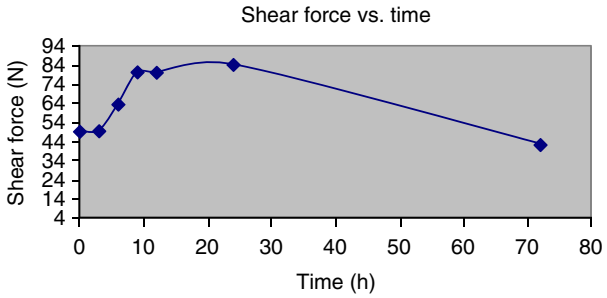

Figure 1 Time course changes in shear force of ovine longissimus during postmortem storage. Maximum contraction occurs somewhere between the arrows as the muscle enters rigor. Data from Wheeler, T.L., Koohmaraie, M., 1994. Prerigor and postrigor changes in tenderness of ovine longissimus muscle. Journal of Animal Science 72, 1232–1238.

Table 1 Warner–Bratzler shear values (N) for muscles measured at 2–3 days postmortem obtained from sides of beef hung by either the Achilles tendon or aitchbone

Muscle	*Method of suspension*	
	Achilles tendon	*Aitchbone*
Semimembranosus	82.4	50.0
Gluteus medius	78.5	39.2
Longissimus	107.9	55.9
Vastus lateralis	86.3	53.0
Biceps femoris	63.7	65.7
Semitendinosus	59.8	58.8
Infraspinatus	62.3	58.8
Psoas major	35.3	49.0

Figure 2 The carcass is suspended by the aitchbone so that the back leg drops and the backbone straightens and maximum tension is placed on these muscles. Photograph courtesy of J.M. Thompson.

The extent of the improvement across a range of muscles is clearly demonstrated in Table 1 for cuts taken from beef carcasses. Shear force was significantly reduced by tenderstretch in the majority of hindquarter muscles. The notable exceptions to this trend were the m. biceps femoris and m. semitendinosus. This latter muscle is stretched in Achilles-hung sides and in the case of the m. psoas major it actually shortens in tenderstretched carcasses.

By weighting the hind legs, a further reduction in shear force (20%) can be achieved, particularly in the loin muscle; it has recently been shown that this technique causes significant disruption of the sarcomere, with distortion of the Z-disk and actual tearing of the filaments (Figure 3). It is this disruption and a decreased overlap of actin and myosin that results in the dramatic reduction in shear force.

The improvement in tenderness is so dramatic that the need for prolonged aging is virtually eliminated; in addition, the variation in tenderness along the loin muscle is reduced. Commercial adoption of this technique has seen resurgence as processors have developed ways to handle and store tenderstretched carcasses, such as adopting methods to rehang carcasses from the Achilles tendon after attainment of rigor and streamlining the processing of carcass movement and boning. Pelvic suspension (or tenderstretch) alone has not been patented. Cargill Incorporated in the US have patented pelvic suspension as part of a wider meat tenderization system incorporating separating vertebrae (a variant of the tendercut technique below), pelvic suspension, electrical stimulation, and immediate subsequent Achilles suspension. In this methodology pelvic suspension is used for less than 10 min, preferably less than 2 min, restricting muscle contraction only as the muscles approach rigor. No claims are made as to the efficacy of this process.

Tendercut

An alternative method to tenderstretch has been developed called 'tendercut.' This method offers an advantage in carcass handling because the leg is still hung by the Achilles tendon. The tendercut process was initiated by Claus and Marriott in 1991 (Virginia Polytechnic Institute and State University, USA). The tendercut process applies tension on muscles by breaking the vertebrae and pelvic bones in the hot carcass. This process involves sawing the vertebral column at the 12th/13th rib junction and/or the ischium at the rump/butt junction (Figure 4). In addition to breaking the vertebrae at the 12th/13th rib junction, all tissues surrounding the loin are cut, such that only a dorsal component is holding the forequarter to the hindquarter. The adipose tissue dorsal to the longissimus muscle is also cut to expose the epimysium and this cut is then continued around the medial side of the loin muscle and the m. multifidus dorsi is completely severed. Intercostal connective tissue and muscle are then cut between the 12th/13th costal bones. This latter cut is extended approximately

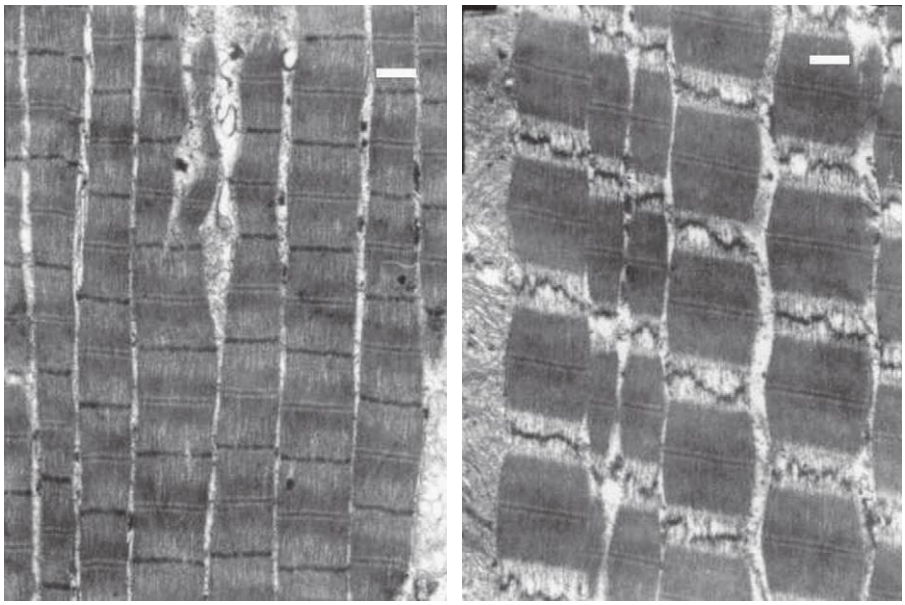

Figure 3 Images of ovine longissimus captured with an electron microscope (original magnification×10 000) from (a) a carcass tenderstretched and weighted with 2 kg weights and (b) a sample from a normally hung (by Achilles tendon) carcass shown for comparison. Figure 4 A photograph showing a severed vertebral column as used as part of the tendercut method. Photograph courtesy of J.R. Claus.

12 cm from the lateral edge of the loin muscle. The second cut severs the ischium at the site used to separate the butt/rump joints, the junction between the 4th/5th sacral vertebrae and connective tissues. The fillet muscle must be freed from its attachment and deflected forward during sawing. In addition, care must be taken while sawing the ischium to minimize damage to the rump cut. The technique can be applied by use of either cuts or a single cut, in which case fewer muscles will be affected.

Compared to tenderstretching, the tendercut process overcomes the need for additional chiller space and avoids the need to train boners on new cutting lines, but is much more difficult to carry out on a processing line. Based on published evidence it also appears that this method does not reduce the shear force of loin and leg muscles to the same extent as tenderstretching. However, like the former method, tendercut does reduce the proportion of unacceptable loin steaks when tested by consumers, and in one study the proportion of unacceptable scores for overall tenderness was reduced from 19% to 2.5%. The magnitude of the gain achieved within either of these hanging methods will be influenced by the chilling regime, with a lower improvement expected under slow chilling conditions.

Electrical Stimulation

Accelerated fall in postmortem pH is one of the main outcomes of electrical stimulation; however, there is some evidence that stimulation does cause physical disruption of muscle. Histological images of stimulated muscle at times show the appearance of contractile bands containing predominantly stretched, ill-defined, and disrupted sarcomeres.

Contracture bands are not a direct consequence of electrical current passing through the muscle, but are rather due to the supercontracture caused through localized excessive release of calcium ions from the sarcoplasmic reticulum. This suggests that they are a consequence of abnormal, perhaps localized, calcium release from the sarcoplasmic reticulum through a

tetanic contracture. This extra calcium could lead to tenderization through activation of enzymes such as the calpains, but any reduction in toughness could alternatively be due to a purely physical effect via a reduction in fiber density in a unit area. It has been shown quantitatively in beef m. longissimus that sarcomeres adjacent to contracture bands have a higher frequency of I-band fracture.

Ultrastructural changes are fiber type-specific and depend on the duration and effectiveness of the applied stimulation, the current frequency, and the interaction between current frequency and voltage. If the time interval between successive stimuli is more than approximately 0.25 s, the muscle tetanic shortening is reversible. However, when a higher frequency of current is applied, muscle may not have enough time for relaxation between succeeding twitches, and irreversible contracture bands are formed. At present, it is not possible to determine how much improvement in tenderness as a result of electrical stimulation stems from a reduction in fiber density in unit area as a consequence of contracture as opposed to increased activity of enzymes due to spikes in the concentration of free cytoplasmic Ca^{2+}. Quantitative studies examining ultrastructural alteration, shortening, and proteolysis are necessary under the same experimental conditions to clarify the contribution of these variables to improvements in tenderness. A combination of stimulation and tenderstretching has not been found to confer a significant additive advantage over separate treatment of muscles with either method.

Cut Methods

It has been demonstrated that if prerigor muscle can be excised from the carcass and held to prevent shortening (e.g., by wrapping), then this can provide a potentially economical way to speed up processing and at the same time minimize toughening. This does require chilling at a temperature that minimizes rigor shortening. Several different approaches have been developed in recent years.

Pi-Vac Elasto-Pack System®

The Pi-Vac Elasto-Pack System® is a method of tightly wrapping hot-boned muscles in an elastic wrapping material prerigor to prevent shortening and toughening of the meat. The system uses a highly flexible packaging sleeve, which is expanded using a partial vacuum to allow the meat to be inserted. Once the vacuum is turned off the flexible packaging retracts to its normal dimensions. This exerts longitudinal forces on the meat, preventing the contraction of the muscle. Almost all of the oxygen is also forced out of the packaging. The subsequent bound meat product has been labeled TenderBound. This technology can come in three different sizes (Figure 5) and some commercialization of this approach has occurred in Europe. By adopting the concept of super tenderstretching by using weights and applying it to hot-boned beef muscle it has been shown that tenderness could be achieved equivalent to that realized with the Pi-Vac Elasto Pack System®. Additionally, the Pi-Vac Elasto Pack System® produced meat with the lowest variation, indicating that this method does something different to meat structure, but there have been few published studies outlining the benefits or otherwise of the technology.

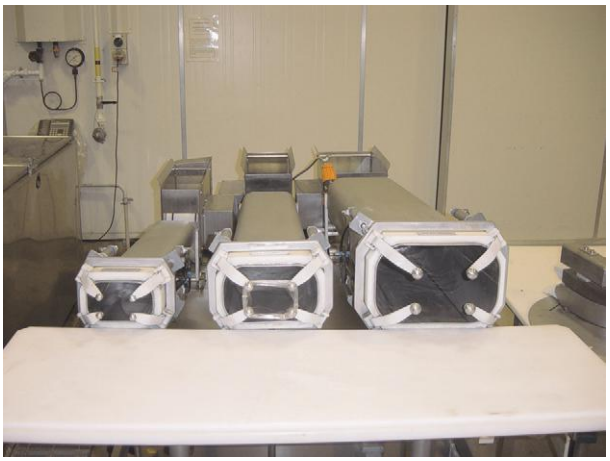

Figure 5 The Pi-Vac Elasto-Pack System showing three different sizes. The middle size shows the plastic film that is used inside the machine. Photograph courtesy of Hans-Werner Meixner.

SmartStretch™

This technology was designed to apply air pressure/vacuum to excised individual prerigor muscles to stretch the muscle into an even form and package it so as to retain the form. The technology was patented by Meat and Wool New Zealand Limited and Meat and Livestock Australia Limited as the 'Boa' and was subsequently registered as SmartStretch™. As with all stretching systems the aim was to either stretch sarcomeres or prevent the contraction of sarcomeres during rigor, with some resultant tenderness benefits. The machine's operation is based on an externally ribbed flexible sleeve surrounded by inflatable bladders that are housed within an airtight chamber that air can be pumped into or out of. Air is pumped out of the chamber to create negative pressure, which causes the sleeve to expand, allowing the meat to be inserted. Air is then pumped into the inflatable bladders causing the meat to be compressed by force perpendicular to the direction of the muscle fibers. This also applies peristaltic action, moving the meat toward the same end of the sleeve that it was inserted into. Positive pressure is then applied to the exterior of the sleeve by pumping air into the chamber, forcing the meat upwards and into packaging as shown in Figure 6.

As with the Pi-Vac system the application of SmartStretch™ is for hot-boned muscles and work has been conducted in Australia, mostly with sheep and beef meat from old animals. Initial experiments with sheep meat were promising. A 24% increase in m. semimembranosus length resulted in shear force reductions of 46% at 0 days aging and 38% at 5 days aging and was matched with a significant increase in sarcomere length. A further study examined the effect when the muscles were stretched as part of a whole sheep meat hind leg. A 14% increase in leg length resulted in a shear force reduction in the m. semimembranosus of just 16% and of 18.4% in the m. biceps femoris at 0 days aging and no significant difference at 5 days aging. Significant increases were found in sarcomere length

following stretching. However, a number of the studies conducted on beef m. semimembranosus, m. longissimus lumborum, and rostbiff (mainly m. gluteus medius) were inconclusive as to the SmartStretch™ system's impact on beef tenderness. Increasing stretch in the m. semimembranosus from 34% to 52% had no impact on shear force, but this was proposed to reflect the fact that once a basal level of stretch was achieved further stretching would not have an effect. A 21% increase in length of the m. semimembranosus and rostbiff also had no significant impact on shear force or on sensory results, although the shear force values were so high that tasters could not discriminate between the tough and the extremely tough product. A reduction in the variability in shear force was found.

By contrast, when younger cattle (maximum dentition score of 2) were used the results showed a significant improvement in hot-boned meat tenderness by the use of SmartStretch™. Initial work in beef comparing SmartStretch™ to Tenderstretch, 'Superstretch' (Tenderstretch plus a pulley system to pull the hindlimb toward the forequarter), and Achilles suspension showed similar tenderness improvements in the m. longissimus lumborum resulting from all three stretching treatments in prime cattle. The results for two stretching treatments are shown in Figure 7. Follow-up work in young cattle showed that tenderness of the rostbiff (m. gluteus medius), as reflected in reduced shear force measurement, was significantly improved in 0 day aged stretched samples over the unstretched hot-boned control. After 8 days aging there was no longer a difference in the tenderness between stretch treatments. Sarcomere length was significantly increased by stretching in both studies.

Blade Tenderization

The physical disruption of muscle structure must reduce the density of cooked meat fibers in unit area and therefore impart an improvement in tenderness. Blade tenderization is used for this purpose commercially. Commonly, cuts of meat are placed on a conveyor and pass through a machine that consists of spear-shaped blades arranged on a mounted head. Blade density can be greater than one blade per 1 cm^2 of head and the pattern of cut can also be varied. Other types of devices, which combine a large screw and pressure to extrude the meat through a slit, also cause significant disruption and reduce toughness (by fracturing fibers). Repeated treatment of cuts by blade tenderization may confer some additional benefit, but the gain is marginal and good sanitation is required to avoid bacterial contamination between cuts.

Commercial blade tenderization devices are often used for infusing solutions into meat and these solutions may contribute to tenderization. Histological examination of treated meat samples shows that the muscle fibers are torn and fragmented by the blade, as is connective tissue, but areas between points of blade penetration will be unaffected. Despite this localized effect, the density of blades compensates and this technique confers significant improvement to a range of cuts (see Figure 8), but particularly for some of the toughest cuts of the hind leg such as the topside (m. semimembranosus). In contrast, there is much less benefit for inherently tender cuts such as the rib-eye (m. longissimus thoracis).

Ultrasonic Waves

Sound waves travel through material at different speeds and impart energy to the transmission material, which has the potential to cause physical disruption, particularly when the wavelength is similar to the size of structural units of the material. Both frequency and wavelength can be varied, but few studies using meat have focused on high-frequency (>1 MHz) ultrasonic waves, with more attention on low-frequency waves. Theoretically, disruption of muscle cell integrity could also lead to a leakage of Ca^{2+} from the sarcoplasmic reticulum and release of cathepsins from the lysosomes, hastening the onset of enzyme activity.

Indeed, there is a suggestion that prerigor treatment of m. semimembranosus from beef with ultrasound at 2.6 MHz

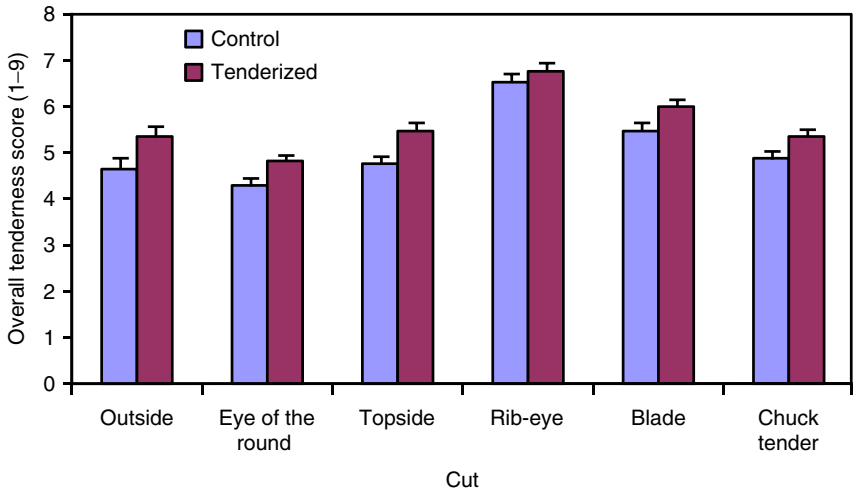

Figure 8 Impact of mechanical tenderization on the tenderness of cuts of meat from beef carcasses. Modified with permission from Jeremiah, L.E., Gibson, L.L., Cunningham, B., 1999. The influence of mechanical tenderization on the palatability of certain bovine muscles. Food Research International 32, 585–591.

(intensity 10 W cm^{-2}) can elevate the levels of free cytosolic Ca^{2+} and does lead to an increase in sarcomere length (~10%). Despite this effect, no clear advantage in reducing toughness has been reported and this applies equally to low-frequency, low-intensity ultrasound.

The size of meat sections and the use of muscles with high connective tissue content (e.g., m. semitendinosus) could be some of the reasons for the apparent lack of effect of ultrasound on toughness. From a practical perspective, the transmission of sound waves causes a dissipation of energy and this results in a rise in material temperature. As a consequence, a number of studies have submerged the meat in cold water, which would potentially limit commercial adoption. It would appear that the use of ultrasound to increase tenderization rate currently has limited applicability, although it may be feasible to integrate its use with hot-boning operations in which meat is passed through a water-cooling submersion system, at which time the meat could be exposed to a barrage of ultrasonic waves.

Hydrodynamic Pressure

One of the most novel techniques that have been developed to reduce toughness is the Hydrodyne process. In this process a small amount of explosive is used to generate a shock wave that travels through water in fractions of a millisecond. The idea was proposed by John Long, a mechanical engineer, who developed the concept further with the help of Morse Solomon (USDA, Beltsville, MD, USA), and Eric Staton who had experience in the use of explosives.

The process requires that the meat be held within a container and surrounded by water; because meat has a high content of water, the shock waves travel through the meat. When the meat is held inside a metal or plastic container, the shock waves are reflected from the walls and intersect; this increases the pressure, leading to physical disruption of the encapsulated meat. Electron micrographs of treated meat show I-band proteins totally separated from the Z-disk and fractures at the A-band/I-band junction, and thus the increase in tenderness would appear to be mediated through physical degradation of muscle structure in particular myofibrillar proteins. As for any method that results in such a degree of disruption, it is also feasible that cellular structure is damaged, leading to the release of protein-degrading enzymes (i.e., calpains or cathepsins) or activators of these enzymes such as Ca^{2+}, hastening proteolysis. A somewhat related method is to apply hydrostatic pressure to meat; in this case it is the pressure of a liquid on immersed meat that results in a reduction in toughness (see next section).

Early development of the Hydrodyne process showed that the reduction in toughness was influenced by the amount of explosive that was used, the number of detonations, and whether the meat was fresh or frozen. The process was more effective for fresh meat and two detonations using 50 g of explosive were as effective as one detonation using 100 g of explosive. The effect on toughness, as measured by shear force, is dramatic (Figure 9), with improvements of up to 70%. The magnitude of improvement is sufficient to make even cuts high in connective tissue acceptable for table meat (e.g., topside, Figure 9). In the case of the data shown in Figure 9, the cuts were excised from the carcass 1.5 h after death and stored for 1 day at 2–4 °C, explaining the high shear values for control cuts, indicative of cold-induced shortening, and suggesting that the Hydrodyne process was able to overcome this toughening effect. As for many techniques, the magnitude of the effect is influenced by the toughness of control samples and when it was applied to relatively tender pork loins the improvement was only 17%, but the evidence indicates that this technique will also reduce the variation in shear force.

The process has not yet been successfully commercialized and the concept is still under development. A current prototype (Figure 10) can tenderize 270 kg of meat at once. The unit consists of a 3.2-ton steel tank filled with water, which is covered with a 2.3-ton steel dome (see photograph below), 2.7 m in diameter. Cuts of meat, encased in water and pressure-resistant wrapping, are placed into the tank, which is 3 m

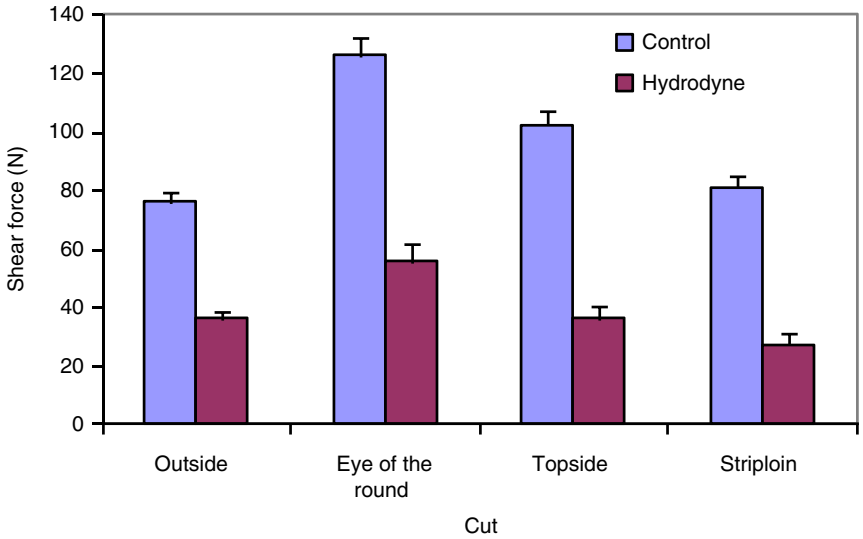

Figure 9 Impact of Hydrodyne treatment on the shear force (N) of beef cuts (8 samples per muscle) after 1 day of aging, and treatment of the cuts after freezing and subsequent thawing. Modified from Solomon, M.B., Long, J.B., Eastridge, J.S., 1997. The Hydrodyne: A new process to improve beef tenderness. Journal of Animal Science 75, 1534–1537.

Figure 10 A large-scale Hydrodyne unit (1060 l) showing the inner section where the encased meat and surrounding water are held, with the large dome in the background. Photograph courtesy of M.B. Solomon.

in the ground, and an explosive charge is detonated in the water less than a meter from the meat. The tank's dome holds in water that is forced upwards. Refinement of the process continues with a focus on variables such as container type (metal vs. plastic), the material used to pack the meat, location of the explosive (distance from meat), and the type of explosive. Future models may be based on generation of shock waves with an alternative to the use of explosives.

Hydrostatic Pressure

Subjecting meat to high pressure via a surrounding liquid has been adopted in countries such as Japan, Australia, and the US in order to extend shelf-life and reduce bacterial counts. The technique is combined with heat treatment (e.g., to 60 °C) while the muscle is under pressure. The method has a high capital cost, limiting adoption, but can also be used to decrease the toughness of meat. First reports on the technique were published in the 1970 s after research in Australia. The technique can be applied to both prerigor and postrigor muscle and, similar to hydrodynamic shock waves, will cause a disruption of muscle structure that is confirmed in electron microscopy studies. Prerigor meat exhibits accelerated glycolysis under pressure/heat treatment and this treatment leads to a significant reduction in shear force (Figure 11). In this case, the shear force values of the m. longissimus from control carcasses indicate cold-induced shortening, yet the negative effects of prerigor excision of muscles through shortening can be overcome by pressure treatment.

Hydrostatic pressure can cause the degradation of specific myofibrillar proteins such as titin and depolymerization of actin, but also appears to decrease the contribution that connective tissue makes to overall toughness. At 100 MPa, structures such as lysosomes are observed to alter shape and, as the pressure rises, disruption of membranes occurs. This disruption leads to the release of catheptic enzymes into the cytoplasm and absorption onto myofibrils. However, given the lack of evidence that these enzymes play a significant role in tenderization, these seem unlikely to contribute to the

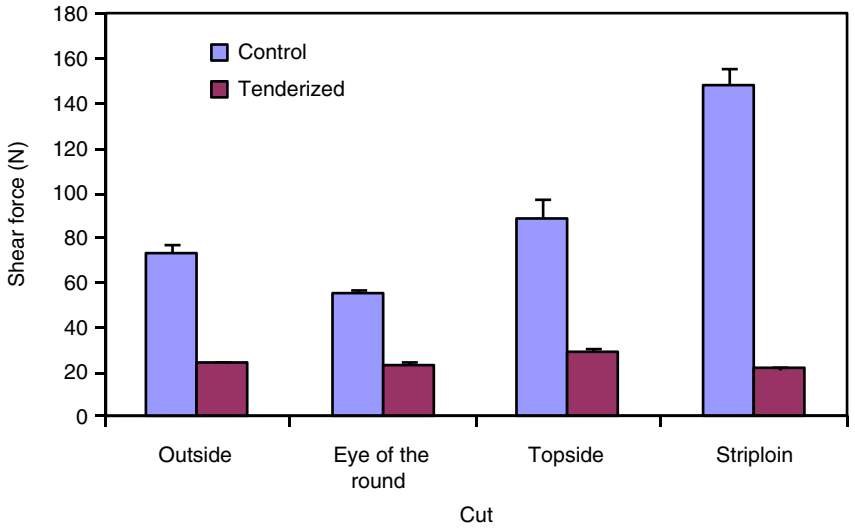

Figure 11 Effect of prerigor pressurization (~100 MPa) at 35 °C for 2 min on the shear force of beef cuts. Modified from MacFarlane, J.J., 1973. Prerigor pressurization of muscle: Effects on pH, shear value and taste panel assessment. Journal of Food Science 38, 294–298.

beneficial effect that arises from this technique. A greater reduction in calpastatin activity than in μ-calpain at pressures above 100 MPa suggests that this enzyme could contribute to the degradation of muscle structure mediated through a rise in the level of free Ca^{2+}, although at pressures above 200 MPa μ-calpain appears to be inactivated. Detailed research examining the effect of this type of pressure on enzyme activity, physical changes in muscle structure, and the impact on tenderness (i.e., shear force) remains to be conducted before the exact mechanism is established. A variation on this approach is to combine pressure treatment with freezing. This involves cooling samples under pressure (200 MPa) to −20 °C and releasing pressure to reach equivalence with atmospheric pressure, causing supercooling of the sample.

Freeze–Thaw

Freezing muscle (i.e., at −20 °C) leads to shrinkage of muscle fibers mediated through a dehydration of cells and significantly increases the fragmentation of myofibrils. The extent of these effects will be influenced by the size of samples and the freezing rate, which impact on thermal gradients within the sample. Reductions of more than 20% in shear force values have been observed in muscle after freezing and thawing during the early stages of aging compared to muscle tested from the fresh state after the same period of aging. The effect will not be observed in 'aged' meat. There are likely to be several explanations for this reduction, which may well interact in a synergistic manner: proteolysis during the thawing phase, physical damage due to the freeze–thaw cycle, or diminished activity of enzyme inhibitors such as calpastatin.

TENDERNESS MEASUREMENT

RW Purchas, Massey University, Palmerston North, New Zealand

Glossary

Intrinsic determinant A feature within the meat that plays a role in determining the level of specific meat quality characteristic such as tenderness.

Proteolysis The chemical reaction that results in breakdown of proteins into smaller parts as peptides or individual amino acids.

Sarcomere length The distance between adjacent Z discs in a muscle fiber or fibril.

Shear force The force required to shear or cut through a piece of meat, that is used as an index of meat tenderness.

Tenderometer An instrument designed to measure the tenderness of meat.

Introduction

Meat tenderness appears at first glance to be simply a measure of the biting effort required. Unfortunately, however, this is an oversimplification as careful mechanical measures of such forces seldom account for more than approximately 60% of the variation in tenderness as assessed by trained panels of people. This is despite the fact that many mechanical devices have been developed, and a number of these are widely used in studies of factors affecting meat tenderness. The inconsistencies between mechanical and sensory assessments of tenderness are at least partly because a consumer's sensory perception of meat tenderness is often influenced by components other than the dominant one of the simple biting force required.

In this article, approaches to the measurement of meat tenderness are outlined, and some terms used to describe tenderness are described first. The main characteristics within meat that play a role in determining its tenderness, the so-called 'intrinsic determinants' of tenderness, are discussed because they influence the extent to which a particular measurement method will be appropriate for a specific situation. Approaches to the measurement of meat tenderness outlined here include primarily the use of mechanical devices such as the Warner–Bratzler shear device, but also the use of descriptive/trained and consumer sensory panels, and some other laboratory methods.

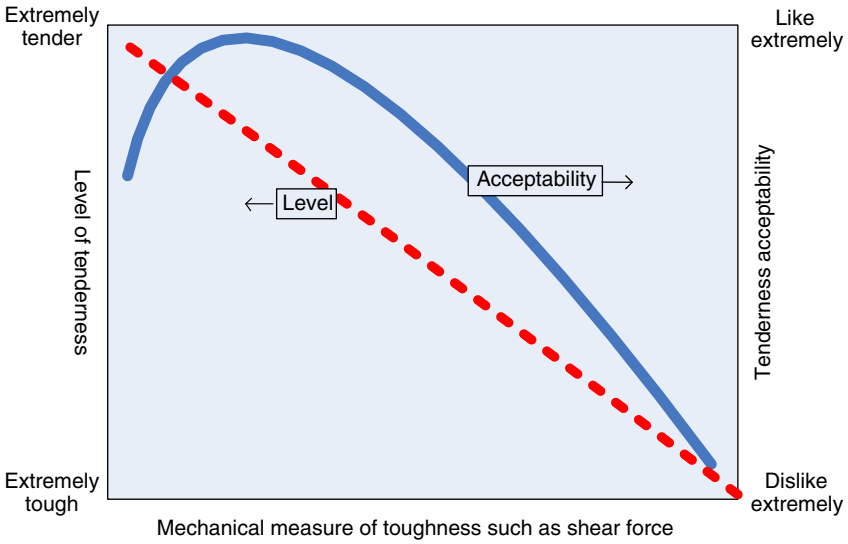

Figure 1 A diagrammatic illustration of how the relationship between sensory tenderness and mechanical measures of tenderness differ depending on whether the sensory panelists score on an acceptability scale (blue solid line), as for a consumer panel, in which case extremely tender meat may be less acceptable, or a level-of-tenderness scale (red dashed line) as used by a trained panel. Note that the closeness of the relationship between mechanical measures and sensory assessments of tenderness is not generally as close as implied by these lines.

Table 1 Some intrinsic determinants of meat tenderness. An intrinsic determinant is a structural or metabolic characteristic within the meat that can be responsible for differences in meat tenderness. The suitability of methods for measuring differences in tenderness for any group of meat samples will depend on which of these or other determinants are responsible for the differences

Intrinsic determinant	*Relationship with tenderness*	*Relative importance and situations where it might be particularly important*
1. Concentration of connective tissue. This tissue consists primarily of the fibrous protein collagen but will also include some elastin and other substances.	Other things being equal, meat containing more connective tissue will be less tender, but this will depend on the nature of the connective tissue and the cooking conditions.	Of medium importance. More important for comparisons (1) between different muscles, (2) between meat samples from older animals or between samples from animals varying widely in age, and (3) when cooking conditions have been mild (i.e., most collagen will not be not dissolved when final internal temperatures are less than approximately 60 °C).
2. The extent of cross-linking between peptide chains within collagen molecules in meat.	Other things being equal, meat containing collagen with less cross-links will be more tender because such collagen will dissolve to form gelatin faster and at lower temperatures.	This is an important source of variation in tenderness if samples vary widely in the level of cross-linking, as might be expected if they are from animals varying widely in age (cross-linking increases with increasing age). It is also more important for fast cooking methods such as frying because the solubilization of collagen is to some extent time dependent. The type of cross-links may influence the extent to which tenderness is affected.
3. The ultimate pH (pH_{ult}) of the meat, as determined primarily by the amount of lactic acid present, which, in turn, is a function of the glycogen levels at the time of slaughter.	Other things being equal, an increase in pH_{ult} from approximately 5.5 (the normal pH_{ult} for meat from a well-fed and unstressed animal) to 6.1 (the peak of toughness, 5.8–6.1) will often lead to tougher meat. With further increases from approximately 6.2 to 7.0, however, the meat becomes tenderer with other deficiencies.	An important determinant of tenderness in some situations where the variability of pH_{ult} is high. In many situations it is of low importance because there is little variation in pH_{ult} between animals.
4. The extent to which muscle is contracted when it sets in rigor mortis, as commonly assessed by the average sarcomere length.	Other things being equal, a greater degree of contraction (shorter sarcomere lengths) will be associated with tougher meat. This relationship is not linear and muscle shortened by more than approximately 40% of its resting length will actually be tenderer due to structural damage.	Very important as a determinant of tenderness under cold shortening conditions when low temperatures prerigor induce muscle contraction. Thaw shortening of meat frozen before the onset of rigor mortis can also lead to very tough meat. If shortening is prevented in some way, this is not an important determinant.
5. The extent to which certain proteins in meat are broken down postmortem through the action of proteolytic enzymes such as the calpains and cathepsins.	Other things being equal, a greater degree of protein breakdown is associated with tenderer meat, but the extent of this effect will depend on the specific proteins that are cleaved.	An important determinant of the extent to which tenderness improves with aging of meat at temperatures above freezing. It also accounts for some genetic differences in tenderness through varying levels of either proteolytic enzymes (e.g., the calpains) and/or their inhibitors (e.g., calpastatin).
6. The concentration of intramuscular fat (marbling) in muscle. Levels vary from less than 2% in many lean meat products through approximately 3–4% when the marbling first becomes clearly visible, up to levels of more than 30% in very heavily marbled products.	Other things being equal, more highly marbled meat will be somewhat tenderer. The reasons for this are unclear but probably include the fact that the meat will tend to be more juicy, muscle fibers and connective tissue are diluted by fat, and a reduced likelihood of prerigor shortening.	This determinant seldom accounts for more than 10% of the variation in tenderness but is more likely to be more important when there is a wide variation in marbling levels.

Descriptive Terms and Scales

When meat tenderness is measured by a sensory panel, higher values usually indicate more tender meat either on an acceptability (hedonic) scale or on a level of tenderness scale. However, these two scales do not necessarily correspond, as, although a lower acceptability of tenderness is usually due to a greater toughness, this is not always the case as meat can also be less acceptable because it is too tender to the point of being mushy and textureless, as illustrated in Figure 1. When measured mechanically, tenderness is usually expressed in terms of some measure of resistance such as shear force in kilogram (kgF) or newtons (N), so that, in contrast to sensory scores, low values indicate more tender meat. Being aware of these distinctions is crucial when interpreting published data on meat tenderness. Unfortunately, there is no harmonization of the shear force values between the various measurement devices. The Warner–Bratzler values are

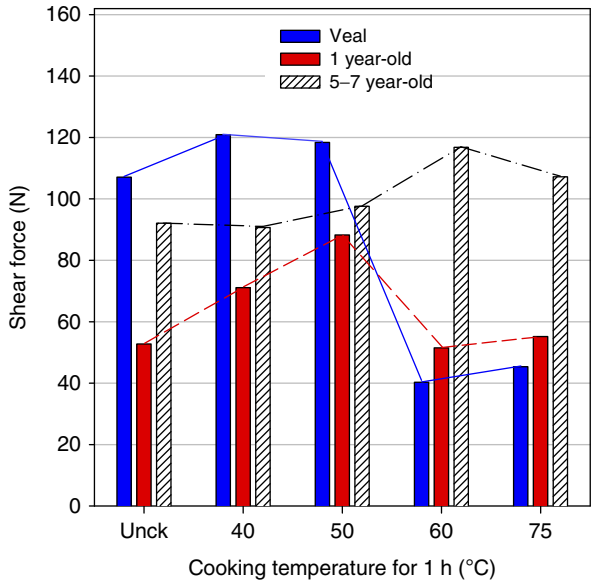

Figure 2 Toughness (as assessed by Warner–Bratzler shear force) of uncooked meat and meat cooked to temperatures from 40 to 75 °C for samples of deep pectoral muscle from veal calves, yearling steers, and 5–7 year old cows. Veal meat was tougher at temperatures <50 °C because of higher collagen concentrations but was more tender at higher temperatures because the collagen present was more readily solubilized on heating. Adapted with permission from Bouton, P.E., Harris, P.V., 1972. The effects of cooking temperature and time on some mechanical properties of meat. Journal of Food Science 37, 140–144.

approximately 0.7 times those of the MIRINZ tenderometer, but the relationships with other devices is not standardized. This is a limiting factor in international usage and comparisons of processing.

Meat texture is a term that is sometimes used as a synonym for tenderness, which can be confusing as it is also used to denote the appearance of fineness or coarseness of meat. When used as a descriptor of palatability rather than appearance, the term will often have a broader meaning than tenderness and may include assessments of features such as mealiness, coarseness, cohesiveness, juiciness, chewiness, and fattiness as well as the force required to bite through a sample.

Intrinsic Determinants of Meat Tenderness

Muscle is a complex and sophisticated biological tissue. It is, therefore, not surprising that there are many structural and metabolic characteristics of meat that can affect its tenderness at the time of consumption or measurement following cooking. Some of these features, which are termed the intrinsic determinants of tenderness, are listed in Table 1. For two similar meat samples any difference in tenderness will sometimes be totally attributable to only one intrinsic determinant, but usually several of those listed in Table 1, and possibly others as well, are involved. This background on intrinsic determinants is relevant to the measurement of tenderness because the suitability of some methods will depend on the extent to which the various determinants are responsible for variation in tenderness.

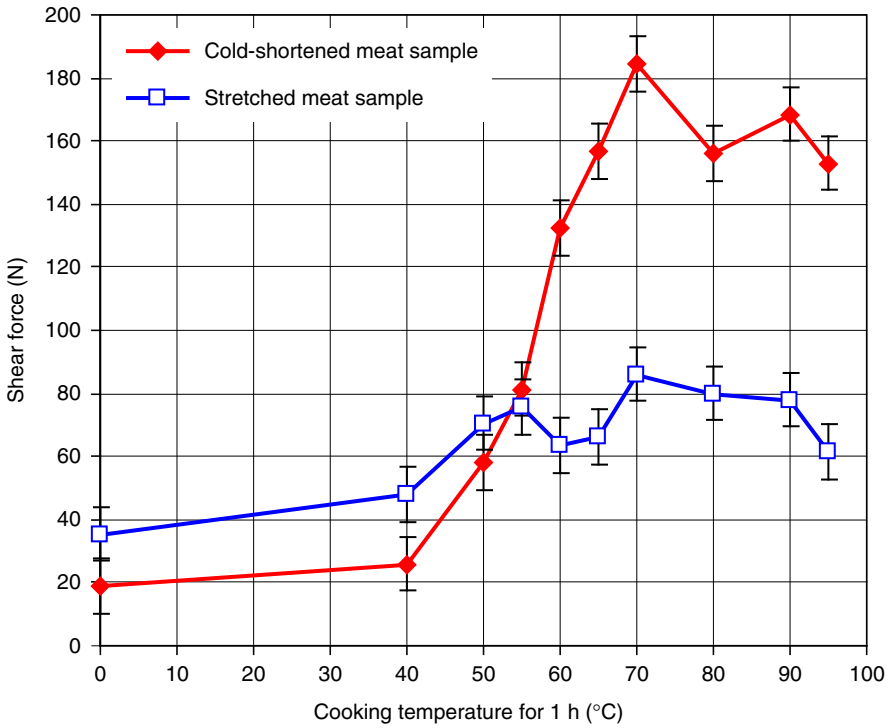

Figure 3 Results showing a large effect of cold shortening on changes in Warner–Bratzler shear force with increasing cooking temperature such that the toughening effect of cold shortening was only apparent after cooking to 60 °C or more. Samples were of beef semitendinosus muscle. Data adapted from Bouton, P.E., Harris, P.V., Shorthose, W.R., 1976. Dimensional changes in meat during cooking. Journal of Textural Studies 7, 179–192.

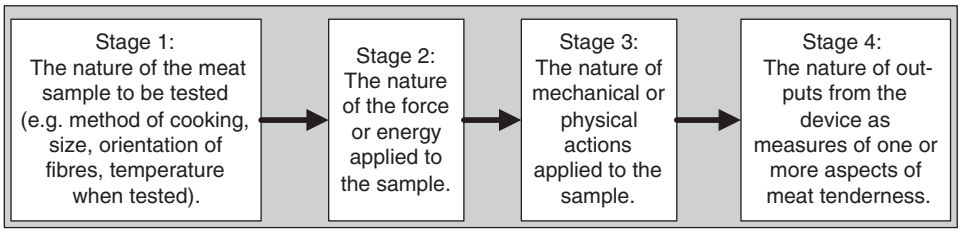

Figure 4 Four stages during any mechanical method of meat tenderness measurement when the nature of the procedure followed may influence the measurements obtained.

Table 2 Examples of mechanical actions used to obtain measures of meat tenderness. Because of variation in tenderness within a muscle, it is usual practice to make from 6 to 12 measurements on cores (1 or 2 per core) from the same steak to obtain a satisfactory overall measurement

Mechanical action	*Examples of devices and the aspects of tenderness measured*
1. A shearing action where the force required to cut through a meat sample is measured by the movement of metal blades relative to each other in a scissors-type action. Measurements made by the so-called shear devices often encompass tensile and compression stresses as well as shear stresses.	The most widely used device in this category is the Warner–Bratzler (WB) shear, which measures the force required to pull a cutting blade with rounded edges between two metal plates when a cylindrical core of meat is placed within a vee-shaped opening in the blade (**Figure 5(a)**). Alternative forms of this basic system involve the replacement of the vee-shaped shearing edges with a straight horizontal edge, and the use of samples that are cuboidal rather than cylindrical. The use of cuboidal samples and a straight edge produces force-deformation curves with higher peak forces. A good example is the slice shear force device that uses a 50 mm square blade to shear through a slab of cooked meat that is 10 mm thick and 50 mm wide and that has been carefully prepared so that the shear is at right angles to the fiber direction. Although WB shear forces primarily reflect the myofibrillar contribution to tenderness, the difference between peak force and initial yield also provides an indication of the connective tissue contribution.
2. A biting action where the force required to bite through a sample is recorded. The biting part is usually in the form of one or two blunt metal that are vee-shaped 'teeth' of the same width as the sample that they bite through (**Figure 5(b)**).	The Volodkevich and MIRINZ tenderometers are good examples of instruments based on this principle, although a number of others have been produced. Results obtained are usually highly correlated with WB shear values and reflect primarily the myofibrillar contribution to tenderness, but differences in tenderness due to other determinants (e.g., connective tissue or marbling fat) also contribute. The 'slice shear force' system and the Meullenet–Owens razor shear are essentially biting-type actions, with a sharper 'tooth' in the latter case.
3. A compressing action where a plunger is pushed into the meat sample which may or may not be constrained on two sides (**Figure 4(c)**). The maximum compression force is usually measured when the sample is compressed to a specified proportion (commonly 80%) of its initial thickness.	A number of devices based on measures of compression have been developed with variation in the nature of the plunger and the way the meat sample is held. Compression tests are well suited to provide information on rheological parameters. Compression tests on uncooked meat have provided useful information on subsequent cooked-meat tenderness in some studies. These tests appear to reflect the connective tissue contribution to tenderness to a greater extent than shear or biting tests.
4. A penetrating action where the force required to penetrate the meat samples is measured.	This approach has been widely tested, usually with a bank of pins of some sort, but the results have been variable and this approach has not been widely used.
5. Measures of tensile strength or the force required to stretch and break a meat sample by pulling in a direction either parallel to the fibers or perpendicular to the fibers.	The force required to separate muscle fibers perpendicular to their length is indicative of the connective tissue contribution to tenderness and is referred to as 'adhesion.' Other tensile strength measures are not commonly used.
6. Measures of the energy (usually electrical energy) required to mince a sample of meat under standard conditions.	Moderately good correlations with sensory tenderness have been shown, but the approach is rarely used.
7. Measures of the effects of a standard homogenizing treatment in terms of the size of the fragments produced. Commonly termed the myofibrillar fragmentation index (MFI).	This is primarily a measure of the fragility of the muscle fibers and is used as an index of the past proteolytic activity within the meat. The fragment size may be measured by levels of turbidity, by filtration, or by direct measures of fragment size using a microscope and often with the aid of an image analysis program.

Measurement of Tenderness of Cooked versus Uncooked Meat

Almost all meat is cooked before consumption, so tenderness measurements are best made on samples that have been cooked in the way the meat is normally eaten. This is the usual practice, but it would also be very useful if meat in an intact carcass could be assessed for tenderness (preferably in a non-intrusive manner) so that the information could be used as a grading criterion and premiums be given for carcasses yielding more tender meat. Unfortunately, the accurate measurement or prediction of cooked-meat tenderness using uncooked meat is difficult for two main reasons. First, changes in tenderness with cooking vary depending on the temperature and time involved and on characteristics such as collagen solubility and the ratio of collagen to muscle fibers in the meat. This is because the collagen contribution to tenderness decreases with increasing temperature as an increasing proportion is converted into insoluble gelatin, whereas the contribution of muscle fibers increases as the proteins within the fibers denature (see Figure 2). Results in Figure 2 illustrate this effect with the shear value for veal being highest at lower temperatures before collagen dissolves, but lowest at higher temperatures because collagen in veal is more soluble. Shear force can potentially be predicted by using noninvasive near-infrared spectroscopy (NIR) on uncooked meat where it has been shown to perform as well as by the reference method – it measures chemical changes as the meat tenderizes. However, NIR tenderness evaluations will be most accurately close to consumption and any prediction will, therefore, need to take account of both the time of measurement and cooking procedures.

Second, some factors, such as cold shortening, have a major effect on the tenderness of cooked meat but no effect or even the opposite effect on uncooked meat. This is illustrated in Figure 3, where the toughening effect of cold shortening only became apparent when samples of beef semitendinosus were cooked to temperatures greater than 55 °C.

Thus, it is only when tenderness differences are due to intrinsic determinants that have similar effects on cooked and uncooked meat that direct measures of tenderness on uncooked meat will be particularly useful. Because of variable cooking effects, it is important in tenderness research experiments that cooking methods be standardized with respect to sample size to be cooked, cooking temperature, final internal temperature, and cooking time. Cooking methods should also be similar to those commonly used for the type of meat involved. Cooking methods differ to some extent between meat research laboratories, which means that the direct comparison of results need to be made with care, but the fact that a range of methods are used increases the chance of important interactions between cooking parameters and other factors affecting tenderness being revealed.

Mechanical Methods of Tenderness Measurement

Many devices have been developed to mechanically or physically measure the forces required to disrupt meat in some way. They can be categorized according to the way the force is applied, the type of action (biting, shearing, compressing, etc.), the way the meat is prepared and orientated within the device, and the way the measurements are expressed (Figure 4).

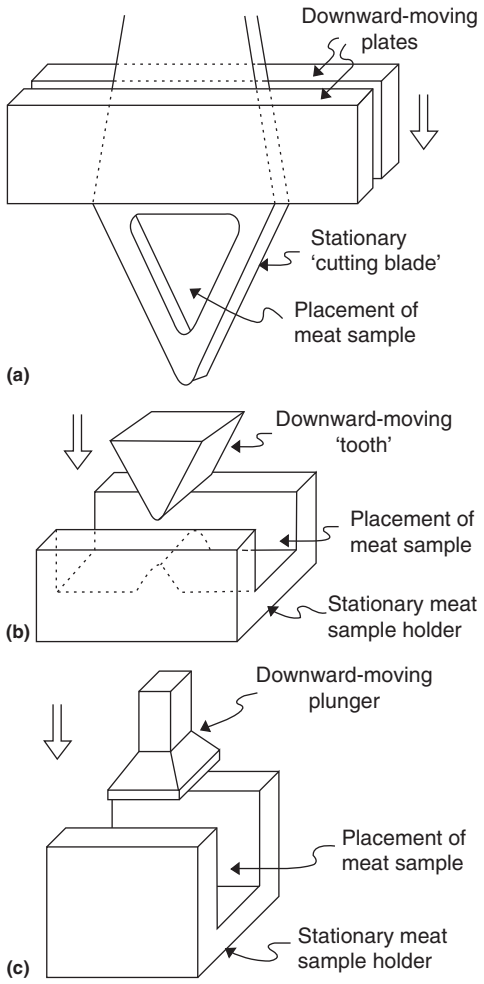

Figure 5 Diagrams showing three examples of types of mechanical action used to measure meat tenderness: (a) shearing; (b) biting; and (c) compressing. For some devices, the part shown as moving will be stationary and vice versa.

Most devices have a constant rate of movement (the crosshead speed) with changes in the force required being measured with movement through the sample to produce a force-deformation curve. For some devices, a sinusoidal change in rate of movement is employed. Alternatively, the force is increased at a constant rate, so that a curve of distance through the sample against force or time is produced. In both cases, the output most commonly reported is the maximum or peak force required to complete the test. Outputs in addition to the peak force that are sometimes reported include:

1. The area under the curve as a measure of the total work done.
2. An initial yield force represented by a shoulder or peak on the rising side of the force-deformation curve. This has been shown to be a useful indicator of the myofibrillar contribution to tenderness.

Table 3 Important aspects of the measurement of meat tenderness by sensory panels are illustrated here by comparing features of a consumer panel and a 'descriptive,' 'analytical,' or 'trained' panel

Feature	*Consumer panel*	*Descriptive or analytical panel*
1. Broad aim	To assess the acceptability of the tenderness of the samples for a specified population of meat consumers.	To determine whether differences in tenderness or certain components of tenderness differ between groups of samples.
2. Number of panelists	Relatively large numbers are required in order to obtain a representative sample of the population. A minimum of 6 would be needed for a trained panel, and absolute minimum of 50 for a consumer panel, with 100 more preferable.	Relatively low numbers may be used, especially if panelists are highly selected and trained.
3. Selection of panelists	Selection should be such that a representative sample of the population of interest is obtained.	Panelists are commonly selected on their ability to detect small differences in the parameters of interest in a repeatable and consistent manner.
4. Training of panelists	Training is minimal or nonexistent as it is important that panelists represent typical consumers.	Training with meat samples of the type to be assessed is important so that all panelists are conversant with the terms used and the ranges that are more likely to be encountered.
5. Site where samples are assessed	The site should be similar to the environment where meat is normally consumed such as in the home or at a commercial eating place.	Tasting is carried out under controlled conditions so that effects of extraneous variables (lighting, smells, other people, etc.) are minimized.
6. Methods of sample preparation	Methods should match closely those normally used by consumers, although detailed instructions on preparation methods will normally be given.	Methods are closely controlled and designed to facilitate the acquisition of answers to the questions being addressed.
7. Number of samples and complexity of the questions asked	A small number of samples and of questions per sample. Questions should be expressed in terms of tenderness acceptability or desirability rather than the level of tenderness or related characteristics. Acceptability scales are referred to as hedonic scales.	The number of samples and the number and complexity of the questions can be greater because the panelists are trained. Panelists should not be expected to provide useful acceptability assessments. An example of characteristics covering a range of tenderness components is given in **Table 4**.

3. The difference between the peak force and initial yield force as an indication of the connective tissue contribution to tenderness.
4. The peak force or work required to pass a certain proportion of the way through or into a meat sample (used mainly with compression tests where compression by 20% or 80% is often used).
5. Rheological parameters such as stress and elasticity can be calculated when more than one cycle of actions are carried out for some forms of measurement such as by compression.
6. A measure of the electrical power required can be used when a meat sample is minced under standard conditions.

Examples of types of mechanical action that have been used to obtain measures of meat tenderness are outlined in **Table 2**. This is not an exhaustive list and some devices involve more than one action, three examples of which are shown in **Figure 5**.

For most mechanical measures of tenderness, the sample is arranged so that the force to cut or shear across muscle fibers is measured, but additional, and sometimes quite distinctly different, information is obtained when the sample is turned by 90° either horizontally or vertically from this usual orientation.

Sensory Methods of Tenderness Measurement

The use of groups of people (sensory panels or taste panels) to assess the tenderness of meat samples is the ultimate test because tenderness has to be defined in terms of people's perceptions. Despite this, sensory methods are not used as widely as mechanical methods because of variation between people (even after a period of training), and because the approach is slower, more expensive and requires larger amounts of meat. Many types of sensory panel have been used, but their main features are summarized in **Table 3** by comparing a consumer panel with a descriptive (also known as an analytical, trained, or laboratory) panel. The items listed in **Table 4** illustrate the multidimensional nature of meat tenderness and hence the limitations of simple mechanical measures, although it should be noted that in that example the closely related characteristics of both tenderness and texture were being assessed.

Within a sensory panel, there are several alternative ways in which panelists may record their assessments, including:

1. On a category scale of 5–9 steps, with each step given a specific description (e.g., a scale from extremely tender to extremely tough). A simplification is where only some of the steps are described.
2. A line scale, usually 100 or 150 mm in length, with no steps but with descriptors at the extremes and sometimes at the midpoint. Panelists mark a point on the line for each sample.
3. An open-ended line scale with a single anchor point that is described. This approach is referred to as 'magnitude estimation' and is a form of ratio scaling where the tenderness of one control sample is assigned a specific value and all others are compared with the control.

Table 4 The complexity of tenderness as a characteristic of meat is illustrated by the examples in this table of characteristics of lamb texture that panelists were asked to assess in a study investigating the texture and tenderness of lamb meat

Aspect of tenderness or texture	*Subcategories within the aspect*
1. Elasticity on partial compression	
2. First bite properties	a. Compressibility
	b. Moisture release
	c. Fat amount
	d. Fattiness
	e. Cohesiveness
3. Mastication properties	a. Number of chews
	b. Chewiness
	c. Rate of breakdown
	d. Fibrousness
	e. Coarseness of fiber
	f. Moisture release
	g. Moisture absorption
	h. Cohesiveness
	i. Fattiness
	j. Fat amount
	k. Uniformity
	l. Density
	m. Connective tissue (6 options)
	n. Connective tissue amount
4. After-feeling properties	a. Ease of swallowing
	b. Mouthcoating type (2 options)
	c. Mouthcoating amount
	d. Fat amount
	e. Particle type (15 options)
	f. Particle amount
	g. Tooth packing
5. Amplitude (an overall impression)	

Source: Adapted from Jeremiah, L.E., 1988. A comparison of flavour and texture profiles for lamb leg roasts from three different geographical sources. Canadian Institute of Food Science and Technology Journal 21, 471–476.

4. Two or more samples are ranked with respect to specific characteristics in a difference test. Panelists may also record the size of the difference between adjacent samples in a ranked list. The triangle test is a special form of difference test where panelists identify the different sample in a set of three, two of which are the same.

Examples of ways in which sensory panels can be made more objective include:

1. Having the panelists count the number of chews required before meat is swallowed.
2. Using electromyography to record the action of the masseter (cheek) muscles during chewing.
3. Using time-intensity methodology whereby the panelist records (with the aid of a computer mouse) the change in tenderness as the meat is consumed.

Other Methods of Tenderness Measurement or Prediction

Generally, methods other than those employing sensory panels or mechanical methods involve measuring characteristics associated with only one or two intrinsic determinants of tenderness (Table 1) and hence will only be useful when only those determinants are responsible for the tenderness differences of interest. Thus, the value of these methods tends to be limited to particular situations. Examples are as follows:

1. Intramuscular fat content: Relationships with tenderness are not close but are almost always positive as explained in Table 1 (item 6). Although intramuscular fat levels are most often measured by solvent extraction, they can also be assessed reasonably accurately by NIR spectroscopy or by visual appraisal or VIA below.
2. Sarcomere length: Shorter sarcomere lengths, which can be measured by microscopy or laser diffraction, tend to be associated with less tender meat as explained in Table 1 (item 4).
3. Collagen content: Higher concentrations of collagen, as assessed by the hydroxyproline content in meat, will often mean lower levels of tenderness (Table 1, item 1).
4. Collagen solubility: High collagen solubility, as assessed by the extent to which it is dissolved by a standard heating treatment, tends to be associated with more tender meat (Table 1, item 2).
5. Ultimate muscle pH: Ultimate pH is either measured by a pH meter and probe or can be predicted from glycogen levels at slaughter. Its relationship with tenderness is outlined in Table 1 (item 3).
6. Video image analysis (VIA): Several characteristics can be measured by VIA including color, marbling fat, and connective tissue content, so the possibility of predicting tenderness exists.
7. Meat color: The relationship with tenderness is not close and probably arises at least in part from the link between color and pH. Meat color may be assessed subjectively with the aid of standard colors, with a reflectance spectrophotometer to give L^*, a^*, and b^* values or by VIA.
8. NIR spectroscopy: This technique will also provide a measure of a number of characteristics of meat when a cut surface of uncooked meat is scanned, including fat content and color as well as meat tenderness. The measurements can be made very quickly and preliminary results have been promising when it is used as a means of sorting carcasses or cuts of meat into two categories. For example, the terms 'predicted tender' and 'not predicted tender' have been used for the two categories in some studies.
9. SDS-PAGE and Western blotting: This technique can be used to quantitate the proteolysis of muscle proteins, which is usually associated with more tender meat. The proteins which are usually targeted are troponin-T, which breaks down to a 30 kDa protein, titin, which breaks down from a singlet to a doublet or triplet, and nebulin. Other muscle proteins have also been used as indicators of proteolysis.
10. Myofibrillar fragmentation index (MFI): This technique can also be used to quantitate the proteolysis of muscle proteins, which is usually associated with more tender meat. The procedure involves homogenizing the meat in a

standard way in buffers and measuring the size of the fragmented myofibrils to get an index.

THERMOPHYSICAL PROPERTIES

SJ Lovatt, AgResearch Ltd., Hamilton, New Zealand

Glossary

Density The ratio of an object's mass to its volume.
Enthalpy The total heat content of an object, often expressed per unit mass.
Freezing temperature The temperature at which a material starts to freeze.
Heat capacity The derivative of enthalpy with temperature, under either constant pressure or constant volume conditions.
Latent heat The amount of heat that is released or absorbed when a material changes phase between solid and liquid (melting/freezing), liquid and gas (boiling/condensing), or solid and gas (subliming/deposition).
Moisture diffusion The movement of water through a solid.

Introduction

The thermophysical properties of meat products are relevant for many purposes, including:

- calculating chilling, freezing and cooking times, and heat loads;
- designing drying, salting, and other value-adding processes;
- modeling meat processing operations;
- calculating yields and mass balances in meat processing; and
- calculating behavior during transportation.

The quality and microbial status of a meat product are usually strongly dependent on the thermal and physical processes to which the meat is subjected, so the ability to model thermal and physical processes accurately is important when one needs to calculate the meat quality attributes and the microbial growth that may result from these processes. In turn, accurate knowledge of the thermophysical properties of meat products and the materials typically found in meat processing operations is essential to the accurate modeling of the thermal and physical processes.

Typical values and simple methods of estimating these properties are provided in this article but when accurate values are required for process design (for instance), reference should be made to the books and articles that report data for the specific materials to be used.

The SI unit for temperature is Kelvin, K, but the degree Celsius, °C, is the same size and is often more convenient for the temperatures of importance to meat science, so both temperature units are used in this article.

Density

The density of a substance is the ratio of its mass to its volume, as shown in eqn [1].

$$\rho = \frac{m}{V} \quad [1]$$

In this equation, ρ is the density in kg m^{-3}, m is the mass of the substance in kg, and V is the volume of the substance in m^3.

The specific volume of the substance, v, in m^3 kg^{-1}, is defined as the reciprocal of the density, as shown in eqn [2].

$$v = \frac{1}{\rho} \quad [2]$$

The concept of density is not as straightforward as one might imagine at first, because it depends on both the mass and volume of the substance. Mass is fairly simple and it can be measured with considerable accuracy but the meaning of a substance's volume is more complex.

The most important issue in measuring volume is whether one should or should not include any void space that may be around or within the substance in which one is interested. A cut of fresh meat would not be expected to contain much void space within itself. Its volume could, therefore, be measured by (for instance) measuring the amount of liquid that it displaces when it is completely submerged. Even then, meat will typically absorb some moisture over time and so the amount of liquid displaced will reduce as this absorption takes place. This effect is particularly important for pieces of meat with high ratios of surface area to volume, such as poultry or offal.

A package containing meat could contain a substantial amount of void space, often air, and one must then take considerable care. The appropriate volume to use when calculating density will depend on the purpose for which it is required. For example, if one was interested in the mass of packaged meat that one could fit into a shipping container, one would use the volume of the whole package and therefore calculate the figure known as the 'bulk density.' Alternatively, when one is calculating the chilling time for the package, one often needs to convert the thermal properties from a

 doi:10.1016/B978-0-12-384731-7.00133-1

volumetric to a mass basis. In this case, one should use the volume of the meat contained in the package.

Finally, some meat products such as free flow frozen meat pieces can contain significant amount of air within their overall dimensions, so the relevant density will depend on whether the product is being heated or cooled as individual pieces or as a collection of pieces in a package.

Fresh meat comprises mostly water, protein, fat, and, sometimes, bone. Dry protein has a density somewhat greater than that of water and dry fat has a density somewhat less than that of water. Many products that are predominantly made of lean meat, therefore, have a density close to that of water, i.e., between approximately 950 and 1080 kg m^{-3} in the range 0–100 °C. If it is necessary to estimate the density of a meat product with greater accuracy, the volume of the whole product is usually equal to the sum of the volumes of the components that make up that product. Exceptions to this rule apply when the components dissolve in each other (as with alcohol and water, for instance), but this does not usually apply for the components making up meat products. Thus, if one knows the composition of a meat product, one can estimate its density as shown in eqn [3].

$$\frac{1}{\rho} = \sum_{i=1}^{n} \frac{x_i}{\rho_i} \qquad [3]$$

In eqn [3], x_i is the mass fraction of the ith component, ρ_i is the density of the ith component in kg m^{-3}, and n is the number of component materials in the meat product.

Table 1 shows density values for some common components of meat products at typical processing temperatures.

The densities of most materials vary with temperature, generally decreasing as the material's temperature increases. For water-based materials, such as meat, the density of the water component is affected by its hydrogen-bonding behavior, with the result that the density of liquid water reaches a peak at approximately 4 °C. Similarly, although the densities of most materials increase when they freeze, water is again unusual and ice is less dense than liquid water under most conditions.

The density of a meat product below its freezing temperature can be estimated using eqn [3], but it is necessary to include both water and ice as components and also to estimate the fraction of water that is still liquid and the fraction that has become ice from the temperature, T, of the meat. An approximate value of the ice fraction at a given temperature, below the initial freezing temperature, is given by eqn [4], where T_f is the initial freezing temperature of the meat in °C, x_{ice} is the mass fraction of ice, and x_{water} is the total mass fraction of water (frozen and unfrozen).

Table 1 Approximate density values for some meat components at typical food processing temperatures

Component	*Density (kg m^{-3})*
Water	1000
Ice	920
Protein	1400
Fat	900–950
Air	1.29 (at 0 °C)

$$\frac{x_{ice}}{x_{water}} = 1 - \frac{T_f}{T} \qquad [4]$$

Equation [4] overestimates the ice fraction when the temperature T is low (typically −20 °C and below) because it does not consider the bound water in the food, which never freezes no matter how low the temperature becomes.

Freezing Temperature

The water content of meat is in the form of a complex solution with many solutes present in different concentrations. The presence of these solutes depresses the initial freezing temperature of the solution (and, hence, of the meat) below the freezing temperature of pure water (0 °C).

The freezing temperature of any solution is depressed from the freezing temperature of the pure solvent. If one assumes that the solute is insoluble in the solid solvent, the freezing point of the solution is determined by the equilibrium of chemical potentials between the pure solid and the liquid solution. The details of the mechanism are described in physical chemistry texts. In simple terms, when the first ice crystal forms in the meat, it comprises almost pure ice, thereby causing the diffusion of the solutes into the remaining solution, increasing the concentration of that solution, and further depressing the solution's freezing temperature. As additional ice crystals form, the concentration of the remaining liquid increases further and its freezing temperature is depressed still further. This results in meat freezing progressively over a range of temperatures.

Meat has a freezing temperature range, depending on the concentration of the water solution at any point in time, so the expression 'freezing temperature' usually refers to the initial freezing temperature at which ice crystals first begin to form. Even this temperature can be difficult to determine, because the formation and growth of ice crystals requires that there be sufficient 'undercooling' or 'supercooling' below the initial freezing temperature to initiate nucleation and drive crystal growth. At high freezing rates (as may be found in cryogenic freezing) or in some special circumstances, the amount of undercooling can be many degrees Celsius. At typical meat industry freezing rates, however, undercooling amounts are typically no more than a few tenths of a degree Celsius, and can, therefore, be neglected. The need for undercooling means, among other things, that it is possible to store meat in an environment that is a little colder than its freezing temperature without ice crystals beginning to form, in order to maximize its storage life while maintaining a chilled state.

The initial freezing temperature of meat depends on its composition, but −1 °C is often assumed to be representative for lean meat with a high (approximately 70–80%) moisture content. Meat products with higher fat content, added components, such as salt, and dried meats can have freezing temperatures several degrees lower than this.

Compositional approaches based on the average molecular weight of solutes have been found to estimate the initial freezing temperature of meat with an average absolute error of approximately 0.25 °C. If a more precise estimate of the initial

freezing temperature is required, the data must be obtained by measurement.

Glass Transition

A glass is a metastable noncrystalline solid with a very high viscosity. This state can be formed when a liquid is cooled very quickly and its molecules slow their movement to the point where they cannot reach the preferred crystallized state. The characteristic temperature, below which a glass is formed, is known as the 'glass transition temperature,' or T_g'. Because the rate of deterioration of a food product is often determined by the diffusion of solutes through the product, the ability to store products near or below T_g', where this diffusion rate is very slow, could be expected to greatly extend the storage life of a product. The absence of ice crystals in a glassy product is also advantageous because the growth of ice crystals can damage cell walls and cause solute diffusion that can degrade the quality of the product over time, or when it is thawed.

T_g' is typically measured using a differential scanning calorimeter, but it is difficult to measure accurately. Values have been reported by some researchers to be in the range $-11\,^{\circ}\mathrm{C}$ to $-13\,^{\circ}\mathrm{C}$ for mackerel, cod, trout, mutton, and beef, and $-13\,^{\circ}\mathrm{C}$ to $-17\,^{\circ}\mathrm{C}$ for chicken.

Enthalpy, Latent Heat, and Specific Heat Capacity

Enthalpy (for which the symbol is usually H) is the heat content of a substance per unit mass of that substance, measured in $\mathrm{J\,kg^{-1}}$. Thus, to change the temperature of a kilogram of meat from an initial temperature, T_1, to a higher temperature, T_2, it would be necessary to add an amount of heat equal to the difference between the enthalpy of that meat at T_1 and its enthalpy at T_2.

Enthalpy has no physically defined zero point, so zero points can be defined arbitrarily. This has the unfortunate consequence that different authorities have defined the zero point differently, and so it is important to ensure that the zero point is defined consistently (or that an appropriate adjustment is made) when comparing enthalpy data from different sources. For foods, the zero point is often defined to be $-40\,^{\circ}\mathrm{C}$ (so that enthalpies in normal ranges of temperature are always positive), or sometimes $0\,^{\circ}\mathrm{C}$, both at a pressure of 1 atm. For other materials that are commonly used in food processing (refrigerants or steam, for instance), the zero point can be defined quite differently – for instance, enthalpy may be set equal to zero for saturated liquid at the material's triple point. None of this should be important as calculations should only be done with enthalpy differences, but it can be a source of confusion. Similarly, there is no significance in an enthalpy value being less than zero because this is just a result of where the zero point has been defined.

The specific heat capacity, C, is the amount of heat required to raise the temperature of a unit mass of material by a unit temperature change, measured in $\mathrm{J\,kg^{-1}\,K^{-1}}$. Specific heat is usually defined under conditions either at constant volume (written as C_v) or constant pressure (written as C_p). This can make a significant difference for the specific heat of a gas but, because the pressure dependence of specific heat for food materials is small except at extremely high pressures, specific heat values for foods are usually reported at constant pressure and these values can be applied with good accuracy for all conventional food processing operations.

Enthalpy and specific heat are related by eqn [5].

$$C = \frac{\mathrm{d}H}{\mathrm{d}T} \qquad [5]$$

When freezing, a substance will release a considerable amount of heat without any temperature change as its liquid content becomes solid. This is known as the latent heat of freezing, H_f, measured in $\mathrm{J\,kg^{-1}}$. For a pure substance, such as water, this results in a discontinuity in eqn [5] at the freezing temperature, T_f, because the enthalpy changes substantially with no change in temperature. Even for meat and other food products, C can become quite large near the initial freezing temperature and this can make some calculations relatively difficult. As a result, it is often better, near the freezing point, to calculate in terms of enthalpy instead of specific heat, if possible.

H_f for water is $334\,\mathrm{kJ\,kg^{-1}}$, but the water content of meat becomes ice over a range of temperatures, as estimated by eqn [4]. As a consequence, some of the water content of a meat product will remain unfrozen even well below the initial freezing temperature and the latent heat content of meat is released during freezing, based on the change in ice fraction with temperature.

For the temperature ranges of practical interest in meat processing, the heat capacity of meat can be estimated from the heat capacities of its components, weighted by their mass fractions, as shown in eqn [6], where C_i is the heat capacity of the ith component in $\mathrm{J\,kg^{-1}\,K^{-1}}$.

$$C = \sum_{i=1}^{n} C_i x_i \qquad [6]$$

When no phase change, such as freezing, takes place, the heat capacities of most materials change only relatively slowly with temperature and so can be assumed to be constant. Some approximate heat capacities for meat components are shown in Table 2.

The heat capacity of meat fat can be strongly dependent on the composition of that fat so, for accurate work, it is necessary to understand that composition in detail or to measure the heat capacity. This can be particularly important for cooking processes, where each fat fraction will melt at a different temperature. The latent heat required to melt each fat fraction can be accounted for either by assuming a higher effective heat capacity

Table 2 Approximate heat capacity values for some meat components at typical food processing temperatures

Component	*Heat capacity ($\mathrm{kJ\,kg^{-1}\,K^{-1}}$)*
Water	4.18
Ice	2.09
Protein	2.01
Fat	1.98
Air	1.005

for the overall fat in that temperature range, or by dealing separately with the thermal properties of each fat fraction.

If eqn [6] is used to calculate a specific heat capacity for frozen meat of a specific composition, C_S, and for unfrozen meat of the same composition, C_L, the change in enthalpy, ΔH, between a frozen temperature, T_1, and an unfrozen temperature, T_2, can be estimated from eqn [7], where x_{ice} is the mass fraction of ice at the temperature T_1.

$$\Delta H = C_S(T_f - T_1) + H_{f,water}x_{ice} + C_L(T_2 - T_f) \qquad [7]$$

It is sometimes useful, particularly when modeling food processing operations, to express enthalpy, latent heat, and specific heat capacity in volumetric terms (i.e., J m^{-3}, J m^{-3} and J m^{-3} K^{-1}, respectively). This can be achieved by multiplying the mass-based property values by the density of the substance.

Thermal Conductivity

The thermal conductivity, k, of a material defines the ease with which heat passes through the material, measured in W m^{-1} K^{-1}. For a slab of material (e.g., meat) where heat passes directly from one side to the other (i.e., the edges are perfectly insulated), thermal conductivity is defined by eqn [8].

$$Q = \frac{kA}{x}(T_a - T_b) \qquad [8]$$

In eqn [8], Q is the rate of heat flow through the slab in W, A is the cross-sectional area of the slab perpendicular to the direction of heat flow in m^2, x is the thickness of the slab in the direction of heat flow in m, and T_a and T_b are the temperatures on each surface of the slab in °C. Although thermal conductivity is defined in eqn [8] as applying to a slab, the concept applies equally to any physical geometry.

The thermal conductivity of a substance depends on the composition of the substance, as with heat capacity, but it is also strongly dependent on the structure of the substance. As a consequence, it is considerably more difficult to predict the thermal conductivity of a material than to predict heat capacity, for instance. Literature reviews have listed dozens of generic theory-based prediction methods. Including empirical curve-fits just for food products would increase this number considerably. At the same time, thermal conductivity is relatively difficult to measure with high levels of accuracy and so even the measured data reported in the literature are often subject to uncertainties of perhaps ±5–10%.

The accuracies of thermal conductivity prediction models are strongly dependent on the ratios of the component thermal conductivities. For small component conductivity ratios, different models typically produce similar, accurate predictions. Thus, referring to Table 3, for fresh meat comprised only of water, protein, and fat, the largest ratio of thermal conductivities is approximately 3 and many models are good enough for most purposes, including an average of the component thermal conductivities weighted by the component mass fractions, as was used above for specific heat capacity. For frozen meat containing ice, unfrozen water, protein, and fat, the thermal conductivity ratio is approximately 12 and it is important to take care over which model is used. For meat packages that include frozen meat and air, the thermal conductivity ratio is nearly 100 and substantial errors could be made by using the wrong predictive model. Owing to the substantial difference between the thermal conductivity of water and that of ice, the thermal conductivity of meat also changes substantially as it freezes or thaws.

Table 3 Approximate thermal conductivity values for some meat components at typical food processing temperatures

Component	*Thermal conductivity (W m^{-1} K^{-1})*
Water	0.57
Ice	2.2
Protein	0.18
Fat	0.18
Air	0.025

Accurate data have been reported in the literature for a range of meat products. A review of the literature shows that for fibrous materials, such as meat, it can even be necessary to determine whether the heat flow is across or along the length of the meat fibers, because the thermal conductivity can be significantly different for these two cases. For rough calculations, however, it is sometimes sufficient to assume typical thermal conductivity values of approximately 0.5 W m^{-1} K^{-1} for unfrozen and 1.5 W m^{-1} K^{-1} for frozen lean meat.

Moisture Diffusivity

The diffusivity of moisture through a material can be defined by analogy with thermal conductivity, following eqn [8], but replacing heat flow with moisture flow and temperature with moisture content. Just as knowledge of the thermal conductivity of a meat product is important when designing or analyzing thermal processes, knowledge of the moisture diffusivity is important when designing or analyzing processes that involve drying. Drying can occur deliberately, such as when manufacturing jerky or biltong, or as a side effect of another process, such as when chilling unwrapped meat cuts or carcasses in air.

Moisture diffusion is arguably even more sensitive to the attributes of the material through which the moisture is to pass than is heat diffusion. As a result, there have been relatively few reliable measurements of moisture diffusivity in meat products and even these measurements differ considerably in their reported values, apparently due to subtle differences in attributes between the different meat products studied.

In addition, for meat and many other materials, moisture diffusivity is strongly dependent on the moisture content of the material. Many methods for measuring moisture diffusivity rely on drying some or all of the sample, so the diffusivity value measured by those methods can change substantially during the measurement process.

The most reliable moisture diffusivity values reported for meat to date have probably been those for raw minced beef, where measurements have ranged from 0.3×10^{-10} to

$5 \times 10^{-10}\ m^2\ s^{-1}$, with dependencies reported based on moisture content and temperature. The accurate measurement and estimation of moisture diffusivity for whole muscle meat remains an active area of research.

Index

Notes
Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by *T*, *F*, and *B* refer to Tables, Figures, and Boxes respectively. *vs*. indicates a comparison.

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. For example, acid meat is alphabetized after acidification, not after acid(s) or *F*-value is after *Fusarium*, and not at the start of the F section. Prefixes and terms in parentheses are excluded from the initial alphabetization.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensiveness of the text.
